

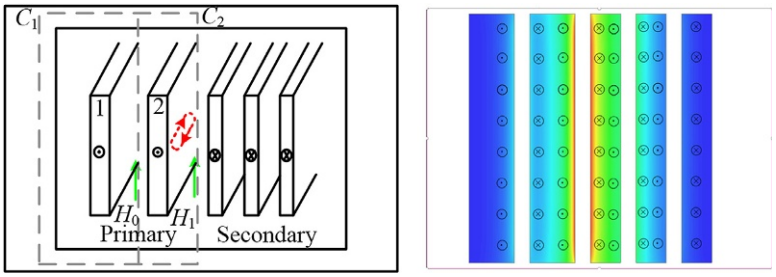

FIG. 17.15 Proximity effect in a transformer winding.

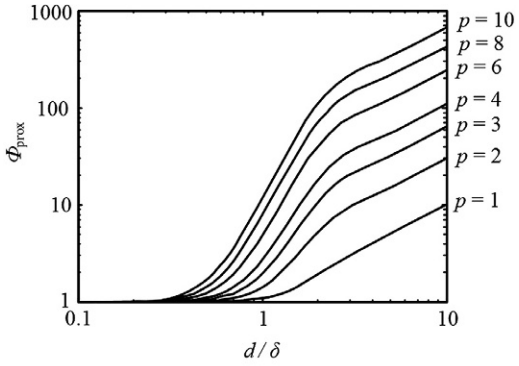

FIG. 17.16 Proximity effect factor in a transformer winding.

where p is the number of layers and Δ is the ratio d/δ, d being the thickness of the layer.

The nature of ϕ_{prox} is illustrated in Fig. 17.16.

As with the skin effect, as designers, we consider the region where $\Delta < 2$ and a useful approximation is

$$\phi_{prox}(\Delta) = 1 + \frac{5p^2 - 1}{45}\Delta^4 \tag{17.65}$$

This result is applicable to sinusoidal waveforms, but in power electronics, there are nonsinusoidal waveforms.

Consider the general case where a current waveform is represented by its Fourier series:

$$i(t) = I_{dc} + \sum_{n=1}^{\infty} \hat{I}_n \cos(n\omega t + \varphi_n) \tag{17.66}$$

where I_{dc} is the DC component and $\hat{I}_n$ is the amplitude of the n^{th} harmonic. The derivative is

$$\frac{di(t)}{dt} = -\omega \sum_{n=1}^{\infty} n\hat{I}_n \sin(n\omega t + \varphi_n) \tag{17.67}$$

The rms value of these expressions may be found from their Fourier coefficients:

$$I_{rms}^2 = I_{dc}^2 + \sum_{n=1}^{\infty} I_{n,rms}^2 \tag{17.68}$$

and

$$I'^2_{rms} = \omega^2 \sum_{n=1}^{\infty} n^2 I_{n,rms}^2 \tag{17.69}$$

where

$$I_{n,rms} = \frac{\hat{I}_n}{\sqrt{2}} \tag{17.70}$$

The proximity effect loss may be found by applying Dowell's formula to each frequency component. Using the approximation in Eq. (17.65), with the definition of skin depth in Eq. (17.3),

$$\phi_{prox}(\Delta_n) = 1 + \frac{5p^2 - 1}{45}\Delta_n^4 = 1 + \frac{5p^2 - 1}{45}n^2\Delta^4 \tag{17.71}$$

The effective resistance taking the harmonics into account is then

$$\begin{aligned} \frac{R_{eff}}{R_{dc}} &= \frac{I_{dc}^2 + \sum_{n=1}^{\infty} \phi_{prox}(\Delta_n) I_{n,rms}^2}{I_{rms}^2} \\ &= \frac{I_{dc}^2 + \sum_{n=1}^{\infty} I_{n,rms}^2 + \frac{5p^2 - 1}{45}\Delta^4 \sum_{n=1}^{\infty} n^2 I_{n,rms}^2}{I_{rms}^2} \end{aligned} \tag{17.72}$$

Simplifying with Eqs. (17.68) and (17.69),

$$\frac{R_{eff}}{R_{dc}} = 1 + \frac{5p^2 - 1}{45}\Delta^4 \left[\frac{I'_{rms}}{\omega I_{rms}}\right]^2 \tag{17.73}$$

Define R_δ as the DC resistance of a layer of thickness δ, rewriting Eq. (17.73)

$$R_{eff} = R_\delta \left\{ \frac{1}{\Delta} + \frac{5p^2 - 1}{45}\Delta^3 \left[\frac{I'_{rms}}{\omega I_{rms}}\right]^2 \right\} \tag{17.74}$$

Recall that Δ is defined at the fundamental frequency of the periodic waveform.

A typical graph of effective resistance versus layer thickness for a periodic waveform is shown in Fig. 17.17. For thin layers (less than a skin depth), the resistance is high and decreases as the thickness increases until the proximity effect kicks in and increases the effective resistance. There is an optimum thickness that minimizes the overall loss, and this may be found by taking the derivative of Eq. (17.74) w.r.t. Δ to yield

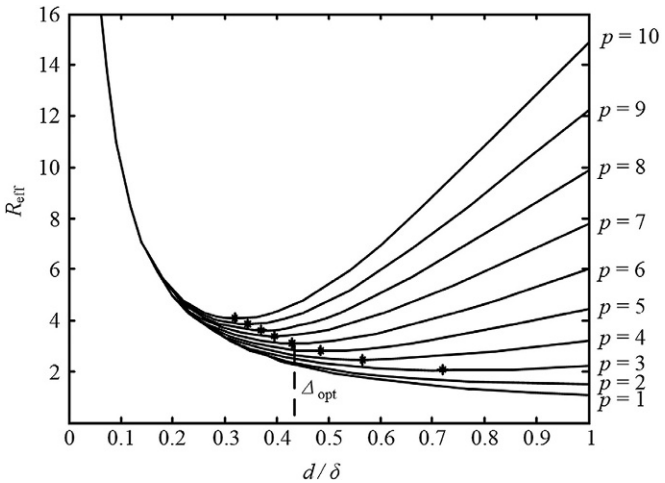

FIG. 17.17 Effective resistance as a function of layer thickness.

$$\Delta_{opt} = \sqrt[4]{\frac{15}{5p^2-1}}\sqrt{\frac{\omega I_{rms}}{I'_{rms}}} \tag{17.75}$$

and at this optimum value of the layer thickness, the effective resistance is

$$\frac{R_{eff}}{R_{dc}} = \frac{4}{3} \tag{17.76}$$

17.5.1 Example: Push-Pull Converter

In the push-pull converter design, we had a choice between the 2.5 mm diameter wire and the 24.5×0.2 mm foil in the secondary. We can approximate the current in the secondary to the pulsed waveform shown in Fig. 17.18 with a finite rise time, and it may be easily established that

$$\begin{aligned} I_{rms} &= I_o\sqrt{D'' - \frac{4t_r}{3T}} \\ I'_{rms} &= I_o\sqrt{\frac{2}{t_r T}} \end{aligned} \tag{17.77}$$

and

$$\Delta_{opt} = \sqrt[4]{\frac{15}{5p^2-1}}\sqrt[4]{\left[D - \frac{4t_r}{3T}\right]2\pi^2\frac{t_r}{T}} \tag{17.78}$$

For a rise time of $t_r/T = 2.5\%$, the optimum value of Δ is 0.459 and the optimum foil thickness at 80 kHz, with a skin depth of 0.233 mm, is 0.1 mm. This is the foil thickness we used in the example for the push-pull converter. The effective resistance is 4/3 times the DC resistance, so the total copper loss in the secondary windings is now $(4/3) \times 0.831 \times 2 = 2.216$ W, bringing the total losses to 3.795 W.

If we had selected the 2.5 mm diameter wire, the AC resistance factor from Eq. (17.62) is 3.0, and the total copper loss would be 3.738 W; coupled with the core loss, the total losses would have exceed the maximum dissipation of 5.0 W.

17.5.2 Fringing Effect

In order to limit the maximum flux density in the magnetic core of an inductor, the air gap is usually placed in the core, as shown in Fig. 17.11. Besides, the air gap is required even for the transformer applied in the LLC resonant converter to guarantee the proper magnetizing inductance. Basically, the reluctance of the air gap could be calculated based on the same cross-sectional area of the magnetic core and the actual gap length, as discussed in Section 17.3. According to the magnetic field distribution between two different materials, that is, ferrite and air, derived by the Maxwell equations, the magnetic flux line around the air gap bulges out as presented in Fig. 17.19, which is normally named the "fringing effect." Due to the variation in the magnetic field of the component, the inductance must be evaluated with the fringing field taken into account which means the calculated method given in Section 17.3 should be improved. The fringing field will increase the power loss of conductors near the air gap under AC conditions because the magnetic field around the conductor is not uniform. Consequently, the fringing effect is significant for the magnetic design.

The magnetic field around the air gap depends on the dimensions of the gap and the position in the core. Typically, finite element analysis (FEA) is the most accurate method to obtain the inductance. Fig. 17.20 shows the fringing flux for an inductor with an air gap in the outer leg of the core.

FEA simulation is resource and time-consuming. A simple and effective method to estimate the increase in inductance due to fringing is presented in Fig. 17.21. The cross section of the gap is a rectangular area with dimensions x by y.

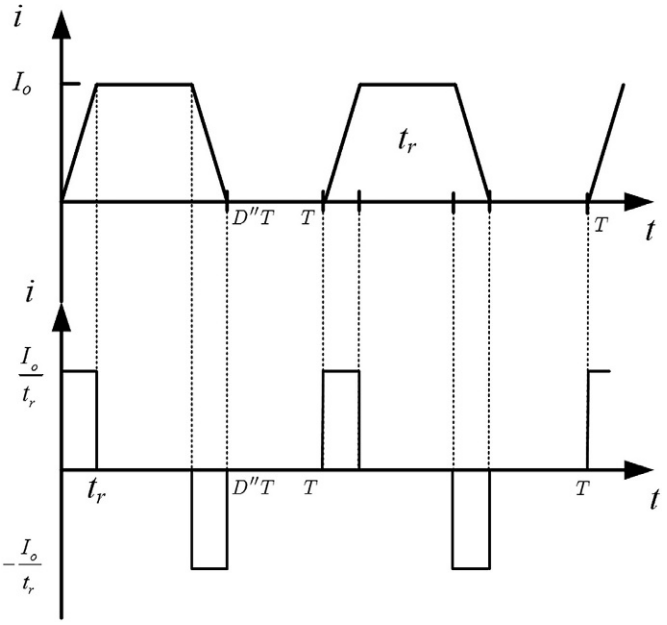

FIG. 17.18 Pulsed waveform for the push-pull converter.

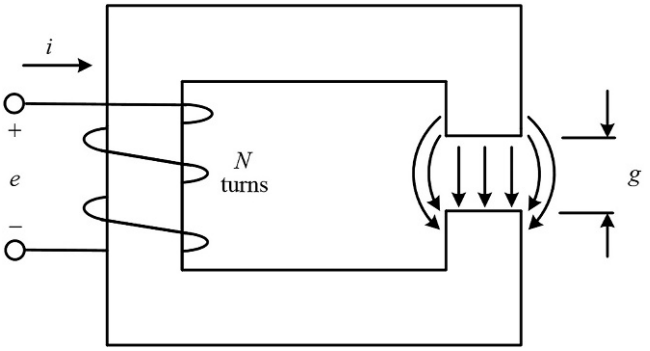

FIG. 17.19 Fringing effect around the air gap.

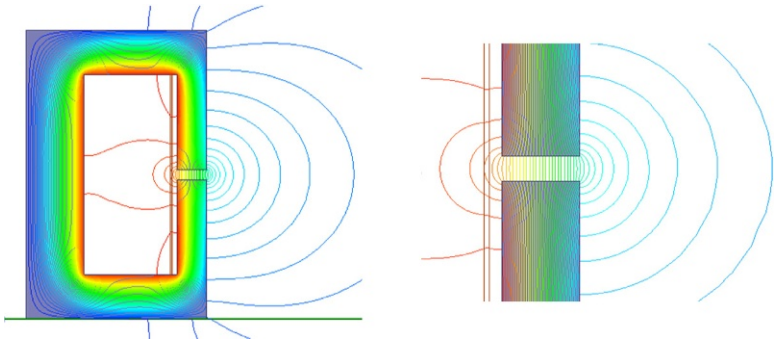

FIG. 17.20 Fringing flux simulated by finite element analysis.

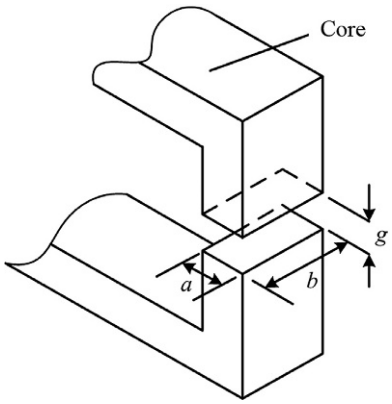

FIG. 17.21 Inductor with an air gap in the core.

Assuming the gap length is g, the equivalent cross-sectional area of the air gap can be set as $(x+g)$ by $(y+g)$ instead of x by y to calculate the inductance by the following equation:

$$L' = \frac{N^2}{R_c + R'_g} \asymp \frac{N^2}{R'_g} = L\frac{(x+g)(y+g)}{xy} \tag{17.79}$$

where R_c and R'_g are the reluctances of the core and the equivalent gap, N is the number of turns in the inductor and L is the inductance calculated by Eq. (17.16).

The gap length would be very small in practice. With the assumption that g is much smaller than x or y, Eq. (17.79) can be rewritten as

$$L' \asymp L\left(1 + \frac{x+y}{xy}g\right) \tag{17.80}$$

For a magnetic core with a square cross section, the inductance will be increased by the factor of $(1 + 2\,g/x)$. If the inductor has a circular core, the equivalent diameter of the air gap should be increased by g.

The fringing field will lead the nonuniform current density in the conductor near the air gap and result in extra loss in the winding. The winding loss due to the air gap is dependent on the operating frequency of the magnetic component. Fig. 17.22 shows the current density in the conductor near the gap for the same inductor at frequencies of 1 and

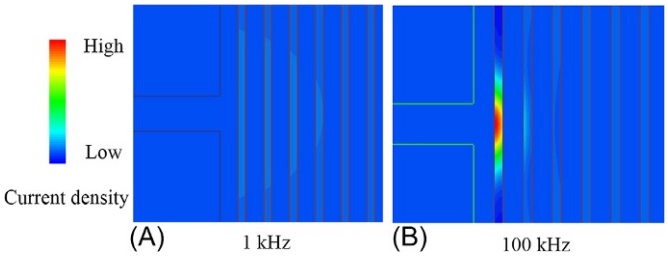

FIG. 17.22 Inductor with an air gap in the core.

100 kHz, respectively. It is obvious that the extra winding loss at high-frequency is significantly larger than it is at low frequency.

Due to the complex fringing field distribution around the gap, a simple and accurate analytic expression to evaluate the winding loss considering the fringing effect is not available. Several representative methods to calculate the fringing loss have been proposed [17–19]; all of these methods have substantial limitations. Simulation by finite element analysis is the most accurate method to evaluate the winding loss due to the air gap.

A number of proposals have emerged to reduce the fringing effect on the winding loss. The windings may be placed away from the air gap or may have a particular shape [20]. The recommended distance between the conductor and the air gap should be larger than twice the gap length. The other frequently implemented method to reduce the fringing loss is to apply a distributed gap in the core to replace the discrete large air gap [21].

17.5.3 High-Frequency Litz Wire

Litz wires consist of a number of fine strands that are twisted together, forming a compact bunch, and are externally connected in parallel. Insulated and enameled copper or aluminum strands are the most commonly used conductors. Multistranded cables are used in order to reduce the AC losses in thick conductors.

An easy process of manufacturing litz wires simply consists of twisting together a set of isolated strands. Other improved manufacturing methods can include some combination of braiding, twisting, or weaving processes. Ideally, strands should be equivalent in order to effectively share the currents and

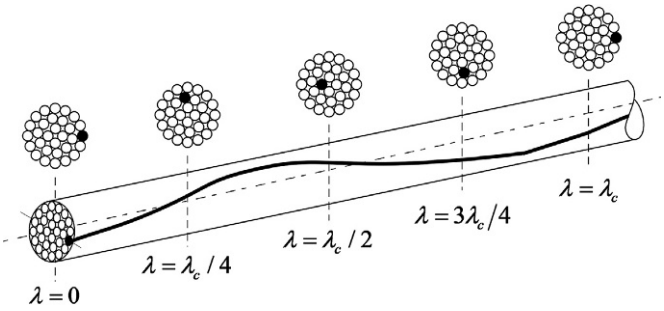

FIG. 17.23 Litz wire ideal structure of a multistranded conductor.

minimize the losses. However, equivalence of strands requires a carefully designed transposition pattern to guarantee that each strand occupies every place in the cross section for a periodic length of the cable λ_c, as it is schematically represented in Fig. 17.23. Achieving the ideal litz wire structure becomes complicated in conventional implementations, especially for cables with a high number of strands.

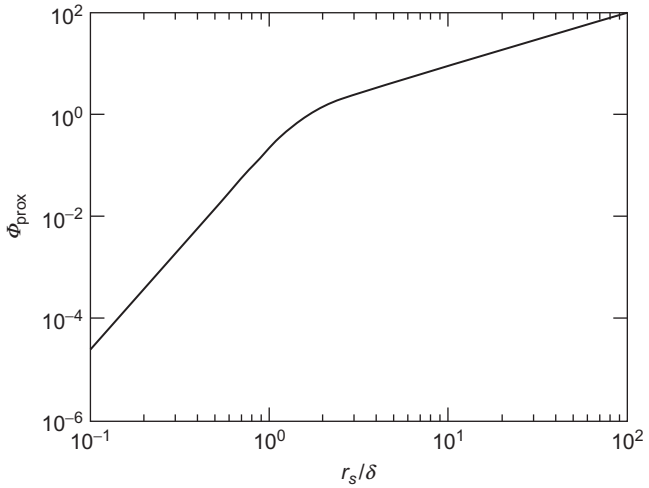

FIG. 17.24 Proximity losses of a round conductor with respect to the ratio of the strand radius to the skin depth.

Considering round conductors, skin and proximity effects are penalized when the ratio of radius to the skin depth is high. The nature of the skin effect was shown in Section 17.5, where the increase of the dc resistance with respect to geometry and frequency was characterized by means of the factor Φ_{skin}. On the other hand, considering the proximity effect, the factor Φ_{prox}, shown in Fig. 17.24, represents the induced losses on a round conductor per unit of length by an external alternating magnetic field (e.g., generated by nearby conductors), with respect to the ratio of the conductor radius to the skin depth. In both cases, the AC losses are strongly penalized when the ratio r_s/δ is higher than one, which points the convenience of using multistranded conductors.

Apart from the reduction of ac losses, litz wires present some disadvantages, including the high cost with respect to round wires. In general, litz wire winding requires more space than the equivalent round wire implementation because the fill factor is deteriorated.

Losses in multistranded wire correspond to the sum of the losses in its individual strands. These loses comprise DC resistance and skin and proximity effects. Skin and proximity effects may be further divided into strand-level and bundle-level effects [22], where the latter effects relate to unequal sharing of current in strands.

Bundle-level proximity effect loss can be controlled by simple twisting, that is, angular transposition. Bundle-level skin effect can be controlled by a complex transposition pattern that involves both radial and angular transposition of the strands. Radial transposition would involve each strand occupying all the other strand positions, whereas in angular transposition all the outside strands are transposed into other outside positions.

Simple twisting achieves angular transposition, but not radial transposition. In practice it is difficult to achieve radial transposition in a manufacturing environment. The skin effect at bundle-level is illustrated in Fig. 17.25 with simple twisting,

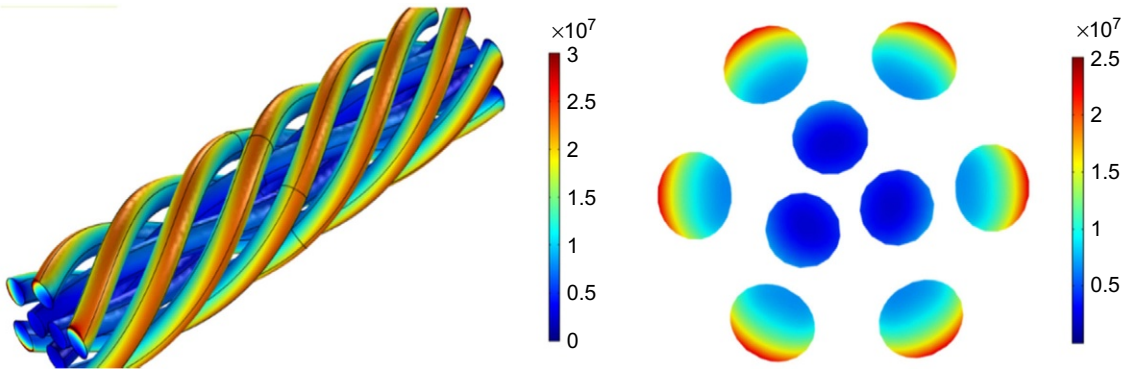

FIG. 17.25 Bundle-level skin effect in a twisted litz wire.

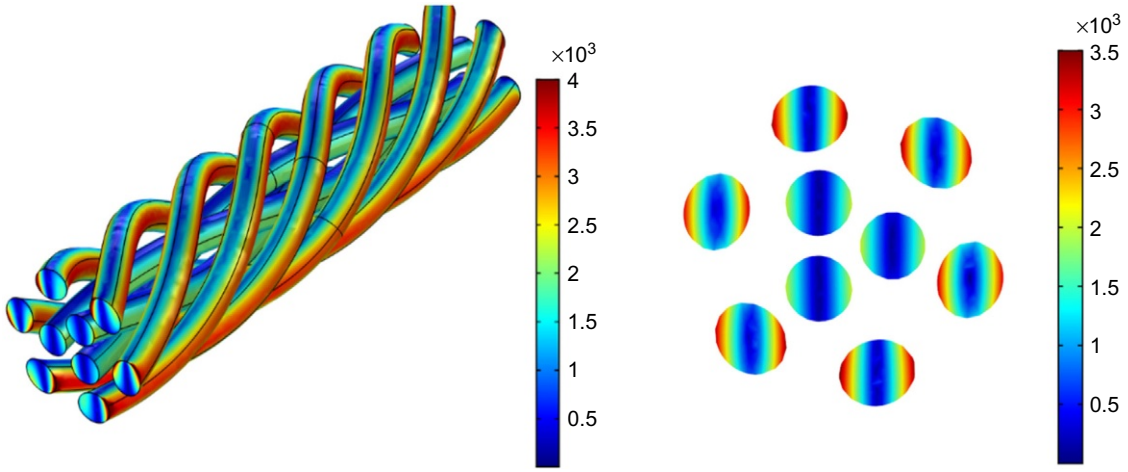

FIG. 17.26 Strand-level external proximity effect in a twisted litz wire.

where to a large extent the wire acts like a solid conductor from the point of view of skin effect.

Skin effect at the strand-level is covered in Section 17.5 where each strand must meet the requirements of individual wires as discussed, that is, $r_s/\delta_s < 1$. The proximity effect at strand-level has two components. The internal component takes into account the losses induced in a strand by the neighboring strands. The external component is generated by the other turns in a winding; this is analogous to the Dowell effect discussed in Section 17.5. The external proximity effect is illustrated in Fig. 17.26, where the Dowell effect is evident.

Several approaches to optimizing litz wire are available in the literature [23,24]; it is difficult to generalize, but as a rule of thumb, the strand diameter should be less than $\delta_s/4$.

Apart from the cost, winding volume restrictions should be taken into account when small strands are used because the copper utilization factor is deteriorated due to the isolation between strands. Values of the utilization factor k_u with respect to the radius of strand were measured and are shown in some references [14]. The fit to these values has the following expression:

$$k_u \asymp \frac{\pi}{4}\frac{\pi}{2\sqrt{3}}\left(\frac{r_s}{r_s + t_{\text{ins}}}\right)^2 \tag{17.81}$$

where t_{ins} is the thickness of the insulation. An image of these values and the fit are shown in Fig. 17.27. Needless to say, the final value of k_u will be even smaller when the insulation to satisfy international standards on electric isolation between the windings is included. The sizing formula for A_p in Eq. (17.45) shows that the reduced value of k_u will greatly influence the overall core size, for example, a 40% reduction in the window utilization factor due to litz wire will result in a 30% increase in core size.

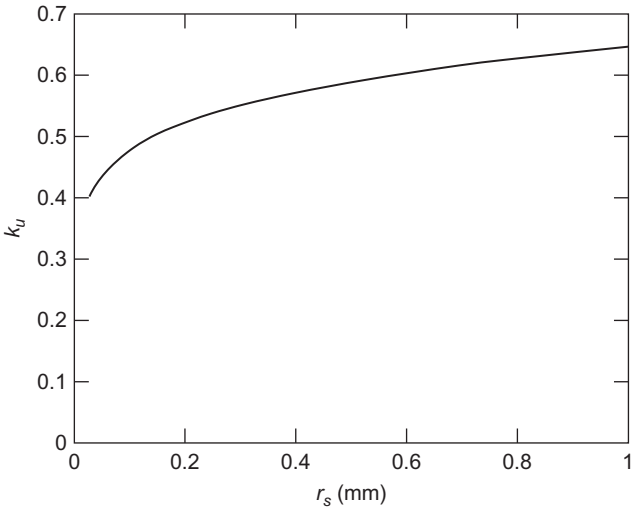

FIG. 17.27 Copper utilization factor in litz wire.

17.5.4 Interleaving

Another approach to reducing losses is to interleave the windings. Take the original transformer in Fig. 17.28; the losses dominate the primary and secondary windings at the interface between the two windings, where the magnetic field intensity is highest.

The plot of current density shows that the highest (red) values are at the interface of the primary and secondary winding; in the interleaved case, the maximum value of the magnetic field is reduced, and the current density is reduced accordingly.

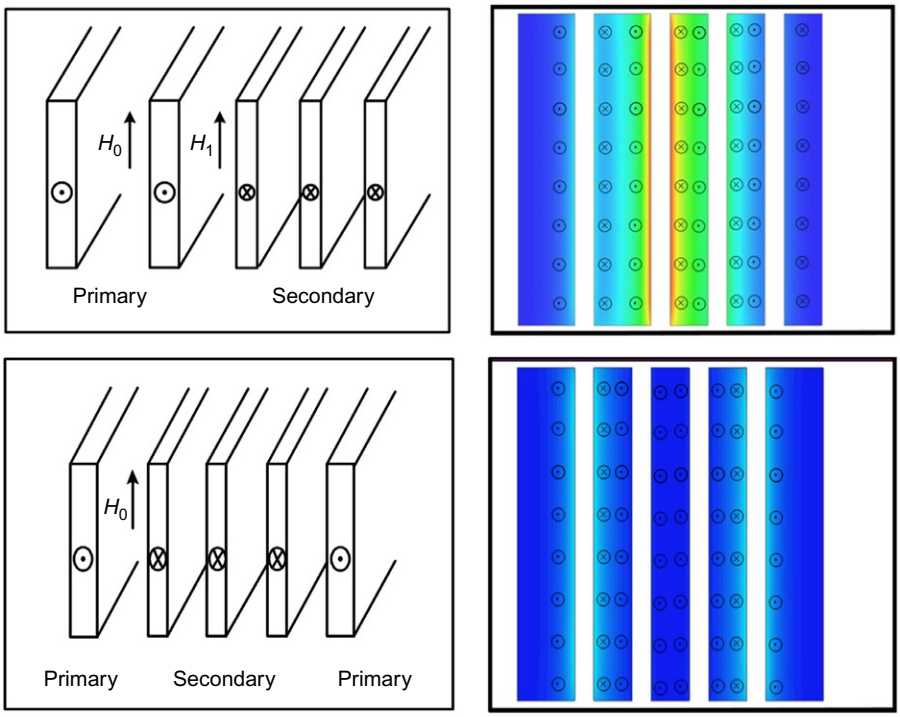

FIG. 17.28 Interleaved windings to reduce proximity effect losses.

18.1 Introduction

Pulsed power, PP, can be considered as the science and technology of accumulating electric energy over a relatively long period of time, followed by the subsequent energy release in very short pulses, a single one or a controlled repetitive sequence, thus increasing the instantaneous peak power. Supposing zero losses, the output energy E_o, delivered at power P_o during T_o, equals the accumulated energy E_i at a power P_i during T_i, bringing

$$E_i \approx E_o \Rightarrow P_i T_i \approx P_o T_o \Rightarrow \frac{P_o}{P_i} \approx \frac{T_i}{T_o} \tag{18.1}$$

An example is shown in Fig. 18.1, where a stored energy of 1 kJ can be discharged into a long pulse of 1 kW for 1 s or a short pulse of 1 GW for 1 μs, respectively, considering the ideal case of a lossless system.

PP is a technique primarily developed for radars, accelerators, and military applications but with great potential for civil applications [1]. In fact, there is a growing variety of environmental, biomedical, commercial, and industrial applications that use positive and/or negative high-voltage, HV, repetitive pulses, for enhancing the properties of a product or a technique [2]. These pulses may last from hundreds of picoseconds to tens of seconds, being released as a single shot or as a repetitive sequence up to several tens of thousands per second.

What makes PP so unique is the concept that extremely high peak powers can be delivered during short times without the demand for highly powerful energetic power sources, custom direct, dc, or alternating, ac, voltage systems being suited.

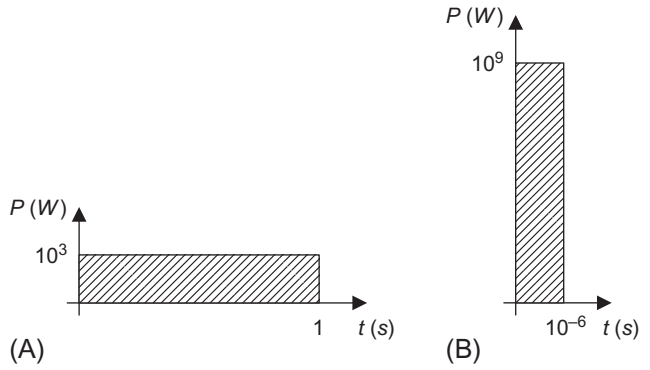

FIG. 18.1 Discharge of 1 kJ energy: (A) 1 kW during 1 s pulse and (B) 1 GW during 1 μs pulse.

In the past, the PP technology was dominated by vacuum or gas tubes (i.e., electronic valves) for switching the high-powers needed for military and large plant physical applications [3]. With the technological advent of power semiconductors in the 1970s and particularly modern power semiconductors in the 1990s, developing PP generators based on power semiconductors was possible. Still, they were lower power rated compared with electronic valve generators but largely rewarded by the higher energetic efficiency and flexibility together with compactness and cost-effectiveness [4].

Nowadays, the applications of PP are driving the need for technological advances in medical, environment, biological, energetic, and industrial applications, for example, in the reduction of pollution emissions from fossil fuels, in killing bacteria and organic pollutants, in melanoma cancer treatment, and in molding metals sheets [5–9].

This chapter provides basic concepts and advanced know-how on the generation of repetitive HV pulses using state-of-the-art power semiconductor technology. Apart from this introduction, in Section 18.2, power semiconductor devices used in solid-state-based high-voltage generators are reviewed together with the latest silicon carbide (SiC) insulated-gate bipolar transistor (IGBT) and metal-oxide-semiconductor field-effect (MOSFET) through the latest gallium nitride (GaN) power junction field-effect transistors (JFET). In Section 18.3, several types of PP applications are presented, and the type of load requirements they present to the high-voltage modulators is described. The most widespread semiconductor-based HV pulse modulator topologies are analyzed and discussed in terms of solid-state device operation in Section 18.4. In Section 18.5, capacitor charging applications are presented and described. The main conclusions about semiconductor use in high-voltage pulse generation are presented in Section 18.6 and the future trends on this technology.

18.2 Power Semiconductors for PP

The demand for high-voltage modulators to generate repetitive high-voltage pulses with optimized performance and characteristics, based in solid-state technology, is being fulfilled through the enhancement of the volt-ampere capabilities and switching speed of modern power semiconductors.

Still, using power semiconductors in PP is a matter of optimizing their use, going beyond the present semiconductor ratings and taking advantage of usually nonuseful phenomena or nonideal characteristics, such as controlled avalanche breakdown (for avalanche transistors), diode reverse recovery sharpness that can generate inductive high-voltage pulses, Zener capacitances, peak currents, and unusual very short pulse behavior.

In the next sections, the particular characteristics of power semiconductors enabling their use in PP applications will be summarized, from silicon (Si) high-voltage diodes, silicon-controlled rectifier thyristors (SCR), gate turn-off thyristor (GTO), gate-controlled thyristor (GCT), integrated gate-commutated thyristor (IGCT), injection enhanced gate transistor (IEGT), insulated-gate bipolar transistor (IGBT), and metal-oxide-semiconductor field-effect transistors (MOSFET) to the latest silicon carbide (SiC) IGBTs or gallium nitride (GaN) power junction field-effect transistors (JFET) (also termed enhancement-mode high-electron-mobility transistor (E-HEMT)). To overcome the still limited hold-off voltages of power semiconductors and their current ratings (Fig. 18.2), regarding the electronic valves, some techniques will be described, including series and parallel semiconductor arrangements, and the source switching of a JFET using a low-voltage MOSFET (cascode stacks).

Much attention is being devoted to power semiconductors based on silicon carbide (SiC) structures, which can switch voltages in the tens of kV range and currents nearing the kA barrier. The 4H-SiC MOSFET is being investigated for 12–15 kV, while SiC IGBTs are now in the 15 kV range (Fig. 18.2). Alternative semiconductor materials, such as gallium nitride (GaN), are being investigated to build GaN enhancement-mode JFETs called HEMTs (available 650 V, 60 A, and 25 mΩ). GaN JFETs are expected to be faster devices (100 MHz switching frequency and 10 ns switching time) than SiC or Si power semiconductors. The cascode switch is expected to attain 10 kV blocking voltages.

Superjunction (SJ) transistors are being researched to build bipolar power transistors; super trench MOSFETs (STM), vertical deep trench (resurf diffusion MOS-VTR-DMOS), SJ DMOS, UMOS, JFET, and JFET-derived structures are also being considered [4].

18.2.1 High-Voltage PIN Diodes (Step Recovery Diodes SRD)

Fig. 18.3A shows the simplified structure of a typical Si high-voltage high-power diode with forward bias carriers in Fig. 18.3A [10]. This type of diode has a heavily doped P^+ anode and N^+ substrate separated by a lightly doped N^- (or near intrinsic, I) epitaxial layer, called drift region [11]. The drift region, usually not found in low-power diodes, has to contain

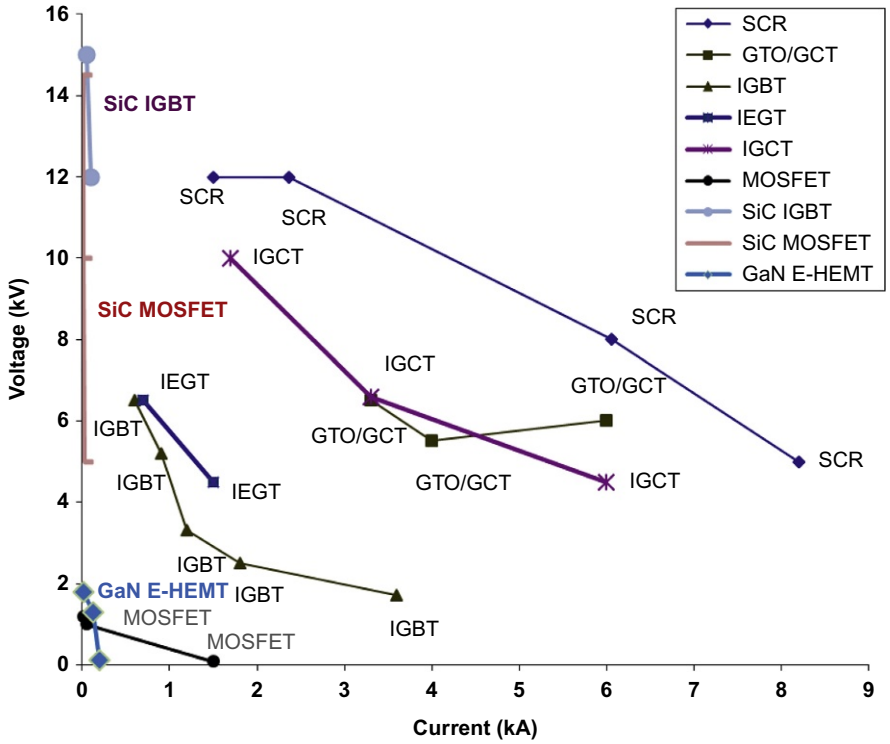

FIG. 18.2 Maximum volt-ampere capabilities of current Si (SCR, GTO/MCT, IGCT, IEGT, IGBT, and MOSDET), SiC (MOSFET and IGBT), and GaN (E-HEMT) high-power semiconductors.

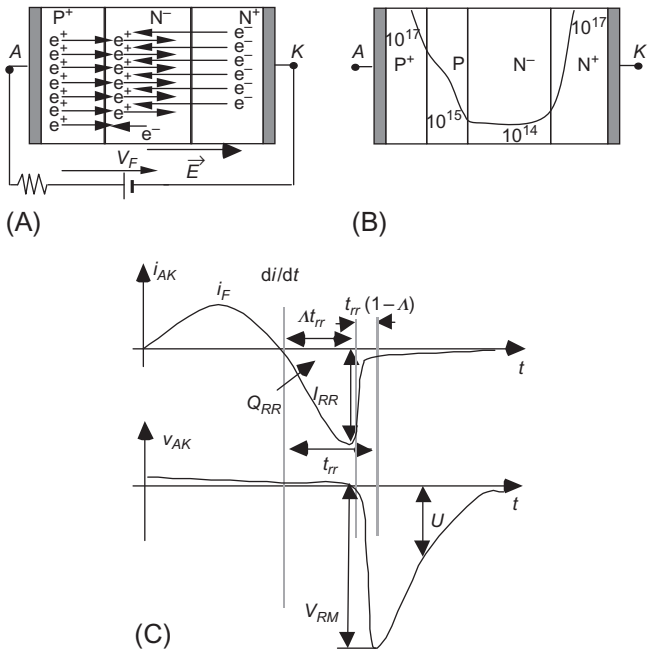

FIG. 18.3 (A) Forward-biased PIN diode, (B) $P^+PN^-N^+$ SOS diode structure and typical doping profile, and (C) SOS diode reverse-blocking behavior.

the thick depletion layer of the reverse-biased high-voltage PIN diode, establishing the diode reverse breakdown (or hold-off) voltage rating (punch-through diodes).

PIN diodes turn-on requires the depletion layer removal (forward voltage recovery, as the diode is reverse-biased prior to turn-on). Removal of the stored depletion charge needs a certain current and time. Forward conduction is dominated by high-level injection of holes (conductivity modulation) in the drift region, which becomes a virtual P region. The minority injected charge is positive if the diode is conducting, the forward current providing minority carriers at the rate they recombine. The *on*-state voltage is relatively high, the electric field extending through the drift region. This electric field is need to the transport of charge carriers from P to N region.

To turn-off the PIN diode, the stored excess carriers, mostly in the drift region, must be discharged before the diode reverse biases, the minority charge becoming negative (reverse recovery). Upon applying a reverse voltage U_R, the forward current will decrease (Fig. 18.3C) at a rate of

$$\frac{di_F}{dt} \approx \frac{I_{RR}}{t_{rr}} \tag{18.2}$$

becoming negative to swept the excess carriers out of the drift region and charge the depletion capacitance C_{eqoff}, which is relatively small due to the wide drift region. At constant reverse U_R voltage applied in inductive circuits (L_S inductor), the diode reverse current rate of rise, considered constant, is

$$\frac{di}{dt} \approx \frac{U_R}{L_S} \tag{18.3}$$

reaching the value I_{RR}

$$I_{RR} = t_{rr} \frac{U_R}{L_S} \tag{18.4}$$

at the reverse recovery time t_{rr}

$$t_{rr} = L_S \frac{I_{RR}}{U_R} \tag{18.5}$$

being the reverse recovery charge Q_{RR}

$$Q_{RR} = \frac{I_{RR} t_{rr}}{2} \tag{18.6}$$

In LC oscillating circuits (Fig. 18.4), the PIN diode may become reverse-biased by a negative fast-rising voltage with high peak value V_{RM}, which can be more than three times higher than the applied direct voltage U (Fig. 18.3C).

At high reverse voltages, the pulse energy must be limited to avoid the impact ionization current destroying the diode by avalanche breakdown and excessive power dissipation. Therefore, PIN diodes should be used with very short pulses, sharpening and increasing the voltage amplitude of the applied pulses.

Semiconductor opening switches (SOS), also known as step recovery diodes (SRD), charge diodes or snap diodes, are modified PIN high-voltage diodes using a $P^+PN^-N^+$ structure with gradually doped P layer (Fig. 18.3B) [12]. The diode injected minority carriers must not have the time to recombine and should not diffuse too far from the junction before they are withdrawn under reverse bias with a reverse current. The minority carrier lifetime of the SOS diode determines the pulse length. SOS diodes are thus optimized to exhibit relatively slow reverse recovery ($\Lambda t_{rr} \approx 50$–$100$ ns) but abrupt recovery (very fast reverse current decay) $(1-\Lambda)t_{rr} \approx 5$ ns (Fig. 18.3C).

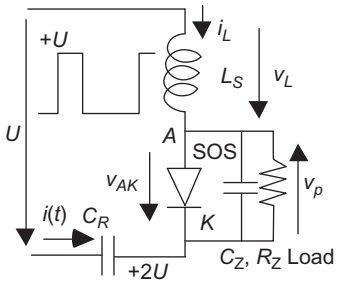

FIG. 18.4 SOS pulse generation using magnetic energy storage.

SOS diode characteristics depend not only on the pumping forward current (current density and very short time to avoid saturation) but also on the doping profile of the $P^+PN^-N^+$ structure and carrier lifetime. The reverse recovery of SOS diodes (e.g., their opening) should differ from PIN diodes, since current interruption ought to occur mostly in the narrower P-doped layer, not in the drift layer. The SOS diode can switch high-currents (kA) in nanosecond opening times, with automatic uniform distribution of reverse voltage (kV) in series-connected SOS diodes during current decay. Series stacks of up to one thousand SOSs can be deployed to obtain working voltages near the megavolt level, peak currents of several kA, peak power of GW, and average powers of tens of kilowatts.

In a simplified circuit for SOS operation (Fig. 18.4), it is supposed that a rectangular prepulse with amplitude U and pulse length T_U is generated and applied to the SOS in series with an inductor L_S to charge the capacitor C_R.

During the positive part of the prepulse, the forward pumping period, the SOS diode is forward-biased, and the inductor near-sinusoidal current rises to build up energy in the resonant $L_S C_R$ circuit and excess carriers in the diode.

Supposing the $L_S C_R$ with zero series resistor r_S ($r_S \to 0$), then this LC is underdamped ($\zeta < 1$), the inductor current being given as

$$\begin{aligned} i_L &= I_m e^{-\zeta \omega_R t} \sin\left(\omega_R \sqrt{1-\zeta^2}\ t + \phi\right) \\ \zeta &= \frac{r_S}{2Z_R} \approx 0;\ \ Z_R = \sqrt{\frac{L_S}{C_R}};\ \ \omega_R = \frac{1}{\sqrt{L_S C_R}} \end{aligned} \tag{18.7}$$

The I_m and ϕ values are obtained from the initial conditions $i_L(0) = 0, v_{CR}(0) \Rightarrow v_L(0) = U$. Therefore,

$$i_L = \frac{U}{Z_R \sqrt{1-\zeta^2}} e^{-\zeta \omega_R t} \sin\left(\omega_R \sqrt{1-\zeta^2}\ t\right) \tag{18.8}$$

where Z_R is the characteristic impedance

$$Z_R = \sqrt{L_S / C_R} \tag{18.9}$$

of the $L_S C_R$ resonant tank with oscillation frequency ω_R, set to allow charging during T_U:

$$\omega_R = \sqrt{L_S C_R}^{-1} = \frac{\pi}{T_U} \tag{18.10}$$

Charging must occur only during half the oscillation cycle; thus, $T_U = (2\pi/\omega_R)/2$.

Neglecting losses ($L_S C_R$ resonant tank damping factor nearly zero), parasitic effects and diode voltage drops, the diode forward current is obtained from

$$i_L = \frac{U}{Z_R} \sin(\omega_R\ t) \tag{18.11}$$

with peak value

$$I_F \approx U/Z_R \tag{18.12}$$

Since $r_S \approx 0$, the capacitor C_R voltage is

$$v_{CR} = \frac{1}{C_R}\int_0^t \frac{U}{Z_R}\sin(\omega_R\, t)dt + v_{CR}(0) = U(1-\cos(\omega_R\, t)) \tag{18.13}$$

At $t = T_U = \pi/\omega_R$, the C_R capacitor will charge to nearly

$$V_{CR} \approx 2U \tag{18.14}$$

Neglecting the recombination decay time constant, the diode forward stored charge is nearly

$$Q_F \approx \frac{2I_F}{\omega_R} \approx \frac{2U}{\omega_R Z_R} \approx 2U\,C_R \tag{18.15}$$

During the sinusoidal negative oscillation interval, the diode is still conducting, the prepulse voltage is nearly zero, and the inductor current goes negative. The SOS diode reverse recovery instant (opening) happens at nearly the C_R discharge peak current

$$I_{RR} \approx \frac{2U}{Z_R} \approx 2I_F \tag{18.16}$$

being the reverse recovery charge

$$Q_{RR} \approx \frac{I_{RR}}{\omega_R} \tag{18.17}$$

nearly equal to the forward injected charge. Thus, the reverse recovery current is nearly the double of the peak forward current $I_{RR} \approx 2U/Z_R \approx 2I_F$, being

$$Z_R = \frac{2U}{I_{RR}} \tag{18.18}$$

Supposing diode abrupt recovery and assuming energy conservation, the v_p pulse voltage is dependent on the load capacitor C_Z and resistor R_Z; for underdamped $L_S C_Z || R_Z$ parallel circuits, ($\xi < 1$) given as

$$\begin{aligned} v_p &= V_m e^{-\xi\omega_Z t}\sin\left(\omega_z\sqrt{1-\xi^2}\; t + \phi\right) \\ \xi &= \frac{Z_z}{2R_z};\;\; Z_z = \sqrt{\frac{L_S}{C_z}};\;\; \omega_z = \frac{1}{\sqrt{L_S C_z}} \end{aligned} \tag{18.19}$$

where the load R_Z is in parallel with Z_Z, being $Z_Z = \sqrt{L_S/C_Z}$ the characteristic impedance of the second-order $L_S C_Z || R_Z$ parallel circuit with damping factor $\xi \approx Z_Z/(2R_Z)$ and undamped resonant frequency $\omega_Z \approx \sqrt{L_S C_Z}^{-1}$, driven by the initial current I_{RR} of inductor L_S.

The V_m and ϕ values are obtained from the initial conditions $v_p(0) = 0$ and $i_{Ls}(0) = I_{RR}$. Therefore,

$$v_p = I_{RR}\frac{Z_z}{\sqrt{1-\xi^2}} e^{-\xi\omega_Z t}\sin\left(\omega_z\sqrt{1-\xi^2}\, t\right) \tag{18.20}$$

The maximum voltage $v_{pmax} = V_{RM}$ occurs at $t = t_{peak}$ and is

$$\begin{aligned} t_{peak} &= \frac{\tan^{-1}\left(\sqrt{1/\xi^2 - 1}\right)}{\omega_z\sqrt{1-\xi^2}} \\ V_{RM} = v_{pmax} &= I_{RR} Z_z\, e^{-\frac{\xi\tan^{-1}\left(\sqrt{1/\xi^2-1}\right)}{\sqrt{1-\xi^2}}} \end{aligned} \tag{18.21}$$

The V_{RM} equation above can be used to determine the needed I_{RR} and then, using Eq. (18.18), the Z_R value.

For near-optimum energy transfer to the load resistor R_Z, a damping value slightly lower than the critical value should be used, the v_p pulse being roughly sinusoidal. Pulse forming networks or lines can be used to almost square it [12].

From the above equations, assuming a damping factor $0.7 < \xi < 0.9$, the design SOS diode pulser follows the steps:

$$\begin{aligned} &(1)\;\; \xi \approx 0.8 \;\; (\text{small oscillations}) \Rightarrow Z_z = 2\xi R_z \\ &(2)\;\; Z_R = \frac{2UZ_z}{v_{Pmax}} e^{-\frac{\xi\tan^{-1}\left(\sqrt{1/\xi^2-1}\right)}{\sqrt{1-\xi^2}}} \\ &(3)\;\; \omega_R = \frac{\pi}{T_U} \\ &(4)\;\; C_R = \frac{1}{\omega_R Z_R} \\ &(5)\;\; L_S = \frac{Z_R}{\omega_R} \\ &(6)\;\; C_Z = \frac{L_S}{Z_Z^2} \end{aligned} \tag{18.22}$$

This design considers the SOS properties are suitable, assuming that SOS diode carrier lifetime is long enough to nearly conserve charge, abrupt reverse recovery and zero *on*-state voltages (regarding the U values). Often, C_Z should account for the intrinsic SOS diode capacitance or nonabrupt diode recovery.

A simplified design, valid nearly for $0.75 < \xi < 1$, leads to slightly higher V_{RM} pulse voltages. Consider

$$V_{RM} \approx I_{RR}(R_Z || Z_Z) \quad \text{for } C_R \gg C_Z \tag{18.23}$$

To obtain a near-critical damped load ($0.7 < \xi < 0.9$), it must be

$$1.4R_Z < Z_Z < 2R_Z \tag{18.24}$$

Then, from the required V_{RM} and I_{RR} the Z_R value, it is

$$Z_R \approx \frac{2U(R_Z || Z_Z)}{V_{RM}} \tag{18.25}$$

and

$$\omega_R = \frac{\pi}{T_U}$$

Then, the resonant tank has values

$$L_S \approx \frac{Z_R}{\omega_R} \tag{18.26}$$

and

$$C_R \approx \frac{1}{\omega_R Z_R} \tag{18.27}$$

From L_S and Z_Z, the load parallel capacitor C_Z, either added or stray capacitance or SOS C_{eqoff}, should be

$$C_Z \approx \frac{L_S}{Z_Z^2} \tag{18.28}$$

For a required V_{RM} in load resistor R_Z and capacitor C_Z, the SOS diode must withstand

- forward current I_F,
- pumping time T_U,
- V_{RM} reverse voltage,
- reverse recovery current I_{RR},
- reverse recovery charge Q_{RR}.

High peak voltages V_{RM} and comparatively low values of I_{RR} need very low values of the load (spurious) parallel capacitance C_Z, or higher values of I_{RR}.

Example 18.1 Determine the circuit parameters of Fig. 18.4 to obtain a 30 ns 1 MV pulse in resistor $R_Z = 1\,\text{k}\Omega$ (1 MW peak) paralleled with C_Z capacitor, from a prepulse having $U = 300$ kV and pulse length T_U.

Solution Supposing volts × second conservation at equal current, the prepulse length should be

$$T_U \approx 30 \times 10^{-9} \times 10^6 / \left(300 \times 10^3\right) \approx 100\text{ ns}$$

Then, from the above equations, it is obtained

$$\omega_R = \pi / T_U = \pi / \left(100 \times 10^{-9}\right) \approx 3.14 \times 10^7\text{ rad/s}$$

If it is assumed $\xi = 0.75$, then

$$Z_Z \approx 2\xi R_Z \approx 1.5\, R_Z \approx 1.5\,\text{k}\Omega$$

$$Z_R = \frac{2UZ_z}{v_{Pmax}} e^{-\frac{\xi \tan^{-1}\left(\sqrt{1/\xi^2 - 1}\right)}{\sqrt{1-\xi^2}}} \approx 396\,\Omega$$

$$L_S \approx Z_R / \omega_R \approx 360 / 3.14 \times 10^7 \approx 12.6\,\mu\text{H}$$

$$C_R \approx 1/(Z_R \omega_R) \approx 1/\left(360 \times 3.14 \times 10^7\right) \approx 81\,\text{pF}$$

and

$$C_Z \approx L_S / {Z_Z}^2 \approx 12.6 \times 10^{-6} / 396^2 \approx 5.6\,\text{pF}$$

This is a low value considering the SOS diode (or diode association) equivalent off-depletion capacitance C_{eqoff}, not to forget stray capacitances. The SOS diode must withstand

$$I_F \approx U / Z_R \approx 300 \times 10^3 / 396 \approx 758\,\text{A}$$

$$I_{RR} \approx 2 I_F \approx 1.52\,\text{kA}$$

$$v_{pmax} = I_{RR} Z_z\, e^{-\frac{\xi \tan^{-1}\left(\sqrt{1/\xi^2 - 1}\right)}{\sqrt{1-\xi^2}}} \approx V_{RM} \approx I_{RR}(R_Z \| Z_Z) \approx 1520 \times 600 \approx 10^6\,\text{V}$$

$$Q_{RR} \approx I_{RR} / \omega_R \approx 1520 / \left(3.14 \times 10^7\right) \approx 50\,\mu\text{C}$$

Excess carrier (holes) mean lifetime (reciprocal of recombination decay) should be higher than 1 μs and diode reverse recovery time should be

$$t_{rr} \approx \pi / (2\omega_R) \approx \pi \sqrt{L_S C_R} / 2 \approx 50\,\text{ns}$$

that is, nearly half of the forward pumping time.

Since the damped resonant frequency is

$$\omega_{Zd} = \omega_Z \sqrt{1 - \xi^2}$$

the pulse duration (settling time) is close to

$$T_p = \pi / \left(\omega_Z \sqrt{1 - \xi^2}\right) = \pi \sqrt{L_S C_Z} / \sqrt{1 - \xi^2} \approx 34\,\text{ns}$$

This is near the required 30 ns, as can be seen in Fig. 18.5. Designs for higher C_Z values require damping factors ξ toward 0.5, which increase SOS diode ratings (I_F, I_{RR}, and Q_{RR}) but would allow the doubling of C_Z capacitances.

This SOS pulse generator multiplies the incoming prepulse amplitude by a factor slightly higher than 3.

Given the present capabilities of SOS diodes (nearly 1 kA and 1 kV), this 1 MV pulse modulator would require

1. an array of some thousands of SOS diodes arranged in a series of few paralleled diodes;
2. oil isolation and cooling, complemented with water/air heat sinking;
3. special care to minimize parasitic inductances and capacitances.

Other SOS devices use unique diffusion techniques to achieve ultrafast switching times, such as the drift step

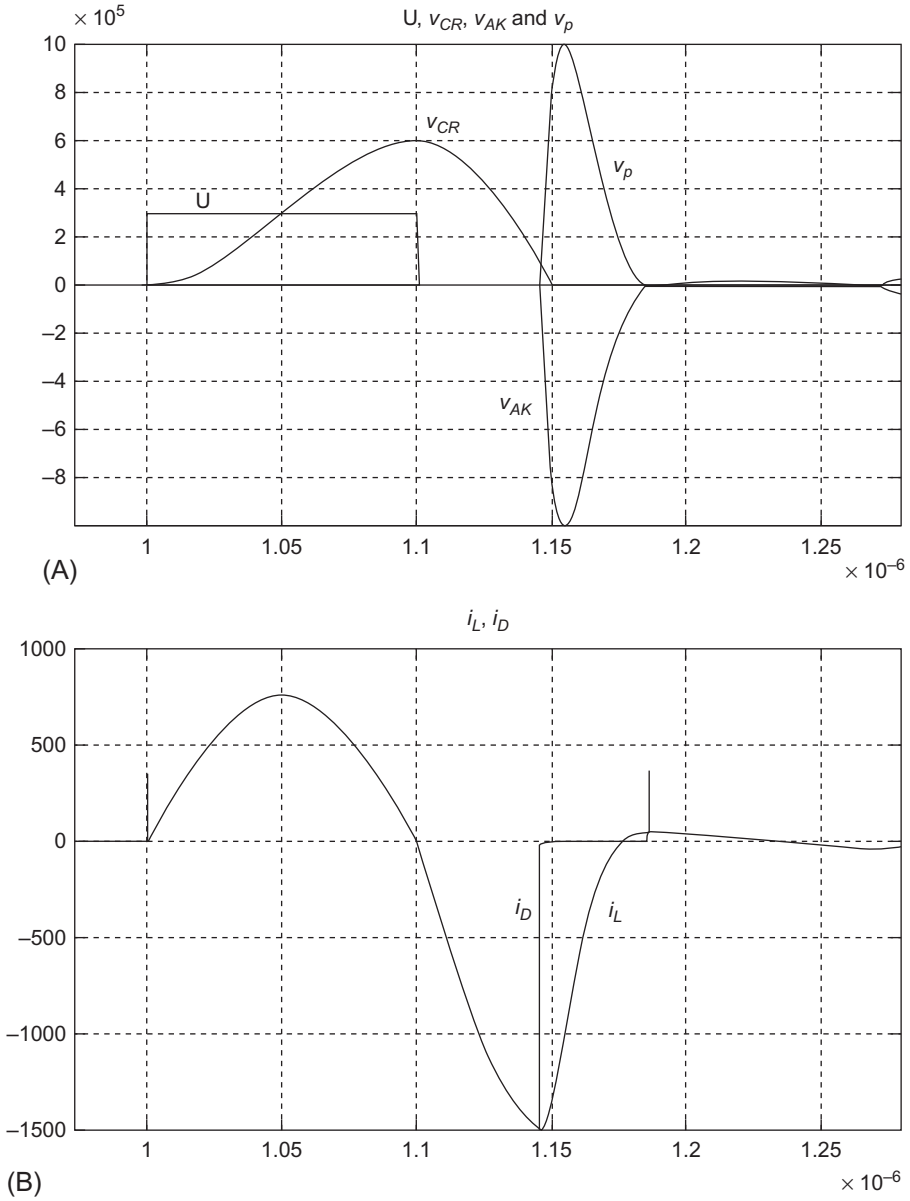

FIG. 18.5 SOS v_p pulse generated using magnetic energy storage. (A) Upper graph shows waveforms of U, v_{CR}, v_{AK}, and v_p in volts and (B) waveforms of i_D and i_L in amperes in the lower graph.

recovery device (DSRD), the inverse recovery diode (IRD), and the delayed ionization device (DID). Each device is capable of producing pulses ranging from 1 to 10 kV, with rise times between 100 ps and 1 ns.

The PIN diode-based silicon avalanche sharpener (SAS) is a sharpening device that shortens the pulse rise time. Usually, it works reverse-biased, a slow rise time and short reverse pulse being applied to the SAS in order to avalanche it. When avalanche breakdown of the SAS drift layer occurs, a very short rise time pulse is applied to the load. Avalanche breakdown does not destroy the SAS if the input pulse is short enough.

18.2.2 Metal-Oxide Semiconductor Technology Transistors

18.2.2.1 Metal-Oxide Semiconductor Field-Effect Transistors (MOSFET)

MOSFETs are very fast unipolar-carrier enhancement-mode semiconductor devices controlled by the electric field associated to the v_{GS} voltage applied at the gate-source terminals (Fig. 18.6A) [10–13]. Their speed is mostly due to the absence of carrier recombination since in N-type MOSFETs the carriers are almost only electrons. MOSFET semiconductor structure forms an $N^+N^-PN^+$ shorted base-emitter bipolar transistor

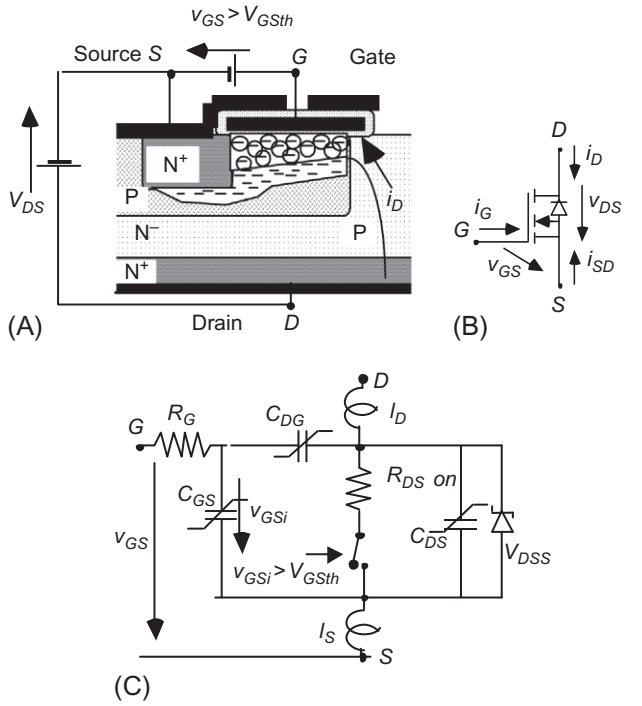

FIG. 18.6 (A) MOSFET structure showing the DS current path, (B) electronic symbol including intrinsic diode, and (C) MOSFET model with parasitic components.

(Fig. 18.6A), which is often referred as behaving as an intrinsic antiparallel PIN diode (Fig. 18.6B).

The MOSFET has the capabilities for high-speed switching in the nanosecond or subnanosecond range [14,15].

In PP applications, MOSFETs should behave as ideal switches, being conductive (switched ON) if v_{GS} exceeds the threshold value V_{GSth}, while maintaining

$$v_{GS} > V_{GSth} + V_{DSon} \tag{18.29}$$

The ON MOSFET behaves almost like a resistor R_{DSon}, with low value and positive temperature coefficient being the drop ON voltage

$$V_{DSon} \approx R_{DSon} I_D \tag{18.30}$$

The MOSFET stops conduction (opens) turning to the *off*-state if

$$v_{GS} < V_{GSth} (off - \text{state}, I_D \approx 0)$$

Usually, the gate driver enforces $v_{GS} < 0$ with $v_{DS} > 0$, to have noise immunity.

If $v_{DS} < 0$, then the intrinsic diode starts to conduct (on voltage $V_{DS} = -V_{PINon}$), which is seldom advantageous since the internal PIN diode usually is not optimized for low-voltage drop or high-speed switching.

In this case, it is better that the gate driver turns on the MOSFET channel in order to prevent the PIN diode conduction, if $-R_{DSon}\ I_D < V_{PINon}$.

The gate current after charging or discharging of gate stray capacitances is almost zero; therefore, the needed gate power is very low. In PP applications, fast switching is required; consequently, the circuit driving the v_{GS} voltage must be designed to charge/discharge the MOSFET parasitic nonlinear capacitances taking into account the effects of device terminal inductances (Fig. 18.6C). The switching speed of existing MOSFETs is limited mainly by packaging (lead inductances) and drain and gate and source resistances together with intrinsic capacitances.

The switching times can be in the order of some nanoseconds or lower and are affected by the driver R_G value.

Resistor R_G dampens the RLC series circuit that contains C_{GS}, C_{DG}, and gate and source stray inductances L_S. The gate resistor can be sized adopting a suitable value for the damping factor ζ of the RLC series circuit

$$\zeta = \frac{R_G}{2Z_G} \tag{18.31}$$

where

$$Z_G = \sqrt{L_S / C_G} \tag{18.32}$$

and C_G is the equivalent gate capacitor, being

$$R_G = 2\zeta \sqrt{L_S / C_G} \approx 1.4 \sqrt{L_S / C_G} \text{ for } \zeta = 0.7 \tag{18.33}$$

The equivalent gate capacitor C_G can be known from the manufacturer datasheets:

$$C_{GS} = C_{iss} - C_{rss} \tag{18.34}$$

$$C_{DG} = C_{rss} \tag{18.35}$$

$$C_{DS} = C_{oss} - C_{rss} \tag{18.36}$$

giving

$$C_G \approx C_{GS} + C_{DG} \frac{dv_{GD}}{dv_{GS}} \tag{18.37}$$

while the gate and source stray inductances L_S can be estimated considering typical per unit values.

For printed circuit boards (striplines) or typical parallel wires, inductance L_S is usually given nearly by 10 nH/cm times the current path total length in centimeters (typical TO220-packaged MOSFETs exhibit source terminal inductances of $l_S \approx 5$ nH).

For twisted wire pairs, coaxial cables, or other low inductance connections, that value can be estimated as low as 3 nH/cm. The inductor estimation (and C_G nonlinear capacitor

calculation) does not need to be very precise since they only affect R_G by their square root values.

Example 18.2 Calculate the gate resistor for a MOSFET with $C_{GS} \approx 800$ pF and $C_{DG} \approx 40$ pF, operating at a drain voltage of 800 V, driven by $v_{GS} = 15$ V through a printed circuit stripline of 5 cm total length.

Solution For the given stripline length, it is obtained

$$L_S \approx 10\,\text{nH/cm} \times 5\,\text{cm} \approx 50\,\text{nH}$$

The gate equivalent capacitance is

$$C_G \approx C_{GS} + C_{DG}(dv_{GD}/dv_{GS}) \approx 10^{-12} \times (800 + 40 \times (800/15)) \approx 2.9\,\text{nF}$$

Therefore, the gate resistor is

$$R_G \approx 1.4\sqrt{L_S/C_G} \approx 5.8\,\Omega$$

As C_{GS} and C_{DG} are nonlinear-voltage-dependent capacitances, using $R_G \ll Z_G$ can establish gate-source overvoltages two to three times the applied v_{GS} voltage, which can disrupt the gate insulation oxide if they exceed the breakdown voltage V_{GSS}, destroying the MOSFET.

To minimize the R_G value, for faster gate capacitor charging and switching, it is essential to strongly reduce the stray inductances (if $L_S \to 0$, then $R_G \to 0$).

Fast driving using avalanche transistors

Fast MOSFET drivers require low stray inductances and often must be based on avalanche transistors [12] (switching bipolar transistors optimized to operate near their collector emitter breakdown voltage V_B but at limited current) or resonant circuits [13]. The avalanche transistors rapidly charge the capacitors C_{GS} and C_{DG}, by transferring capacitor charge from a capacitor reservoir C_a to C_{GS} and C_{DG} (Fig. 18.7A).

Supposing charge continuity, the MOSFET gate voltage should be

$$V_{GS} \approx \frac{V_B C_a}{(C_a + C_G)} \tag{18.38}$$

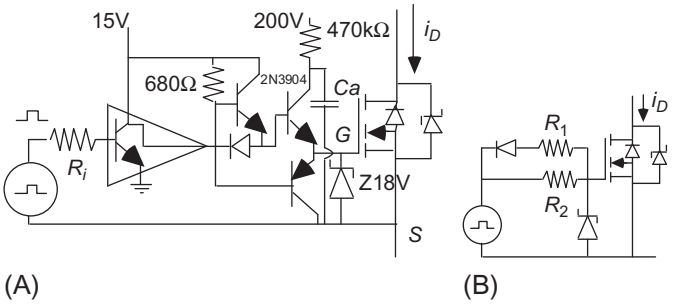

FIG. 18.7 (A) Avalanche transistor MOSFET driver and (B) tailoring switching speed using two resistors.

The Zener diode Z18V helps protect the gate oxide against disruption, but the Zener junction capacitance, if significant, should be added to the C_G value above.

MOSFET switching behavior includes crossing the saturation zone (MOSFET active zone) where

$$i_D \approx K_M(v_{GS} - V_{GSth})^2$$

being K_M a MOSFET structural parameter dependent on width and length of the device channel and electron mobility [16]. The crossing path may imply higher switching losses when switching PP capacitive loads.

Switch-on t_{on} and switch-off t_{off} times can be tailored using different resistive gate current paths to turn-on (R_2) and to turn-off ($R_1||R_2$) (Fig. 18.7B), limiting the charging current and the drain voltage rise or fall rates, at the expense of increased switching losses.

Considering the on and off switching times (t_{on} and t_{off}), the dissipated switching power at the switching frequency f_S in inductive loads is

$$P_S = \left[\left(t_{on} + t_{off}\right) V_{DS} I_D + C_{DS} V_{DS}^2\right] \frac{fs}{2} \tag{18.39}$$

while in resistive loads, it can be quite smaller:

$$P_S = \left[\left(t_{on} + t_{off}\right) V_{DS} I_D + 3 C_{DS} V_{DS}^2\right] \frac{fs}{6} \tag{18.40}$$

PP applications often need semiconductor *switch protection to limit load short-circuit current*. Since in MOSFETs $V_{DSon} \approx R_{DSon} I_D$ and R_{DSon} is fairly constant, then short-circuit protection circuits can be based on the measured V_{DSon} voltage (Fig. 18.8A) [10]. Sensed by diode D_{b3}, this voltage if low enough maintains the C_z voltage low preventing D_z to avalanche and maintaining Q_{t2} off. However, if V_{DSon} rises then D_{b3} turns off, C_z voltage rises and D_z avalanches turning Q_{t2} into saturation that shorts the v_{GS} voltage and turns off the MOSFET. Capacitor C_z acts as a memory, creating a delay that enables the MOSFET turn-on. Fig. 18.8B and C shows alternatives in which the rate of the v_{GS} decay is slowed to lower the rate of rise of the v_{DS} preventing this voltage to exceed the MOSFET hold-off (avalanche) voltage V_{DSS}. Fig. 18.8B shows a capacitive method in which $C_g \gg C_G$, while in Fig. 18.8C, the low-power P MOSFET M_p, in series with the main MOSFET gate, is turned off, putting the high-valued resistor R_{g2} in the turn-off path to limit the v_{GS} decay and v_{DS} rate of rise.

The maximum turn-off overvoltage can also be limited either by using MOSFET parallel connected Zeners (or voltage clamping metal oxide varistors (MOV)) or alternatively by using an avalanche diode (with avalanche voltage higher than the supply voltage but somewhat lower than maximum semiconductor voltage rating) in series with a blocking diode connected to the gate-drain terminals (Fig. 18.9).

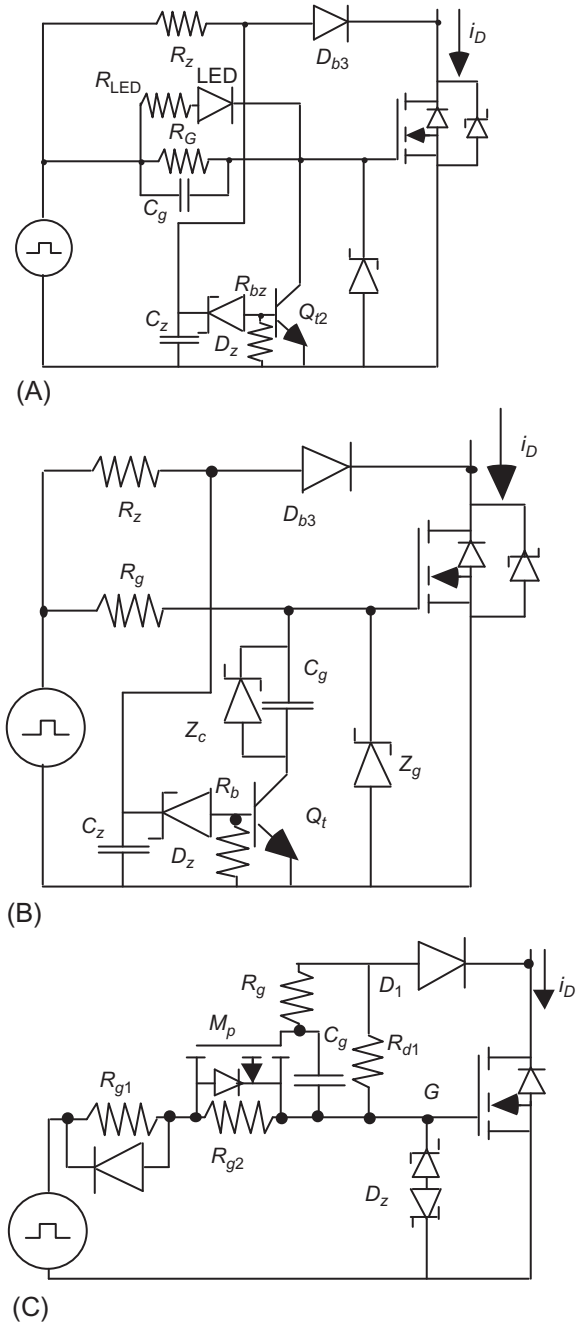

FIG. 18.8 (A) Active protection against load short-circuits, (B) active protection including capacitive v_{DS} rate limiter, and (C) active protection including resistive v_{DS} rate limiter.

18.2.2.2 Insulated-Gate Bipolar Transistors (IGBT)

IGBTs are MOS technology-based semiconductor devices with reduced *on*-state voltage drop, obtained by adding an extra P^+ semiconductor layer in the drain side (punch-through IGBT) or by substituting the N^+ by a P^+ layer (nonpunch-through (NPT) or reverse-blocking IGBT (RB-IGBT)) [10,11,13]. The P^+ layer injects holes in the drift layer reducing voltage drop

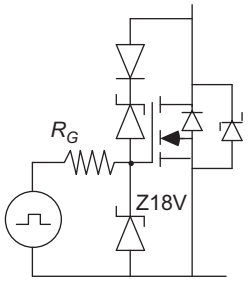

FIG. 18.9 MOSFET overvoltage protection circuit.

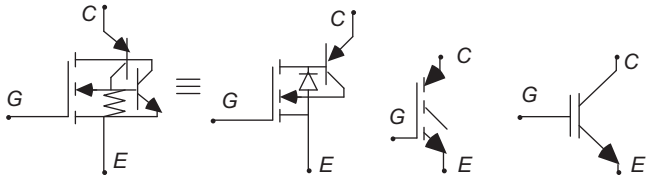

FIG. 18.10 IGBT equivalent circuit and common symbols.

by conductivity modulation. The resulting device can be viewed as a low gain high-voltage PNP bipolar transistor driven by a power MOSFET (Fig. 18.10). Then, gate drivers for IGBTs are similar to those of MOSFETs.

IGBTs can turn-on almost as fast as MOSFETs, using

$$v_{GE} > V_{GEth} \Rightarrow \text{IGBT } on - \text{state} \tag{18.41}$$

The *on*-state saturation voltage V_{CEon}

$$V_{CEon} = V_{CEsat} + r_{CEon} I_{CE} \approx V_{CEsat@I_{CE}} \tag{18.42}$$

where $V_{CEsat@I_{CE}}$ is the *on*-state voltage at current I_{CE} and depends on the I_{GE} value and increases rapidly for $V_{GE} < 12$ V, the device risks working into the active zone for lower V_{GE} values.

Due to the injected minority recombination into the base, however, IGBTs are relatively slow turn-off devices and exhibit tail currents. Switching losses are higher than in MOSFETs.

However, Si IGBTs can withstand much higher hold-off voltages (up to 6.5 kV) and currents (up to 3 kA) than Si MOSFETs that are limited to nearly 1.2 kV, 100 A peak current. At 6 kV voltages and 3 kA currents, IGBTs *on*-state losses are significant, degrading efficiency and causing heat removal problems, yet they are being used in very high-voltage systems [17–20].

Most considerations about the MOSFET drive and protections are still valid for IGBTs. In particular, in shoot-through situations, the IGBT device can be protected by detecting desaturation voltage and then shutting down the IGBT using gate drive circuits similar to those in Fig. 18.8.

18.2.2.3 Injection Enhanced Gate Transistors (IEGT)

IEGTs are IGBT-like structures with deep trench gates and wider cell widths. Hole concentration in the P layer under the gate electrode is enhanced due to hole accumulation,

similar to the conductivity modulation of a PIN diode, lowering the *on*-state voltage and increasing the efficiency specially in high-voltage devices. The enhanced carrier distribution under the gate electrode leads to higher conductivity of the N-base region in the trench-gate IGBT structure, as the gate region extends into the N-base region below the P-base layer. This phenomenon has been called the injection enhancement effect in deep trench-gate IGBT structures and enables higher device voltage rating. As this phenomenon of carrier enhancement under the gate electrode occurs in all IGBT structures, including the planar-gate structures, the IEGT device is a kind of IGBT and can be viewed as such, although their particular physical structure enables them to withstand higher voltages and currents than planar IGBTs structures. The same is valid for similar proposed structures such as the carrier-stored trench-gate bipolar transistor (CSTBT-IGBT).

18.2.3 Thyristors and Turn-Off Thyristor Devices

High-voltage high-power *thyristors*, also termed silicon-controlled rectifiers (SCR), are PNIPN structures (Fig. 18.11A) that can be gated-on by injecting a relatively small gate current into the device gate terminal. In PP applications, thyristors can be used in capacitor discharging circuits, since they can be easily turned on by a small gate current [10,11,13]. Thyristor turn-off behavior is not gate-controlled, being similar to the PIN diode and of little use in PP.

Thyristors can block voltages near 12 kV (the silicon limit is near 15 kV) and can conduct currents up to 8 kA.

Modern thyristor structures like the light-activated silicon-controlled rectifier (LASCR) or the light-triggered thyristor (LTT) are optically triggered (Fig. 18.11B) using an optical fiber and can be valuable in high-voltage applications to enable reducing stray capacitances.

Gate turn-off thyristors (GTO and sometimes called gate-controlled thyristors (GCT)) are distributed gate thyristor structures, roughly equivalent to an NPN-PNP bipolar transistor association [10,11,13]. As such, they have turn-on and turn-off gate capability, present low forward drop voltage, and maintain the PNIPN structure, which enable blocking voltages up to 6 kV and forward currents up to 6 kA.

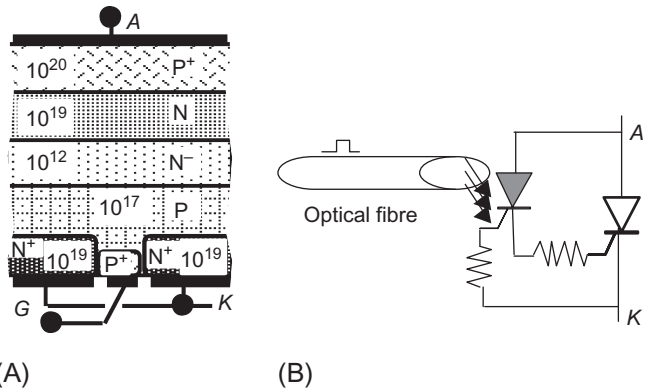

FIG. 18.11 (A) High-voltage thyristor structure and (B) LTT operating principle.

The GTO, although turn-off controlled, is much slower than MOSFET or IGBTs, since it is a bipolar carrier device, and it needs high turn-off gate currents, only slightly lower than their anode currents, meaning their turn-off current gain is low (between 2 and 10). Therefore, the GTO use in pulse power is usually limited to the generation of relatively long prepulses to be applied, through transformers, in sharpening devices such as the SOS diode. Symmetrical GTO structures are even slower than asymmetrical GTOs, although they can block both forward and reverse voltages (symmetrical gate-controlled thyristor (SGCT)).

The GTO turn-on peak and back-porch gate currents are also significantly higher than in thyristors, since the PNP transistor must have low enough current gain to preserve the turn-off capability. Therefore, GTO gate drivers usually need roughly 100 times more power than the gate power needed by a MOSFET or IGBT.

Second breakdown of GTO bipolar junctions (transistors) and the distributed gate structure mean that the GTO needs turn-off (dv_{AK}/dt) and usually turn-on snubbers (di_{AK}/dt) (Fig. 18.12). Considering an $R_V L_V C_V$ series circuit with $\xi = 1$,

$$C_V \approx \frac{I_{AK}}{(dv_{AK}/dt)} \tag{18.43}$$

$$L_V \approx \frac{V_{AK}}{(di_{AK}/dt)} \tag{18.44}$$

$$R_V \approx 2\sqrt{L_V/C_V} \tag{18.45}$$

which dissipates relatively high-power, thus requiring the use of low GTO switching frequencies. GTO thyristors also exhibit current tail at turn-off.

The above drawbacks bound the application of GTO like semiconductor devices to high-voltage and high-current applications, where the low *on*-state voltage is mandatory for high efficiency, but the switching speed, gate drive power, and reliability are not at concern.

The GTO device is difficult to protect against short-circuit currents due to its long storage time, long turn-off delay, and comparatively low turn-off current capability.

Some GTO-derived devices, such as the *integrated gate-commutated thyristor* (IGCT) and sometimes the GCT,

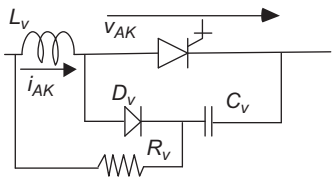

FIG. 18.12 Typical GTO combined di_{AK}/dt and dv_{AK}/dt snubbers.

incorporate distributed gate drives in close association with the GTO, being a single device, thus improving reliability [19]. This approach tries to circumvent the gate wiring inductances and enables accurate control of the turn-on speed. It is useful for series association of IGCTs, including overvoltage and short-circuit protections, together with redundancy. Still, the gate power is significant, and the IGCT needs a turn-on snubber.

Some GTO devices integrating MOSFET-based distributed gate turn-off drivers, with very low gate stray inductances, are sometimes called *MOS turn-off thyristors* (MTO) [13] (Fig. 18.13A). They have the potential to block up to 9 kV and can be faster than the GTO itself, although they need hybrid gate drives to turn-on.

If low-voltage high-current MOSFETs are connected in series with the GTO cathodes (cascode connection) and are used to turn-on and off the GTO, then the whole device is usually called the *emitter turn-off thyristor* (ETO) Fig. 18.13B [13], which has higher switching speed, higher reliability, and easier gate drive than the GTO itself. The ETO *on*-state voltage can be lower than in a comparable IGBT and even lower than in IGCT/GTOs. Thus, emitter switched GTOs can present efficiencies and switching speeds higher than comparable high-voltage IGBTs or IGCTs at 4.5 kV and 4 kA, although at higher costs than IGBTs but lower than IGCTs or even GTOs. Like IGCTs, ETOs include a GTO and need a turn-on snubber but can be fully optical fiber controlled (stray and electromagnetic interference reduction). The ETO drivers can easily generate the needed gate power (self-gate-drive power) and include minimum on/off time generation needed by the GTO, voltage, current and temperature sensors, and easy overcurrent protection (MOS turn-off).

The *MOS-controlled thyristors* (MCT) [13] are silicon fully integrated devices that try to improve GTOs, using integrated both turn-on and turn-off MOS devices, Fig. 18.13D. They can have lower *on*-state losses than IGBTs, current densities higher than IGBTs, working temperatures up to 200°C and block forward voltages of few kV. Switching speed is higher than in the GTO or even in the higher voltage IGBTs. The MCT promises to withstand much higher values of dv_{AK}/dt and di_{AK}/dt than GTOs, needing almost no snubbers and benefiting of simple MOSFET like gate drivers. As MOSFETs, MCTs can easily be connected in series or parallel associations to increase their voltage or current ratings.

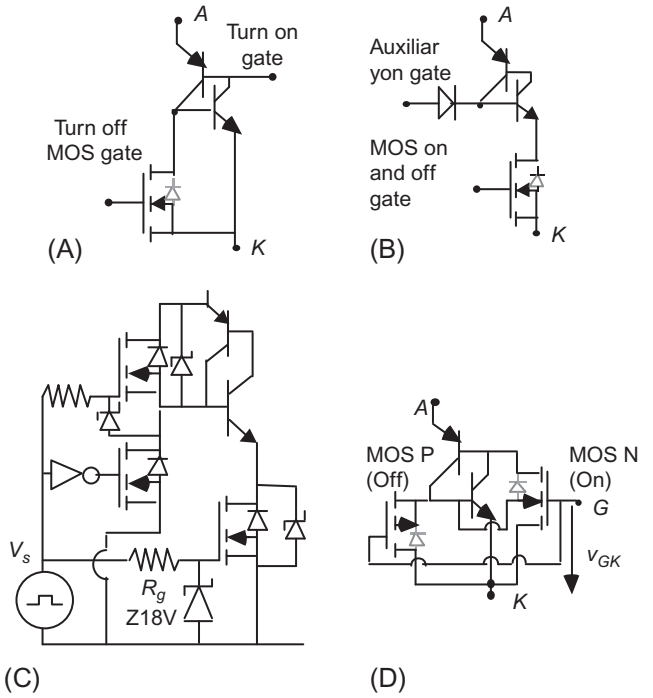

FIG. 18.13 Functional equivalent models of (A) MTO, (B) ETO, (C) conceptual ETO driver, and (D) MCT.

18.2.4 Power JFETs and Derived Devices

Power junction field-effect transistors (JFET) (Fig. 18.14), also termed static induction transistors (SIT), are short-channel depletion-type junction field-effect devices operating in the prepunch-through zone [13]. Their operation depends on the flow of majority carriers (electrons) only (unipolar device), and they have very low stray capacitances. Therefore, SITs have low switching losses and the potential to switch at very high frequencies, even higher than MOSFETs, up to the THz band.

The SIT is normally on a device (with $v_{GS}=0$, it is in the *on*-state) that turns off by applying negative gate-source voltages $v_{GS}<0$, up to several tens of volts. The v_{GS} negative voltage reverse biases the PN gate-source junction, pinching off the conducting epidrain and interrupting the flow of majority carriers.

Unlike SCRs, GTOs, MOSFETs, or IGBTs, the SIT normally on property enables its used in high-speed pulse generation circuits similar to those of SOS diodes, the main difference being the controlled turn-off with a negative gate voltage $v_{GS}\approx -v_{DS}/\upsilon$, where υ is the SIT blocking gain:

$$\upsilon \approx \frac{\Delta v_{DS}}{\Delta v_{GS}}$$

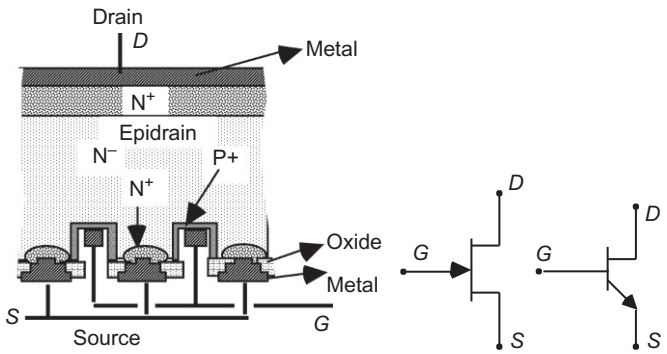

FIG. 18.14 Power JFET structure and possible symbols.

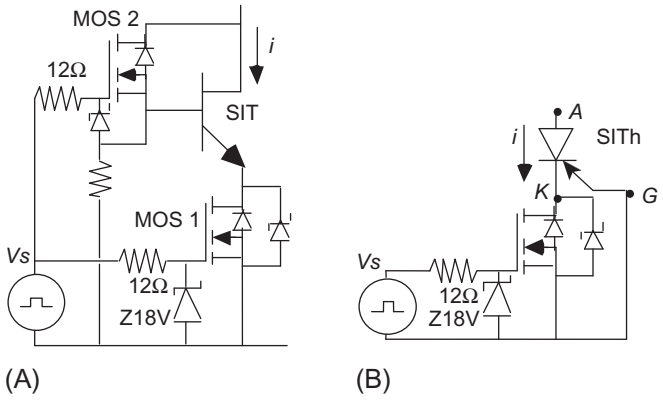

FIG. 18.15 (A) JFET cascode using two MOSFETs. MOS2 can be used to operate the SIT in the bipolar mode and (B) SITh cascode.

The normally on property of the SIT can increase its gate drive circuit complexity. A power JFET usually requires larger power and gate voltages compared with a similar MOSFET. These two SIT drawbacks can be advantageously solved using a cascode connection (Fig. 18.15A) in which a JFET is source-switched by a low-voltage high-current MOSFET.

The SIT device presents positive temperature coefficient, enabling easy paralleling like the MOSFET, and is a unipolar voltage-controlled device enabling relatively easy series connection. The SIT does not need turn-on or turn-off snubbers; simple RC clamping circuits (Fig. 18.16) are enough for stray inductance overvoltage protection.

The SIT can be operated in the bipolar mode (called bipolar mode SIT, BSIT, or BMSIT), if they are designed to allow positive gate currents to inject holes in the drain channel. The *on*-state of the BSIT is almost like that of a bipolar carrier device, increasing the turn-off time, but current density is much higher and useful phenomena for PP might occur [10,11,13].

A SIT-derived structure, which is being used in PP, is the static induction thyristor (SITh) also called field-controlled thyristor (FCTh) or field-controlled diode (FCD). It includes (Fig. 18.17) a P^+ layer (instead of the SIT drain N^+ layer) to obtain a PN junction (hence the name pinched diode). Present SITh devices block 4 kV and can switch peak currents in the kA range, presenting long lifetimes.

The SITh behaves like a diode if $v_{GK}=0$ (gate-cathode short). This diode can be turned off with almost no reverse recovery, making v_{GK} negative. However, the depletion capacitance gate current to turn-off can be as high as half of the anode current, making the SITh gate driver difficult to design and operate. An alternative to ease the gate driver is to use a cascode connection (Fig. 18.15B).

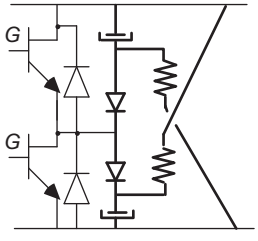

FIG. 18.16 SIT voltage clamper.

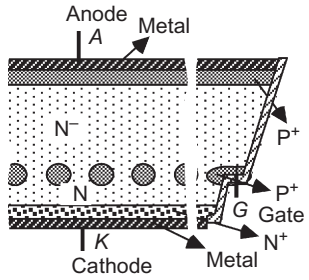

FIG. 18.17 Typical SITh (GTO-SIT) structure.

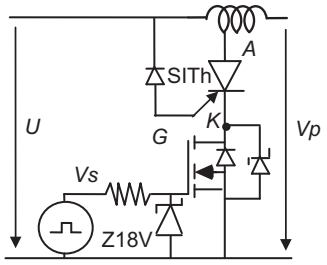

FIG. 18.18 SITh cascode pulse generation using magnetic energy storage.

The SITh is being used for pulse generation as an opening switch in inductive circuits (Fig. 18.18), much like the SOS diode (the SITh behaves as a controlled diode), and holds the pulse voltage *Vp* during the output phase. The gate current needed to extract carriers out of the device, to cause depletion and the off-state, is obtained by switching off the inductive current (with the cascode SITh) in a step-up autotransformer. The switching off induces the fast-rising negative v_{GK} voltages necessary to extract SITh carriers and to apply the load pulse. Speed switching in this case can be enhanced by positive feedback, the fast gate current decay creating a depleted SITh that helps in turning off the current.

18.2.5 Semiconductor Series Stacks and Generalized Cascodes, Semiconductor Parallel Stacks

18.2.5.1 Semiconductor Series Stacks

For applications where the needed working voltage is higher than the available semiconductor ratings, one possible solution is to series connect several power devices. Steady-state and transient balance or sharing of the voltage between series semiconductor devices is very important, since most power semiconductor devices do not hold voltages above their rating and their reverse currents, and reverse recovered charges differ

from device to device even within the same type and maker; the semiconductor with the least reverse leakage current will hold higher voltages.

Example 18.3 Consider a string of two series diodes, and suppose the total voltage $U=10$ kV, the two diodes both with nominal repetitive reverse voltage $V_{RRM}=6$ kV but reverse leakage currents of $I_{Rmax}=40$ mA and $I_{Rmin}=10$ mA. Calculate the diode reverse voltages.

Solution We can determine (Fig. 18.19)

$$R_{eqoffmin}=V_{RRM}/I_{Rmax}=150\,\text{k}\Omega$$

and

$$R_{eqoffmax}=V_{RRM}/I_{Rmin}=600\,\text{k}\Omega$$

Therefore, the diode with $R_{eqoffmin}$ would have the voltage

$$V_{Reqoffmin}=10\times10^3\times150/(150+600)=2\,\text{kV}$$

while the $R_{eqoffmax}$ diode

$$V_{Reqoffmax}=10\times10^3\times600/(150+600)=8\,\text{kV}$$

that exceeds the diode maximum rating. This diode would operate near its avalanche voltage ($\approx$6 kV) that could be destructive.

From the above, $V_{Reqoffmax}$ could be evaluated as

$$V_{Reqoffmax}=\frac{U\,I_{Rmin}}{[I_{Rmax}+(n-1)I_{Rmin}]}. \tag{18.46}$$

Steady-state balancing can be achieved using high-value parallel resistors R_h, so that the parallel of R_h with $R_{eqoffmin}$ or $R_{eqoffmax}$ should give a resistance able to maintain the semiconductor reverse voltage within acceptable limits.

Considering n-series-connected power semiconductors and one of them with

$$I_{Rmin}=0\left(R_{eqoffmax}\approx\infty\right)$$

while the remaining $n-1$ has the typical value R_{eqoff}, the total value R_T of the string of resistors is (Fig. 18.20)

$$R_T=R_h+(n-1)\left(R_h\|R_{eqoff}\right) \tag{18.47}$$

The maximum voltage occurs in the diode with $R_{eqoffmax}\approx\infty$ being

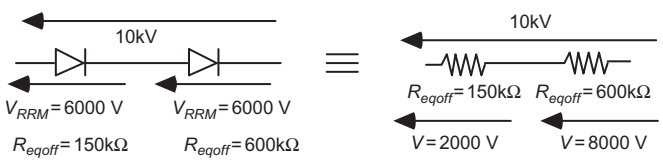

FIG. 18.19 Series connection of power semiconductors.

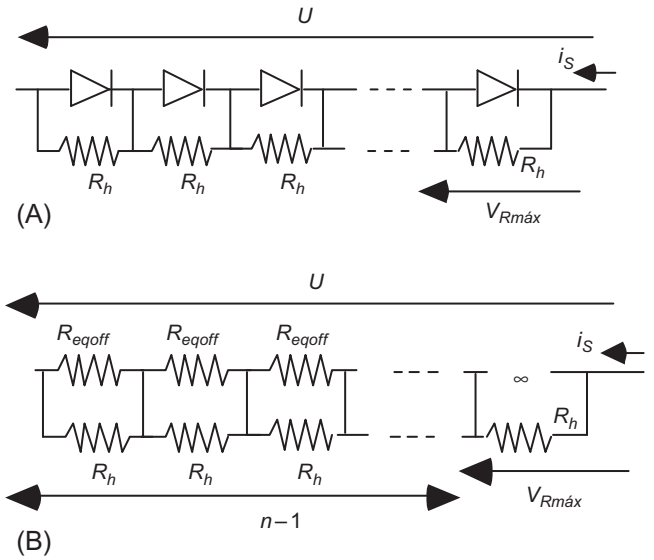

FIG. 18.20 (A) Steady-state balancing of a series connection of power semiconductors and (B) equivalent model.

$$V_{Rmax}=\frac{U\,R_h}{R_T} \tag{18.48}$$

This value should observe a safety margin:

$$U/n<V_{Rmax}<\kappa V_{RRM} \tag{18.49}$$

where $\kappa<1$, giving

$$n>\frac{U}{V_{Rmax}}\Rightarrow n>\frac{U}{\kappa V_{RRM}} \tag{18.50}$$

and

$$R_h=R_{eqoff}\frac{n\kappa V_{RRM}-U}{U-\kappa V_{RRM}} \tag{18.51}$$

Note that

$$U>\kappa V_{RRM}\ \text{and}\ n\kappa V_{RRM}>U \tag{18.52}$$

The R_h resistors should be as high as possible to minimize their dissipated power. The maximum R_h value can be obtained considering the I_{Rmin} and I_{Rmax} semiconductor currents (instead of $I_{Rmin}=0$) to obtain

$$R_h<\frac{(n\kappa V_{RRM}-U)}{(n-1)(I_{Rmax}-I_{Rmin})} \tag{18.53}$$

An alternative to the use of the dissipative resistors is to anti-parallel avalanche or Zener diodes or metal MOV with each series device.

To help share the voltage during transients, R_SC_S parallel snubbers must be also included (Fig. 18.21). If they are designed

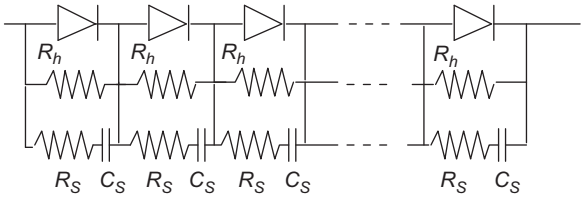

FIG. 18.21 Dynamic and steady-state balancing of series-connected power semiconductors.

just to balance the reverse recovered charge Q_{RR}, then the capacitor value can be given by

$$C_{Smin} \approx \frac{\Delta Q_{RR}}{\Delta U} \tag{18.54}$$

being ΔU the allowed voltage mismatch and ΔQ_{RR} the Q_{RR} variation among devices.

Resistor R_S limits the discharge current when the power semiconductor turns on.

To operate the $R_S C_S$ as a parallel snubber, then the circuit associated stray inductance L_S should be estimated or measured. Then, assuming energy conservation, a rough estimation of the C_S value is

$$C_S \approx \frac{L_S {I_{RR}}^2}{n(\kappa V_{RRM})^2} \tag{18.55}$$

Resistor R_S should define the damping factor ξ of the equivalent RLC series circuit, being

$$R_S = 2\xi\sqrt{L_S/(nC_S)} \tag{18.56}$$

For controlled turn-on and turn-off devices, the $R_S C_S$ parallel snubber can be improved using an extra diode ($R_V C_V D_V$ in Fig. 18.12, with $L_V = L_S$). To obtain near-balanced turn-on t_r and turn-off t_f times for each series semiconductor, with direct current I_{AK}, hold-off voltage κV_{DRM}, and pulse on minimum peak time T_{pmin}, L_S should have the value

$$L_S \approx \frac{\kappa V_{RRM} t_r}{I_{AK}} \tag{18.57}$$

and

$$C_V \approx \frac{I_{AK} t_f}{\kappa V_{DRM}} \tag{18.58}$$

being

$$R_V \approx 2T_{pmin} \cdot \frac{\xi\sqrt{1-\xi^2}}{\pi C_V} \tag{18.59}$$

18.2.5.2 Generalized Cascodes

To use a series stack of controlled turn-off semiconductors such as MOSFETs, SITs, or even IGBTs, the generalized cascode association (Fig. 18.22) is a valuable alternative to the simple series connection [10,14,15]. The simple series association of turn-off devices usually needs optical fiber isolated gate drivers using transformer isolated current source power inverters with series connection through closed-loop high-voltage cables, to assure the insulation between the voltage levels.

The cascode association is faster than other associations when unipolar-carrier semiconductors such as MOSFETs or SITs are used. For MOSFET devices (Fig. 18.22B), the capacitor C must hold the charge to turn the MOSFET on, being

$$C_a \approx \frac{V_{GS} C_G}{(V_{Dsoff} - V_{GS})} \tag{18.60}$$

Zener diodes should be used to protect the gate-source oxide. In Fig. 18.22B, the charge holding gate capacitors are placed in a configuration where the m capacitor C_m should have the value

$$C_m \approx C_a(n - m + 1) \tag{18.61}$$

being n the total number of MOSFETs and $m > 1$ [15].

For stacking IGBTs, care must be taken when designing the drivers of the totem pole IGBTs [21,22]. The positive voltage of each driver can be obtained from the capacitor of the below $R_S C_S$ snubber through a blocking diode connecting the resistor R_S to a turn-off MOSFET driving the IGBT [21,22]. The C_S capacitor should hold the charge to turn-on the IGBT.

When dealing with Cascodes, it is mandatory to minimize the source (or emitter) inductances as they can badly affect the charging rate of the gate capacitances. Bare chips (bare dice) and surface mount design should be used, instead of packaged MOSFETs, IGBTs, or SITs.

18.2.5.3 Parallel Stacks

Parallel associations of power devices can be used when the available semiconductors do not present the needed current ratings.

For positive temperature coefficient devices such as MOSFETs, SITs, and most of their derived structures, the devices can be just connected in parallel, taking care of symmetry to minimize stray inductances and capacitances and to balance junction temperatures. Individual gate drivers and protection circuits (except if stray effects are not a concern) should also be used. This is not valid for the MOSFET intrinsic diode, which must be disabled using channel conduction or extra external diodes.

For negative temperature coefficient devices such as diodes, thyristors, bipolar transistors, GTO, and other bipolar devices, several methods could be used:

(a) To select devices with very small relative parameter variations (matched devices) and to balance their junction temperatures by using a single heat sink and symmetrical disposition.
(b) To use current sharing transformers or coupled inductors (Fig. 18.23).

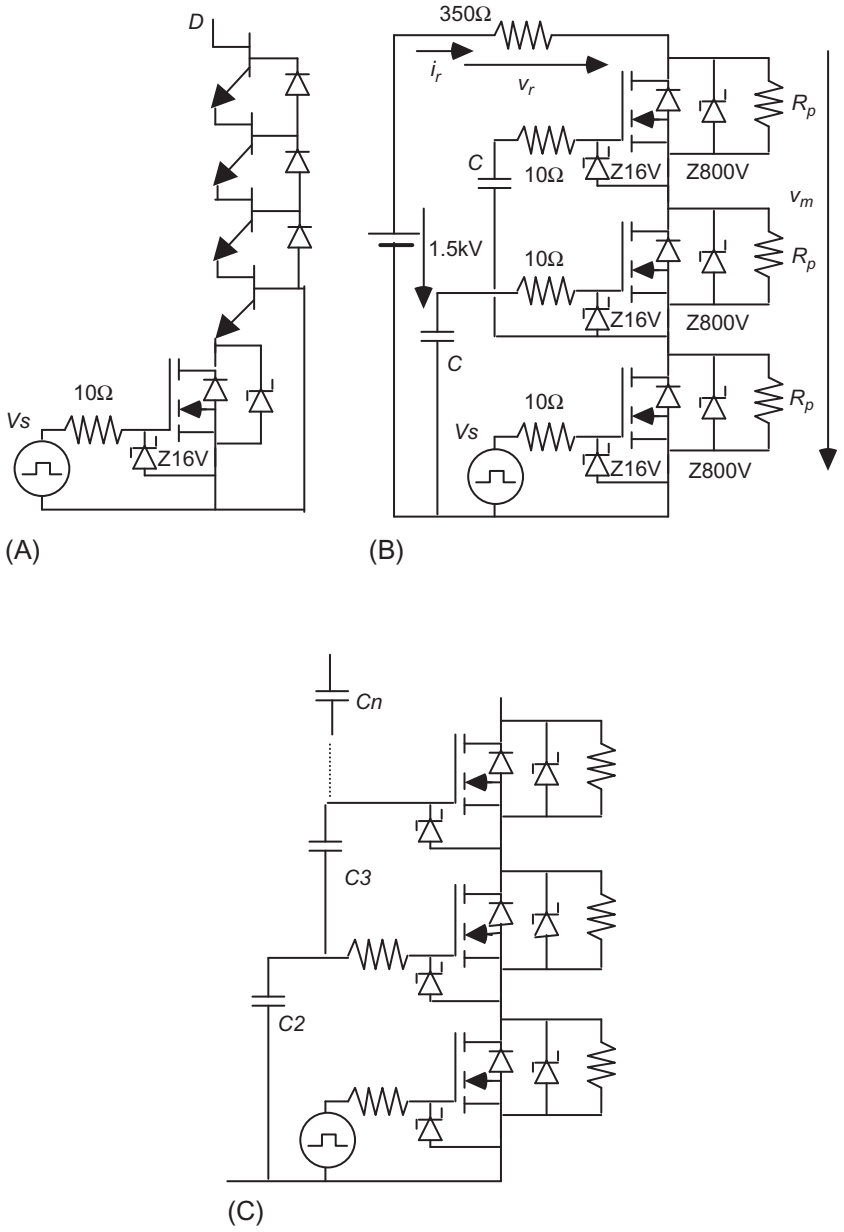

FIG. 18.22 Generalized cascade associations: (A) using SIT devices, (B) using only MOSFETs, and (C) using alternative connection of gate capacitor.

(c) To use current feedback control techniques [23] if the paralleled devices have turn-off capability.

(d) To use small resistors in series with each power semiconductor device (Fig. 18.24), calculated upon the maximum, minimum, and typical device parameters. It is possible to show that a rough estimate for the series resistor R_E is

$$R_E \approx \frac{(V_{1max} - V_{2min})}{(I_2 - I_1)} \tag{18.62}$$

where V_{1max} is the device family maximum on voltage at the minimum allowed current I_1 and V_{2min} is the device type minimum on voltage at the maximum allowed current I_2 ($I_2 > I_1$) [10].

One of the previous approaches has to be selected upon the PP application to minimize costs and maximize performance.

18.2.6 Wide Band Gap Power Semiconductor Devices

Silicon carbide (SiC) and gallium nitride (GaN) are new semiconductor materials with wider bandgaps than silicon (nearly three times higher) resulting in a higher critical electric field

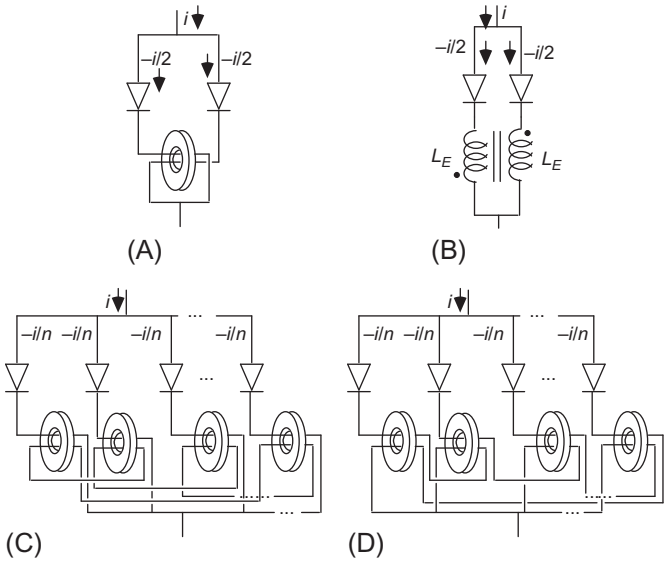

FIG. 18.23 Using transformers or coupled inductors for paralleling power devices: (A) two diodes, (B) modeling the parallel connection of two diodes, and (C and D) alternatives to n-paralleled power semiconductors.

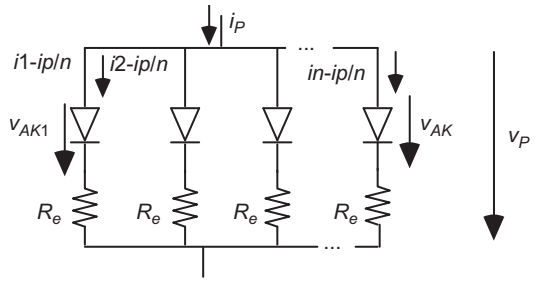

FIG. 18.24 Parallel connection of power semiconductors using current sharing resistors.

and lower *on*-state resistance. In particular, the structure 4H-SiC presents high thermal conductivity (three times higher than Si), high electric field breakdown strength (10 times higher than Si), high maximum current density, very low thermal expansion coefficient, and higher electron saturation velocity. These properties allow higher switching frequency (ns switching time) and 10 times lower switching losses in power applications. Therefore, SiC is a much more promising semiconductor material than Si to build high-powered devices.

SiC allows a very low drift region resistance, enabling *on*-state current densities near 100 A/cm^2 at 25°C with forward voltage drops at 3–4 V in SiC Schottky diodes and power MOSFETs rated at several kV. SiC devices would need approximately 20 times less area than corresponding Si devices, and could operate at higher temperatures and higher breakdown voltages than conventional Si devices.

Schottky barrier diodes use a suitable metal-semiconductor junction. Being unipolar-carrier devices show almost no minority recombination. SiC Schottky diodes have extremely low reverse recovery time, negligible switching losses, and 20 times lower reverse recovery charge than Si while needing a ringing correcting RC snubber, as the reverse-biased diode has a capacitive behavior, causing ringing with stray inductances. Since minority carrier injection is not present in SiC Schottky diodes and SiC transistors, they are expected to have fast switching characteristics, low switching losses, and high reliability.

To profit from the advantageous performance of high-voltage SiC devices, a gate driver design tailored for each particular device is required to provide fast switching for the SiC devices while preventing ringing. Some form of current sensing and limitation is absolutely needed and dv/dt limitation using dedicated gate drivers, RC parallel tuning, and protection Zeners. Gate voltages of nearly 20 V are usually needed for *on*-state, together with a suitable gate ON resistor to limit switching dv/dt and di/dt and the turn-on current spike due to charge/discharge of the freewheeling Schottky barrier diode equivalent capacitance. A too small gate ON resistor can increase switching times and switching energy losses relatively to the optimum values, which are roughly 10 times lower than in the Si technology.

To turn off the SiC device, a negative voltage near −5 V should be applied through a gate OFF resistor, usually much smaller than the gate ON resistance.

High-voltage SiC devices feature *on*-state equivalent resistances with a positive thermal coefficient θ_r ($\theta_r \approx 0.001\ \Omega/°C$). Their *on*-state resistance R_{ON} increases with junction temperature T_j, $T_j \in$ (25 and 175°C):

$$R_{ON} = R_{ON0} + \theta_r T_j \tag{18.63}$$

The SiC threshold voltage V_T (18.64) shows a negative thermal coefficient θ_v ($\theta_v \approx -0.0015$ V/°C) similar to the Si coefficient (−2 mV/°C). However the SiC *on*-state voltage increases with T_j (18.65) for I_{ON} currents bigger than a few amps, as long as $\theta_r I_{ON} + \theta_v > 0$:

$$V_T = V_{T0} + \theta_v T_j \tag{18.64}$$

$$V_{ON} = V_T + R_{ON} I_{ON} = V_{T0} + R_{ON0} I_{ON} + T_j(\theta_r I_{ON} + \theta_v) \tag{18.65}$$

This behavior is advantageous when needing to parallel SiC devices, since they will share the total current. However, for single devices, thermal runaway can occur when high-current is applied. A gate driver able to cope with this phenomenon may be advisable, and the heat sink should be designed to minimize temperature T_j for the required average and root mean square values of I_{ON}. The thermal runaway can further be mitigated by using SiC devices with extra P^+ implantations in the device structure.

GaN enhancement-mode JFETs (E-HEMTs) are very fast unipolar-carrier devices controlled by the electric field associated to the v_{GS} voltage applied at the gate-source terminals.

These normally *off*-state GaN E-HEMTs are conductive with $v_{GS} \approx 6$ V, while they are blocking with $v_{GS} = 0$ V if $v_{DS} > 0$. However, if $v_{DS} < 0$ with $v_{GS} = 0$ V, then device conducts in the reverse direction with zero reverse recovery charge. Negative gate bias $v_{GS} < 0$ V could be used for noise immunity in the *off*-state but increases reverse conduction losses, since the gate-drain voltage must exceed the gate threshold voltage. The gate turn-on resistor has values between 12 and 30 Ω for optimal performance, while the gate turn-off resistor should be 10 times smaller to almost cancel Miller voltage effects (Fig. 18.7B). It is claimed E-HEMTs have 1% switching losses of the corresponding Si transistor.

GaN E-HEMTs have a positive temperature coefficient *on*-state resistance that is useful to balance the current when paralleling several devices. However, given the fast switching speed, to minimize oscillations and to enable balanced dynamic current sharing, the driver circuit layout should be carefully designed to ensure circuit symmetry and to equalize the loop length of the gate drive striplines (using a star connection to all paralleled devices and adding an extra 10% gate resistor to each device).

Superjunction (SJ) transistors are being researched to build high-voltage bipolar power transistors with very short switching times and high base current gain. They present a low *on*-state voltage drop (less than 1 V) at current densities near 100 A/cm^2, due to very low minority injected carries, the device acting nearly as a majority carrier device.

18.3 Load Types and Requirements

PP applications present some of the most demanding loads to the modulators in terms of pulse requirements, as, normally, almost rectangular pulses are needed to many applications in capacitive and inductive loads.

Nowadays, when evaluating a PP modulator topology, it is important to consider, in addition to cost, size, simplicity of operation, and efficiency, the flexibility for different operating conditions into various load conditions (i.e., resistive, capacitive, and inductive).

In fact, the growing variety of environmental, biological, medical, and industrial applications using positive or negative high-voltage repetitive pulses, for enhancing the characteristics of a product or method, impose various load conditions to the modulator circuits [24].

For example, applications with plasmas or gases present normally capacitive behavior, like plasma implantation or air processing for pollution control [25,26]. Applications that use coils present an inductive behavior, like electromagnetic forming, or whenever a high-voltage transformer is associated to the modulator to further increase the output voltage [27,28]. In addition, food processing, water treatment present resistive behavior.

Pulse feeders distributed capacitance and inductance might be important to be considered in PP loads, often needing some sort of resistive compensation added to the PP load.

18.3.1 Resistive (*R*) Loads

Pure resistive-type loads are not common in PP applications, being the processing of liquids one of the exceptions, in applications such as liquid food sterilization, wastewater decontamination, and biomedical materials. However, resistive loads are used frequently as a load reference for testing and comparison the pulse voltage waveform between different types of modulators.

The problem is to find a resistor that can handle the generated power, the voltage level and, at the same time, without presenting inductive behavior. Although there are expensive commercially available types for HV and kW operation, alternatively, it is possible to fabricate, much cheaper, water resistors for any power and voltage needed.

A water resistor is essentially an insulator tube filed with an aqueous electrolytic solution and a metal electrode in each extremity, capable of dissipating the average power and holding the high-voltage from the modulator. Typically, it is made up of dilute solution of copper sulfate ($CuSO_4$) in deionized water (a good electric insulator), which does not degrade the copper electrodes. The higher the $CuSO_4$ concentration, the lower the resistance being the total resistance proportional to the length of the tube [29].

The energy dissipated in the water produces a change in its temperature Δt, which can be determined by knowing the specific heat of water, C_p,

$$\Delta t = \frac{Q}{mC_p} \tag{18.66}$$

where Q is the change in thermal energy and m is the mass of the water resistance tube.

Nevertheless, the use of water resistances brings some limitations. First, with the temperature increase, air bubbles are formed that change the resistance value. Second, the $CuSO_4$ molecule breakdown linked with electrolysis phenomenon has undesirable results: (i) With gas release that increases the pressure inside the tube, a gas release aperture is advisable in the tube edges to prevent the increase of the pressure inside the tube, and (ii) the metallic copper decomposition in the cathode (i.e., copper transport from the anode to the cathode) changes the test conditions. With time, the performance of a water resistance may change in consequence of these effects.

Example 18.4 Consider an HV pulse modulator that produces a 20 kV/10 A pulse during 10 μs with 100 Hz repetition rate. Calculate the temperature increment of $l = 1$ m tube (made from insulating material) with an internal diameter of $d = 2.5$ cm when used as a load to the modulator during 60 s.

Solution The energy per pulse is

$$E_p = V_p I_p t_{on} = 20 \times 10^3 \times 10 \times 10^{-5} = 2\,\text{J}$$

The energy in 60 s is

$$E_{60} = 60 f E_p = 60 \times 100 \times 2 = 12\,\text{kJ}$$

The volume of water inside of the tube is

$$V_W = \pi r^2 l = \pi \times 0.0125^2 = 0.491 \times 10^{-3}\,\text{m}^3 = 491\,\text{g}$$

Then, considering that 1 Cal = 4.2 J, results in

$$\Delta t = \frac{Q}{mC_p} = \frac{12{,}000}{491 \times 4.2} = 5.8\,^\circ\text{C}$$

Hence, for an initial water temperature at 25ºC, after 60 s, the temperature will increase to 30.8°C.

18.3.2 Capacitive (*C*) and *RC* Loads

Pulse power applications associated with plasma and gas processing, and occasionally liquids, present typically capacitive behavior to the PP modulators. In fact, some of the most challenging operating conditions are related with the operation with plasmas.

A typical example is plasma-based ion implantation (PBII), where a target is immersed in a plasma, produced in a confined volume, and almost rectangular negative HV pulses are applied to it. This results into a high-current peak at the beginning of the pulse, rapidly decreasing to a much smaller value. The initial transient current that charges the main system capacitances can be several orders of magnitude greater than the stationary current at the pulse end, when the load imposes almost open-circuit impedance, presenting an additional challenge to the modulator. The above load dynamic characteristics can be represented in an RC electric equivalent circuit as in Fig. 18.25 [30,31].

For plasma loads such as PBII, considering plasma characteristics and typical wanted results, the modulator requirements can be sought: (a) The voltage pulse waveform must be independent of the load impedance, (b) the pulse rise time must be in the order of the μs and small compared with the pulse width, (c) the pulse duty-cycle must be a few percent, (d) the pulse width and frequency should allow some load variation, (e) there must be a current limit in case of short-circuit, and (f) in order to be practical, the power supply cannot be too complex and bulky while including all the necessary protection systems for personnel and equipments.

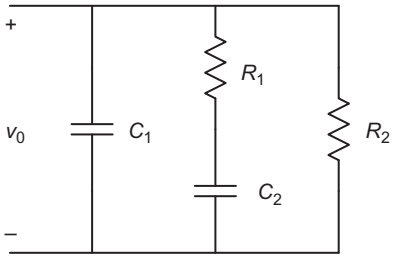

FIG. 18.25 Simplified electric equivalent circuit of a PBII load.

In capacitive-type loads, it is extremely important, also, that the modulator topology has the capability to short-circuit the load after the HV pulse, quickly discharging all the load and parasitic capacitances to zero; otherwise, the load stays charged to almost full pulse voltage. Occasionally, this type of load must be compensated by adding parallel resistors.

18.3.3 Inductive (*L*) and *LR* Loads

Inductive-type loads are present when a pulse transformer is used to further increase the voltage level of a modulator or when voltage pulses are applied to inductive loads such as coils. An example of the last is electromagnetic metal forming application, EMF, where HV resonant topologies apply kA current pulses, during hundreds of μs, into very low inductance systems [8].

For inductive operation, the modulator must clamp the load with an opposite polarity voltage after each HV pulse, during enough time to guarantee a zero average load voltage. In general, this is not accomplished with turn-off capability semiconductor switches but rather with freewheeling diodes. Also, the topology either can be dissipative or can send the energy stored in the magnetic circuit back to the power supply, increasing the efficiency of the modulator.

18.4 Solid-State PP Topologies

The use of innovative techniques, supported on dc-dc isolated converter topologies, brought from solid-state power electronics, taking advantage of all the capabilities of such devices, circumventing their limitations, is playing an important role to the expansion of pulse power technology to a wide range of new applications, needing compact, small size and efficient pulse modulators, spreading to almost every industrial and commercial fields, from food sterilization, biomedical applications and pollution control to surface engineering [31–37].

Nevertheless, each PP application represents a different challenge for the PP technology and the load requirements normally imposes limits to the use of each type of power converter topology. One important characteristic associated with many pulse power applications is the low duty ratio, *D*, pulse operation (i.e., usually lower than 5% [1,2]), where the pulse width is much shorter than the pulse period, which reduces significantly the modulator average power and also the dissipated power into the load, as

$$P_{av} = V_p I_p D \tag{18.67}$$

where V_p and I_p are, respectively, the pulse voltage and current amplitude, supposing a rectangular pulse with $D = t_{on}/T$ duty ratio.

In order to take the most of each topology and also to be able to extend these concepts to other topologies that have potential for high-voltage pulsed generation, it is important to understand the concepts and to know the advantages and limitations when using each topology.

In this section, several topologies capable of generating high-voltage pulses based on relatively low-voltage semiconductors devices are analyzed. The study begins with the most common configurations for pulse generation that switch the HV voltage directly into the load, using stacks of series semiconductors.

The dc-dc isolated converter topologies, forward, flyback, full-bridge, and half-bridge, which can be modified to produce high-voltage rectangular repetitive pulses, with techniques that enable the use of relatively low semiconductor devices, are presented next. Here, the use of a step-up transformer provides galvanic isolation and further increases the output voltage pulse amplitude, although the transformer presents limitations to its use. In order to overcome various technical hitches in assembling a unique high-voltage circuit, stacked associations of lower voltage topologies are also discussed with and without the use of output transformers. Finally, the mature Marx generator pulse power topology is discussed with the intensive use of semiconductors. This concept is also proposed for distributing the voltage in series stacks of semiconductors.

It is important to define some of the pulse parameters mentioned in the following sections, as shown in Fig. 18.26 for the practical shape of unipolar voltage pulses.

Considering Fig. 18.26, the voltage pulse can be characterized by several parameters:

- Rise time, t_r: period of time from 0.1 to 0.9V, where V is the plateau amplitude of the pulse
- Overshoot, ΔV_s: voltage excursion, after the rise time, above the pulse plateau V
- Width, Δt: pulse duration in the 0.5 V region
- Undershoot, ΔV_d: voltage excursion, after the fall time, below minimum voltage, 0 V
- Droop, ΔV: in relation to the plateau amplitude V, $\Delta V = V - V_f$
- Fall time, t_f: period of time from 0.9 to 0.1V_f, where V_f is the final pulse voltage, different from V because of ΔV
- Tail: voltage descend during pulse fall

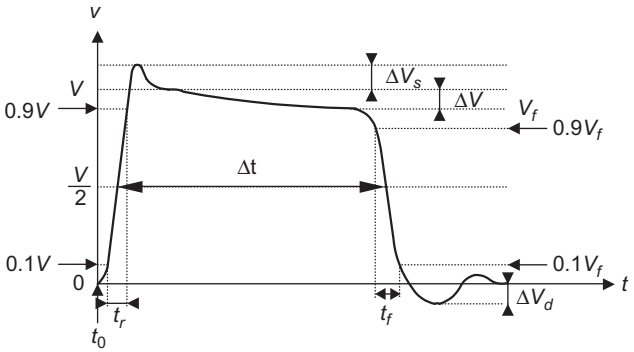

FIG. 18.26 Voltage pulse wave practical shape.

18.4.1 Direct Switching

The most straightforward technique for high-voltage pulse generation consists in switching directly the voltage from a dc capacitor bank charged with high-voltage into the load, using a floating or a grounded switch, as shown in Figs. 18.27 and 18.29, respectively.

18.4.1.1 Floating Switch

Consider the circuit in Fig. 18.27 where the HV power supply, PS, V_{dc} charges an energy storage capacitor bank C_{dc}. The PS internal resistance added by the switch and wiring ohmic resistances is represented by R_{dc} that limits the maximum charging current. Sometimes, a series inductor L_{aux} is also added, which acts as a current limiter and causes some boost of the capacitor voltage during the charging period.

The voltage is modulated into the load by the series floating switch Sp, which operates with duty ratio D. The switch-*on* and *off* control applies the full bank voltage to the load with the pulse width and frequency being controlled by the gate trigger. Supposing C_{dc} charged with V_{dc}, when S_m is *on*, during t_{on}, the C_{dc} capacitor applies a voltage V_{dc} into the load. During this period the inductance L_{aux} limits the discharge of the Power Supply to the load.

If the load has capacitive behavior, an auxiliary circuit must be added to discharge the load capacitance to zero after the voltage pulse. For low duty ratio operation or low-power operation, a permanent parallel resistor R_{a1} can be connected to the load, which must hold off the applied voltage. The R_{a1} value depends on its average power dissipation

$$P_{R_{a1}} = \frac{V_{dc}^2}{R_{a1}} D \tag{18.68}$$

and the required load voltage fall time.

As an alternative, for high duty ratio operation or high-power operation, it is preferable to use an auxiliary series switch S_a with R_{a2} to short the load after the pulse. In this case, the value of R_{a2} can be significantly reduced.

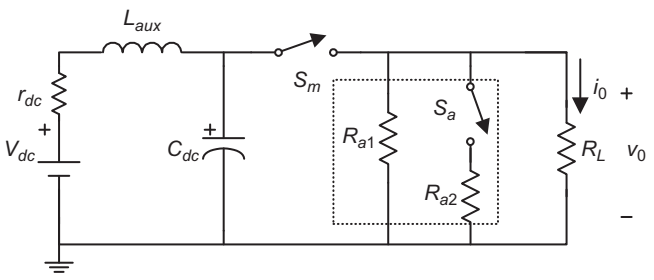

FIG. 18.27 Direct modulator simplified circuit with floating switch.

The main advantages of Fig. 18.27 topology are associated with the generation of voltage pulses with low rise time, low-voltage droop, and also the flexibility to change the frequency and duty ratio operation. However, the pulse characteristics are limited by the energy stored in the capacitor bank and on the performance and power dissipated in the switches and also on the rate of charge of C_{dc}.

The energy initially stored in the C_{dc} capacitor is

$$E_{C_{dci}} = \frac{C_{dc} V_{dc}^2}{2} \tag{18.69}$$

if the S *off* time, $T - t_{on}$, is enough for the PS V_{dc} to charge C_{dc}. Following and during t_{on}, the energy delivered to the load is

$$E_0 = \frac{V_{dc}^2}{R_L} t_{on} \tag{18.70}$$

For PP applications, only a small fraction of the stored energy should be transferred to the output during the pulse mode; otherwise, the pulse voltage has a typical RC discharge waveform, shown Fig. 18.28, and not an almost rectangular shape, as shown in Fig. 18.26.

For a resistive load, the pulse voltage decay V_{dcf} can be calculated as

$$V_{dcf} = V_{dci} e^{-\frac{t}{R_L C_{dc}}} \tag{18.71}$$

Considering a resistive load R_L, the capacitance of the C_{dc} capacitor (Fig. 18.27 circuit) can be determined according to energy delivered to the load. For the required pulse voltage droop ΔV_0,

$$\Delta v_0 = \frac{V_{C_{dcf}}}{V_{C_{dci}}} \tag{18.72}$$

where $V_{C_{dcf}}$ is the capacitor voltage at the end-of-pulse, t_{on}, and $V_{C_{dci}}$ is the capacitors voltage immediately before the pulse. Considering Eq. (18.70), the difference between Eqs. (18.68), (18.69) is the energy stored in the C_{dc} capacitor at end-of-pulse mode, $E_{C_{dcf}}$:

$$E_{C_{dci}} - E_0 = E_{C_{dcf}} \tag{18.73}$$

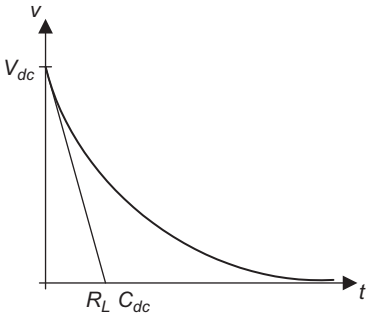

FIG. 18.28 Typical RC discharge waveform.

where Eq. (18.71) for this case results in

$$\frac{C_{dc} V_{dc}^2}{2} - \frac{V_{dc}^2}{R_L} t_{on} = \frac{C_{dc} (\Delta v_0 V_{dc})^2}{2} \tag{18.74}$$

considering that $V_{C_{dci}} = V_{dc}$. Equating (18.72), the capacitor value should satisfy the condition

$$C_{dc} \geq \frac{2 t_{on}}{R_L (1 - \Delta v_0{}^2)} \tag{18.75}$$

Considering Eqs. (18.68) through (18.73), it is mandatory to store in C_{dc} an energy greater than five times the pulse energy in order to have an output voltage droop better than 10%, but if a 1% voltage droop is expected, a 50 times storage energy is required, which may impose limits to the design of the modulator.

In addition, the V_{dc} power supply must be able to recharge the C_{dc} capacitor with an energy equal to the delivered pulse energy, E_0, plus losses, during the charging, $T - t_{on}$, and pulse, t_{on}, periods

$$P_{V_{dc}} = \frac{E_0}{T - t_{on}} + P_{loss} \tag{18.76}$$

During the initial charging of the capacitor C_{dc}, the PS takes a longer time in order to limit the power dissipation in the R_{dc} resistor.

The main disadvantages associated with the circuit in Fig. 18.27 are the S_m switch floating trigger terminals, resulting in a trigger signal that must be transmitted with galvanic isolation. Also, switch S_m must hold the total V_{dc} voltage during the *off* period, $T - t_{on}$, and conduct the load current during the *on* period.

Example 18.5 Consider the HV pulse modulator of Fig. 18.27 where $V_{dc} = 20$ kV. Calculate the value of the capacitor C_{dc} for applying 50 μs and 1600 Hz into an $R_L = 1$ kΩ load and the minimum power of the power supply, V_{dc}, considering 20% losses during the charging and pulse modes.

Solution Considering the capacitor C_{dc} initially charged with V_{dc} and a voltage droop of 5%, then Eq. (18.72),

$$\Delta v_0 = \frac{V_{C_{dcf}}}{V_{C_{dci}}} = \frac{19{,}000}{20{,}000} = 0.95$$

which results Eq. (18.75)

$$C_{dc} \geq \frac{2 t_{on}}{R_L (1 - \Delta v_0{}^2)} = \frac{2 \times 50 \times 10^{-6}}{1000 (1 - 0.95^2)} = 1.025\,\mu\text{F}$$

Choosing a 1.2 μF, then, the energy stored in C_{dc} initially is

$$E_{C_{dci}} = \frac{C_{dc} V_{dc}^2}{2} = \frac{1.2 \times 10^{-6} \times 20{,}000^2}{2} = 240\,\text{J}$$

The energy delivered to the pulse is

$$E_0 = \frac{V_{dc}^2}{R_L} t_{on} = \frac{20{,}000^2}{1000} \times 50 \times 10^{-6} = 20\text{J}$$

This means that after the pulse, the energy stored in the C_{dc} capacitor is 220 J, corresponding to a final pulse voltage of 19.149 V that is 4.2% voltage droop.

Finally, the PS V_{dc} must recharge the 20 J and 4 J (i.e., 10% losses) in $T - t_{on} = 625$ μs, and then,

$$P_{V_{dc}} = \frac{E_0}{T - t_{on}} + P_{loss} = \frac{20 + 4}{625 \times 10^{-6}} = 38.4\text{kW}$$

18.4.1.2 Ground Switch

It is possible to connect the switch S_m referenced to ground and the C_{dc} capacitor floating as shown in Fig. 18.29. Considering this circuit, when S_p is *off*, the C_{dc} capacitor is charged through the load. Supposing C_{dc} charged with V_{dc}, when S_m turns on the positive terminal of C_{dc} is grounded and a voltage of V_{dc} is applied into the load.

The main advantage of Fig. 18.29 configuration in relation to Fig. 18.27 is that S_m is grounded, which makes easier the triggering process. However, in the Fig. 18.29 circuit, during the pulse period t_{on}, the V_{dc} power supply is shorted, increasing dramatically the power dissipation in R_{dc}, which is a significant disadvantage that limits the operation to very low duty ratios.

If inductive-type loads are to be connected in both circuits, it is mandatory to use a freewheeling diode in parallel with the load to reset it after the pulse and, also, to maintain the magnetic energy continuity.

18.4.1.3 Series Stacks of Semiconductors

Considering the dozens of kV range pulse amplitude in the majority of PP applications and the limited maximum reverse voltage of semiconductor switches, such as power BJT, MOSFET, IGBT, GTO, and IGCT, it is necessary to connect many semiconductors in series to assemble the S_m and S_a switches in Figs. 18.27 and 18.29, as shown in Fig. 18.30 [38–43].

As seen, sharing resistors for steady-state and *RCD* snubber circuits for transient voltage balance are needed for *on-off* controlled semiconductors. In addition, it is complex to synchronously trigger many devices in series, placed at different floating high-voltage potentials.

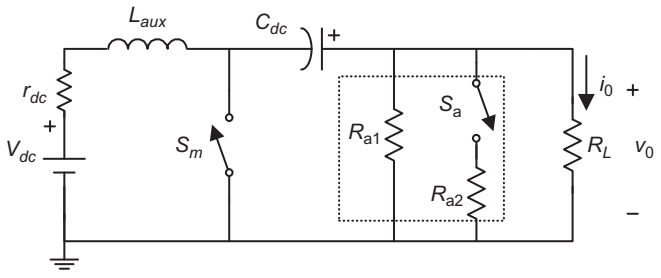

FIG. 18.29 Direct modulator simplified circuit with grounded switches.

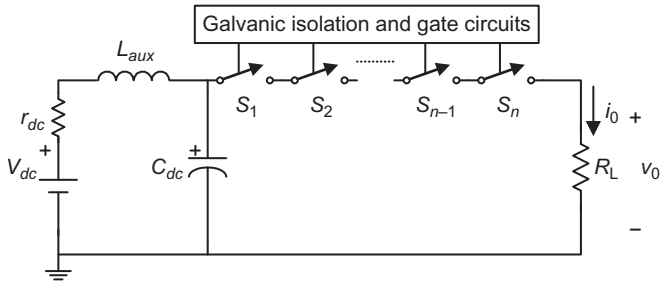

FIG. 18.30 Series-stacked semiconductor topology for high-voltage pulse generation.

Gate-control delay techniques or generalized cascades are used to force the synchronized operation of semiconductors with mismatched switching *on*/*off* characteristics [44].

Nevertheless, in order to prevent shutdown of a series-stacked semiconductor switch due to a defect arising in one semiconductor, redundant switches are, usually, included in the series, about 20% more, such that the surviving semiconductors share the voltage and the failed semiconductor is still able to carry the load current. This is true since the power switches used are built to short-circuit when failing [45].

In order to decrease the voltage hold-off stress on the semiconductors, it is possible to add a high-voltage step-up pulse transformer in the output, further increasing the output voltage to the desired amplitude. However, several issues must be taking into consideration before designing the circuit [44–47]:

1. The parasitic elements (i.e., distributed capacitance and leakage inductance) normally associated with the assembling of the transformer impose limitations to the output pulse waveform, degrading the pulse rise time and voltage plateau.
2. The transformer core volt-second product limits the transformer flexibility to accommodate different operating conditions, such as duty ratio and frequency.
3. After the pulse, it is mandatory to reset the transformer core magnetic flux back to the initial status before the next pulse, which imposes an auxiliary circuit.

Some of the topologies used in power electronics, designed for dc-dc isolated converters, can be specially modified for pulse generation, where the addition of the transformer gives the galvanic insulation and contributes to the reduction of the hold-off voltage in the semiconductors as described in the following sections.

18.4.2 dc-dc Isolated Converters

The use of classic high-voltage modulator topologies, such as the ones described in the last section, substituting the hard-tube

switches by stacked semiconductors is frequently not the best solution for high-voltage pulse generation when using semiconductors, due to the still high-voltage limitations of the devices and their sensibility to overvoltage and overcurrents.

Alternatively, it is advantageous to take into account the topologies that were originally designed for power semiconductors such as the dc-dc isolated converters. The literature refers the use of full-bridge, half-bridge, forward, and flyback converters in hard-switching and resonant topologies for applications such as rapid capacitor high-voltage charging, food processing, X-ray, plasma processing, and air and water pollution control [33–37].

The use of a transformer for galvanic isolation in the forward converter, derived from the buck dc-dc converter; the flyback converter, derived from the buck-boost dc-dc converter; and the bridge topologies can significantly reduce the voltage stress on the semiconductors. In this section, the focus is placed on the particular characteristics that enable high-voltage pulse generation, using relatively low-voltage semiconductor devices.

As the objective is to generate high-voltage pulses at the output, several changes must be introduced in the typical topologies and operating conditions of these circuits. The most obvious is the elimination of the output LC filter, used to keep the output voltage nearly constant.

In the following analysis, it is considered that the semiconductor switches have ideal switching behavior, instantaneous commutation times, zero voltage drop, and zero leakage current.

18.4.2.1 Forward Topology

The simplified forward-type circuit used to generate negative unipolar high-voltage pulses into a load is shown in Fig. 18.31 and the theoretical key waveforms in Fig. 18.32. For positive unipolar pulses, the ground should be placed on the opposite

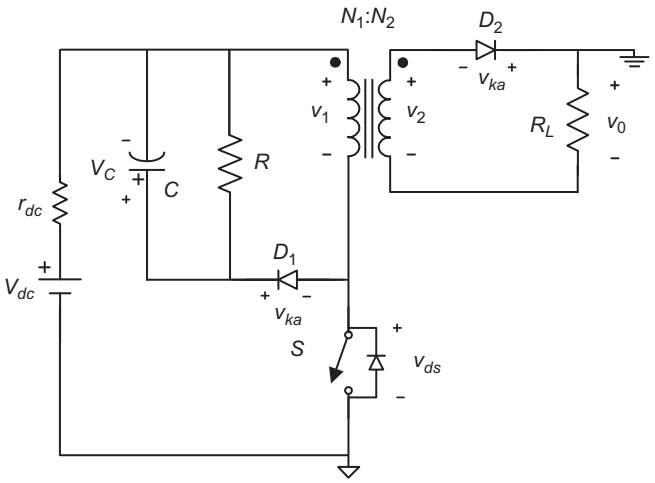

FIG. 18.31 Simplified layout of the pulsed power forward-type circuit used to generate negative high-voltage pulses to a load.

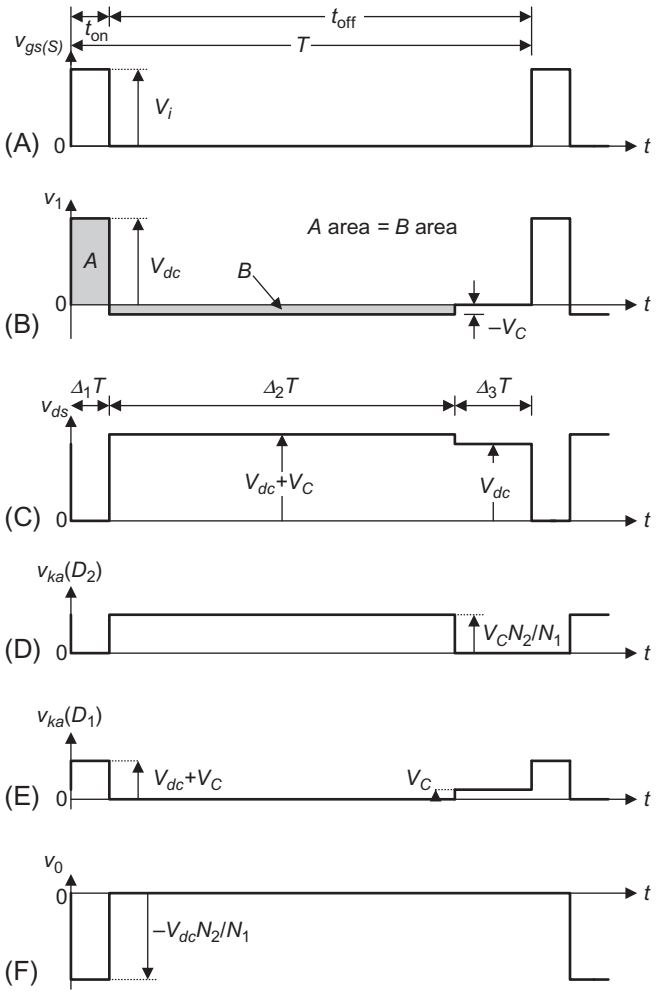

FIG. 18.32 Theoretical key waveforms for the circuit in Fig. 18.31, for a resistive load: (A) switch trigger signal v_{gs}, (B) primary winding voltage v_1, (C) switch voltage v_s, (D) D_2 reverse voltage, (E) D_1 reverse voltage, and (F) load voltage v_0.

secondary transformer terminal. The auxiliary RCD voltage clamp circuit connected to the transformer primary winding is used to reset the transformer using the lowest constant voltage. Considering that the RCD clamp capacitance C_s is sufficiently large, the voltage V_C across it can be assumed constant [48,49].

For pulse generation, the circuit operation can be explained considering only three operating modes [33,50]. In the first mode, the pulse mode, when the main switch S is turned *on* during $\Delta_1 T = DT = t_{on}$, where $\Delta_1 T = D$ and T are, respectively, the S duty ratio and operating period, the energy is transferred from the transformer primary winding circuit to the output. As the voltage applied to the transformer primary winding N_1 is V_{dc}, the secondary winding N_2 diode D_2 is *on*; thus, the voltage applied to the load is

$$v_0 = \frac{N_2}{N_1} V_{dc} \tag{18.77}$$

where N_2/N_1 is the transformer turn ratio, N. In addition, the RCD diode D_1 is *off*, with a reverse voltage of

$$v_{ka(D1)} = V_{dc} + V_C \tag{18.78}$$

For a resistive load R_L, the pulse amplitude is given by

$$i_0 = \frac{\frac{N_2}{N_1}V_{dc}}{R_L} \tag{18.79}$$

In the second mode, the reset mode, when the main switch S turns *off*, the RCD diode D_1 goes *on* and the voltage applied to transformer primary winding is $-V_C$, which resets the transformer core. During this time, $\Delta_2 T$, the secondary diode D_2 is *off*, holding off a reverse voltage of

$$v_{ka(D_2)} = \frac{N_2}{N_1}V_C \tag{18.80}$$

which results to a zero load voltage. From Eq. (18.80), the lower the V_C voltage and the transformer turns ratio N, the lower is the voltage hold-off by diode D_2. In addition, the switch S must hold off a voltage

$$v_s = V_{dc} + V_C \tag{18.81}$$

where V_C must be as low as possible to decrease this voltage.

Finally, in the third mode, the safety mode, following the transformer reset period, during $\Delta_3 T$, still with S *off*, the voltage applied to S is

$$v_s = V_{dc} \tag{18.82}$$

and the voltage applied to the transformer is zero. It is important to have $\Delta_3 T > 0$ in order to guarantee a safety operating margin for the transformer core reset. For practical operation, values between 20% and 30% should be sufficient. This is done be increasing the V_C clamp voltage above the calculated value.

The operation of the Fig. 18.31 circuit for high-voltage pulse generation imposes several conditions:

1. The use of a step-up transformer in order to decrease the voltage on the devices connected on the primary side
2. A minimum reset voltage V_C to guarantee the complete transformer core reset during the S off period, $\Delta_3 T > 0$, reducing at the same time the hold-off voltage of D_2 Eq. (18.80) and of S Eq. (18.81)

Considering the last, it is important to understand the relation between the reset voltage V_C with the operating conditions, such as the duty ratio D.

The reset voltage V_C can be calculated by equating the integral of the primary winding voltage, v_1, over one time period to zero

$$\begin{aligned}\frac{1}{T}\int_0^T v_1 dt = 0 \Leftrightarrow \frac{1}{T}\left[\int_0^{\Delta_1 T} V_{dc} dt\right. \\ \left. + \int_{\Delta_1 T}^{\Delta_1 T + \Delta_2 T} (-V_C) dt + \int_{\Delta_1 T + \Delta_2 T}^{T} 0 dt\right] = 0 \\ \Leftrightarrow V_C = V_{dc}\frac{D}{\Delta_2} = V_{dc}\frac{t_{on}}{\Delta_2 T}\end{aligned} \tag{18.83}$$

where $\Delta_2 T = \tau$ is the transformer core reset period.

For the boundary condition $\Delta_3 T = 0$ (i.e., $\Delta_1 T + \Delta_2 T = T$ and $\Delta_2 = D$), then, Eq. (18.83) becomes

$$V_c = \frac{D}{1-D}V_{dc} \tag{18.84}$$

substituting Eq. (18.84) in Eq. (18.80) the v_{ka} in diode D_2 is:

$$V_{ka(D_2)} = \frac{N_2}{N_1}V_C = \frac{N_2}{N_1}V_{dc}\frac{D}{\Delta_2} \tag{18.85}$$

Considering Eqs. (18.83), (18.85), introducing the load voltage module $|V_0|$, the ratio of τ/t_{off}, the reset time and the time when switch S is *off* it is received:

$$\frac{V_{ka(D_2)}}{|V_0|} = \frac{t_{on}}{\Delta_2 T} = \frac{t_{on}}{\Delta_2 T\frac{t_{off}}{t_{off}}} = \frac{t_{on}}{\frac{\Delta_2 T}{t_{off}}(T - t_{on})} = \frac{DT}{\frac{\Delta_2 T}{t_{off}}(T - t_{on})} \tag{18.86}$$

by simplifying becomes

$$\frac{V_{ka}}{|V_0|} = \left(\frac{D}{\frac{\tau}{t_{off}}(1-D)}\right) \tag{18.87}$$

which can be represented graphically by Fig. 18.33, where

$$\frac{\tau}{t_{off}} = \frac{\Delta_2 T}{(\Delta_2 + \Delta_3)T} = \frac{\Delta_2}{\Delta_2 + \Delta_3} \tag{18.88}$$

with $\Delta_1 + \Delta_2 + \Delta_3 = 1$ and $\Delta_1 = D$

The graphics in Fig. 18.33 shows the maximum load voltage hold-off by diode D_2 as a function of S duty ratio, D, and the transformer reset factor, τ/t_{off}.

Various conditions can be presented for high-voltage pulse generation by forward converters using low-voltage solid-state devices:

1. If the switching duty ratio is only a few percent and the resetting time extends to almost all the main switch-*off* time (i.e., $\Delta_2 T + \Delta_3 T$), diode D_2 holds off a small fraction of the output voltage.

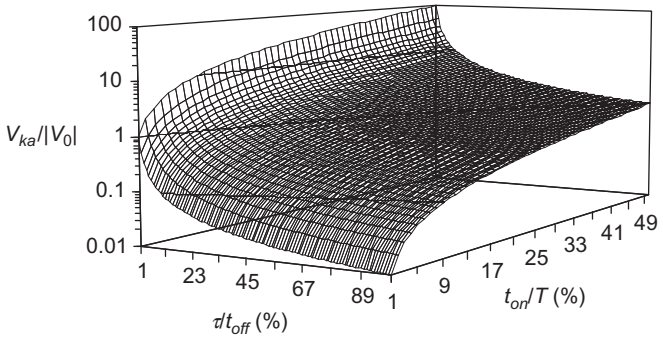

FIG. 18.33 Graphic representation of the reverse voltage of diode D_2 as a function of the reset time and duty ratio of the forward topology (Fig. 18.31).

2. If a step-up transformer is used, $N \gg 1$, this topology enables, also, the use of low hold-off voltage semiconductors in the primary transformer side, when compared with the output load voltage.

For safety reasons in order to ensure that the transformer core is fully reset, the transformer resetting time must end before the *off*-state of the *S* switch ends, $\Delta_3 T > 0$.

The short duty cycles required for generation HV pulses with low-voltage semiconductors are not a shortcoming, as most PP applications require short pulse widths and large recovery times.

Much care should be put in the design and assembling of the transformer as this element must sustain the HV between its terminals. In addition, this topology requires the polarity of the primary winding of the transformer to be identical to that of the secondary winding, and so, the energy of the load is obtained during the *on*-state of the switching device. Therefore, it behaves like a true transformer, wherein energy storage is undesirable, associated with the leakage inductance. However, the forward converter transformers have the poorest utilization and efficiency ratios, because neither the core nor the windings are used during the lengthy core reset interval.

Due to the low main switch *S* duty-cycle operation and transformer behavior, the RCD clamp voltage is designed for a low current, typically, a few % of the main circuit current.

The RCD clamp can be considered a buck-boost converter in discontinuous mode of operation, and designed so that, under any load conditions, during the *S* switch-*off* period the transformer core is fully reset [49].

For resetting the transformer core, other solutions can be implementing, such as a third auxiliary winding, but the fact that this transformer is for HV pulse generation limits in terms of parasitic, assembling complexity and safety.

EXAMPLE 18.6 Suppose the generation of −5 kV amplitude pulses with 5 μs and $f = 10$ kHz ($D = 5\%$) from the circuit in Fig. 18.31. The circuit is supplied from a mains transformer at $V_{dc} = 500$ V, and an $N = 10$ pulse transformer is used. Calculate the semiconductor switches *S*, D_1, and D_2 hold-off voltage.

SOLUTION Consider first boundary condition Eq. (18.84), and then,

$$V_C = \frac{D}{1-D} V_{dc} = \frac{0.05}{1-0.05} 500 = 26.3\,\text{V}$$

The semiconductors hold off 526.3 V for the *S* switch and diode D_1 and 263 V for diode D_2, respectively, 10.5% and 5.26% of the output voltage.

Consider now a reset factor of $\tau/t_{off} \approx 65\%$, and then, $\Delta_1 = 5\%$, $\Delta_2 \approx 62.5\%$, and $\Delta_3 \approx 32.5\%$. From (18.83),

$$V_C = V_{dc} \frac{t_{on}}{\Delta_2 T} = 40\,\text{V}$$

resulting in 540 V for the *S* switch and diode D_1 and 400 V for diode D_2, respectively, 10.8% and 8% of the output voltage.

Hence, for generating 5 kV pulse, 800 V semiconductors could be used, considering a 100% safety factor.

18.4.2.2 Flyback Topology

The simplified flyback-type circuit used to generate negative high-voltage pulses into a load is shown in Fig. 18.34, for positive pulses the ground should be placed on the opposite terminal.

The circuit in Fig. 18.34 is similar to the circuit in Fig. 18.31, but the polarity of the diode D_2 on the secondary winding is reversed. However, this simple change imposes completely different circuit behavior [48].

Considering the circuit in Fig. 18.34 and the theoretical key waveforms of Fig. 18.35, for boundary conditions, when the main switch *S* turns *on*, the energy is stored in the transformer

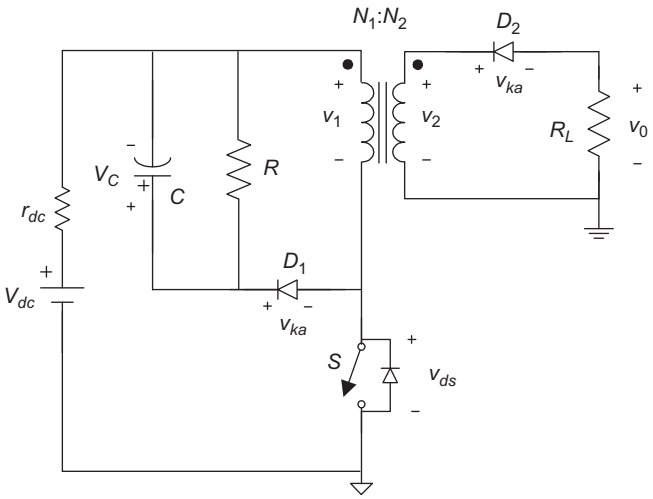

FIG. 18.34 Simplified layout of the pulsed power flyback-type circuit used to generate negative high-voltage pulses to a load.

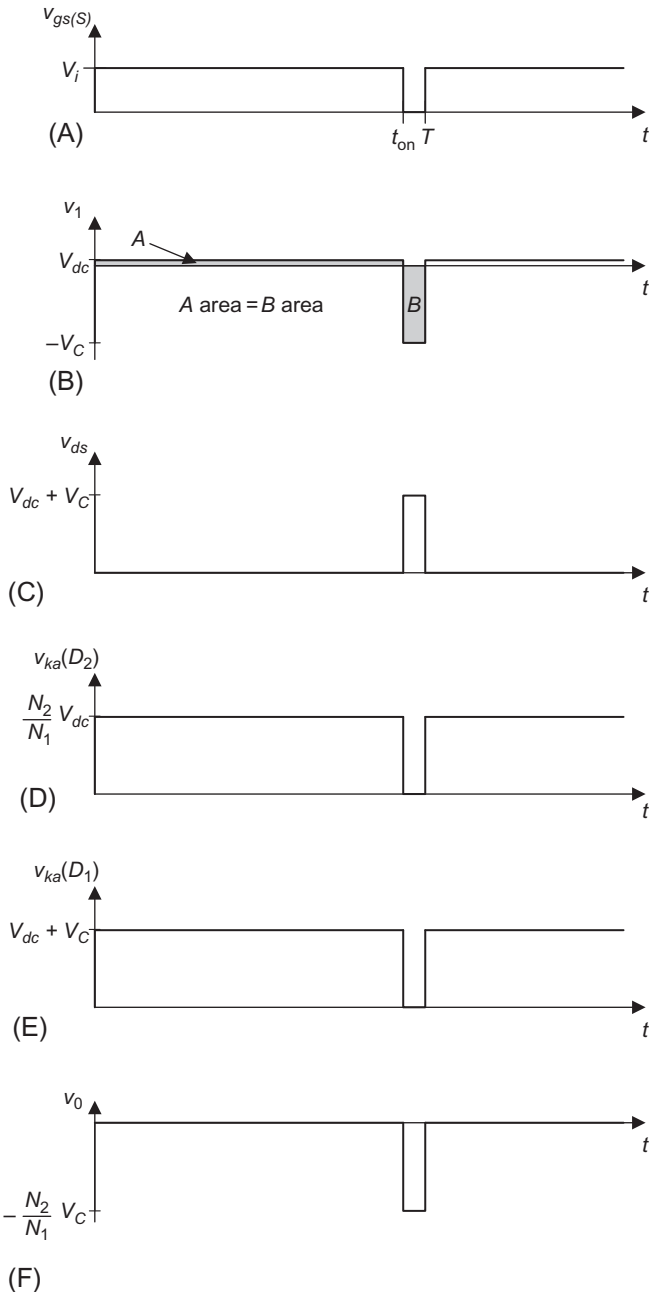

FIG. 18.35 Theoretical key waveforms for the circuit in Fig. 18.34, for a resistive load: (A) switch trigger signal v_{gs}, (B) primary winding voltage v_1, (C) Switch voltage v_s, (D) D_2 reverse voltage, (E) D_1 reverse voltage, and (F) load voltage v_0.

as magnetic flux, the transformer must act as a coil storing energy. The voltage applied to the transformer primary winding is V_{dc}, the RCD diode D_1 and the secondary winding diode D_2 are *off*, thus the voltage applied to the load is zero. The secondary diode D_2 reverse voltage is

$$v_{ka(D_2)} = \frac{N_2}{N_1} V_{dc} \tag{18.89}$$

and the RCD diode D_1 reverse voltage is

$$v_{ka(D_1)} = V_{dc} + V_C \tag{18.90}$$

When the main switch S is turned *off*, the energy stored in the transformer is transferred to the output. The voltage applied to the transformer primary winding is $-V_C$, and the RCD diode D_1 and the secondary winding diode D_2 are *on*, and voltage applied to the load is, approximately,

$$v_0 = -\frac{N_2}{N_1} V_C \tag{18.91}$$

The hold off voltage of the main switch S is

$$v_{ds} = V_{dc} + V_C \tag{18.92}$$

The RCD clamp voltage has two purposes: (i) reduce the voltage spike that occurs due to the resonance between the transformer leakage inductance and the switch S output capacitance, in the *off*-state and (ii) establish the pulse voltage during the same period of time.

Considering the transformer primary winding voltage waveform given in Fig. 18.35 the clamp voltage, V_C, can be approximately derived by equating the integral of the primary winding voltage, V_1, over one time period to zero

$$V_C = \frac{D}{1-D} V_{dc} \tag{18.93}$$

similar to the V_C voltage in the buck-boost topology Eq. (18.84).

Regarding high-voltage pulse generation [50], if the switching duty ratio is near 100%, D_2 blocks only a small fraction of the output voltage. Additionally, if the RCD diode D_1 is *on* during the S switch-*off* time, meaning the flyback circuit runs in continuous mode, the output voltage pulse is well defined by the RCD capacitors voltage V_C. Moreover, with a step-up transformer ($N \gg 1$), this topology also enables relatively low-voltage semiconductor devices in the primary side.

For efficiency reasons, the flyback circuit parameters should be calculated in order that the circuit works at the boundary between the continuous and noncontinuous state. This is done by assuring that the RCD diode D_1 turns *off* at the same instant the switch S turning *on*. The RCD clamp voltage is sized by the main circuit current due to the high duty ratio operation of switch S and the coil-like transformer behavior.

The flyback transformer design is more complex than the forward transformer, as the energy is supplied to the load during the *off*-state of the S switch, meaning that the transformer must be designed to store energy during the *on*-state of the S switch, behaving as a coupled inductor.

The S switch current interruption requirements and the coupled inductor design can be much more challenging in the flyback topology at power levels of interest and represent

a limitation of this topology. This is normally the realm of much higher current devices such as the IGBT and GTO or the use of parallel semiconductors.

Nevertheless, the flyback circuit is much more fault tolerant to a short-circuit in the load or load faults since the switch S is in the *off*-state during the output pulse and will not see the fault current as would the forward converter topology.

Comparing the forward with flyback topologies for HV pulse generation for the same output voltage pulse amplitude, using the same turn ratio transformer, the forward circuits need a high-amplitude dc PS voltage V_{dc}, but the RCD voltage is lower, and the switch S duty ratio is low. Also, in the flyback topology, the voltage pulse width is not as well defined as in the forward, because it is generated by the RCD circuit.

The two topologies have problems in dealing with capacitive loads, because the dynamic variations in the load impedance mismatch the output of the transformer. The solution requires the use of a permanent dummy load, but this increases the power dissipation. Another possibility is the use of a switch dummy load, which will put a semiconductor device in the high-voltage region.

Example 18.7 Suppose the generation of −5 kV amplitude pulses with 5 μs and $f = 10$ kHz ($D = 95\%$) from the circuit in Fig. 18.34. The circuit is supplied at $V_{dc} = 25$ V, and an $N = 10$ pulse transformer is used. Calculate the semiconductor switches S, D_1, and D_2 hold-off voltage.

Solution Consider Eq. (18.93), and then,

$$V_C = \frac{D}{1-D} V_{dc} = \frac{0.95}{1-0.95} 26.3 = 500\,\text{V}$$

The semiconductors hold off 526.3 V for the S switch and diode D_1 and 263 V for diode D_2, respectively, 10.5% and 5.26% of the output voltage.

Hence, for generating 5 kV pulse, 800 V semiconductors could be used, considering a 100% safety factor.

18.4.2.3 Bridge Topologies

The forward and flyback topologies are suitable for the generation of unipolar HV pulses. If bipolar pulses are needed, bridge configurations should be used, like the full- and half-bridge topologies with or without a step-up transformer [33,34,36,37].

Considering a half-bridge topology, Fig. 18.36A shows the configuration for obtaining positive pulses, where the switch S_1 applies the pulse to the load and switch S_2 is capable of applying a zero voltage to the load, which can be important if the load is capacitive, as shown in Fig. 18.36B, otherwise the load will stay charged. If antiparallel diodes are connected to the switches, pulses can be applied to inductive loads, where the S_2 antiparallel diode reset the load after the pulse. For negative pulses, the circuit is presented in Fig. 18.37A; similar operating behavior applies now for opposite polarity, as shown in Fig. 18.37B.

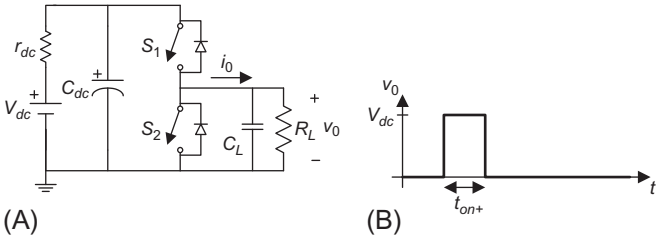

FIG. 18.36 Half-bridge topology for generating positive HV pulses: (A) simplified circuit and (B) output voltage, V_0, for a capacitive load, $C_L||R_L$.

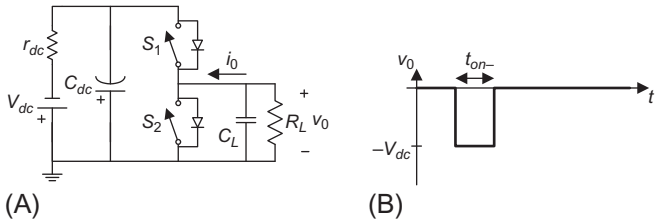

FIG. 18.37 Half-bridge topology for generating negative HV pulses: (A) simplified circuit and (B) output voltage, V_0, for a capacitive load, $C_L||R_L$.

The main limitation of this topology is the hold-off voltage of the semiconductors, which must block the same voltage as the dc HV power supply V_{dc}. If a transformer is connected in parallel with switch S_2, its antiparallel diode can reset the transformer core after the pulse, but this is limited to low duty ratio operation due to the low reset voltage impose by the diode.

If positive and negative pulse (i.e., bipolar) need to be generated using a half-bridge topology, then two power supplies are required, as shown in Fig. 18.38. In this case, each switch S_i must hold off the sum of the two power supplies voltages, that is, $2V_{dc}$. However, for capacitive-type loads, it is not possible to discharge the load capacitance after the pulse, as shown in Fig. 18.38B, since both S_1 and S_2 must be off.

In order to decrease the switches' voltage hold-off, it is common to use instead the full-bridge topology, shown in Fig. 18.39A, which also uses one less power supply. Each switch hold-off voltage is only V_{dc}. The use of more switches also increases the capability to deal with different load conditions, as shown in Fig. 18.39B. In fact, with the full-bridge topology

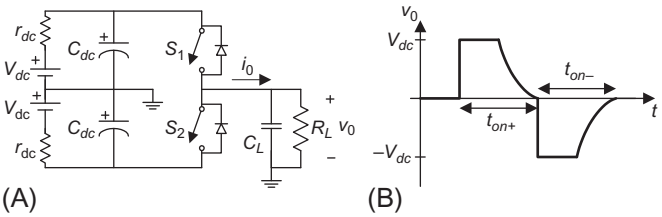

FIG. 18.38 Half-bridge topology for generating positive and/or negative HV pulses: (A) simplified circuit and (B) output voltage, V_0, for a capacitive load, $C_L||R_L$.

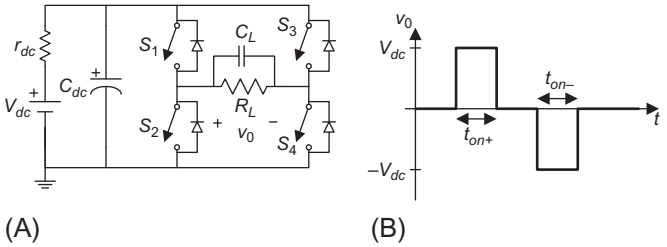

FIG. 18.39 Full-bridge topology for generating positive and/or negative HV pulses: (A) simplified circuit and (B) output voltage, V_0, for a capacitive load, $C_L||R_L$.

positive and/or negative pulses can be applied to any type of load. Nevertheless, depending on the flux of energy not all the controlled turn-off switches are always required.

These topologies are used in applications such as rapid high-voltage capacitor charging, food processing or air pollution control, where bipolar pulses enhance the process [27–31].

It is also possible to connect a transformer at the output terminals to increase the output voltage amplitude and to lower the hold-off voltage in the semiconductors switches if high-voltage pulses are to be generated, with the limitations already described. In order to limit the switches losses, it is common to use auxiliary inductors and capacitors in series or parallel configurations to couple the H-bridge to the HV transformer and also to guarantee a zero average voltage applied to the primary winding.

18.4.3 Cascaded Topology

The assembling of a single modulator circuit with very HV can be a very complex task and result in a number of problems:

- Transformer assembled with very high turn ratio and voltage output
- Many semiconductors stacked in series
- The presence of HV in small distributed volume and safety distances
- Coupling parasitic capacitances and inductances between devices

In order to avoid these problems, it is possible to cascade single modulators circuits where the output voltage is the sum of the individual outputs. However, care is needed in the connection of each circuit as voltage sharing between them is essential.

18.4.3.1 Modulators Without Output Transformers

In the topology shown in Fig. 18.40, there is no transformer between the energy storing capacitors and the load; the system is composed of basic pulse generator cells, made by a capacitor C_i and a switch S_i, stacked in series. The challenge in this type of generator is the uniform distribution of the voltage between each cell due to the floating nature of each cells and the high dv/dt with respect to the ground occurring during the rise

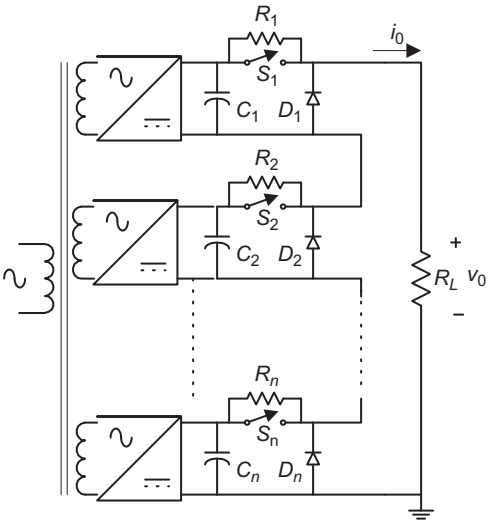

FIG. 18.40 Series-stacked modulator topology.

and falling time of the pulse. For this reason, great care must be taken in order to limit capacitance between each cell and the ground [18].

For proper operation, the capacitors in each cell of Fig. 18.40 circuit need to be charged using a galvanically isolated power supply. One of the possible methods includes the use of floating transformer secondary windings connected to an ac-dc converter, as shown in Fig. 18.40, using full-bridge converters operating as unity power factor rectifiers.

During the pulse period, the voltages of the individual cells are added up; hence, the output voltage is

$$v_0 = v_1 + v_2 + \cdots + v_n \tag{18.94}$$

and the current through all the switches is almost the same.

The freewheeling diode D_i in the output of each cell enables the switch of each cell *on* and *off* independently of other cells, which makes the system capable of adjusting the output voltage. This technique protects also the switches during the *on-off* commutation transient for any mismatch in the voltage distribution, where the R_i resistors help on equalizing the voltage in the S_i switches during *off*-state (see Section 18.2.5).

18.4.3.2 Modulators With Output Transformers

The construction of a single high-voltage pulse transformer, needing a high enough turns ratio ($N \gg 1$) to increase the output voltage, is complex due to the transformer nonideal behavior leading to significant parasitic effects as the output voltage rises. To solve this problem, it is possible to stack series several pulse transformers with lower turns ratio, in order to have only a fraction of the total voltage in each one [28,34,51]. With a careful design, the leakage inductance and distributed capacitances of the equivalent circuit are reduced as compared with one single equivalent transformer, leading

to a better rise time performance [52]. Another alternative is to use auxiliary windings in the transformer to couple leakage fluxes [47,53].

The most common ways to associate pulse transformers are shown in Fig. 18.41 [54]. The autotransformer-type cascade layout is shown in Fig. 18.41A, with three transformers, each one holding one-third of the output voltage v_0:

$$v_0 = v_1 + v_2 + v_3 \tag{18.95}$$

In this topology, power is supplied to T_{p2} and T_{p3} from the previous transformers. Transformer T_{p1} and T_{p2} have three secondary terminals, two of them to feed the primary of the next transformer, and the third to step-up the voltage of the next transformer. This configuration decreases significantly the distributed capacitive between windings.

The major advantage of the cascade association, of Fig. 18.41A, is that the isolation voltage between windings of each transformer is the same and equal to $v_0/3$. However:

- Considering transformers with equal turn ratio N and primary voltage, v_{in}, as each transformer is fed by the previous one, each transformer has a different power. Considering Fig. 18.41A, if the load power is P, neglecting the losses, in the first transformer, the input cascade power is P. The following transformer withstands $2P/3$, and the third transformer withstands $P/3$, being the total installed transformer power $2P$.
- Due to the inclusion of an extra terminal in the high-voltage side with different current ratings, the transformer assembling is complex.

Alternatively, Fig. 18.41B presents three transformers with the secondary windings in series, each one designed for one-third of the output voltage v_0. In the primary side, windings are in parallel, supplied by v_{in}, and referenced to ground. Hence, the isolation voltage between windings of each transformer is different.

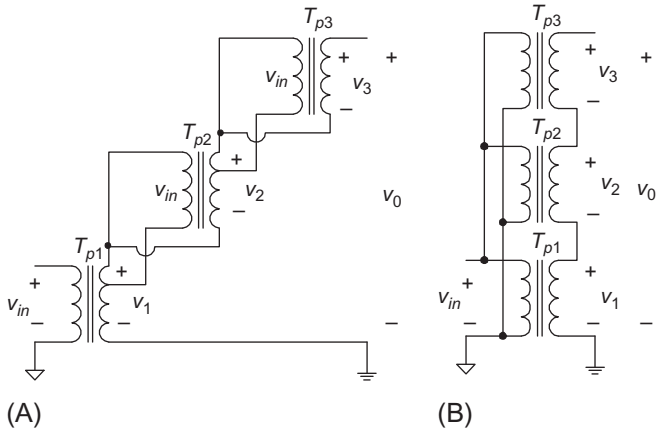

FIG. 18.41 Simplified transformers association: (A) cascade and (B) secondary windings in series.

Considering Fig. 18.41B, while the secondary winding potential in transformer T_{p2} and T_{p3} is, respectively, increased by $v_0/3$ and $2v_0/3$ through the secondary winding of transformer T_{p1} and T_{p2}, in the primary windings, the reference potential stays constant. As a result, each transformer holds a different voltage between windings, depending on the series position of each transformer, which increases toward higher potentials. Thus, transformer galvanic isolation between windings must be designed to $v_0/3$ for T_{p1}, $2v_0/3$ for T_{p2}, and v_0 for T_{p3}.

The above drawback sets serious difficulties for pulse applications of the Fig. 18.41B circuit. Since the pulse transformers placed at higher potentials hold higher voltages, the isolation distance should be increased. Consequently, the pulse waveform is distorted due to the increase of the parasitic leakage inductance with the isolation distance.

To overcome this problem, it is possible to feed the primary windings of the pulse transformers with galvanic isolated power supplies. This can be achieved with the introduction of isolation transformers, in order to keep the secondary windings of the pulse transformers in series but with the same isolation voltage between windings. This solution has the immediate advantage that all the pulse transformers are similarly built, with the same minimum isolation distance, which helps to reduce the output pulse rise time. Two configurations can be considered (Fig. 18.42):

- Independent isolation transformers (Fig. 18.42A)
- Cascade connected isolation transformers (Fig. 18.42B)

For both circuits in Fig. 18.42, the secondary windings of the pulsed transformer are series-connected, delivering each one (T_{p1}, T_{p2}, and T_{p3}) $v_0/3$ of the total output voltage v_0. In the circuit of Fig. 18.42A, the primary windings of T_{p1}, T_{p2}, and T_{p3} are fed, respectively, by the secondary windings of the isolation transformers T_{i1}, T_{i2}, and T_{i3}, these ones being fed by the input voltage v_{in}. In this way, the pulse transformers T_{p1}, T_{p2}, and T_{p3} can be assembled with the same structure and characteristics, for the same isolation voltage of $v_0/3$. The voltage increase due to the secondary winding series connection of T_{p2} and T_{p3} is sustained by the isolation transformer T_{i2} and T_{i3}. Then, for the worst running condition (considering a high capacitance between primary and secondary of the pulse transformers), the galvanic isolation of T_{i2} and T_{i3} must be predicted to hold, respectively, $v_0/3$ and $2v_0/3$. The isolation transformer T_{i1} is not necessary.

In the circuit of Fig. 18.42B, the primary windings of T_{p1}, T_{p2}, and T_{p3} are fed, respectively, by the secondary windings of T_{i1}, T_{i2}, and T_{i3}, with primary windings fed successively by the secondary windings of the previous transformer (i.e., T_{i3} fed by T_{i2}, which is fed by T_{i1}, which is fed by v_{in}). In this way, the pulse transformers T_{p1}, T_{p2}, and T_{p3} can be assembled with the same structure and characteristics, for the same isolation voltage of $v_0/3$. The voltage increase due to the secondary winding series connection of T_{p2} and T_{p3} is held by the isolation transformer T_{i2} and T_{i3}. The isolation transformer T_{i1} is not needed.

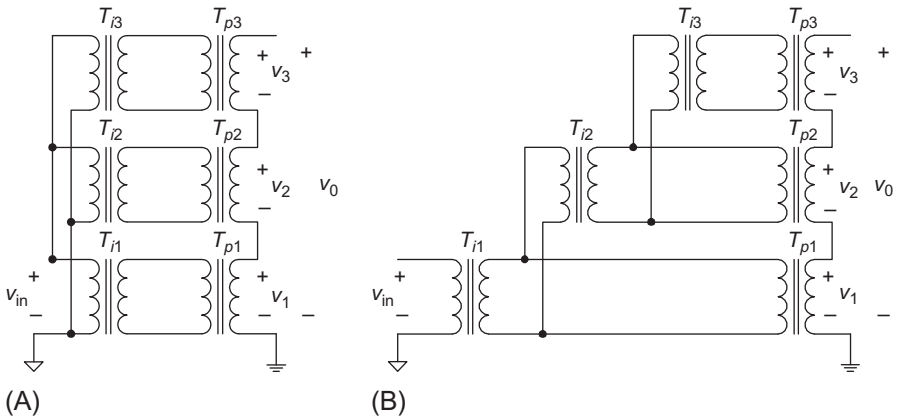

FIG. 18.42 Simplified layout of series-connected secondary winding transformers fed by (A) independent isolation transformers and (B) cascade isolation transformers.

Taking into account the two circuits of Fig. 18.42:

- In Fig. 18.42A, considering a load power P and neglecting the losses in the transformers, each one is assembled for a power of $P/3$ (i.e., the power installed in all the transformers is $2P$). However, in Fig. 18.42B, the pulse transformers are assembled with a power of $P/3$, but the isolation transformers have successive powers of P, $2P/3$, and $P/3$. The total power installed in all the transformers is $3P$.
- In Fig. 18.42B, all the transformers have the same isolation voltage, while in Fig. 18.42A, the isolation voltage in isolation transformers is different.

Considering only the pulse transformers, the two topologies, in Fig. 18.42, are equivalent. Hence, the choice between the two should be based on the characteristics preferred for the isolation transformers and the features desired for the pulse generator.

Regarding the last, it is considered a great advantage for the high-voltage pulse generator to be of modular construction, built upon several equal modules, where each one could occupy any position in the generator.

Example 18.8 Consider the generation of −15 kV pulse from a series stack of three −5 kV forward HV pulse generators based on the topology shown in Fig. 18.31, with the operating conditions of Example 18.6. Select the stack method to implement and draw the complete assembly, taking into consideration a modular perspective. Specify, also, the energy supply to the three stages, the selection of semiconductors and their triggering.

Solution The modular high-voltage generator construction is based on three main principles:

- Distribute the total voltage of a high-voltage circuit by holding the potential of several points in the circuit relatively to ground.
- Distribute the total voltage for several transformers connected in series.
- Use isolation transformers to feed the primary of the series-connected transformers, as shown in Fig. 18.42A.

The proposed circuit layout is shown in Fig. 18.43. If positive pulses are desired, it is only necessary to invert the polarity of the secondary diodes D_{ri}, where $i \in \{1, 2, \ldots, n\}$. Power is supplied to the three modules via isolation transformers (1:1), T_{ii}, which must hold off a maximum voltage of 1 kV between primary and secondary. These transformers are assembled with primary windings in parallel, connected to a dc-ac high-frequency inverter to reduce the size and increase the efficiency of the system. In addition, each secondary winding is connected to an ac-dc rectifier that produces the necessary v_{dci} voltage to the forward converters.

Considering the −5 kV voltage at each individual forward pulse generator with the operating condition of Example 18.3, then, 800 V semiconductors can be used. Hence, MOSFETs can be select for switches S_i.

Considering the three modules, in Fig. 18.43, with switch S_i *on*, diodes D_{ri} are conducting, and the voltage applied to the load is

$$v_0 = -(v_{01} + v_{02} + v_{03}) = -3 \times 5000 = -15\text{kV}$$

considering three equal modules, $v_{01} = v_{02} = v_{03} = v_{0i}$. During this time, the voltage reference at the secondary terminal with a dot point of each pulse transformer is raised:

$$v_{ref\ Tp1} = 0\text{V}$$

$$v_{ref\ Tp2} = (2-1)v_{0i} = -5\text{kV}$$

$$v_{ref\ Tp3} = (3-1)v_{0i} = 2 \times 5000 = -10\text{kV}$$

During the off time of switches S_i, the voltage applied to the load goes to zero, diodes D_{ri} in each module hold off only

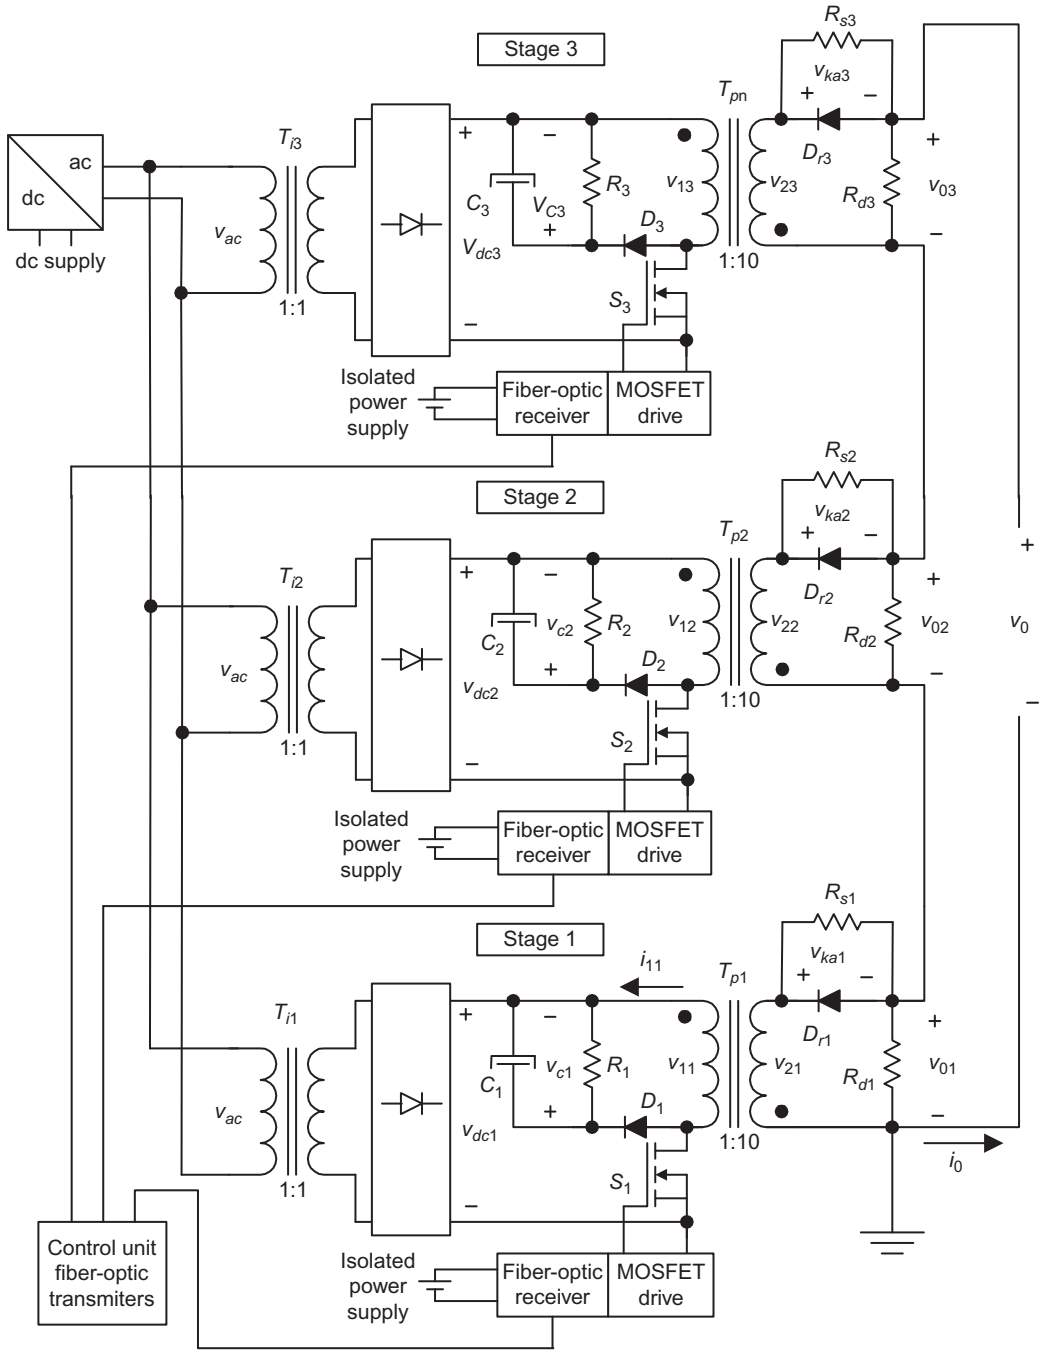

FIG. 18.43 Modular pulsed generator simplified layout for −15 kV output pulses.

the reset voltage of their respective pulse transformer. Voltage sharing resistors, R_{si}, are used to equally distribute the reset voltages of each module through diodes D_{ri}. In order to hold the high-voltage potential in each module relative to ground, high-valued R_{di} resistances can also be used.

Regarding the triggering of the MOSFETs in each stage, dc isolated power supplies are used in each stage to supply the necessary energy to the trigger drives that receives the signals by optical fiber from the ground control circuit.

18.4.4 Solid-State Marx Generators

The use of voltage multiplication techniques for generating HV repetitive pulses is not limited to the use of transformers. More complex methods can be used without the limitation of transformers. The most common is the Marx generator concept [55].

The Marx generator concept is presented in the circuit of Fig. 18.44, which comprises a number of modular stages

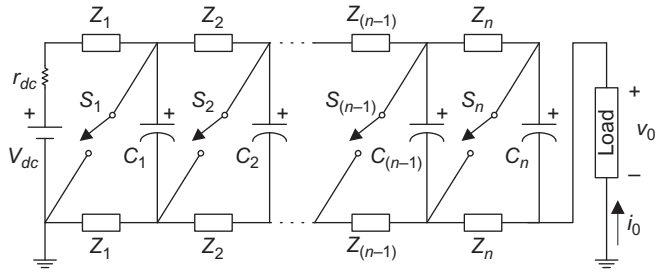

FIG. 18.44 Marx generator topology for producing repetitive negative high-voltage pulses into a load.

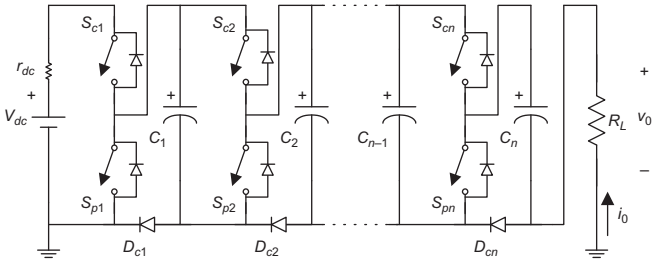

FIG. 18.45 Circuit for applying HV negative repetitive pulses into resistive load.

constituted by an energy storage capacitor C_i, two impedances Z_i (resistive and/or inductive) for charging and limiting the self-short-circuit capacitor paths and a switch S_i, for $i \in \{1, 2, \ldots, n\}$. During the charging period, a relatively low-voltage dc power supply V_{dc} charges the C_i capacitors in parallel through impedances Z_i.

When switches S_i are turned *on*, the C_i capacitors are connected in series and apply a voltage into the load, equal to

$$v_0 = -nV_{dc} \tag{18.96}$$

depending that the capacitors are charged to the power supply full voltage, V_{dc}. During this time, the bottom impedances Z_i limit the self-short-circuit path of the C_i capacitors.

The circuit in Fig. 18.44 is assembled in such a way that there is voltage modularity, meaning that each stage holds the power supply voltage V_{dc}. However, due to this parallel process, the first stages carry the total charging current, which sets different power requirements for the devices in each stage.

This concept has been used intensively through the years, with spark gaps used as switch S_i for very high-voltages and powers, but the spark gap only turns *off* when the current goes to zero. Recent technological upgrades with the addition of solid-state switches and the replacement of most of the passive elements increased the lifetime of the modulator and allowed higher pulse repetition rates, meaning an improved performance [22,56–58].

18.4.4.1 Generation of Negative Pulses

During the last years, various semiconductor-based Marx and SM topologies have been described, with analogous characteristics in order to reduce the losses and increase the performance of the circuit for different types of applications and loads [22,56–58].

Fig. 18.45 shows a typical SM topology, with n stages able to deliver negative high-voltage repetitive pulses into a load R_L; the theoretical key waveforms are shown in Fig. 18.46. Each stage of the SM consists of an energy storing capacitor C_i, a diode D_{ci}, and two switches S_{ci} and S_{pi}, with antiparallel diodes, where the subscript $i \in \{1, 2, \ldots, n-1, n, n+1\}$. The S_i switches can be implemented with BJTs, GTOs, IGCTs, IGBTs, MOSFETS, or other *on-off* devices. The inclusion of

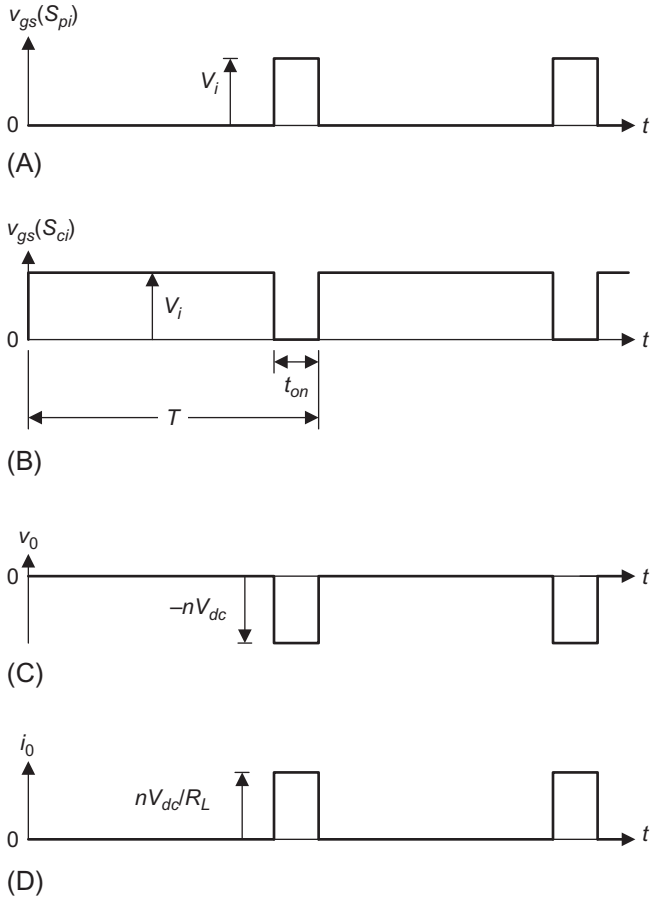

FIG. 18.46 Theoretical waveform for the operation of the circuit in Fig. 18.45: (A) trigger signal of switches S_{pi}, $v_{gs(Spi)}$; (B) trigger signal of switches S_{ci}, $v_{gs(Sci)}$; (C) output voltage, v_0; and (D) output current, i_0.

S_{c1} guarantees that during the pulse period, the dc charging power supply V_{dc} is not short-circuited, preventing high-current-load pulses through the power supply.

Considering resistive load, R_L, the operation of the Fig. 18.45 modulator can be understood considering two operating modes, for a switch duty ratio $D = t_{on}/T$. In the first one, switches S_{ci} and S_{pi} are, respectively, turned *on* and turned *off*. During the charging period, $(T - t_{on})$, capacitors C_i are

charged from the dc charging power supply, V_{dc}, with current limited by the internal resistance of the semiconductors, the wires, and the dc charging power supply internal resistance (or externally added) R_{dc}, resulting in a small time constant that enables kHz operation. The *on*-state of D_{ci} ensures that during this period, the voltage, V_0, applied to the load is, approximately, zero.

In the second operating mode, switches S_{ci} and S_{pi} are, respectively, turned *off* and turned *on*. During the pulse mode, t_{on}, capacitors C_i are connected in series and their voltage applied to the load. The load voltage v_0 is proportional to the charging power supply:

$$v_0 = -knV_{dc} \tag{18.97}$$

where n is the number of stages and $k<1$ characterizes the nonideal behavior of the passive and active elements in the circuit and operating conditions.

The D_{ci} diodes guarantee, also, that the S_{pi} switches only block a maximum voltage of V_{dc}, even in fault condition, such as the lack of synchronization. Considering Fig. 18.45, for example, if switch T_{pn} is *off* during pulse mode, D_{cn} conducts and short-circuits the last stage, imposing an output voltage of

$$v_0 = -k(n-1)V_{dc} \tag{18.98}$$

The operation of Fig. 18.45 circuit can be represented by its equivalent model during both operating modes, considering ideal switches and $C_i = C$. During the charging mode, the C_i capacitors are in parallel, and the circuit can be model as shown in Fig. 18.47A, where nC is the equivalent capacitance, seen by the power supply, charged with V_{dc}. In addition, during pulse mode, the C_i capacitors are in series, where C/n is the equivalent capacitance, seen by the load, charged with nV_{dc}, as shown in Fig. 18.47B.

The energy stored in the C_i capacitors, during $T-t_{on}$, is

$$E_{C_i} = \frac{n}{2}CV_{dc}^2 \tag{18.99}$$

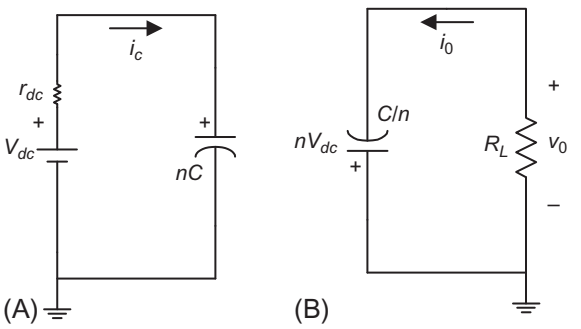

FIG. 18.47 Equivalent circuit of Fig. 18.45: (A) the charging mode and (B) the pulse mode, for negative output pulses.

and the energy delivered to the load, during t_{on}, is

$$E_0 = n^2\frac{V_{dc}^2}{R_L}t_{on} \tag{18.100}$$

For pulse power applications, only a small fraction of the stored energy should be transferred to the output during the pulse mode, otherwise the pulse voltage has a typical RC discharge waveform, not an almost rectangular shape. Considering a resistive load R_L, the capacitance of the C_i capacitors in Fig. 18.45 circuit can be determined according to energy delivered to the load. For the required pulse voltage droop,

$$\Delta v_0 = \frac{V_{C_f}}{V_{C_i}} \tag{18.101}$$

where V_{C_f} is the capacitor voltage at the end-of-pulse mode, t_{on}, and V_{C_i} is the capacitors voltage immediately before pulse mode. Considering Eq. (18.101), the difference between Eqs. (18.99) and (18.100) is the energy stored in the C_i capacitors at end-of-pulse mode, E_{C_f}:

$$E_{C_i} - E_0 = E_{C_f} \tag{18.102}$$

where Eq. (18.102) for this case results in

$$\frac{n}{2}CV_{dc}^2 - n^2\frac{V_{dc}^2}{R_L}t_{on} = \frac{n}{2}C(\Delta v_0 V_{dc})^2 \tag{18.103}$$

Assuming that $V_{C_i} = V_{dc}$, equating (18.103), the capacitor value should satisfy the condition

$$C \geq \frac{2nt_{on}}{R_L(1-\Delta v_0^2)} \tag{18.104}$$

Considering Eqs. (18.99) through (18.104), it is mandatory to have storage energy greater than five times the pulse energy in order to have an output voltage droop better than 10%, but if a 1% voltage droop is expected, a 50 times storage energy is required, which impose limits to the design of the modulator.

The power dissipation in the switches and the capacitors charging time impose a high-voltage pulse frequency limitation. Therefore, this circuit operates better with low duty ratio, D, pulses as required in most PP applications.

In addition, the V_{dc} power supply must be able to charge the C_i capacitors with an energy equal to the delivered pulse energy, E_0, plus losses during the charging time, $T-t_{on}$:

$$P_{V_{dc}} = \frac{E_0}{T-t_{on}} - P_{loss} \tag{18.105}$$

where the P_{loss} term represents the power dissipated in the circuit wiring and switches.

This determines the maximum power rating for the V_{dc} power supply that imposes the maximum operating frequency, pulse duty ratio, and load power to the modulator.

To build and operate the circuit of Fig. 18.45, some design consideration must be considered. First, during start-up, when the energy storing capacitors are completely discharged, the charging voltage V_{dc} must be slowly increased in order to limit the charging current on the switches S_{ci} and D_{ci}, which is critical in the first stages due to the parallel charging topology of the capacitors.

Actually, in the parallel charging method, the semiconductor modules current loading is not equal. For instance, in the Fig. 18.45 circuit, switch S_{c1} conducts current required to capacitors C_1, C_2…, C_{n-1}, C_n, switch S_{c2} conducts charging current for C_2, C_3…, C_{n-1}, C_n, and so forth. Thus, in practical implementation, modules with successive decreasing current ratings can be used, the benefits of standardization being somewhat compromised.

Also, the S_{ci} and S_{pi} switches conduct different current values, respectively, the discharge and pulse current. Hence, instead of switches needing to block unequal voltages, they are required to conduct unequal currents.

Consequently, when choosing semiconductors to implement the *S* switches, it is fundamental that the semiconductor current rating must be selected to guarantee that the devices work always in the saturation region inside the forward safe operating area. If not, during the first instants of the *on*-state (when the current is high) the semiconductors can operate in the active region where the voltage drop and losses are higher, which might destroy the devices.

The switches triggering is another important concern in these circuits. There are two drive signals, $v_{gs(Spi)}$ and $v_{gs(Sci)}$, respectively, to S_{pi} and S_{ci}, which should be triggered synchronously. Since all the semiconductor switches are at different high-voltage potentials, gate drive circuits with galvanic isolation are required (the use of optical fibers is mandatory to transmit the gate signals and to reduce stray capacitances to ground and neighbor cells), together with isolated power supplies to further process the transmitted gate signal and supply power to the gate drivers.

Several authors have come up with solutions to supply power to semiconductor triggering drivers for high-voltage applications. The most common include isolation transformers [59], but diode strings are also described [57].

The circuit in Fig. 18.45 enables the use of typical half-bridge semiconductor structures currently integrated in modular packages, which is advantageous to assemble the circuit and trigger the semiconductors, since it allows bootstrap operation [10].

However, the circuit topology shown in Fig. 18.45 is not suitable for dealing with capacitive loads. In fact, if a capacitive-type load is connected to the circuit output, the load stays charged after the HV pulse with a negative voltage until the charging mode of the energy storing capacitors. However, during the charging period, the load is not shorted by the D_{ci}, except if the energy stored in the load is very low and the charging current of capacitors C_i is sufficient to turn-on diodes D_{ci}.

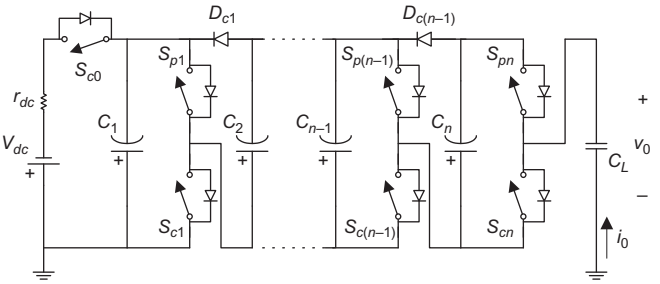

FIG. 18.48 Circuit for applying HV negative repetitive pulses into a capacitive load, with a negative dc power supply, V_{dc}.

In order to guarantee the discharge of the load capacitances after the negative HV pulse, it is necessary to change the Fig. 18.45 circuit topology for the one shown in Fig. 18.48, which also produces negative HV pulses into the load.

Considering the circuit in Fig. 18.48, as the V_{dc} power supply is negative, it is necessary to change the topology in comparison with Fig. 18.45 in order to maintain a similar operating behavior. The two main differences are the addition of an extra switch, S_{c0}, which guarantees that during the pulse period, the dc charging power supply V_{dc} does not participate in the pulse mode, t_{on}. The most important regards the fact that during the charging period, $T-t_{on}$, the S_{ci} switches short-circuit the load discharging any capacitance, as the one shown in Fig. 18.48.

Considering now the application of negative HV pulses into inductive loads, the circuit in Fig. 18.45 requires an additional half-bridge switching structure that connects to the load, as shown in Fig. 18.49.

As shown in Fig. 18.50, the operation of the circuit in Fig. 18.49 in comparison with circuit of Fig. 18.45, has some changes, which includes one additional time period for enabling the reset of the inductive load by the freewheeling diodes, T_{ab}, besides the charging, T_c, and pulse modes, t_{on}, in order to impose a zero average voltage to the load.

During the charging period, the *on*-state of D_{ci} and the $S_{p(n+1)}$ antiparallel diode ensures that the output voltage, V_0, applied to the load is approximately zero.

After the HV negative pulse, t_{on}, the S_{ci} and S_{pi} switches are turned *off*, but in order to conserve energy, the inductive load current, i_0, must have an alternative path. This path is set by

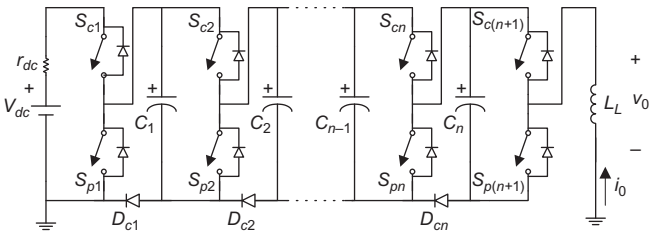

FIG. 18.49 Circuit for applying HV negative repetitive pulses into an inductive load.

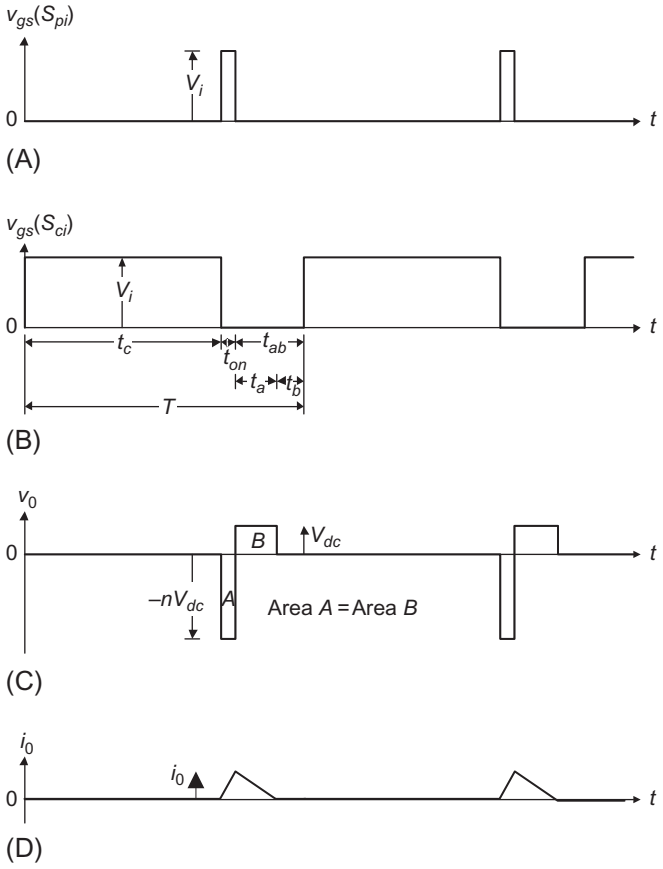

FIG. 18.50 Theoretical waveform for the operation of the circuit in Fig. 18.49: (A) trigger signal of switches S_{pi}, $v_{gs(Spi)}$; (B) trigger signal of switches S_{ci}, $v_{gs(Sci)}$; (C) output voltage, v_0; and (D) output current, I_0.

freewheeling diodes (S_{ci} antiparallel diodes and D_{ci} diodes) and the capacitor with the lowest voltage, which is charged. Normally, C_n has the lowest voltage; thus, the current path is through the $S_{c(n+1)}$ antiparallel diode D_B, capacitor C_n, and diodes $D_{c1}-D_{cn}$. During this time, T_a, the voltage applied to the load is, about, V_{dc} (voltage in capacitor C_n), resetting the inductive load. Capacitor C_n is charged until its voltage is equal to the capacitor C_{n-1} voltage, after which, if there is still energy in the load, the current path changes to capacitor C_{n-1}. As the maximum clamping voltage is V_{dc}, the higher the number of stages the longer the resetting time.

In this way, most of the load magnetic energy is sent back to energy storing capacitors C_i, after which the load current i_0 goes to zero, and it can be imposed again the charging mode of operation. It is important to have a safety time t_b in order to guarantee the completely reset of the load. Due to this load energy recovery method, the power supply energy needed to charge the capacitors after each pulse is lower, and the yield of this modulator can be higher.

Example 18.9 A negative solid-state Marx generator needs to be assembled for delivering −9 kV and 25 μs pulses into a 900 Ω resistive load, with less than 20% voltage droop. Considering the existing equipment, there are two alternatives: (1) $V_{dc}=1.5$ kV, $n=6$, and $C_i=1$ μF and (2) $V_{dc}=1$ kV, $n=9$, and $C_i=1$ μF. Determine which is the best alternative.

Solution Considering the capacitance of 1 μF in each stage, then, the pulse voltage droop can be determined by Eq. (18.104). Hence, for the first alternative,

$$C=\frac{2nt_{on}}{R_L(1-\Delta v_0{}^2)}\Leftrightarrow 10^{-6}=\frac{2\times 6\times 25\times 10^{-6}}{900(1-\Delta v_0{}^2)}\Leftrightarrow \Delta v_0=0.816$$

and for the second alternative,

$$C=\frac{2nt_{on}}{R_L(1-\Delta v_0{}^2)}\Leftrightarrow 10^{-6}=\frac{2\times 9\times 25\times 10^{-6}}{900(1-\Delta v_0{}^2)}\Leftrightarrow \Delta v_0=0.707$$

which gives, respectively, 18.35% and 29.23% voltage droop, meaning that after the pulse the capacitors stay charged with about Eq. (18.101), respectively, 1224.7 and 707.1 V. Hence, only the first alternative keeps the pulse voltage droop below 20%. In this case, the energy stored in the capacitors is Eq. (18.99) 6.75 J, three times bigger than the energy delivered to the load during each pulse Eq. (18.100) 2.25 J.

18.4.4.2 Generation of Positive Pulses

The solid-state Marx modulators for generating positive HV pulses, with different load conditions, have equivalent properties as the ones for negative pulses, shown in the last section, besides the necessary modifications to enable the change in the output polarity. Thus, Fig. 18.51 shows the basic topology of the SM, with n stages, able to deliver positive high-voltage repetitive pulses into resistive and capacitive loads, R_LC_L.

During the pulse mode, t_{on}, the switches S_{ci} and S_{pi} are, respectively, turned *off* and turned *on*. Capacitors C_i are connected in series and their voltage applied to the load. The load voltage v_0 is proportional to the charging power supply:

$$v_0=knV_{dc} \tag{18.106}$$

where n is the number of stages and $k<1$ characterizes the nonideal behavior of the passive and active elements in the

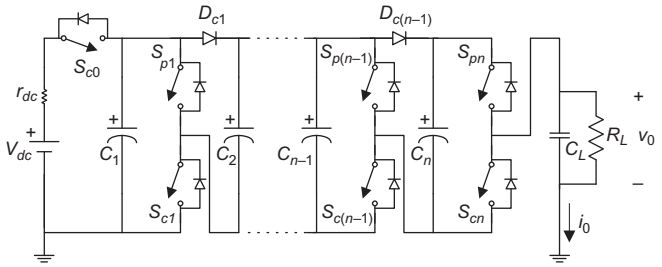

FIG. 18.51 Circuit for applying HV positive repetitive pulses into resistive and capacitive loads.

circuit and operating conditions. Also, in this topology, for example, if S_{pn} is *off* during pulse mode, the antiparallel S_{cn} diode conducts and short-circuits the last stage, imposing an output voltage of

$$v_0 = k(n-1)U_{dc} \tag{18.107}$$

Actually, the Fig. 18.51 circuit is equivalent to Fig. 18.45 circuit, whereas in this case with a positive V_{dc} power supply, it can produce positive HV pulses for both resistive and capacitive loads. The capacitive load can be driven, given that during the charging mode of capacitors C_i, the load is short-circuited by the S_{ci} switches, stray inductances limiting the discharge rate.

Considering now the application of positive HV pulses into inductive loads, the circuit in Fig. 18.51 requires an additional switch S_{p0} and diode D_0 at the input, as shown in Fig. 18.52.

The circuit operation requires, also, an additional time period for resetting the inductive load by the added freewheeling diodes, t_{ab}, in addition to the charging, t_c, and pulse modes, t_{on}, in order to impose a zero average voltage to the load.

Considering an inductive load, after the HV positive pulse, the S_{ci} and S_{pi} switches are *off*, and the path for the inductive current i_0 is set by the capacitor C_n, which usually has the lowest voltage, the S_{ci} antiparallel diode and diode D_B. During this time, the voltage applied to the load is approximately $-V_{dc}$ (the voltage in capacitor C_n), resetting the inductive load. After the load current i_0 goes to zero, the charging mode of operation can be imposed.

18.4.5 Solid-State Marx-Based High-Voltage Switches

The solid-state Marx generator concept described in the last section can be used for distributing the voltage in series-stacked semiconductors. Further, the Marx generator circuit can be used as a series switch, maintaining some intrinsic properties, which are desirable for the use with relatively low-voltage semiconductors, such as equal voltage distribution between stages and the fact the semiconductors in each stage hold off only the stage voltage capacitor.

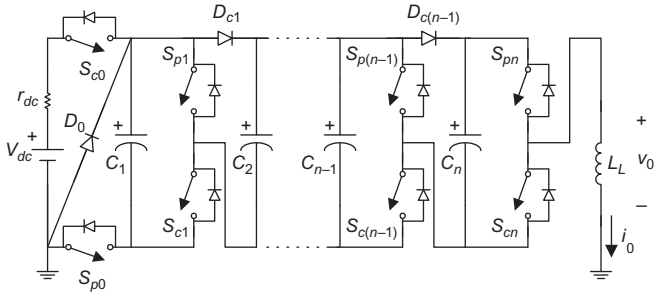

FIG. 18.52 Circuit for applying HV positive repetitive pulses into an inductive load.

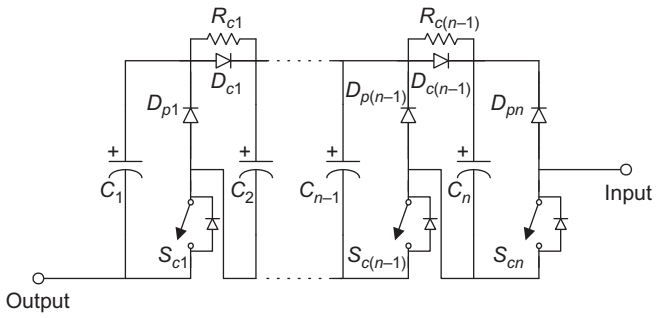

FIG. 18.53 Series switch for positive voltages based on the Marx concept.

The Marx series switch, based on the solid-state Marx of Fig. 18.51, for positive voltages, is shown in Fig. 18.53 not to apply voltage but to hold it between its terminals. Therefore, the input power supply V_{dc} is removed, and the S_{pi} switches are replaced by diodes D_{pi}. Also, resistors R_{ci} are connected in parallel with the D_{ci} diodes in order to balance the voltage in the capacitors C_i.

Consider the common HV pulse power topology of Fig. 18.54, where switches S_1 and S_2 commutate alternately. A HV power supply, V_{dc}, charges an energy storage capacitor C_{dc}, with current limited by resistor R_{dc}. The switch S_1 applies the capacitor C_{dc} voltage v_c to the capacitive load $C_L||R_L$, during the pulse period, t_{on}. Subsequently, switch S_2 discharges the load and other circuit parasitic capacitances to zero.

Taking into account the proposed operating scheme, each switch S_i, where $i \in \{1, 2\}$, holds a maximum voltage equal to the power supply voltage amplitude, V_{dc}, considering that the capacitor C_{dc} is charged with the voltage V_{dc}. When S_1 is conducting, S_2 holds off the voltage V_{dc}, and when S_2 is conducting, S_1 holds off the voltage V_{dc}. Hence, if the voltage V_{dc} is greater than a couple of kV, a solid-state switch comprising series-stacked semiconductors is mandatory for implementing switches S_1 and S_2.

The switching frequency of S_1 and S_2 and the pulse *on* time depend on the energy stored in the C_{dc} capacitor, on the load consumption, and on the power dissipated in the switches during commutation.

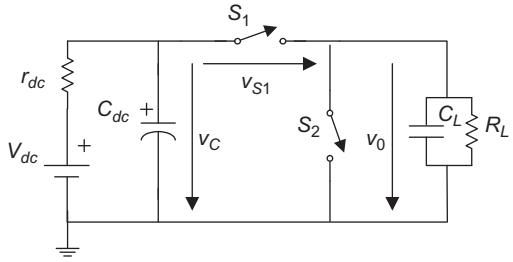

FIG. 18.54 Proposed pulsed power HV topology for describing the operation of the series switch (buck type) of Fig. 18.53.

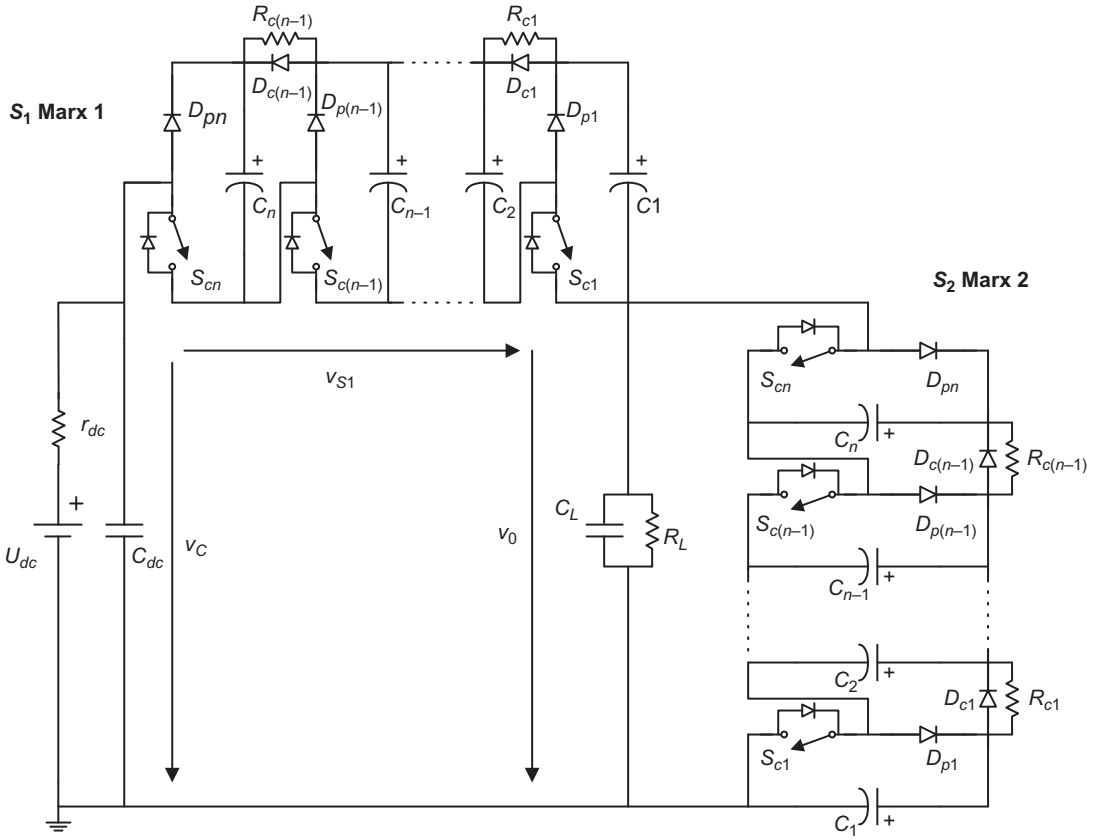

FIG. 18.55 Proposed pulsed power topology for testing the new series switches.

The proposed PP topology in Fig. 18.54 implemented with the series switch of Fig. 18.53 as series switch S_1 (Marx 1) and S_2 (Marx 2) is shown in Fig. 18.55.

The operation of Fig. 18.55 circuit can be understood considering the concept presented in Fig. 18.53 and the voltage waveforms presented in Fig. 18.57. For the first operating mode, during time t_{on}, the S_{ci} switches in Marx 1 are *on*, the C_i capacitors in Marx 1 are in parallel, and the S_{ci} switches in Marx 2 are *off*, as shown in Fig. 18.56A. The capacitor C_{dc} voltage, v_c, is applied into the load, v_0, and the C_i capacitors in Marx 2 are stacked in series, through the D_{pi} diodes, distributing the voltage across the S_{ci} switches, in parallel with the load.

Subsequently, in the second operating mode, during time $T-t_{on}$, the S_{ci} switches in Marx 1 are *off* and the S_{ci} switches in Marx 2 are *on*, and the load is discharged to zero, as shown in Fig. 18.56B. The v_c voltage appears between the Marx 1 terminals as shown in Fig. 18.57D, where this voltage is sustained by the C_i capacitors in series through the D_{pi} diodes, distributing the voltage across the S_{ci} switches.

Unlike in a typical Marx generator, the C_i capacitors in both Marx 1 and Marx 2 of Fig. 18.55 can suffer from voltage imbalance problems due to the fact that the C_i capacitors are charged in series: (i) in Marx 1 during period $T-t_{on}$ when the load is short-circuited and the voltage v_C appears between the Marx 1 terminals, $v_{S1,}$ and (ii) in Marx 2 during period t_{on} when the voltage is applied to the load and the voltage V_C appears between the Marx 2 terminals.

Two main causes contribute to this voltage imbalance: (i) The C_i capacitance values are not equal, and (ii) the C_i capacitors placed near the V_{dc} power supply are charged with a higher voltage due to the voltage droop in the semiconductors in each stage. Considering the last, the D_{ci} diodes do not conduct, and R_{ci} are used in parallel to uniformly distribute the voltage between the C_i capacitors during (i) t_{on} in the Marx 1 switch and (ii) $T-t_{on}$ in Marx 2 switch. Alternatively, extra switches can be placed in antiparallel with diodes D_{ci}.

18.4.6 Solid-State Marx-Based Bipolar Generators

The Marx generator concept was extended in Ref. [60] to allow the generation of positive and/or negative pulses. This bipolar Marx generator is shown in Fig. 18.58, based in n modules with four controlled semiconductors T_{fi}, T_{ei}, T_{ai}, T_{bi}, ($i \in \{1,2,\ldots,n\}$), two diodes D_{hi}, D_{gi}, and energy storage capacitor C_i.

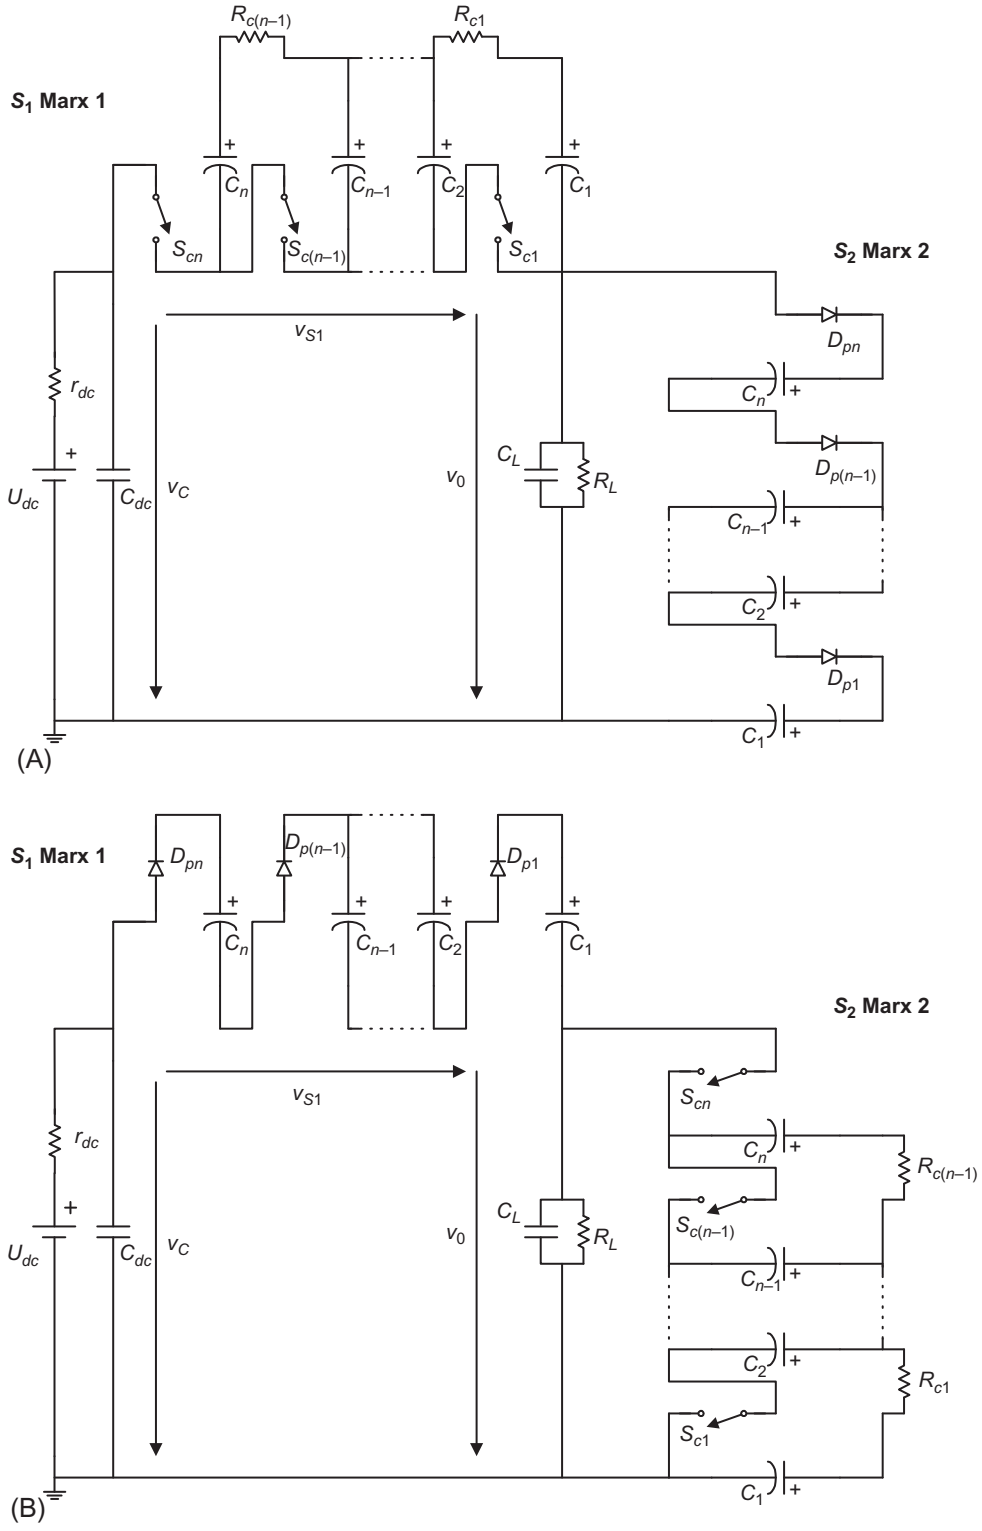

FIG. 18.56 Operating modes for the Fig. 18.55 circuit: (A) voltage applied to the load and (B) load discharge.

During the charging period, the dc power supply V_{dc} charges the C_i capacitors in parallel from the power supply and C_0 capacitor by turning ON switches T_{dc}, D_{dc}, T_{fi}, and T_{ei}, through diodes D_{hi} and D_{gi} (Fig. 18.59). The *on*-state of T_{ei} and D_{gi} switches, during this period, may guarantee a near-zero value to the load voltage, V_0, provided the charging current is bigger than the load current.

To obtain positive pulses, only switches T_{fi} and T_{ai} are driven *on* (Fig. 18.60). For negative pulses, only switches T_{bi} and T_{ei} are driven *on* (Fig. 18.61).

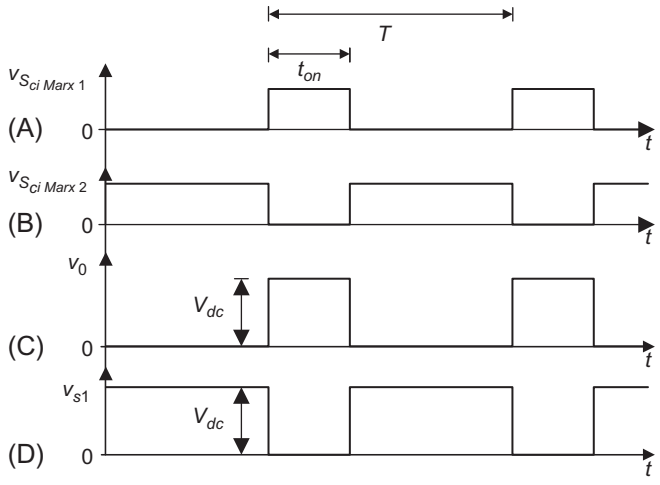

FIG. 18.57 Theoretical waveforms for Fig. 18.55 circuit operation: (A) Marx 1 S_{ci} drive signal, (B) Marx 2 S_{ci} drive signal, (C) load voltage v_0, and (D) Marx 1 voltage V_{s1}.

18.4.7 Solid-State Marx-Based Multilevel Bipolar Generators

Some of the previous presented Marx modulators may be used to generate staircase like voltage waveforms with multiple voltage levels, which can be useful to reduce electromagnetic interference since the rate of change of the pulse voltage is reduced regarding the two level voltage pulse.

The solid-state Marx-based high-voltage switch of Fig. 18.55 can be enhanced by adding an antiparallel transistor to diodes D_{pi}, to obtain one of the $2(n-1)$ modules of the multilevel bipolar generator in Fig. 18.62A, able to output n voltage levels [61]. The extra transistor and the $D_{k\text{-}1,k}$ module interconnecting diode enable a better control of the charge/discharge of the storage capacitors C_k, since they can be connected in series with the capacitors in other modules to charge/discharge, or in parallel with some other capacitors to balance their voltages Fig. 18.62B, provided diode $D_{k\text{-}1,k}$ is forward-biased [61].

The C_k capacitors are charged in series (being $U_{Ck} \approx U_{dc}/(n-1)$).

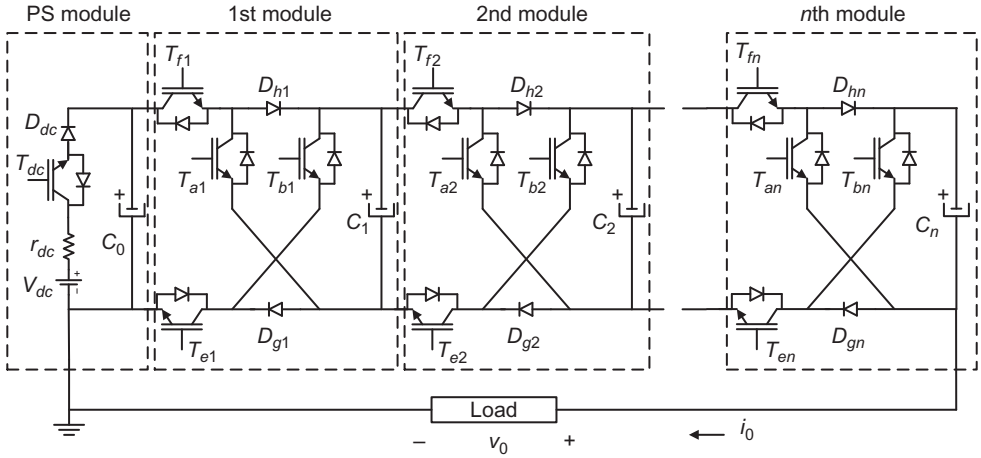

FIG. 18.58 Solid-state Marx-type bipolar generator topology, with n modules of four switches, enabling unipolar or bipolar pulse generation [60].

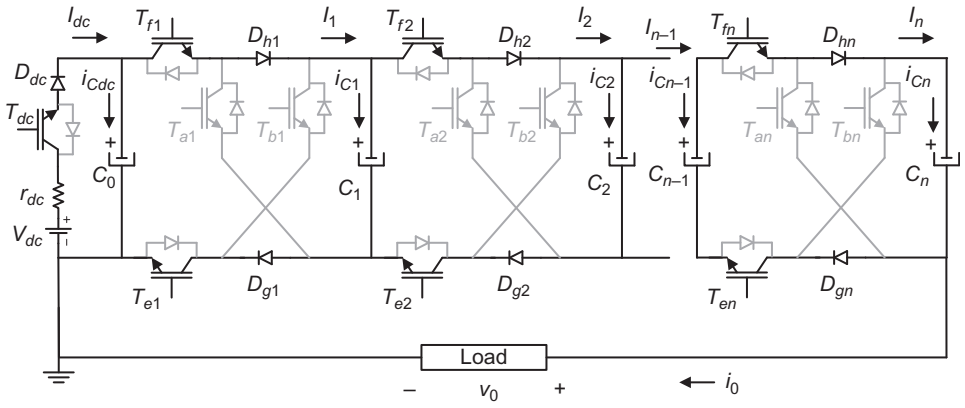

FIG. 18.59 Charging mode in the solid-state Marx-type bipolar generator [60].

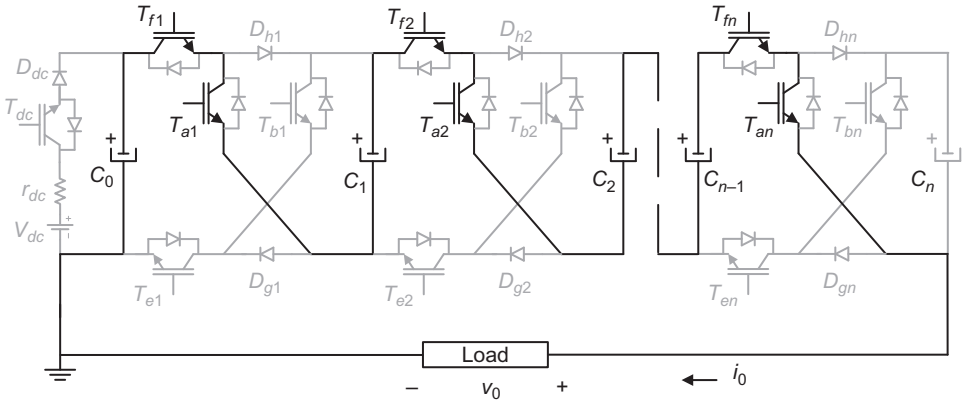

FIG. 18.60 Positive pulse operation in the solid-state Marx-type bipolar generator [60].

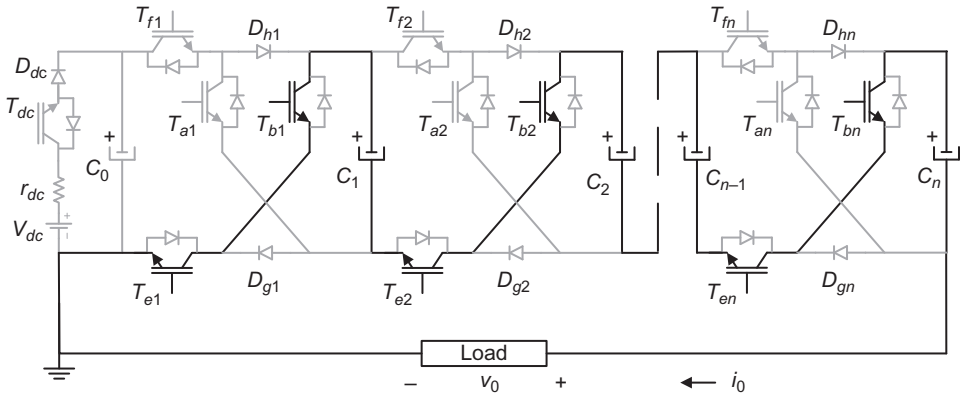

FIG. 18.61 Negative pulse generation in the solid-state Marx-type bipolar topology [60].

Considering a boolean switching function γ_k, the voltage U_k of each module is written as

$$U_k = \gamma_k U_{Ck}, \text{ being } \gamma_k = \begin{cases} 0 \text{ if } S_k, S_{k-1,k} \text{ are ON } \wedge \ S_{ka} \text{ is OFF} \\ 1 \text{ if } S_k, S_{k-1,k} \text{ are OFF } \wedge \ S_{ka} \text{ is ON} \end{cases} \tag{18.108}$$

Neglecting parasitic voltage drops, the load pulse voltage U_{Load} is

$$U_{Load} = U_{CA} - \sum_{k=1}^{n-1} \gamma_k U_{Ck} = -U_{CB} + \sum_{k=n}^{2(n-1)} \gamma_k U_{Ck} \tag{18.109}$$

Supposing $U_{CA} = U_{CB} = U_{dc}/2$, summing and subtracting the two previous equations, it can be obtained:

$$\begin{aligned} U_{Load} &= \frac{1}{2}\left(\sum_{k=n}^{2(n-1)} \gamma_k U_{Ck} - \sum_{k=1}^{n-1} \gamma_k U_{Ck} \right) \\ U_{dc} &= \sum_{k=n}^{2(n-1)} \gamma_k U_{Ck} + \sum_{k=1}^{n-1} \gamma_k U_{Ck} = \sum_{k=1}^{2(n-1)} \gamma_k U_{Ck} \end{aligned} \tag{18.110}$$

To obtain the maximum output voltage $U_{Loadmax} = U_{dc}/2$, it must be $\sum_{k=1}^{n-1} \gamma_k U_{Ck} = 0$, which from the second equation of (18.110) means $\sum_{k=n}^{2(n-1)} \gamma_k U_{Ck} = U_{dc}$. Supposing balanced capacitor voltages, then, each capacitor voltage is $U_{Ck} = U_{dc}/(n-1)$. To generate the minimum voltage, $U_{Loadmin} = -U_{dc}/2$, and then, $\sum_{k=n}^{2(n-1)} \gamma_k U_{Ck} = 0$, being $U_{dc} = \sum_{k=1}^{n-1} \gamma_k U_{Ck}$. These relationships show that each generator half arm must hold off the high-voltage U_{dc}. From $U_{dc} = \sum_{k=1}^{n-1} \gamma_k \frac{U_{dc}}{n-1} \Rightarrow \sum_{k=1}^{n-1} \gamma_k = n-1$, which must be used to define the γ_k values needed for each level n. This means that half of the total $2(n-1)$ modules must have $\gamma_k = 1$, while the remaining half must have $\gamma_k = 0$. The γ_k values can create redundant states that must be used to balance the C_k capacitor voltages [61].

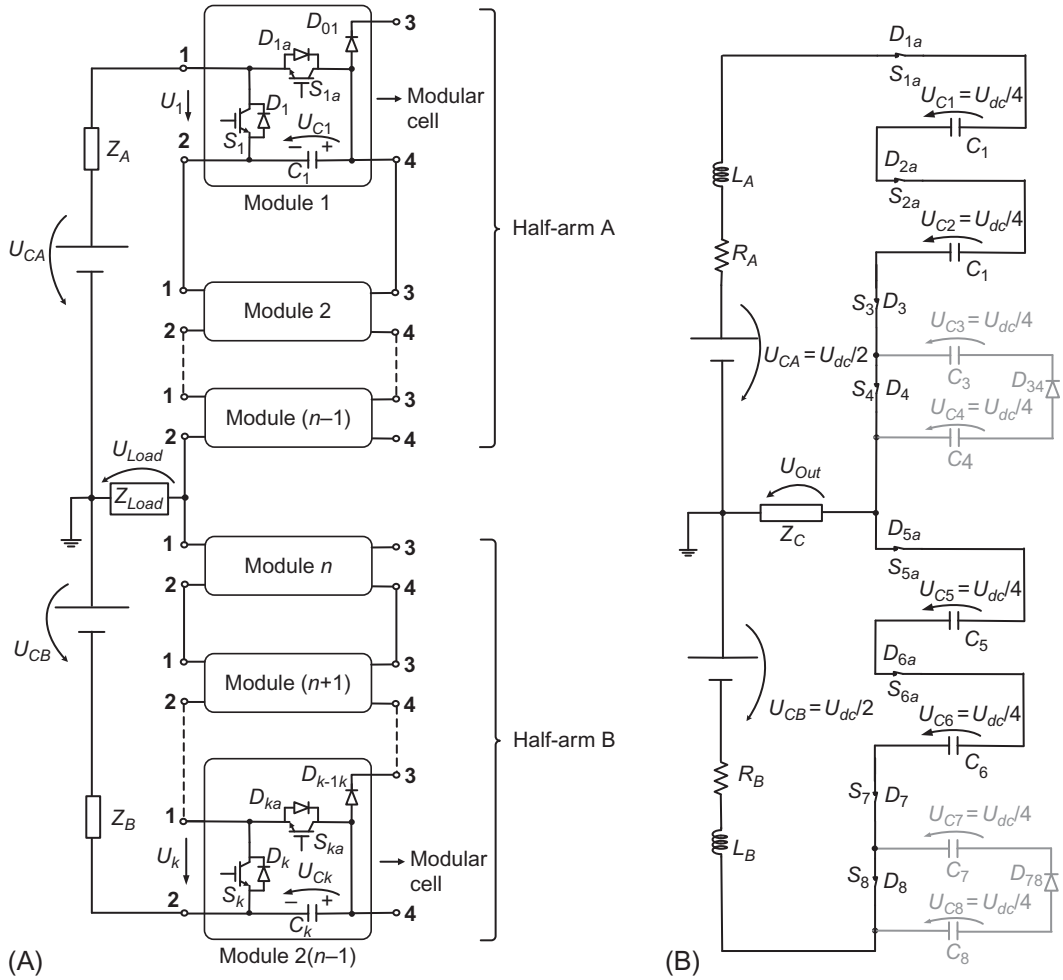

FIG. 18.62 (A) Solid-state Marx-based multilevel bipolar generator with n levels using $2(n-1)$ modules and (B) five-level generator with level 0 V, $U_{Out}=0$ V, showing one possibility of series and parallel connection of energy storage capacitors.

Fig. 18.63 shows the simulated output voltage of a seven levels (500 V each) 12 modules bipolar generator, including the zero voltage level.

18.5 Power Electronics in Capacitor Charging Applications

18.5.1 Introduction

Conventional dc power supplies operate at a given dc output voltage into a constant or near-constant load. However, pulse loads such as lasers, flashlamps, rail guns, and radar require short but intense bursts of energy. Typically, this energy is stored in a capacitor and then released into the load. The rate at which the capacitor is charged and discharged is called the repetition rate, T, and may vary from 0.01 Hz for large capacitor banks to a few kHz for certain lasers. Recharging the capacitor voltage to a specified voltage is tasked to a capacitor charging power supply (CCPS). The role of power electronics devices, topologies, and charging strategies for capacitor charging applications is presented in this chapter.

Fig. 18.64 shows the voltage across the energy storage capacitor connected to the output of a CCPS. This figure shows that the CCPS has three modes of operation. The first mode is the charging mode in which the capacitor is charged from an initial voltage of zero to a specified final voltage. The duration of the charging mode is determined by the capacitance of the energy storage capacitor and the rate at which the CCPS delivers energy. The next mode of operation is the refresh mode, which can be considered a "standby mode," where the stored energy is simply maintained. When the output voltage drops below a predetermined value, the CCPS should turn-on and deliver the energy necessary to compensate for capacitor leakage. Since energy is lost during the refresh mode, the duration of the refresh mode should be as brief as possible. Issues that lead to nonzero refresh times include safety margins for worst-case charging and discharging mode times and SOA requirements

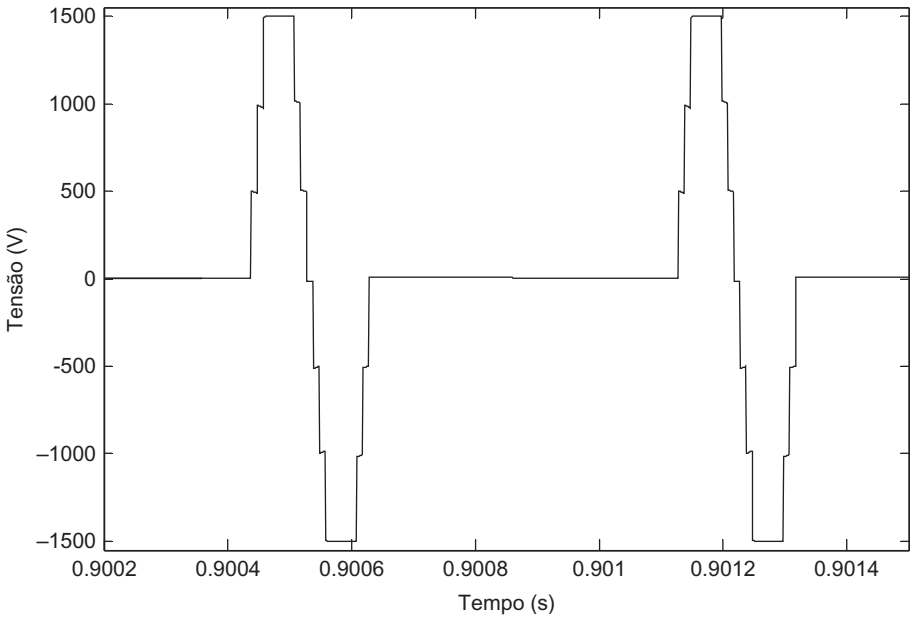

FIG. 18.63 Seven-level bipolar pulse obtained using the Marx-based multilevel bipolar generator (500 V/div and 200 μs/div).

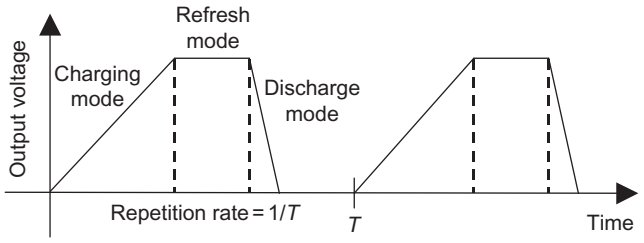

FIG. 18.64 Three modes of operation of a capacitor charging power supply.

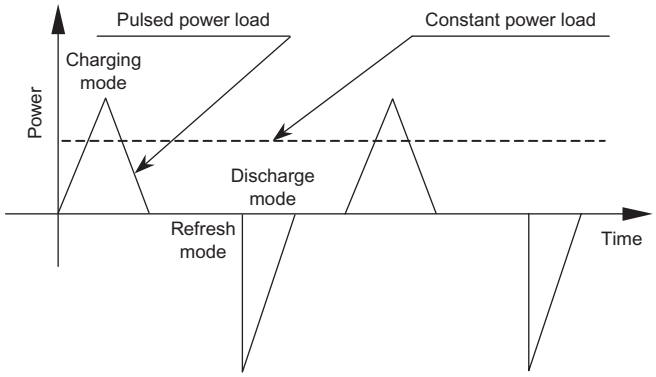

FIG. 18.65 Power requirements for pulsed power and constant power loads.

of switching devices. The final mode of operation is the discharge mode in which the load is actively discharging the capacitor. The CCPS does not supply any energy to the load in this mode. The amount of time the CCPS remains in this mode is determined by how quickly the load can discharge the capacitor.

The instantaneous output power for a CCPS varies over a wide range in comparison to a conventional dc power supply that supplies a near-constant power to its load. This is shown in Fig. 18.65; the output power for the PP load is drawn as linear for illustration purposes only. The charging mode is characterized by high peak power. At the beginning of this mode, the output power is zero (i.e., there is no voltage present but current is flowing). Thus, the load capacitor is equivalent to a short-circuit. In addition, at the end of the charging mode, the output power is again zero (i.e., there is an output voltage present but no current is flowing). Now, the load capacitor is equivalent to an open-circuit. The refresh mode is typically a low-power mode because the current required to compensate for capacitor leakage is small. The CCPS does not supply any power during the discharge mode when the energy storage capacitor is being discharged by the pulsed load.

The average output power for a CCPS depends on the discharge mode energy and the repetition rate of the load. It is maximum when the energy storage capacitor is discharged at the end of the charging mode (large voltage and current), which corresponds to operation without a refresh mode. Because the CCPS power is not constant, the rating of a CCPS is often given in kJ/s instead of kW. The kJ/s rating can be written as

$$\text{kJ/s} = \frac{W_{LOAD}}{T}$$

where W_{LOAD} is the energy delivered to the load per charging cycle and T is the repetition rate. In the optimum case with no refresh and instantaneous discharge, the kJ/s rating is limited to

how fast a particular capacitor can be charged by its specified voltage.

18.5.2 High-Voltage dc Power Supply With Charging Resistor

In this technique, the energy storage capacitor is charged by a high-voltage dc power supply through a charging resistor as shown in Fig. 18.66. The charging mode ends when the capacitor voltage equals the output voltage of the power supply. The capacitor is continually refreshed by the power supply. During the discharge mode, the charging resistor isolates the power supply from the pulse load. The advantages of this technique are its simplicity, reliability, and low cost.

The major disadvantage of this technique is its poor efficiency. In the charging mode, the energy dissipated in the charging resistor is equal to the energy stored in the capacitor in the ideal case; therefore, the maximum efficiency is 50%. As a result, this technique is utilized only in applications where the charge rate is low, that is, 200 J/s. Another disadvantage of this technique is related to the charging time, which is determined by the RC time constant. Some laser applications require that the output voltage be within 0.1% of a target voltage. For this technique, more than five time constants are required for the capacitor voltage to meet this voltage specification.

18.5.3 Resonance-Charging

The basic resonance-charging technique is shown in Fig. 18.67. An ac input voltage is stepped up with a transformer, rectified, and filtered with capacitor C_2 to produce a high dc voltage V_0. In this circuit, C_2 is much greater than C_1. Thyristor T_1 is gated and current flows through the inductor and diode D_1 is transferring energy from C_2 to C_1. The voltage $v(t)$ and current $i(t)$ are described by the following equations assuming that $C_2 \gg C_1$. The charge time, t_c, for this circuit can be calculated by finding the time at which the current, described by Eq. (18.112), reaches zero and is given below. The voltage $v(t)$ has a value of $2\,V_0$ at the end of the charging mode:

$$v(t) = V_0(1 - \cos\omega_0 t) \tag{18.111}$$

$$i(t) = V_0\sqrt{\frac{C_1}{L}}\sin\omega_0 t \tag{18.112}$$

$$\omega_0 = \frac{1}{\sqrt{LC_1}} \tag{18.113}$$

$$t_c = \pi\sqrt{LC_1} = \frac{\pi}{\omega_0} \tag{18.114}$$

Even though this technique is simple and efficient, it is not without its limitations. A high-voltage capacitor with a large capacitance value is needed for C_2, which increases the cost. A single thyristor is shown in Fig. 18.67. Multiple thyristors connected in series or a thyratron may be required depending on the voltage level. The repetition rate of the pulse load should be such that C_1 is fully charged and $i(t)$ has reached zero before the load discharges to prevent latch up of T_1. It is not possible for this circuit to operate in the refresh mode because of the switch characteristics; therefore, $v(t)$ will drift due to capacitor leakage. The charge time is a function of the circuit parameters and will drift as they change with temperature or due to aging.

Because all of the energy stored in C_1 is transmitted from C_2 in a single pulse, it can be difficult to achieve precise voltage regulation with the resonance-charging technique. However, regulation can be improved with the addition of a dequeing circuit as shown in Fig. 18.68. The voltage $v(t)$ is monitored with a sensing network. Before $v(t)$ reaches the desired level, thyristor T_2 is fired, which terminates the charging mode. The remaining energy stored in the inductor is dissipated in R. The addition of the dequeing circuit reduces the circuit efficiency and increases the circuit complexity and cost but still does not enable a refresh mode to compensate for capacitor leakage.

Boost charging, a variation on the resonance-charging technique, is shown in Fig. 18.69 [62]. An extra switch is added to

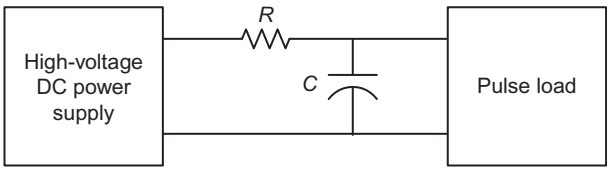

FIG. 18.66 High-voltage dc power supply and charging resistor.

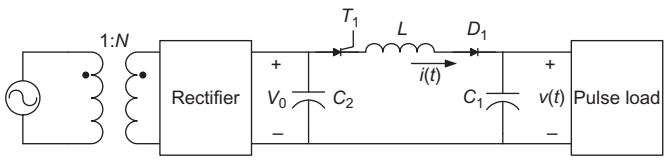

FIG. 18.67 Resonance-charging.

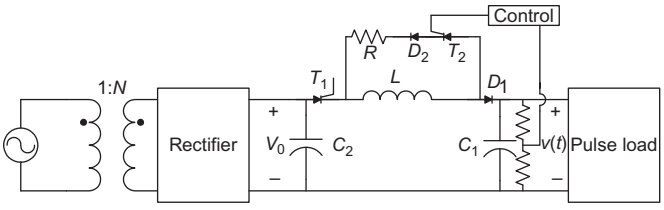

FIG. 18.68 Resonance-charging with dequeing.

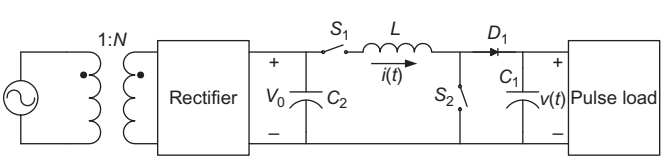

FIG. 18.69 Boost charging.

the circuit of Fig. 18.67, allowing energy to be stored in both C_2 and L. This can be modeled as an increase in the voltage gain of the CCPS. With switches S_1 and S_2 closed, the current $i(t)$ is given by

$$i(t) = \frac{V_0}{L}t \tag{18.115}$$

When $t = t_{on}$, S_2 is opened, and the current is now described by

$$i(t) = I_0 \cos\omega_0 t + V_0\sqrt{\frac{C_1}{L}}\sin\omega_0 t \tag{18.116}$$

where

$$I_0 = \frac{V_0}{L}t_{on} \tag{18.117}$$

is the inductor current initial value at t_{on}. The voltage $v(t)$ is then

$$v(t) = I_0\sqrt{\frac{L}{C_1}}\sin\omega_0 t + V_0(1 - \cos\omega_0 t) \tag{18.118}$$

The time required for the current to reach zero and for the voltage $v(t)$ to reach its peak value can be calculated from

$$\tan(\omega_0 t_c) = -\frac{I_0\sqrt{\frac{L}{C_1}}}{V_0} = -\omega_0 t_{on} \tag{18.119}$$

This is also the charge time, t_c, or the length of the charging mode. Note from Eq. (18.119) that the charge time depends on t_{on}, which is the on-time of switch S_2. In addition, the peak capacitor voltage is a function of t_{on}. The peak capacitor voltage is limited to $2V_0$ without S_2; voltage gains as high as 20 are possible with the addition of S_2 [62].

The switching elements in Figs. 18.67 and 18.68 are realized with thyristors. Simple switches are shown for the boost charging technique in Fig. 18.69. Switch S_1 could be implemented with a thyristor. The boost capability provided by switch S_2 is best realized with a gate-controlled semiconductor device such as a GTO or an IGBT.

18.5.4 Switching Converters

The poor efficiency when charging a capacitor through a resistor from a high-voltage power supply limits its application to low charging rates. In the resonance-charging concepts, the energy is transferred to the load capacitor in a single pulse, and it is not possible to compensate for capacitor leakage. Energy storage capacitors may be charged utilizing the same power electronic technology that has been applied in switching converters for constant power loads. Instead of charging the energy storage capacitor with a single pulse, switching converters can charge the capacitor with a series of pulses or pulse train. The peak current is reduced when charging with a series of pulses, thus improving the efficiency of the charging process. In addition, soft-switching techniques may be used in the switching converter to increase the efficiency. The regulation of the output voltage is also improved with the pulse train because the energy is passed to the energy storage capacitor as small packets. Common control techniques such as pulse width modulation can be used to control the size of the energy packet. This capability to control the size of the energy packet permits the CCPS to operate in the refresh mode and compensate for capacitor leakage. As a result, the CCPS may operate over a broad range of load repetition rates and still maintain tight output voltage regulation during refresh mode. During the refresh mode, energy lost due to capacitor leakage may be replaced in a burst fashion [63] or in a continuous fashion similar to trickle charging a battery [64].

In the switching converter, semiconductor switches may be operated on the lower side of the transformer permitting the use of MOSFETs or IGBTs in the CCPS. Because the CCPS begins the charging mode with a short-circuit across its output, the switching converter must be capable of operating under this severe load condition. This may require the implementation of a current limiting scheme in the converter control circuit.

One switching converter as shown in Fig. 18.70 consists of a resonant converter. Note that the MOSFETs and resonant components L_r and C_r are connected on the low-voltage side of the transformer. Only the rectifier diodes and energy storage capacitor must have high-voltage ratings. When the output rectifier is conducting, the energy storage capacitor C_1 is connected in series with the resonant capacitor C_r. For a transformer turn ratio of $1/N$, reflecting C_1 through the transformer yields a capacitance of N^2C_1. Since N is typically large, this reflected capacitance is much larger than C_r, thus the resonant frequency, which is defined in Eq. (18.120), is not affected by C_1. For high-voltage, high-frequency operation, the leakage inductance of the transformer may be utilized as L_r. Thus, the resonant frequency can be expressed as

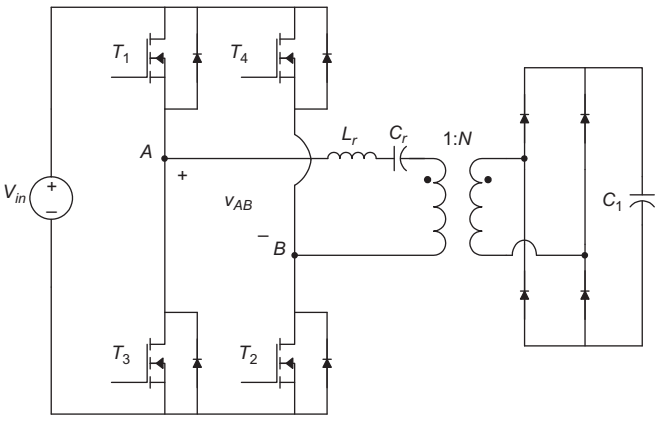

FIG. 18.70 Series resonant converter.

$$\omega_r = \frac{1}{\sqrt{L_r((NC_rC_1)/(C_r + NC_1))}} \tag{18.120}$$

One characteristic of this converter, which makes it attractive for capacitor charging, is the ability to operate under the short-circuit conditions present at the beginning of the charging mode. The voltage across C_1 is zero at the beginning of this mode. The current in the switches is limited by the input voltage and impedance Z_0 as is defined in Eq. (18.121).

$$Z_0 = \sqrt{\frac{L_r}{C_r}} \tag{18.121}$$

Another method for current limiting is to vary the ratio of f_s, the switching frequency of the MOSFETs, and the resonant frequency, f_r, which is $\omega_r/2\pi$. This effectively controls the flow of energy from the source to C_1. The ratio f_s/f_r may be set to a low value at the beginning of the charging mode and increased toward unity as the voltage across C_1 increases. This limits the current when the voltage across C_1 is low and allows increased energy transfer as the voltage approaches the target voltage. The disadvantage of this approach is that variable frequency operation complicates device and component selection and degrades EMI/EMC performance of the CCPS.

The flyback converter, shown in Fig. 18.71, also may be utilized for capacitor charging applications [65,66]. When the MOSFET is turned on, current increases in the primary winding, storing energy in the magnetic field. When it reaches a specified level, the MOSFET is turned off and the energy is transferred from the magnetic field to C_1. This energy transfer is terminated when the MOSFET is turned on again.

In cases where precise output regulation is not required and the packet energy is low, the diode in Fig. 18.71 can be replaced with a Zener diode with a Zener voltage of

$$V_Z = nV_{in} + V_{O,nom}$$

where $V_{O,nom}$ is the nominal value of V_O [67]. Once $V_{O,nom}$ is reached, the next energy packet will force the diode into a brief

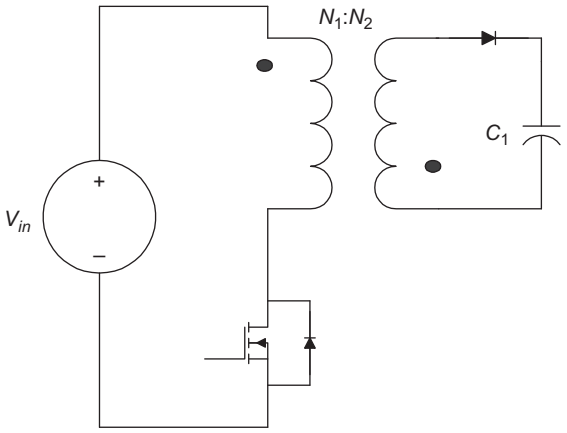

FIG. 18.71 Flyback converter.

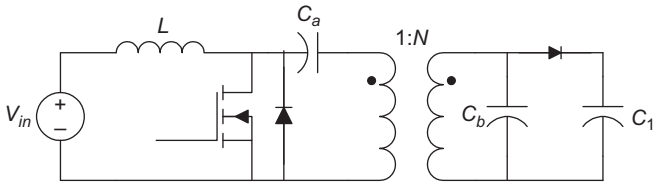

FIG. 18.72 Ward converter.

period of breakdown with the excess energy partially recycled to the input circuit. If the packet energy is small enough, the breakdown is not destructive and V_O is limited to

$$V_O = V_{O,nom} + V_{O,\Omega}$$

where $V_{O,\Omega}$ is the small excess voltage caused by the last energy packet.

Sokal and Redl [68] have investigated different control schemes for charging capacitors using the flyback converter. Their recommendation is to charge C_1 with current pulses that are nearly flat-topped. This strategy results in higher average current for a given peak current. The capacitor is charged faster because the charge delivered to it during a pulse is directly proportional to the average current. This desired pulse shape is achieved by turning on the MOSFET to terminate the transfer of energy to C_1 soon after the MOSFET is turned off, which increases the switching frequency. When the primary current rises to a preset minimum level, the MOSFET is again turned off. This switching strategy is essentially hysteretic current mode control, in which the switch current is limited between two preset bounds.

Another converter for capacitor charging applications is the Ward converter [69–71] shown in Fig. 18.72. When the MOSFET is turned on, energy is stored in the inductor, and capacitor C_a transfers energy into the energy storage capacitor C_1 and capacitor C_b. The energy stored in the inductor is transferred to C_a when the MOSFET is turned off. The leakage inductance of the transformer and C_a resonate producing a sinusoidal current that flows in the primary winding of the transformer and the MOSFET. When the primary current reaches zero and starts negative, the diode turns on, which allows the MOSFET to be turned off efficiently at zero-current.

In some converter operating conditions, the voltage across C_a is very small because most of the energy has been transferred from C_a to C_1. The energy stored in C_a may be too small to ensure zero-current turnoff of the MOSFET. In this case, the energy stored in C_b helps to ensure that the amplitude of the current is large enough for zero-current turnoff of this device.

18.6 Conclusions and Future Trends

This chapter reviewed some of the most typical semiconductors and topologies used for generating repetitive unipolar and bipolar high-voltage pulses based on semiconductor devices

for various load conditions. These topologies have in common the techniques for limiting the high-voltage stress onto the power semiconductor switches, still relatively low-voltage devices, considering the tens of kV needed for pulse power applications. High-voltage techniques spread from the series (and parallel) stacks of semiconductors switches to generalized cascodes, passing through the modified dc-dc isolated converters for pulse generation and their cascade association, to the Marx-type solid-state generators topologies and Marx-derived bipolar generators.

With semiconductor-based generators, pulse power applications have expanded into many new fields such as material modification, environment protection, and biological and medical developments. The presented topologies can bring a completely new extent of capability in repetition rate, efficiency, lifetime, compactness, and portability.

In addition to the methods to generate high-voltage pulse, the performances of the semiconductor switches determine the performance of the pulse power generators. In this way, power semiconductor devices have made significant progress in both power capability and operation speed. Various semiconductor switching units have become commercially available and have been used in various pulse power applications. The most typical devices such as SOS diodes, GTOs, IGBTs MOSFETs, SIThs, and the emerging devices based on SiC or GaN technology, such as SiC MOSFETs, JFETs, cascode JFETs, IGBTs, and GaN E-HEMTs, were described. As the performance of SiC devices continues to improve, it is expected they will replace the existing switching Si devices in high-voltage applications, reducing the number of needed stages.

State-of-the-art HV pulse generators must use several stages to obtain the desired final high-voltage pulse: the first stage can use SCRs and start at 1–2 kV, and then, intermediate full-bridge resonant stage using IGBTs or full-bridge associations can boost this voltage to 4–10 kV, which is applied to HV high-frequency or pulse transformers to obtain 50–100 kV in the secondary. Diode polyphase rectifiers in the transformer secondary windings or saturated pulse transformers can boost the voltage roughly to 300 kV. If needed, a final stage using a SOS or SAS diode can boost the voltage up to 1 MV. Alternatively, other solutions such as solid-state Marx generators are being used, each Marx module operating at 2–10 kV (using SiC semiconductors or series stacks if needed). The required number of Marx modules should be minimized and arranged in shielded groups, the groups being connected to obtain the full HV generator. Droop voltage control and balancing may be necessary to design a practical HV pulse generator. Power generators based in existing power electronics converters are also used to charge capacitors for high-voltage pulse generators.

The future of solid-state pulse power is linked to the capability of making semiconductor-based high-voltage generators with better characteristics in compactness, weight, cost, efficiency, modularity, and portability, very important to deal with future applications near the consumer.

19.1 Introduction

Power distortions such as power interruptions, voltage sags and swells, voltage spikes, and voltage harmonics can cause severe impacts on sensitive loads in the electric systems. Uninterruptible power supply (UPS) systems are used to provide uninterrupted, reliable, and high-quality power for these sensitive loads. Applications of UPS systems include medical facilities, life-supporting systems, data storage and computer systems, emergency equipment, telecommunications, industrial processing, and online management systems [1–3]. The UPS systems are especially required in places where power outages and fluctuations occur frequently. A UPS provides a backup power circuitry to supply vital systems when a power outage occurs. In situations where short-time power fluctuations or disturbed voltage occur, a UPS provides constant power to keep the important loads running. During extended power failures, a UPS provides backup power to keep the systems running long enough so that they can be gracefully powered down.

Most of the UPS systems also suppress line transients and harmonic disturbances. Generally, an ideal UPS should be able to simultaneously deliver uninterrupted power and provide the necessary power conditioning for the particular power application. Therefore, an ideal UPS should have the following features: regulated sinusoidal output voltage with low total harmonic distortion (THD) independent from the changes in the input voltage or in the load, online operation that means zero transition time from normal to backup mode and vice versa, low THD sinusoidal input current and unity power factor, high reliability, high efficiency, low EMI and acoustic noise, electric isolation, low maintenance, low cost, weight, and size. Obviously, there is not a single configuration that can provide all of these features. Different configurations of UPS systems emphasize on some of the features mentioned above. Classifications of UPS systems are described in Section 19.2.

19.2 Classifications

19.2.1 Standby UPS

This configuration of UPS system is also known as "off-line UPS" or "line-preferred UPS" [4,5]. Fig. 19.1 shows the configuration of a typical standby UPS system. It consists of an AC/DC converter, a battery bank, a DC/AC inverter, and a static switch. A passive low-pass filter may also be used at the output of the UPS or inverter to remove the switching frequency from the output voltage. The static switch is on during the normal mode of operation. Therefore, load is supplied from the AC line directly without any power conditioning. At the same time, the AC/DC rectifier charges the battery set. This converter is rated at a much lower power rating than the power demand of the load. When a power outage occurs or the primary power is out of a given preset tolerance, the static switch is opened and the DC/AC inverter provides power to the load from the battery set for the duration of the preset backup time or till the AC line is back again. This inverter is rated at 100% of the load power demand. It is connected in parallel to the load

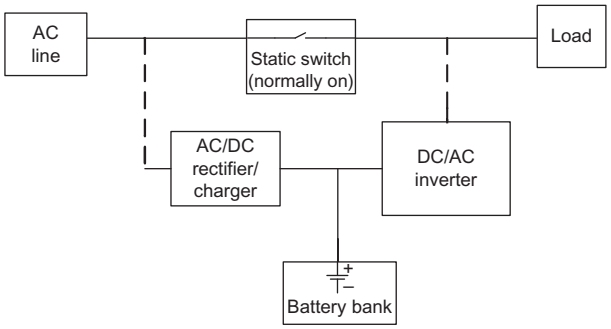

FIG. 19.1 Configuration of a typical standby UPS system.

and stays standby during the normal mode of operation. The transition time from the AC line to DC/AC inverter is usually about one-quarter of the line cycle, which is enough for most of the applications such as personal computers. The main advantages of this topology are simple design, low cost, and small size. On the other hand, the lack of real isolation of the load from the AC line, no output voltage regulation, long switching time, poor performance with nonlinear loads, and no line conditioning are the main disadvantages of this configuration.

Different configurations of AC/DC rectifiers such as linear or switching may be used in this system. To reduce the cost, a simple diode-bridge rectifier with a capacitor at the front end is used. A full-bridge or half-bridge full controlled converter is also used to charge the battery bank. Two typical topologies for a single-phase UPS system are shown in Fig. 19.2. The full controlled topologies can provide power factor correction (PFC) to meet the corresponding standards. To optimize the charging process, the charging cycle is divided into "constant current" and "constant voltage" modes. In the constant current mode, the converter injects a constant current into the battery till the battery is charged up to about 95% of its capacity. After this mode, the constant voltage mode starts that applies a constant voltage on the battery. In this mode, the input current of the battery declines exponentially until it is fully charged.

The purpose of the DC/AC inverter is to provide high-quality AC power to the load when the static switch is opened. A full- or half-bridge topology is used for this inverter. Fig. 19.3 shows two simple single-phase topologies for the DC/AC inverter.

In some topologies of standby UPS systems, an isolating transformer is used at the output stage of the UPS. This topology is called ferroresonant standby UPS system. The transformer also acts as a low-pass filter that cancels out switching frequency from the output voltage of the DC/AC inverter. On the other hand, the transformer stores electromagnetic energy in the core and acts as a buffer when a power

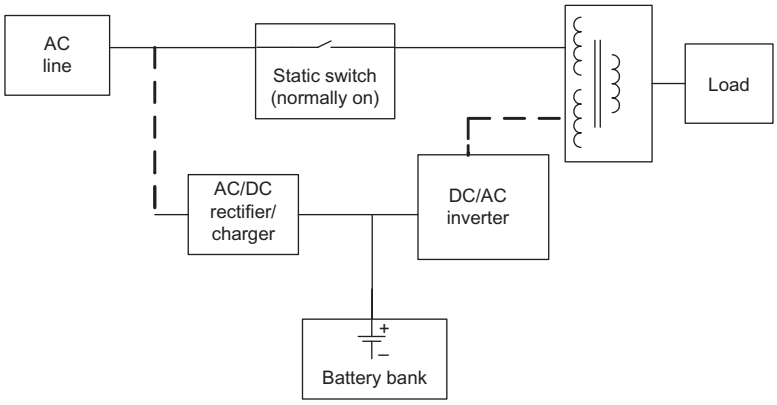

FIG. 19.4 Typical configuration of ferroresonant standby UPS system.

outage occurs. For a short time, the transformer provides power to the load and protects sensitive equipment from being affected during the transfer time from the input AC to the UPS. Fig. 19.4 shows the configuration of a ferroresonant standby UPS system. Since the transformer is bulky and expensive, this configuration is more appropriate for high-power applications.

19.2.2 On-Line UPS System

Similar to standby UPS systems, online UPS systems also consist of a rectifier/charger, a battery set, an inverter, and a static switch (bypass). Other names for this configuration are "true UPS," "inverter-preferred UPS," and "double-conversion UPS" [6,7]. Fig. 19.5 shows the block diagram of a typical online UPS. The rectifier/charger continuously supplies power to the DC bus. The power rating of this converter must be designed appropriately to supply power to the load and charge the battery bank at the same time. The batteries are rated in order to supply full power to the load during the backup time. The duration of this time varies in different applications. The inverter is rated at 100% of the load power since it must supply the load during the normal mode of operation and during the backup time. It is connected in series with the load; hence, there is no transfer time associated with the transition from normal mode to stored energy mode. This is the main advantage of online UPS systems. The static switch provides redundancy of the power source in the case of UPS malfunction or overloading. The AC line and load voltages must be in phase in order to use the static switch. This can be achieved easily by a phase-locked loop control. During the normal mode of operation, the power to the load is continuously supplied via the rectifier/charger and inverter. In fact, a double conversion from AC to DC and then from DC to AC takes place. This configuration of the UPS allows good power conditioning. The AC/DC converter charges the battery set and also supplies power to the load via the inverter. Therefore, it has the highest power rating in this topology, thereby increasing the cost. When the AC input voltage is outside the preset tolerance, the inverter and battery maintain continuity of power to the load. The duration of this mode is the duration of preset UPS backup time or till the AC line returns within the preset tolerance.

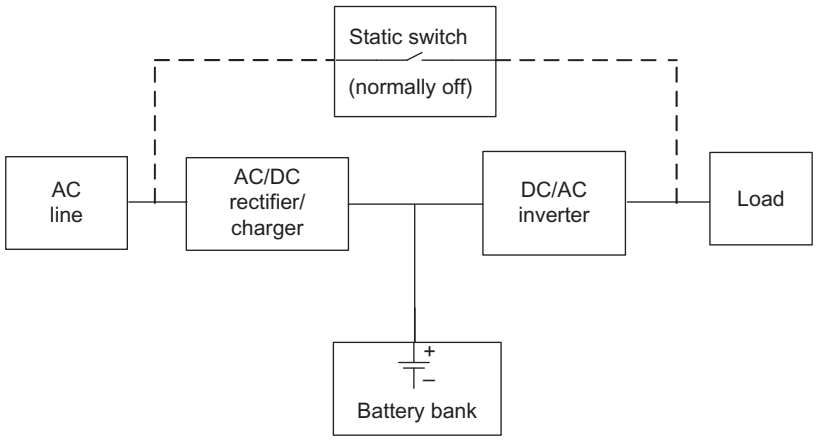

FIG. 19.5 Block diagram of an online UPS system.

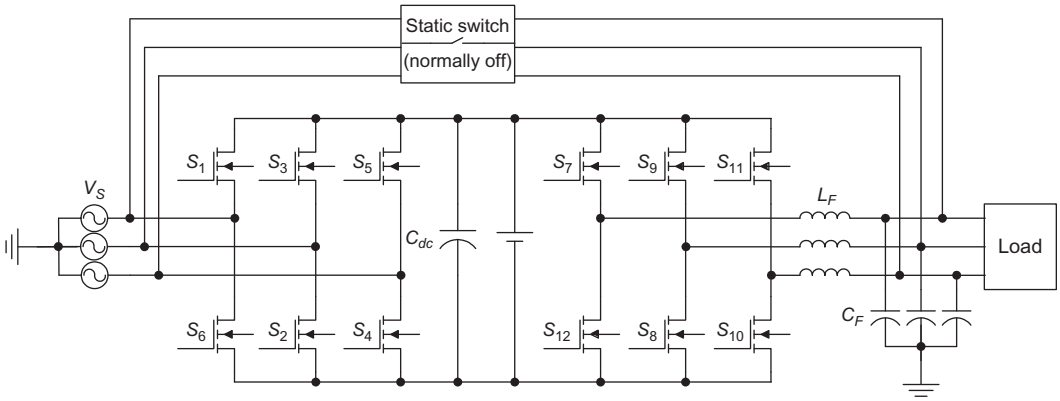

FIG. 19.6 Configuration of a three-phase online UPS system.

The main advantages of online UPS are very wide tolerance to the input voltage variation and very precise regulations of output voltage. In addition, there is no transfer time during the transition from normal to stored energy modes. It is also possible to regulate or change the output frequency [8]. The main disadvantages of this topology are low-power factor, high THD at the input, and low efficiency. The input current is distorted by the rectifier unless an extra PFC circuit is added; but, this adds to the cost of the UPS system [9].

As mentioned for the standby UPS system, different topologies are employed for the AC/DC rectifier and DC/AC inverter. Unlike standby UPS system, in this system, these converters provide power to the load continuously. Therefore, more care should be given to the quality of the input current and output voltage and the efficiency of the system. Fig. 19.6 shows the configuration of a three-phase online UPS system. The proper switching method such as pulse-width modulation (PWM) is employed for the AC/DC rectifier to minimize the input current harmonics and provide regulated DC bus voltage. A low-pass filter at the output of the system removes the switching frequency from the output voltage.

19.2.3 Line-Interactive UPS

Line-interactive UPS systems consist of a static switch, a series inductor, a bidirectional converter, and a battery bank. An optional passive filter can be added at the output of the bidirectional converter or at the input side of the load. A line-interactive UPS can operate either as an online UPS or as an off-line UPS. For an off-line line-interactive UPS, the series inductor is not required. However, most of the line-interactive UPS systems operate online in order to either improve the power factor of the load or regulate the output voltage for the load. When the AC line is within the preset tolerance, it feeds the load directly. The AC/DC converter is connected in parallel with the load and charges the battery. This converter may also be used to improve the power factor of the system and compensate the load current harmonics [10,11]. Typical configuration of a line-interactive UPS is shown in Fig. 19.7.

When a power outage occurs or input voltage falls outside the preset tolerance, the system goes to bypass mode. In this mode, the bidirectional converter operates as a DC/AC inverter and supplies power to the load from the battery set. The static switch disconnects the AC line in order to prevent back-feed from the inverter. The main advantages of the line-interactive UPS systems are simple design and, as a result, high reliability and lower cost compared with the online UPS systems. They also have good harmonic suppression for the input current. Since this is a single-stage conversion topology, the efficiency is higher than online UPS system. The main disadvantage is the lack of effective isolation of the load from the AC line. Employing a transformer in the output can eliminate this; but, it will add to the cost, size, and weight of the UPS system. Furthermore, the output voltage conditioning is not good because the inverter is not connected in series with the load. In addition, since the AC line supplies the load directly during the normal mode of operation, there is no possibility for regulation of the output frequency.

19.2.4 Universal UPS

This type of UPS is also called “series parallel” or “delta conversion.” Its topology is derived from unified power quality conditioner topology and combines the advantages of both online and line-interactive UPS systems [12,13]. It can achieve unity power factor, precise regulation of the output voltage, and high efficiency simultaneously. Its configuration is shown in Fig. 19.8. It consists of two bidirectional converters connected to a common battery set, a static switch, and a series transformer. The series bidirectional converter is rated at about 20% of the output power of the UPS system, and it is connected via a transformer in series with the AC line. The second bidirectional converter is the usual inverter for a line-interactive UPS connected in parallel to the load and rated at 100% of the output power.

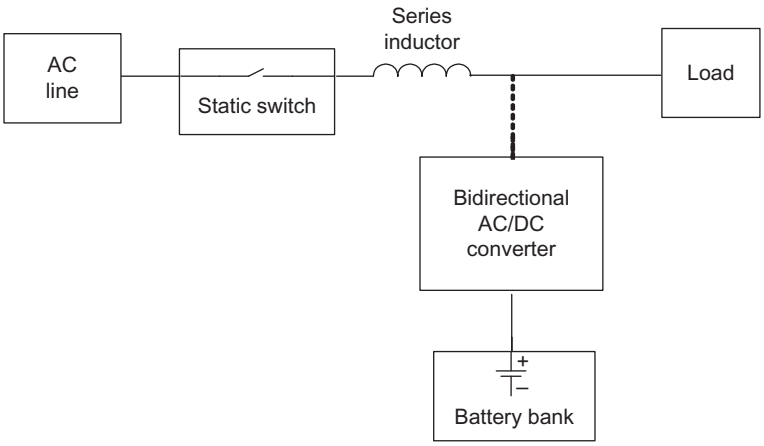

FIG. 19.7 A typical configuration of a line-interactive UPS system.

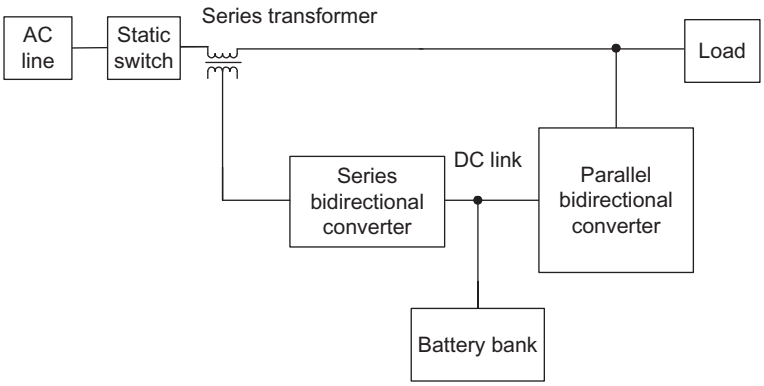

FIG. 19.8 Block diagram of a universal UPS system.

When the input voltage is in the acceptable range, the system is in the bypass mode. In this mode, parallel converter deals with current-based distortions. It mitigates load current harmonics and improves input power factor. At the same time, it charges the battery pack. Series converter deals with voltage-based distortions. It cancels input voltage harmonics and compensates voltage sags and swells. Most of the power is supplied directly from the AC line to the load. Only a small percentage of the input power is absorbed by parallel converter. This power is used to compensate the differences between input and reference voltages and to charge the battery pack. On the other hand, when the input voltage shuts down, the static switch separates the source and the load, and the system goes to backup mode. In this situation, the parallel inverter acts as a DC/AC inverter and supplies power to the load. Since a large portion of the power flows without any conversion from the AC line to the load, the efficiency is higher than that of an online UPS system. Having eliminated the main drawback of double-conversion UPS systems, the universal UPS topology appears to be a strong competitor of online UPS systems in many applications. Fig. 19.9 shows the topology of a three-phase universal UPS system.

19.2.5 Rotary UPS

Rotary UPS systems use the stored kinetic energy in the electric machines to provide power to the load when a power outage occurs. There are different configurations for rotary UPS systems. The simplest topology consists of an AC motor and an AC generator, which are mechanically coupled. A flywheel is also used on the shaft of the machines to store more kinetic energy in the system. In normal operation, the input AC line provides power to the AC motor, and this AC motor drives the AC generator. The configuration of this system is shown in Fig. 19.10A. In backup mode, the kinetic energy stored in the motor, flywheel, and generator is converted to electric power and supplies the load. This simple topology is designed to provide short-time backup power to the load (typically less than 2 s) in case of power interruption. In another configuration of rotary UPS system that is shown in Fig. 19.10B, an AC

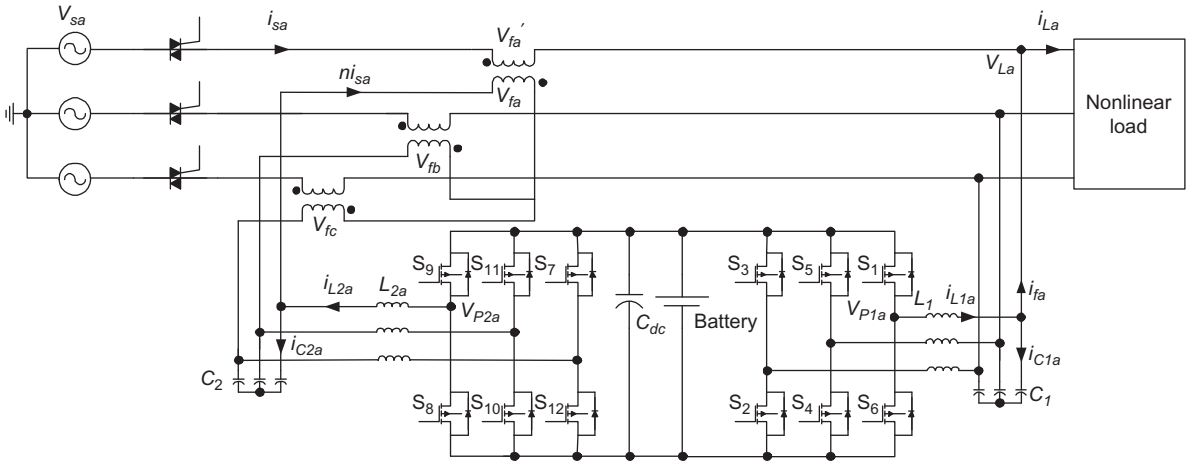

FIG. 19.9 A universal UPS topology based on two three-leg bidirectional converters.

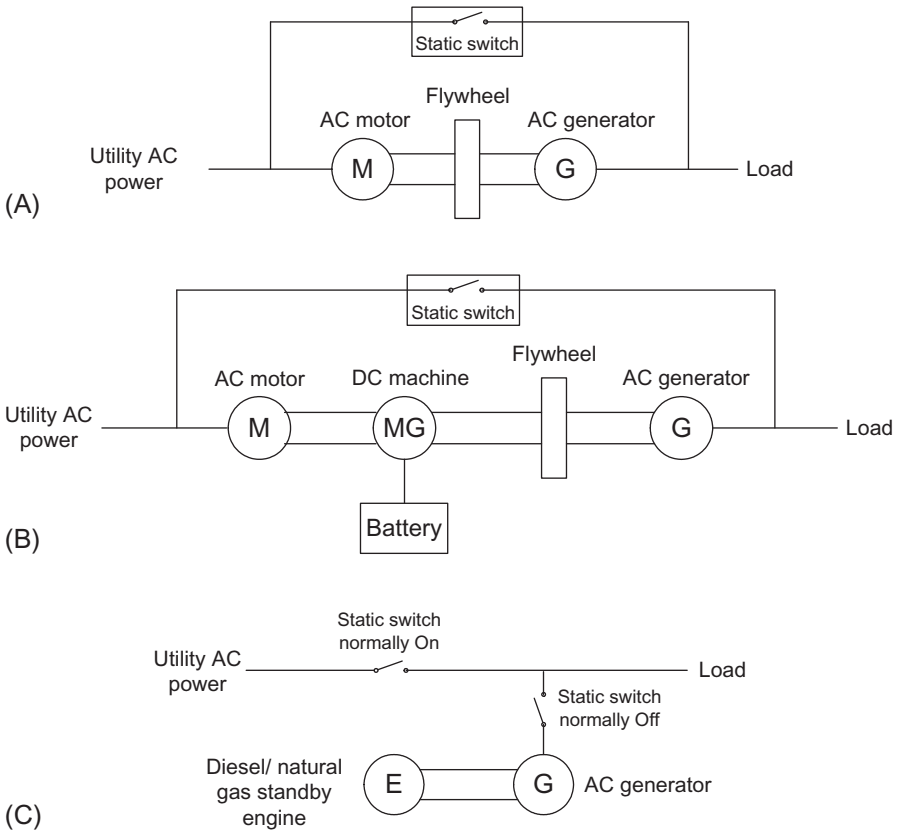

FIG. 19.10 Different configuration of rotary UPS systems: (A) motor-generator set, (B) rotary UPS with battery backup, and (C) rotary UPS with standby diesel/natural gas engine.

motor, a DC machine, an AC generator, and a battery bank are used. During the normal mode of operation, the AC line supplies the AC motor, which drives the DC machine. The DC machine drives the AC generator, which supplies the load. During the backup mode of operation, the battery bank supplies the DC machine, which, in turn, drives the AC generator and the AC generator supplies the load. This system can provide long-time backup power to the load depending on the capacity of the battery set. These two rotary UPS systems are much more reliable than the static UPS systems and provide complete electric isolation between the load and input AC line. Yet, they require more maintenance and have much bigger size and weight.

Therefore, they are usually used for high-power applications [14,15]. The configuration of a standby rotary UPS system is shown in Fig. 19.10C. This system does not provide electric isolation between the load and input AC. There is also a transition delay for switching from main AC to backup AC generator. However, it can provide power to the load as long as needed.

19.2.6 Hybrid Static/Rotary UPS

Hybrid static/rotary UPS systems combine the main features of both static and rotary UPS systems. They have low output impedance, high reliability, excellent frequency stability, and low maintenance requirements [16]. Typical configurations of hybrid static/rotary UPS are depicted in Fig. 19.11. They are usually used in high-power applications. In the system shown in Fig. 19.11A, during normal operation, the input AC power feeds the AC motor. The power is provided to the load from the AC generator, which is driven by the AC motor. In case of low input power quality or power interruption, the bidirectional AC/DC converter acts as an inverter and feeds the AC motor from battery pack. Configuration of a hybrid UPS system with power conditioning at the input is shown in Fig. 19.11B. Fig. 19.11C shows the configuration of a more complicated hybrid UPS system. This system has three operation modes. In normal operation, the load is directly supplied by the main AC input, and the AC motor is rotated at no-load. In the case of short power interruption, main breaker and generator breaker are opened and the inverter breaker is closed. The DC/AC inverter provides power to the load from the

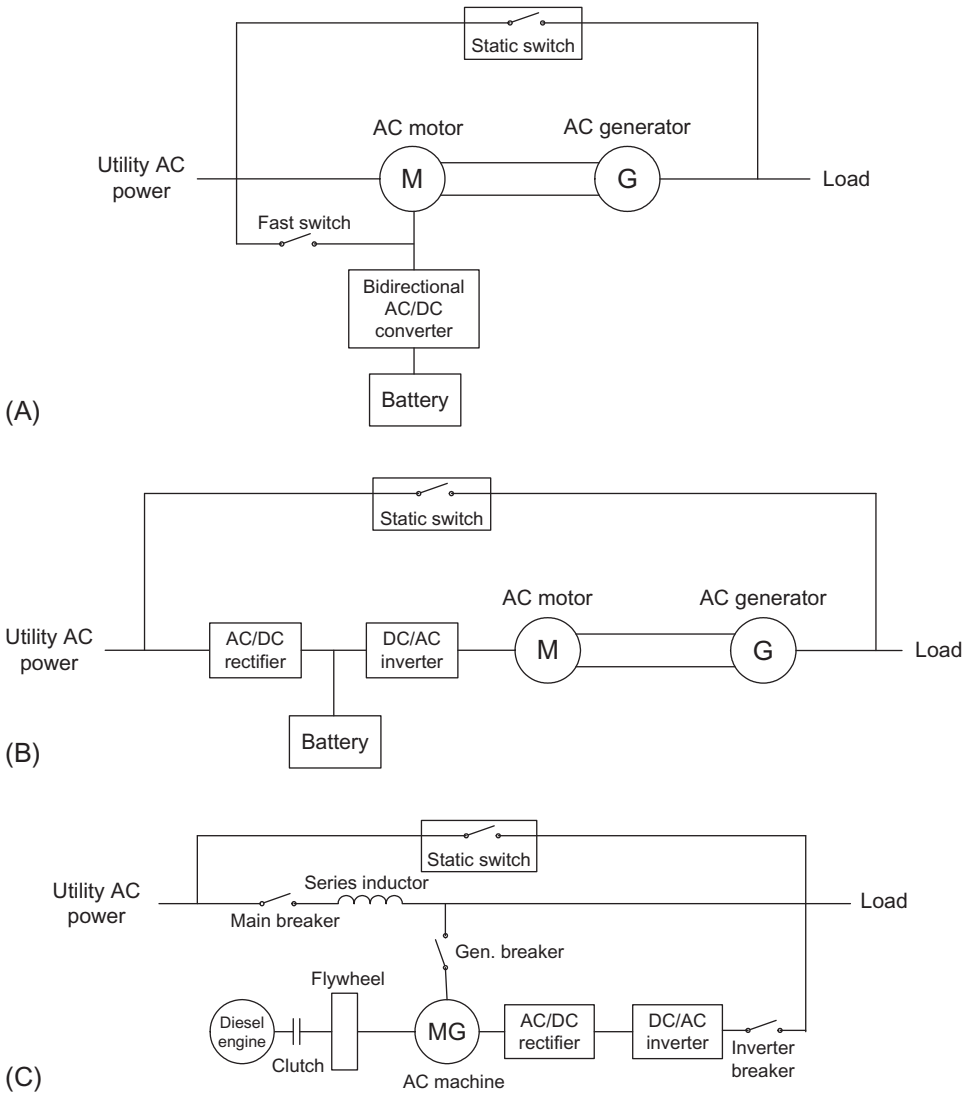

FIG. 19.11 Three configurations of hybrid rotary-static UPS systems: (A) motor-generator set with battery backup, (B) motor-generator set with power conditioning at input side, and (C) batteryless hybrid UPS system.

kinetic energy stored in the AC machine. If power is not restored in the short term, the diesel engine is turned on, which provides power to the load through the AC generator. In this mode, the main breaker and inverter breaker remain open. One of the advantages of this topology is operation without a battery set to minimize cost, space, and required maintenance. The second advantage is avoiding double power conversion in long-term power interruption.

19.2.7 DC UPS

All the aforementioned UPS configurations systems, including static, rotary, and hybrid UPS systems, are AC-based UPS systems as most UPS systems currently are available in the industry. In these systems, the AC main source directly or through several power conversions is connected to the load, and the power exchanged between different parts of the system has an AC format, except for the battery. The DC UPS system is based on the DC concept where the power flow in the system has DC characteristics, or in other words, the system shares power through a DC bus that connects all main parts, including source, loads, and energy storage, while in AC system, this link is an AC bus. The DC UPS system has several advantages with respect to the online three-phase UPS that is extensively used in industry, such as lower size, cost, and weight due to replacing the three-phase dual converter in the online UPS system with a single-stage single-phase DC/DC converter, and thus, higher efficiency is expected.

Fig. 19.12 illustrates the block diagram of the DC line-interactive UPS system. This UPS shares a DC bus between the attached sources and loads. The DC link is also integrated with a battery pack through a DC/DC bidirectional power converter. The DC UPS consists of an AC/DC rectifier, a DC/DC bidirectional converter, and the battery pack. This UPS configuration is designed for pulse loads where frequent high-power pulses with short-time duration, that is, less than 10 s, are required. The DC/DC converter regulates the DC link voltage and controls the charging and discharging processes of the battery pack. The AC/DC rectifier operates in such a way to provide unity power factor. The rectifier is designed to supply the load average power plus the battery charging power while the DC/DC converter rated for the load peak power.

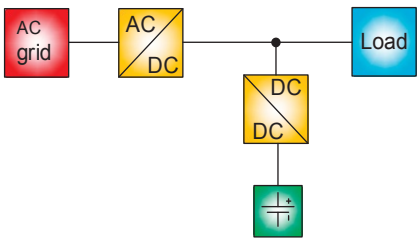

FIG. 19.12 Block diagram of the proposed DC line-interactive UPS system.

The DC UPS system will also provide load leveling feature for the main AC/DC rectifier that has not been offered by conventional AC UPS systems. It applies load power smoothing to reduce the rating of the incoming AC line and consequently reduce the installation cost and time.

The DC UPS, as shown in Fig. 19.12, is integrated with safe and high-power-density battery, which links to the DC link through a bidirectional DC/DC converter. In case of utility power disruptions, the proposed system provides power from the battery to directly energize the DC section and ensure continue and reliable operation.

The DC UPS system operates in four different modes, which are defined based on the load profile, battery pack status, and connection of the main AC source. These modes include high-rate discharging mode, a so-called load leveling mode, the standby mode, online mode, and UPS or islanded mode. The first mode is the high-rate discharging mode in which the load requires a pulsed peak power provided by the battery though DC/DC converter, following by a rest time in which battery is charged from the grid power. The third mode begins when the battery is fully charged during second mode. Finally, the fourth mode is when the AC main source is not available and the entire power provided by the battery pack.

19.2.8 Comparison of UPS Configurations

Table 19.1 provides the comparison between the characteristics of different types of UPS systems.

19.3 Performance Evaluation

There are four criteria for evaluating the performance of a UPS system: quality of output voltage, input PFC and current harmonic cancellation, transition time, and efficiency.

The quality of output voltage is the most important factor. The output voltage of an AC UPS system should be sinusoidal with low THD in different loading conditions even with nonlinear loads. The control system should have small transient responses to provide appropriate line conditioning in different loading profiles. Typically, rotary UPS systems, which employ an AC generator at the load side, have better output voltage quality than static UPS systems. In these systems, there is no converter switching frequency present at the output voltage. Among the static UPS systems, online UPS configuration provides better output voltage quality. In this system, output voltage is provided by a DC/AC inverter regardless of input voltage quality. Usually, a PWM method is used to regulate the output voltage. This kind of UPS should be designed to have minimum switching frequency at the output and provide pure sinusoidal voltage at different loading conditions. Followed by online UPS system are universal and line-interactive configurations. In universal topology, during normal mode of operation,

TABLE 19.1 Performance comparison of different configurations of UPS systems

Parameter	Online	Line interactive	Off-line	Universal	Rotary	Hybrid	DC
Surge protection	Excellent	Good	Good	Good	Excellent	Excellent	Good
Transition time	Excellent	Good	Poor	Good	Excellent	Excellent	Good
Line conditioning	Poor	Good	Poor	Excellent	Good	Good	Good
Backup duration	Depends on battery	Depends on battery	Depends on battery	Depends on battery	Typically 0.1–0.5 s	Depends on battery	Depends on battery
Efficiency	Low around 80%	High up to 95%	High	High up to 95%	High typically above 85%	High typically around 95%	High up to 95%
Input/output isolation	Poor	Poor	Poor	Poor	Perfect	Perfect	Good
Load leveling	No	No	No	No	No	No	Excellent
Cost	High	Medium-high	Low	High	Very high	Very high	Low-medium

the series converter provides voltage conditioning and regulates output voltage. In the backup mode, the parallel converter provides the load with sinusoidal voltage. In the line-interactive topology, during normal operation mode, input voltage directly supplies the load and no voltage conditioning is provided. In the backup mode, the DC/AC inverter provides the load with sinusoidal voltage.

The second criterion is transition time from normal mode of operation to stored energy mode. Online rotary, DC, and static UPS systems have superior performance in this regard. The output voltage is always provided by the output generator or output converter, and there is no transition time between operation modes of the systems. However, some of the rotary and hybrid configurations shown in Figs. 19.10 and 19.11 can only provide power to the load for a limited time. This time is determined by the amount of kinetic energy stored in the mechanical system. The transfer time in universal and line-interactive topologies depends on the time necessary for converting the power flow from the battery bank through the inverter to the load. Improved performance is achieved by choosing the DC bus capacitor voltage at the battery side to be slightly higher than the floating voltage of the batteries. Therefore, when the AC line fails, it is not necessary to sense the failure because the DC bus voltage will immediately fall under the floating voltage of the batteries and the power flow will naturally turn to the load. For off-line UPS systems, the transfer time is the longest. It depends upon the speed of sensing the failure of the AC line and starting the inverter.

The next important factor is the input power factor and the ability of the system to provide conditioning for load power. Universal UPS system has better performance followed by line-interactive and online UPS in this regard. During normal mode of operation, the parallel converter acts as an active filter and compensates reactive current and current harmonics generated by the load. In the line-interactive system, the bidirectional AC/DC converter performs this task. In an online UPS system, an additional system must be added to improve PFC and mitigate current harmonics.

The last criterion for performance evaluation is efficiency. To emphasize this factor, it should be noted that losses in UPS systems represent about 5%–12% of all the energy consumed in data centers. Efficiency in rotary and hybrid configurations depends on the topology of the system, but typically, for low-power application due to mechanical loss in the motor and generator, the efficiency is not very high. Among the static UPS systems, online UPS system has the poorest efficiency due to double conversion. Line-interactive and universal topologies provide higher efficiencies since most of the power directly flows from the input AC to the load during normal operation. The DC UPS has efficiency close to the line-interactive UPS type and higher than online UPS due to lower number of power conversion stages between source and load.

19.4 Applications

The UPS systems have wide applications in a variety of industries. Their common applications range from small power rating for personal computer systems to medium power rating for medical facilities, life-supporting systems, data storage, and emergency equipment and high power rating for telecommunications, industrial processing, and online management systems. Different considerations should be taken into account for these applications. For emergency systems and lighting, the UPS should support the system for at least 90 min. Except for emergency systems, the UPS is designed to provide backup power to sensitive loads for 15–20 min. After this time, if the power is not restored, the system will be gracefully shut down. If a longer backup period is considered, a larger battery with higher cost and space is required. For process equipment and high-power applications, some UPS systems are designed to provide enough time for the secondary power sources such as diesel generators to start up.

For industrial applications, it should be noted that UPS systems add to the complexity of the electric system. They also add installation and ongoing maintenance costs. They may

also add nonlinearity to the system, decrease the efficiency, and deteriorate the input PFC mechanism. The power rating of the UPS should be appropriately selected considering the existing load and future extensions. For many applications, input voltage surges and spikes cause more damage than power outages. For these systems, another device instead of UPS can be utilized. Load characteristics should also be considered in UPS selection. For motor loads, the inrush current, which is sometimes 2.5 times of the rated current, should be considered. A good UPS for the motor loads is the one with higher transient overloads. For nonlinear loads such as switching power supplies, the input current is not sinusoidal. Therefore, the instantaneous current is higher than the RMS current. This high instantaneous current should be considered in UPS selection.

For a power distribution network, two different approaches are taken to support sensitive loads. In a distributed approach, which is more suitable for highly proliferated loads such as medical equipment, data processing, and telecommunications, many separate UPS units operate in parallel to supply critical loads. UPS units are placed flexibly in the system to form a critical load network. A typical online distributed UPS system is shown in Fig. 19.13. High flexibility and redundancy are the main advantages of distributed systems. Individual load increase can be supported by adding more UPS systems. Consideration for future extension can also be delayed until the loads are added. On the other side, this method has some disadvantages. The load sharing between different UPS units is a difficult task. Complicated digital control methods and communication between units are required to perform optimal load sharing. The second disadvantage is that the monitoring of the whole system is difficult and requires specially trained staff.

The other method to support distributed loads is to use a large UPS unit to supply all the critical loads in a centralized approach. This approach is more desirable for industrial and utility applications. The advantage of this method is easier maintenance and troubleshooting. The disadvantages on the other side are the lack of redundancy and high installation cost. In addition, consideration for system expansion should be taken into account when the original UPS unit is selected.

19.5 Control Techniques

The main task of the control system in an UPS unit is to minimize the output voltage THD in different loading profiles. In addition, it should provide the proper mechanism to recharge the battery set and maintain high input power factor and low total input current harmonic distortion. Other factors considered for a good control technique are nearly zero steady-state inverter output voltage error, good voltage regulation, robustness, fast transient response, and protection of the inverter against overload under linear/nonlinear loads.

The most common switching technique is sinusoidal PWM. This method can be utilized for both single-phase and three-phase systems. The advantage of this method is low output voltage harmonic and robustness. This strategy uses a single feedback loop to provide well-regulated output voltage with low THD. The feedback control can be continuous or discontinuous. Analog techniques are used in continuous approach. The sinusoidal PWM (SPWM) can be of natural sampling type, average type, or instantaneous type [17,18].

In natural sampling type, the peak value of the output voltage is detected and compared with a reference voltage in order to obtain the error, which is used to control the reference to the modulator. The average approach is basically the same; but, the sensed voltage is converted to an average value and, after that, is compared with a reference signal. These approaches control only the amplitude of the output voltage and are good only at high frequencies. In an instantaneous voltage feedback SPWM control, the output voltage is continuously compared with the reference signal improving the dynamic performance of the UPS inverter.

A typical block diagram of a three-phase DC/AC inverter for UPS systems and SPWM switching control technique is shown in Fig. 19.14. The disadvantage of this method is lack of flexibility for nonlinear loads. Other programmed PWM techniques such as selective harmonic elimination, minimum THD, minimum loss, minimum current ripple, and reduced acoustic noise may be used for the inverter.

Better performance even with nonlinear and step-changing loads can be achieved by multiple control loop strategies [19].

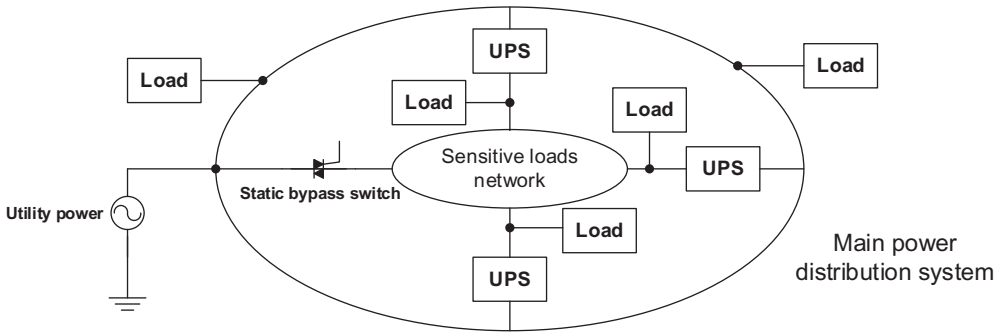

FIG. 19.13 Typical configuration of a distributed UPS network.

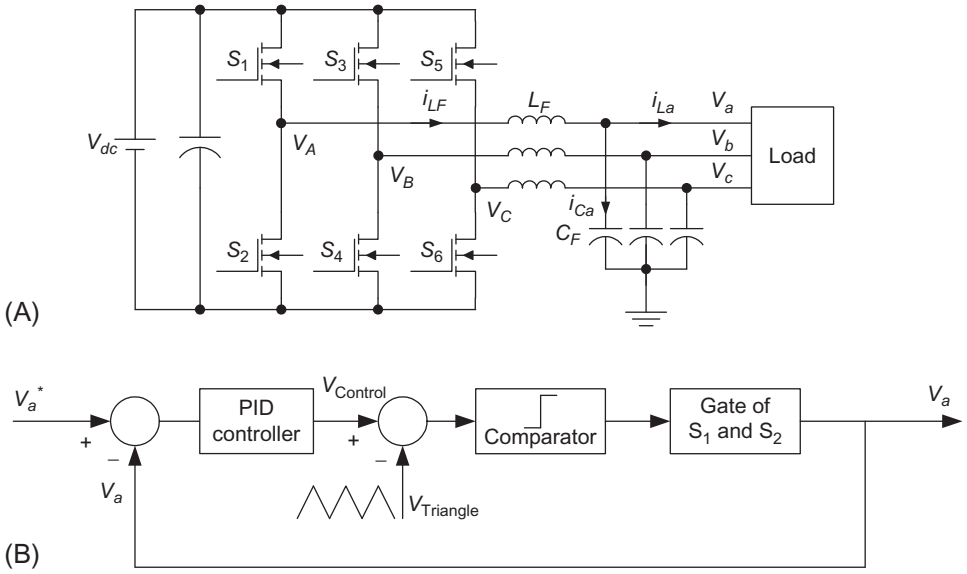

FIG. 19.14 (A) Configuration of a three-phase DC/AC inverter for UPS systems and (B) simple voltage controller using PWM technique.

As shown in Fig. 19.15, there are two-control loops: an outer and an inner. The outer control loop uses the output voltage as a feedback signal, which is compared with a reference signal. The error is compensated by a PI integrator to achieve stable output voltage under steady-state operation. This error is also used as a reference signal for the inner current regulator loop, which uses the inductor or the capacitor output filter current as the feedback signal. The minor current loop ensures fast dynamic responses enabling good performance with nonlinear or step-changing loads. The basic current regulators employed as minor current loop are hysteresis regulators, sinusoidal PWM regulator, and predictive regulators. In a typical hysteresis regulator, the reference signal is compared with the feedback signal. The sign and predetermined amplitude of the error determine the output of the modulator. The duration between two successive levels is determined by the slope of the reference signal. The output voltage tracks the reference signal within the upper and lower boundary levels. This hysteresis control has fast transient response; but, the switching frequency varies widely [20].

In SPWM control technique, the output voltage feedback is compared with a sine reference signal, and the error voltage is compensated by a PI regulator to produce the current reference. The current through the inductor or the capacitor is sensed and compared with the reference signal. After being compensated by a PI regulator, the error signal is compared with a triangular waveform to generate SPWM signal for switching control. The SPWM current control has a constant switching frequency and also provides fast dynamic responses. In predictive current control method, the switching instants are determined by suitable error boundaries. When the current vector touches the boundary line, the next switching state vector is determined by prediction and optimization in order to minimize the error. Predictive current control requires a good knowledge of the load parameters. All these current regulators are typically used as an inner loop to regulate the current in the filter inductor. The current reference for the current regulator is obtained by summing together the error in an outer voltage loop with the actual load current to yield the rated output voltage.

With the increase of speed and reliability of digital processors and a decrease in their cost, digital processors have been facing an enormous growth of popularity in

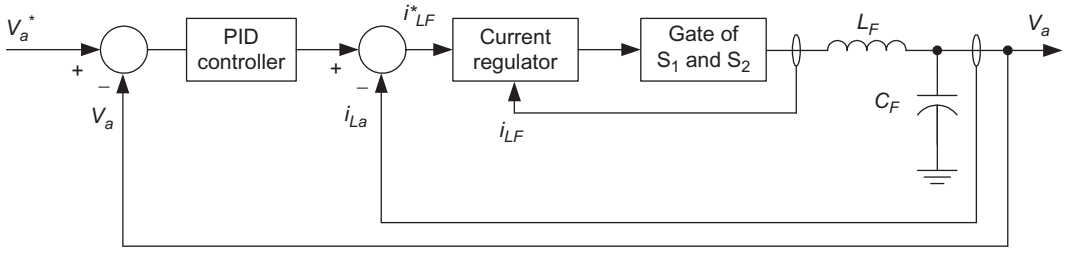

FIG. 19.15 Typical current and voltage control loops for UPS inverter.

control applications in the past few years. Many digital and discrete control techniques such as deadbeat control [21], dissipativity-based control [22], sliding-mode control [23], space vector-based control [24], and multiple-feedback loop [25] have been developed using digital signal processors.

In this section, fundamental analysis of a deadbeat control method is explained for the three-phase UPS configuration shown in Fig. 19.14A. The state-space equations of one phase of this system in the continuous time domain are as follows:

$$C_F\frac{dV_a}{dt}=i_{LF}-i_{La} \tag{19.1}$$

$$L_F\frac{di_{LF}}{dt}=V_A-V_a \tag{19.2}$$

Considering V_a and i_{LF} as state variables, the state-space equation of the system is as follows:

$$\begin{bmatrix}V_a\\ i_{LF}\end{bmatrix}^{\bullet}=\begin{bmatrix}0 & 1/C_F\\ -1/L_F & 0\end{bmatrix}\begin{bmatrix}V_a\\ i_{LF}\end{bmatrix}+\begin{bmatrix}0\\ 1/L_F\end{bmatrix}V_A+\begin{bmatrix}-1/C_F\\ 0\end{bmatrix}i_{La} \tag{19.3}$$

These continuous time-domain state-space equations are converted to the discontinuous time domain with a sampling period of T_s [26]:

$$\begin{aligned}\begin{bmatrix}V_a(k+1)\\ i_{LF}(k+1)\end{bmatrix}=&\begin{bmatrix}\cos\omega_0T_s & \dfrac{\sin\omega_0T_s}{\omega_0C_F}\\ -\dfrac{\sin\omega_0T_s}{\omega_0L_F} & \cos\omega_0T_s\end{bmatrix}\begin{bmatrix}V_a(k)\\ i_{LF}(k)\end{bmatrix}\\&+\begin{bmatrix}1-\cos\omega_0T_s\\ \dfrac{1}{\omega_{02}L_F}\sin\omega_0T_s\end{bmatrix}V_A(k)\\&+\begin{bmatrix}-\dfrac{1}{\omega_0C_F}\sin\omega_0T_s\\ 1-\cos\omega_0T_s\end{bmatrix}i_{La}(k)\end{aligned} \tag{19.4}$$

where ω_0 is the angular resonance frequency of L_F and C_F. The sampling frequency of the system is always considered much higher than the resonance frequency of L_F and C_F. With this assumption, Eq. (19.4) is simplified to Eq. (19.5). This conversion is valid for almost $f_s\geq 20f_0$:

$$\begin{aligned}\begin{bmatrix}V_a(k+1)\\ i_{LF}(k+1)\end{bmatrix}=&\begin{bmatrix}1 & T_s/C_F\\ -T_s/L_F & 1\end{bmatrix}\begin{bmatrix}V_a(k)\\ i_{LF}(k)\end{bmatrix}\\&+\begin{bmatrix}0\\ T_s/L_F\end{bmatrix}V_A(k)+\begin{bmatrix}-T_s/C_F\\ 0\end{bmatrix}i_{La}(k)\end{aligned} \tag{19.5}$$

The current equation according to Eq. (19.5) is given by

$$i_{LF}(k+1)=i_{LF}(k)+\frac{T_s}{L_F}[V_A(k)-V_a(k)] \tag{19.6}$$

Alternatively, this equation can be achieved by converting Eq. (19.2) from a differential equation to a difference equation. The same suggestion of $f_s\geq 20f_0$ has to be made for this conversion as well. If V_a and i^*_{LF} are considered constant over the next switching period, the output voltage of the inverter, which corrects the error of i_{LF} after two sampling periods, is described by

$$V_A(k+1)=V_a(k+1)+\frac{L_F}{T_s}\left[i^*_{LF}(k+1)-i_{LF}(k+1)\right] \tag{19.7}$$

A linear estimation of $V_a(k+1)$ can be achieved from previous values:

$$V_a(k+1)=V_a(k)+[V_a(k)-V_a(k-1)]=2V_a(k)-V_a(k-1) \tag{19.8}$$

By substituting Eqs. (19.8) and (19.10) in Eq. (19.9) and updating reference current for i_{LF} in every two sampling periods, the deadbeat digital control for series converter is described by

$$V_A(k+1)=\frac{L_F}{T_s}\left[i^*_{LF}(k)-i_{LF}(k)\right]-V_A(k)+3V_a(k)-V_a(k-1) \tag{19.9}$$

Eq. (19.9) ensures that the current error between i_{LF} and i^*_{LF} at time $k+2$ goes to zero with a delay of two sampling periods. Avoiding interaction between voltage and current control loops, load voltage, V_a, is sampled at half of the current sampling frequency. The voltage equation according to Eq. (19.5) is as follows:

$$V_a(k+1)=V_a(k)+\frac{T_s}{C_F}i_{CF}(k) \tag{19.10}$$

$$\begin{aligned}V_a(k+2)&=V_a(k+1)+\frac{T_s}{C_F}i_{CF}(k+1)\\&=V_a(k)+\frac{T_s}{C_F}i_{CF}(k)+\frac{T_s}{C_F}i_{CF}(k+1)\end{aligned} \tag{19.11}$$

As current control is suggested to be deadbeat with a delay of two sampling periods, capacitor current at time k and $(k+1)$ are given by

$$i_{CF}(k)=i^*_{CF}(k-2),i_{CF}(k+1)=i^*_{CF}(k-1) \tag{19.12}$$

Substituting Eq. (19.12) in Eq. (19.11) and updating the reference current at each of the two sampling periods, $V_a(k+2)$ is given by

$$V_a(k+2)=V_a(k)+\frac{2T_s}{C_F}i^*_{CF}(k-2) \tag{19.13}$$

The current of i^*_{CF} at time k that corrects the voltage error of V_a at time $k+4$ is as follows:

$$i^*_{CF}(k)=\frac{C_F}{2T_s}\left[V^*_a(k)-V_a(k)\right]-i^*_{CF}(k-2) \tag{19.14}$$

A block diagram of the implementation of voltage and current control of the inverter is shown in Fig. 19.16. Block diagram of the current and voltage controller for the inverter is also shown in Fig. 19.17. Voltage regulator is a pure deadbeat controller

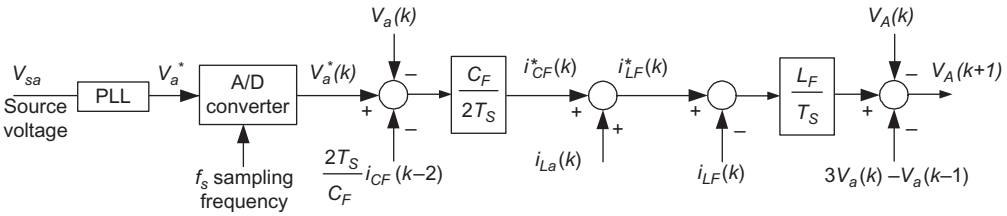

FIG. 19.16 Implementation of the current and voltage control for the inverter shown in Fig. 19.13A.

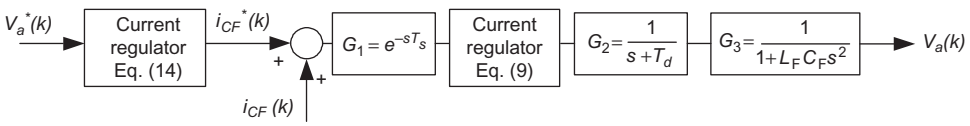

FIG. 19.17 Block diagram of the current and voltage controller for the inverter shown in Fig. 19.13A.

with a delay of two sampling periods including the consumed time for calculation. G_1 is the time delay needed for calculations and analog-to-digital conversions. G_2 is the time delay caused by the PWM inverter, and G_3 is the transfer function of the low-pass filter. Current regulator is also considered as a pure delay. The output voltage of the inverter follows its reference with four sampling periods of delay. In practice, the dynamics of the current regulator is not a pure delay and shows some deviation from the deadbeat controller.

Fig. 19.18 shows the schematic of the DC UPS. The system consists of two main converters, an AC/DC converter that manages power flow from grid to the DC bus and a DC/DC converter that regulates the DC bus voltage and also manages battery charging/discharging process. The goal for the grid-tied AC/DC rectifier is to deliver constant power to the DC link. In order to satisfy the goal, the rectifier operates on current mode and is controlled by the direct power control (DPC) method [27]. In the direct power control scheme, the direct and quadrature components of the grid currents are used to control active and reactive power independently. Fig. 19.19 illustrates the block diagrams of the AC/DC converter and the control technique.

A two-control loop method is used to manage the DC/DC converter. The controller consists of two main loops, an inner current loop and an outer voltage loop to monitor battery current while regulating the DC link voltage. Fig. 19.20 depicts the block diagram of the two-loop control technique. G_{vd} is the transfer functions of DC link voltage versus duty ratio of the DC/DC converter, and G_{id} is the transfer function of battery current versus duty ratio of the converter. G_{ci} and G_{vi} are the compensations, which need to be designed appropriately. There are several ways to design the compensators, such as desired pole/zero placement, step response, or frequency response. The frequency response characteristics are desired phase margin and crossover frequency (w_{wc}). It is desired for the system to have a crossover frequency 5–10 times lower than switching frequency and a phase margin of equal or greater than 40 degrees to have enough marginal stability.

19.6 Energy Storage Devices

In this section, three dominant main energy storage devices for the existing and future UPS systems are described. These energy storage devices are battery, flywheel, and fuel cell.

19.6.1 Battery

Battery is the energy storage component of current static UPS systems. It determines the capacity and run time of the UPS. For small units, it is the size of battery that determines the size of the UPS. Different types of batteries are used in UPS systems, but the most commonly used types are lead-acid, nickel-cadmium, and lithium-ion batteries. The lead-acid batteries used in this application are the same as the ones used in the cars. However, there is one small difference. Car batteries generate electricity by the reaction of sulfuric acid on lead plates that are drowned under the liquid. These types of battery cells are not suitable for UPS applications because there is a chance of acid spillage from them. In addition, during the charging process, they release hydrogen that is explosive and dangerous in a closed environment. Lead-acid batteries used in UPS systems are a special kind called sealed or valve-regulated. The nickel-cadmium batteries are another popular type of batteries used in UPS systems. They usually provide higher energy and power density compared with lead-acid batteries. The nominal voltage of nickel-cadmium cells is 1.2 V, which is smaller than 1.5 V of lead-acid batteries. However, the cell voltage variation throughout different charge levels is less than lead-acid batteries. These batteries also have less series resistance and can provide higher surge currents.

Lithium-ion batteries have much higher energy density. This kind of battery can be molded into different shapes. They have a nominal voltage of 4.2 V. These batteries have higher power and energy densities compared with lead-acid batteries. A long life cycle without memory effect, together with high columbic efficiency and low self-discharge characteristics, makes this type of battery the preferred energy storage choice for a wide variety of applications including UPS systems.

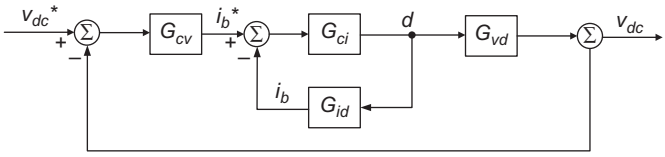

FIG. 19.20 Block diagram of the two-control loop method used to manage the DC/DC converter in the DC UPS.

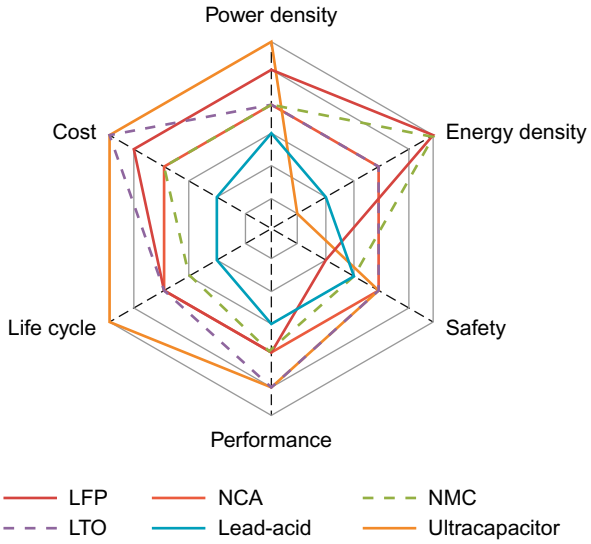

FIG. 19.21 Comparison of different Li-ion batteries, lead-acid, and ultracapacitor.

The electrode material greatly influences the battery specifications in terms of power and energy density, voltage characteristics, lifetime, and safety. A typical cathode, that is, the positive active electrode, is made of a lithium metal oxide and common materials such as cobalt ($LiCoO_2$ or LCO) and manganese ($LiMn_2O_4$ or LMO). Combined chemistries including nickel-cobalt-aluminum (NCA), nickel-manganese-cobalt (NMC), and iron phosphate (LFP) are also employed for the cathode. Graphite and lithium titanate ($Li_4Ti_5O_{12}$ or LTO) are the typical choices for the anode, that is, the negative active electrode [28]. Fig. 19.21 compares different Li-ion batteries with lead-acid and ultracapacitor.

19.6.2 Flywheel

Flywheel is simply a mechanical mass that is placed on the shaft of a motor-generator set and stores mechanical energy in the form of kinetic energy. When the electric power is required, this kinetic energy is converted to electricity by the generator coupled with the flywheel. Flywheels are the oldest type of energy storage devices. The advantages of flywheel energy storage systems are high efficiency, high energy and power density, and long life. On the other hand, flywheels are more expensive and require more space than batteries and fuel cells. There are also some safety concerns about flywheels rotating at high speeds.

19.6.3 Fuel Cell

Due to high efficiency and low emissions, fuel cell systems have been gaining popularity in recent years. A fuel cell uses hydrogen as fuel and produces electricity, heat, and water from the reaction between hydrogen and oxygen. Each cell consists of an electrolyte and two electrodes as anode and cathode. Fig. 19.22 shows the configuration of a typical fuel cell system. There are different kinds of fuel cell system depending on the types of electrolyte and hydrogen sources. Some fuel cell systems have an onboard fuel reformer and generate hydrogen from natural gas, methanol, and other hydrocarbons. Recent technology development in this field has made fuel cells a more reliable and cost-effective alternative for batteries. Fuel cells currently have a variety of applications in automotive, electric utility, and portable power industries. Table 19.2 provides a comparison between the most popular types of fuel cells.

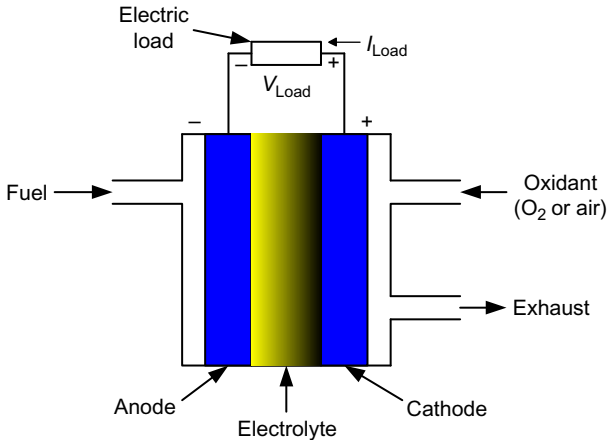

FIG. 19.22 Configuration of a typical fuel cell system.

TABLE 19.2 A comparison between the different types of fuel cell system

Fuel cell type	Applications	Advantages	Disadvantages
Proton exchange membrane (PEM)	• Electric utility • Portable power • Automotive	• Solid electrolyte reduces corrosion and management problems • Low temperature • Quick start-up	• Expensive catalysts • High sensitivity to fuel impurities
Alkaline (AFC)	• Military • Space	• High performance	• Expensive removal of CO_2 from fuel and air streams required
Phosphoric acid (PAFC)	• Electric utility • Automotive	• Up to 85% efficiency in cogeneration of electricity and heat • Can use impure H_2 as fuel	• Expensive catalysts • Low power • Large size/weight
Molten carbonate (MCFC)	• Electric utility	• High efficiency • Fuel flexibility • Can use a variety of catalysts	• High temperature enhances corrosion and breakdown of cell components
Solid oxide fuel cell (SOFC)	• Electric utility	• High efficiency • Fuel flexibility • Can use a variety of catalysts • Solid electrolyte reduces corrosion and management problems • Low temperature • Quick start-up	• High temperature enhances the breakdown of cell components
Direct alcohol fuel cell (DAFC)	• Automotive • Portable power	• Compactness • High energy density	• Lower efficiency • Alcohol passing between electrodes without reacting

20.1 Introduction

Power supplies are used in most electric equipment. Their applications cut across a wide spectrum of product types, ranging from consumer appliances to industrial utilities, from milliwatts to megawatts, and from handheld tools to satellite communications.

By definition, a power supply is a device that converts the output from an ac power line to a steady dc output or multiple outputs. The ac voltage is first rectified to provide a pulsating dc and then filtered to produce a smooth voltage. Finally, the voltage is regulated to produce a constant output level despite variations in the ac line voltage or circuit loading. Fig. 20.1 illustrates the process of rectification, filtering, and regulation in a dc power supply. The transformer, rectifier, and filtering circuits are discussed in other chapters. In this chapter, we will concentrate on the operation and characteristics of the regulator stage of a dc power supply.

In general, the regulator stage of a dc power supply consists of a feedback circuit, a stable reference voltage, and a control circuit to drive a pass element (a solid-state device such as transistor and MOSFET). The regulation is done by sensing variations appearing at the output of the dc power supply. A control signal is produced to drive the pass element to cancel any variation. As a result, the output of the dc power supply is maintained essentially constant. In a transistor regulator, the pass element is a transistor, which can be operated in its active region or as a switch, to regulate the output voltage. When the transistor operates at any point in its active region, the regulator is referred to as a *linear voltage regulator*. When the transistor operates only at cutoff and at saturation, the circuit is referred to as a *switching regulator*.

Linear voltage regulators can be further classified as either series or shunt types. In a series regulator, the pass transistor is connected in series with the load as shown in Fig. 20.2. Regulation is achieved by sensing a portion of the output voltage through the voltage divider network R_1 and R_2 and comparing this voltage with the reference voltage V_{REF} to produce a resulting error signal that is used to control the conduction of the pass transistor. This way, the voltage drop across the pass transistor is varied and the output voltage delivered to the load circuit is essentially maintained constant.

In the shunt regulator shown in Fig. 20.3, the pass transistor is connected in parallel with the load, and a voltage-dropping resistor R_3 is connected in series with the load. Regulation is achieved by controlling the current conduction of the pass transistor such that the current through R_3 remains essentially constant. This way, the current through the pass transistor is varied, and the voltage across the load remains constant.

As opposed to linear voltage regulators, switching regulators employ solid-state devices, which operate as switches: either completely *on* or completely *off*, to perform power conversion. Because the switching devices are not required to operate in their active regions, switching regulators enjoy a much lower

power loss than those of linear voltage regulators. Fig. 20.4 shows a switching regulator in a simplified form. The high-frequency switch converts the unregulated dc voltage from one level to another dc level at an adjustable duty cycle. The output of the dc supply is regulated by means of a feedback control that employs a pulse-width modulator (PWM) controller, where the control voltage is used to adjust the duty cycle of the switch.

Both linear and switching regulators are capable of performing the same function of converting an unregulated input into a regulated output. However, these two types of regulators have significant differences in properties and performances. In designing power supplies, the choice of using certain type of regulator in a particular design is significantly based on the cost and performance of the regulator itself. In order to use the more appropriate regulator type in the design, it is necessary to understand the requirements of the application and select the type of regulator that best satisfies those requirements. Advantages and disadvantages of linear regulators, as compared with switching regulators, are given below:

1. Linear regulators exhibit efficiency of 20%–60%, whereas switching regulators have a much higher efficiency, typically 70%–95%.
2. Linear regulators can only be used as a step-down regulator, whereas switching regulators can be used in both step-up and step-down operations.
3. Linear regulators require a mains frequency transformer for off-the-line operation. Therefore, they are heavy and bulky. On the other hand, switching regulators use high-frequency transformers and can therefore be small in size.
4. Linear regulators generate little or no electric noise at their outputs, whereas switching regulators may produce considerable noise if they are not properly designed.
5. Linear regulators are more suitable for applications of less than 20 W, whereas switching regulators are more suitable for large-power applications.

In this chapter, we will examine the circuit operation, characteristics, and applications of linear and switching regulators. In Section **20.2**, we will look at the basic circuits and properties of linear series voltage regulators. Some current-limiting techniques will be explained. In Section **20.3**, linear shunt regulators will be covered. The important characteristics and uses of linear integrated circuit (IC) regulators will be discussed in Section **20.4**. Finally, the operation and characteristics of switching regulators will be discussed in Section **20.5**. Important design guidelines for switching regulators will also be given in this section.

20.2 Linear Series Voltage Regulator

A zener diode regulator can maintain a fairly constant voltage across a load resistor. It can be used to improve the voltage regulation and reduce the ripple in a power supply. However, the regulation is poor, and the efficiency is low because of the nonzero resistance in the zener diode. To improve the regulation and efficiency of the regulator, we have to limit the zener current to a smaller value. This can be accomplished by using an amplifier in series with the load as shown in Fig. 20.5. The effect of this amplifier is to limit the variation of the current I_D through the zener diode D_z. This circuit is known as a linear series voltage regulator because the transistor is in series with the load.

Because of the current-amplifying property of the transistor, I_D is reduced by a factor of $(\beta+1)$, where β is the dc current gain of the transistor. Hence, there is a small voltage drop across the diode resistance, and the zener diode approximates an ideal voltage source. The output voltage V_o of the regulator is

$$V_o = V_z + V_{BE} \tag{20.1}$$

where V_z is the zener voltage and V_{BE} is the base-to-emitter voltage of the transistor. The change in output voltage is

$$\begin{aligned}\Delta V_o &= \Delta V_z + \Delta V_{BE} \\ &= \Delta I_D r_d + \Delta I_L r_e\end{aligned} \tag{20.2}$$

where r_d is the dynamic resistance of the zener diode and r_e is the output resistance of the transistor. Assume that V_i and V_z are constant. With $\Delta I_D \approx \Delta I_L/(\beta+1)$, the change in output voltage is then

$$\Delta V_o \approx \Delta I_L r_e \tag{20.3}$$

If V_i is not constant, then the current I will change with the input voltage. In calculating the change in output voltage, this current change must be absorbed by the zener diode.

In designing linear series voltage regulators, it is imperative that the series transistor must work within the rated safe operation area (SOA) and be protected from excess heat dissipation because of current overload. The emitter-to-collector voltage V_{CE} of Q_1 is given by

$$V_{CE} = V_i - V_o \tag{20.4}$$

Thus, with specified output voltage, the maximum allowable V_{CE} for a given Q_1 is determined by the maximum input voltage to the regulator. The power dissipated by Q_1 can be approximated by

$$P_{Q_1} \approx (V_i - V_o) I_L \tag{20.5}$$

Consequently, the maximum allowable power dissipated in Q_1 is determined by the combination of the input voltage V_i and the load current I_L of the regulator. For a low output voltage and a high loading current regulator, the power dissipated in the series transistor is about 50% of the power delivered to the output.

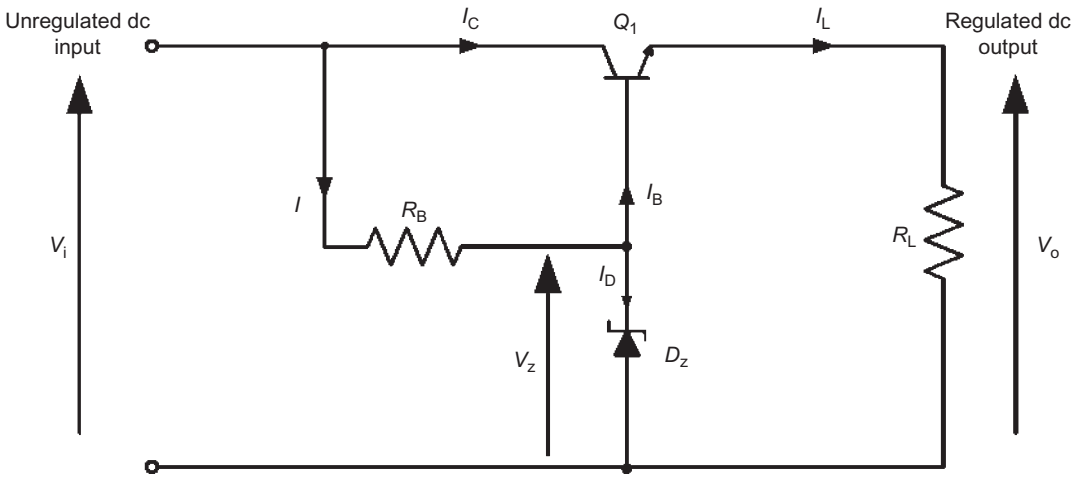

FIG. 20.5 Basic circuit of a linear series regulator.

In many high-current high-voltage regulator circuits, it is necessary to use a Darlington-connected transistor pair so that the voltage, current, and power ratings of the series element are not exceeded. The method is shown in Fig. 20.6. An additional desirable feature of this circuit is that the reference diode dissipation can be reduced greatly. The maximum base current I_{B1} is then $I_L/(\beta_1+1)(\beta_2+1)$, where β_1 and β_2 are the dc current gain of Q_1 and Q_2, respectively. This current is usually of the order of less than 1 mA. Consequently, a low-power reference diode can be used.

20.2.1 Regulating Control

The series regulators shown in Figs. 20.5 and 20.6 do not have feedback loop. Although they provide satisfactory performance for many applications, their output resistances and ripples cannot be reduced. Fig. 20.7 shows an improved form of the series regulator, in which negative feedback is employed to improve the performance. In this circuit, transistors Q_3 and Q_4 form a single-ended differential amplifier, and the gain of this amplifier is established by R_6. Here, D_z is a stable zener diode reference, biased by R_4. For higher accuracy, D_z can be replaced by an IC reference such as REF series from Burr-Brown. Resistors R_1 and R_2 form a voltage divider for output voltage sensing. Finally, transistors Q_1 and Q_2 form a Darlington pair output stage. The operation of the regulator can be explained as follows. When Q_1 and Q_2 are on, the output voltage increases, and hence, the voltage V_A at the base of Q_3 also increases. During this time, Q_3 is off and Q_4 is on. When V_A reaches a level that is equal to the reference voltage V_{REF} at the base of Q_4, the

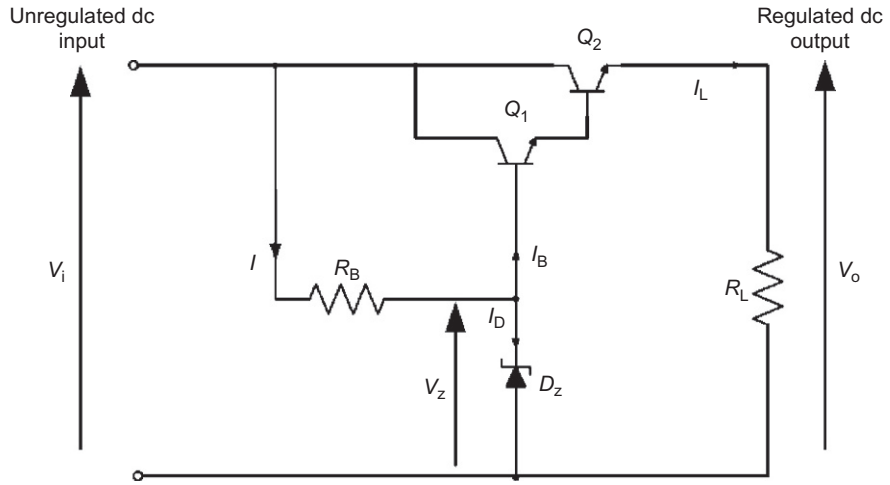

FIG. 20.6 A linear series regulator with Darlington-connected amplifier.

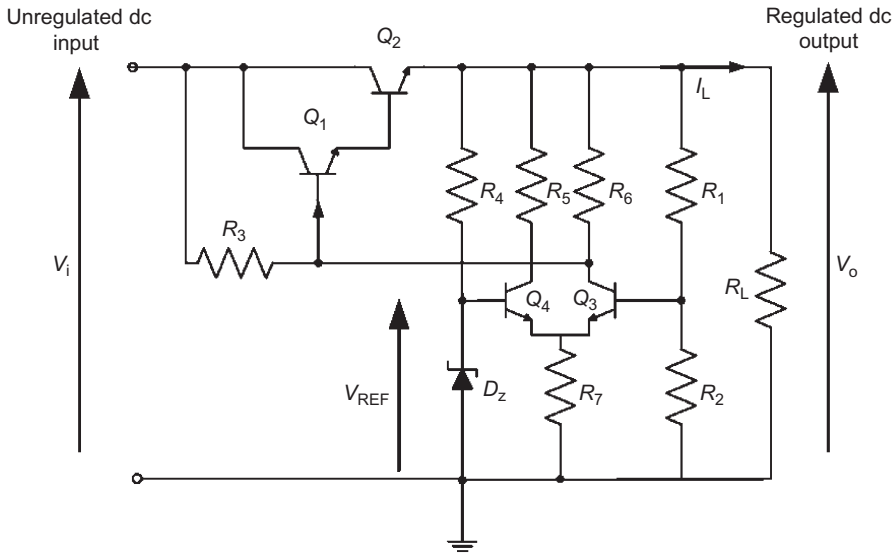

FIG. 20.7 An improved form of discrete component series regulator.

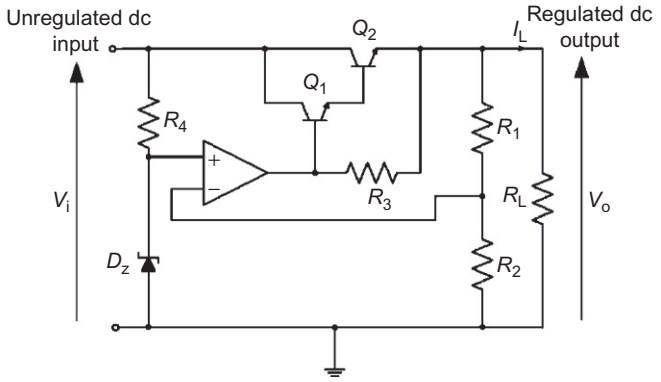

FIG. 20.8 An improved form of op-amp series regulator.

base-emitter junction of Q_3 becomes forward-biased. Some Q_1 base current will divert into the collector of Q_3. If the output voltage V_o starts to rise above V_{REF}, Q_3 conduction increases to further decrease the conduction of Q_1 and Q_2, which will in turn maintain output voltage regulation. Fig. 20.8 shows another improved series regulator that uses an operational amplifier to control the conduction of the pass transistor.

One of the problems in the design of linear series voltage regulators is the high-power dissipation in the pass transistors. If an excess load current is drawn, the pass transistor can be quickly damaged or destroyed. In fact, under short-circuit conditions, the voltage across Q_2 in Fig. 20.7 will be the input voltage V_i, and the current through Q_2 will be greater than the rated full-load output current. This current will cause Q_1 to exceed its rated SOA unless the current is reduced. In the next section, some current-limiting techniques will be presented to overcome this problem.

20.2.2 Current Limiting and Overload Protection

In some series voltage regulators, overloading causes permanent damage to the pass transistors. The pass transistors must be kept from excessive power dissipation under current overloads or short-circuit conditions. A current-limiting mechanism must be used to keep the current through the transistors at a safe value as determined by the power rating of the transistors. The mechanism must be able to respond quickly to protect the transistor and yet permit the regulator to return to normal operation as soon as the overload condition is removed. One of the current-limiting techniques to prevent current overload, called the constant current-limiting method, is shown in Fig. 20.9A. Current limiting is achieved by the combined action of the components shown inside the dashed line. The voltage developed across the current-limit resistor R_3 and the base-to-emitter voltage of current-limit transistor Q_3 is proportional to the circuit output current I_L. During current overload, I_L reaches a predetermined maximum value that is set by the value of R_3 to cause Q_3 to conduct. As Q_3 starts to conduct, Q_3 shunts a portion of the Q_1 base current. This action, in turn, decreases and limits I_L to a maximum value $I_{L(max)}$. Since the base-to-emitter voltage V_{BE} of Q_3 cannot exceed above 0.7 V, the voltage across R_3 is held at this value and $I_{L(max)}$ is limited to

$$I_{L(max)} = \frac{0.7\text{V}}{R_3} \tag{20.6}$$

Consequently, the value of the short-circuit current is selected by adjusting the value of R_3. The voltage-current characteristic of this circuit is shown in Fig. 20.9B.

In many high-current regulators, foldback current limiting is always used to protect against excessive current. This technique is similar to the constant current-limiting method, except that as the output voltage is reduced as a result of load impedance moving toward zero, the load current is also reduced. Therefore, a series voltage regulator that includes a foldback current-limiting circuit has the voltage-current characteristic shown in Fig. 20.10. The basic idea of foldback current limiting, with reference to Fig. 20.11, can be explained as follows. The foldback current-limiting circuit (in dashed outline) is similar to the constant current-limiting circuit, with the exception of resistors R_5 and R_6. At low output current, the current-limit transistor Q_3 is cutoff.

A voltage proportional to the output current I_L is developed across the current-limit resistor R_3. This voltage is applied to the base of Q_3 through the divider network R_5 and R_6. At the point of transition into current limit, any further increase in I_L will increase the voltage across R_3 and hence across R_5, and Q_3 will progressively be turned on. As Q_1 conducts, it shunts a portion of the Q_1 base current. This action, in turn, causes the output voltage to fall. As the output voltage falls, the voltage across R_6 decreases and the current in R_6 also decreases, and more current is shunted into the base of Q_3. Hence, the current required in R_3 to maintain the conduction state of Q_3 is also decreased. Consequently, as the load resistance is reduced, the output voltage and current fall, and the current-limit point decreases toward a minimum when the output voltage is short-circuited. In summary, any regulator using foldback current limiting can have peak load current up to $I_{L(max)}$. But when the output becomes shorted, the current drops to a lower value to prevent overheating of the series transistors.

20.3 Linear Shunt Voltage Regulator

The second type of linear voltage regulator is the shunt regulator. In the basic circuit shown in Fig. 20.12, the pass transistor Q_1 is connected in parallel with the load. A voltage-dropping resistor R_3 is in series with this parallel network. The operation of the circuit is similar to that of the series regulator, except that regulation is achieved by controlling the current through Q_1. The operation of the circuit can be explained as follows. When the output voltage tries to increase because of a change in load

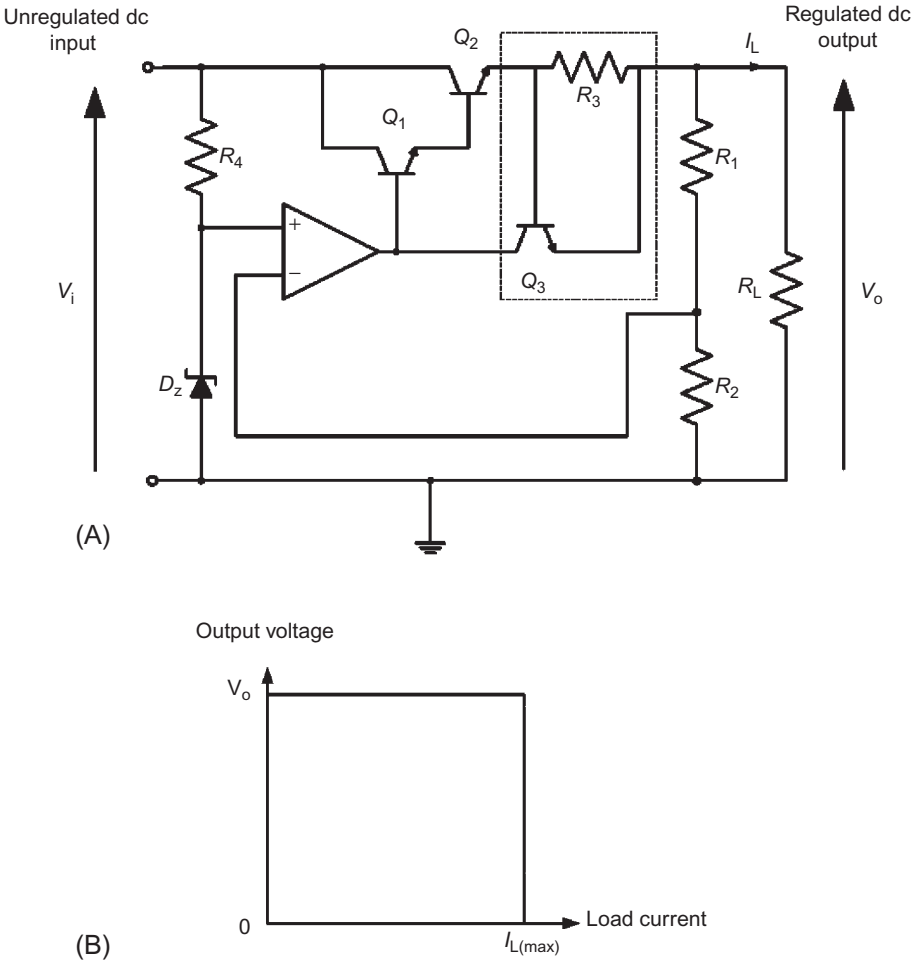

FIG. 20.9 Series regulator with constant current limiting: (A) circuit and (B) voltage-current characteristic.

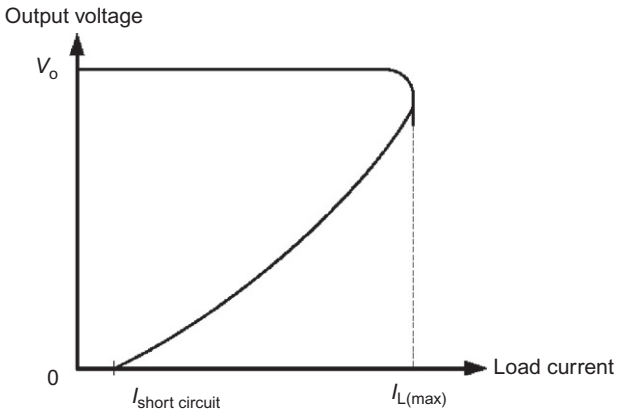

FIG. 20.10 Voltage-current characteristic of foldback current limit.

resistance, the voltage at the noninverting terminal of the operational amplifier also increases. This voltage is compared with a reference voltage, and the resulting difference voltage causes Q_1 conduction to increase. With constant V_i and V_o, I_L will decrease, and V_o will remain constant. The opposite action occurs when V_o tries to decrease. The voltage appearing at the base of Q_1 causes its conduction to decrease. This action offsets the attempted decrease in V_o and maintains it at an almost constant level.

Analytically, the current flowing in R_3 is

$$I_{R3} = I_{Q1} + I_L \tag{20.7}$$

and

$$I_{R3} = \frac{V_i - V_o}{R_3} \tag{20.8}$$

With I_L and V_o constant, a change in V_i will cause a change in I_{Q_1}:

$$\Delta I_{Q1} = \frac{\Delta V_i}{R_3} \tag{20.9}$$

With V_i and V_o constant,

$$\Delta I_{Q1} = -\Delta I_L \tag{20.10}$$

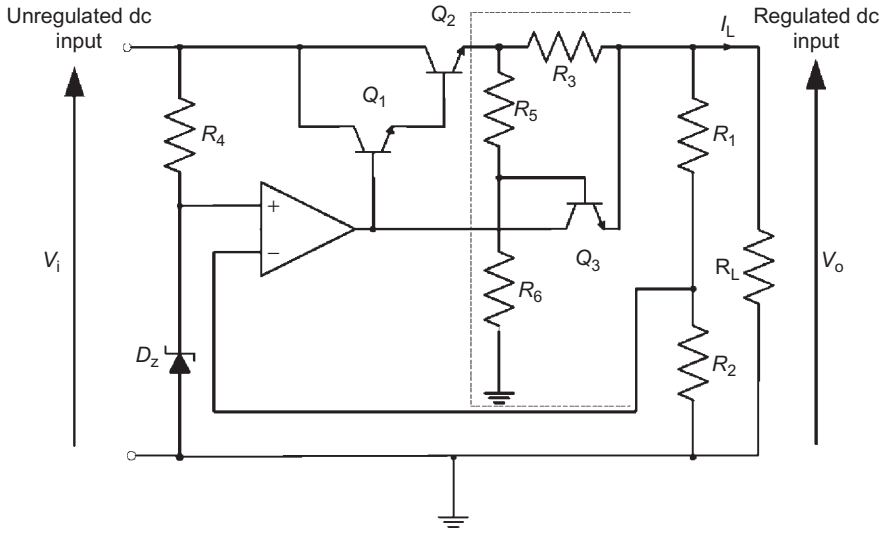

FIG. 20.11 Series regulator with foldback current limiting.

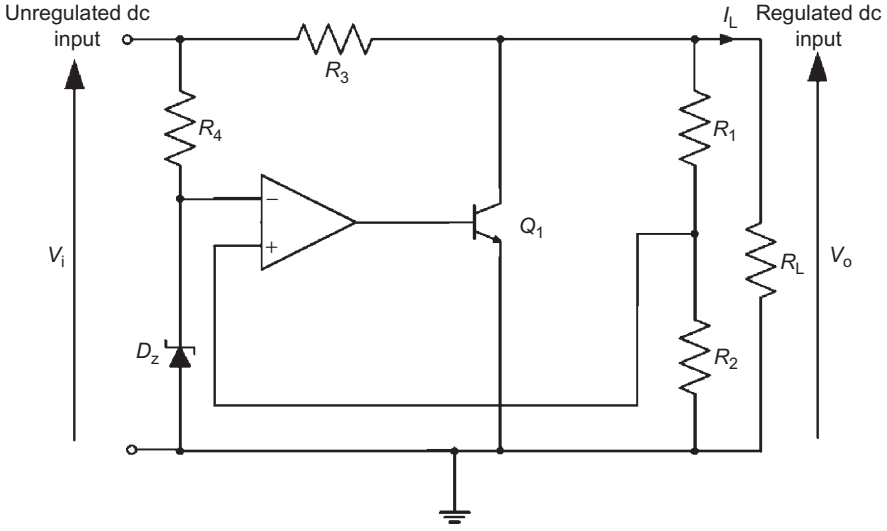

FIG. 20.12 Basic circuit of a linear shunt regulator.

Eq. (20.10) shows that if I_{Q1} increases, I_L decreases and vice versa. Although shunt regulators are not as efficient as series regulators for most applications, they have the advantage of greater simplicity. This topology offers inherently short-circuit protection. If the output is shorted, the load current is limited by the series resistor R_3 and is given by

$$I_{L(max)} = \frac{V_i}{R_3} \tag{20.11}$$

The power dissipated by Q_1 can be approximated by

$$\begin{aligned} P_{Q1} &\approx V_o I_C \\ &= V_o(I_{R3} - I_L) \end{aligned} \tag{20.12}$$

For a low value of I_L, the power dissipated in Q_1 is large, and the efficiency of the regulator may drop to 10% under this condition.

To improve the power handling of the shunt transistor, one or more transistors connected in the common-emitter configuration in parallel with the load can be employed, as shown in Fig. 20.13.

20.4 Integrated Circuit Voltage Regulators

The linear series and shunt voltage regulators presented in the previous sections have been developed by various solid-state

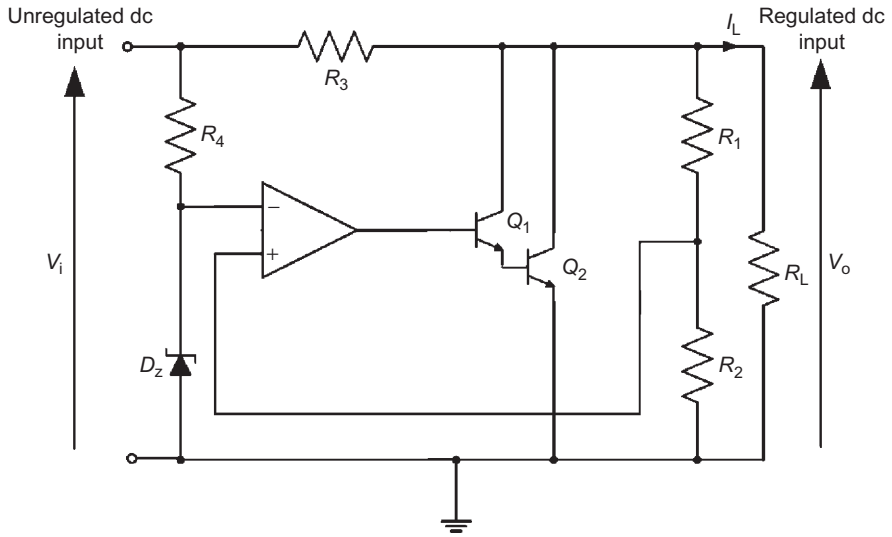

FIG. 20.13 Linear shunt regulator with two transistors as shunt element.

device manufacturers and are available in integrated circuit (IC) form. Like discrete voltage regulators, linear IC voltage regulators maintain an output voltage at a constant value despite variations in load and input voltage.

In general, linear IC voltage regulators are three-terminal devices that provide regulation of a fixed positive voltage, a fixed negative voltage, or an adjustable set voltage. The basic connection of a three-terminal IC voltage regulator to a load is shown in Fig. 20.14. The IC regulator has an unregulated input voltage V_i applied to the input terminals, a regulated voltage V_o at the output, and a ground connected to the third terminal. Depending on the selected IC regulator, the circuit can be operated with load currents ranging from milliamperes to tens of amperes and output power from milliwatts to tens of watts. Note that the internal construction of IC voltage regulators may be somewhat more complex and different from that previously described for discrete voltage regulator circuits. However, the external operation is much the same. In this section, some typical linear IC regulators are presented, and their applications are also given.

20.4.1 Fixed Positive and Negative Linear Voltage Regulators

The 78XX series of regulators provide fixed regulated voltages from 5 to 24 V. The last two digits of the IC part number denote the output voltage of the device. For example, a 7824 IC regulator produces a +24 V regulated voltage at the output. The standard configuration of a 78XX fixed positive voltage regulator is shown in Fig. 20.15. The input capacitor C_1 acts as a line filter to prevent unwanted variations in the input line, and the output capacitor C_2 is used to filter the high-frequency noise that may appear at the output. In order to ensure proper operation, the input voltage of the regulator must be at least 2 V above the output voltage. Table 20.1 shows the minimum and maximum input voltages of the 78XX series fixed positive voltage regulator.

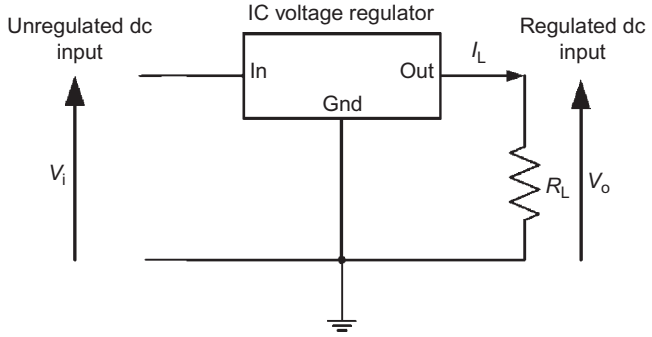

FIG. 20.14 Basic connection of a three-terminal IC voltage regulator.

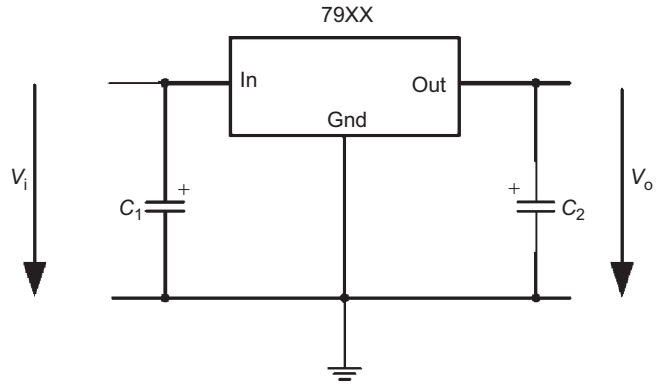

FIG. 20.16 The 79XX series fixed negative voltage regulator.

TABLE 20.2 Minimum and maximum input voltages for 79XX series regulators

Type number	Output voltage V_o (V)	Minimum V_i (V)	Maximum V_i (V)
7805	−5	−7	−20
7806	−6	−8	−21
7808	−8	−10.5	−25
7809	−9	−11.5	−25
7812	−12	−14.5	−27
7815	−15	−17.5	−30
7818	−18	−21	−33
7824	−24	−27	−38

The 79XX series voltage regulator is identical to the 78XX series except that it provides negative regulated voltages instead of positive ones. Fig. 20.16 shows the standard configuration of a 79XX series voltage regulator. A list of 79XX series regulators is provided in Table 20.2. The regulation of the circuit can be maintained as long as the output voltage is at least 2–3 V greater than the input voltage.

20.4.2 Adjustable Positive and Negative Linear Voltage Regulators

The IC voltage regulators are also available in circuit configurations that allow the user to set the output voltage to a desired

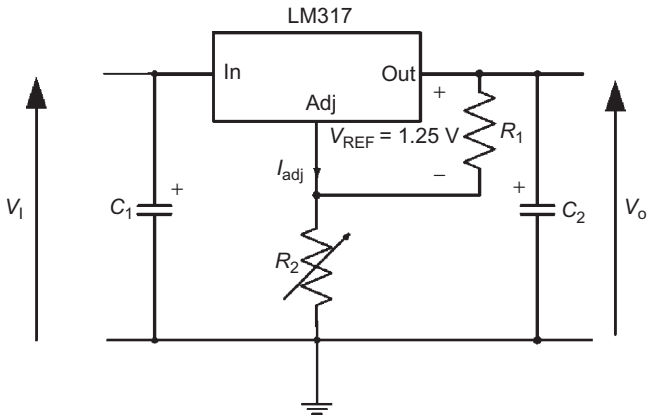

FIG. 20.17 The LM317 adjustable positive voltage regulator.

regulated value. The LM317 adjustable positive voltage regulator, for example, is capable of supplying an output current of more than 1.5 A over an output voltage range of 1.2–37 V. Fig. 20.17 shows how the output voltage of an LM317 can be adjusted by using two external resistors R_1 and R_2. The capacitors C_1 and C_2 have the same function as those in the fixed linear voltage regulator.

As indicated in Fig. 20.17, the LM317 has a constant 1.25 V reference voltage, V_{REF}, across the output and the adjustment terminals. This constant reference voltage produces a constant current through R_1 regardless of the value of R_2. The output voltage V_o is given by

$$V_o = V_{REF}\left(1 + \frac{R_2}{R_1}\right) + I_{adj}R_2 \tag{20.13}$$

where I_{adj} is a constant current into the adjustment terminal and has a value of approximately 50 μA for the LM317. As can be seen from Eq. (20.13), with fixed R_1, V_o can be adjusted by varying R_2.

The LM337 adjustable voltage regulator is similar to the LM317 except that it provides negative regulated voltages instead of positive ones. Fig. 20.18 shows the standard configuration of an LM337 voltage regulator. The output voltage can

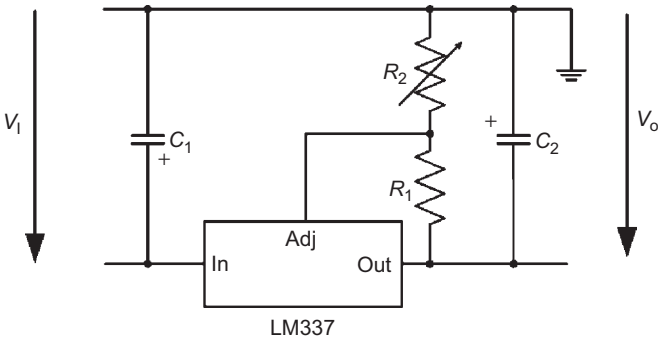

FIG. 20.18 The LM337 adjustable negative voltage regulator.

be adjusted from −1.2 to −37 V, depending on the external resistors R_1 and R_2.

20.4.3 Applications of Linear IC Voltage Regulators

Most IC regulators are limited to an output current of 2.5 A. If the output current of an IC regulator exceeds its maximum allowable limit, its internal pass transistor will dissipate an amount of energy more than it can tolerate. As a result, the regulator will be shutdown.

For applications that require more than the maximum allowable current limit of a regulator, an external pass transistor can be used to increase the output current. Fig. 20.19 illustrates such a configuration. This circuit has the capability of producing higher current to the load but still preserving the thermal shutdown and short-circuit protection of the IC regulator.

A constant current-limiting scheme, as discussed in Section 20.2.2, is implemented by using the transistor Q_2 and the resistor R_2 to protect the external pass transistor Q_1 from excessive current under current-overload or short-circuit conditions. The value of the external current-sensing resistor R_1 determines the value of current at which Q_1 begins to conduct. As long as the current is less than the value set by R_1, the transistor Q_1 is off, and the regulator operates normally as shown in Fig. 20.15. But when the load current I_L starts to increase, the voltage across R_1 also increases. This turns on the external transistor Q_1 and conducts the excess current. The value of R_1 is determined by

$$R_1 = \frac{0.7\text{V}}{I_{\max}} \tag{20.14}$$

where $I_{\max}$ is the maximum current that the voltage regulator can handle internally.

20.5 Switching Regulators

The linear series and shunt regulators have control transistors that are operating in their linear active regions. Regulation is achieved by varying the conduction of the transistors to maintain the output voltage at a desirable level. The switching regulator is different in that the control transistor operates as a switch, either in cutoff or saturation region. Regulation is achieved by adjusting the on-time of the control transistor. In this mode of operation, the control transistor does not dissipate as much power as that in the linear types. Therefore, switching voltage regulators have a much higher efficiency and can provide greater load currents at low voltage than linear regulators.

Unlike their linear counterparts, switching regulators can be implemented by many different topologies such as forward and flyback. In order to select an appropriate topology for an application, it is necessary to understand the merits and drawbacks of each topology and the requirements of the application. Basically, most topologies can work for various applications. Therefore, we have to determine from the factors such as cost, performances, and application that make one topology more desirable than the others. However, no matter which topology we decide to use, the basic building blocks of an off-the-line switching power supply are the same, as depicted in Fig. 20.1.

In this section, some popular switching regulator topologies, namely, flyback, forward, half-bridge, and full-bridge topologies, are presented. Their basic operation is described, and the critical waveforms are shown and explained. The merits, drawbacks, and application areas of each topology are discussed. Finally, the control circuitry and PWM of the regulators will also be discussed.

20.5.1 Single-Ended Isolated Flyback Regulators

An isolated flyback regulator consists of four main circuit elements: a power switch, a rectifier diode, a transformer, and a filter capacitor. The power switch, which can be either a power transistor or a MOSFET, is used to control the flow of energy in the circuit. A transformer is placed between the input source and the power switch to provide dc isolation between the input and the output circuits. In addition to being an energy storage element, the transformer also performs a stepping up or down function for the regulator. The rectifier diode and filter

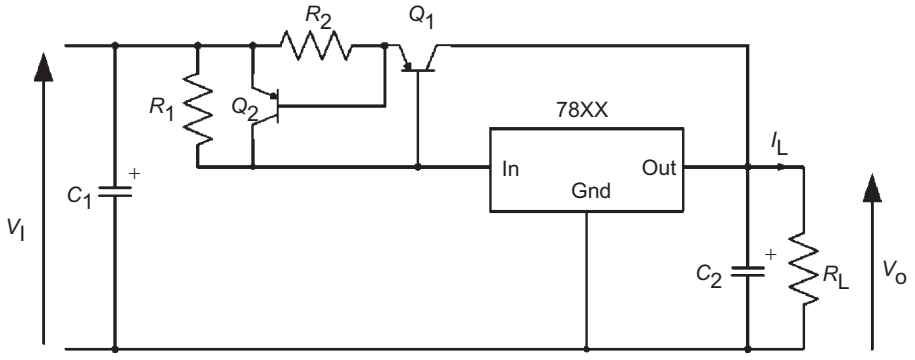

FIG. 20.19 A 78XX series regulator with an external pass transistor.

capacitor form an energy transfer mechanism to supply energy to maintain the output voltage of the supply. Note that there are two distinct operating modes for flyback regulators: *continuous* and *discontinuous*. However, both modes have an identical circuit. It is only the transformer magnetizing current that determines the operating mode of the regulator. Fig. 20.20A shows a simplified isolated flyback regulator. The associated steady-state waveforms, resulting from a discontinuous-mode operation, are shown in Fig. 20.20B. As shown in the figure, the voltage regulation of the regulator is achieved by a control circuit, which controls the conduction period or duty cycle of the switch, to keep the output voltage at a constant level. For clarity, the schematics and operation of the control circuit will be discussed in a separate section.

20.5.1.1 Discontinuous-Mode Flyback Regulators

Under steady-state conditions, the operation of the regulator can be explained as follows. When the power switch Q_1 is on, the primary current I_p starts to build up and stores energy in the primary winding. Because of the opposite polarity arrangement between the input and output windings of the transformer, the rectifier diode D_R is reverse-biased. In this period of time, there is no energy transferred from the input to the load R_L. The output voltage is supported by the load current I_L, which is supplied from the output filter capacitor C_F. When Q_1 is turned off, the polarity of the windings reverses as a result of the fact that I_p cannot change instantaneously. This causes D_R to turn on. Now, D_R is conducting, charging the output capacitor C_F, and delivering current to R_L. This charging action ends at the point where all the magnetic energy stored in the secondary winding during the first half cycle is emptied. At this point, D_R will cease to conduct and R_L absorbs energy just from C_F until Q_1 is switched on again.

During the Q_1 on-time, the voltage across the primary winding of the transformer is V_i. The current in the primary winding I_p increases linearly and is given by

$$I_p = \frac{V_i t_{on}}{L_p} \tag{20.15}$$

where L_p is the primary magnetizing inductance. At the end of the on-time, the primary current reaches a value equal to $I_{p(pk)}$ and is given by

$$I_{p(pk)} = \frac{V_i D T}{L_p} \tag{20.16}$$

where D is the duty cycle and T is the switching period. Now, when Q_1 turns off, the magnetizing current in the transformer forces the reversal of polarities on the windings. At the instant of turnoff, the amplitude of the secondary current $I_{s(pk)}$ is

$$I_{s(pk)} = \left(\frac{N_p}{N_s}\right) I_{p(pk)} \tag{20.17}$$

This current decreases linearly at the rate of

$$\frac{dI_s}{dt} = \frac{V_o}{L_s} \tag{20.18}$$

where L_s is the secondary magnetizing inductance.

In the discontinuous-mode operation, $I_{s(pk)}$ will decrease linearly to zero before the start of the next cycle. Since the energy transfer from the source to the output takes place only in the first half cycle, the power drawn from V_i is then

$$P_{in} = \frac{L_p I_p^2}{2T} \tag{20.19}$$

Substituting Eq. (20.15) into Eq. (20.19), we have

$$P_{in} = \frac{(V_i t_{on})^2}{2TL_p} \tag{20.20}$$

The output power P_o may be written as

$$\begin{aligned} P_o &= \eta P_{in} \\ &= \frac{\eta (V_i t_{on})^2}{2TL_p} = \frac{V_o^2}{R_L} \end{aligned} \tag{20.21}$$

where η is the efficiency of the regulator. Then, from Eq. (20.21), the output voltage V_o is related to the input voltage V_i by

$$V_o = V_i D \sqrt{\frac{\eta R_L T}{2L_p}} \tag{20.22}$$

Since the collector voltage V_{Q1} of Q_1 is maximum when V_i is maximum, the maximum collector voltage $V_{Q1(max)}$, as shown in Fig. 20.20B, is given by

$$V_{Q1(max)} = V_{i(max)} + \left(\frac{N_p}{N_s}\right) V_o \tag{20.23}$$

The primary peak current $I_{p(pk)}$ can be found in terms of P_o by combining Eq. (20.16) and Eq. (20.21) and then eliminating L_p as

$$\begin{aligned} I_{p(pk)} &= \frac{2V_o^2}{\eta V_i D R_L} \\ &= \frac{2P_o}{\eta V_i D} \end{aligned} \tag{20.24}$$

The maximum collector current $I_{C(max)}$ of the power switch Q_1 at turn on is

$$\begin{aligned} I_{C(max)} &= I_{p(pk)} \\ &= \frac{2P_o}{\eta V_i D} \end{aligned} \tag{20.25}$$

As can be seen from Eq. (20.21), V_o will be maintained constant by keeping the product $V_i t_{on}$ constant. Since maximum

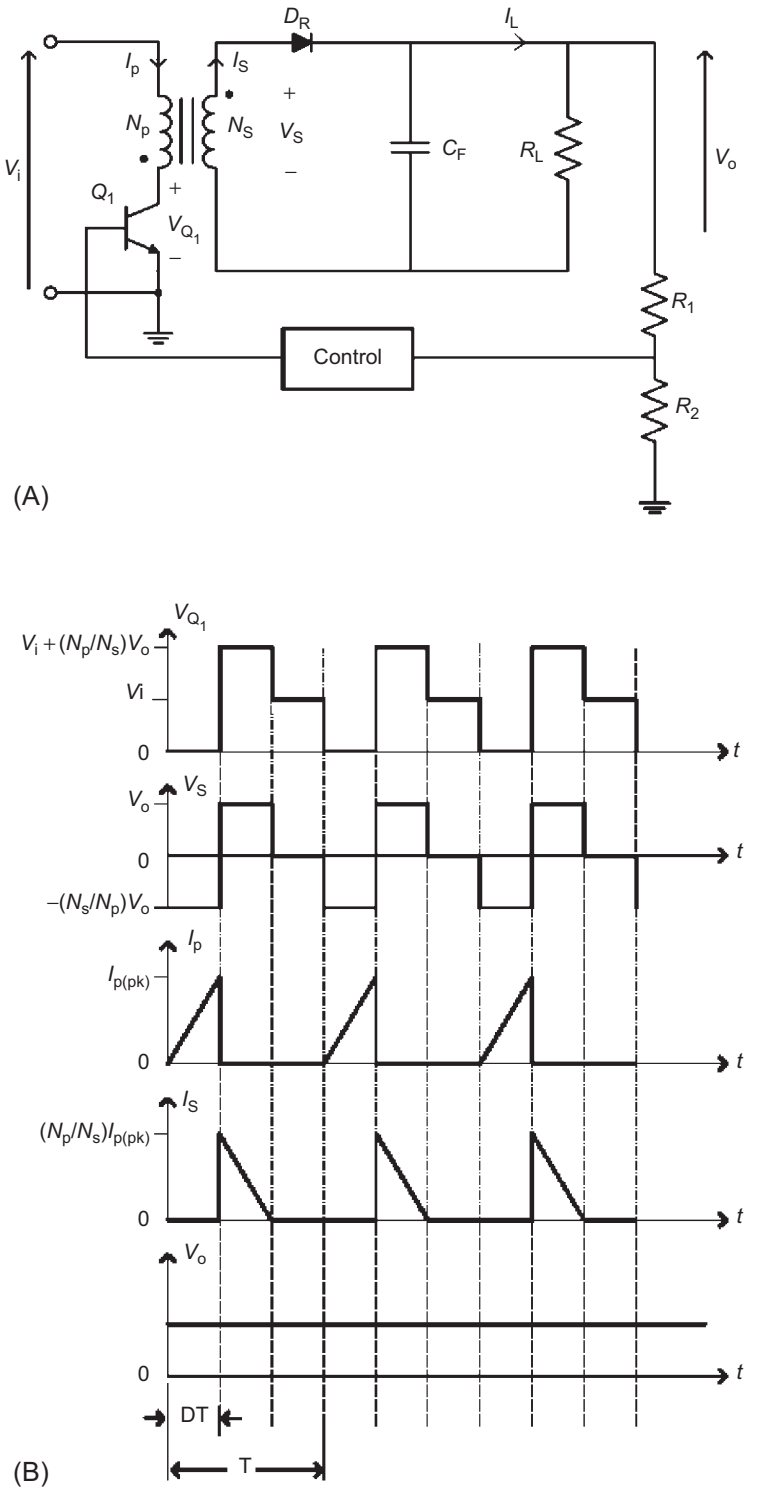

FIG. 20.20 A simplified isolated flyback regulator: (A) circuit and (B) the associated waveforms.

on-time $t_{on(max)}$ occurs at minimum supply voltage $V_{i(min)}$, the maximum allowable duty cycle for the discontinuous mode can be found from Eq. (20.22) as

$$D_{max} = \frac{V_o}{V_{i(min)}}\sqrt{\frac{2L_p}{\eta R_L T}} \tag{20.26}$$

and V_o at D_{max} is then

$$V_o = V_{i(min)} D_{max}\sqrt{\frac{\eta R_L T}{2L_p}} \tag{20.27}$$

20.5.1.2 Continuous-Mode Flyback Regulators

In the continuous-mode operation, the power switch is turned on before all the magnetic energy stored in the secondary winding empties itself. The primary and secondary current waveforms have a characteristic appearance as shown in Fig. 20.21. This mode produces a higher-power capability without increasing the peak currents. During the on-time, the primary current I_p rises linearly from its initial value $I_p(0)$ and is given by

$$I_p = I_p(0) + \frac{V_i t_{on}}{L_p} \tag{20.28}$$

At the end of the on-time, the primary current reaches a value equal to $I_{p(pk)}$ and is given by

$$I_{p(pk)} = I_p(0) + \frac{V_i DT}{L_p} \tag{20.29}$$

In general, $I_p(0) \gg V_i DT/L_p$; thus, Eq. (20.29) can be written as

$$I_{p(pk)} \approx I_p(0) \tag{20.30}$$

The secondary current I_s at the instant of turn off is given by

$$\begin{aligned} I_{s(pk)} &= \left(\frac{N_p}{N_s}\right) I_{p(pk)} \\ &= \left(\frac{N_p}{N_s}\right)\left(I_p(0) + \frac{V_i DT}{L_p}\right) \\ &\approx \left(\frac{N_p}{N_s}\right) I_p(0) \end{aligned} \tag{20.31}$$

This current decreases linearly at the rate of

$$\frac{dI_s}{dt} = \frac{V_o}{L_s} \tag{20.32}$$

The output power P_o is equal to V_o times the time average of the secondary current pulses and is given by

$$\begin{aligned} P_o &= V_o I_s \frac{T - t_{on}}{T} \\ &\approx V_o I_{s(pk)} \frac{T - t_{on}}{T} \end{aligned} \tag{20.33}$$

or

$$I_{s(pk)} = \frac{P_o}{V_o(1 - t_{on}/T)} \tag{20.34}$$

For an efficiency of η, the input power P_{in} is

$$\begin{aligned} P_{in} &= \frac{P_o}{\eta} \\ &= V_i I_p \frac{t_{on}}{T} \\ &\approx V_i I_{p(pk)} \frac{t_{on}}{T} \end{aligned} \tag{20.35}$$

or

$$I_{p(pk)} = \frac{P_o}{\eta V_i (t_{on}/T)} \tag{20.36}$$

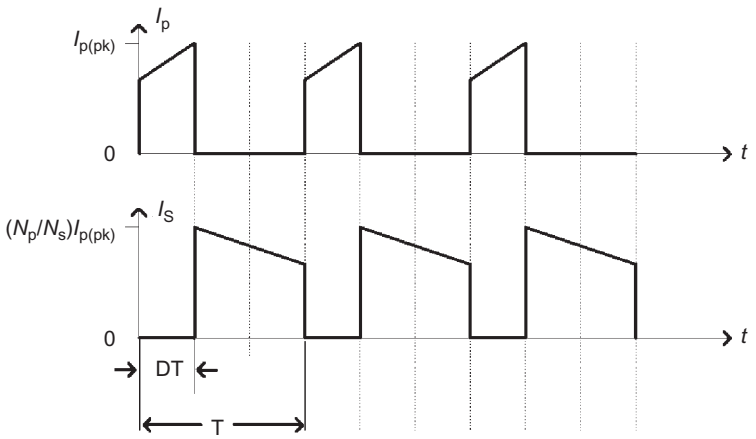

FIG. 20.21 The primary and secondary winding currents of a flyback regulator operated in the continuous mode.

Combining Eqs. (20.31), (20.34), and (20.36) and solving for V_o, we have

$$V_o = \left(\frac{N_s}{N_p}\right)\frac{\eta V_i D}{1-D} \tag{20.37}$$

The output voltage at D_{max} is then

$$V_o = \left(\frac{N_s}{N_p}\right)\frac{\eta V_{i(min)} D_{max}}{1-D_{max}} \tag{20.38}$$

The maximum collector current $I_{C(max)}$ for the continuous mode is then given by

$$\begin{aligned} I_{C(max)} &= I_{p(pk)} \\ &= \frac{P_o}{\eta V_i D_{max}} \end{aligned} \tag{20.39}$$

The maximum collector voltage of Q_1 is the same as that in the discontinuous mode and is given by

$$V_{Q1(max)} = V_{i(max)} + \left(\frac{N_p}{N_s}\right)V_o \tag{20.40}$$

The maximum allowable duty cycle for the continuous mode can be found from Eq. (20.38) and is given by

$$D_{max} = \frac{1}{1+\left(\frac{N_s}{N_p}\right)\frac{\eta V_{i(min)}}{V_o}} \tag{20.41}$$

At the transition from the discontinuous mode to continuous mode (or from continuous mode to discontinuous mode), the relationships in Eqs. (20.27) and (20.38) must hold. Thus, equating these two equations, we have

$$V_{i(min)} D_{max}\sqrt{\frac{\eta R_L T}{2L_p}} = \frac{N_s}{N_p}\frac{D_{max}}{1-D_{max}}\eta V_{i(min)} \tag{20.42}$$

Solving this equation for L_p to give the critical inductance $L_{p(limit)}$, at which the transition occurs, we have

$$\begin{aligned} L_{p(limit)} &= \frac{1}{2\eta}TR_L\left[(1-D_{max})\frac{N_p}{N_s}\right]^2 \\ &= \frac{1}{2\eta}T\frac{V_o^2}{P_o}\left[(1-D_{max})\frac{N_p}{N_s}\right]^2 \end{aligned} \tag{20.43}$$

Replacing V_o with Eq. (20.38) and solving for $L_{p(limit)}$, we have

$$L_{p(limit)} = \frac{1}{2}\eta T\frac{D_{max}^2 V_{i(min)}^2}{P_o} \tag{20.44}$$

Then, for a given D_{max}, input, and output quantities, the inductance value $L_{p(limit)}$ in Eq. (20.44) determines the mode of operation for the regulator. If $L_p < L_{p(limit)}$, then the circuit is operated in the discontinuous mode. Otherwise, if $L_P > L_{p(limit)}$, the circuit is operated in the continuous mode.

In designing flyback regulators, regardless of their operating modes, the power switch must be able to handle the peak collector voltage at turnoff and the peak collector currents at turnon as shown in Eqs. (20.23), (20.25), (20.39), and (20.40). The flyback transformer, because of its unidirectional use of the *B-H* curve, has to be designed so that it will not be driven into saturation. To avoid saturation, the transformer needs a relatively large core with an air gap in it.

Although the continuous and discontinuous modes have an identical circuit, their operating properties differ significantly. As opposed to the discontinuous mode, the continuous mode can provide higher-power capability without increasing the peak current $I_{p(pk)}$. It means that, for the same output power, the peak currents in the discontinuous mode are much higher than those operated in the continuous mode. As a result, a higher current rating and, therefore, a more expensive power transistor are needed. Moreover, the higher secondary peak currents in the discontinuous mode will have a larger transient spike at the instant of turnoff. However, despite all these problems, the discontinuous mode is still much more widely used than its continuous-mode counterpart. There are two main reasons. First, the inherently smaller magnetizing inductance gives the discontinuous mode a quicker response and a lower transient output voltage spike to sudden changes in load current or input voltage. Second, the continuous mode has a right-half-plane zero in its transfer function, which makes the feedback control circuit more difficult to design.

The flyback configuration is mostly used in applications with output power below 100 W. It is widely used for high output voltages at relatively low power. The essential attractions of this configuration are its simplicity and low cost. Since no output filter inductor is required for the secondary, there is a significant saving in cost and space, especially for multiple output power supplies. Since there is no output filter inductor, the flyback exhibits high ripple currents in the transformer and at the output. Thus, for higher-power applications, the flyback becomes an unsuitable choice. In practice, a small *LC* filter is added after the filter capacitor C_F in order to suppress high-frequency switching noise spikes.

As mentioned previously, the collector voltage of the power transistor must be able to sustain a voltage as defined in Eq. (20.23). In cases where the voltage is too high for the transistor to handle, the double-ended flyback regulator shown in Fig. 20.22 may be used. The regulator uses two transistors that are switched on or off simultaneously. The diodes D_{R1} and D_{R2} are used to restrict the maximum collector voltage to V_i. Therefore, the transistors with a lower voltage rating can be used in the circuit.

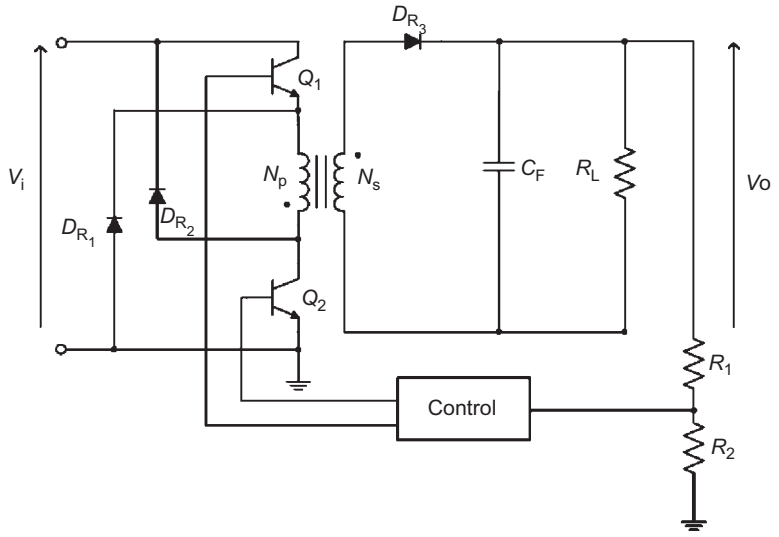

FIG. 20.22 A double-ended flyback regulator.

20.5.2 Single-Ended Isolated Forward Regulators

Although the general appearance of an isolated forward regulator resembles that of its flyback counterpart, their operations are different. The key difference is that the dot on the secondary winding of the transformer is so arranged that the output diode is forward-biased when the voltage across the primary is positive, that is, when the transistor is *on*. Energy is thus not stored in the primary inductance as it was for the flyback. The transformer acts strictly as a transformer. An inductive energy storage element is required at the output for proper and efficient energy transfer.

Unlike the flyback, the forward regulator is very suitable for working in the continuous mode. In the discontinuous mode, the forward regulator is more difficult to control because of a double pole at the output filter. Thus, it is not as much used as the continuous mode. In view of it, only the continuous mode will be discussed here.

Fig. 20.23 shows a simplified isolated forward regulator and the associated steady-state waveforms for the continuous-mode operation. Again, for clarity, the details of the control circuit are omitted from the figure. Under steady-state condition, the operation of the regulator can be explained as follows. When the power switch Q_1 turns on, the primary current I_p starts to build up and stores energy in the primary winding. Because of the same polarity arrangement of the primary and secondary windings, this energy is forward transferred to the secondary and onto the L_1C_F filter and the load R_L through the rectifier diode D_{R2}, which is forward-biased. When Q_1 turns off, the polarity of the transformer winding voltage reverses. This causes D_{R2} to turn off and D_{R1} and D_{R3} to turn on. Now, D_{R3} is conducting and delivering energy to R_L through the inductor L_1. During this period, the diode D_{R2} and the tertiary winding provide a path for the magnetizing current returning to the input.

When the transistor Q_1 is turned on, the voltage across the primary winding is V_i. The secondary winding current is reflected into the primary, and the reaction current I_p, as shown in Fig. 20.24, is given by

$$I_p = \frac{N_s}{N_p} I_s \tag{20.45}$$

The magnetizing current in the primary has a magnitude of I_{mag} and is given by

$$I_{mag} = \frac{V_i t_{on}}{L_p} \tag{20.46}$$

The total primary current I_p' is then

$$\begin{aligned} I_p' &= I_p + I_{mag} \\ &= \frac{N_s}{N_p} I_s + \frac{V_i t_{on}}{L_p} \end{aligned} \tag{20.47}$$

The voltage developed across the secondary winding V_s is

$$V_s = \frac{N_s}{N_p} V_i \tag{20.48}$$

Neglecting diode voltage drops and losses, the voltage across the output inductor is $V_s - V_o$. The current in L_1 increases linearly at the rate of

$$I_{L1} = \frac{(V_s - V_o) t_{on}}{L_1} \tag{20.49}$$

At the end of the on-time, the total primary current reaches a peak value equal to $I'_{p(pk)}$ and is given by

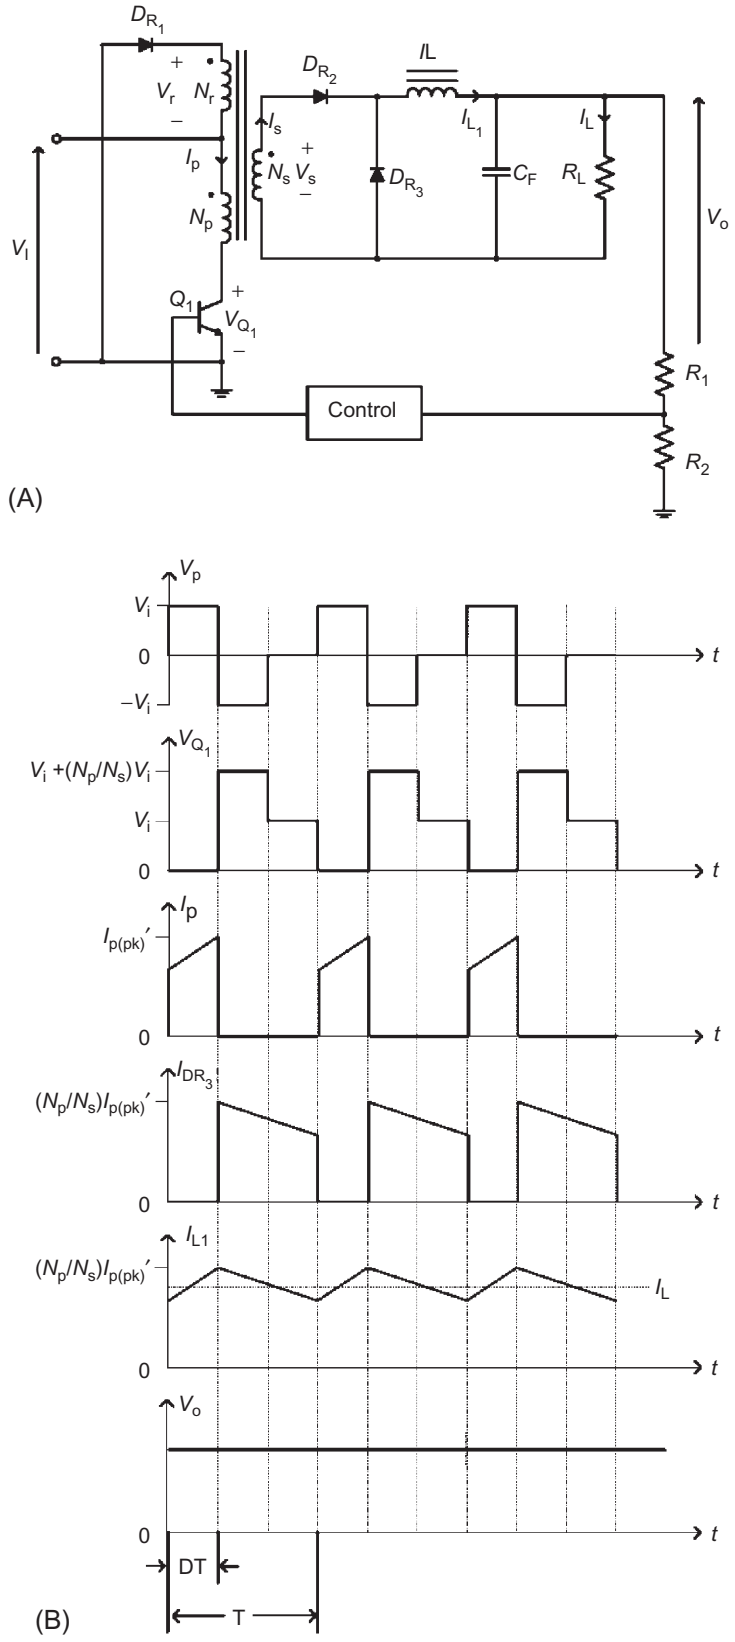

FIG. 20.23 A simplified isolated forward regulator: (A) circuit and (B) the associated waveforms.

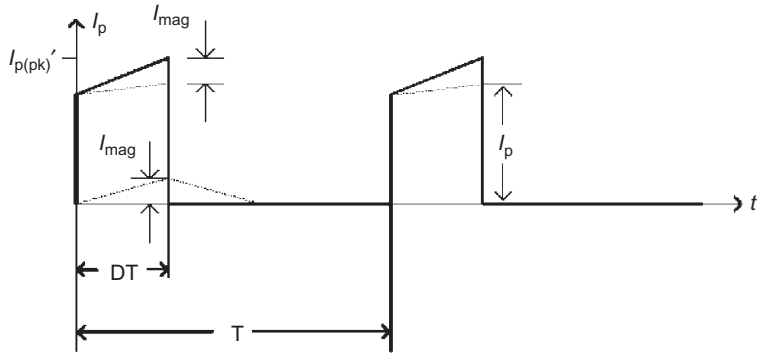

FIG. 20.24 The current components in the primary winding.

$$I'_{p(pk)} = I'_p(0) + \frac{V_i DT}{L_p} \tag{20.50}$$

The output inductor current I_{L1} is

$$I_{L1(pk)} = I_{L1}(0) + \frac{(V_s - V_o)DT}{L_1} \tag{20.51}$$

At the instant of turn-on, the amplitude of the secondary current has a value of $I_{s(pk)}$ and is given by

$$\begin{aligned} I_{s(pk)} &= \left(\frac{N_p}{N_s}\right) I'_{p(pk)} \\ &= \left(\frac{N_p}{N_s}\right)\left[I'_p(0) + \frac{V_i DT}{L_p}\right] \end{aligned} \tag{20.52}$$

During the off-time, the current I_{L1} in the output inductor is equal to the current I_{DR3} in the rectifier diode D_{R3}, and both decrease linearly at the rate of

$$\begin{aligned} \frac{dI_{L1}}{dt} &= \frac{dI_{DR3}}{dt} \\ &= \frac{V_o}{L_1} \end{aligned} \tag{20.53}$$

The output voltage V_o can be found from the time integral of the secondary winding voltage over a time equal to DT of the switch Q_1. Thus, we have

$$\begin{aligned} V_o &= \frac{1}{T}\int_0^{DT} \frac{N_s}{N_p} V_i dt \\ &= \frac{N_s}{N_p} V_i D \end{aligned} \tag{20.54}$$

The maximum collector current $I_{C(max)}$ at turn-on is equal to $I'_{p(pk)}$ and is given by

$$\begin{aligned} I_{C(max)} &= I'_{p(pk)} \\ &= \left(\frac{N_s}{N_p}\right)\left[I'_p(0) + \frac{V_i DT}{L_p}\right] \end{aligned} \tag{20.55}$$

The maximum collector voltage $V_{Q_1(max)}$ at turnoff is equal to the maximum input voltage $V_{i(max)}$ plus the maximum voltage $V_{r(max)}$ across the tertiary winding and is given by

$$\begin{aligned} V_{Q_1(max)} &= V_{i(max)} + V_{r(max)} \\ &= V_{i(max)}\left(1 + \frac{N_p}{N_r}\right) \end{aligned} \tag{20.56}$$

The maximum duty cycle for the forward regulator operated in the continuous mode can be determined by equating the time integral of the input voltage when Q_1 is on and the clamping voltage V_r when Q_1 is off.

$$\int_0^{DT} V_i dt = \int_{DT}^{T} V_r dt \tag{20.57}$$

that leads to

$$V_i DT = V_r(1 - D)T \tag{20.58}$$

Grouping the D terms in Eq. (20.58) and replacing V_r/V_i with N_r/N_p, we have

$$D_{max} = \frac{1}{1 + N_r/N_p} \tag{20.59}$$

Thus, the maximum duty cycle depends on the turn ratio between the demagnetizing winding and the primary one.

In designing forward regulators, the duty cycle must be kept below the maximum duty cycle D_{max} to avoid saturating the transformer. It should also be noted that the transformer magnetizing current must be reset to zero at the end of each cycle. Failure to do so will drive the transformer into saturation, which can cause damage to the transistor. There are many ways of implementing the resetting function. In the circuit shown in Fig. 20.23A, a tertiary winding is added to the transformer so that the magnetizing current will return to the input source V_i when the transistor turns off. The primary current always starts at the same value under the steady-state condition.

Unlike flyback regulators, forward regulators require a minimum load at the output. Otherwise, excess output voltage will be produced. One commonly used method to avoid this situation is to attach a small load resistance at the output terminals. Of course, with such an arrangement, a certain amount of power will be lost in the resistor.

Because forward regulators do not store energy in their transformers, for the same output power level, the transformer can be made smaller than for the flyback type. The output current is reasonably constant owing to the action of the output inductor and the flywheel diode; as a result, the output filter capacitor can be made smaller, and its ripple current rating can be much lower than that required for the flybacks.

The forward regulator is widely used with output power below 200 W, though it can be easily constructed with a much higher output power. The limitation comes from the capability of the power transistor to handle the voltage and current stresses if the output power were to increase. In this case, a configuration with more than one transistor can be used to share the burden. Fig. 20.25 shows a double-ended forward regulator. Like the double-ended flyback counterpart, the circuit uses two transistors that are switched on and off simultaneously. The diodes are used to restrict the maximum collector voltage to V_i. Therefore, the transistors with low voltage rating can be used in the circuit.

20.5.3 Half-Bridge Regulators

The half-bridge regulator is another form of an isolated forward regulator. When the voltage on the power transistor in the single-ended forward regulator becomes too high, the half-bridge regulator is used to reduce the stress on the transistor. In a half-bridge regulator, the voltage stress imposed on the power transistors is subject to only the input voltage and is only half of that in a forward regulator. Thus, the output power of a half bridge is double to that of a forward regulator for the same semiconductor devices and magnetic core.

Fig. 20.26 shows the basic configuration of a half-bridge regulator and the associated steady-state waveforms. As seen in Fig. 20.26A, the half-bridge regulator can be viewed as two back-to-back forward regulators, fed by the same input voltage, each delivering power to the load at each alternate half cycle. The capacitors C_1 and C_2 are placed between the input and ground terminals. As such, the voltage across the primary winding is always half the input voltage. The power switches Q_1 and Q_2 are switched on and off alternatively to produce a square-wave ac at the input of the transformer. This square wave is either stepped down or up by the isolation transformer and then rectified by the diodes D_{R1} and D_{R2}. Subsequently, the rectified voltage is filtered to produce the output voltage V_o.

Under steady-state condition, the operation of the regulator can be explained as follows. When Q_1 is on and Q_2 off, D_{R1} conducts and D_{R2} is reverse-biased. The primary voltage V_p is $V_i/2$. The primary current I_p starts to build up and stores energy in the primary winding. This energy is forward transferred to the secondary and onto the L_1C filter and the load R_L, through the rectifier diode D_{R1}. During the time interval Δ, when both Q_1 and Q_2 are off, D_{R1} and D_{R2} are forced to conduct to carry the magnetizing current that resulted in the interval during which Q_1 is turned on. The inductor current I_{L1} in this interval is equal to the sum of the currents in D_{R1} and D_{R2}. This interval terminates at half of the switching period T, when Q_2 is turned on. When Q_2 is on and Q_1 off, D_{R1} is reverse-biased and D_{R2} conducts. The primary voltage V_p is now $-V_i/2$. The circuit operates in a likewise manner as during the first half cycle.

With Q_1 on, the voltage across the secondary winding is

$$V_{s1} = \frac{N_{s1}}{N_p}\left(\frac{V_i}{2}\right) \tag{20.60}$$

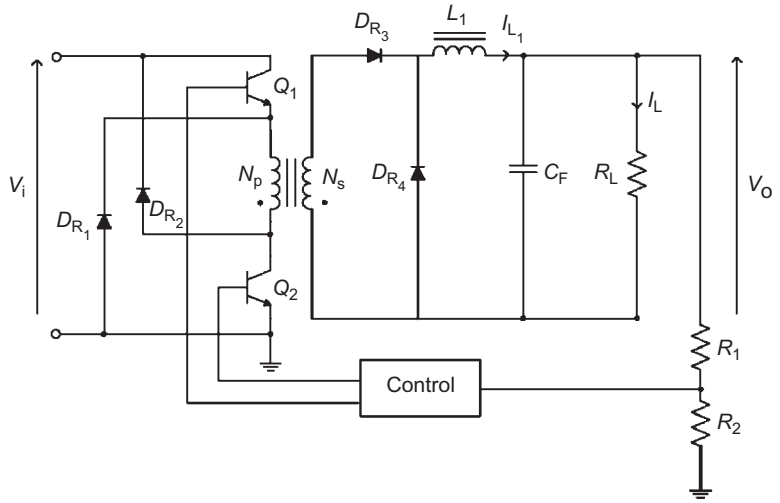

FIG. 20.25 Double-ended forward regulator.

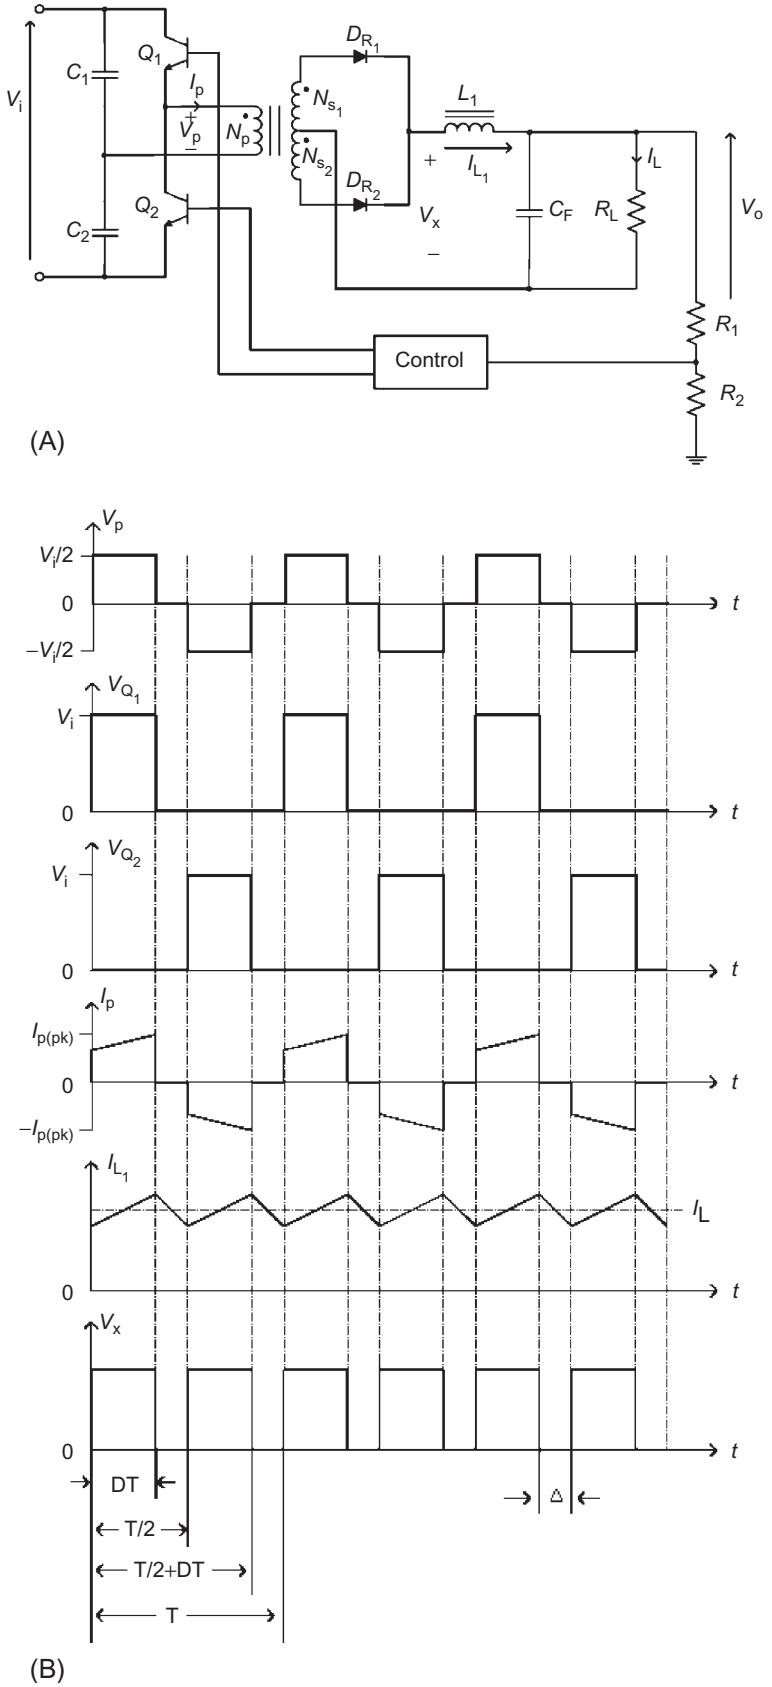

FIG. 20.26 A simplified half-bridge regulator: (A) circuit and (B) the associated waveforms.

Neglecting diode voltage drops and losses, the voltage across the output inductor is then given by

$$V_{L1} = \frac{N_{s1}}{N_p}\left(\frac{V_i}{2}\right) - V_o \tag{20.61}$$

In this interval, the inductor current I_{L1} increases linearly at the rate of

$$\begin{aligned}\frac{dI_{L1}}{dt} &= \frac{V_{L1}}{L_1} \\ &= \frac{1}{L_1}\left[\frac{N_{s1}}{N_p}\left(\frac{V_i}{2}\right) - V_o\right]\end{aligned} \tag{20.62}$$

At the end of Q_1 on-time, I_{L1} reaches a value that is given by

$$I_{L1(pk)} = I_{L1}(0) + \frac{1}{L_1}\left[\frac{N_{s1}}{N_p}\left(\frac{V_i}{2}\right) - V_o\right]DT \tag{20.63}$$

During the interval Δ, I_{L1} is equal to the sum of the rectifier diode currents. Assuming the two secondary windings are identical, I_{L1} is given by

$$I_{L1} = 2I_{DR1} = 2I_{DR2} \tag{20.64}$$

This current decreases linearly at the rate of

$$\frac{dI_{L1}}{dt} = \frac{V_o}{L_1} \tag{20.65}$$

The next half cycle repeats with Q_2 on and for the interval Δ.

The output voltage can be found from the time integral of the inductor voltage over a time equal to T. Thus, we have

$$V_o = 2 \times \frac{1}{T}\left[\int_0^{DT}\left(\frac{N_{s1}}{N_p}\left(\frac{V_i}{2}\right) - V_o\right)dt + \int_{T/2}^{T/2+DT} - V_o dt\right] \tag{20.66}$$

Note that the multiplier of 2 appears in Eq. (20.66) because of the two alternate half cycles. Solving Eq. (20.66) for V_o, we have

$$V_o = \frac{N_{s1}}{N_p}V_i D \tag{20.67}$$

The output power P_o is given by

$$\begin{aligned}P_o &= V_o I_L \\ &= \eta P_{in} \\ &= \eta\frac{V_i I_{p(avg)} D}{2}\end{aligned} \tag{20.68}$$

or

$$I_{p(avg)} = \frac{2P_o}{\eta V_i D} \tag{20.69}$$

where $I_{p(avg)}$ has the value of the primary current at the center of the rising or falling ramp. Assuming the reaction current I_p' reflected from the secondary is much greater than the magnetizing current, then the maximum collector currents for Q_1 and Q_2 are given by

$$\begin{aligned}I_{C(max)} &= I_{p(avg)} \\ &= \frac{2P_o}{\eta V_i D_{max}}\end{aligned} \tag{20.70}$$

As mentioned, the maximum collector voltages for Q_1 and Q_2 at turnoff are given by

$$V_{C(max)} = V_{i(max)} \tag{20.71}$$

In designing half-bridge regulators, the maximum duty cycle can never be greater than 50%. When both the transistors are switched on simultaneously, the input voltage is short-circuited to ground. The series capacitors C_1 and C_2 provide a dc bias to balance the volt-second integrals of the two switching intervals. Hence, any mismatch in devices would not easily saturate the core. However, if such a situation arises, a small coupling capacitor can be inserted in series with the primary winding. A dc bias voltage proportional to the volt-second imbalance is developed across the coupling capacitor. This balances the volt-second integrals of the two switching intervals.

One problem in using half-bridge regulators is related to the design of the drivers for the power switches. Specifically, the emitter of Q_1 is not at ground level, but is at a high ac level. The driver must therefore be referenced to this ac level. Typically, transformer-coupled drivers are used to drive both switches, thus solving the grounding problem and allowing the controller to be isolated from the drivers.

The half-bridge regulator is widely used for medium-power applications. Because of its core-balancing feature, the half bridge becomes the predominant choice for output power ranging from 200 to 400 W. Since the half bridge is more complex, for application below 200 W, the flyback or forward regulator is considered to be a better choice and more cost-effective. Above 400 W, the primary and switch currents of the half bridge become very high. Thus, it becomes unsuitable.

20.5.4 Full-Bridge Regulators

The full-bridge regulator is yet another form of isolated forward regulator. Its performance is improved over that of the half-bridge regulator because of the reduced peak collector current. The two series capacitors that appeared in half-bridge circuits are now replaced by another pair of transistors of the same type. In each switching interval, two of the switches are turned on and off simultaneously such that the full input voltage appears at the primary winding. The primary and the switch currents are only half that of the half bridge for the same power level. Thus, the maximum output power of this topology is twice that of the half bridge.

Fig. 20.27 shows the basic configuration of a full-bridge regulator and the associated steady-state waveforms. Four power switches are required in the circuit. The power switches Q_1 and Q_4 turn on and off simultaneously in one of the half cycles. Q_2 and Q_3 also turn on and off simultaneously in the other half cycle but with opposite phase as Q_1 and Q_4. This produces a square-wave ac with a value of $\pm V_i$ at the primary winding of the transformer. Like the half bridge, this voltage is stepped down, rectified, and then filtered to produce a dc output voltage. The capacitor C_1 is used to balance the volt-second integrals of the two switching intervals and prevent the transformer from being driven into saturation.

Under steady-state conditions, the operation of the full bridge is similar to that of the half bridge. When Q_1 and Q_4 turn on, the voltage across the secondary winding is

$$V_{s1} = \frac{N_{s1}}{N_p} V_i \tag{20.72}$$

Neglecting diode voltage drops and losses, the voltage across the output inductor is then given by

$$V_{L1} = \frac{N_{s1}}{N_p} V_i - V_o \tag{20.73}$$

In this interval, the inductor current I_{L1} increases linearly at the rate of

$$\begin{aligned} \frac{dI_{L1}}{dt} &= \frac{V_{L1}}{L_1} \\ &= \frac{1}{L_1}\left[\frac{N_{s1}}{N_p} V_i - V_o\right] \end{aligned} \tag{20.74}$$

At the end of Q_1 and Q_4 on-time, I_{L1} reaches a value that is given by

$$I_{L1(pk)} = I_{L1}(0) + \frac{1}{L_1}\left[\frac{N_{s1}}{N_p} V_i - V_o\right] DT \tag{20.75}$$

During the interval Δ, I_{L1} decreases linearly at the rate of

$$\frac{dI_{L1}}{dt} = \frac{V_o}{L_1} \tag{20.76}$$

The next half cycle repeats with Q_2 and Q_3 on, and the circuit operates in a similar manner as in the first half cycle.

Again, as in the half bridge, the output voltage can be found from the time integral of the inductor voltage over a time equal to T. Thus, we have

$$V_o = 2 \times \frac{1}{T}\left[\int_0^{DT}\left(\frac{N_{s1}}{N_p} V_i - V_o\right) dt + \int_{T/2}^{T/2+DT} -V_o dt\right] \tag{20.77}$$

Solving Eq. (20.77) for V_o, we have

$$V_o = \frac{N_{s1}}{N_p} 2 V_i D \tag{20.78}$$

The output power P_o is given by

$$\begin{aligned} P_o &= \eta P_{in} \\ &= \eta V_i I_{p(avg)} D \end{aligned} \tag{20.79}$$

or

$$I_{p(avg)} = \frac{P_o}{\eta V_i D} \tag{20.80}$$

where $I_{p(avg)}$ has the same definition as in the half-bridge case.

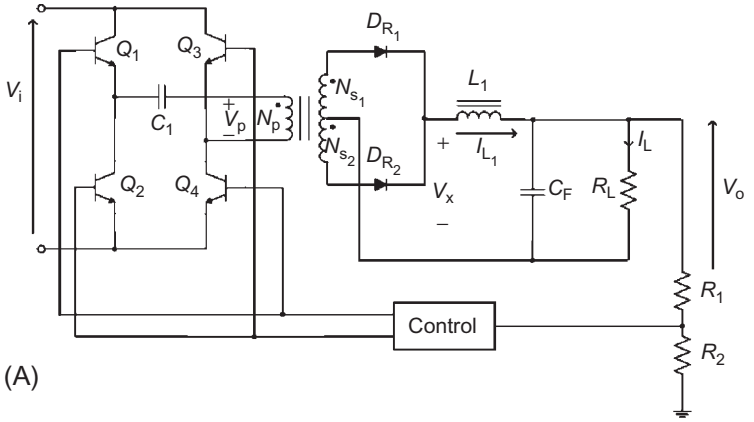
Comparing Eq. (20.80) with Eq. (20.69), we see that the output power of a full bridge is twice that of a half bridge with same input voltage and current. The maximum collector currents for Q_1, Q_2, Q_3, and Q_4 are given by

$$\begin{aligned} I_{C(max)} &= I_{p(avg)} \\ &= \frac{P_o}{\eta V_i D_{max}} \end{aligned} \tag{20.81}$$

Comparing Eq. (20.81) with Eq. (20.70), for the same output power, the maximum collector current is only half that of the half bridge.

As mentioned, the maximum collector voltage for Q_1 and Q_2 at turnoff is given by

$$V_{C(max)} = V_{i(max)} \tag{20.82}$$



The design of the full bridge is similar to that of the half bridge. The only difference is the use of four power switches instead of two in the full bridge. Therefore, additional drivers are required by adding two more secondary windings in the pulse transformer of the driving circuit.

For high-power applications ranging from several hundred to thousand kilowatts, the full-bridge regulator is an inevitable choice. It has the most efficient use of magnetic core and semiconductor switches. The full bridge is complex and therefore expensive to build and is only justified for high-power applications, typically over 500 W.

20.5.5 Control Circuits and Pulse-Width Modulation

In previous subsections, we presented several popular voltage regulators that may be used in a switching mode power supply. This section discusses the control circuits that regulate the output voltage of a switching regulator by constantly adjusting the conduction period t_{on} or duty cycle d of the power switch. Such adjustment is called *pulse-width modulation* (PWM).

The duty cycle is defined as the fraction of the period during which the switch is on, that is,

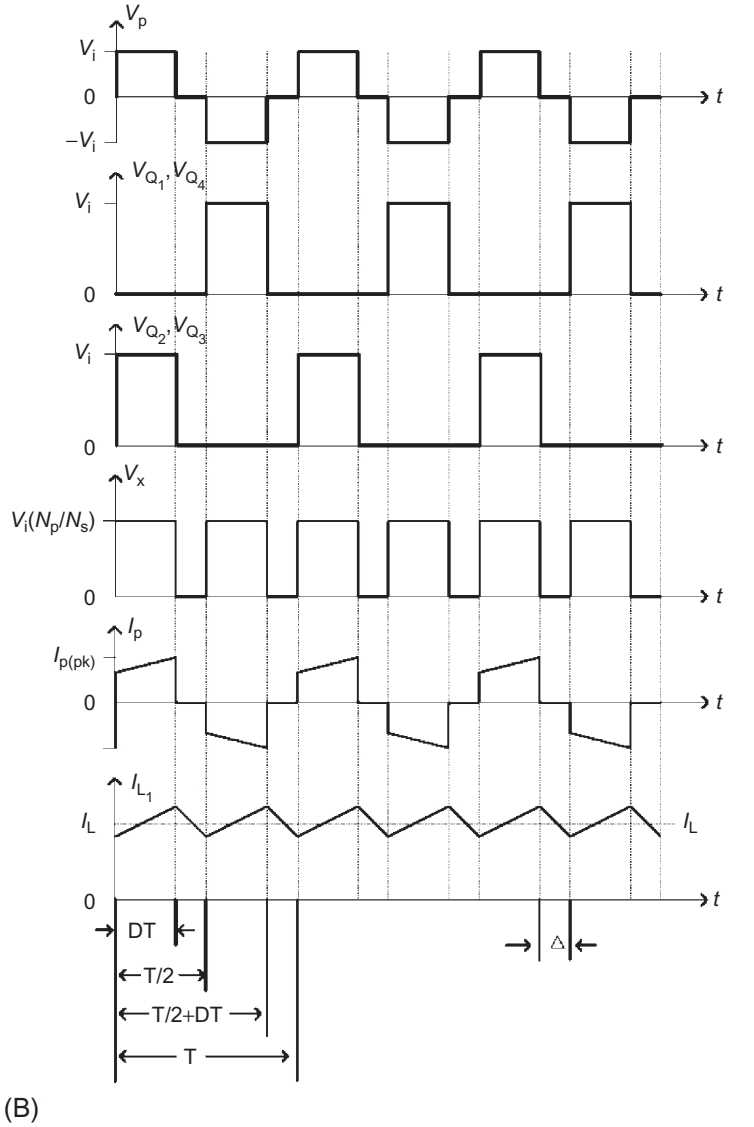


FIG. 20.27 A simplified full-bridge regulator: (A) circuit and (B) the associated waveforms.

$$d = \frac{t_{on}}{T} = \frac{t_{on}}{t_{on} + t_{off}} \tag{20.83}$$

where T is the switching period, that is, $t_{off} = T - t_{on}$. By adjusting either t_{on} or t_{off} or both, d can be modulated. Thus, PWM controlled regulators can operate at variable frequency and fixed frequency.

Among all types of PWM controllers, the fixed-frequency controller is by far the most popular choice. There are two main reasons for their popularity. First, low-cost fixed-frequency PWM IC controllers have been developed by various solid-state device manufacturers, and most of these IC controllers have all the features that are needed to build a PWM switching power supply using a minimum number of components. Second, because of their fixed-frequency nature, fixed-frequency controllers do not have the problem of unpredictable noise spectrum associated with variable frequency controllers. This makes EMI control much easier.

There are two types of fixed-frequency PWM controllers, namely, *the voltage-mode controller* and the *current-mode controller*. In its simplified form, a voltage-mode controller consists of four main functional components: an adjustable clock for setting the switching frequency, an output voltage error amplifier for detecting deviation of the output from the nominal value, a ramp generator for providing a sawtooth signal that is synchronized to the clock, and a comparator that compares the output error signal with the sawtooth signal. The output of the comparator is the signal that drives the controlled switch. Fig. 20.28 shows a simplified PWM voltage-mode controlled forward regulator operating at fixed frequency and its associated driving signal waveform. As shown, the duration of the on-time t_{on} is determined by the time between the reset of the ramp generator and the intersection of the error voltage with the positive-going ramp signal.

The error voltage v_e is given by

$$v_e = \left(1 + \frac{Z_2}{Z_1}\right) V_{REF} - \frac{Z_2}{Z_1} v_2 \tag{20.84}$$

From Eq. (20.84), the small-signal term can be separated from the dc operating point by

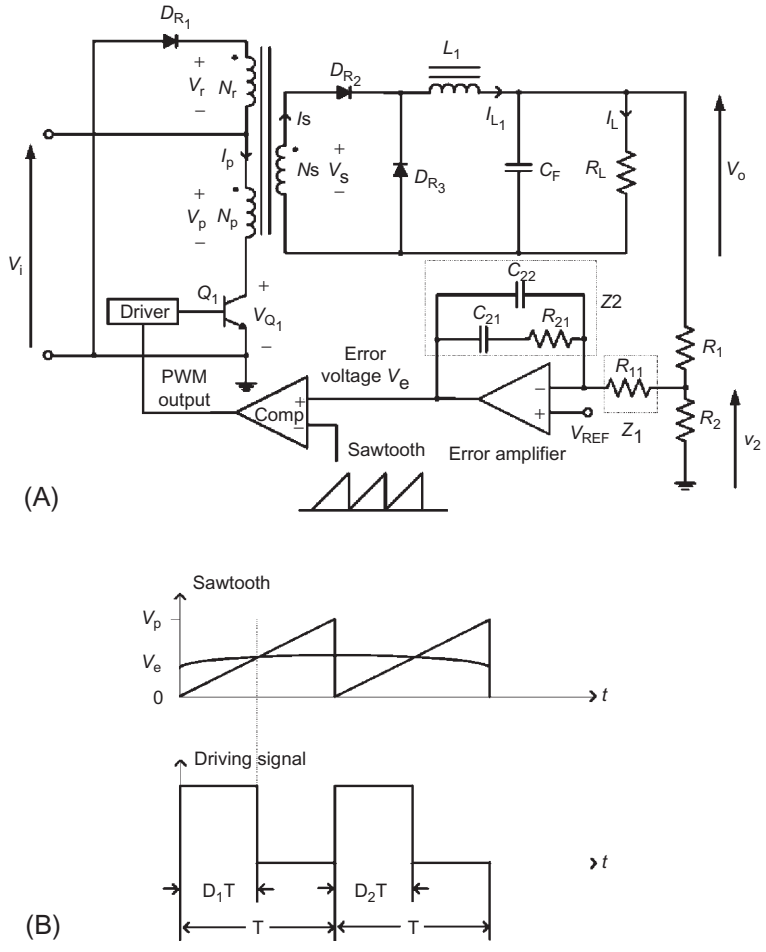

FIG. 20.28 A simplified voltage-mode controlled forward regulator: (A) circuit and (B) the associated driving signal waveform.

$$\Delta v_e = -\frac{Z_2}{Z_1}\Delta v_2 \tag{20.85}$$

$$V_e = \left(1 + \frac{Z_2}{Z_1}\right) V_{REF} - \frac{Z_2}{Z_1} V_2 \tag{20.86}$$

The dc operating point is given by

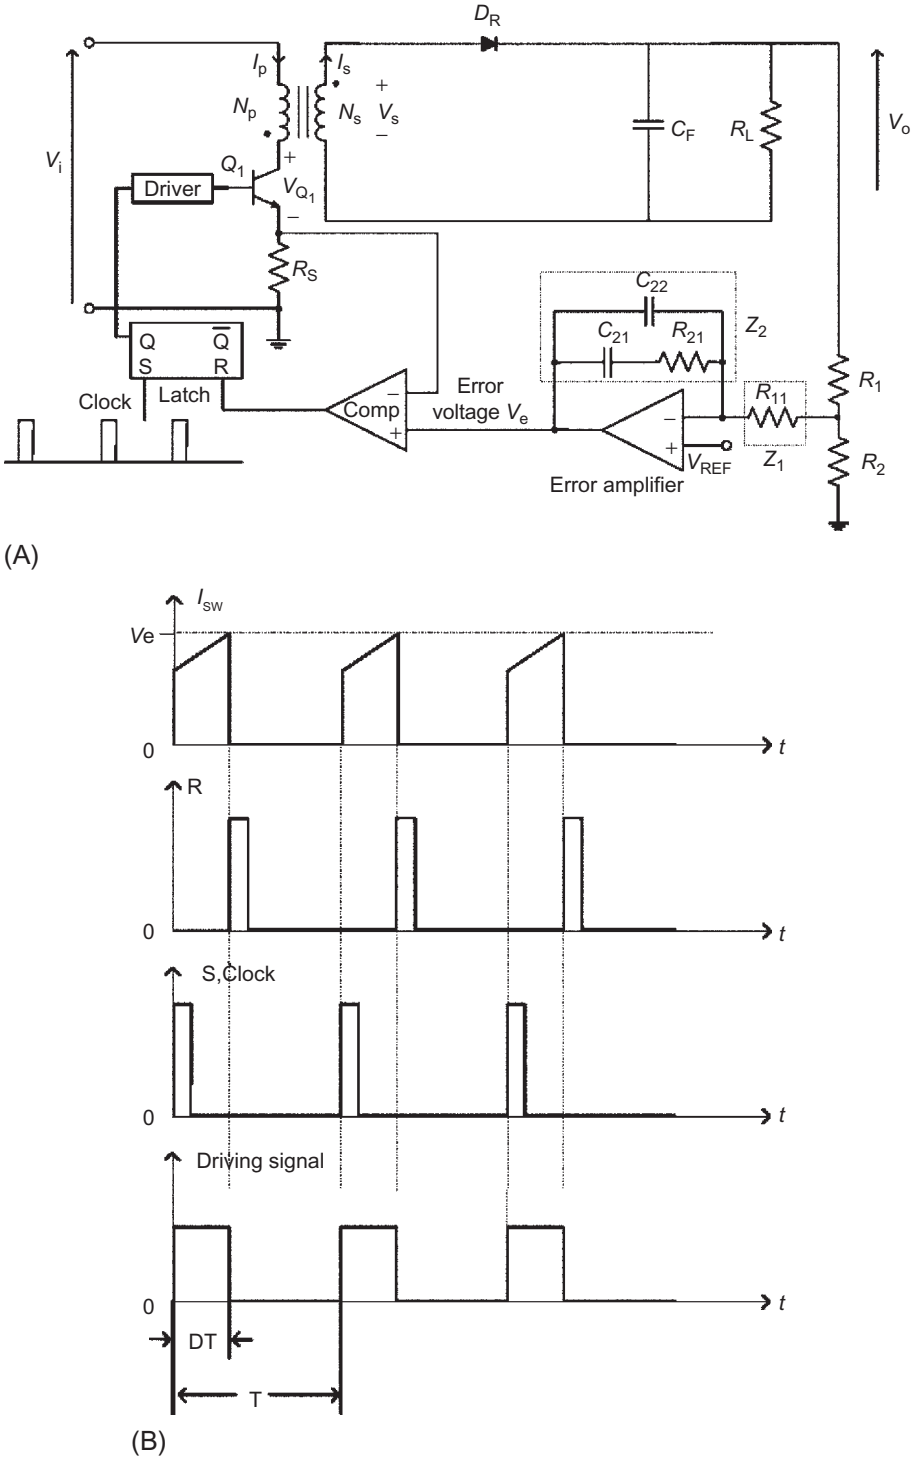

FIG. 20.29 A simplified peak current-mode controlled flyback regulator: (A) circuit and (B) the associated waveforms.

Inspecting the waveform of the sawtooth and the error voltage shows that the duty cycle is related to the error voltage by

$$d = \frac{v_e}{V_p} \tag{20.87}$$

where V_p is the peak voltage of the sawtooth.

Hence, the small-signal duty cycle is related to the small-signal error voltage by

$$\Delta d = \frac{\Delta v_e}{V_p} \tag{20.88}$$

The operation of the fixed-frequency voltage-mode controller can be explained as follows. When the output is lower than the nominal dc value, a high error voltage is produced. This means that Δv_e is positive. Hence, Δd is positive. The duty cycle is increased to cause a subsequent increase in output voltage. The feedback dynamics (stability and transient response) is determined by the operational amplifier circuit that consists of Z_1 and Z_2. Some of the popular voltage-mode control ICs are SG1524/25/26/27, TL494/5, and MC34060/63.

The current-mode control makes use of the current information in a regulator to achieve output voltage regulation. In its simplest form, current-mode control consists of an inner loop that samples the inductance current value and turns the switches off as soon as the current reaches a certain value set by the outer voltage loop. In this way, the current-mode control achieves faster response than the voltage mode. There are two types of fixed-frequency PWM current-mode control, namely, the *peak current-mode control* and the *average current-mode control*.

In the peak current-mode control, no sawtooth generator is needed. In fact, the inductance current waveform is itself a sawtooth. The voltage analog of the current may be provided by a small resistance or by a current transformer. Also, in practice, the switch current is used since only the positive-going portion of the inductance current waveform is required. Fig. 20.29 shows a peak current-mode controlled flyback regulator.

In Fig. 20.29, the regulator operates at fixed frequency. Turn-on is synchronized with the clock pulse, and turnoff is determined by the instant at which the input current equals the error voltage V_e.

Because of its inherent peak current-limiting capability, the peak current-mode control can enhance reliability of power switches. The dynamic performance is improved because of the use of the additional current information. One main disadvantage of the peak current-mode control is that it is extremely susceptible to noise, since the current ramp is usually small compared with the reference signal. A second disadvantage is its inherent instability property at duty cycle exceeding 50%, which results in subharmonic oscillation. Typically, a compensating ramp is required at the comparator input to eliminate this instability. The third disadvantage is that it has a nonideal loop response because of the use of the peak, instead of the average current sensing.

Fig. 20.30 shows an average current-mode controlled flyback regulator. In the circuit, a PWM modulator (instead of a clocked SR latch in the peak current-mode control) is employed to compare the current error with an externally generated sawtooth signal to formulate the desired control signal. The main advantages of this method over the peak current control are that it has excellent noise immunity property, it is stable at duty cycle exceeding 50%, and it provides good tracking of average current. However, since there are three compensation networks (Z_1, Z_2, and Z_3), the analysis and optimal design of these networks are nontrivial. This is a major obstacle for adopting the average current-mode control.

It should be noted that current-mode control is particularly effective for the flyback and boost-type regulators that have an inherent right-half-plane zero. Current-mode control effectively reduces the system to first order by forcing the inductor current to be related to the output voltage, thus achieving faster

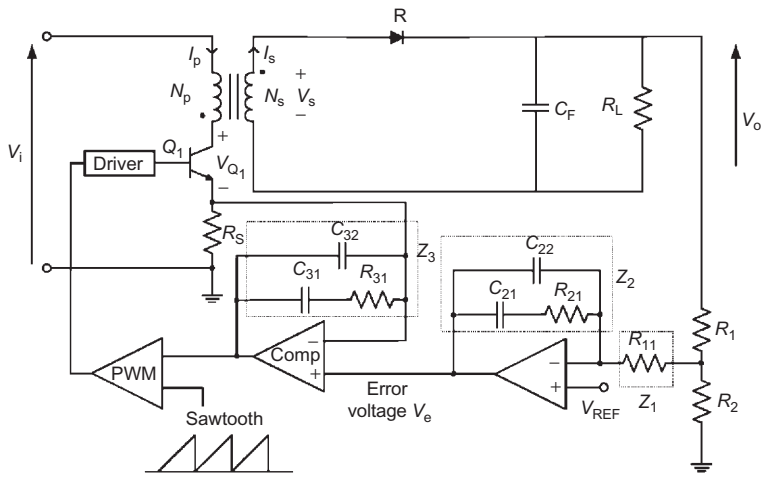

FIG. 20.30 A simplified average current-mode controlled flyback regulator: (A) circuit and (B) the associated waveforms.

response. In the case of the buck-type regulator, current-mode control presents no significant advantage because the current information can be derived from the output voltage, and hence, faster response can still be achieved with a proper feedback network. Some of the popular current-mode control ICs are UC3840/2, UC3825, MC34129, and MC34065.

21.1 Introduction

Electronic ballasts, also called solid-state ballasts, are those power electronic converters used to supply discharge lamps. The modern age of electronic ballasts began with the introduction of power bipolar transistors with low storage time, allowing to supply fluorescent lamps at frequencies of several kilohertz and increasing lamp luminous efficacy by operating at these high frequencies. Later, electronic ballasts became very popular with the development of low-cost power MOSFETs, with unique features that make them very attractive to implement solid-state ballasts. The main benefits of electronic ballasts are the increase in the lamp and ballast overall efficiency, increase in lamp life, reduction of ballast size and weight, and improvement in lighting quality. This chapter attempts to give a general overview about the more important topics related to this type of power converters.

21.1.1 Basic Notions

Discharge lamps generate electromagnetic radiation by means of an electric current passing through a gas or metal vapor. This radiation is discrete, as opposed to the continuous radiation emitted by an incandescent filament. Fig. 21.1 shows the electromagnetic spectrum of an electric discharge, which consists of a number of separate spectral lines.

As can be seen in Fig. 21.1, only the electromagnetic radiation emitted within the visible region (380–780 nm) of the radiant energy spectrum is useful to provide lighting. The total power in watts emitted by an electric discharge can be obtained by integrating the spectral energy distribution. However, this is not a suitable parameter to measure the amount of light emitted by a discharge lamp.

The human eye presents different responses to the different types of electromagnetic waves within the visible range. As illustrated in Fig. 21.2, there exist two response curves. First, the photopic curve, also called $V(\lambda)$, is the characteristic used to represent the human eye under normal illuminating level conditions or daylight vision. Second, the scotopic curve $V'(\lambda)$ is the response of the human eye for situations with low illuminating levels, also known as nocturnal vision. The reason for this different behavior is physiological. The human eye consists of two types of photoreceptors: rods and cones. Rods are much more sensitive at low lighting levels than cones, but they are not sensitive to the different light colors. On the other hand, cones are responsible for normal color vision at higher lighting levels. Normally, only the photopic function is considered in lighting design and used to calibrate photometers [1,2].

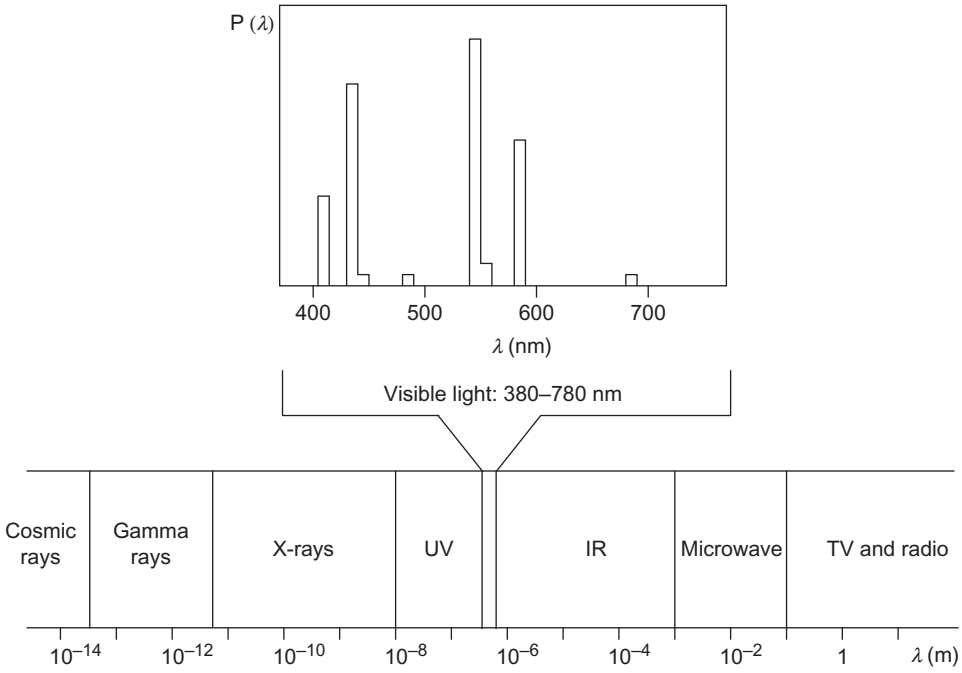

FIG. 21.1 Spectral energy distribution of an arc discharge and radiant energy spectrum.

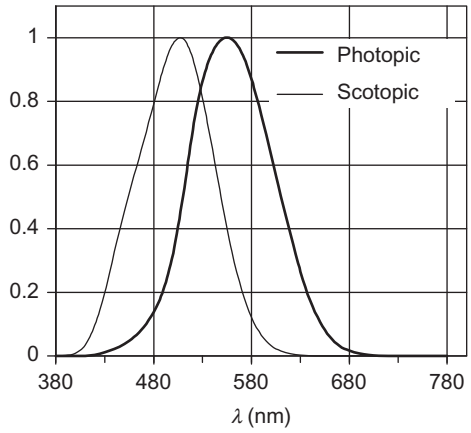

FIG. 21.2 Spectral luminous efficiency functions for standard photopic and scotopic observers.

Since the human eye responds in different ways to the different wavelengths or colors, the output power of a lamp, measured in watts, is no longer applicable to represent the amount of light generated. Thus, a new unit is used to incorporate the human eye response, which is called *lumen*. The total light output of a lamp is then measured in lumens, and it is known as luminous flux of the lamp, which is obtained by integrating the radiant power as follows:

$$\Phi = K_{\mathrm{m}} \int_{380\mathrm{nm}}^{780\mathrm{nm}} P(\lambda) V(\lambda) d\lambda \qquad (21.1)$$

where K_{m} represents the maximal spectral luminous efficacy, which is equal to 683 lm/W (at $\lambda = 555$ nm) for photopic vision and 1700 lm/W (at $\lambda = 507$ nm) for scotopic vision. The standard photopic and scotopic functions were defined by the International Commission on Illumination (CIE) in 1924 and 1951, respectively.

The measurement of the total luminous flux of the lamp is very useful to know whether the lamp is working properly. This can be measured by means of an integrating sphere and using the substitution method. The integrating sphere, also known as Ulbricht photometer, is internally coated with a perfectly diffusing material. Thus, the integral of the sphere is performed in Eq. (21.1), and the illuminance on the internal surface is proportional to the total luminous flux. A photometer with a $V(\lambda)$ filter is placed so that the internal illuminance can be measured, and a baffle is located to avoid direct illumination of the photometer probe by the lamp. The measurement is made in two steps, one with the lamp under test in place and the other with a standard lamp of known total luminous flux. From the two measurements, the total luminous flux of the lamp under test is deduced by linear relationship. Fig. 21.3 illustrates an integrating sphere photometer.

An important parameter related to the supply of discharge lamps is the *luminous efficacy*. Luminous efficacy is defined as the rate of the lamp total luminous flux to the total electric power consumed by the lamp, usually expressed in lumens per watt. The luminous efficacy of a discharge lamp can be increased by proper designing of the electronic ballast, which finally results in energy saving.

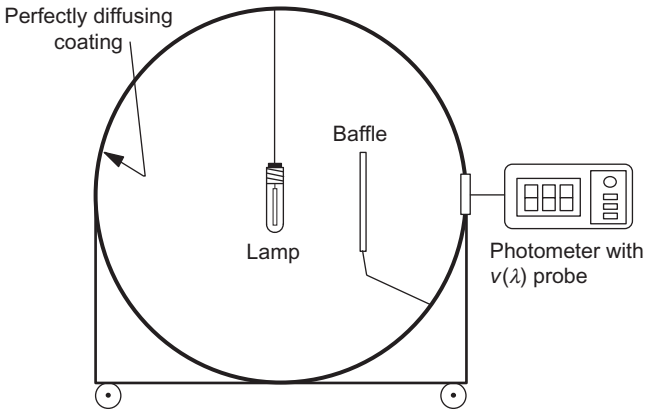

FIG. 21.3 Integrating sphere used for measurement of the lamp total luminous flux.

21.1.2 Discharge Lamps

Basically, discharge lamps consist of a discharge tube inside, which the electric energy is transformed into electromagnetic radiation. The discharge tube is made of a transparent or translucent material with two sealed-in electrodes placed at both ends, as shown in Fig. 21.4. The discharge tube is filled with an inert gas and a metal vapor. The electrodes generate free electrons, which are accelerated by the electric field existing in the discharge. These accelerated electrons collide with the gas atoms, resulting in both elastic and inelastic collisions depending on the electron kinetic energy. The basic processes inside the discharge tube are illustrated in Fig. 21.4. They are as follows [3]:

1. *Heat generation*. When the kinetic energy of the electron is low, an elastic collision takes place, and only a small part of the electron energy is transferred to the gas atom. The result of this type of collisions is an increase in the gas temperature. In this case, the electric energy is consumed to produce heat dissipation. However, this is also an important process because the discharge has to be set in its optimum operating temperature.
2. *Gas atom excitation*. Some electrons can have a high kinetic energy so that the energy transferred in the collision is used to send an electron of the gas atom to a higher orbit. This state is unstable, and the electron tends to recover its original level, emitting the absorbed energy in the form of electromagnetic radiation. This radiation is used to directly generate visible light, or in other case, ultraviolet radiation is first generated and then transformed into visible radiation by means of a phosphor coating existing in the inside wall of the discharge tube.
3. *Gas atom ionization*. In some cases, electrons have gained such high kinetic energy that during the collision with the gas atom, an electron belonging to the gas atom is freed, resulting in a positively charged ion and a free electron. This freed electron can play the same roles as those generated by the electrodes. This process is especially important during both discharge ignition and normal running because ionized atoms and electrons are necessary to maintain the electric current through the lamp.

The number of free electrons in the discharge can increase rapidly due to continuing ionization, producing an unlimited current and finally a short circuit. This is illustrated in Fig. 21.5, which shows how the voltage-current characteristics of a gas discharge exhibit a negative differential resistance. Therefore, in order to limit the discharge current, the use of an auxiliary supply circuit is mandatory. This circuit is called *ballast*.

Focusing on discharge lamps, the complete stabilization process consists of two main phases:

1. *Breakdown phase*. Most of the gases are very good insulators, and an electric discharge is only possible if a sufficient concentration of charged particles is present. Normally, a high voltage is used to provide electricity carriers and to initiate the discharge. The minimum voltage applied to initiate the discharge is called *starting voltage*. The starting voltage mainly depends on the type of gas, gas pressure, and distance between electrodes. Fig. 21.6A represents the starting voltage as a function of the gas pressure multiplied by electrode distance, for different gases. These functions are known as Paschen curves.

Usually, auxiliary inert gases are used to decrease the starting voltage. Particularly, there exist some special

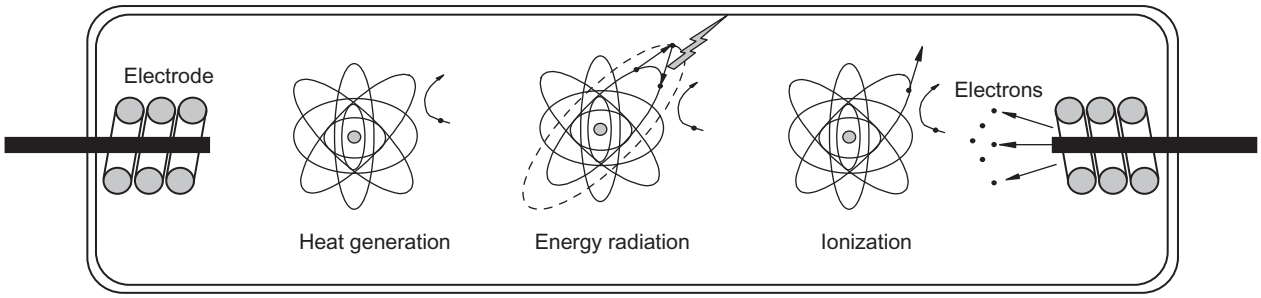

FIG. 21.4 Basic processes inside the discharge tube.

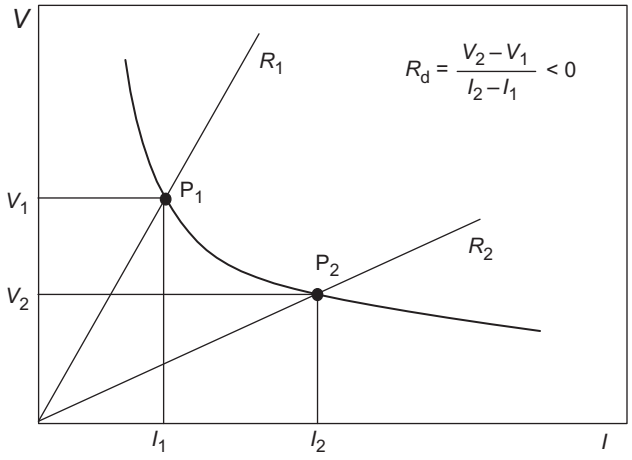

FIG. 21.5 Voltage-current characteristics of a gas discharge.

inert gas mixtures presenting a very low starting voltage, which are called *Penning mixtures*. These Penning mixtures are very often used as initial starting gas. Fig. 21.6A shows a typical Penning mixture constituted by neon with 0.1% of argon.

2. *Warm-up phase*. Once the lamp is ignited, the collisions between free electrons and atoms generate heat, and discharge temperature increases until reaching the normal operation conditions. During this phase, the heat is used to evaporate the metal atoms existing in the discharge tube, and the emitted electromagnetic radiation has the characteristics of a metal vapor discharge instead of an inert gas discharge. From the electric point of view, the discharge warm-up phase shows initially low discharge voltage and high discharge current. As long as more and more metal atoms are evaporated, the discharge voltage increases, and the discharge current decreases. Finally, an equilibrium is reached at steady-state operation with the normal values of voltage and current. The time constant of the warm-up phase strongly depends on the lamp type. It varies from seconds for fluorescent lamps to minutes for high-intensity discharge lamps. Fig. 21.6B illustrates some discharge waveforms during the warm-up phase.

The basic elements used in lamps to generate radiation in the visible part of the spectrum are sodium and mercury. The former generates radiation directly within the visible part of the spectrum; the latter generates radiation mainly in the ultraviolet region, but this radiation can be easily transformed to visible radiation by means of a phosphor coating on the internal wall of the discharge tube. Besides the element used, a very important parameter related to the efficiency and richness of the emitted radiation is the discharge pressure. For the sodium and mercury elements, there exist two pressure values around which the luminous efficacy of the discharge is higher. The first is obtained at quite low pressures, about 1 Pa, and the second at higher pressures around 10^5 Pa (1 at). This is the reason why there exist two main types of discharge lamps:

1. *Low-pressure discharge lamps*. This type of lamps operates with pressures around 1 Pa, and they feature low current density inside the discharge and low power/unit of discharge length. Therefore, these lamps present normally a quite large discharge volume with low power rating. Most representative examples are low-pressure mercury lamps, also known as fluorescent lamps and low-pressure sodium lamps.
2. *High-pressure discharge lamps*. The operating pressure in this type of lamps is around 10^5 Pa and higher, in order to achieve a considerable increase in the luminous efficacy of the discharge. These lamps present a high current density in the discharge and a high power/discharge length ratio, thus showing much smaller discharge tubes.

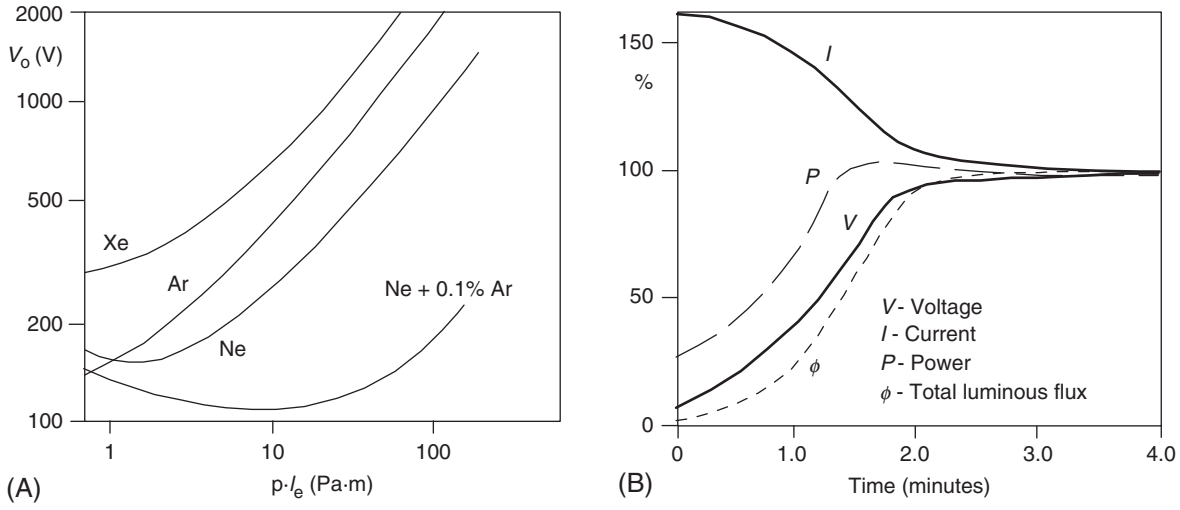

FIG. 21.6 (A) Paschen curves for different inert gases and (B) stabilization curve of a discharge lamp.

Examples of these lamps are high-pressure sodium lamps, high-pressure mercury lamps, and metal halide lamps.

Finally, to characterize the light produced by a discharge lamp, it is necessary to know two important concepts: the correlated color temperature (CCT) and the color rendering index (CRI).

The CCT is defined as the temperature of the blackbody radiator whose perceived color most closely resembles that of the discharge lamp. The color of an incandescent body changes from deep red to orange, yellow, and finally white as its temperature rises. Thus, a cool-white fluorescent lamp has a CCT around 3500 K, and it is perceived as a white source of light, whereas a high-pressure sodium lamp presents a CCT of about 2000 K, and it appears as yellow.

The CRI of a light source is the effect that the source has on the color appearance of the objects under it, when compared with their appearance under a reference source of equal CCT. The measurement gives a value lower than 100, and the higher the CRI, the better the color rendition. For example, daylight and incandescent lamps have a CRI equal to 100.

To conclude this introduction on the discharge lamps, some comments regarding the most important types of discharge lamps will be given. Table 21.1 provides some additional data on the different discharge lamps for comparison.

1. *Fluorescent lamps*. These lamps belong to the category of low-pressure mercury vapor discharge lamps. The discharge generates two main lines at 185 and 253.7 nm and other weak lines in the visible range of the spectrum. A fluorescent powder on the inside wall of the discharge tube converts the ultraviolet radiation into visible radiation, resulting in a broadband spectral distribution and good color rendition. In these lamps, the optimum mercury vapor pressure (which gives the maximum luminous efficacy) is 0.8 Pa. For the tube diameters normally used, this pressure is reached at a wall temperature of about 40°C, not much higher than typical ambient temperature. The heat generated inside the discharge is sufficient to attain the required operating temperature without using an outer bulb. However, this structure causes a great variation of the lamp lumen output with the temperature, which is one important drawback of the fluorescent lamps. One solution to this problem is the addition of amalgams to stabilize the light output. This is specially used in compact fluorescent lamps.
2. *Low-pressure sodium lamps*. These lamps are the most efficient source of light. The reason is the almost monochromatic radiation that they generate, with two main lines at 589 and 589.6 nm, very close to the maximum human eye sensitivity. Therefore, color rendition of these lamps is very poor; however, contrasts are seen more clearly under this light. This is the reason for using these lamps in situations where the recognition of objects and contours is essential for safety, such as motorway bridges, tunnels, and intersections. The optimum pressure for the low-pressure sodium discharge is about 0.4 Pa, which is attained in normal discharge tubes at a temperature of 260°C. An outer bulb is normally used to reach and maintain this temperature.
3. *High-pressure mercury vapor lamps*. The increase in the pressure of the mercury vapor produces a radiation richer in spectral lines; some of them are in the visible part of the spectrum (405, 436, 546, and 577/579 nm). This leads to an increase in the luminous efficacy, reaching values of 40–60 lm/W at pressures 10^5–10^7 Pa (1–100 at). These lamps operate with unsaturated mercury vapor, which means that all the mercury in the discharge tube has evaporated and the number of mercury atoms/unit volume remains constant. Thus, the operation of this type of lamps is more independent of the temperature than most other discharge lamps. One drawback of these lamps is the lack of spectral lines in the long wavelengths (reds) of the spectrum, thus showing low CRI. An increase of the color rendition can be obtained by adding metal halide compounds into the discharge tube, in order to generate radiation all over the visible spectrum. These lamps are known as *metal halide lamps*.
4. *High-pressure sodium lamps*. This is a very popular source of light due to its high luminous efficacy and long life. The increase in the sodium vapor pressure produces a very widening spectrum, with good color rendition compared with the low-pressure sodium lamps. This also leads to a lower luminous efficacy, but it is still higher than the other high-intensity discharge lamps. Some of these lamps also incorporate mercury in the form of

TABLE 21.1 Comparison of different discharge lamps

Lamp	Wattage (W)	Luminous efficacy (lm/W^{-1})	Life (h)	CCT (K)	CRI
Fluorescent	4–100	62	20,000	4200	62
Compact fluorescent	7–30	60–80	10,000	2700–5000	82
Low-pressure sodium	50–150	110–180	15,000	1800	<0
Mercury vapor	50–1000	40–70	24,000	4000–6000	15–50
Metal halide	40–15,000	80–125	10,000	4000	65
HPS	35–1000	65–140	24,000	2000	22
HPS (amalgam)	35–1000	45–85	10,000	2200	65

sodium amalgam to increase the field strength of the discharge, thus decreasing the discharge current. A lower lamp current and a higher lamp voltage allow to reduce the size and cost of the ballast. However, the addition of sodium amalgam strongly reduces the life of the lamp.

21.1.3 Electromagnetic Ballasts

Electromagnetic ballasts are commonly used to stabilize the lamp at the required operating point by limiting the discharge current. The operating point of the lamp is given by the intersection of both lamp and ballast characteristics, as shown in Fig. 21.7. The ballast line is the characteristic that shows the variation of the lamp power versus lamp voltage for a constant line voltage, and it can be measured during the warm-up phase of the lamp. The lamp line is the characteristic that gives the variation of the lamp power as a function of the lamp voltage for different line voltages, and it can be measured by varying the line voltage. Some lamps, such as high-pressure sodium lamps, exhibit a great variation of lamp voltage with changes in the lamp wattage. Because of this characteristic, trapezoids have been established that define maximum and minimum permissible lamp wattage versus lamp voltage for purposes of ballast design, as shown in Fig. 21.7.

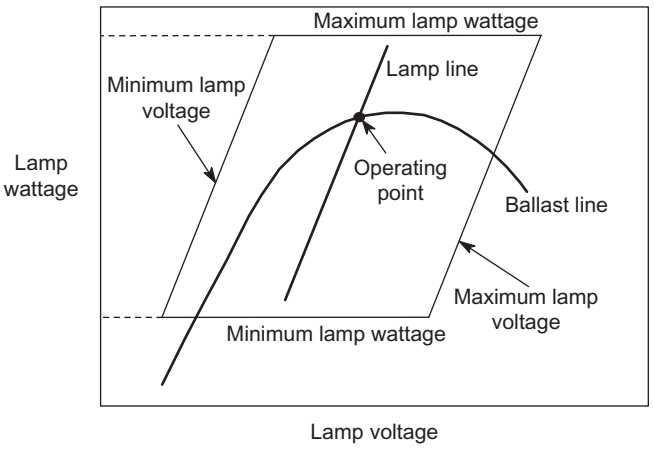

FIG. 21.7 Lamp and ballast characteristics.

Fig. 21.8 shows a basic electromagnetic ballast used to supply low- and high-pressure lamps at line frequencies (50–60 Hz). Fig. 21.8A illustrates the typical circuit used to supply fluorescent lamps with preheating electrodes, which basically uses a series inductor to limit the current through the discharge. Initially, the glow switch is closed, and the short circuit current flows through the circuit, heating the electrodes. A fraction of a second later, the glow switch is opened, and the energy stored in the ballast inductor causes a voltage spike between the lamp electrodes (about 800 V), which finally produces the discharge breakdown. Once ignited, the lamp voltage is lower than the line voltage, and the glow switch remains open during the normal lamp operation. Typical glow switches are based on two bimetal strips inside a small tube filled with an inert gas. An external capacitor of about 10 nF is used to enhance the glow-switch operation and also to reduce radio interference during lamp starting. Finally, in this type of inductive ballasts, a capacitor placed across the line input is mandatory to achieve a reasonable value of the input power factor.

Starting voltages of high-pressure discharge lamps are normally higher than low-pressure discharge lamps and can range from 2500 V for a lamp at room temperature to 30–40 kV to reignite a hot lamp. Thus, the simple ignition system based on the glow switch is no longer applicable for these lamps. Fig. 21.8B and C shows two typical arrangements to supply

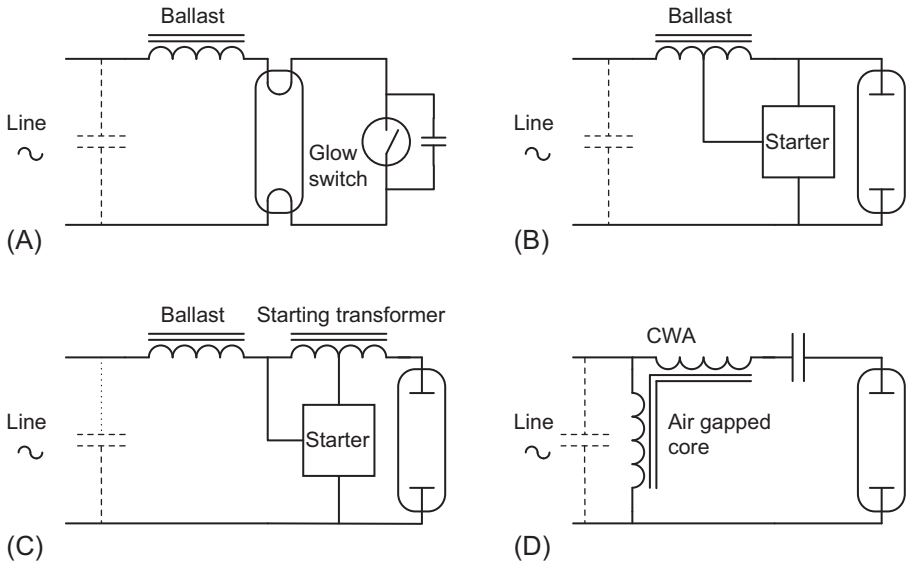

FIG. 21.8 Typical electromagnetic ballast used to supply discharge lamps at low frequency.

high-intensity discharge lamps. A series inductor is also used to limit the lamp current at steady-state operation, but autotransformers are used to attain higher voltage spikes for lamp ignition. For higher line voltages and short distances between starter and lamp, the inductor ballast can be used as an ignition transformer as shown in Fig. 21.8B. In other cases, a separate igniting transformer is needed to provide higher voltage spikes and to avoid the effect of parasitic capacitance of connection cables (Fig. 21.8C).

The inductive ballast provides low-lamp-power regulation against line voltage variation, and therefore, it is only recommended in those installations with low voltage fluctuations. When a good lamp power regulation is necessary, the circuit shown in Fig. 21.8D is normally used. This circuit is commonly named as constant wattage autotransformer (CWA) and incorporates a capacitor in series with the lamp to limit the discharge current. Compared with the normal inductive ballast, the CWA also exhibits higher input power factor, lower line extinguishing voltage, and lower line starting currents.

The main advantage of electromagnetic ballasts is their simplicity, which in turn provides low cost and high reliability. However, since they operate at line frequencies, typically 50–60 Hz, they also feature high size and weight. Other important drawbacks of electromagnetic ballasts are as follows:

- Low efficiency especially for those ballasts featuring good lamp-power regulation against line voltage variation.
- Low reliability for ignition and reignition. If the voltage spike is not well located within the line period, the ignition of the lamp can fail.
- Difficult to control the lamp luminous flux (dimming).
- Lamp operating point changes due to lamp aging process, thus reducing lamp life.
- Low input power factor and high harmonic distortion. Large capacitors are needed across the line input to increase power factor.
- Overcurrent risk due to ballast saturation caused by rectifying effect of some discharge lamps, especially at the end of their life.
- *Flickering* and *stroboscopic effect* due to low frequency supply. The energy radiated by the lamp is a function of the instantaneous input power. Therefore, when supplied from an ac line, an instantaneous variation of the light output occurs, which is called *flicker*. For a line frequency of 60 Hz, the resulting light frequency is 120 Hz. This variation is too fast for the human eye, but when rapidly moving objects are viewed under these lamps, the objects seem to move slowly or even halted. This is called *stroboscopic effect*, and it can be very dangerous in industrial environments. A flicker index is defined with values from 0 to 1.0 [4]. The higher the flicker index the higher is the possibilities of noticeable stroboscopic effect.
- Unsuitable for dc applications (emergency lighting, automobile lighting, etc.).

21.2 High Frequency Supply of Discharge Lamps

21.2.1 General Block Diagram of Electronic Ballasts

Fig. 21.9 shows the general block diagram of a typical electronic ballast. The main stages are the following:

- *EMI filter*. This filter is mandatory for commercial electronic ballast. Usually, it consists of two coupled inductors and a capacitor. The input filter is used to attenuate the electromagnetic interference (EMI) generated by the high-frequency stages of the ballasts. It also protects the ballast against possible line transients.
- *AC-DC converter*. This stage is used to generate a dc voltage level from the ac line. Normally, a full-bridge diode rectifier followed by a filter capacitor is used. However, this simple rectifier provides low input power factor and poor voltage regulation. In order to obtain a higher power factor and a regulated bus voltage, active converters can be used as expounded later in this chapter.

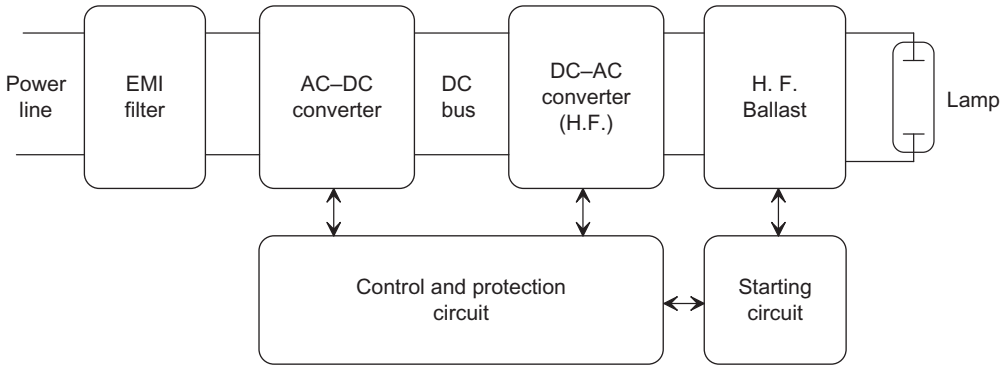

FIG. 21.9 Block diagram of a typical electronic ballast.

- *DC-AC inverter and high-frequency ballast*. These stages are used to supply the lamp at high frequency. The inverter generates a high-frequency waveform, and the ballast is used to limit the current through the discharge. Both inductors and capacitors can be used to perform this function, with the advantage of low size and weight, because they operate at high frequencies.
- *Starting circuit*. In most electronic ballast, especially those for low-pressure discharge lamps, the high-frequency ballast is used to both ignite the lamp and limit the lamp current at steady state. Therefore, no extra starting circuit is necessary. However, when supplying high-pressure discharge lamps, the starting voltages are quite higher, and separate ignition circuits are needed, especially if hot reignition is pursued.
- *Control and protection circuit*. This stage includes the main oscillator, error amplifiers to regulate lamp current or power, output overvoltage protection, timers to control the ignition times, overcurrent protection, and lamp failure protection. It can vary from very simple circuits, those used in self-oscillating ballasts, to very complicated ones, which sometimes include a microprocessor-based control circuit.

There are several important topics when designing electronic ballasts:

- *Operating frequency*. The operating frequency should be high in order to take benefit of the lower size and weight of the reactive elements used to stabilize the discharge. Usually, the operating frequency should be higher than 20 kHz to avoid audible frequencies, which can produce annoying noises. On the other hand, a higher frequency produces higher switching losses, and the practical limit of the switching frequency is about 100 kHz when using MOSFET switches. It is also important to avoid frequencies in the range of 30–40 kHz because these frequencies are normally used in IR remote controls and could generate some kind of interference.
- *Lamp current waveform*. In order to attain the maximum lamp life, it is important to drive the lamp with symmetrical alternating currents, thus making use of both the lamp electrodes alternately. Also, an important parameter is the *lamp current crest factor* (CF), which is the ratio of the peak value to the rms value of the lamp current. In case of electronic ballasts, the ratio of the peak value of the low-frequency-modulated envelope to the rms value should be used. The higher the CF, the lower the lamp life. The ideal situation is to supply the lamp with a pure sinusoidal waveform. Usually, a CF lower than 1.7 is recommended to avoid early aging of the lamp [5].
- *Lamp starting procedure*. This is a very important issue when developing commercially available electronic ballasts. The reason is that the life of the lamp greatly depends on how well the lamp starting is performed, especially for hot-cathode fluorescent lamps. During the starting process, electrodes must be warmed up to the emission temperature, about 800°C, and no high voltage should be applied until their temperature is sufficiently high, thus avoiding sputtering damage. Once the electrodes reach the emission temperature, the starting voltage can be applied to ignite the lamp. For lamps with cold cathodes, the starting voltage must be applied rapidly to prevent harmful glow discharge and cathode sputtering. In any case, starting voltage must be limited to the minimum value to ignite the lamp, since higher voltages could provide undesirable starting conditions that would reduce the life of the lamp.
- *Dimming*. This is an important feature, which allows the ballast to control lamp power and thereby lighting output. Usually, the switching frequency is used in solid-state ballasts as a control parameter to provide dimming capability. Variations in frequency affect the high-frequency ballast impedance and allow to change the discharge current. For example, if an inductor is used as high-frequency ballast, a frequency increase yields an increase in the ballast impedance, thus decreasing lamp current. Dimming should be carried out smoothly, avoiding abrupt changes in lamp power when passing from one level to another. In an eventual power cutoff, the lamp should be restarted at maximum lighting level and then slowly reduced to the required output level.
- *Acoustic resonance*. The HID lamps exhibit an unstable operation when they are supplied at high frequency. At certain operating frequencies, the arc fluctuates and becomes unstable, which can be observed as a high flicker due to important changes in the lamp power and thus in the lighting output. This can be explained by the dependence of the damping of acoustic waves on the plasma composition and pressure. More information about this topic can be found in [6]. The avoidance of acoustic resonance is mandatory to implement commercial electronic ballasts. This can be performed by selecting the operating frequency in a range free of acoustic resonances, typically below 1 kHz and over 100 kHz. Other methods are frequency modulation, square-wave operation, and sine-wave superposed with the third harmonic frequency [7,8].

21.2.2 Classification of Electronic Ballast Topologies

Typical topologies used to supply discharge lamps at high frequency can be classified into two main groups: nonresonant ballasts and resonant ballasts.

21.2.2.1 Nonresonant Ballasts

These topologies are usually obtained by removing the output diode of dc-to-dc converters, in order to supply alternating

current to the lamp. Current mode control is normally employed to limit the discharge lamp current. The lamp is supplied with a square current waveform, which can exhibit a dc level in some cases. A small capacitor is used to initially ignite the lamp, but its effect at steady-state operation can be neglected.

Examples of nonresonant electronic ballasts are shown in Fig. 21.10. Fig. 21.10A and b illustrates a boost-based and a flyback-based ballast, respectively. Other topologies, which can supply symmetrical alternating current through the lamp, are shown in Fig. 21.10C (symmetrical boost) and Fig. 21.10D (push-pull).

These topologies present several drawbacks such as high-voltage spikes across the switch, which necessitates the use of high-voltage transistors, and high switching losses due to hard switching, which gives low efficiency especially for high powers. Besides, since the ideal situation is the lamp being supplied with a sine wave, these circuits produce an early aging of the lamp. To conclude, typical applications of these topologies are portable and emergency equipments, in which lamp power is low and the number of ignitions during its life is not very high. Some applications of these circuits can be found in [9–12].

21.2.2.2 Resonant Ballasts

These ballasts use a resonant tank circuit to supply the lamp. The resonant tank filters the high-order harmonics, thus obtaining a sine current waveform through the lamp. Resonant ballasts can be classified into two categories:

Current-Fed resonant ballasts

These ballasts are supplied with a dc current source, usually obtained by means of a choke inductor in series with the input dc voltage source. The dc current is transformed into an alternating square current waveform by switching power transistors. Typical topologies of this type of ballasts are shown in Fig. 21.11.

The topology shown in Fig. 21.11A corresponds to a class E inverter. Inductor Le is used to obtain a dc input current with low current ripple. This current supplies the resonant tank through the power switch formed by Q1-D1. The resonant tank used in this topology can vary from one ballast to another; the circuit shown in Fig. 21.11A is the one, which is normally used. The main advantage of this topology is that zero voltage switching (ZVS) can be attained in the power switch, thus reducing the switching losses and making the operation at very high frequencies, which can reach several megahertz. This allows to drastically reduce the size and weight of the ballast. However, the adjustment of the circuit parameters to obtain the optimum operation results is quite difficult, especially for mass production. Another important drawback is the high voltage stress across the switch, which can reach values of three times the dc input voltage. For these reasons, the main applications of this circuit are battery-supplied ballasts with low input voltage and low lamp power, as those used in emergency lighting and portable equipment. Typical power range of this ballast varies from 5 to 30 W. Applications of this circuit can be found in [13,14].

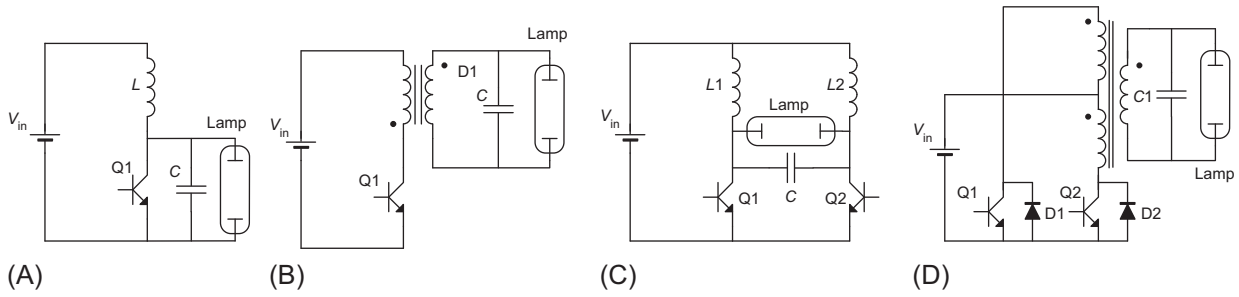

FIG. 21.10 Nonresonant electronic ballasts.

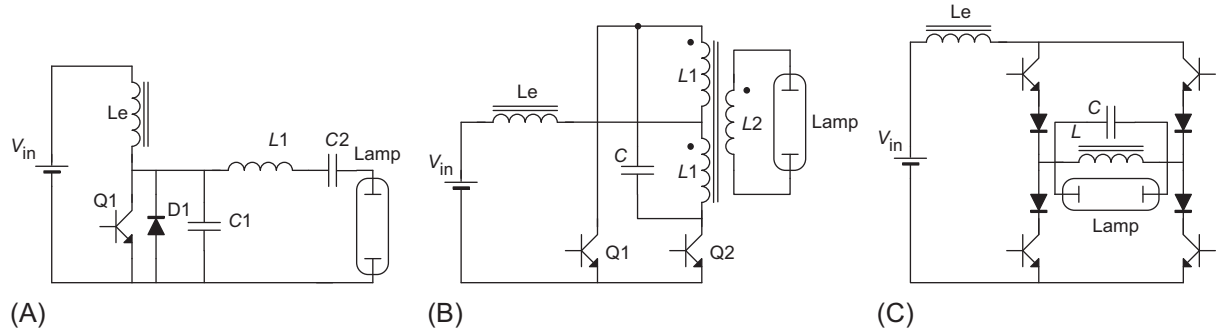

FIG. 21.11 Three typical current-fed resonant inverters: (A) class E inverter, (B) current-fed push-pull inverter, and (C) current-fed full-bridge resonant inverter.

Another typical topology in this group is the current-fed push-pull inverter shown in Fig. 21.11B. In this circuit, a dc input current is obtained by means of choke inductor Le. Transistors are operated with a 50% duty cycle, thus providing a current square wave, which supplies the current-fed parallel resonant circuit formed by the mutual inductance of the transformer and capacitor *C*. This circuit has the advantage of being relatively easy to implement in a self-oscillating configuration, avoiding the use of extra control circuits and thereby reducing the cost. Also, ZVS can be obtained in the power switches. However, the switches also present a high voltage stress, about three times the dc input voltage, which makes this topology unsuitable for power line applications. This circuit is also normally used in battery-operated applications in a self-oscillating arrangement. The typical power range is 4–100 W. Applications based on this circuit can be found in [15,16].

Finally, Fig. 21.11C shows a current-fed full-bridge resonant inverter, which can be used for higher power rating. Also, this circuit allows to control the output power at constant frequency by switching the devices of the same leg simultaneously, generating a quasi-square current wave through the resonant tank [17].

Voltage-fed resonant ballasts

At present, electronic ballast manufacturers mostly use voltage-fed resonant ballasts, especially for applications supplied from the ac mains. The circuit is fed from a dc voltage source, normally obtained by line voltage rectifying. A square-wave voltage waveform is then obtained by switching the transistors with a 50% duty cycle and is used to feed a series resonant circuit. This resonant tank filters the high-order harmonics and supplies the lamp with a sine current waveform. One advantage of the voltage-fed series resonant circuit is that the starting voltage can be easily obtained without using extra ignition capacitors by operating close to resonant tank frequency. Fig. 21.12 shows electric diagrams of typical voltage-fed resonant ballasts.

The voltage-fed version of the push-pull inverter is illustrated in Fig. 21.12A. This inverter includes a transformer, which can be used to step up or down the input voltage in order to obtain an adequate rms value of the output square-wave voltage. This not only provides higher design flexibility but also increases the cost. One disadvantage is that the voltage across transistors is twice the input voltage, which can be quite high for line applications. Therefore, this inverter is normally used for low-voltage applications. Another important drawback of this voltage-fed inverter is that any asymmetry in the two primary windings (different number of turns) or in the switching times of power transistors would provide an undesirable dc level in the transformer magnetic flux, which in turn could saturate the core or decrease the efficiency due to the circulation of dc currents.

Fig. 21.12B and C illustrates two possible arrangements for the voltage-fed half-bridge resonant inverter. The former is normally referred as asymmetrical half bridge, and it uses one of the resonant tank capacitors (*C*1 in the figure) to block the dc voltage level of the square wave generated by the bridge. This means that capacitor *C*1 will exhibit a dc level equal to half the dc input voltage superimposed to its normal alternating

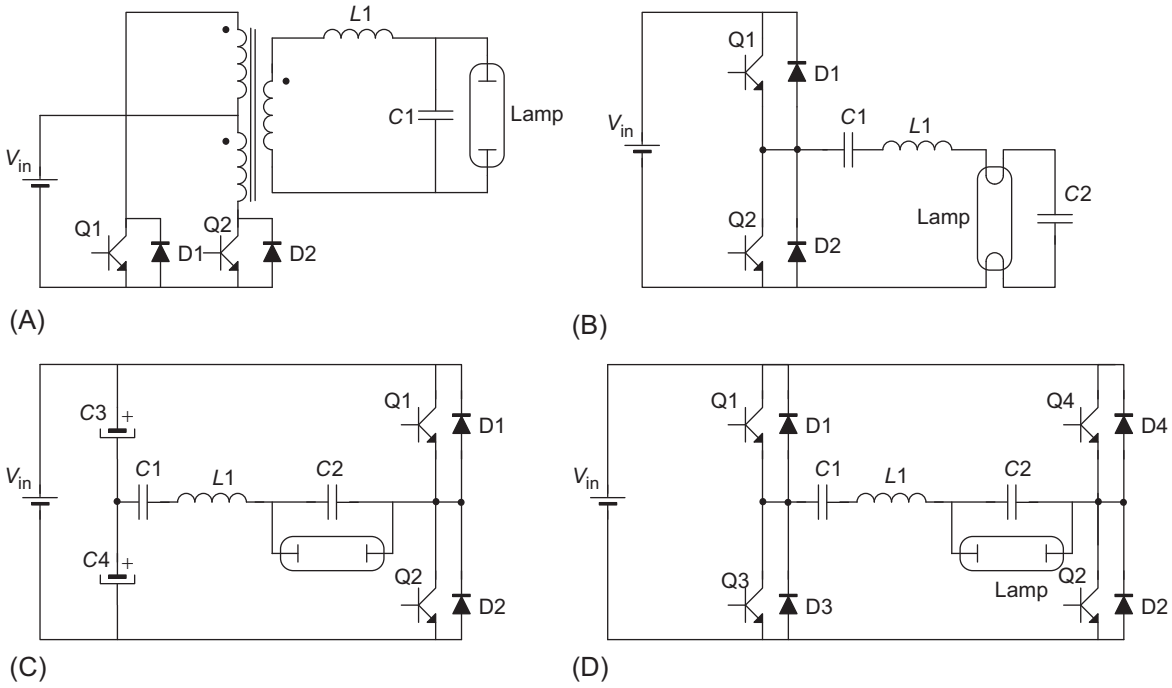

FIG. 21.12 Typical voltage-fed resonant inverters: (A) push-pull, (B)–(C) half-bridge, and (D) full-bridge.

voltage. A transformer can also be used in this inverter to step up or down the input voltage to the required level for each application. In this case, the use of the series capacitor $C1$ prevents any dc current from circulating through the primary winding, thus avoiding transformer saturation. This topology is widely used by ballast manufacturers to supply fluorescent lamps, especially in the self-oscillating version, which allows to drastically reduce the cost. When supplying hot-cathode fluorescent lamps, the parallel capacitor $C2$ is normally placed across two electrodes, as shown in Fig. 21.12B, in order to provide a preheating current for the electrodes and achieve soft ignition. Fig. 21.12C shows another version of the half-bridge topology, using two bulk capacitors to provide a floating voltage level equal to half the input voltage. In this case, capacitor $C1$ is no longer used to block a dc voltage, thus showing lower voltage stress.

Finally, for the high power range (>200 W), the full-bridge topology shown in Fig. 21.12D is normally used. The transistors of each half bridge are operated with a 50% duty cycle, and their switching signals are phase-shifted by 180 degrees. Thus, when switches Q1 and Q2 are activated, direct voltage V_{in} is applied to the resonant tank; when switches Q3 and Q4 are activated, the reverse voltage $-V_{in}$ is obtained across the resonant circuit. One of the advantages of this circuit is that the switching signals of the two branches can be phase-shifted by angles between 0 and 180 degrees, thus controlling the rms voltage applied to the resonant tank ranging from 0 to V_{in}. This provides an additional parameter to control the output power at constant frequency, which is useful to implement dimming ballast.

21.3 Discharge Lamp Modeling

The low frequency of the mains is not an adequate power source for supplying discharge lamps. At these low frequencies, electrons and ionized atoms have enough time to recombine at each current reversal. For this reason, the discharge must be reignited twice within each line period. Fig. 21.13A illustrates the current and voltage waveforms and the I–V characteristics of a 150 W HPS lamp operated with an inductive ballast at 50 Hz. As can be seen, the reignition voltage spike is nearly 50% higher than the normal discharge voltage, which is constant during the rest of the half cycle.

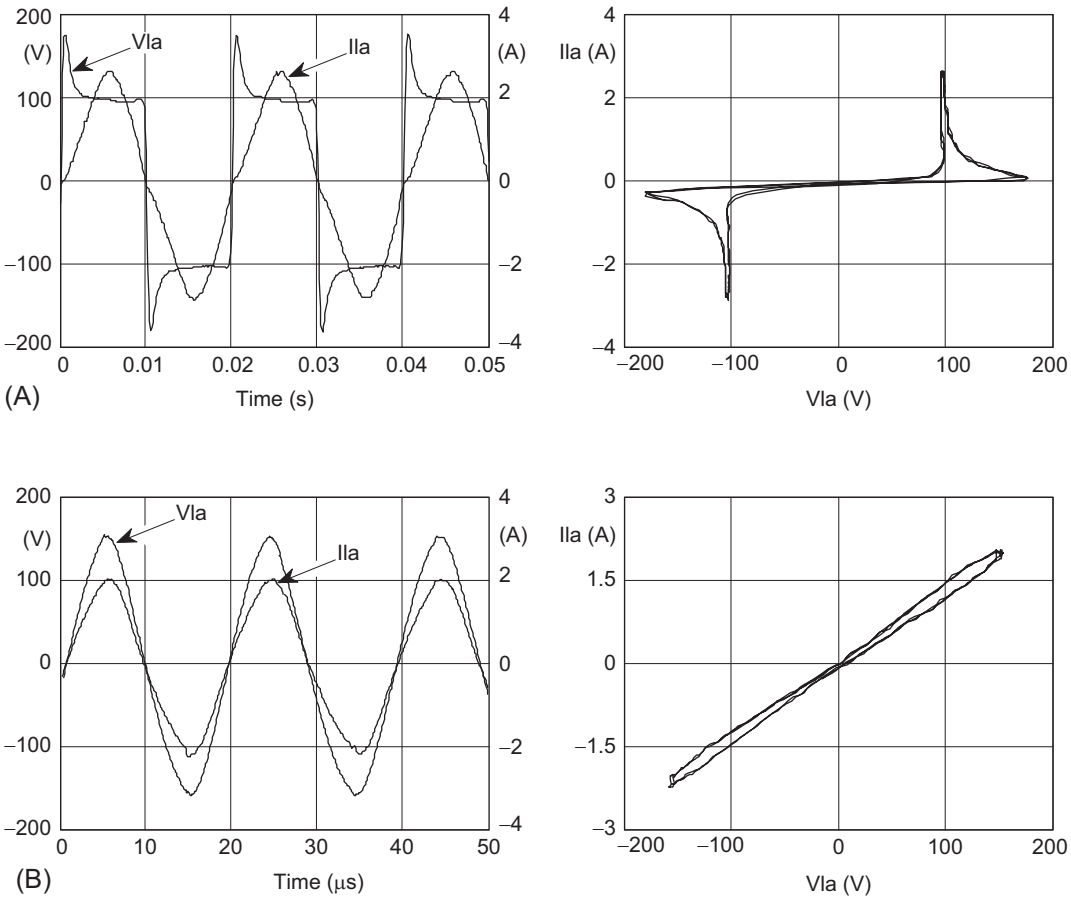

FIG. 21.13 150 W HPS lamp waveforms and I–V characteristics at (A) 50 Hz and (B) 50 kHz.

When lamps are operated at higher frequencies (above 5 kHz), electrons and ions do not have enough time to recombine. Therefore, charge carrier density is sufficiently high at each current reversal, and no extra power is needed to reignite the lamp. The result is an increase in the luminous flux compared with that at low frequencies, which is especially high for fluorescent lamps (10%–15%).

Fig. 21.13B shows the lamp waveforms and *I–V* characteristics for the same 150 W HPS lamp when supplied at 50 kHz. It also shows how the reignition voltage spikes disappear, and the lamp behavior is nearly resistive.

Fig. 21.14 illustrates how the voltage waveforms change in a fluorescent lamp when increasing the supply frequency. As can be seen, at a frequency of 1 kHz, the voltage is already nearly sinusoidal, and the lamp exhibits a resistive property.

Therefore, a resistor can be used to model the lamp at high frequencies for ballast design purposes. However, most lamp manufacturers provide only lamp data for operating at low frequencies, where the lamp acts as a square-wave voltage source. Table 21.2 shows the low-frequency electric data of different discharge lamps provided by the manufacturer and the measured values at high frequency for the same lamps. As can be seen, a power factor close to unity is obtained at high frequency.

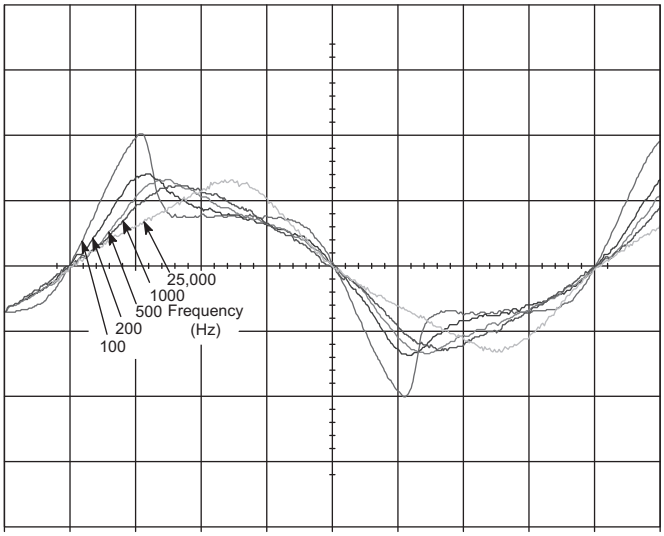

FIG. 21.14 Voltage waveforms for a 36 W linear fluorescent lamp supplied through a resistive ballast at nominal power and different operating frequencies. Vertical scale, 100 V/DIV.

The equivalent lamp resistance at high frequencies can be easily estimated from the low-frequency data. Lamp power at any operating frequency can be expressed as follows:

$$P_{LA} = V_{LA}\ I_{LA}\ FP_{LA} \tag{21.2}$$

where V_{LA} and I_{LA} are the rms values of lamp voltage and current and FP_{LA} is the lamp power factor.

At line frequencies, the lamp power factor is low (typically 0.8), due to the high distortion in the lamp voltage waveform. However, at high frequencies, the lamp power factor reaches nearly 1.0. Then, lamp voltage and current at high frequency ($V_{LA,hf}$ and $I_{LA,hf}$) can be estimated from the following equation:

$$I_{LA,hf}\, V_{LA,hf} = P_{LA} \tag{21.3}$$

where P_{LA} is the nominal lamp power provided by the manufacturer.

As can be seen in Table 21.2, fluorescent lamps tend to maintain nearly the same rms current at low and high frequency, whereas high-pressure discharge lamps tend to maintain nearly the same rms voltage. Based on these assumptions, the equivalent lamp resistance at high frequency estimated from the low frequency values is shown in Table 21.3.

Low-pressure sodium lamps maintain neither voltage nor current constant at high frequency, and they also exhibit an equivalent resistance quite dependent on the frequency. Therefore, their equivalent resistance can only be obtained by laboratory testing.

Note that the values given in Table 21.3 are only an approximation to the real value, which should be obtained by

TABLE 21.3 Estimated electric data of discharge lamps at high frequency

Lamp	$V_{LA,hf}$	$I_{LA,hf}$	$R_{LA,hf}$

[a]Lamps aged for 100 h.

measurement at the laboratory. This can be used as the first starting point in the design of the electronic ballast, but final adjustments should be made at the laboratory.

Another important issue is that the lamp equivalent resistance is strongly dependent on power delivered to the lamp, which is especially important for designing electronic ballasts with dimming feature. The characteristic lamp resistance versus lamp power is different for each discharge lamp type and must be obtained by laboratory testing. One of the best possibilities to fit the lamp resistance versus power characteristic is the hyperbolic approximation. For example, Mader and Horn propose in [18] the following simple approximation:

$$R_{LA}(P_{LA}) = \frac{V_0^2}{P_{LA} + P_0} \tag{21.4}$$

where R_{LA} is the equivalent lamp resistance, P_{LA} is the average lamp power, and V_0 and P_0 are two parameters that depend on each lamp. This characteristic has been plotted in Fig. 21.15 for a particular lamp with $V_0 = 100$ V and $P_0 = 1$ W.

This model can be implemented very easily in circuit simulation programs, such as SPICE-based programs. Fig. 21.16 shows the electric circuit and the description used to model the characteristic of lamp in a SPICE-based simulation program. The voltage-controlled voltage source EL is used to model the resistive property of the lamp. The voltage source Vs is used to measure the lamp current, so that the instantaneous and average lamp current can be calculated; for this reason, its voltage value is equal to zero. GP is a voltage-controlled current source used to calculate the instantaneous lamp power, which is then filtered by RP and CP in order to obtain the averaged lamp power. Finally, the hyperbolic relationship between the lamp resistance and power is implemented by means of the voltage-controlled voltage source EK. The time constant $\tau = RP \cdot CP$ is related to the ionization constant of the discharge.

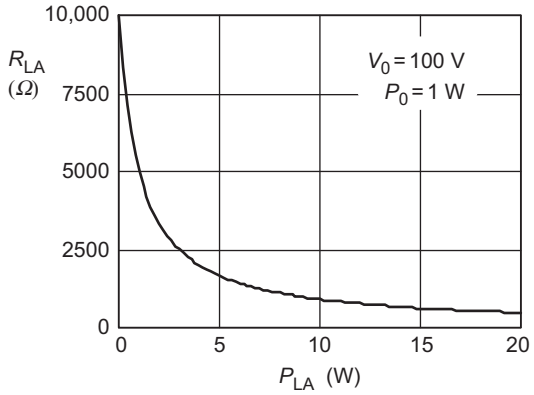

FIG. 21.15 Lamp resistance versus lamp power characteristic.

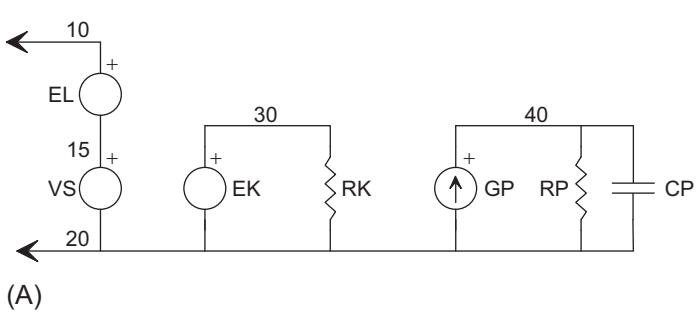
Fig. 21.17 illustrates some simulation results at low frequency when the lamp is supplied from a sinusoidal voltage source and stabilized with an inductive ballast.

The Mader-Horn model can also be used at high frequencies, which makes the lamp resistive. The equivalent lamp resistance at high frequency will also exhibit a hyperbolic variation with the averaged lamp power and with a time constant given by τ. This model is then useful to simulate an electronic ballast with dimming feature.



Discharge lamp modeling has become an important subject, since its results are very useful to optimize the electronic ballast performance. Some improvements on the Mader-Horn model and other interesting models can be found in the literature [18–20].

21.4 Resonant Inverters for Electronic Ballasts

Most modern domestic and industrial electronic ballasts use resonant inverters to supply discharge lamps. They can be implemented in two basic ways: current-fed resonant inverters and voltage-fed resonant inverters.

21.4.1 Current-Fed Resonant Inverters

One of the most popular topologies belonging to this category is the current-fed push-pull resonant inverter, previously shown in Fig. 21.11. For this reason, this inverter will be studied here to illustrate the operation of the current-fed resonant ballasts.

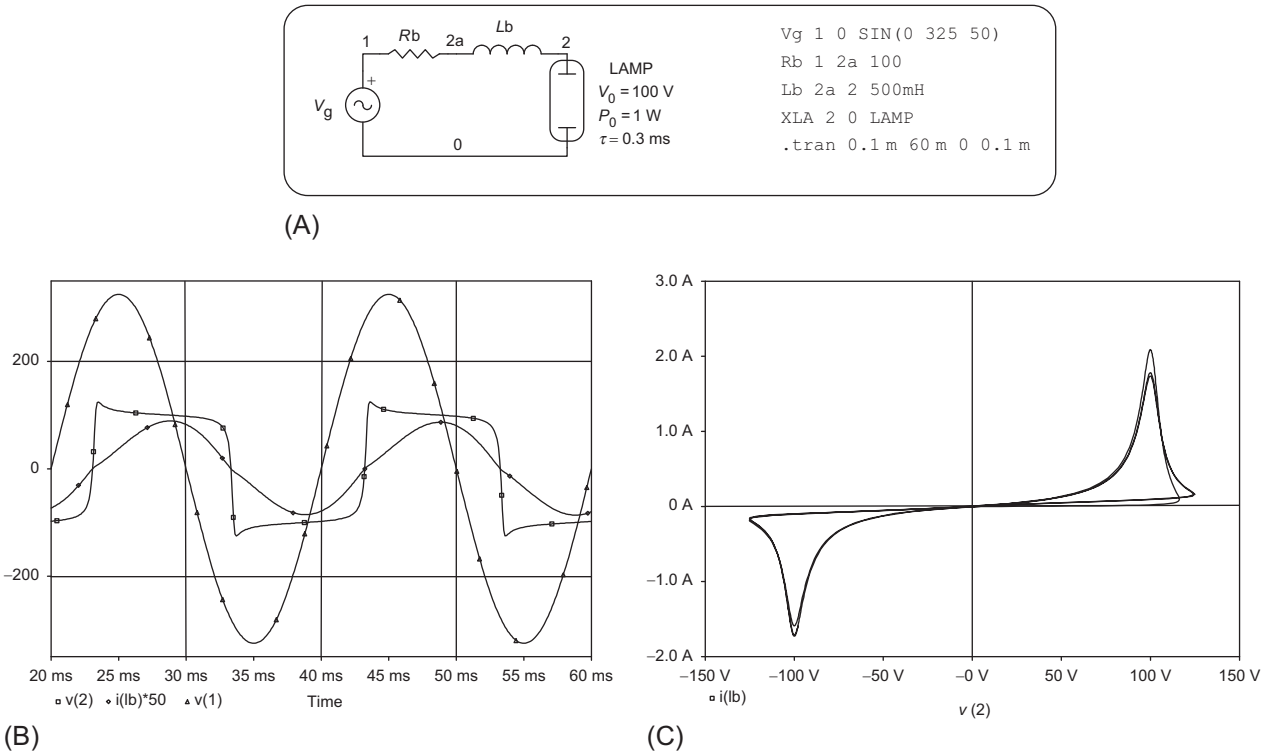

FIG. 21.17 (A) Example of simulation with an inductive ballast at low frequency, (B) operating waveforms, and (C) lamp *I*–*V* characteristics.

The current-fed push-pull inverter uses an input choke to obtain a dc input current with low current ripple. This current is alternatively conducted by the switches so that a parallel resonant tank can be supplied with a current square wave. Fig. 21.18 shows the equivalent circuit and the operating waveforms of a current-fed parallel resonant inverter.

The input current can be expressed as a Fourier series in the following way:

$$i_s(t) = \sum_{n=1,3,5} \ldots I_{S,n} \sin n\omega t = \sum_{n=1,3,5} \ldots \frac{4I_S}{n\pi} \sin n\omega t \qquad (21.5)$$

$I_{S,n}$ being the peak value of each current harmonic and I_S the DC input current of the inverter. The output voltage for each current harmonic is obtained by multiplying the input current $I_{S,n}$ by the equivalent parallel impedance $Z_{E,n}$, which is given below:

$$V_{0,n} = I_{S,n} Z_{E,n} = I_{S,n} \frac{1}{1/R + jn\omega C - j(1/n\omega L)} \qquad (21.6)$$

Usually, normalized values are employed in order to provide more general results. Then, the output voltage can be expressed as follows:

$$V_{0,n} = I_{S,n} Z_B \frac{1}{1/Q + jn\Omega - j(1/n\Omega)} \qquad (21.7)$$

where Z_B is the base impedance of the resonant tank, Q is the normalized load, Ω is the normalized frequency, and ω_0 is the natural frequency of the resonant circuit, given by

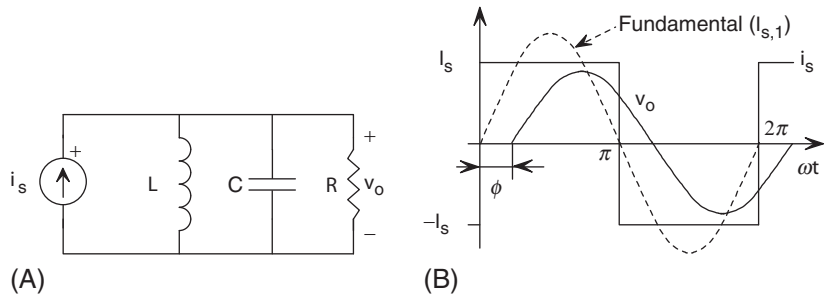

FIG. 21.18 (A) Equivalent circuit of a current-fed parallel resonant inverter and (B) operating waveforms.

$$Z_B = \sqrt{L/C}\ Q = R/Z_B\ \Omega = \omega/\omega_0 = \omega\sqrt{LC}\ \ \omega_0 = 1/\sqrt{LC} \tag{21.8}$$

From Eq. (21.7), the peak output voltage $V_{0,n}$ and phase angle φ_n can be obtained for each harmonic as follows:

$$V_{0,n} = I_{S,n}Z_B \frac{1}{\sqrt{1/Q^2 + (n\Omega - 1/n\Omega)^2}} \tag{21.9}$$

$$\varphi_n = -\tan^{-1}Q(n\Omega - 1/n\Omega) \tag{21.10}$$

The total harmonic distortion (THD) of the output voltage can be calculated as follows:

$$\text{THD}(\%) = \frac{\sqrt{\sum_{n=3,57} V_{0,n}^2}}{V_{0,1}} \cdot 100 \tag{21.11}$$

Based on these equations, the analysis and design of the current-fed resonant inverter can be performed. Normally, the circuit operates close to the natural frequency ω_0, and the effect of the high frequency harmonics can be neglected. To probe this, Fig. 21.19A obtained by plotting Eq. (21.11) illustrates the THD of the output voltage as a function of the normalized load and frequency. As can be seen, for values of Q higher than 1 and for operation close to the natural frequency ($\Omega = 1$), the THD is low, which means that the output voltage is nearly a sinusoidal waveform. However, for low values of Q, the output voltage tends to be a square waveform, and the THD tends to the value of about 48%, corresponding to the THD of a square waveform. Fig. 21.19B illustrates the normalized output voltage for the fundamental component.

As stated previously, when used as lamp ballast, the current-fed parallel resonant inverter operates at the natural frequency of the resonant tank to both ignite the lamp and limit the current at normal running. Neglecting the effect of high-order harmonics, the rms output voltage is given by the fundamental component and can be obtained using $\Omega = 1$ in Eq. (21.9) as follows:

$$V_{0(\text{rms})} \asymp V_{0,1(\text{rms})} = I_{S,1(\text{rms})}Z_B Q = \frac{4I_S R}{\pi\sqrt{2}} \tag{21.12}$$

In a current-fed resonant inverter, the dc input current I_S is supplied from a dc voltage source V_{in} with a series choke, as stated previously. Then, the dc input current can be obtained, assuming 100% efficiency, by equaling input and output power as follows:

$$P_{in} = V_{in}I_S = \frac{V_{0(\text{rms})}^2}{R} \tag{21.13}$$

And then,

$$I_S = \frac{V_{0(\text{rms})}^2}{V_{in}R} \tag{21.14}$$

Using Eq. (21.14) in Eq. (21.12) and solving for the output voltage,

$$V_{0(\text{rms})} = \frac{\pi\sqrt{2}}{4}V_{in} = 1.1\ V_{in} \tag{21.15}$$

As can be seen, when operating at the natural frequency, the rms output voltage is independent of the resonant tank load. The peak output voltage is equal to $\pi V_{in}/2$. This value is directly related to the peak voltage stress in the switches. For a full-bridge topology, as shown in Fig. 21.11C, this value is equal to the switch voltage stress. However, for the current-fed push-pull inverter, the voltage stress is twice this value, which is πV_{in}, due to the presence of the transformer. This gives a very high voltage stress for the switches in this topology, which is the reason why the current-fed push-pull is mainly used to implement low-input-voltage ballasts.

On the other hand, lamp starting voltage can vary from 5 to 10 times the lamp voltage in normal discharge mode. This

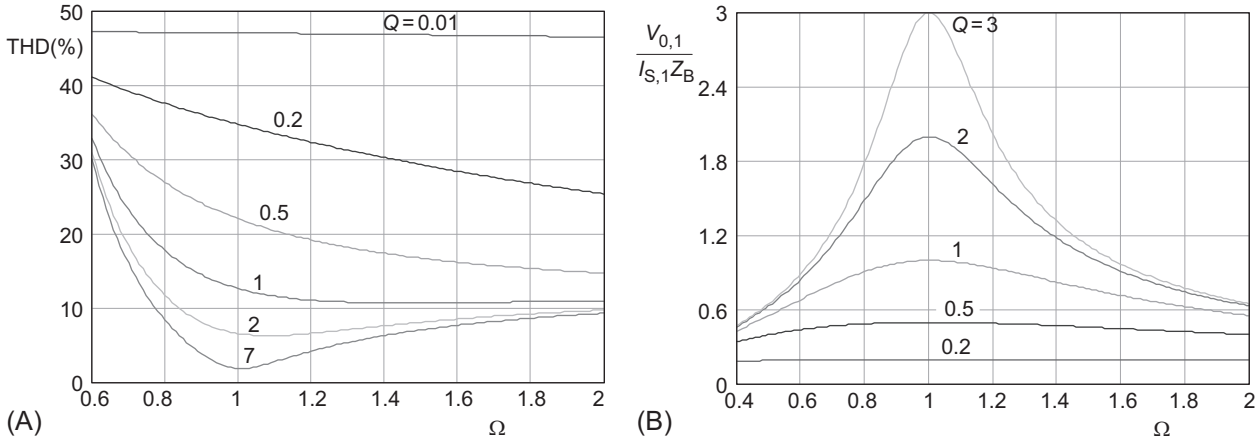

FIG. 21.19 Characteristics of the current-fed parallel resonant inverter: (a) THD and (b) fundamental output voltage.

makes the use of the current-fed parallel resonant inverter at constant frequency to both ignite the lamp and supply it at steady state difficult, since the output voltage is independent of the resonant tank load.

One solution to this problem is to ignite the lamp at the resonant tank natural frequency and then change the frequency to decrease the output voltage and output current to the normal running values of the lamp. This solution makes the use of extra circuitry to control the frequency necessary, normally in closed loop to avoid lamp instabilities, which increase the ballast cost.

Another solution, very often used in low-cost ballasts, is to design the parallel resonant tank to ignite the lamp and limit the lamp current in discharge mode by using an additional reactive element in series with the lamp. Normally, a capacitor is used to limit the lamp current in order to minimize the cost of the ballast. This solution is used in combination with the self-oscillating technique, which assures the operation at a constant frequency equal to the natural frequency of the resonant tank. Fig. 21.20A illustrates this circuit. Normally, the effect of the series capacitor is neglected, and the resonant tank is assumed to act as a sinusoidal voltage source during both ignition and normal operation, as shown in Fig. 21.20B. The high lamp starting voltage is obtained by means of a step-up transformer, which is the reason why typically a push-pull topology is used. If V_{in} is the dc input voltage and V_{ig} is the lamp ignition voltage, then the necessary transformer turn ratio is given by the following expression:

$$\frac{N_2}{N_1} = \frac{V_{ig}}{\pi V_{in}/2} \tag{21.16}$$

The rms lamp current in discharge mode can be approximated as follows:

$$I_{LA} = \frac{1.1\ (N_2/N_1)V_{in}}{\sqrt{R^2 + (1/2\pi f C_S)^2}} \tag{21.17}$$

where R is the equivalent resistance of the lamp. From Eq. (21.17), the necessary value of the series capacitor C_S, used to limit the lamp current to the nominal value I_{LA}, can be easily obtained.

Finally, Fig. 21.21A and B illustrates a typical ballast based on a current-fed resonant inverter and its equivalent circuit, respectively.

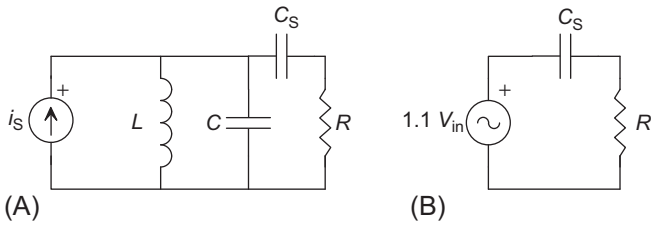

FIG. 21.20 (A) Typical parallel resonant circuit used to supply discharge lamps and (B) equivalent circuit.

21.4.2 Voltage-Fed Resonant Inverters

Some voltage-fed resonant inverters used to supply discharge lamps were previously shown in Fig. 21.12. Basically, they use two or more switches to generate a square voltage waveform. The different topologies are mainly given by the type of resonant tank used to filter this voltage waveform. There are three typical resonant tanks; their equivalent circuits are shown in Fig. 21.22. These circuits are the series-loaded resonant tank (Fig. 21.22A), the parallel-loaded resonant tank (Fig. 21.22B), and the series-parallel-loaded resonant tank (Fig. 21.22C). The typical operating waveforms are shown in Fig. 21.22D.

Similar to the current-fed resonant inverter, the input voltage can be expressed as a Fourier series in the following way:

$$v_s(t) = \sum_{n=1,3,5\ldots} V_{S,n} \sin\ n\omega t = \sum_{n=1,3,5\ldots} \frac{4V_S}{n\pi} \sin\ n\omega t \tag{21.18}$$

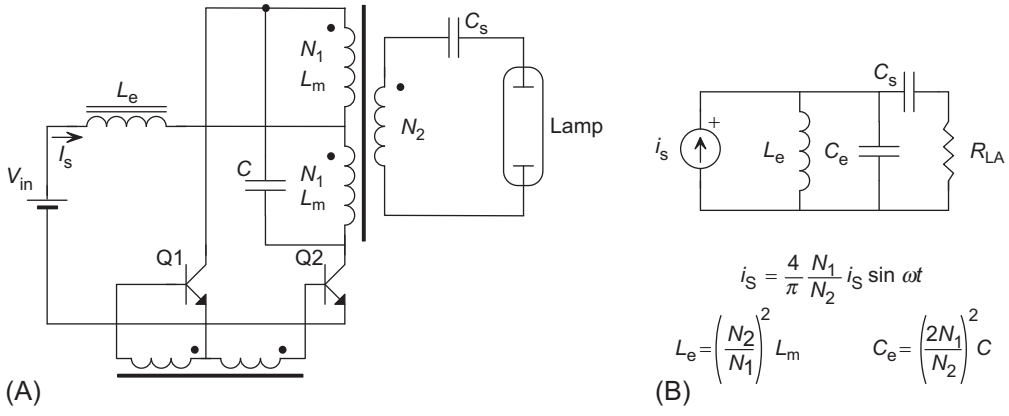

FIG. 21.21 (A) Self-oscillating current-fed push-pull electronic ballast and (B) equivalent circuit.

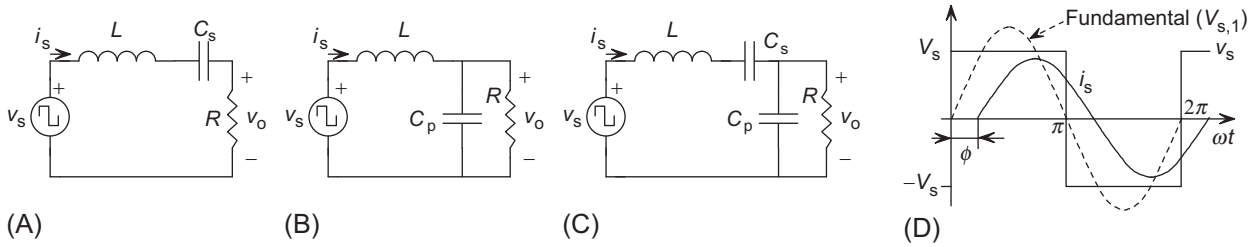

FIG. 21.22 (A–C) Equivalent circuits of voltage-fed resonant inverters and (D) typical operating waveforms.

$V_{S,n}$ being the peak value of each voltage harmonic and V_S the dc input voltage of the inverter. The same methodology as that used to analyze the current-fed resonant inverter will be used here to study the property of the three basic voltage-fed resonant inverters.

21.4.2.1 Series-Loaded Resonant Circuit

The output voltage corresponding to the n-order harmonic is easily obtained as follows:

$$V_{0,n} = V_{S,n} \frac{1}{\sqrt{1 + \frac{1}{Q_S^2}\left(n\Omega - \frac{1}{n\Omega}\right)^2}} \tag{21.19}$$

where Q_S and Ω are the normalized load and switching frequency given by the following expressions:

$$Q_S = R/Z_B = R(L/C_S)^{-1/2} \quad \Omega = \omega/\omega_0 = \omega\sqrt{LC_S} \tag{21.20}$$

Fig. 21.23A shows the THD of the series-loaded circuit, and Fig. 21.23B shows the fundamental output voltage, which is normally considered for design purposes.

In this circuit, the input and output currents are equal and can be calculated by dividing the output voltage by the load impedance. This current is also circulating through the inverter switches and therefore represents an important parameter for the design. Another important parameter is the phase angle of the input current, which defines the type of commutations in the inverter switches. For the fundamental harmonic, the phase angle of the current circulating through the resonant tank can be calculated as follows:

$$\varphi = -\tan^{-1}\frac{\Omega - 1/\Omega}{Q_S} \tag{21.21}$$

At the natural frequency (ω_0), the input voltage and current will be in phase, which means that there is no reactive energy handled by the circuit and all the input energy is transferred to the load at steady-state operation. For frequencies higher than ω_0, the current is lagged, and some reactive energy will be handled. In this case, the inverter switches will present ZVS [21]. For frequencies lower than ω_0, the current is in advance, and also some reactive energy will be handled. In this case, the inverter switches will present zero current switching (ZCS).

As can be seen in Fig. 21.23A, the THD is lower for the lower values of the normalized load and for frequencies close to the natural frequency of the resonant tank. For the higher values of Q_S, the THD tends to the value corresponding to a square wave. The output voltage is always lower than the input voltage, and for frequencies around the natural frequency, the circuit acts as a voltage source, especially for the high values of Q_S. This

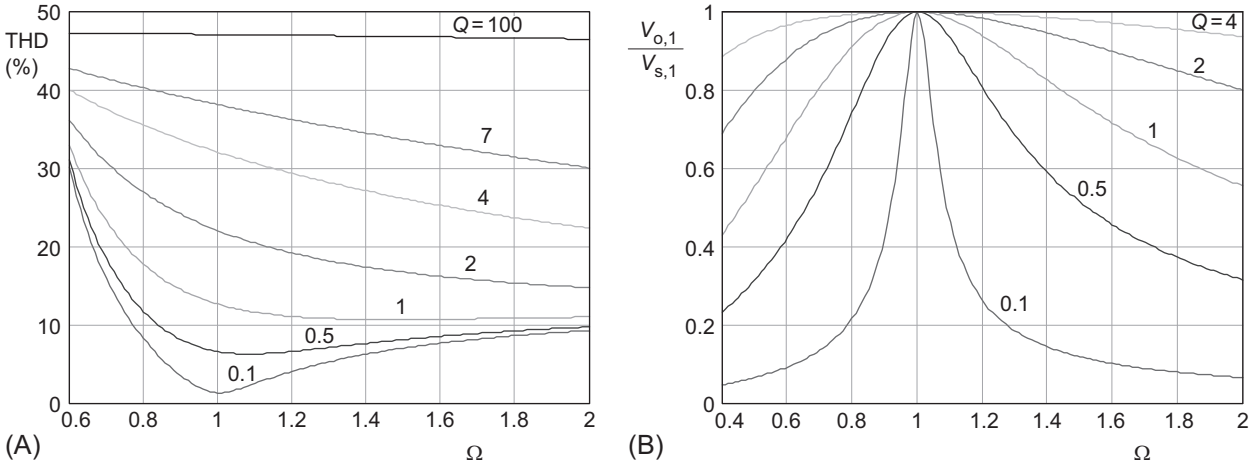

FIG. 21.23 Characteristics of series-loaded resonant inverter: (A) THD and (B) fundamental output voltage.

means that the lamp cannot be ignited and supplied in discharge mode, maintaining a constant switching frequency. This property is similar to that encountered for the current-fed resonant inverter. The use of step-up transformers is mandatory to achieve lamp ignition, especially for the low input voltages. In order to maintain the operating frequency constant, a series element will be necessary to limit the lamp current at normal discharge operation. A capacitor can also be used as expounded in the previous section. In summary, this circuit is mainly used in high input voltage and low-current applications, and it is not very frequently used to implement electronic ballasts.

21.4.2.2 Parallel-Loaded Resonant Circuit

In this circuit, the output voltage corresponding to the n-order harmonic is given by the following expression:

$$V_{0,n} = V_{S,n} \frac{1}{\sqrt{\dfrac{n^2\Omega^2}{Q_P^2} + \left(n^2\Omega^2 - 1\right)^2}} \tag{21.22}$$

where

$$Q_P = R/Z_B = R(L/C_P)^{-1/2} \quad \Omega = \omega/\omega_0 = \omega\sqrt{LC_P} \tag{21.23}$$

The THD and fundamental output voltage are shown in Fig. 21.24. This circuit has characteristics very much useful to implement electronic ballasts than the series-loaded resonant circuit. First, the THD of the output voltage around the natural frequency is in general quite lower than that of the series circuit. For the lower values of Q_P, the THD tends to a value of 12%, which corresponds to the THD of a triangular wave. As a result, the lamp voltage and current waveforms will be very similar to a sine wave, which is an adequate waveform to supply the lamp. Second, the frequency response of the output voltage (Fig. 21.24B) makes it possible to both ignite the lamp and limit the lamp current at steady state, maintaining a constant operating frequency. During ignition, the lamp shows a very high impedance, thus giving a high value of Q_P. Under these conditions, the parallel circuit can generate a very high output voltage, provided that the operating frequency is close to the natural frequency. Once the lamp is ignited, the normalized load Q_P decreases, and the circuit can limit the lamp current without changing the operating frequency. In fact, the parallel circuit operating close to the natural frequency acts as a current source for the load, as will be shown later. This is adequate to supply discharge lamps because it assures a good discharge stability, avoiding the lamp being easily extinguished by transitory power fluctuations.

The maximum value of the voltage gain shown in Fig. 21.24 can be calculated to be equal to $Q_P/\sqrt{1-1/4Q_P^2}$, and it appears at a frequency $\Omega_m = \sqrt{1-1/2Q_P^2}$. This means that a maximum is only present if Q_P is greater than $1/\sqrt{2} \asymp 0.71$. For the higher values of Q_P, the maximum gain can be approximated to Q_P, and the frequency of maximum gain can be approximated to the natural frequency ω_0.

The input current of the parallel resonant circuit is another important parameter to calculate the current handled by the inverter switches. Since the operating frequency is normally around resonance, only the fundamental component is considered. The value of this fundamental current and its phase angle can be obtained as follows:

$$I_{S,1} = \frac{V_{S,1}}{Z_B}\sqrt{\frac{1+Q_P^2\Omega^2}{\Omega^2 + Q_P^2\left(\Omega^2 - 1^2\right)}} \tag{21.24}$$

$$\varphi = \tan^{-1}\frac{-1}{\Omega Q_P} - \tan^{-1} Q_P\left(\Omega - \frac{1}{\Omega}\right) \tag{21.25}$$

The condition for the input voltage being in phase with the input current can be obtained by equaling Eq. (21.25) to zero.

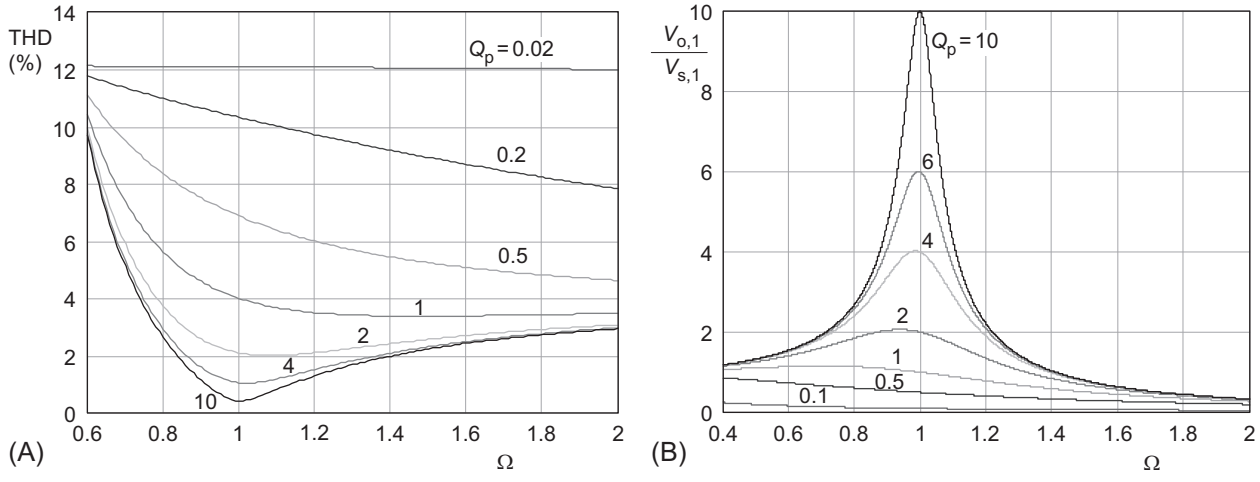

FIG. 21.24 Characteristics of parallel-loaded resonant inverter: (A) THD and (B) fundamental output voltage.

This gives a value of the normalized frequency, which is $\Omega_{\varphi=0}=\sqrt{1-1/Q_P^2}$. For a frequency greater than that value, the input current will lag the input voltage, and the inverter switches will present ZVS. For frequencies lower than that value, the current will be in advance, and zero current switching is obtained. The output voltage gain at that frequency is equal to Q_P.

Finally, it is very interesting to study the characteristic of this circuit for frequencies close to the natural frequency ω_0 ($\Omega=1$), since this is the normal region selected to operate for ballast applications. At this frequency, the output voltage gain is equal to Q_P, and then, the output current will be $V_{S,1}/Z_B$. This means that when operated at the natural frequency, the parallel circuit acts as a current source, whose value only depends on the input voltage. At the natural frequency, the input current is equal to $V_{S,1}\sqrt{1+Q_P^2}/Z_B$, and the phase angle is equal to $\tan^{-1}(-1/Q_P)$. The circuit is always inductive, with ZVS, and the phase angle decreases when Q_P increases, which means that less reactive energy is handled by the circuit.

21.4.2.3 Series-Parallel-Loaded Resonant Circuit

This circuit is also very widely used to implement electronic ballasts. The fundamental output voltage is given by the following expression:

$$V_{0,1}=V_{S,1}\frac{1}{\sqrt{\frac{1}{Q_{SP}^2}\left(\Omega-\frac{1-\alpha}{\Omega}\right)^2+\frac{1}{\alpha^2}\left(\Omega^2-1\right)^2}} \tag{21.26}$$

where

$$Q_{SP}=R/Z_B=R(L/C_E)^{-1/2}\qquad \Omega=\omega/\omega_o=\omega\sqrt{LC_E}$$
$$\alpha=C_E/C_P=1-C_E/C_S \tag{21.27}$$

and $C_E=C_SC_P/(C_S+C_P)$ is the series equivalent of the two capacitors present in this resonant circuit.

The fundamental input current and its phase angle are the following:

$$I_{S,1}=\frac{V_{S,1}}{Z_B}\left[\frac{1+\left(\Omega^2Q_{SP}^2/\alpha^2\right)}{\left(\Omega-(1-\alpha/\Omega)\right)^2+\left(Q_{SP}^2/\alpha^2\right)\left(\Omega^2-1\right)^2}\right]^{1/2} \tag{21.28}$$

$$\varphi=\begin{cases}\tan^{-1}\dfrac{-\alpha}{Q_{SP}\Omega}-\tan^{-1}\left(\dfrac{Q_{SP}}{\alpha}\dfrac{\Omega^2-1}{\Omega-((1-\alpha)/\Omega)}\right)+180^\circ \\ \quad \text{if}\quad \Omega<\Omega_C=\sqrt{1-\alpha} \\ \tan^{-1}\dfrac{-\alpha}{Q_{SP}\Omega}-\tan^{-1}\left(\dfrac{Q_{SP}}{\alpha}\dfrac{\Omega^2-1}{\Omega-((1-\alpha)/\Omega)}\right) \\ \quad \text{if}\quad \Omega\geq\Omega_C=\sqrt{1-\alpha}\end{cases} \tag{21.29}$$

Fig. 21.25 shows the characteristics corresponding to the THD of the output voltage and the fundamental output voltage for $\alpha=0.5$. As can be seen, the THD is also very low around the natural frequency, especially for the higher values of the normalized load Q_{SP}. Regarding the output voltage, this circuit acts as a parallel circuit around the natural frequency ω_0, with a maximum gain voltage of about Q_{SP}/α. Around the natural frequency of the series circuit given by L and C_S, $\omega_{0S}=\omega_0\sqrt{1-\alpha}$, the circuit acts as a series-loaded circuit with a maximum voltage gain equal to unity.

The series-parallel circuit can also be used to both ignite and supply the lamp at constant frequency, since it also acts as a current source at the natural frequency. Besides, this circuit allows to limit the ignition voltage by means of the factor α, thus avoiding sputtering damage of lamp electrodes. Also, the series capacitor can be used to block any dc component of the inverter square output voltage, as that existing in the asymmetrical half bridge. In summary, the series-parallel circuit combines the best features of the series-loaded and the

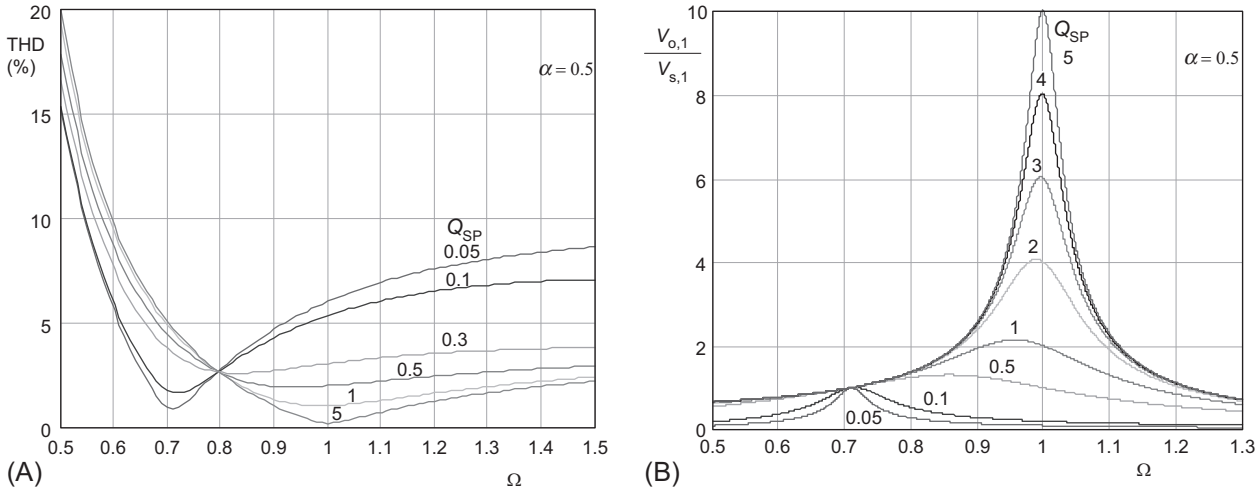

FIG. 21.25 Characteristics of series-parallel-loaded resonant inverter: (A) THD and (B) fundamental output voltage.

parallel-loaded; this is the reason why it is used widely to implement electronic ballasts.

When operated at frequency ω_0, the output voltage gain is equal to Q_{SP}/α, and then, the circuit acts as a current source equal to $V_{S,1}/\alpha Z_B$, which is independent of the load. As stated previously, this current source behavior is adequate to supply discharge lamps because it allows the lamp current to be limited all the time. The input current phase angle at this frequency is equal to $\tan^{-1}(-\alpha/Q_{SP})$, and the input current always lags the input voltage, thus showing ZVS operation.

Finally, the condition to have input current in phase with the input voltage can be obtained by equaling Eq. (21.27) to zero. This gives the following value:

$$Q_{SP,\varphi=0} = \frac{\alpha}{\Omega}\sqrt{\frac{\Omega^2-(1-\alpha)}{(1-\Omega^2)}} \tag{21.30}$$

Eq. (21.30) defines the borderline between the ZVS and the ZCS modes. The output voltage gain in this borderline can be obtained by using Eq. (21.30) in Eq. (21.26), and it is equal to $\alpha/\sqrt{\alpha(1-\Omega^2)}$.

21.4.3 Design Issues

The design methodology of a resonant inverter for discharge lamp supply can be very different depending on the lamp type and characteristics, inverter topology, design goals, etc. Some guidelines, especially focused for supplying fluorescent lamps with voltage-fed resonant inverters, are presented in this section to illustrate the basic design methodology.

A typical starting process for a hot-cathode fluorescent lamp is shown in Fig. 21.26. Initially, lamp electrodes are heated up to the emission temperature. During this phase, the inverter should assure a voltage applied to the lamp not high enough to produce sputtering damage in lamp electrodes, thus avoiding premature aging of the lamp. Once electrodes reach the emission temperature, the lamp can be ignited by applying the necessary starting voltage. Following this procedure, a soft starting is achieved, and a long lamp life is assured.

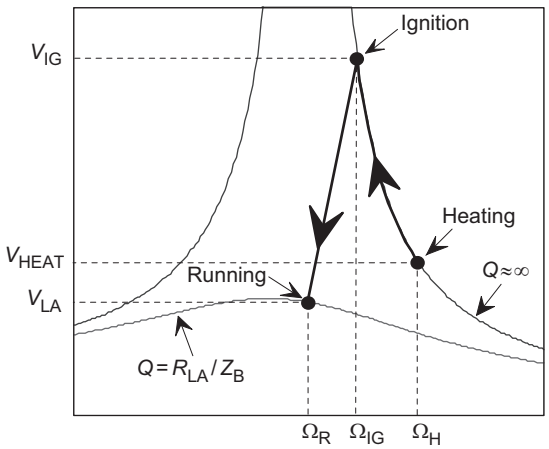

FIG. 21.26 Typical starting process of discharge lamps.

The best method to perform this soft starting is to control the inverter switching frequency, so that the lamp voltage and current are always under control. During the heating process, the operating frequency is adjusted to a value above the natural frequency of the resonant tank. In this way, the heating current can be adjusted to the necessary value, maintaining a lamp voltage quite lower than the starting voltage. Since normally MOSFET or bipolar transistors are used, the operation over the natural frequency is preferable because they provide ZVS, and the slow parasitic diodes existing in these transistors can be used. After a short period of time, the switching frequency is reduced until the starting voltage is obtained, and then, the lamp is ignited. Normally, the final operating point at steady-state operation is adjusted to be at a switching frequency equal to the natural frequency, so that a very stable operation for the lamp is assured.

Fig. 21.27A shows a fluorescent lamp supplied using a series-parallel-loaded resonant tank. The input data for the design are normally the fundamental input voltage V_S, the switching frequency in normal discharge operation (running) f_S, the lamp voltage and current at high frequency V_{LA} and I_{LA}, the electrode heating current I_H, the maximum lamp voltage during heating process V_H, and the lamp starting voltage V_{IG}.

The equivalent circuit during the heating and ignition phase is shown in Fig. 21.27B. The current circulating in this circuit is the electrode heating current, which can be calculated by using $Q_{SP}=\infty$ in Eq. (21.24):

$$I_H = \frac{V_S/Z_B}{\Omega - 1/\Omega} \tag{21.31}$$

where the electrode resistance has been neglected for simplicity. For a given heating current I_H, the necessary switching frequency is obtained from Eq. (21.31) as follows:

$$\Omega_H = \frac{V_S}{2Z_B I_H} + \sqrt{1+\left(\frac{V_S}{2Z_B I_H}\right)^2} \tag{21.32}$$

Regarding the heating voltage, it can be calculated from Eq. (21.26) using $Q_{SP}=\infty$, and the following value is obtained:

$$V_H = \frac{\alpha V_S}{\Omega_H^2 - 1} \tag{21.33}$$

The frequency at which the starting voltage is achieved can also be obtained using $Q_{SP}=\infty$ in Eq. (21.26), giving the following value:

$$\Omega_{IG} = \sqrt{1+\alpha\frac{V_S}{V_{IG}}} \tag{21.34}$$

Once the lamp is ignited, the new operation circuit is shown in Fig. 21.27C. Normally, the switching frequency is selected to be

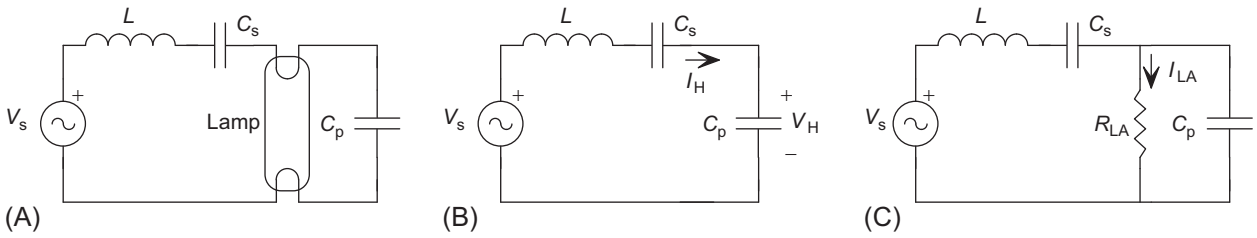

FIG. 21.27 (A) Fluorescent lamp supplied with a series-parallel circuit, (B) equivalent circuit during heating and ignition, and (C) equivalent circuit during normal discharge mode.

very close to the natural frequency, and the circuit characteristics can be obtained by using $\Omega = 1$. Thus, as stated previously, the circuit acts as a current source of the following value:

$$I_{LA} = \frac{V_S}{\alpha Z_B} \tag{21.35}$$

From this equation, the impedance Z_B needed to provide a lamp current equal to I_{LA} is easily obtained:

$$Z_B = \frac{V_S}{\alpha I_{LA}} \tag{21.36}$$

Using Eqs. (21.31)–(21.36), the design procedure can be performed as follows:

Step 1 Steady-state operation. Choose a value for the factor α; normally, a value of 0.8–0.9 will be adequate for most applications. From Eq. (21.36), calculate the value of Z_B for the resonant tank. Since the natural frequency is equal to the switching frequency, the reactive elements of the resonant tank can be calculated as follows:

$$L = \frac{Z_B}{2\pi f_S} \quad C_P = \frac{1}{2\pi f_S \alpha Z_B} \quad C_S = \frac{1}{2\pi f_S (1-\alpha) Z_B} \tag{21.37}$$

Step 2 Heating phase. From Eq. (21.32), calculate the switching frequency for a given heating current I_H. Then, calculate the value of the heating voltage V_H from Eq. (21.33).

Step 3 Check if the heating voltage is lower than the maximum value allowed to avoid electrode sputtering. If the voltage is too high, choose a lower value of α and repeat steps 1 and 2. Also, the maximum heating frequency can be limited to avoid excessive frequency variation. The lower the α, the lower is the frequency variation from heating to ignition, since the output voltage characteristics are narrower for the lower values of α.

The described procedure to achieve lamp soft ignition requires the use of a voltage-controlled oscillator to control the switching frequency. This can increase the cost of the ballast. A similar soft ignition can be achieved using the resonant circuit shown in Fig. 21.28. This circuit is very often used in self-oscillating ballasts, where the switches are driven from the resonant current using a current transformer [22].

In the circuit shown in Fig. 21.28, the PTC is initially cold, and capacitor C_{P1} is practically short-circuited by the PTC.

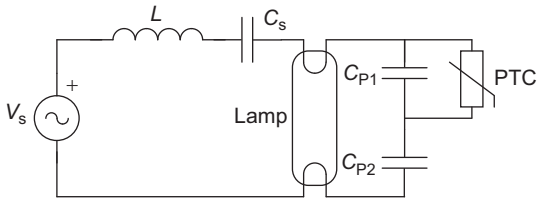

FIG. 21.28 Resonant circuit using a PTC resistor.

The resonant tank under these conditions is formed by L-C_S-C_{P2}, which can be designed to heat the lamp electrodes with a heating voltage low enough to avoid lamp cold ignition. Since the PTC is also heated by the circulating current, after a certain period of time, it reaches the threshold temperature and trips. At this moment, the new resonant tank is formed by L, C_S, and the series equivalent of C_{P1} and C_{P2}. This circuit can be designed to generate the necessary ignition voltage and to supply the lamp in normal discharge mode. Once the lamp is ignited, the PTC maintains its high impedance since the dominant parallel capacitor in this phase is C_{P1} (usually $C_{P1} \ll C_{P2}$).

21.5 High-Power Factor Electronic Ballasts

As commented in a previous section, when electronic ballasts are supplied from the ac line, an ac-dc stage is necessary to provide the dc input voltage of the resonant inverter (see Fig. 21.9). Since the introduction of harmonic regulations, as IEC 1000-3-2, the use of a full-bridge diode rectifier followed by a filter capacitor is no longer applicable for this stage due to the high harmonic content of the input current. Therefore, the use of an ac-dc stage showing a high input power factor (PF) and a low total harmonic distortion (THD) of the input current is mandatory. The inclusion of this stage can significantly increase the cost of the complete ballast, and therefore, the search for low-cost high-power-factor electronic ballasts is presently an important field of research.

Fig. 21.29A shows a first possibility to increase the input power factor of the ballast by removing the filter capacitor across the diode rectifier. However, since there are no low-frequency storage elements inside the resonant inverter, the

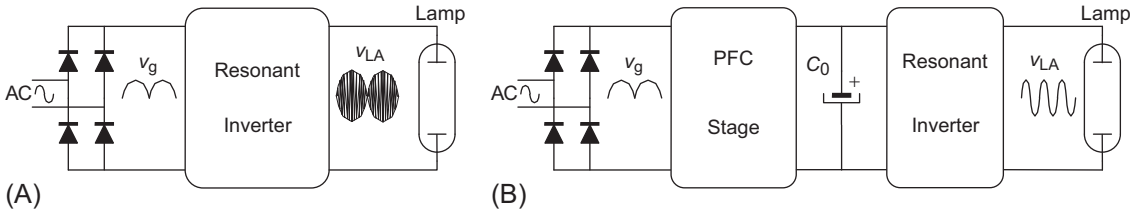

FIG. 21.29 High-power-factor ballasts.

output power instantaneously follows the input power, thus producing an annoying light flicker. Besides, the resulting lamp current crest factor is very high, which considerably decreases lamp life.

In order to avoid flicker and increase lamp current crest factor, continuous power must be delivered to the lamp. This can only be accomplished by using a PFC stage with a low-frequency storage element. This solution is shown in Fig. 21.29B, where capacitor C_0 is used as energy storage element. The main drawback of this solution is that the input power is handled by the two stages, which reduces the efficiency of the complete electronic ballast.

21.5.1 Harmonic Limiting Standards

The standards IEC 1000-3-2 and EN 61000-3-2 [23] are the most popular regulations regarding the harmonic pollution produced by electronic equipment connected to the mains. These standards are a new version of the previous IEC 555-2 regulation, and they are applicable to the equipment with less than 16 A/phase and supplied from low voltage lines of 220/380 V, 230/400 V, and 240/415 V at 50 or 60 Hz. Limits for equipment supplied from voltages lower than 220 V have not yet been established.

This regulation divides the electric equipment in several classes from class A to class D. Class C is especially for lighting equipment, including dimming devices; the harmonic limits for this class are shown in Table 21.4. As shown in Table 21.4, this regulation establishes a maximum amplitude for each input harmonic as a percentage of the fundamental harmonic component. The harmonic content established in Table 21.4 is quite restrictive, which means that the input current wave must be quite similar to a pure sine wave. For example, for a typical input power factor equal to 0.9, the THD calculated from Table 21.1 is only 32%.

TABLE 21.4 IEC 1000-3-2. Harmonic limits for class C equipment

21.5.2 Passive Solutions

A first possibility to increase the ballast power factor and to decrease the harmonic content of the input current is the use of passive solutions. Fig. 21.30 shows two typical passive solutions, which can be used to improve the input power factor of electronic ballasts.

Fig. 21.30A shows the most common passive solution based on a filter inductor L. Using a large inductance L, a square input current can be obtained, with an input power factor of 0.9 and a THD of about 48%. However, a square input waveform does not satisfy the IEC 1000-3-2 requirements, and then, it is not a suitable solution. The addition of capacitor C across the ac terminals can increase the power factor up to 0.95, but still, the standard requirements are difficult to fulfill.

A simple variation of this circuit is shown in Fig. 21.30B, where a parallel circuit tuned to the third harmonic of the line frequency is used to improve the shape of the line current. The input power factor obtained with this circuit can be close to unity.

A third possible solution, known as valley-fill circuit, is shown in Fig. 21.31A. The typical filter capacitor following the diode rectifier is split into two different capacitors that are alternately charged using three extra diodes. The addition of a small series resistor improves the power factor by about two points, maintaining a low cost for the circuit. An inductor in place of the resistor can also be used to improve the power factor but with a higher cost penalty. Fig. 21.31B shows the output voltage and input current of the valley-fill circuit. The main disadvantage of this circuit is the high ripple of the output voltage, which produces lamp power and luminous flux fluctuation and high lamp current crest factor.

Passive solutions are reliable, rugged, and cheap. However, the size and weight of these solutions are high, and their design to fulfill the IEC 1000-3-2 requirements is usually difficult. Therefore, they are normally applied in the lower power range.

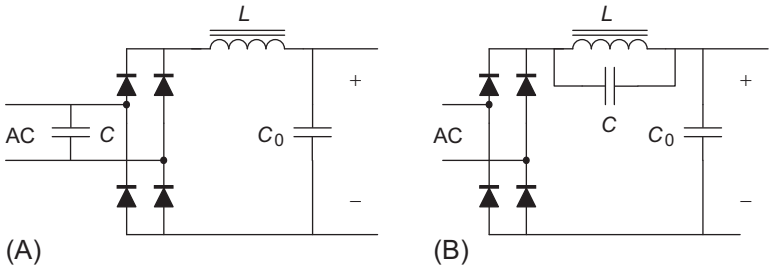

FIG. 21.30 Passive circuits to improve input power factor: (A) LC filter and (B) tuned LC filter.

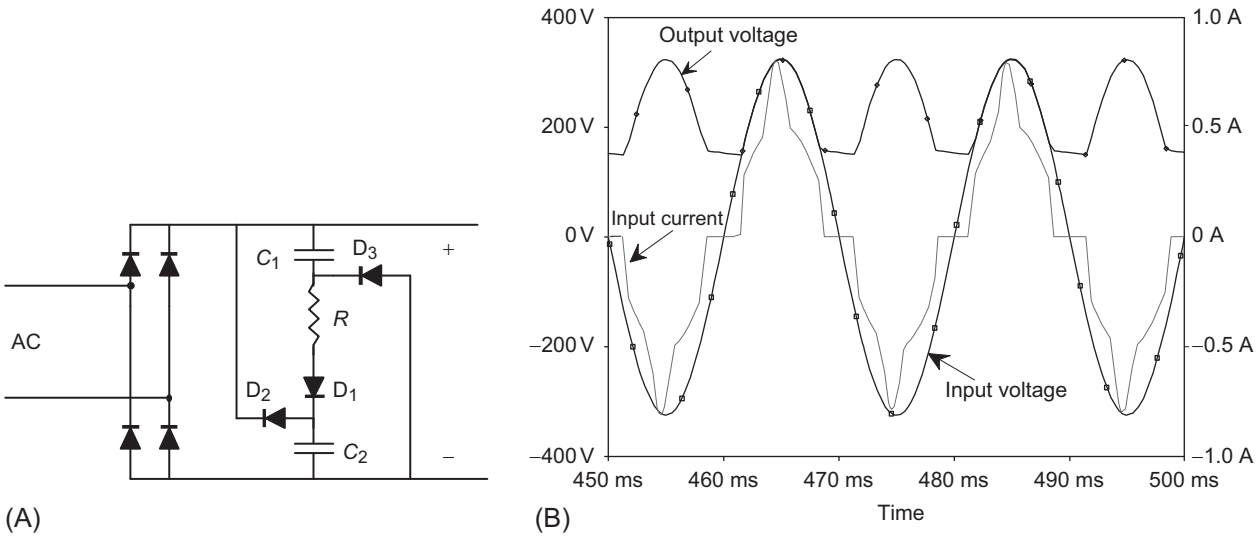

FIG. 21.31 Valley-fill circuit: (A) electric diagram and (B) waveforms.

21.5.3 Active Solutions

Active circuits are the most popular solutions to implement high-power-factor electronic ballasts. They use controlled switches to correct the input power factor and in some cases to include galvanic isolation via high-frequency transformers. Active circuits normally used in electronic ballasts operate at a switching frequency well above the line frequency and over the audible range.

Some typical active circuits used in electronic ballasts are shown in Fig. 21.32. Buck-boost and flyback converters shown in Fig. 21.32A and B, respectively, can be operated in discontinuous conduction mode (DCM) with constant frequency and constant duty cycle in order to obtain an input power factor close to unity [24].

Fig. 21.32C shows the boost converter, which is one of the most popular active circuits used to correct the input power factor of electronic ballasts [25–27]. If the boost converter is operated in DCM, an input power factor close to unity is obtained, provided that the output voltage is about twice the peak input voltage [25]. The main disadvantage of DCM operation, when compared with the CCM mode, is the high distortion of the input current (due to the discontinuous high-frequency current) and the higher current and voltage stresses

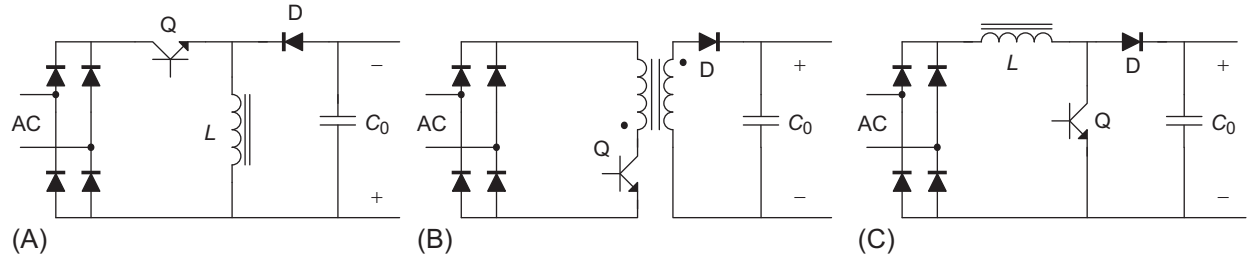

FIG. 21.32 Power factor correction circuits for ballasts: (A) buck-boost, (B) flyback, and (C) boost.

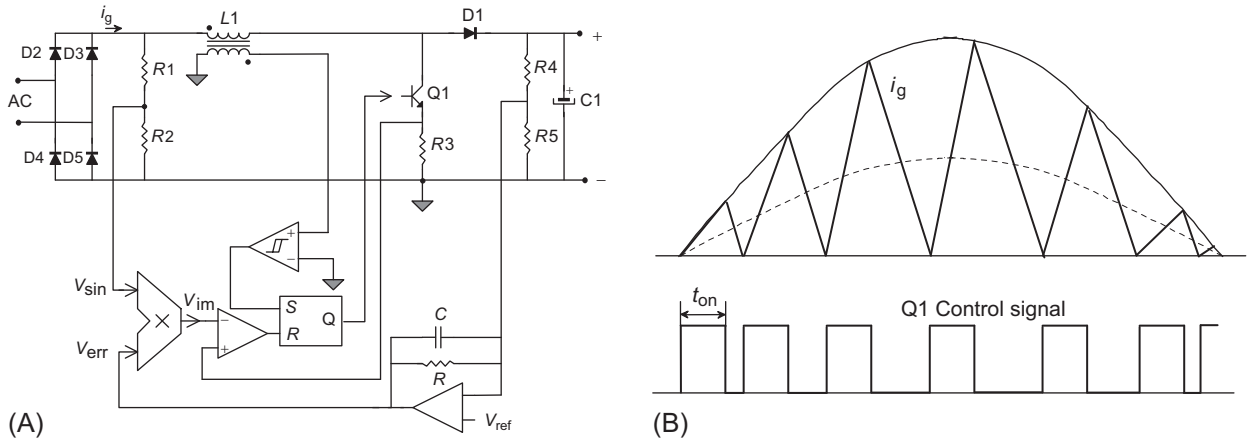

FIG. 21.33 (A) Boost power factor corrector with borderline control and (B) input current waveform.

in the switches. Therefore, the DCM operation is only used for the lower power range.

For the medium power range, the operation of the boost converter at the DCM-CCM borderline is preferred. In this solution, the on time of the controlled switch is maintained constant within the whole line period, and the switching frequency is adjusted to allow the input current to reach zero at the end of the switching period. The typical control circuit used and the input current waveform are shown in Fig. 21.33A and B, respectively. The inductor current is sensed using a resistor in series with the switch, and the peak inductor current is programmed to follow a sine wave using a multiplier. A comparator is employed to detect the zero crossing of the inductor current in order to activate the switch. Most IC manufacturers provide a commercial version of this circuit to be used for electronic ballast applications.

The boost circuit operating with borderline control provides a continuous input current, which is easier to filter. Besides, it presents low switch turn-on losses and low recovery losses in the output diode. The main disadvantages are the variable switching frequency and the high output voltage, which must be higher than the peak line voltage.

For the higher power range, the boost converter can be operated in continuous conduction mode (CCM) to correct the input power factor. The input current in this scheme is continuous with very low distortion and easy to filter. The current stress in the switch is also lower, which means that more power can be handled maintaining a good efficiency. The normal efficiency obtained with a boost circuit operating either in the DCM-CCM borderline or in CCM can be as high as 95%.

21.6 Applications

Electronic ballasts are widely used in lighting applications, such as portable lighting, emergency lighting, automotive applications, home lighting, and industrial lighting. They provide low volume and size, making it possible to reduce the luminaire size as well, which is a very interesting new trend in lighting design.

21.6.1 Portable Lighting

In this application, a battery is used as power source, and then, a low input voltage is available to supply the lamp. Examples are hand lanterns and backlightings for laptop computers. Typical input voltages in these applications range from 1.5 to 48 V. Therefore, a step-up converter is necessary to supply the discharge lamp, and then, electronic ballasts are the only suitable solution. Since the converter is supplied from a battery, the efficiency of the ballast should be as high as possible in order to optimize the use of the battery energy, thus increasing the operation time of the portable lighting. Typical topologies used are the class E inverter and the push-pull resonant inverter, obtaining efficiencies up to 95%.

21.6.2 Emergency Lighting

Emergency lightings are used to provide a minimum lighting level in case of a main supply cutoff. Batteries are employed to store energy from the mains and to supply the lamp in case of a main supply failure. A typical block diagram is shown in Fig. 21.34. An ac-dc converter is used as a battery charger to store energy during normal line operation. A control circuit continuously measures the line voltage and activates the inverter in case of a main supply failure. Normally, a minimum operating time of 1 h is required for the system in emergency state. Thus, the use of highly efficient electronic ballasts is mandatory to reduce the battery size and cost. Typical topologies used include class E inverters, push-pull resonant inverters, and half-bridge resonant inverters. Fluorescent lamps are mainly used in emergency ballasts, but high-intensity discharge lamps, such as metal halide lamps or high-pressure sodium lamps, are also used in some special applications.

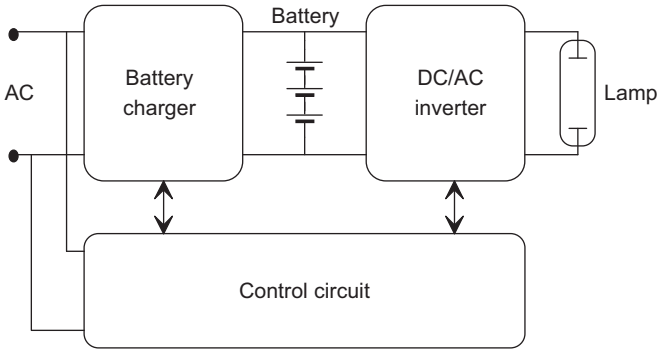

FIG. 21.34 Block diagram of an emergency lighting.

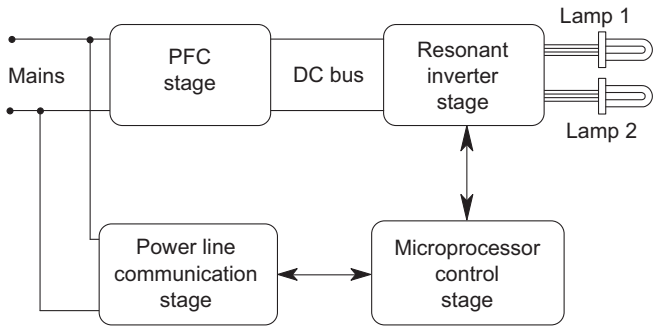

FIG. 21.35 Block diagram of a microprocessor-based lighting.

21.6.3 Automotive Lighting

Electronic ballasts are used in automotive applications such as automobiles, buses, trains, and aircrafts. Normally, a low-voltage dc bus is available to supply the lamps. These applications are similar to portable and emergency lightings previously commented. In modern aircrafts, a 120/208 V, 400 Hz, three-phase electric system is also available and can be employed for lighting. Fluorescent lamps are typically used for automotive indoor lighting, whereas high-intensity discharge lamps are preferred in the exterior lighting, for example, in automobile headlights.

21.6.4 Home and Industrial Lighting

Electronic ballasts, especially for fluorescent lamps, are also very often used in home and industrial applications. The higher efficiency of fluorescent lamps supplied at high frequency provides an interesting energy saving when compared with incandescent lamps. A typical application is the use of compact fluorescent lamps with the electronic ballast inside the lamp base, which can directly substitute an incandescent lamp reducing the energy consumption four or five times. A self-oscillating half-bridge inverter is typically used in these energy saving lamps, since it allows to reduce the size and cost. The power of these lamps is normally below 25 W.

Other applications for higher power include more developed ballasts based on a power factor correction stage followed by a resonant inverter. Hot-cathode fluorescent lamps are mostly used in these electronic ballasts. Also, with the development of modern HID lamps such as metal halide lamps and very-high-pressure sodium lamps (both showing very good color rendition), the use of HID lamps is being more and more frequent in home, commercial, and industrial lighting.

21.6.5 Microprocessor-Based Lighting

The use of microprocessors in combination with electronic ballasts is very interesting from the point of view of energy saving [28–30]. The inclusion of microprocessor circuits allows to incorporate control strategies for dimming, such as scheduling, task tuning, and daylighting [31]. Using these strategies, the achieved energy saving can be as high as 35%–40%. Another advantage of using microprocessors is the possibility of detecting lamp failure or bad operation, thus increasing the reliability and decreasing the maintenance cost of the installation. Most advanced electronic ballasts can include a communication stage to send and receive information regarding the state of the lighting to or from a central control unit. In some cases, communications can be performed via power line, thus reducing the installation costs. Fig. 21.35 shows the block diagram of a microprocessor-based electronic ballast.

22.1 Introduction

Wireless power transfer (WPT), in its general term, has been around us for decades in applications such as telemetry, satellite communications, and radio frequency identification (RFID) tags. Most of these applications transfer low amounts of power, in the range of microwatts to milliwatts, for data transfer. For higher-power applications, from few watts to several kilowatts, over moderate distances, the WPT has recently been the focus of the industrial developments. The most common method of high power WPT is through inductive coupling that was invented by Nikola Tesla more than a century ago. The recent developments in semiconductor industry for high frequency and high-power applications have paved the path for high-power inductive WPT improvements. Inductive WPT offers several benefits over the wired connection and is applied in numerous applications such as wearable electronics, health care, and automotive industry. This chapter starts by reviewing various methods of WPT, followed by the design and analysis of inductive WPT. The overall inductive WPT is studied step by step and component by component; therefore, it is recommended to refer to the references for detailed analysis and information.

22.2 Methods of Wireless Power Transfer

There are different methods to wirelessly transfer power between a source and a receiver. Each method has its own characteristics that are useful for certain applications. Here, the most common methods of wireless power transfer are briefly discussed.

Radio frequency waves. Radio frequency (RF) is the most common way of transmitting data as the waves can propagate through vacuum (Fig. 22.1A). RF waves can also be used to transmit power such as in microwave oven and in RF heater and welding machines. The operating principle of RF transmitting and receiving antennas is based on the interaction of electric and magnetic inductions determined by the full set of Maxwell's equations [1].

Optical link. Optical links use the light—in the ultraviolet, visible, and infrared regions of electromagnetic frequency spectrum—to transfer energy between source and receiver over long distances (Fig. 22.1B). The light-emitting source can be sun or power laser diodes for high power delivery and LED for data transmission [2]. The receiver unit is a light-sensitive device such as photovoltaic converter, solar cell, or photodiode. The optical link can be free space, air, fiber optics (it can be considered a wireless link due to the

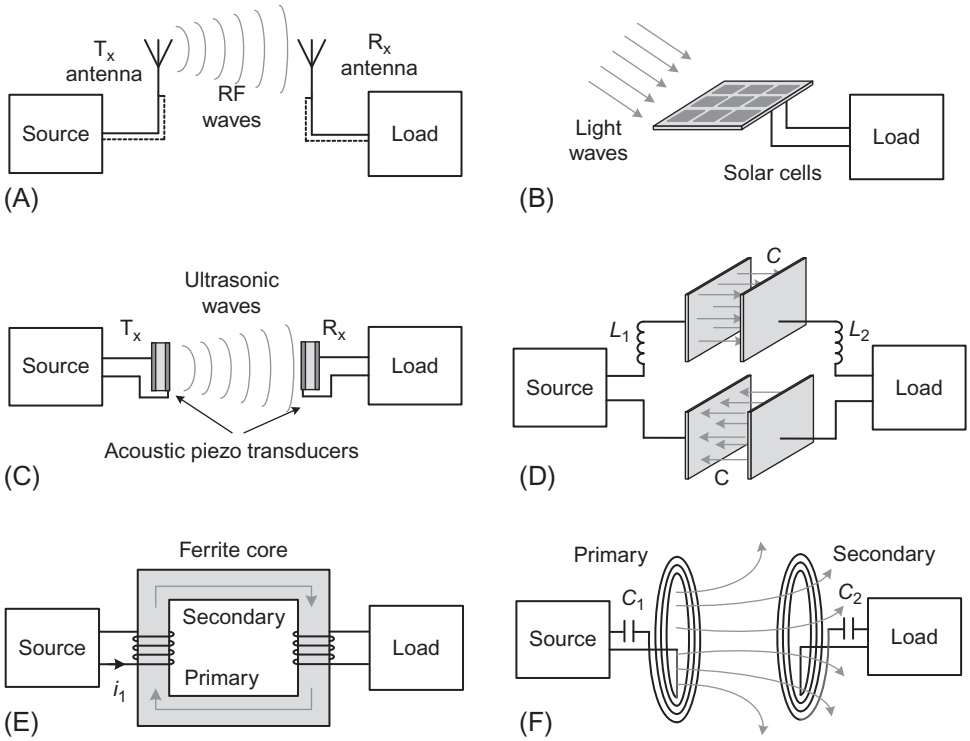

FIG. 22.1 Several methods of wireless power transfer. (A) WPT in radio-frequency waves, (B) solar radiation in optical WPT, (C) WPT using ultrasonic waves, (D) capacitive power transfer, (E) tightly coupled inductive power transfer, and (F) loosely coupled resonant inductive power transfer.

absence of conductive materials), etc. Although the optical links have been mostly used for data transmission, higher power in the form of solar and laser can also be transmitted [3]. One application is laser power transfer through optical fiber that has the advantage of electric isolation between the source and receiver.

Ultrasound. Ultrasonic waves propagate in a physical medium such as air, water, metal pipe, human tissue, etc., by exchanging in between kinetic and potential energies inside the medium (Fig. 22.1C). The ultrasound frequency is above the hearing limit of humans, about 20 kHz, and goes up to several megahertz. The ultrasound power delivery has been mostly applied in low power data transmission, nondestructive testing, remote sensing, and navigation systems [4]; however, higher power transfer for biomedical implants and consumer electronics has gained notable attention recently [5]. The ultrasound wave can be converted to electricity and vice versa, using piezoelectric crystal [6]. One of the advantages of ultrasound power delivery is the ability to travel long distances (depending on the attenuation in the link medium) and through the nontraditional curved power paths. In addition, the low propagation speed of ultrasound wave leads to a more achievable design of directional transceivers compared with RF waves.

Capacitive power transfer. Capacitive power transfer (CPT) uses time-varying electric field between capacitor electrodes to transfer power wirelessly (Fig. 22.1D). The coupling capacitance and the transferred power are limited to the available area and the minimum distance between the electrodes. The CPT has mostly been applied to low power and data transmission systems such as in biomedical implants, bioinstruments, integrated circuits, and the isolated power supply due to galvanic isolation of the source and receiver. The CPT can be implemented in different circuit topologies such as resonance to achieve higher power transfer with increased efficiency [7].

Inductive power transfer. Inductive power transfer (IPT) uses time-varying magnetic field between mutually coupled coils to transfer power wirelessly. As the amount of transferred power depends on the mutual coupling between the coils, IPT systems are divided into two categories, namely loosely and tightly coupled systems. In the tightly coupled systems, the coupling factor (coupling coefficient) is close to unity; therefore, the transferred power efficiency is quite high. A well-known application for tightly coupled systems is a power transformer (Fig. 22.1E). In loosely or weakly coupled systems, the coupling factor is quite low; depending on the application, it can range between 0.01 and 0.5. The main reasons for the low coupling coefficient are the large distance between the coupled coils compared with the coil sizes and/or the absence of high permeable magnetic path connecting them. The low coupling coefficient reduces the power transfer efficiency; therefore, the receiving coil needs to be resonated to increase the efficiency. This chapter is mainly focused on loosely coupled inductive WPT systems (Fig. 22.1F).

22.3 Inductive WPT System Applications

Inductive WPT systems are increasingly getting popular in applications where (a) the flexibility of relative movement between source and load is an advantage, (b) there is limited space for energy storage elements in the load, (c) there is limited access to the load side, and (d) cordless connection improves safety. Some applications that use inductive WPT include the following:

Consumer electronics. As the power density and usage of consumer electronic devices such as notebook, smartphone, and wearables keep increasing, the wireless power connection to the device is a significant advantage. The WPT in consumer electronics is a fast pace industry, and with several standards already in place, the time from product development to the market is short compared with health care and automotive sectors.

Health care. As medical therapies are getting more dependent on implantable electronics, WPT becomes a promising technology in health-care devices [8]. One such application is ventricular assist device (VAD) that circulates the blood inside the body as a pump. The use of inductive WPT eliminates the wire connection between the power source (outside the body) and the VAD (inside the body) [9], which is beneficial to the patient in many aspects.

Another benefit of WPT in electronic implants is the possible reduction or elimination of energy storage element in the implant. This leads to smaller size and lighter weight electronics that brings comfort to the patient. It also reduces the costs and risks associated with the replacement of the energy storage device inside the body. One such application is in retinal implants with the WPT device powering a chip implanted in the eye that (partially) restores vision to the patients with specific retinal diseases.

Electric vehicles. Wireless inductive charging for electric vehicles (EVs) is a step forward toward the mainstream adaptation of EVs as the main transportation systems. The EVs can get the wireless power while in motion (dynamic charging) [10] or in parked position (stationary charging). The dynamic charging can be applied by implementing numerous transmitter coils along the driving path, all connected to each other in parallel and fed by a single source [11]. This is currently most applicable for EVs with predetermined driving path such as electric busses. In the stationary charging, the EV gets the wireless power by having the receiver and transmitter coils aligned and stationary. Since a slight misalignment of the coils would drop the efficiency, specific coil arrangements or multiple coils can be used to make the WPT more tolerant to misalignment [12].

22.4 Resonant Inductive WPT System Design

22.4.1 System Components

Fig. 22.2 shows an inductive WPT system block diagram. The power source feeding the WPT system typically consists of AC-DC-AC (rectification-inversion) stages. The transmitter coil can be compensated to increase the overall system efficiency and reduce the volt-ampere rating of power source. However, this compensation (assuming loss-less) does not affect the magnetic link efficiency, η_{link}, defined from power source output up to the receiver rectification.

The power is transmitted from the source coil (transmitter) to the load coil (receiver) using Faraday's law of induction. Having the two mutually coupled coils, the higher the coupling coefficient between them, the higher the power transfer efficiency. The transmitter and receiver coils can be made up of various components. Magnetic core can be used to shape the flux path, increase the inductance, and enhance the coupling. Metallic shields can be used to reduce the high frequency magnetic fields around the system and reduce the electromagnetic interference (EMI). However, there will be eddy current losses inside the coil conductor and the metallic shield in addition to the magnetic core losses, which bring up the significance of efficient coil design in WPT systems. The high quality factor and highly coupled coils will be discussed in more details later in the chapter.

The wireless power is delivered to the load through the receiver coil, reactive compensation, and electronic rectification for DC loads. The link efficiency depends on the receiver coil compensation and the value of load resistance. The

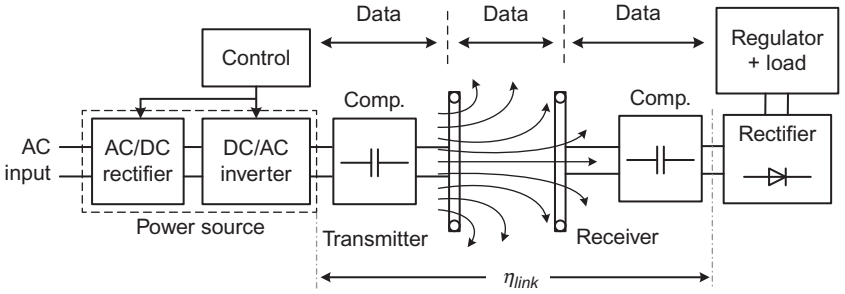

FIG. 22.2 Block diagram of a two-coil inductive WPT system.

feedback control electronic sensors are used in order to operate the WPT system reliably and efficiently.

22.4.2 Operating Field Region

The electromagnetic power transfer is based on Maxwell's equations. For a coil used in WPT system, the governing Maxwell's equations would have exact or simplified formats depending on the coil material, operating frequency, and the power transfer distance, leading the system to operate in one of the three near, Fresnel, or far-field regions [1] (Fig. 22.3). In the near-field region, the reactive energy storage is dominant, and there is negligible radiative power transfer. The transition from near-field in to far-field is through the Fresnel region where the reactive energy storage is still dominant but the coil has radiation patterns. At distances far from the coil, the system operation is in the far-field region where the coil has radiation patterns and the power is transmitted through radiation resistance, for example, RF WPT. In the far-field region, the coil electromagnetic fields are based on the exact set of Maxwell's equations.

For coils (antennas) much smaller than the electromagnetic wavelength λ, the transition happens from the near-field in to far-field, and the Frensel region may not exist. This boundary is typically defined at the distance $\lambda/2\pi$ from the coil. In the inductive WPT systems focused in this chapter, the frequency and the distance between the transmitter and receiver coils are small enough (up to several megahertz in frequency and from several millimeters to few meters in distance) for the system to remain in the near-field region.

22.4.3 Efficiency Equations

There are different methods for the analysis of inductive WPT systems depending on the complexity of the system and accuracy of the analysis. The most accurate method is mesh theory that uses the resistance, inductance, and capacitance matrices to solve for the voltage and current in the system: $\left(R + j\omega L + {}^{1}/_{j\omega C}\right) I = V$. This method is beneficial for systems with multiple coils (including transmitter, receiver, or repeaters), as the inductance matrix contains the self and mutual inductances for all the coils. The mutual capacitance (capacitive coupling) between the coils is neglected in inductive WPT systems, and the capacitance matrix is a diagonal matrix with compensating capacitors as the diagonal elements of that matrix.

The other method is based on the impedance reflection and is useful for simple WPT systems such as a two-coil system (can be modified to single transmitter/receiver system with repeaters/resonators in between). The advantage of this method is the ability to derive closed-form formulas for different variables such as voltage gain, input/output impedances, and link/system efficiencies. The focus of this section is on a typical two-coil inductive WPT system. Fig. 22.4 shows the equivalent circuit of the two-coil WPT system. The power dissipations inside the remote electronics, rectifier, regulator, and the load are included in the equivalent AC load R_L.

In the WPT system, the amount of impedance seen by the power source inverter is a key parameter that directly contributes to the inverter, link, and system efficiencies, along with voltage gain and maximum wireless power transfer. In order to find this impedance, all the impedances in the secondary side need to be reflected to the primary side. In a two mutually coupled coils with mutual inductance of M, the reflected impedance to the primary side is ${}^{(\omega M)^2}/_{Z_2}$ in which Z_2 is the total impedance in the secondary coil, $Z_2 = R_2 + R_L + Z_{L_2} + Z_{C_2}$. When the secondary side is resonant at $\omega = \omega_0$ (Z_2 is real), the reflective impedance to the primary side is pure resistive and is defined by

$$R_{ref1,2} = k^2 R_1 Q_1 \frac{Q_2 Q_L}{Q_2 + Q_L} \tag{22.1}$$

In the Eq. (22.1), k is the coupling coefficient between the primary and secondary coils, and R_1 and Q_1 are the primary coil resistance and quality factor, respectively. And Q_L is the secondary coil load quality factor that is defined by

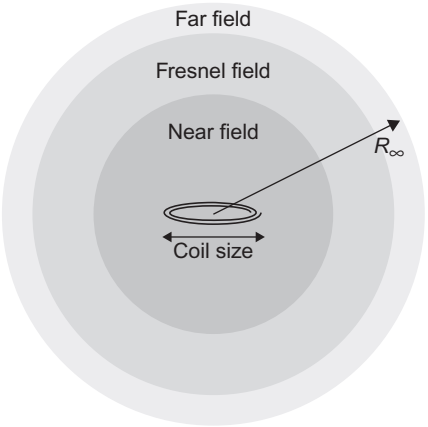

FIG. 22.3 The classification of electromagnetic field regions, inductive WPT systems are in the near-field region.

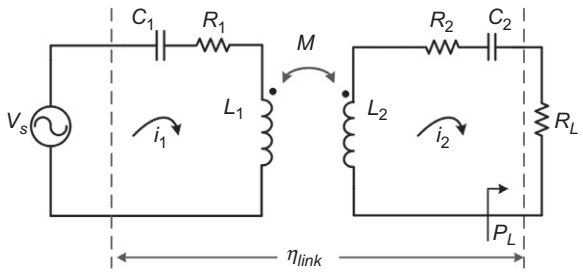

FIG. 22.4 A two-coil inductive WPT system equivalent circuit.

$Q_L = {}^{\omega_0 L_2}/_{R_L}$. Using the reflected impedance approach, the link efficiency is then defined by

$$\eta_{link} = \frac{R_{ref1,2}}{R_1 + R_{ref1,2}} \times \frac{R_L}{R_2 + R_L} \tag{22.2}$$

Eq. (22.2) is valid for both resonant and nonresonant secondary coils. In order to increase the link efficiency, the transmitter side efficiency that is the first term in Eq. (22.2) needs to be maximized by increasing the reflected resistance. As the reflected resistance is limited by the low coupling factor in weakly coupled inductive systems, resonating the secondary tank helps increasing the reflected resistance. This is the main reason to resonate the secondary side to increase the link efficiency.

There are three common optimization objectives for inductive WPT system design [13]. First, increasing the link efficiency that is the objective used in this chapter. Second, desensitizing the link gain versus coupling factor k variations. For example, in a bell-shaped link gain versus k, the maximum gain that corresponds to $k_{critical}$ has the least sensitivity to k variations. The disadvantage of this method is that the theoretical limit for the link efficiency is reduced. Third, stagger tuning that is the combination of the first two objectives to have higher limits for link efficiency while the link gain is not very sensitive to coupling factor changes.

The two-coil inductive WPT system, in its basic configuration, can have six different compensation topologies depending on the type of resonance in the primary and secondary coils (Fig. 22.5). The secondary coil is assumed to be resonated at $\omega = \omega_0$ in series or parallel. The series-resonant secondary has current output type and is suitable for small values of R_L. The parallel-resonant secondary, in the other hand, has voltage output type and is suitable for large loads. The advantage of parallel-resonant secondary is that the coil parasitic capacitance can be included in the compensating capacitor in parallel. The disadvantage of parallel resonance is that resonant frequency depends on the value of R_L.

The primary coil can be resonated (series or parallel) or nonresonated as it does not affect the link efficiency η_{link}. The series-resonant primary requires high-current and low-voltage output from the switched-mode power supply FETs, while the parallel resonant requires high-voltage and low-current output. High values of current increase the FET driver losses, and high voltages increase the FET capacitive losses. A combination of series- and parallel-resonant primary coil can be implemented to operate the system at high efficiencies[13]. Fig. 22.5 shows the different primary and secondary compensation topologies. In all these topologies, the system operating frequency is at $f = f_0$. The power supply output may not be pure sinusoidal; however, the power is transferred to the secondary only at fundamental frequency f_0. The other harmonics do not contribute to power transfer, but they increase the losses in the primary side.

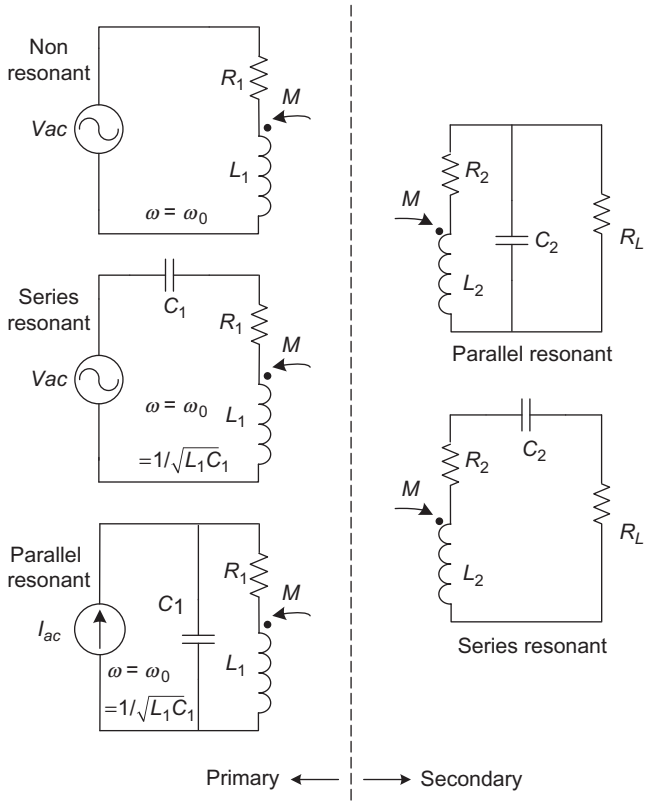

FIG. 22.5 Six different compensation topologies for primary and secondary sides of inductive WPT system.

Table 22.1 shows a summary of the key system parameters for a two-coil WPT system including the resonance frequency, reflected impedance to the primary side, load quality and dissipation factors, and link efficiency. Not to mention that the above-mentioned parameters do not depend on the primary coil compensation topology. In addition, the maximum link efficiency has the same equation for both the series- and parallel-resonant secondary coil.

It is observed from the Table 22.1 that the link efficiency η_{link} is a function of load factor α and $k^2Q_1Q_2$; and, $\eta_{link-max}$ is only a function of $k^2Q_1Q_2$. Fig. 22.6 shows the link efficiency of a two-coil inductive WPT system with a resonant (series or parallel) secondary side. For a fixed $k^2Q_1Q_2$, there is a load factor α that maximizes the link efficiency. The maximum link efficiency increases by increasing $k^2Q_1Q_2$, meaning that in inductive WPT systems, increasing not only the coupling factor but also the coil quality factors boost the efficiency.

In inductive WPT systems, the coupling factor is typically small, that is, in the range of 0.01–0.5. The low coupling factor leads to small values of impedance being reflected to the primary side. This brings the power supply close to unloaded operation mode at which its dissipation dominates the total power dissipated in the primary coil and transferred to the secondary side. Therefore, in loosely coupled systems, it is essential to optimize for the whole system efficiency by including the

TABLE 22.1 Inductive WPT system parameters for series- and parallel-resonant secondary

Secondary compensation	Series resonant	Parallel resonant
Resonance frequency	$\omega_0 = \frac{1}{\sqrt{L_2 C_2}}$	$\omega_0 = \sqrt{\frac{1}{L_2 C_2} - \frac{1}{R_L^2 C_2^2}}$
Load quality (Q)/dissipation (D) factors	$Q_L = \frac{\omega_0 L_2}{R_L} = \frac{1}{\omega_0 C_2 R_L}$	$D_L = \omega_0 R_L C_2$
Reflected resistance to primary	$R_{ref} = k^2 R_1 Q_1 \frac{Q_2 Q_L}{Q_2 + Q_L}$	$R_{ref} = k^2 R_1 Q_1 \frac{Q_2 D_L}{Q_2 + D_L}$
Reflected reactance to primary	$X_{ref} = 0$	$X_{ref} = 0$
Load factor	$\alpha = \frac{Q_L}{Q_2}$	$\alpha = \frac{D_L}{Q_2}$
Link efficiency	$\eta_{link} = \frac{k^2 Q_1 Q_2}{\left(1 + k^2 Q_1 Q_2 \frac{\alpha}{\alpha+1}\right)} \frac{\alpha}{(\alpha+1)^2}$	$\eta_{link} = \frac{k^2 Q_1 Q_2}{\left(1 + k^2 Q_1 Q_2 \frac{\alpha}{\alpha+1}\right)} \frac{\alpha}{(\alpha+1)^2}$
Maximum link efficiency	$\eta_{link-max} = \frac{k^2 Q_1 Q_2}{\left(1 + \sqrt{1 + k^2 Q_1 Q_2}\right)^2}$	$\eta_{link-max} = \frac{k^2 Q_1 Q_2}{\left(1 + \sqrt{1 + k^2 Q_1 Q_2}\right)^2}$

power supply, magnetic link, and also secondary side remote electronics.

22.5 WPT Systems With Multiple Coils

In WPT systems, there can be multiple coils in the transmitter, receiver, or in between them that help extend the use of WPT to practical applications. Here, the most common types of multiple-coil inductive WPT systems are reviewed, discussing their applications, (dis)advantages, and challenges.

22.5.1 Single Transmitter and Receiver With Multiple Coils in Between

The single transmitter and receiver WPT structure can include one, two, or more repeaters (resonators) in between. There are different applications that implement such structures. One application is to transmit power to large distances using repeaters along the path or even transmit power along a curved path. The other application is to have the repeater tightly coupled to either the transmitter or the receiver [14] (three-coil WPT, Fig. 22.7A), similarly, two repeaters in a four-coil WPT [15] (Fig. 22.7B). There are two main reasons for such configurations: (a) to have more degrees of freedom to maximize the efficiency and desensitize the link gain versus coupling factor without scarifying one objective for the other as was discussed earlier in the chapter and (b) to have the highly coupled transmitter-repeater or repeater-receiver coils act as practical and efficient impedance matching elements in both the source and load sides.

22.5.2 Multiple Transmitters and Single Receiver

The applications that implement multiple transmitter coils and a single receiver are mainly classified into two areas, one is dynamic WPT and the other is misalignment tolerant systems. The dynamic WPT systems transfer the power wirelessly while the receiver is in motion. A known example is EV dynamic charging in which multiple transmitter coils are placed along

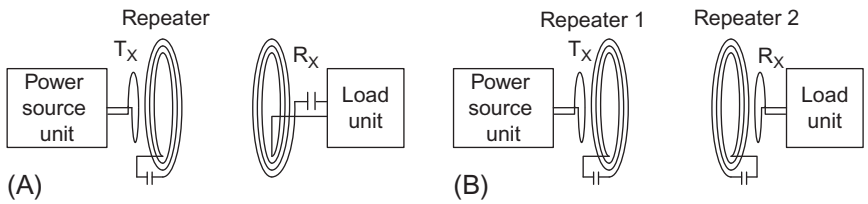

FIG. 22.7 Three-coil and four-coil WPT structures. (A) Three-coil WPT and (B) four-coil WPT.

the driving path and the receiver coil is placed in the moving vehicle. The challenge of such systems is to efficiently power the transmitter coils. A simple method is to have a power supply for each transmitter, and the power is transferred to the receiver by sensing it when it is aligned to it. The drawback of this method is the use of numerous power supplies. The other method is to have a long transmitter pad along the vehicle driving path. The disadvantage of this method is that only a portion of the coil transmits power while all of it is dissipating power. A way to solve these problems is to have multiple transmitters coils connected in parallel to one power supply. The current flows in a coil that is aligned with the receiver coil using reflected impedance while there is no current flowing in the other transmitter coils [11] (Fig. 22.8).

The other application with multiple transmitter coils is to have a misalignment tolerant system. As the coupling (and so the efficiency) of a two mutually coupled coils drops sharply by a slight misalignment between them, implementing multiple transmitter coils can increase this tolerance [12]. Multiple transmitter coils can also be used to provide a uniform magnetic field across a surface area giving the receiver the freedom of movement over that area [16].

22.5.3 Single Transmitter and Multiple Receivers

In some WPT applications, multiple receivers need to get the power simultaneously from a single transmitter pad (Fig. 22.9). The amount of power transferred to each receiver is linearly related to the resistance it reflects to the transmitter. In such systems, the first challenge is that the change of power transfer to one receiver could affect the amount of power transfer to other receivers. To avoid this, constant-current-flow topologies such as LCL in the transmitter coil are required.

With the transmitter coil having a constant current, power sharing to the receivers can be implemented using dynamic (active) tuning in each receiver side. The dynamic tuning can be implemented using L-C network [17], standard boost [18], or tristate boost [19]. In the L-C network method, a discrete matrix of L and C components is actively switched to control the reflected impedance to the transmitter side. The standard boost method controls the active power transfer to the receiver by changing the reflected resistance to the transmitter coil. Similarly, the tristate boost controls the active power flow, but also, the reactive power flow to the receiver can be controlled in case of detuning. The tristate boost has an extra degree of freedom compared with standard boost by shorting the inductive energy in boost (freewheeling).

One of the challenges in multiple-receiver WPT systems is the magnetic cross coupling between the receivers when they are in close proximity to each other (Fig. 22.9). The cross coupling would change the expected power transfer to the receivers and impose system performance issues. One method to reduce the cross coupling is to use multiresonant WPT system in which each receiver is resonant at one of the transmitter carrier frequencies [20].

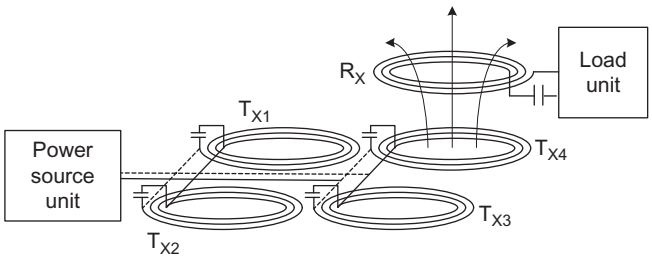

FIG. 22.8 A dynamic WPT structure with parallel-connected transmitter coils.

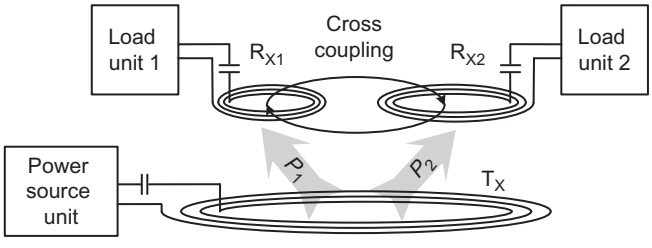

FIG. 22.9 Single transmitter coil WPT with multiple receivers.

22.6 A Glance Into WPT Power Source Converter

In weakly coupled inductive powering applications, the design of transmitter coil power converter is directly linked to magnetic link design and therefore needs to be part of the whole WPT system optimization. The main reason is due to the weak coupling, as the amount of reflected resistance to the transmitter coil is quite small, the converter operates close to freewheeling. And large amount of current is needed to flow in the coil to generate the required magnetic field and power.

The choice of transmitter coil power converter depends on the WPT application, power level, and operating frequency. For example, in EVs, the amount of power required to wirelessly charge the battery can range from 3.3 kW up to several tens of kilowatts, with frequency ranges from 20 kHz up to few hundreds of kilohertz. For such power and frequency levels, highly efficient AC-AC power converters such as full-bridge AC-DC rectifier and DC-AC inverter can be used to drive the transmitter coil. These power converters have been well stablished in the past few decades in terms of efficiency, reliability, and cost.

An important benefit of inductive WPT is in applications with small size and medium to high power requirements. As the magnetic link size reduces, the reflected resistance to the transmitter coil gets reduced as well. To compensate for this reduction, the operating frequency needs to increase to keep

the power level up. For example, in electronic devices such as phones, wearables, and laptops, the power rating can range from 1 W up to about few hundred watts. For inductive WPT in the megahertz frequency region, the operating frequency is typically bound to industrial, scientific, and medical (ISM) band of 6.78, 13.56 MHz, and so on. The power converter design in the megahertz region is critical as the dynamic losses increase in the FETs. There are several typically used DC-AC power inverters in the megahertz frequency range such as classes A, B, AB, C, D (ZCS and ZVS), and E. In this section, the focus is on switched-mode class-D and class-E power inverters as they deliver highest efficiencies of all the classes [21,22].

22.6.1 Class-D Inverter

Class-D inverter has a voltage output characteristic that is good to feed series-resonant transmitter coil. The resonance is not a critical requirement for class-D inverter although it increases the current for a fixed voltage. And the inverter can power resistive, inductive, and capacitive loads [23]. Fig. 22.10 shows the schematic of the class-D inverter with ideal waveforms. At resonance, the impedance seen by the inverter is the transmitter coil resistance R_1, in addition to the reflected resistance from the receiver side R_{ref}. In weakly coupled WPT systems, the R_{ref} is very small and can bring the inverter to the freewheeling operation. At this condition, the static conduction losses in the FETs dominate both the power dissipated in the transmitter and transferred to the receiver ($R_{on} > R_1 + R_{ref}$).

The class-D output voltage is square wave and fixed, independent of the load or coupling variations. Only the fundamental harmonic of current (at receiver coil resonance ω_0) contributes to the wireless power transfer, and the other harmonics (although small as are blocked by the resonance) cause dissipation in the transmitter coil. For moderately large transmitter coil loaded quality factor ($Q_{1L} = \dfrac{\omega_0 L_1}{R_1 + R_{ref}} > 20$), the coil current would be close to sinusoidal, operating at its series resonance frequency that is also ω_0.

One of the challenges of class-D inverter in the megahertz frequency range is the switch output capacitive losses during S_2 turn-on. A solution is to have the inverter output current lag the output voltage so it can self-commute to zero value during S_2 turn-on (ZVS). To do so, one method is to have the impedance seen by the inverter to be slightly inductive by operating above the transmitter coil resonance frequency ($\omega L_1 - \dfrac{1}{\omega C_1} = \omega L_{eff} > 0$) (Fig. 22.11). Note that the receiver coil is resonant at the operating frequency. Another way to provide lagging output current while not shifting the frequency from the transmitter coil resonance frequency is to add an inductive element L_{sh} in parallel to the inverter output [24] (Fig. 22.12). The L_{sh} provides the negative current required for the V_{sw} to self-commute to zero during S_2 turn-on (ZVS).

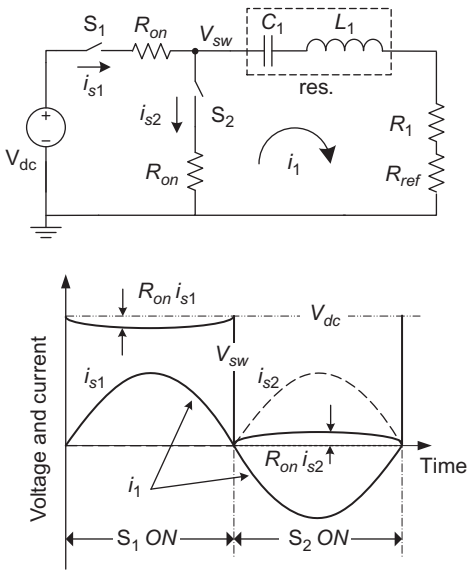

FIG. 22.10 Class-D inverter with ideal waveforms.

22.6.2 Class-E Inverter

The series-resonant transmitter coil (as for class-D) requires high amount of current that increases FET gate driver losses. The parallel-resonant coil, in the other hand, reduces the current rating of the switches by circulating it through the resonant tank. However, it produces high voltages across the switches that increase the FET output capacitive losses. A combination of series- and parallel-resonant transmitter coil would take advantage of low voltage rating of series-resonant and low current rating of parallel-resonant coil. Class-E

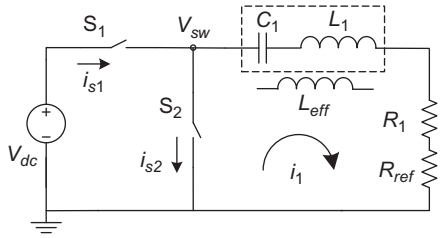

FIG. 22.11 Class-D ZVS operating above the primary coil resonance frequency.

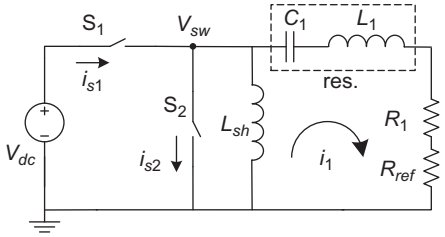

FIG. 22.12 Class-D ZVS with additional inductor in parallel to the switch output.

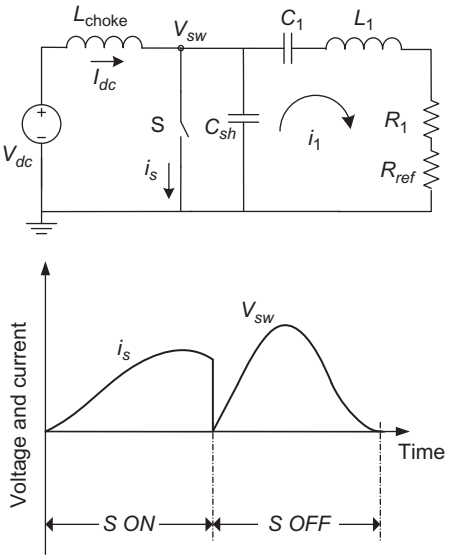

FIG. 22.13 Class-E inverter with ideal waveforms.

inverter satisfies these conditions with doubled-tuned output circuit [25]. Fig. 22.13 shows the class-E inverter with ideal waveforms. The inverter operates between the transmitter series resonance frequency and the one of transmitter in parallel with the C_{sh}.

An advantage of class-E compared with class-D with ZVS is that the output voltage slope approaches zero during the S turn-on and makes class-E generally more efficient than class-D. For the switch voltage and its slope to be zero at switch turn-on, it is a function of L_{choke}, C_{sh}, $R_1 + R_{ref}$, and the oscillations in the C_{sh}-C_1-L_1 tank during switch turn-off. This makes the class-E inverter more complicated to design and prone to nonoptimum operation when coupling factor and load vary, which are common characteristics of WPT systems [22].

22.7 Efficient Magnetic Link Design

Earlier in the chapter, it was shown that the maximum link efficiency $\eta_{link-max}$ is a function of $k^2Q_1Q_2$ in which k is the coupling factor between the transmitter and receiver coils with quality factors of Q_1 and Q_2, respectively. To enhance the link efficiency, not only the coupling factor needs to increase, but also the coil quality factors should improve. This section's focus would be on the methods to increase the coupling and quality factors.

22.7.1 Effect of Link Dimension

The magnetic design of inductive WPT system includes the design of link dimensions, coil shape, placement, and the type of material and conductor used in them. The coupling factor between the transmitter and receiver coils, with

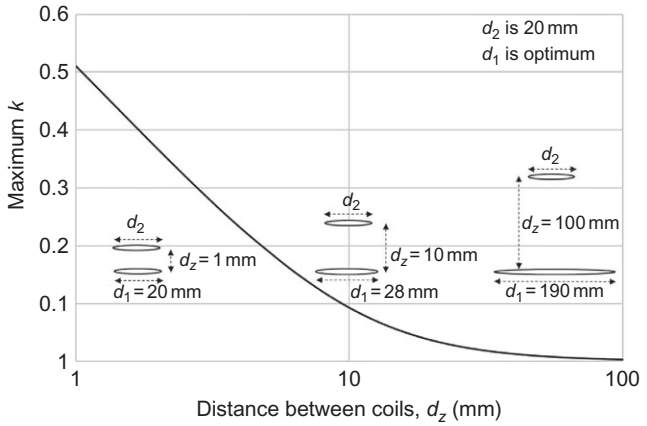

FIG. 22.14 The maximum coupling factor k_{max} versus coil relative sizes and distance.

self-inductances of L_1 and L_2, is $\frac{M}{\sqrt{L_1L_2}}$ in which M is the mutual inductance between the two coils. In simple approximation for concentric-turn coils, the coupling factor is related to the ratio of the two-coil surface areas and inversely to the distance between them. The closer the transmitter and receiver coils to each other, the larger the coupling between them. And for coils that are very close to each other, the maximum coupling happens with coils having the same sizes. As the distance between the coils increases, there is an optimum ratio between the coil surface areas that leads to maximum coupling factor. Fig. 22.14 shows an example of the effects of distance between coils and their relative sizes on the link maximum coupling factor.

22.7.2 Effect of Coil Shape and Alignment

Circular coil is the most common form for the WPT resonator due to its symmetry, simplified analysis, and ease of fabrication. Other common coil forms include square and rectangular types.

Another important criterion that affects the coil shape is the misalignment between the transmitter and receiver coils. Misalignment tolerant inductive WPT systems are designed such that a specified misalignment between the coils does not drop the efficiency and power transfer significantly [12]. Such systems provide spatial freedom of movement to the receiver coil that is beneficial for most WPT applications. For example, Fig. 22.15A shows the coupling factor k changes versus misalignment between the transmitter and receiver coils for two transmitter sizes. The more misalignment tolerant system has a larger transmitter coil to allow for small movements in the receiver coil while having minimal changes in k. Fig. 22.15B shows that for a fixed misalignment distance, the coupling factor drop is lower for large transmitter coil compared with the small coil. Another method to improve the misalignment tolerance is to have multiple transmitter coils [26]. There are other factors, beside the misalignment tolerance,

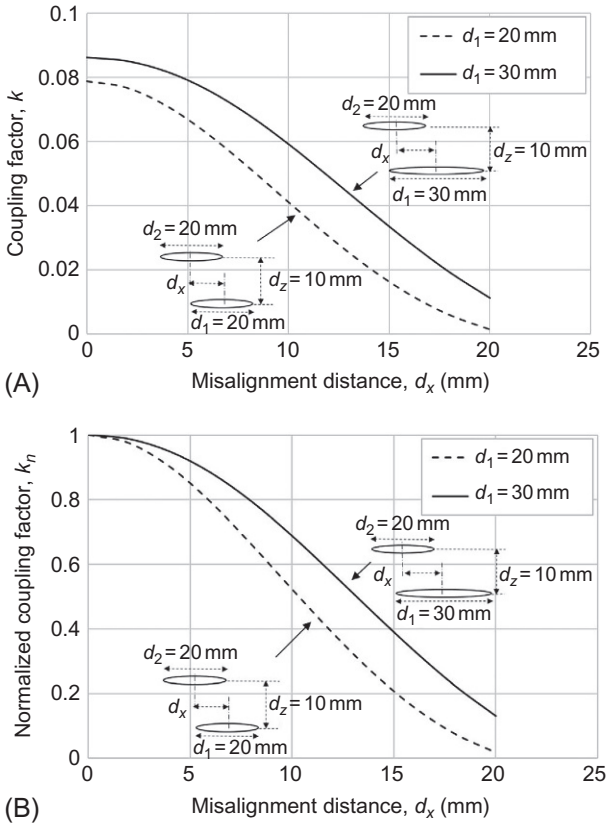

FIG. 22.15 "Normalized" coupling factor k drop versus misalignment between transmitter and receiver coils. (A) Coupling factor k versus misalignment distance d_x. (B) Normalized coupling factor k_n versus d_x.

that affect the size and shape of coil, such as self-inductance and geometric constraints. The receiver side coil has typically more geometric constraints—for example, in a biomedical implant inside the body—and the WPT design process starts with the receiver coil followed by the transmitter.

22.7.3 Effect of Ferrite Core

Another way to increase the coupling factor is to use soft magnetic materials such as ferrite cores. The magnetic flux lines follow the path of minimum reluctance; therefore, the high permeable ferrite core can be used to shape the field and increase the coupling. As the ferrite cores are placed on one side of the transmitter/receiver coils to enhance the coupling, they also shield the magnetic field from being exposed to the surrounding objects. This helps the inductive WPT system satisfy the health and safety requirements associated with high magnetic field strengths. In some applications, adding a metal plate to the coil helps shielding the high frequency magnetic fields from penetrating into nearby objects and reducing the EMI disturbance (Fig. 22.16).

A ferrite material with high saturation flux density, low AC power loss, and high bulk resistivity and permeability is beneficial in WPT systems. The most common types of ferrites used

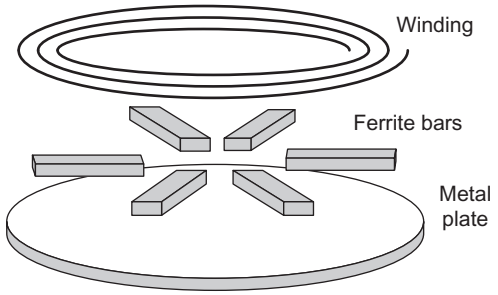

FIG. 22.16 An example structure of inductive WPT coil including winding, ferrite, and metal plate.

in inductive WPT systems are MnZn and NiZn ferrites. The MnZn ferrite has high permeability and high saturation flux density, while the NiZn ferrite has lower permeability and high bulk resistivity. The high-permeability ferrite increases the magnetic energy storage per geometric constraints, such as coil self-inductance. A ferrite with high bulk resistivity reduces the high-frequency-induced eddy and displacement currents.

A ferrite core increases not only the coupling factor and inductance but also the power dissipation. For sinusoidal excitation, the core loss is a function of frequency and magnetic flux density in the core. Its effects on the coil are well described by the coil quality factor Q. Increasing the coil inductance and resistance is somehow compensated in the quality factor that directly influences the link efficiency. However, other system requirements such as high inductance, magnetic field shielding, and high coupling factor are achieved by using ferrite cores in the transmitter and receiver coils.

22.7.4 Effect of Coil Winding

Reducing the coil winding AC resistance is an important step in magnetic link design as it increases the coil quality factor and link efficiency. Depending on the operating frequency, the winding conductor can be solid, foil, tubular, or litz. Solid round conductor is the most basic type of conductor, and its properties (such as resistance and inductance) have been well studied and determined. Solid wire is a building block of many types of wires such litz, and understanding its behavior is a critical step in the winding design. The AC power loss inside a current-carrying conductor is due to the high frequency eddy currents induced in it by the time-varying (1) internal magnetic field (skin effect) and (2) external magnetic field (proximity effect). The skin and proximity effects are orthogonal in round conductors and can be investigated separately. In the skin effect, the current flows mostly in the skin-depth region of the conductor, leaving the inner part having almost zero current flow (tubular conductor) that increases the AC resistance. One solution is to have multiple insulated concentric tubular conductors with optimum current flow to reduce the AC resistance [27]. With the conductor radius close to skin depth, the current flow is close to uniform. At high frequencies—mostly

above a megahertz—the solid conductor can be superior to other conductor types due to its low AC power loss, low cost, and ease of manufacturing.

A potential type of conductor is foil wire that can be used in inductive WPT systems [28]. Copper foils with thicknesses close to skin depth in the multimegahertz frequency range (Cu skin depth is between 65 and 15 μm in the 1–20 MHz) are commercially available and affordable. In addition, with the state-of-the-art printed wiring (flexible) boards and electroplating methods, efficient inductors can be designed and fabricated. The other advantages of using foil conductor include high-current-carrying capability due to large cross-sectional area and improved thermal performance, and the inductors with low overall thickness can be designed. The foil conductor characteristics such AC resistance and inductance have been extensively studied in the literature for various applications. The most common application is in transformer windings with magnetic core surrounding the conductor [29]. This forces the magnetic field contours to be parallel with the foil and simplifies the determination of foil impedance in to a 1D analysis. In inductive WPT, however, the magnetic core—if present—is located on one side of the coil, and the field contours have 2D pattern requiring numerical methods such as finite element (FE) analysis to determine the inductor impedance.

Another way to reduce the AC resistance of a conductor—with thickness (or radius) much bigger than the skin depth—is to have the current flow uniform across the conductor cross section. To do so, the conductor needs to be divided into multiple insulated skin-depth-sized strands, with each strand seeing the same amount of magnetic flux. This can be done by twisting the strands such that each one of them occupies all the positions across the conductor in a full twist. This structure is litz wire, and its principles can be applied on different types of conductors to reduce the AC resistance [30]. The most common type of litz wire is made of solid round strands. However, same principles can be applied to design other forms of litz wire with rectangular foil strands [31]. Litz wire is a common choice of inductor wire at frequencies up to few megahertz, above which the need for very thin strands (close to skin depth) makes the manufacturing of litz wire expensive.

In the inductors with multiple turns, the power losses are divided into skin and proximity dissipations. The skin effect loss can be reduced by optimum design of a single-turn winding. The proximity effect, in the other hand, depends on the field of nearby turns. The complete structures of coil, including the number of turns, layers, distance between them, and existence of ferrite core, are the design parameters for minimizing proximity effect and AC resistance. For efficient coil design in WPT system, the coil quality factor Q is the main parameter of interest. Therefore, not only the winding AC resistance needs to be reduced, but also the coil inductance would have to increase. As a coil structure with minimum AC resistance does not necessarily have the maximum inductance, the coil quality factor would be the main optimization objective. In a broader link design objective, both the transmitter and receiver need to be considered by maximizing $k^2Q_1Q_2$.

22.8 Summary

This chapter covered different methods of WPT with the main focus on weakly coupled inductive WPT systems. Such systems are increasingly getting popular due to the advantages they bring compared with wired power transfer. Not only inductive WPT systems offer extended freedom of movement for source and load (relatively) such as in EVs, but also they are beneficial in applications where there is limited access to the load such as in biomedical implants. A typical two-coil inductive WPT was analyzed, and the system parameters including the magnetic link efficiency were derived. In order to increase the maximum link efficiency, both the coupling factor and coil quality factors need to increase. The effects of coil size, shape, structure, and placement were discussed to maximize link efficiency. In weakly coupled inductive WPT systems, the impedance reflected to the transmitter coil as seen by the inverter is quite small, and the inverter needs to be designed depending on the magnetic link. For high frequency (megahertz range) inverters, class-D (ZCS and ZVS) and class-E inverters were analyzed, and their (dis) advantages were discussed.

23.1 Introduction

In modern societies, development level and economic well-being of a society are directly measured by energy generation and consumption. Energy plays an important role in the economic health of a country that is reflected by the gross national product (GNP). The per capita GNP of a country is correlated to the per capita energy consumption. There is a steady demand to increase the energy generation capacity all over the world since the global energy consumption is rising. The main reasons are the technological developments, industrial revolution, and increase in population. In a modern and industrialized community, energy is used in every single human activity. Some major examples are the following:

- Household applications such as heating, cooking, lighting, and air conditioning
- Transportation—passenger cars, buses, trains, trucks, and aircrafts
- Manufacturing heat and electricity as well as user end or industrial products
- Irrigation and fertilizing in agricultural organizations

The worldwide energy consumption has been growing steadily and rapidly right after the industrial revolution. Today's global energy consumption has reached more than 500 EJ. This amount of energy is consumed with an hourly rate of 15 TW [1]. Global energy consumption of 1900 was 0.7 TW. The United States consumes the greatest amount of energy per capita worldwide. The amount of energy consumed in the United States was 105 EJ or 29,000 TWh in 2005, with equivalent rate of 3.3 TW [2,3]. If the hourly consumed power is 3.3 TW, 1 year of consumption corresponds to 29,000 TWh, by $3.3\ \text{TW} \times 24\ \text{h} \times 365$ days. Between 1980 and 2004, the worldwide energy consumption annual growth rate was 2%. The total consumption in 2004 is given in Table 23.1 according to the US Energy Information Administration [1]. The estimated 15 TW total global consumption is mainly generated from the fossil fuels such as coal, oil, and gas.

This 15 TW of total consumption is shared among several sectors. Around 37% of the total 15 TW is consumed by industrial sectors such as manufacturing, mining, construction, and agriculture. Twenty percent of the total consumption is by the personal and commercial transportation. Residential consumption such as residential lighting, heating, and household appliances corresponds to 11% of the total. Consequently, commercial lighting, heating, cooling, and water provision and sewing services consume 5% of the total [4]. The other 27% of world's energy is lost in the energy generation and transmission stages. The overall energy consumption percentages by sector are shown in Fig. 23.1.

According to Fig. 23.1, the generation and transmission losses are considerably high. In order to generate 2 TW of electric power, approximately 5 TW of power is required. This is due to the fact that efficiency of a typical power plant is around 38% [5]. Fig. 23.1 also imposes that more than a quarter of the

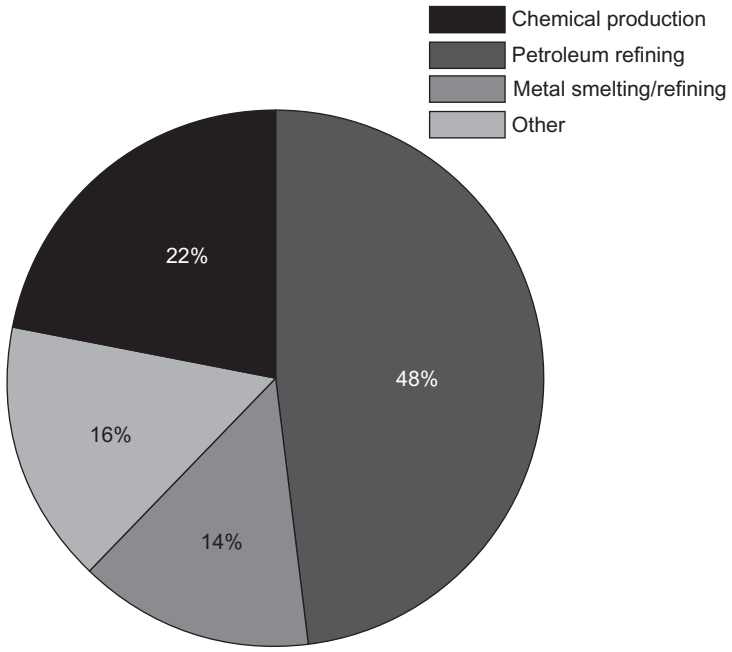
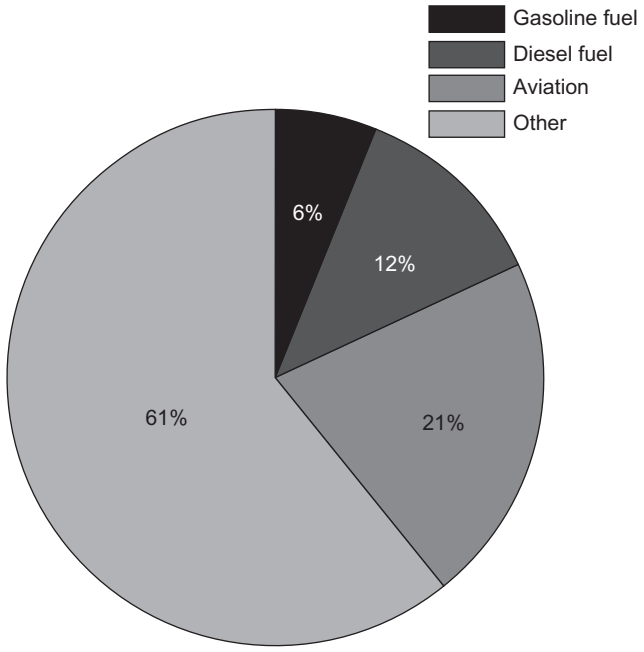
produced energy is lost in low efficient conventional energy conversion systems and transmission lines. This issue encourages the increased focus on high efficient renewable energy systems, which may also reduce or eliminate the transmission losses if they are built as distributed energy generation units. In comparison with the efficiency of conventional power plants, new generation of power plants using gas turbines or microturbines may reach a substantially higher efficiency of 55%; however, they still rely on another fossil fuel, which is natural gas [6].

After the invention of steam engines, coal began to be the main source of energy in the eighteenth and nineteenth centuries. Since automobiles were invented and electricity usage became more common, coal left its popularity to the oil during the twentieth century. From 1920 to 1973, oil was the main resource fueling the industry and transportation, and its price steadily dropped during these years. Oil kept its expansiveness until the 1970s. In the oil crises of 1973 and 1979, price per barrel boosted from 5 to $45, and oil was not the best and most common source of energy production anymore [7]. From these dates, coal and nuclear became the sources for electric power generation. In those years, energy conversation and increasing the energy efficiency gained importance. However, the use of fossil fuels has continued over the last 30 years, and their contribution to overall energy production has increased. During the last 3 years, coal has become the fastest growing fossil fuel, since it has large remaining reserves [7]. On the other hand, renewable energy sources have gained interest due to the depletion of fossil fuels, followed by high oil prices, and climate change concerns related to the carbon emissions. Therefore, government support on development, deployment, incentives, and commercialization of renewable energies are ever increasing. For instance, in March 2007, it is agreed by the European Union members that at least 20% of their nations' energy should be produced from renewable sources by 2020. This is also a part of environmental concerns such as global warming [8] and building a sustainable energy economy by reducing the nations' dependence on imported fossil fuels. However, although there is a large availability of renewable sources, their contribution to globally consumed energy is relatively poor.

In developed countries such as Germany and Japan, the national gross product is 6 kW per person and 11.4 kW per person in the United States. Bangladesh has a low consumption with 0.2 kW per person, while it is around 0.7 kW per person for a developing country such as India. Twenty-five percent of the overall world's energy is consumed by the United States, while its share of global energy generation is 22% [4]. Energy consumption in the United States is shared by four broad sectors according to the US Department of Energy. Similar to the world's energy consumption, the largest user is the industrial sector, currently consuming 33% of the total energy. Next largest amount of energy is consumed for transportation followed by residential and commercial users. Energy consumption shares of the United States for four major energy consumption sectors (industrial, transportation, residential, and commercial) are demonstrated in Table 23.2 [4,9,10].





Most of the electric power generation of the United States is provided by conventional thermal power plants. Most of these power plants are operated by coal. However, from 1990 to 2000, the number of natural gas or other types of gas-operated power plants was increased significantly. 270 GW of new gas-operated thermoelectric power plants were built in United States from 1992 to 2005. Only 14 GW capacity belonged to new nuclear and coal-fired power plants, with 2.315 GW of this amount being nuclear, while the remaining is the coal-fired power plants [11]. The significant shift to the gas-operated power plants is due to the deregulation, political, and economic factors; however, nuclear and coal are considerably capital-intensive. On the other hand, there is a great potential for renewable energies in the United States. For instance, the US wind power capacity is close to 20 GW, which is sufficient to supply power to 4.5 million typical households [12]. Although there is a great availability of the solar power, solar power percentage

of total capacity is only 0.04% retrieved by plants that are currently in operation, including the new Nevada Solar One plant with 64 MW capacity and the largest solar thermal power station in the Mojave Desert with a total generation capacity of 354 MW, which is the world's largest solar plant [13].

Electric power generation in the United States for 2006 is summarized in Table 23.3 in terms of total capacity (MW), annual production (billion kWh), and units in operation [14].

According to Table 23.3, it is seen that the most contributing power source to the US energy production is the coal-fired

TABLE 23.2 US nationwide energy consumption sectors

Sector	Major use shares
Industrial: This sector mainly consumes 33% of total energy for the manufacturing, producing, and processing goods such as chemical refining, metal production, paper, and cement production	
Transportation: Twenty-eight percent of the total energy consumption is shared by this sector for land, sea, and air vehicles transporting people and goods

thermoelectric power plants. Although the established power capacity of the nuclear power plants is less than that of the combined cycle natural gas plants and combustion turbine generators, nuclear power plants are the second greatest source in annual energy production. This is due to the higher efficiency of these plants and under-capacity operation of natural gas power plants and combustion turbine generators. Other than the nuclear power plants and fossil-fueled power plants, hydroelectric power plants have a significant contribution to the annual production although they require a relatively large number of units in operation. This is mainly due to the relatively lower power capacity of the hydroelectric power plants. Renewable energy sources of wind and solar still have insignificant number of units in operation, and their annual contribution is considerably insignificant to the nation's total energy production although the available potential capacity of these sources are really high.

The energy production rates of energy sources are given in Fig. 23.2 [14].

The energy demand of the world is rapidly and steadily increasing. In 2007, the electric power demand of the United States was 783 GW in summer and 640 GW in the winter. It is projected by the North American Electric Reliability Corporation (NERC) that the electric power demand of the United States will increase to 925 GW for summer and 756 GW winter in 2017 [15]. Therefore, environmental concerns on global warming and sustainability along with the political considerations on the supplies' security will shift the overall energy consumption away from the fossil fuels. Nowadays, many researchers and politicians call for immediate actions for long-term sustainable energy solutions. Based on a growing consensus, peak oil may be reached in the near future, and this will result in severe oil price increases [16]. If a long-term solution cannot be developed prior to the peak oil scenario, the world economy may face a grinding halt.

This chapter focuses on naturally available energy sources and deals with the efficient utilization of these sources. Moreover, renewable and sustainable energy generation techniques are discussed in this chapter. In addition, the operating principles, efficient utilization, and grid-connection issues as well as power electronic interfaces for these renewable energy sources are demonstrated. While inventing new methodologies to maximize the efficient usage of traditional sources such as coal, oil, and natural gas, it is of great importance to develop new technologies to produce emerging sources of energy from renewables.

Consequently, by efficient use of conventional energy sources and utilizing alternate sources of energy, the reserves of the conventional energy resources can last for longer, global warming can be slowed down, and environmental pollution can be reduced [17].

23.2 Available Energy Sources

Primary sources of energy are fossil fuels such as oil, natural gas, coal, and other sources such as nuclear, solar, wind, hydroelectricity, or potential sources available in oceans. The energy that has not been converted or transformed into another form is known as primary energy source. More convenient form of energy such as electric energy is obtained by transforming primary energies in energy conversion processes. These converted forms are called as secondary energy sources.

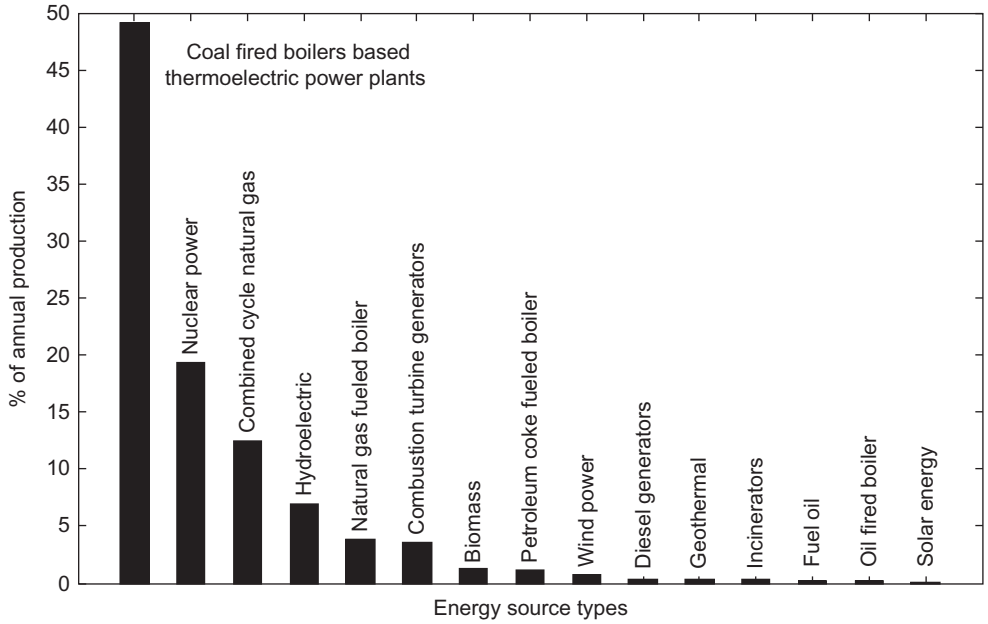

FIG. 23.2 Percentage of the energy sources to the annual energy generation.

23.2.1 Coal

Coal is the most abundant fossil fuel of the world with around 909 billion tons of reserves. It is expected to sustain for the next 155 years at the current production rate [4]. Coal is the fastest growing fossil fuel to meet the energy demand of the global community. However, coal is the dirtiest energy source with numerous pollutants and high emissions [11].

23.2.2 Oil

It is estimated that there is 57 ZJ of oil reserves on Earth. This amount includes the available but not necessarily recoverable reserves. Other estimates vary from 8 ZJ including currently proved and recoverable reserves to a maximum of 110 ZJ including nonrecoverable reserves [18]. World's current oil consumption is 85 mbd, and it is estimated that the peak consumption will be 93 mbd in 2020. Oil and its chemical derivatives are mainly used for transportation and electric power generation.

23.2.3 Natural gas

There is not any certain number indicating world's available natural gas reserves. However, according to the US Energy Information Administration, there are 237,726 billion cubic feet (cu-ft) of dry natural gas reserves in the United States, while the liquid natural gas reserves are of 9143 million barrels [19]. Natural gas has become one of the major sources of electric power generation through the steam turbines and gas turbines due to their higher efficiency. Natural gas is cleaner than any other fossil fuels and produces fewer pollutants per generated unit energy. Burning natural gas produces about 30% less carbon dioxide than burning petroleum and about 45% less than burning coal for an equivalent amount of heat [20]. Some of the natural gas power plants are operated in combined cycle mode to obtain higher efficiencies. In this operation, gas turbines are combined with the steam turbines in order to get the benefit of waste heat using steam turbines.

23.2.4 Hydropower

Hydroelectric power plants supplied 16.4% of the world's electric power in 2005 [21]. The hydroelectric power is not an effective solution, since most of the potential sites are already in use or they are not feasible to be exploited due to environmental and economical concerns. In addition, the life span of hydroelectric power plants is limited, due to soil erosion and accumulation. Because of these concerns, the construction of large hydroelectric power plants has stagnated. The new trend all over the world has been building smaller hydro power units called as *microhydro* since they can be a part of distributed generation, opening up many locations for power generation and they have less or negligible environmental effects [22,23]. On the other hand, hydroelectric power plants have no emissions since no fuel is burnt. Hence, hydropower is a clean energy source in comparison with fossil-fuel-based energy sources. In 2005, the worldwide hydroelectricity consumption reached 816 GW with 66 GW of small hydro plants and 750 GW of large plants [24].

23.2.5 Nuclear Power

In 2006, 16% of the world's total electric power production was supplied by nuclear power that is accounted 2658 TWh [11,25,26]. Total power capacity of the established nuclear power plants was about 372 GW by November 2007 [25]. The remaining uranium resources are estimated to be 2500 ZJ by the International Atomic Energy Agency [27]. Since there is plenty of available sources and developed technology, the contribution of nuclear power to the future's energy demand is not limited. However, there are political and environmental constraints, which restrict the growth of nuclear power plants. The cost of generating nuclear power is approximately equal to that of the coal power. Moreover, nuclear power has zero pollutant emissions such as CO, CO_2, NO, and SO_2.

23.2.6 Solar

Earth receives around 120,000 TW of solar energy resource per year. As an energy source, less than 0.02% of available solar resources are capable of entirely replacing all nuclear power and fossil fuels [28,29]. Although it is still expensive in comparison with conventional energy conversion techniques, the fastest growing energy source in 2007 were grid-connected photovoltaic (PV) systems. The total installed capacity reached to 8.7 GW by increasing all PV installations by 83% in 2007 [30]. High cost of manufacturing solar cells, reliance on weather conditions, storage, and grid-connection problems are the major barriers of further development of solar generation.

23.2.7 Wind

Wind is one of the greatest available potential energy sources. The available wind energy is estimated to be from 300 [31] to 870 TW [32]. Only 5% of the available energy is capable of supplying the current worldwide energy demands. However, due to fewer obstacles, most of this wind energy is available on the open oceans on which construction of wind turbines and energy transmission is relatively difficult and expensive. From 2006 to 2007, the installed wind turbines' capacity was increased by 27% to total of 94 GW according to the Global Wind Energy Council [33]. However, the actual generated power is less than the nominal capacity since the nominal capacity represents the peak output, and the actual output is around 40% of the nominal capacity due to efficiency issues and lower wind speeds [34].

23.2.8 Ocean

Energy of ocean can be categorized in three major methods: *ocean wave power*, *ocean tidal power*, and *ocean thermal power*. All of these three methods can be installed as onshore or offshore applications.

Wave energy harvesting is a concept that the kinetic energy of waves of the deep water or waves hitting the shores is captured and converted to electric energy. The kinetic energy of waves is converted to electric energy using several different methods. It is estimated that the deep-water wave power resources vary from 1 to 10 TW [35], while the total power of the waves hitting the shores may add an additional power of 3 TW [31,36]. Capturing this entire amount of power is not practical and feasible. It is estimated that 2 TW of this power can be usefully captured [37,38].

Ocean tides occur due to the tidal forces of the moon and the sun, in combination with the earth's rotation. Tidal power has a great potential for future energy generation since it is cleaner in comparison with fossil fuels and it is more predictable in comparison with other renewable energies such as wind and solar. The kinetic energy of the moving water can be captured by tidal stream or tidal current turbines. Alternatively, the barrages can be used to capture the potential energy created due to the height difference between the low and high tides. Various methods can be employed for the realization of these concepts. The total estimated tidal power potential is 3.7 TW [39]. However, only around 0.8 TW of this amount is available due to the dissipation of tidal fluctuations. The amount of energy generated from ocean tides was 0.3 GW at the end of 2005 [40], which is much less than the available potential.

The other way of generating power from the oceans is the ocean thermal energy conversion (OTEC). In this method, the temperature difference between the warm shallow water and the cold deep water is used to drive a heat engine, which in turn drives an electric generator [41]. The efficiency of OTEC power plants is relatively low [41,42] due to the power requirements of the auxiliary OTEC devices such as water intake and discharge pumps. Moreover, this technique is expensive since the efficiency is low and greater capacities of installations are required to produce reasonable amounts of energy [43].

23.2.9 Hydrogen

Hydrogen is an energy carrier [44,45]; in other words, it is an intermediate medium for energy storage and carriage. Hydrogen is the most abundant element of the Earth (approximately corresponding 75% of the elemental mass of the universe) [46], and it is the simplest and lightest element of all chemical elements with an atomic number of 1. Hydrogen exists in nature in combination with other elements such as carbon and nitrogen in fossil fuels, biological materials, or with oxygen in water [47]. Hydrogen can be combusted in air, or it can react with oxygen using fuel cells to produce energy. The resultant combustion energy or electric energy does not cause any CO or CO_2 emissions. However, splitting hydrogen from the combination of other elements require additional energy. The main source of global hydrogen production is natural gas (48%). Other sources of hydrogen production are oil (30%), coal (18%), and water electrolysis (4%) [48]. Currently, most of the hydrogen is produced from gas derivatives such as natural gas, ethane, methane, ethanol, or methanol. Hydrogen production from fossil fuels, known as reformation, contains several pollutant emissions. Although electrolysis is clean, this method has various challenges and still has very poor efficiencies and high production costs. Biological or fermentative reactions can be another method of hydrogen production; however, this method has some obstacles such as the amount of products is not significant [48,49]. Using hydrogen in hydrogen combustion engines is several percent more efficient than the conventional internal combustion engines. On the other hand, using hydrogen in the fuel cells is twice or three times more efficient than that of the internal combustion engines. However, there are several challenges for the commercialization of fuel cells such as the size, weight, cost, and durability. Other major technical difficulties related to hydrogen are the production, delivery, and storage issues.

23.2.10 Geothermal

Geothermal energy is the utilization of heat stored in the inner layers of the earth or collecting the absorbed heat derived from underground. The geothermal energy production has reached to 37.3 GW at the end of 2005 [24]. 9.3 GW of this amount is used for electric power generation, while the rest of it is used for residential or commercial heating purposes. Enhanced geothermal systems (EGS) is a technique that extends the potential for the use of geothermal energy. In this technique, the heat is extracted by building subsurface fractures to which water can be added through injection wells. Through this technique, the electric generation capacity can reach to about 138 GW [50]. The overall EGS capacity of the world is calculated to be more than 13 YJ, where 200 ZJ of this amount is extractable. By the technological improvements and investments, this amount is projected to increase over 2 YJ [51]. However, in contrary to this enormous potential, geothermal supplies less than 1% of the world's energy demand as of 2008 [21]. Geothermal energy has high availability (average daily availabilities more than 90%) and in fact has no pollutant emissions since it does not require any fuel or combustion. Furthermore, geothermal power stations do not rely on weather conditions. In addition, it is considered to be a sustainable source of energy since the extracted heat is relatively small in comparison with the heat reservoir's size. In other words, geothermal heat energy is replenished from deeper layers of the earth; therefore, it is not exhaustible.

23.2.11 Biomass

Biomass is a fuel that is also called biofuel, and the bioenergy is the energy enclosed in the biomass. Today, biomass has a small contribution to the overall energy supply, although it was the major fuel until the nineteenth century. In 2005, electric power from biomass was about 44 GW, while more than 230 GW biomass power is used for heating [40]. As a sustainable energy source, biomass is a developing industry in many countries such as Brazil, the United States, and Germany. As an alternative to the fossil fuels, biomass production is significantly increasing worldwide. The biodiesel production increased by 85% to 1.03 billion gallons in 2005, and biodiesel became the world's fastest growing renewable source of energy. Bioethanol production was also increased by 8% and reached 8.72 billion gallons during 2005 [40]. Even though it is commonly believed that biomasses may be carbon neutral, their current farming methods cause substantial carbon emissions [52,53].

23.3 Electric Energy Generation Technologies

Electric energy generation is a process where the energy sources or energy potential is converted to electric energy. Energy generation can be done in various techniques. Due to the upcoming emerging challenges in the global energy supply systems, energy from the conventional sources needs more efficiency. In addition, there should be an increase in utilization of energy generation from alternative and renewable energy sources. In the following subsections, the alternative energy sources along with their conversion to electric energy are described.

23.3.1 Thermoelectric Energy

Thermoelectric power plants are mainly coal-fired power stations. In a thermoelectric power plant, coal or other fuels are burnt in order to heat up the water in the boiler. In this system, the high pressurized steam rotates a steam turbine, which is coupled to an electric generator. After the steam passes through the turbine, it is cooled and condensed back to water in the condenser. This is known as Rankine cycle [54]. More than 80% thermal power plants all over the world operate based on this cycle. In the Rankine cycle, there are four processes in which the working fluid's state is changed as shown in Fig. 23.3 [55]. These processes can be described as follows [56,57]:

Process 1–2: When the fluid is condensed and converted to liquid form, the liquid is pumped from low to high pressure. The pumping process requires a small amount of energy.

Process 2–3: The high-pressure liquid that pumped into the boiler is heated at constant pressure until it becomes saturated dry vapor. The boiler is energized by a heat source such as a coal furnace.

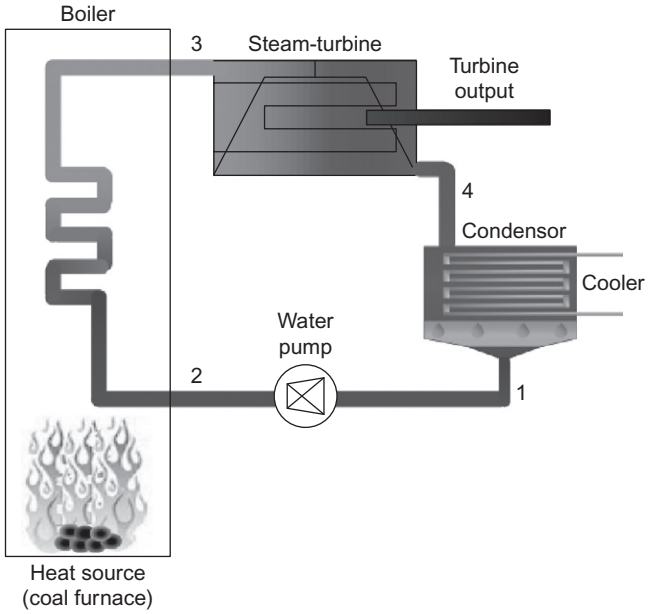

FIG. 23.3 Rankine cycle block diagram.

Process 3–4: During this process, saturated vapor passes through the steam turbine. The heat energy is converted into mechanical energy. While the steam passes through the turbine, it may somehow get condensed since this process decreases the pressure and temperature of the vapor.

Process 4–1: In this process, the vapor is condensed at a constant pressure and temperature in a condenser. As a result, wet vapor is converted to saturated liquid. The cooler helps keeping the temperature constant as the vapor changes its phase from steam to liquid.

These four processes of the Rankine cycle are shown in Fig. 23.3.

Since coal is the most abundant energy source of the world, coal-fired power plants have been widely used in electric power generation all over the world [58]. Coal is a cheap energy source, and coal-fired power plants have mature technology. Therefore, the generation cost is less, and thermoelectric power plants can be constructed anywhere close to fuel and water supply. Although the consumption sites might be relatively far away from the coal mines or water supplies, fuel and water can be transported to the generation plants. Since the coal has been the backbone of the electric power industry since the late 1800s, approximately 49% of the electric power generated in the world is supplied by coal-fired thermoelectric power plants [59].

In a simple form, the operation of a coal-fired power plant can be similar to Rankine cycle. In this form, the plant consists of a boiler, a steam turbine driving an electric generator, a condenser, and a feedwater pump. Coal is first pulverized and burnt in the steam generation furnaces. The water in the boiler tubes is heated, and steam is generated in this way at high pressures. The steam generation process is composed of three

subprocesses that are economizing, boiling, and superheating. In the economizer, the water is heated to a point that is close to the boiling point. Then, the steam is raised in the boiler. Finally, the steam is further heated and dried at the superheater. The steam at its final form is then conveyed to the steam turbine. The mechanical force pushing the turbine blades yields the steam turbine to rotate, which in turn drives the electric generator producing electricity. The cooler steam with lower pressure is released from the turbine. This steam is conveyed to the condenser to be liquefied. This water is pumped back to the steam generator, and the closed loop system is completed [56]. Considering the other auxiliary devices and peripheral components such as cooling tower, coal conveyor, and ash and waste management units, the schematic of a coal-fired thermoelectric power plant can be presented in Fig. 23.4.

The components of the thermoelectric power plant are described in Table 23.4.

TABLE 23.4 Thermoelectric power plant components

1—Coal conveyor	10—Air intake pipe	19—Low-pressure turbine
2—Coal hopper	11—Air preheater	20—Condenser

8—Reheater	17—Precipitator	26—Chimney stack
9—Economizer	18—Boiler feed pump from condenser	27—Transmission network

The operation of the cola-fired power plant begins with the coal conveyor. From an exterior stack, coal is conveyed through a coal hopper to the pulverizing fuel mill where it is grounded and converted to a fine powder. The pulverized coal is mixed with preheated air. The air is taken by an air intake pipe and pumped to be mixed with pulverized coal. This preheated air is supplied by the forced draught fan. In the boiler, where the air-fuel mixture is ignited at high pressure, the generated heat increases the temperature of the water. The water then changes its phase to steam where it flows vertically up the boiler tubes. This steam is passed to the boiler drum where its remaining water content is separated. This dry steam is then passed through a manifold from the drum into the superheater. In the superheater, further pressure and temperature increase; steam reaches about 200 bar and 570°C. The turbine process of the power plant comprises three stages: high-pressure turbine, intermediate-pressure turbine, and low-pressure turbine. First, the steam passes to the high-pressure turbine through the pipes. Both the manual turbine control and the automatic set-point following can be provided by a steam governor valve. The temperature and the pressure of the steam decrease when it is exhausted from the high-pressure turbine. This steam is returned to the boiler reheater for further use. The reheated steam passes to the intermediate-pressure turbine. The steam released from the intermediate-pressure turbine is passed directly to the low-pressure turbine. Now, the steam is cooler and just above its boiling point. This steam is then condensed in the condenser by contacting thermally with the cold water tubes of the condenser. As a result, the steam is converted back into water, and the condensation causes a vacuum effect inside the condenser chest. The condensed water is prewarmed by the feed heater using the heat of the steam released from the high-pressure turbine and then in the economizer. Then, this prewarmed water is deaerated and passed by a feedwater pump,

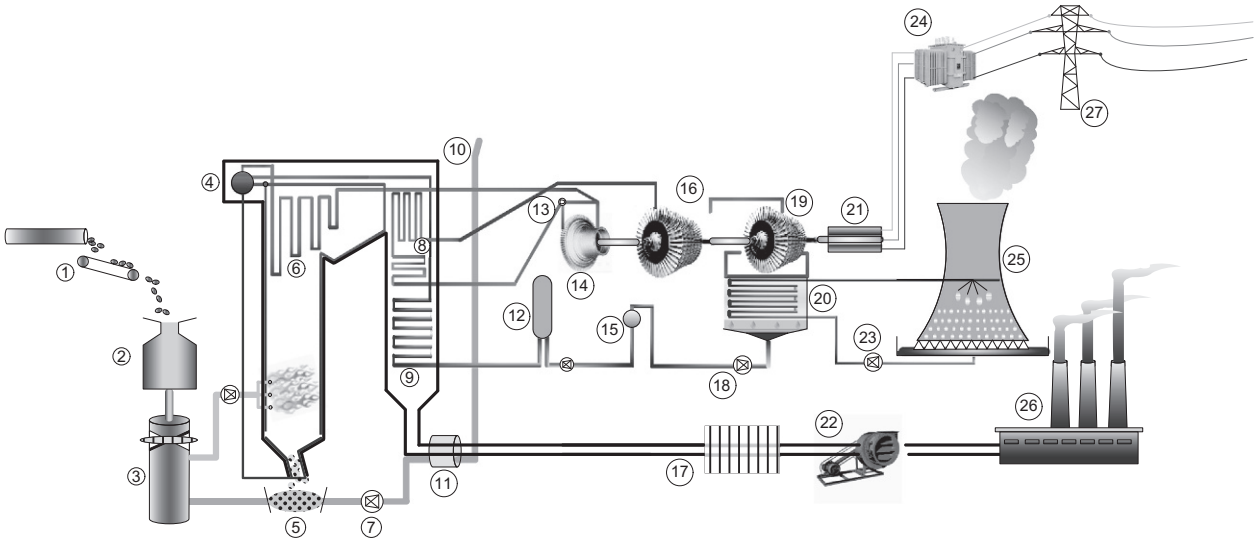

FIG. 23.4 Schematic diagram of the thermoelectric power plant.

which completes the closed cycle. The cooling tower cools down the water from the condenser creating an intense and visible plume. Finally, the water is pumped back to the cooling water cycle. The induced draft fan draws the exhaust gas of the boiler. Here, an electrostatic precipitator is used. Finally, this exhaust gas is vented through the chimneys of the power plant.

In the thermoelectric power plants, load-following capability, efficiency, fuel and water management, and emissions are important issues. In addition, the active and reactive outputs of the power plant's generators and frequency and voltage regulations have impact on the power plant operation.

23.3.2 Hydroelectric Energy

Hydroelectric energy is generated by the kinetic and potential energy of flowing or falling water by the effect of gravitational force. Hydroelectric is the most mature and widest utilized form of renewable energies. Hydroelectric energy has approximately 20% contribution to the overall world energy generation [60]. No fuel is burnt at hydroelectric power plants; therefore, they do not have greenhouse gas emissions. The operating cost is relatively low since the water running the plant is supplied free by the nature. It is a renewable source of energy since the rainfall renews and enriches the water reservoirs.

Hydroelectric energy is generally obtained from the potential energy of dammed or reservoired water. When the water falls from a certain height of the reservoir output, it loses its potential energy and gains kinetic energy. The water flow drives a water turbine that is coupled to an electric generator, which in turn generates electricity. This generated energy is a function of the water volume and the difference between the source and outflow of the water [61]. This height difference between the water output and turbine is called as "head." The potential energy of the water is proportional to the head. In order to generate greater amounts of energy, the head can be increased by running the water for hydraulic turbine through a large and long pipe called as penstock [62]. The cross-sectional view of a hydraulic dam and the hydroelectric power plant components are represented in Fig. 23.5.

In Table 23.5, these components are explained.

Electric power generation in a hydroelectric power plant can be approximately calculated as [63]:

$$P = (hrg)\eta_t\eta_g \tag{23.1}$$

where P is the generated power (kW), h is the height (m), r is the water flow rate (m^3/s), and g is the gravitational acceleration (m/s^2). In Eq. (23.1), the term hrg represents the potential energy of the water. η_t and η_g represent the efficiency of the water turbine and the generator, respectively. These efficiency rates are required for the water potential energy conversion into the electric energy.

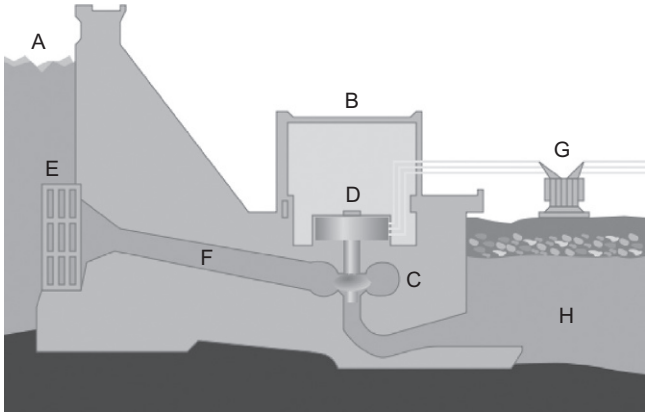

FIG. 23.5 A hydroelectric dam and power plant components [62].

TABLE 23.5 Hydroelectric power plant components

A—Reservoir	E—Water intake
B—Intake	F—Penstock
C—Water turbine	G—Transformer and transmission lines
D—Electric generator	H—River

The other methods of electric generation by hydroelectricity are the pumped storage hydroelectric power plants and run-of-the-river plants. In pumped storage method, the water is pumped into higher elevations by using the excess generation capacity during the periods when electric demand is lower. The water is released back into lower elevations through a turbine when the electric power demand is higher. In this method, water acts as an energy carrier in order to compensate the generation-consumption difference in a commercial device by improving the daily load factor [61–63]. In run-of-the-river plants, water reservoirs are not used, and the kinetic energy of the flowing water through a river is captured using waterwheels.

23.3.3 Solar Energy Conversion and Photo-Voltaic Systems

Solar energy is one of the growing renewable energy sources, which is plentiful and has the greatest availability among other energy sources. The amount of solar energy supplied from the sun to the earth is capable of satisfying the total energy requirements of the earth for 1 year [64]. Furthermore, solar energy does not produce pollutants or harmful by-products; it is free of emissions. Solar energy is applicable to many fields such as vehicular, residential, space, and naval applications.

23.3.3.1 Photovoltaic Effect and Semiconductor Structure of PVs

PV effect is known as a physical process in which a PV cell converts the sunlight into electricity. When a PV cell is subject to the sunlight, the absorbed amount of light generates electric

energy, while remaining sunlight can be reflected or passed through. The electrons in the atoms of the PV cell are energized by the energy of the absorbed light. With this energy, these electrons move from their normal positions in the semiconductor PV material, and they create an electric flow, that is, electric current through an external electric circuit connected to the PV cell terminals. The built-in electric field that is a specific electric feature of the PV cells provides the voltage potential difference that drives the current through an external load [65]. Two layers of different semiconductor materials are placed in contact with each other in order to induce the built-in electric field within a PV cell. The first layer that is *n-type* has abundance of electrons, and it is negatively charged. The other layer that is *p-type* has abundance of holes, and it is positively charged. Since the *n-type* silicon has excess electrons and *p-type* silicon has excess holes, contacting these layers together creates a p/n junction at their interface, thereby creating an electric field. In this contact, excess electrons move from the n-type side to the p-type side. As a result, a positive charge is built up along the n-type side of the interface and negative charge along the p-type side. Thus, an electric field is created at the surface where the layers meet, called the p/n junction. This electric field is due to the flow of electrons and holes. This electric field causes the electrons to move from the semiconductor toward the negative surface to carry current. At the same time, the holes move in the opposite direction, toward the positive surface, where they wait for incoming electrons [65]. The basic structure of a p-n junction in a PV cell is illustrated in Fig. 23.6.

23.3.3.2 PV Cell/Module/Array Structures

A PV or solar cell is the basic building block of a PV (or solar-electric) system. An individual PV cell is usually quite small, typically producing about 1 or 2 W of power [66]. PV cells can be connected together to form a larger unit called modules in order to increase the power output of PV cells. Modules can be connected together and form larger units that are called arrays to generate more electric power. The output voltage of a PV system can be boosted by connecting the cells or modules in series. On the other hand, the output current can reach higher values by connecting them in parallel.

23.3.3.3 Active and Passive Solar Energy Systems

Based on the solar tracking capability, solar energy systems can be categorized into two types, passive and active systems [67,68]. In passive solar energy systems, there are not any moving mechanisms for the panels. In this technique, the energy is absorbed and retained, and spaces are designed that naturally circulate air to transfer energy and referencing the position of a building to the sun to enhance energy capture. On the other hand, in active solar energy systems, typically, there are electric and mechanical components such as tracking mechanisms, sensors, motors, pumps, and fans to capture sunlight and process it into usable forms such as heating, lighting, and electricity. The panel positions are controlled in order to maximize exposure to the sun.

23.3.3.4 Components of a Complete Solar Energy System

In Fig. 23.7, the block diagram of a solar energy system is demonstrated. In this system, the sunlight is captured by the PV array. The photodiode or photosensor signals determine the sun-tracking motor positions. This sun-tracking control helps following the daily and seasonal solar position changes to face the sun directly and capture the most available sunlight.

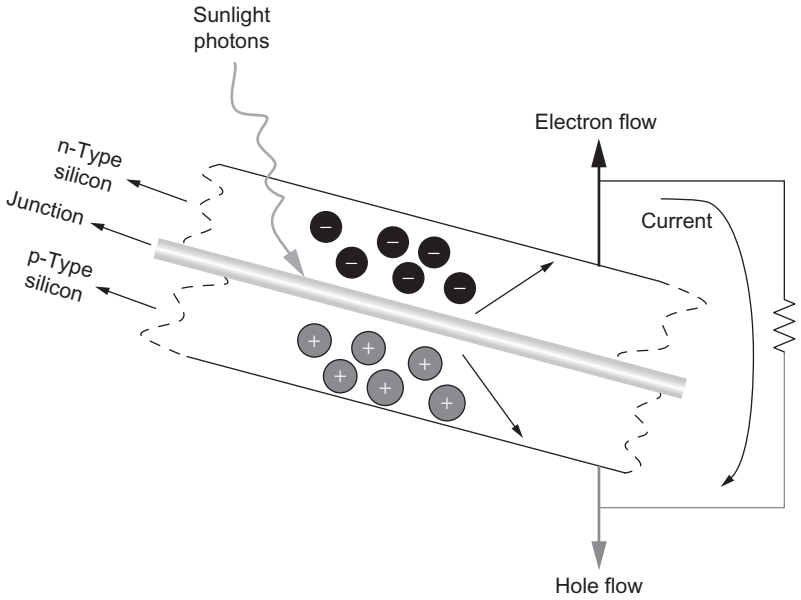

FIG. 23.6 P-n junction structure and current flow in a PV cell.

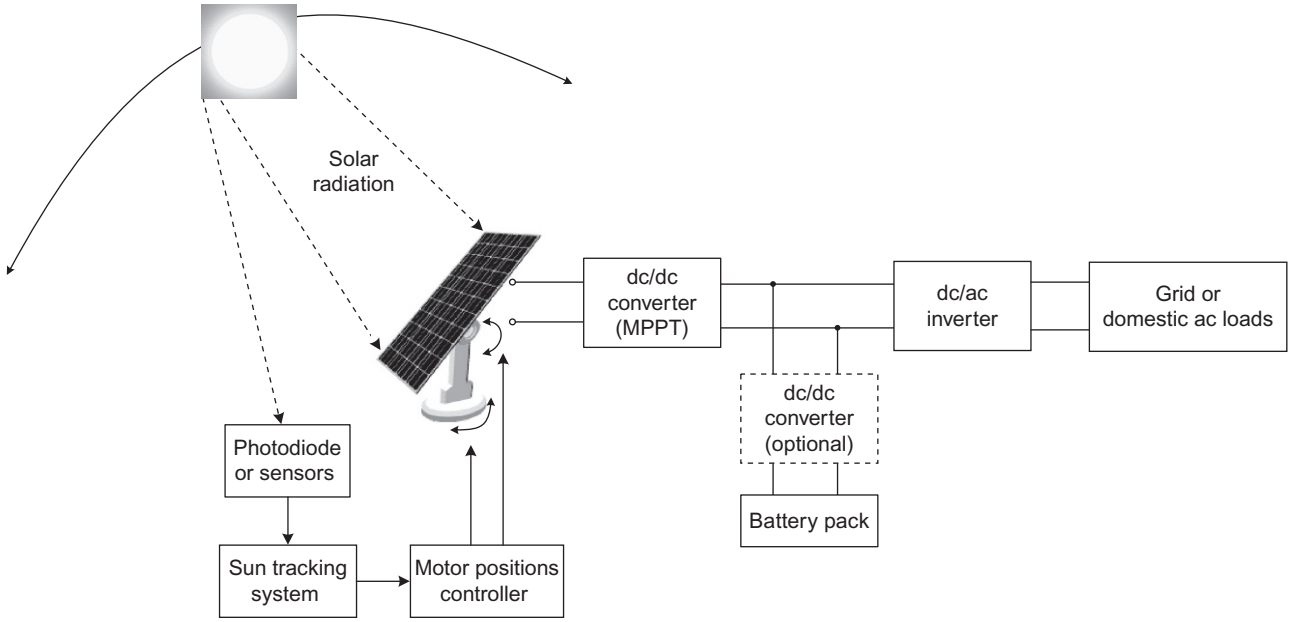

FIG. 23.7 A solar energy system.

A dc/dc converter is employed at the PV panels' output in order to operate at the maximum power point (MPP) based on the current-voltage (*I-V*) characteristics of the PV array [69]. This dc/dc converter is controlled to operate at the desired current and voltage output of the PV array. A dc/ac inverter is usually connected to the output of this MPPT dc/dc converter in order to feed the ac loads for grid interconnection. A battery pack can be connected to the dc bus of the system to provide extra power that might not be available from the PV module during night and cloudy periods. The battery pack can also store energy when the PV module generates more power than the demanded. A grid connection is also useful to draw/inject power from/to the utility network to take the advantage of excess power or to recharge the batteries using grid power during the peak-off periods of the utility network.

23.3.3.5 *I-V* Characteristics of Photovoltaic (PV) Systems, PV Models, and Equivalent PV Circuit

PV systems have a special current-voltage characteristic. As more current is drawn from the PV system, the system output voltage decreases. These characteristic curves differ at different solar insulation and temperature conditions; hence, the curves can be obtained by varying the load resistance (varying the output current) and measuring the output voltage for many different current values. *I-V* curve passes through two points for zero voltage and zero current.

- The short-circuit current (I_{sc}): I_{sc} is the current produced when the positive and negative terminals of the cell are short-circuited, and the voltage between the terminals is zero, which corresponds to zero load resistance.
- The open-circuit voltage (V_{oc}): V_{oc} is the voltage across the positive and negative terminals under open-circuit conditions, when the current is zero, which corresponds to infinite load resistance.

In order to extract maximum power from a PV system, for a constant ambient condition, there is only one current-voltage pair. On the *I-V* curve, the maximum power point (Pm) occurs when the product of current and voltage is maximum. Although the current is maximum, no power is produced at the short-circuit current due to zero voltage. In addition, no power is produced at the open-circuit voltage due to zero current. The MPP is somewhere between these two points. Maximum power is generated at about the "knee" of the curve. This point represents the maximum efficiency of the solar device in converting sunlight into electricity [70]. A typical *I-V* curve characteristic of a PV system is given in Fig. 23.8.

PV systems exhibit nonlinear *I-V* characteristics [71]. There are various models available to mathematically model the *I-V* characteristics of the PV systems. An equivalent circuit expressing the PV model characteristics is shown in Fig. 23.9. This model is known as single-diode model and is one of the most common equivalent circuits representing PV system behaviors.

In this model, open-circuit voltage and short-circuit current are the key parameters. Illumination or solar radiation affects the short-circuit current, while the open-circuit voltage is affected by the material and temperature. In this model, I_{SC} is the short-circuit current, I_s is the diode reverse saturation current, m is the diode ideality factor (generally various between 1 and 5), and V_T is the temperature voltage expressed as $V_T = kT/q$, which is 25.7 mV at 25°C. The equations defining this model are

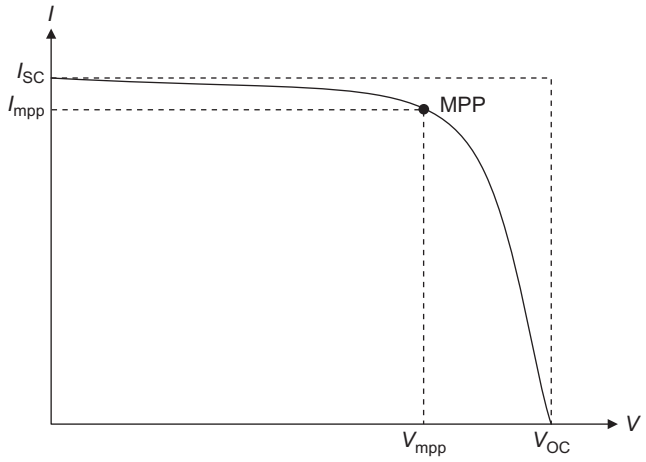

FIG. 23.8 A typical *I-V* curve characteristic of a PV system.

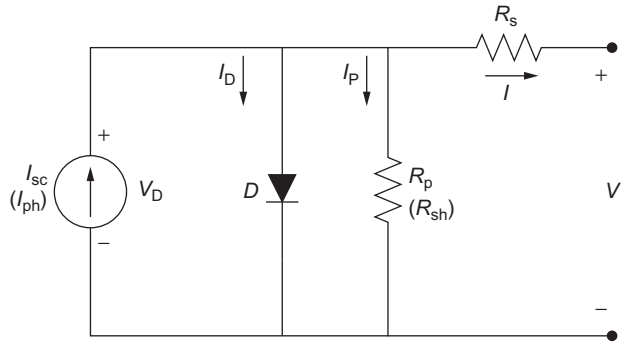

FIG. 23.9 Single-diode model of solar cell equivalent circuit.

$$I_D = I_S\left[e^{\frac{V}{mV_T}} - 1\right] \tag{23.2}$$

$$I = I_{SC} - I_D \tag{23.3}$$

and

$$V = mV_T \ln\left[\frac{I_{SC} - I}{I_S} + 1\right] \tag{23.4}$$

The *I-V* characteristic of the solar cell can be alternatively defined by [72]

$$\begin{aligned} I &= I_{ph} - I_D \\ &= I_{ph} - I_0\left[\exp\left(\frac{q(V + R_sI)}{Ak_BT}\right) - 1\right] - \frac{V + R_sI}{R_{sh}} \end{aligned} \tag{23.5}$$

where V is the PV output voltage (V), I is the PV output current (A), I_{ph} is the photocurrent (A), I_D is the diode current (A), I_0 is the saturation current (A), A is the ideality factor, q is the electronic charge (C), k_b is Boltzmann's constant (JK^{-1}), T is the junction temperature (K), R_s is the series resistance (Ω), and R_{sh} is the shunt resistance (Ω).

23.3.3.6 Sun Tracking Systems

Incident solar radiation is the most important parameter for the power generated by solar energy systems. Sun changes its position during the day from morning to night. Moreover, the sun orbit differs from one season to another. By properly following the sun, through utilizing sun-tracking systems, the incident solar irradiance can be effectively increased [73]. A sun tracker is an electromechanical component used for orienting a solar PV panel, concentrating solar reflector, or lens toward the sun. Solar panels require a high degree of accuracy to ensure that the concentrated sunlight is directed precisely to the PV device. Solar tracking systems can substantially improve the amount of power produced by a system by enhancing morning and afternoon performance. For instance, the orientation of PV panels can increase the solar-electric energy conversion efficiency between 20% and 50% [74–78]. A fixed system oriented to a fixed sun-facing direction will have a relatively low annual production because they do not move to track the sun, which yields significant increase of incident irradiation. An efficient sun-tracking system should be capable of movement from north to south and from east to west as shown in Fig. 23.10.

23.3.3.7 Maximum Power Point Tracking (MPPT) Techniques

The conditions of radiation and temperature affect the current-voltage (*I-V*) characteristics of solar cells. The voltage and current should be controlled to track the maximum power of the PV systems in order to operate the PV systems at the point of (V_{max} and I_{max}). Maximum power point tracking (MPPT) techniques are used to extract maximum available power from the solar cells by controlling the voltage and current. Systems composed of various PV modules located at different positions should have individual power conditioning systems to ensure the MPPT for each module [79]. In this section, most common and applicable MPPT techniques are described.

Incremental conductance (INC) based maximum power point tracking (MPPT) technique

The incremental conductance technique is the most commonly used MPPT for PV systems [72,80–82]. The technique is based

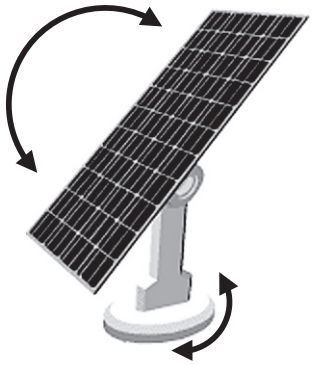

FIG. 23.10 Rotations of a sun-tracking system.

on the fact that the sum of the instantaneous conductance I/V and the incremental conductance $\Delta I/\Delta V$ is zero at the MPP, negative on the right side of the MPP, and positive on the left side of the MPP.

If the change of current and change of voltage is zero at the same time, no increment or decrement is required for the reference current. If there is no change for the current, while the voltage change is positive, reference current should be increased. Similarly, if there is no change for the current while the voltage change is negative, reference current should be decreased. Contrarily, the change of the current might not be zero. If the current change is not zero, while $\Delta V/\Delta I = -V/I$, the PV is operating at MPP. If the current change is not zero and $\Delta V/\Delta I \neq -V/I$, then $\Delta V/\Delta I > -V/I$. If $\Delta V/\Delta I \neq -V/I$ and $\Delta V/\Delta I > -V/I$, the reference current should be decreased. However, if $\Delta V/\Delta I \neq -V/I$ and $\Delta V/\Delta I < -V/I$, the reference current should be increased in order to track the MPP.

Practically, due to the noise and errors, satisfying the condition of $\Delta I/\Delta V = -I/V$ may be very difficult [83]. Therefore, this condition can be satisfied with good approximation by

$$|\Delta I/\Delta V + I/V| < \varepsilon \tag{23.6}$$

where ε is a positive small value. Based on this algorithm, either the operating point is located in BC interval, or it is oscillating among the AB and CD intervals as shown in Fig. 23.11.

Selecting the step size (ΔV_{ref}), shown in Fig. 23.11, is a tradeoff of accurate steady tracking and dynamic response. If larger step sizes are used for quicker dynamic responses, the tracking accuracy decreases, and the tracking point oscillates around the MPP. On the other hand, when small step sizes are selected, the tracking accuracy will increase. In the meantime, the time duration required to reach the MPP will increase [84].

The normalized IV, PV (power-voltage), and absolute derivative of PV characteristics of a PV array are shown in Fig. 23.12.

From these characteristics, it is seen that the $|dp/dV|$ decreases as the MPP is approached and it gets greater when the operating point gets away from the MPP. This relation can be given by

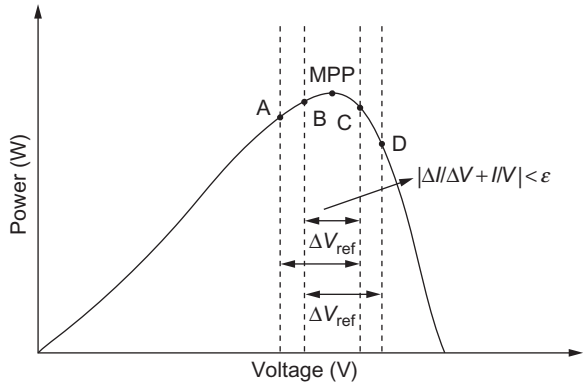

FIG. 23.11 Operating point trajectory of incremental-conductance-based MPPT.

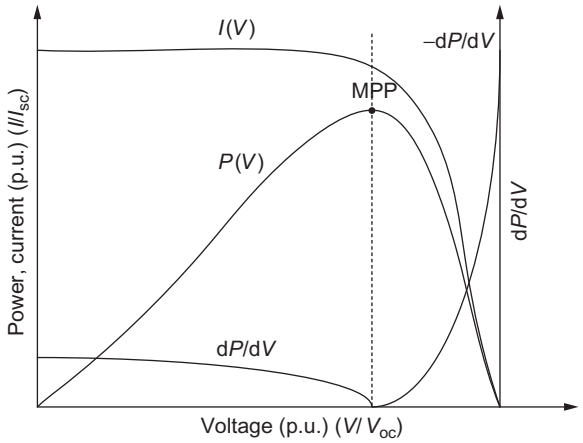

FIG. 23.12 Normalized IV, PV, and $|dP/dV|$ characteristics of a PV array.

$$\begin{cases} dP/dV < 0, \text{right of MPP} \\ dP/dV = 0, \text{ at MPP} \\ dP/dV > 0, \text{ left of MPP} \end{cases} \tag{23.7}$$

In order to obtain the operating MPP, dP/dV should be calculated. The dP/dV can be obtained by only measuring the incremental and instantaneous conductances of the PV array, that is, $\Delta I/\Delta V$ and I/V [80].

$$\frac{dP}{dV} = \frac{d(IV)}{dV} = I + V\frac{dI}{dV} \tag{23.8}$$

Other maximum power point tracking techniques

In the perturb-and-observe technique, the current drawn from the PV array is perturbed in a given direction, and if the power drawn from the PV array increases, the operating point gets closer to the MPP, and thus, the operating current should be further perturbed in the same direction [85]. If the current is perturbed and this results in a decrease in the power drawn from the PV array, this means that the point of operation is moving away from the MPP, and therefore, the perturbation of the operating current should be reversed.

The P-V and I-V characteristics of a roof-mounted PV array are monotonously increasing or decreasing under stable insulation conditions. The I-V characteristic is a function of voltage, insulation level, and temperature. From these characteristics, MPPT controllers can be developed based on the linearized I-V characteristics [86–88].

Fractional open-circuit voltage-based method [89–96], fractional short-circuit-based method [96,97], fuzzy-logic-controller-based method [88,98–106], neural-network-based method [107–112], ripple-correlation-based method [113], current-sweep-based method [114], and dc-link capacitor

droop-control-based method [115,116] are the other applicable methods for MPP tracking.

23.3.3.8 Power Electronic Interfaces for PV Systems

Power electronic interfaces are used either to convert the dc energy to ac energy to supply ac loads or connection to the grid or to control the terminal conditions of the PV module to track the MPP for maximizing the extracted energy. They also provide wide operating range, capability of operation over different daily and seasonal conditions, and reaching the highest possible efficiency [117]. There are various ways to categorize power electronic interfaces for solar systems. In this book, power electronic interfaces are categorized as power electronic interfaces for grid-connected PV systems and stand-alone PV systems.

Power electronic interfaces for grid connected PV systems

The power electronic interfaces for grid-connected PV systems can be classified into two main criteria: classification based on inverter utilization and classification based on converter stage and module configurations.

Topologies based on inverter utilization: The centralized inverter system is illustrated in Fig. 23.13.

In this topology, PV modules are connected in series and parallel to achieve the required current and voltage levels. Only one inverter is used in this topology at the common dc bus. In this topology, the inverter's power losses are higher than string inverter or multi-inverter topologies due to the mismatch between the modules and necessity of string diodes that are connected in series. In this topology, voltage boost may not be required since the voltage of series-connected string voltages is high enough [118].

In string inverter topology, the single string of modules is connected to the separate inverters for each string [119]. In this topology, voltage boosting may not be required if enough number of components are connected in series in each string.

In the multistring inverter topology, several strings are interfaced with their own integrated dc/dc converter to a common dc/ac inverter [120,121] as shown in Fig. 23.14.

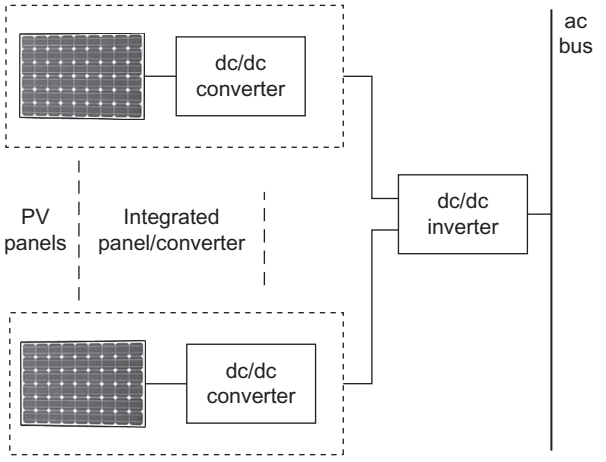

FIG. 23.14 Multistring inverters topology.

Therefore, this is a flexible design with high efficiency. In this topology, each PV module has its integrated power electronic interface with utility. The power loss of the system is relatively lower due to the reduced mismatch among the modules, but the constant losses in the inverter may be the same as for the string inverter. In addition, this configuration supports optimal operation of each module, which leads to an overall optimal performance [118]. This is due to the fact that each PV panel has its individual dc/dc converter and maximum power levels can be achieved separately for each panel.

Topologies based on module and stage configurations: The power electronic conditioning circuits for solar energy systems can be transformerless, or they can utilize high-frequency transformers embedded in a dc/dc converter, which avoids bulky low-frequency transformers. The number of stages in the presented topologies refers to the number of cascaded converters/inverters in the system.

Isolated dc/dc converters consist of a transformer between the dc/ac and ac/dc conversion stages [122]. This transformer provides isolation between the PV source and load. A typical topology is depicted in Fig. 23.15.

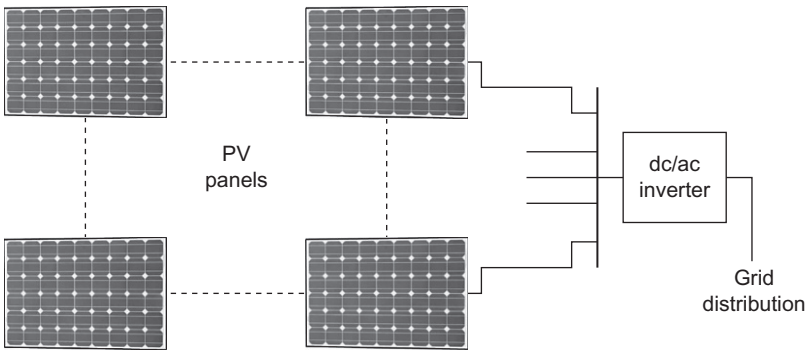

FIG. 23.13 Conventional PV system technology using centralized inverter system topology.

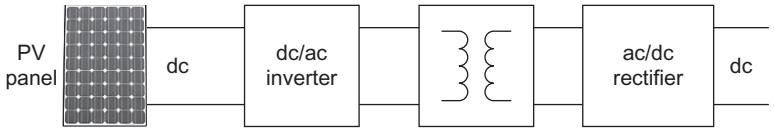

FIG. 23.15 Isolated dc/dc converter topology.

In the topology shown in Fig. 23.15, the outputs of the PV panel and dc/dc converter are dc voltages. The two-stage dc/dc converter consists of a dc/ac inverter, a high-frequency transformer, and a rectifier. In this topology, a capacitor can be used between the bottom leg of the high-frequency inverter and the transformer, forming an LC resonant circuit with the equivalent inductance of the transformer. This resonance circuit reduces the switching losses of the inverter. Alternatively, only two switches are enough if a push-pull converter is used; however, this topology requires a middle terminal outputted transformer [118].

The topologies shown in Fig. 23.16A and B are two-stage single-module topologies, in which a dc/dc converter is connected to a dc/ac converter for grid connection. The dc/dc converter deals with the MPP tracking, and the dc/ac inverter is employed to convert the dc output to ac voltage for grid connection. These are nonisolated converters since they are transformerless.

Instead of using a full-bridge inverter for the dc/ac conversion stage, a half-bridge inverter can also be used. In this way, number of switching elements can be reduced, and the controller can be simplified; however, for the dc bus, two-series-connected capacitor is required to obtain the midpoint. This midpoint of two-series-connected capacitors will be used as the negative terminal of the ac network of the half-bridge configuration.

The single-stage inverter for multiple modules is depicted in Fig. 23.17, which is the simplest grid-connection topology [123]. The inverter is a standard voltage-source PWM inverter, connected to the utility through an LCL filter. The input voltage, generated by the PV modules, should be higher than the peak voltage of the utility. The efficiency is about 97%. On the other hand, all the modules are connected to the same MPPT device. This may cause severe power losses during partial shadowing. In addition, a large capacitor is required for power decoupling between PV modules and utility [124].

A topology for multimodule multistring interfaces is shown in Fig. 23.18 [121,125]. The inverter in Fig. 23.18 consists of up to three boost converters, one for each PV string, and a common half-bridge PWM inverter. The circuit can also be constructed with an isolated current- or voltage-fed push-pull or full-bridge converter [126] and a full-bridge inverter toward the utility. The voltage across each string can be controlled individually [121,126].

As an alternative to the topology shown in Fig. 23.18, other types of dc/dc converter can be employed to the first stage, such as isolated dc/dc converters.

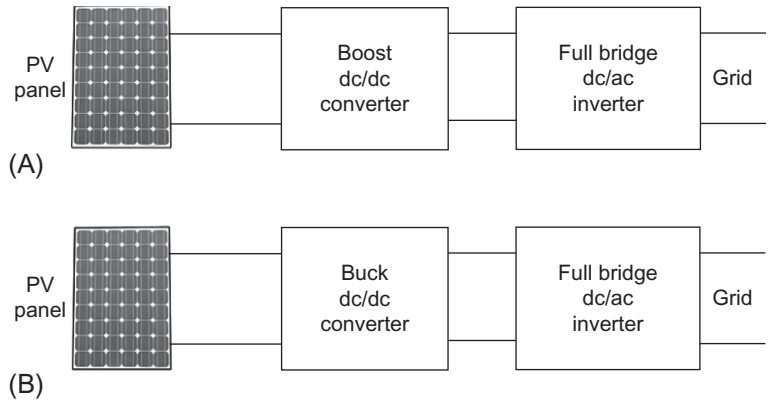

FIG. 23.16 (A) Boost converter with full-bridge inverter; (B) buck converter with full-bridge inverter.

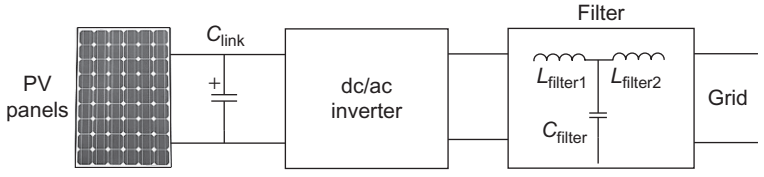

FIG. 23.17 Single-stage inverter for multiple modules.

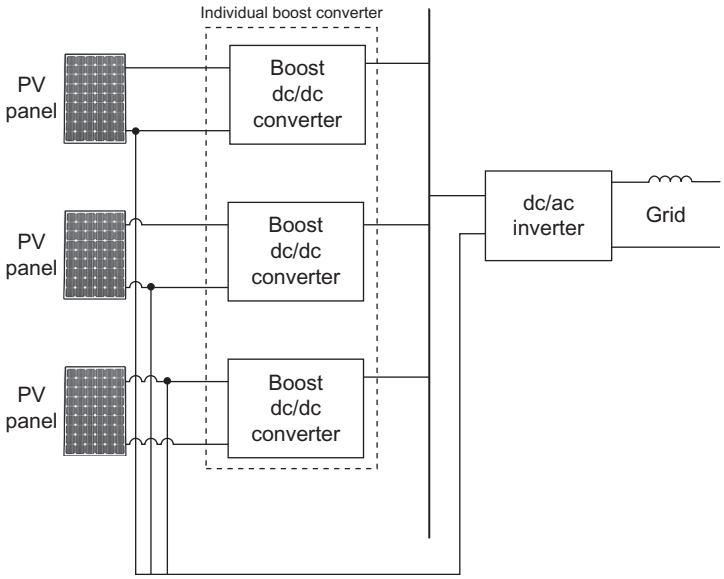

FIG. 23.18 Topology of the power electronics of the multistring inverter.

Power electronic interfaces for stand-alone PV systems
The stand-alone PV systems are composed of a storage device and its controller for sustainable satisfaction of the load power demands [127]. The storage device with the controller should provide the power difference when the available power from the PV panel is smaller than the required power at the load bus [128]. When the available power from the PV panel is more than the required power, the PV panel should supply the load power, and the excess power should be used to charge the storage device. A simple PV panel/battery connection topology is shown in Fig. 23.19.

In this simple topology, the dc/dc converter between the battery and the PV panel is used to capture all the available power from the PV panel. In this system, battery pack acts as an energy buffer, charged from the PV panel and discharged through the dc/ac inverter to the load side. The charging controller determines the charging current of the battery, depending on the MPP of the PV panels at a certain time. When there is no solar insulation available, the dc/dc converter disables, and the stored energy within the battery supplies the load demands. The battery size should be selected so that it can supply all the power demands during a possible no-insulation period. In addition, it could be fully charged during the insulated periods to store the energy for future use. Since the combined model produces ac electric energy, it should be converted to ac electric energy for domestic electric loads. The combined system requires a dc/ac inverter, which is also used to match the different dynamics of the combined energy system and various loads. The proper response of the PV/battery system to the overall load dynamics can be achieved by generating appropriate switching signals to the inverter while modulating for both active and reactive powers. The load bus voltage can be controlled by the modulation index control of the inverter; while the load control can be achieved by the phase angle control of the inverter.

23.3.4 Wind Turbines and Wind Energy Conversion Systems

Wind turbines are devices that are capable of capturing the kinetic energy of winds. This kinetic energy is converted to mechanical energy to rotate the turbine that is coupled to an electric generator. In this way, kinetic energy of the wind can be converted into a usable form of energy, that is, electric

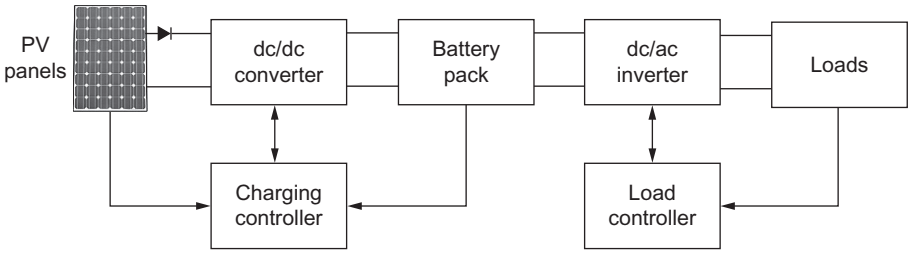

FIG. 23.19 PV/battery connection for stand-alone applications.

energy. Wind turbines can be installed stand-alone to power remote or isolated locations, or they can be grid-connected, to supply power to the utility grid. Wind power is renewable, widely distributed, plentiful, and it is a clean way of energy conversion. Additionally, it contributes in reducing the greenhouse gas emissions since it can be used as an alternative to fossil-fuel-based power generation [129]. Although wind energy has a great potential to significantly contribute the world's power generation, only 1% of worldwide power requirement is supplied by wind turbines [130].

Several key parameters such as air density, area of the blades, wind speed, and rotor area need to be considered in order to efficiently capture wind energy. Wind force is converted into a torque that rotates the blades of wind turbine. The wind force is stronger in higher air densities. In other words, kinetic energy of the wind depends on air density, and heavier winds carry more kinetic energy. At normal atmospheric pressure and at 15°C, the weight of the air is 1.225 kg/m^3, but if the humidity increases, the density decreases slightly. The other fact that determines the air density is whether the air is warm or cold. Warmer winds are less dense than cold ones, so at high altitudes, the air is less dense [131]. Besides the area of the blades (air swept area), the diameter of the blade plays important role in captured wind energy. Under the same conditions, more wind can be captured with longer blades and bigger rotor area of wind turbine [130,131]. The other parameter is the wind speed. It is expected that wind kinetic energy arises as wind speed increases [131].

Kinetic energy of the wind can be expressed as

$$E_k = \frac{1}{2} m \cdot v^2 = \frac{1}{2} \rho \cdot R^2 \cdot \pi \cdot d \cdot v^2 \tag{23.9}$$

where E_k represents kinetic energy of the wind, m stands for the mass of the wind, v is wind speed, ρ is air density, A is rotor area, R is blade length, and d stands for thickness of the "air disc" shown in Fig. 23.20.

Hence, the overall wind power (P) is [131]

$$P = \frac{E_k}{t} = \frac{1}{2} \rho \cdot R^2 \cdot \pi \cdot v^3 \tag{23.10}$$

From (23.10), it can be seen that the power content of the wind varies with the cube (the third power) of the average wind speed as shown in Fig. 23.21.

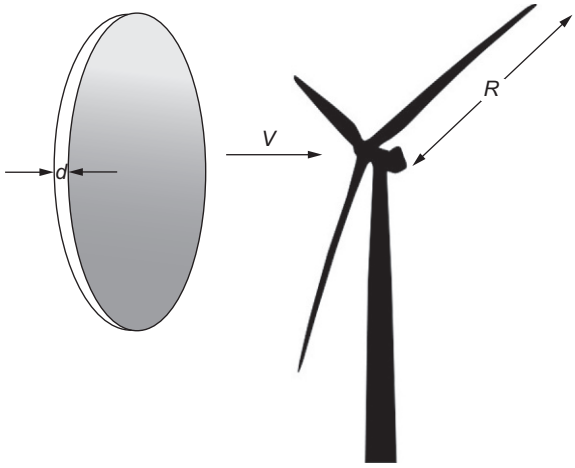

FIG. 23.20 Kinetic energy of wind.

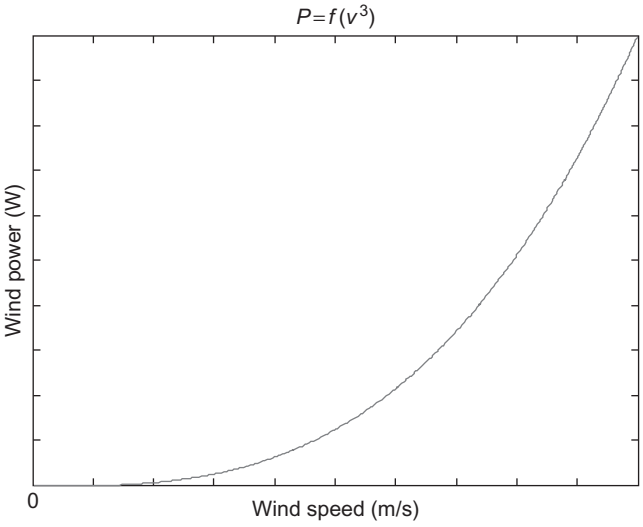

FIG. 23.21 Specific wind power due to wind speed variation.

23.3.4.1 Wind Turbine Power

Betz's law

The theoretical maximum power that can be extracted from the wind is demonstrated by Betz's law [132,133]. The wind turbines extract the kinetic energy of the wind. Higher wind speed results in higher extracted energy. It should be noted that the wind speed after turbine (after passes through turbine) is much lower than before it comes to the turbine (before energy is extracted) since the wind loses its speed by transferring its kinetic energy to wind turbine. That means wind speed before wind approaches (in front of) the turbine and its speed after (behind) turbine are different. Fig. 23.22 shows both speeds. The wind after the turbine has less amount of energy due to decreased speed of wind.

The decreased wind speed, after turbine, provides information on the amount of possible extracted energy from the wind. The extracted power from the wind can be calculated using (23.7)

$$P_{extract} = \frac{E_k}{t} = \frac{1}{2} \rho \cdot R^2 \cdot \pi \cdot \frac{v_a + v_b}{2} \cdot \left(v_b^2 - v_a^2 \right) \tag{23.11}$$

where $P_{extracted}$ shows maximum extracted power from the wind, v_a and v_b are wind speeds after and before passing through the turbine, ρ is the air density, and R demonstrates the radius of the blades.

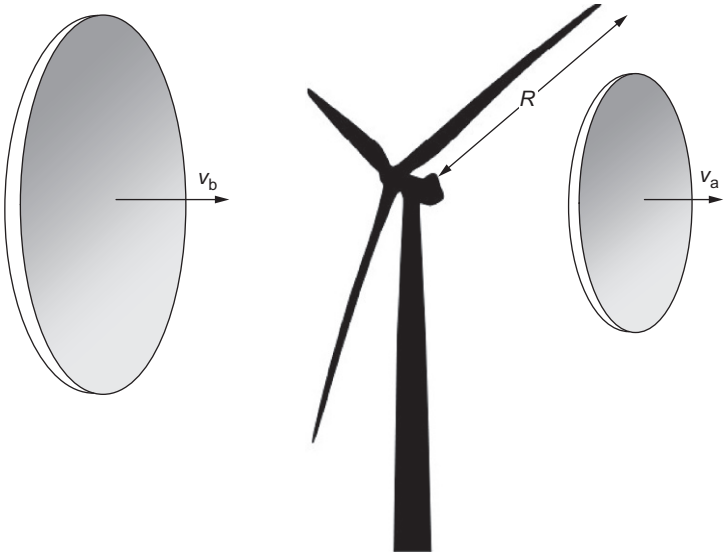

FIG. 23.22 Wind speed before and after turbine.

The relation of total amount of power P_{total} to the extracted power $P_{extracted}$ can be calculated as

$$\frac{P_{extract}}{P_{total}} = \frac{\frac{v_a + v_b}{2} \cdot \left(v_b^2 - v_a^2\right)}{v_b^3} = \frac{1}{2}\left(1 - \frac{v_a^2}{v_b^2}\right) \cdot \left(1 + \frac{v_a}{v_b}\right) \quad (23.12)$$

For the maximum power extraction, the ratio of the wind speed after and before the turbine can be calculated using $\frac{d(P_{extract}/P_{total})}{d(v_a/v_b)} = 0$.

Solving (23.12) for v_a/v_b yields

$$\frac{v_a}{v_b} = \frac{1}{3} \quad (23.13)$$

As a result, (23.12) reaches its maximum value for $\frac{v_a}{v_b} = \frac{1}{3}$.

$$\left.\frac{P_{extract}}{P_{total}}\right|_{\frac{v_a}{v_b} = \frac{1}{3}} \approx 59.3\% \quad (23.14)$$

Eq. (23.14) shows that the maximum extracted power from the wind is 59.3% of the total available power. In other words, it is not possible to extract all 100% of wind energy since the wind speed after turbine cannot be 0.

Betz's law indicates that the maximum theoretical extracted wind power is 59%. However, in practice, the real efficiency of wind turbine is slightly different.

23.3.4.2 Different Electrical Machines in Wind Turbines

There are many types of electric machines that are used in wind turbines. There is no clear criterion for choosing a particular machine to work as a wind generator. Based on the installed power, site of turbine, load type, and simplicity of control, the wind generator can be chosen. Squirrel-cage induction or brushless DC (BLDC) generators are usually used for small wind turbines in household applications. Doubly fed induction generators are usually used for megawatt size turbines. Synchronous machines and permanent-magnet synchronous machines (PMSM) can also be used for wind-turbine applications.

Brushless DC (BLDC) machines

Brushless DC machines (BLDC) are very popular in many applications due to the recent advances in their development. In addition, the development of fast semiconductor switches, cost-effective DSP processors, and other microcontrollers have influenced the development of the motor/generator drives. Brushless DC machines (BLDC) are widely used because of their simple control, efficiency, compactness, lightweight, ease of cooling, less noise, and low maintenance [134,135]. Usually, BLDC machines are used in small wind turbines (up to 15 kW).

The simplified equivalent circuit of the BLDC generator connected to a diode rectifier is shown in Fig. 23.23. This is the simplest way of using BLDC machine for wind applications, because there is no switch to control the phase current. The full bridge rectifies the induced voltages of variable frequency (because of variable wind speeds). Basically, the waveform of the induced electromotive force (EMF) is converted to dc voltage regardless of the input waveform. Usually, these types of wind turbines are connected to batteries; therefore, rectified electric power is used to charge the battery.

Three-phase active synchronous rectifiers can be used with BLDC generators. In this case, the controlled rectifier is used for BLDC phase current control. Usually, hysteresis regulators are used to control current. In synchronous rectifiers, active switching devices such as IGBTs or MOSFETs are used.

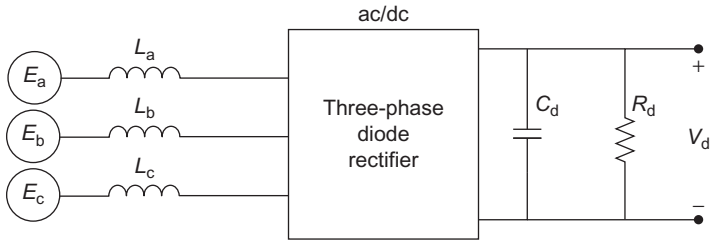

FIG. 23.23 Diode rectifier connected to BLDC generator.

By employing a PWM control strategy for the synchronous rectifier, MPP tracking of the wind turbine can be achieved. An inverter can be placed at the dc bus for grid interconnection or powering the ac loads.

Permanent magnet synchronous machines

For both fixed and variable speed applications, permanent-magnet (PM) synchronous machines can be used. The permanent-magnet synchronous generator (PMSG) is very efficient and suitable for wind-turbine applications. PM synchronous generators allow direct-drive energy conversion for wind applications. Direct-drive energy conversion helps eliminating the gearbox between the turbine and generator; thus, these systems are less expensive, and less maintenance is required [136,137]. However, lower speed determined by the turbine shaft is the operating speed for the generator.

A wind power system where a PM synchronous generator is connected to a full-bridge rectifier followed by a boost converter is shown in Fig. 23.24. In this case, the boost converter controls the electromagnetic torque. The supply side converter regulates the dc-link voltage and controls the input power factor. One drawback of this configuration is the use of diode rectifier that increases the current amplitude and losses. The grid-side converter can be used to control active and reactive power being supplied to the grid. Automatic voltage regulator (AVR) obtains the information of speed of turbine, dc-link voltage, current, and grid-side voltage and current. It calculates PWM pattern (control scheme) for converter. This configuration has been considered for small size (less than 50 kW) wind power systems (WPS) [138].

Instead of using a diode rectifier cascaded by a dc/dc converter, both rectifier and inverter can be controllable. A PMSG where the PWM rectifier is placed between the generator and the dc link, and PWM inverter is connected to the utility is shown in Fig. 23.25. In this case, the back-to-back converter can be used as the interface between the grid and the stator windings of the PMSG [139]. The turbine can be operated at its maximum efficiency, and the variable speed operation of PMSG can be controlled by using a power converter that is utilized to regulate the maximum power flow. The stator terminal voltage can be controlled in several ways [140]. In this system, utilizing the field orientation control (FOC) allows the generator to operate near its optimal working point in order to minimize the losses in the generator and power electronic circuit.

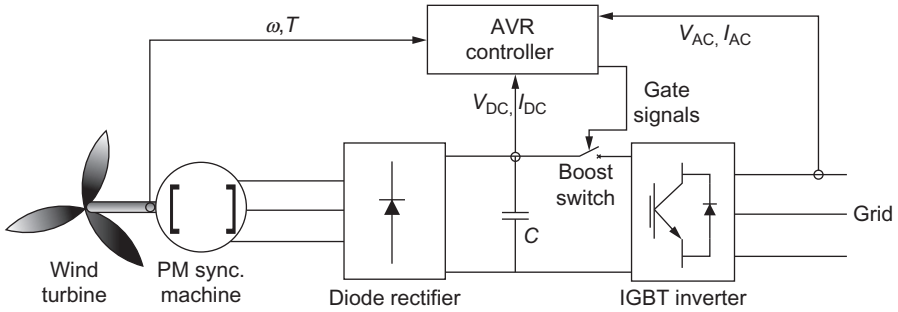

FIG. 23.24 PM synchronous generator with rectifier/inverter.

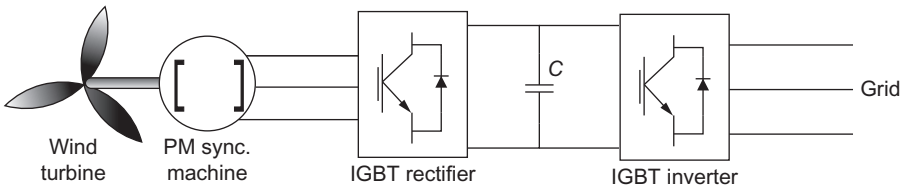

FIG. 23.25 PM synchronous generator with back-to-back inverter.

However, the performance depends on the knowledge of the generator parameter that varies with temperature and frequency. The main drawbacks are the cost of PMs that increases the price of the machine and demagnetization of the PMs. In addition, it is not possible to control the power factor of the machine [134].

Squirrel cage induction machines

The three-phase induction machines are commonly used in industrial motor applications. However, they can also be effectively used as generators in electric power systems. The main issue with induction machines as electric power generators is the need for an external reactive power source that will excite the induction machine, which is certainly not required for synchronous machines in similar applications. If induction machine is connected to the grid, the required reactive power can be provided by the power system. Induction machine may be used in cogeneration with other synchronous generators, or the excitation might be supplied from capacitor banks (only for stand-alone self-excited generator application) [141–146]. The reactive power required for excitation can be supplied using static VAr compensators [147,148] or static compensators (STATCOMs) [149].

Due to its low cost, brushless rotor construction does not need a separate source for excitation. No maintenance and self-protection against severe over loads, short circuits, and self-excited induction generators are used in wind-turbine applications [142–146]. The only drawback of these types of generators can be their inherent generated voltage and frequency regulation under varied loads [150].

Common structure of a squirrel-cage induction generator with back-to-back converters is shown in Fig. 23.26. In this structure, stator winding is connected to utility through a four-quadrant power converter. Two PWM VSI are connected back-to-back through a dc link. The stator-side converter regulates the electromagnetic torque and supplies reactive power, while the grid-side converter controls the real and reactive power delivered from the system to the utility and regulates the dc link. This topology has several practical advantages, and one of them is the possibility of fast transient response for speed variations. In addition, the inverter can operate as a VAR/harmonic compensator [151].

On the other hand, the main drawback is the complex control system. Usually, FOC is used to control this topology, where its performance relies on the generator parameters, which vary with temperature and frequency. Hence, in order to supply the magnetizing power requirements, that is, to magnetize the machine, the stator-side converter must be oversized 30%–50% with respect to rated power.

Doubly fed induction generator (DFIG)

Fig. 23.27 presents a topology consisting of a doubly fed induction generator (DFIG) with ac/dc and dc/ac converters, that is, a four-quadrant ac/ac converter using IGBTs connected to the rotor windings. In the DFIG topology, the induction generator is not a squirrel-cage machine, and the rotor windings are not short-circuited. Instead, they are used as the secondary terminals of the generator that provides the capability of controlling the machine power, torque, speed, and reactive power. To control the active and reactive power flow of the DFIG topology,

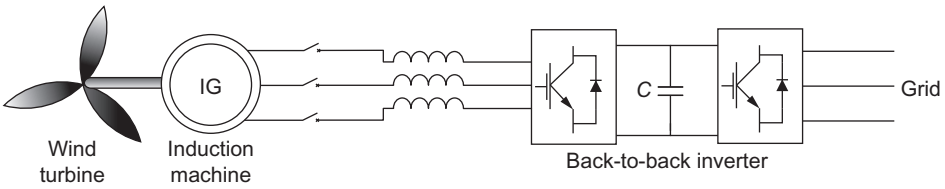

FIG. 23.26 Induction machine controlled by back-to-back inverter.

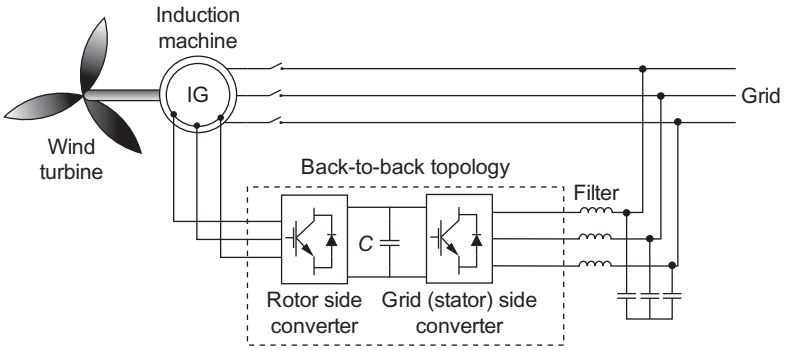

FIG. 23.27 Doubly fed induction machine topology.

rotor- and grid-side converters should be controlled separately [152–155].

Wounded rotor induction machines can be supplied from both rotor and stator sides. The speed and the torque of the wounded rotor induction machine can be controlled by regulating voltages from both rotor and stator sides of machine. The DFIG can be considered as a synchronous/asynchronous hybrid machine. In the DFIG, similar to the synchronous generator, the real power depends on the rotor voltage magnitude and angle. In addition, the induction machine slip is also a function of the real power [156]. DFIG topology offers several advantages in comparison with systems using direct-in-line converters [157,158]. These benefits are the following:

- The main power is transferred through the stator windings of the generator that is directly connected to the grid. Around 65%–75% of the total power is transmitted through stator windings. The remaining power is transmitted using the rotor windings, that is, through the converters, which is about 25% of the total power. Since the inverter rating is 25% of total system power, the inverter cost and size can considerably be reduced.
- While the generator losses are the same in both topologies (direct-in-line and DFIG), the inverter losses can be reduced from around 3% to 0.75%, because the inverter is supposed to only transfer 25% of the total power. Therefore, approximately 2%–3% efficiency improvement can be obtained.
- DFIG topology offers a decoupled control of generator active and reactive powers [159,160].
- Cost and size of the inverter and EMI filters can be reduced since the inverter size is reduced. In addition, the inverter harmonics are lowered because the inverter is not connected to the main stator windings.

In the rotor circuit, two voltage-fed PWM converters are connected back to back, while the stator windings are directly connected to the ac grid side as shown in Fig. 23.27. The direction and magnitude of power between the rotor windings and stator windings can be controlled by adjusting the switching of the PWM signals of the inverters [161–163]. This is very similar to connecting a controllable voltage source to the rotor circuit [164]. This can also be considered as a conventional induction generator without a zero rotor voltage.

To take the benefits of variable speed operation, the optimum operating point of the torque-speed curve should be tracked precisely [165]. By controlling the torque of the machine, speed can be adjusted. Thus, using the instantaneous rotor speed value and by controlling the rotor current i_{ry} in stator-flux-oriented reference frame, the desired active power can be obtained. Operation at the desired active power results in the desired speed and torque [153]. On the other hand, the grid-side converter is controlled to keep the fixed dc-link voltage independent of the direction of rotor power flow. By using supply voltage vector-oriented control, the decoupled control of active and reactive power flow between rotor and grid can be obtained.

Using doubly fed induction generator, the oversizing problem can be solved. Still, speed range of turbine is wide enough; thus, a power converter, which is rated for much lower powers, can be placed in rotor side only, and stator is connected to grid directly. Since power flowing through rotor is usually around 25%–30% of power going through stator, the power electronic interface is designed for only 25%–30% of total power. This is the most important advantage of DFIG.

Synchronous generators

Synchronous generators are commonly used for variable speed wind-turbine applications, due to their low rotational synchronous speeds that produce the voltage at grid frequency. Synchronous generators can be an appropriate selection for variable speed operation of wind turbines [166,167]. They do not need a pitch control mechanism. The pitch control mechanism increases the cost of the turbine and causes stress on turbine and generator [168]. Synchronous generators in variable speed operation will generate variable voltage and variable frequency power. Using an AVR for the excitation of the field voltage, the output voltage of the synchronous generator can be controlled. However, induction generators require controlled capacitors for voltage control. In addition, their operating speed should be over synchronous speed in order to operate in generating mode [169].

Multipole synchronous generators can be used more efficiently since the gear can be eliminated, and direct drive of the turbine and generator can be achieved [170,171]. However, synchronous generators without multipoles require gearboxes in order to produce the required frequency for grid connection. On the other hand, a dc voltage source or an ac/dc converter is required for synchronous generators in wind applications in order to produce the required excitation voltage for the field windings. The synchronous generator connection with wind turbine is shown in Fig. 23.28.

23.3.4.3 Energy Storage Applications for Wind Turbines

The batteries and other dc energy storage devices can be connected to the dc links of any topologies. The main purpose of batteries is to assist the generator to meet the load demand. When the load current is smaller than generator current, the extra current is used to charge the battery energy storage. On the other hand, when the load current is larger than generator current, the current is supplied from the battery to the load. With this strategy, the voltage and frequency of the generator can be controlled for various load conditions. Energy storage decreases system inertia, improves the behavior of the system in the case of disturbances, compensates transients, and therefore improves the efficiency [172]. However, it brings an initial cost to the system and requires periodical maintenance depending on the storage devices. Therefore, the voltage and frequency control can be modified by using batteries as the controllable load of the VSI as presented in Fig. 23.29. In this way, the load can be regulated by controlling the power flow to the batteries. A bidirectional inverter/converter can be used for

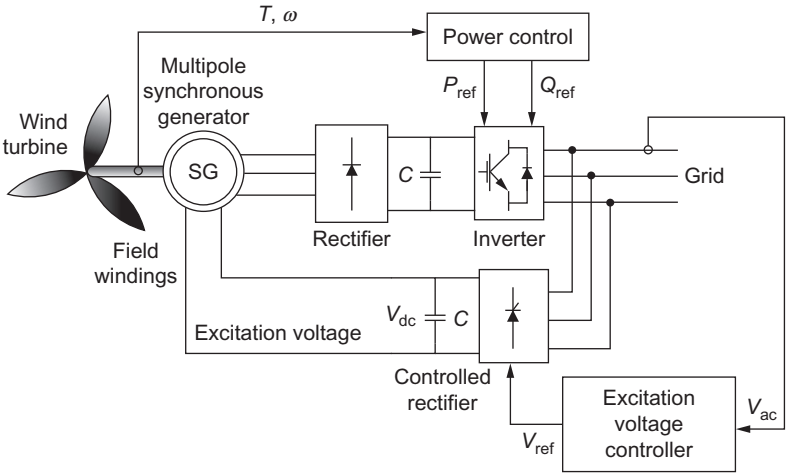

FIG. 23.28 Multipole synchronous generator for wind-turbine applications.

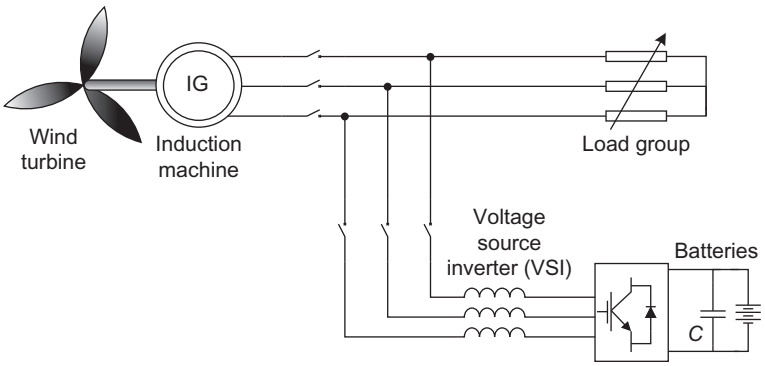

FIG. 23.29 Voltage and frequency control using energy storage.

power flow from/to the batteries. As another alternative, the battery voltage can be converted to ac voltage with another individual inverter to provide power to AC loads. Although an induction generator is shown in Fig. 23.29, these energy storage systems are applicable to any other topologies.

Storage systems can be connected in various forms to the wind-turbine systems [173–177]. Generally, a bidirectional dc/dc converter is required for the integration of the storage system to the doubly fed induction generator system [178]. In this topology, one of the converters regulates the storage power, whereas the other is responsible for dc bus voltage control. The bidirectional energy storage topology for DFIGs in wind applications is shown in Fig. 23.30.

23.3.5 Ocean Energy Harvesting

23.3.5.1 Ocean Wave Energy

Ocean waves are a plentiful, clean, and renewable source of energy. The total power of waves breaking around the world's coastlines is estimated at 2–3 million megawatts. The west coasts of the United States and Europe and the coasts of Japan and New Zealand are good sites for harnessing wave energy [179]. Wave energy conversion is one of the feasible future energy technologies; however, it is not mature enough. Therefore, the construction cost of wave power plants is considerably high. These energy systems are not developed and maturated commercially due to the problems of dealing with sea conditions, complexity, and difficulty of interconnection and transmission of electricity.

A wave power absorber, a turbine, a generator, and the power electronic interfaces are the main components of a typical ocean wave energy harvesting technique. The kinetic energy of the ocean waves are captured by absorbers. Either the absorbed kinetic energy of the waves is conveyed to turbines or the absorber directly drives the generator. The shaft of the electric generator is driven by the turbine. Turbines are generally used within the systems including rotational generators. Linear motion generators are used in systems without turbines, which can be direct driven by the power absorber or movement of the device. Due to the varying amplitude and period of the ocean waves, both linear and rotational generators generate variable frequency—variable amplitude ac voltage. This ac voltage can be rectified to dc voltage to take the benefit of dc energy transmission through the salty ocean water. dc transmission in salty water does not require an additional cable for the negative polarity. Thus, it will be more cost-effective than transmitting

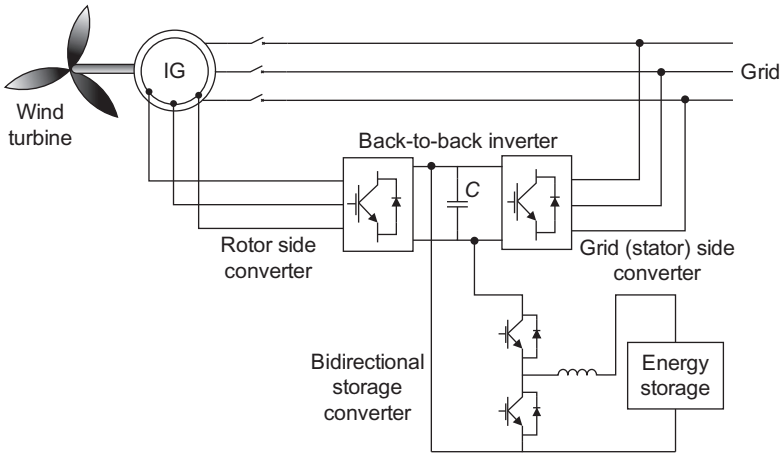

FIG. 23.30 Energy storage with bidirectional converter in DFIG systems.

the power in ac form, which requires three-phase cables. Transmission cable length varies depending on the location of the application, which is either nearshore or offshore. However, the main idea and the principles are the same for both types of applications. After the dc power is transmitted from ocean to the land, a dc/dc converter or a tap-changing transformer can be used for voltage regulation. Depending on the utilized voltage regulation system, a dc/ac inverter is used before or after the voltage regulator. The voltage synchronization is provided by the inverter, and the output terminals of the inverter can be connected to the grid.

In Fig. 23.31, a system level diagram of the ocean wave energy harvesting technology is shown. At an in-water substation, wave energy conversion devices (including the absorber, turbine, and generator) are interconnected. The substation consists of the connection equipments and controllers for individual devices. The outputs of the generators are connected to a common dc bus using dc/ac converters for transforming power before transmission to the shore. A transmission line connects the cluster to shore. An onshore inverter converts the dc voltage to a 50 or 60 Hz ac voltage for grid connection. An optional shore transformer with tap changer or a dc/dc converter compensates the voltage variations. A group of absorber, turbine, and generators could be used in a farm structure; thus, the captured energy can be increased.

Alternatively, the land converters might be moved offshore to come up with space limitations that may occur in land stations. This brings some complexity to the system and may require more maintenance, which is harder to deal, in comparison with landside converters. Moreover, the transformer can be installed offshore. This would increase the power transmission capability, since the higher voltage transmission will result in less transmission losses. However, in this case, the advantage of dc transmission will not exist. As a different option, boost dc/dc converters can be used after the ac/dc converter of the generator. This allows a high-voltage dc transmission link. In this case, both transmission losses will be kept at minimum, and only single-line dc transmission through the ocean water will be required.

Energy of ocean waves

The total potential and kinetic energy of an ocean wave can be expressed as

$$E = \frac{1}{2}\rho g A^2 \tag{23.15}$$

where g is the acceleration of gravity (9.8 m/s^2), ρ is the density of water (1000 kg/m^3), and A is the wave amplitude (m).

The power of a wave in a period is equal to the energy E multiplied by the speed of wave propagation, v_g, for deep water

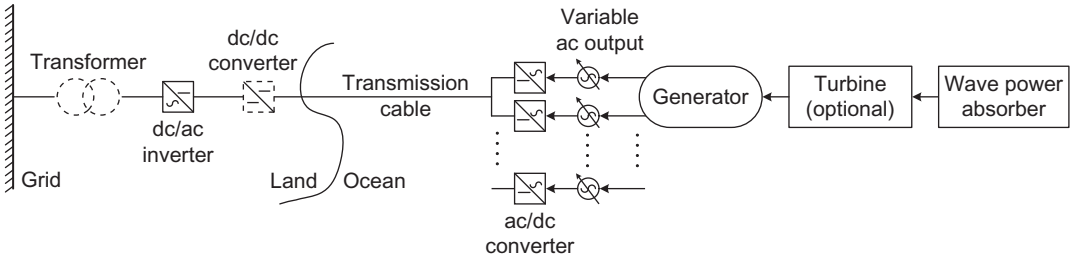

FIG. 23.31 System level diagram of ocean wave energy harvesting.

$$v_g = \frac{L}{2T} \tag{23.16}$$

where T is the wave period (seconds) and L is the wave length (m) [180].

$$P_w = \frac{1}{2}\rho g A^2 \frac{L}{2T} \tag{23.17}$$

The dispersion relationship describes the connection between the wave period T and the wave length L as

$$L = \frac{gT^2}{2\pi}. \tag{23.18}$$

If (23.18) is substituted in (23.17), the power or energy flux of an ocean wave can be calculated as

$$P_w = \frac{\rho g^2 T A^2}{8\pi}. \tag{23.19}$$

Instead of using the wave amplitude, wave power can also be rewritten as a function of wave height, H [m]. Considering that the wave amplitude is the half of the wave height, the wave power becomes

$$P_w = \frac{\rho g^2 T H^2}{32\pi}. \tag{23.20}$$

Ocean wave energy harvesting technologies

In general, ocean wave energy harvesting technologies can be classified into two types with respect to their distance from the shore: offshore ocean wave energy harvesting technologies and onshore ocean wave energy harvesting technologies. These are discussed in details in following subsections.

Off-shore ocean wave energy harvesting technologies: Off-shore applications are located away from the shore, and they generally use a floating body as wave power absorber and another body that is fixed to the ocean bottom. Generally, linear generators with buoys are used in offshore applications. Linear generators are directly driven by the movement of a floating body on the ocean. Salter cam and buoys with air-driven turbines are the only applications involving rotational generators in offshore applications.

23.3.5.1.2.1.1 Air-Driven Turbines based Off-Shore Technologies

In air-driven turbine systems for offshore applications, the primary conversion is from wave to the pressurized air. Secondary conversion stage is the conversion to mechanical energy by rotating shaft of the turbine. The last stage is converting mechanical rotation into electric power by electric generators.

The operating principle of an offshore application that consists of a floating buoy with an air chamber and an air-driven generator is shown in Fig. 23.32. In this system, the water level inside channel of the buoy increases when the waves hit the body. This increase in water level applies a pressure to the air in the air chamber. When the air is pressurized, it applies a force to the ventilator turbine and rotates it. This turbine drives the electric generator, and electricity is generated at the output terminals of this generator. When the waves are pulled back to the ocean, the air in the air chamber is also pulled back since the water level in the buoy channel decreases. Due to the syringe effect, this time, turbine shaft rotates in the contrary direction but produces electricity. There should be very good mechanical insulation through the air chamber and the ventilating generator to achieve higher efficiencies. However, this brings design complexity and additional cost to the system.

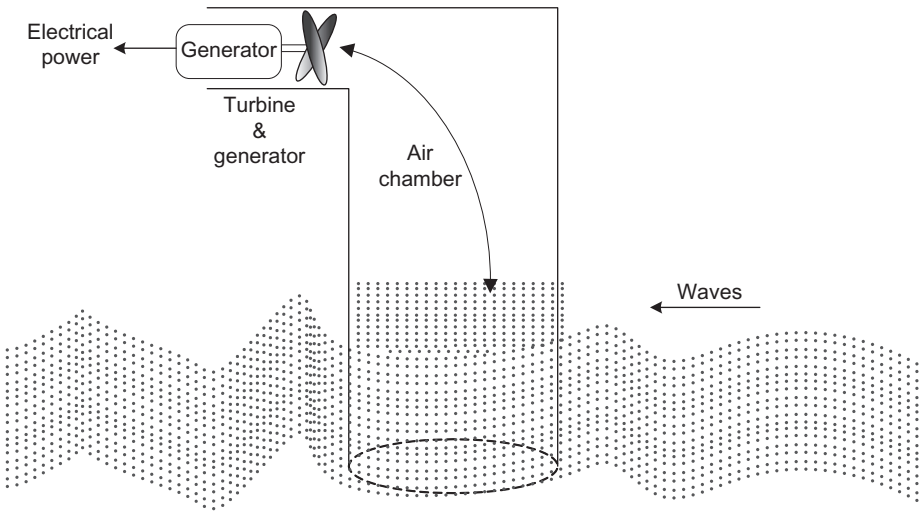

FIG. 23.32 Spinning the air-driven turbines using wave power [181].

In another method, water level increases, and air is taken out from the upper outlets while spinning the turbines as shown in Fig. 23.33A. Contrarily, when the waves are pulled back to the sea, water level decreases. This results in sucking the air back from the upper inlets while spinning the turbines, as shown in Fig. 23.33B.

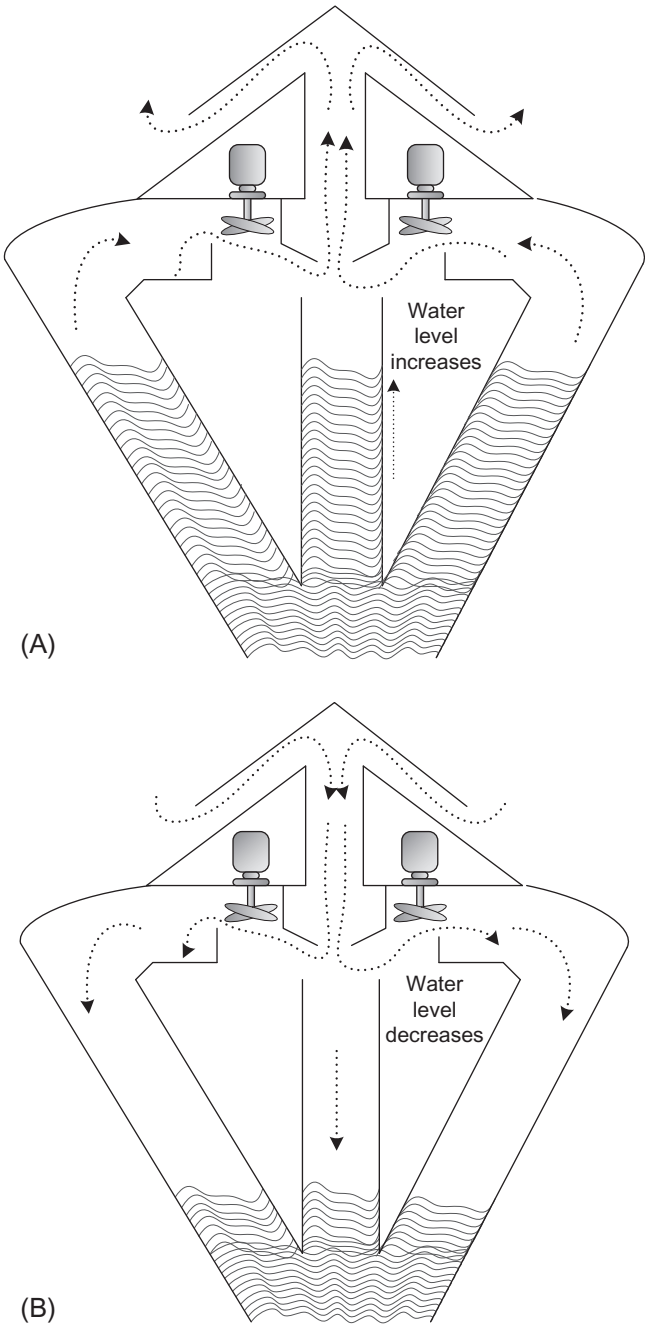

FIG. 23.33 Air-pressure ring buoy: (A) water level increases, and air is taken out from the upper outlets; (B) Water level decreases, and air is pulled back from upper inlets.

23.3.5.1.2.1.2 Direct-drive permanent-magnet linear generator-based buoy applications

The height differences of the wave top and bottom levels yield an up and down motion for the piston that is the transaxle of the linear generator. When the wave is floating on the ocean surface, the buoy follows the motion of the wave. Buoy can move vertically on a pillar, which is connected to a hull. On the surface of the hull, PMs are mounted, while outside of the hull contains the coil windings. The pillar and stator are connected together on a concentrate foundation standing on the seabed of the ocean. The hull and mounted magnets, called rotor or piston, are the moving parts of the generator. Since the motion is linear, this generator is called a linear generator.

In Fig. 23.34, the linear generator in the floating buoy and fixed pillar are shown.

When the wave rises, the buoy will drive the generator piston through a stiff rope. When the wave subsides, the generator will be driven by the spring that stores the mechanical energy in the first case. Thus, electric generation is provided during both up and down motion. Due to the existence of variable frequency in the current and voltage from the stator, an ac/dc rectifier followed by a dc/ac converter is required to make the grid connection possible. Instead of placing moving parts to the ocean bottom, the PMs and the stator windings can be placed at the sea level [182]. Fig. 23.35 shows the x-y plane of the cross-sectional view of one pole of the longitudinal flux surface mounted linear PM generator.

23.3.5.1.2.1.3 Salter Cam Method

Salter cam method implementation is shown in Fig. 23.36. Salter cam rolls around a fixed inner cylinder by activation of an incoming wave. Through the differential rotation between the cylinder and the cam, power can be captured. The motion of the cam is converted from wave to a hydraulic fluid. Then, hydraulic motor is used to convert the pressurized hydraulic fluid to rotational mechanical energy. Finally, rotational mechanical energy is converted to electricity by utilizing electric generators. Flywheels or pressurized liquids can be used as an intermediate step in order to reduce the intermittencies of the wave power.

Near-shore ocean wave energy harvesting technologies: Nearshore topologies are applied within the surfing zone of the ocean or right on the shore. Nearshore applications have some advantages and disadvantages in comparison with the offshore applications.

23.3.5.1.2.2.1 Channel/reservoir/turbine based near-shore wave energy harvesting method

Wave currents can be tapered into a narrow channel to increase their power and size in order to harness the wave energy. As shown in Fig. 23.37, waves can be channeled into a catch basin and used directly to rotate the turbines. Since this method

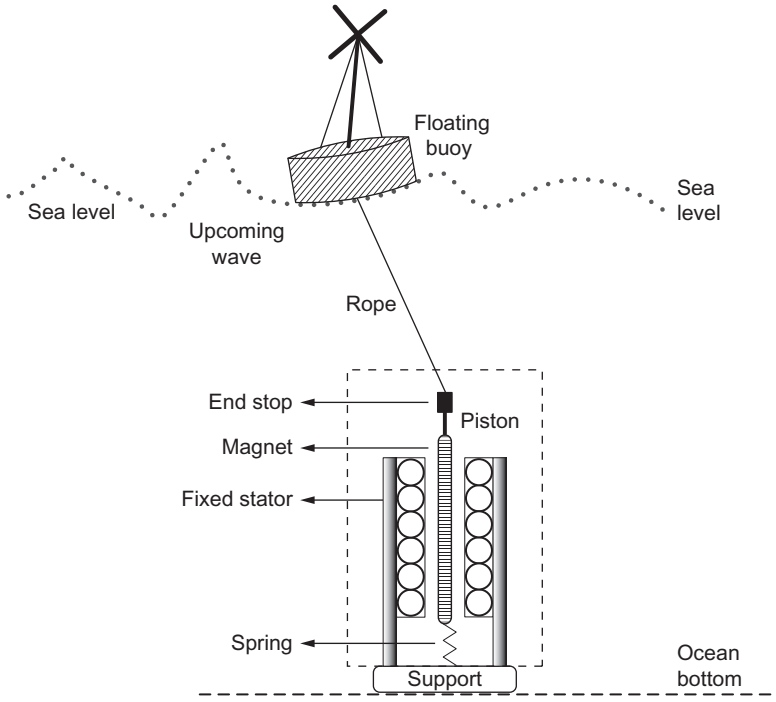

FIG. 23.34 Linear generator-based buoy type wave energy harvesting method.

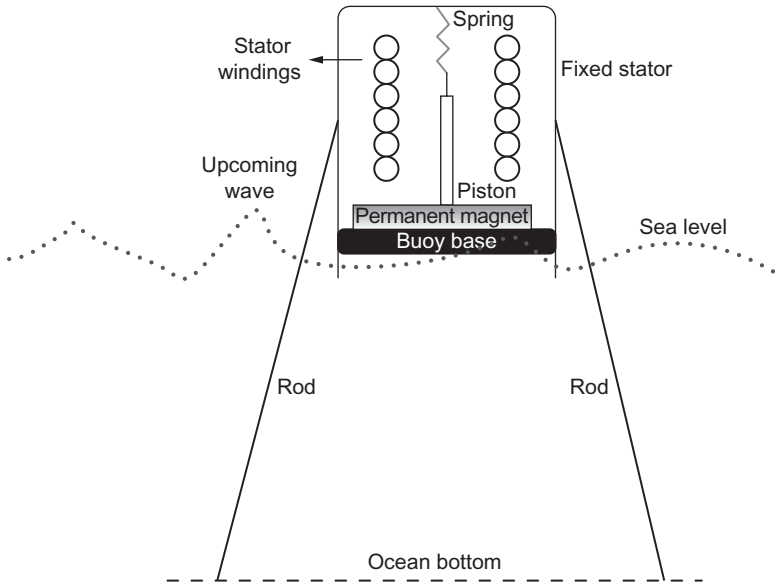

FIG. 23.35 Schematic of a longitudinal flux permanent-magnet generator used for wave energy conversion.

requires building a reservoir to collect the water coming with the waves to drive the turbine, it is more expensive in comparison with the other buoy-shaped offshore applications. However, it requires less maintenance in comparison with the offshore applications, since all components of the wave energy conversion system are located on land. Additionally, since a reservoir collects the ocean water, the intermittencies can be eliminated. This will create a convenient platform for voltage and frequency regulation. Building these types of plants in the locations, where they have regular and sustaining wave regimes, is more advantageous.

23.3.5.1.2.2.2 Air-driven turbines based near-shore wave energy harvesting method

Using oscillating water columns (OWC) that generates electricity from the wave-driven rise and fall of water in a cylindrical

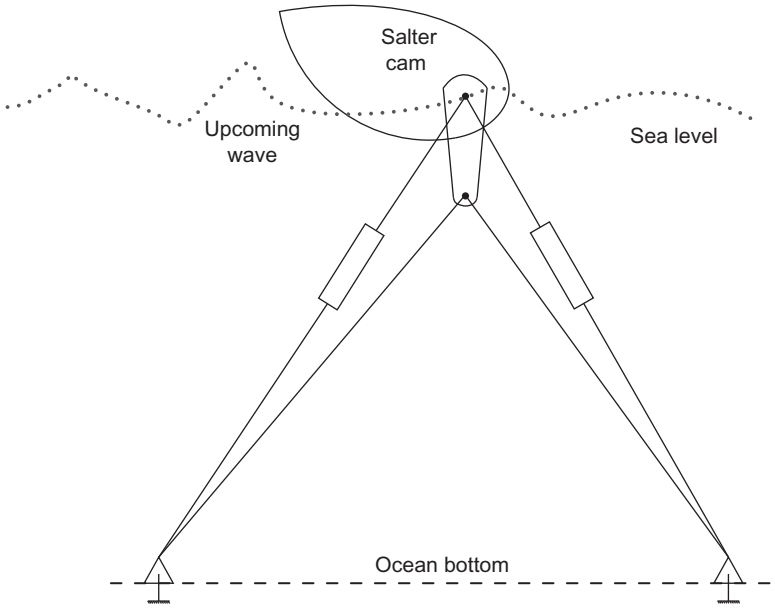

FIG. 23.36 A schematic illustrating the fixation of salter cam wave energy conversion device.

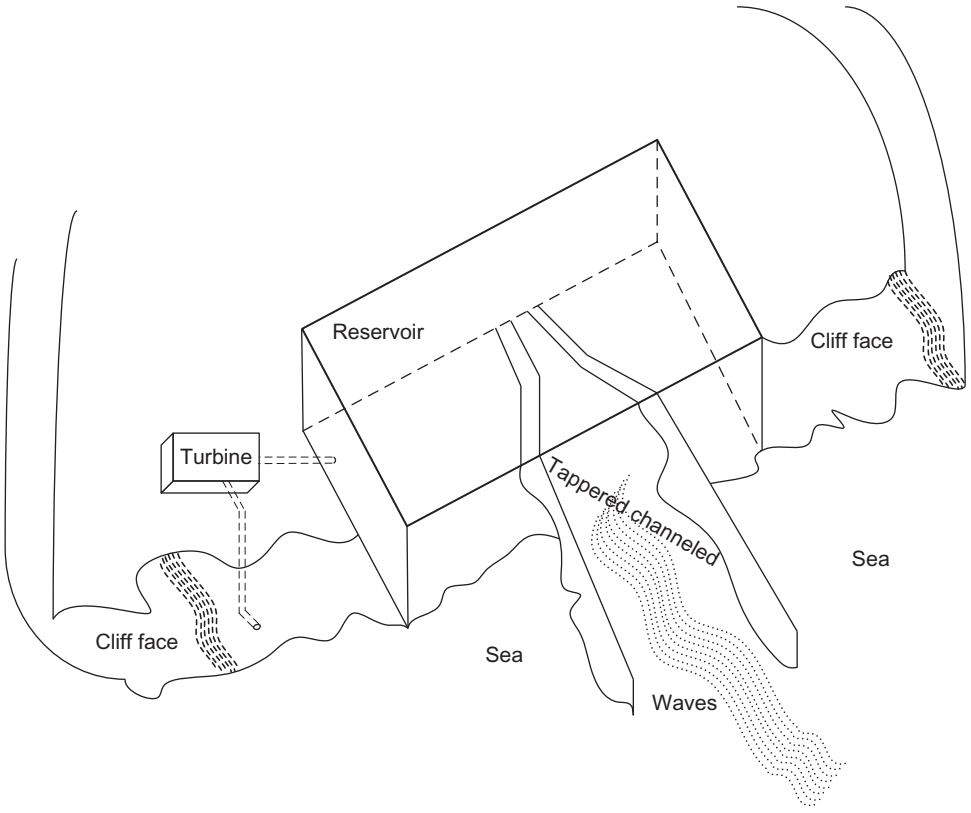

FIG. 23.37 Channeled ocean wave to a reservoir to spin the turbines.

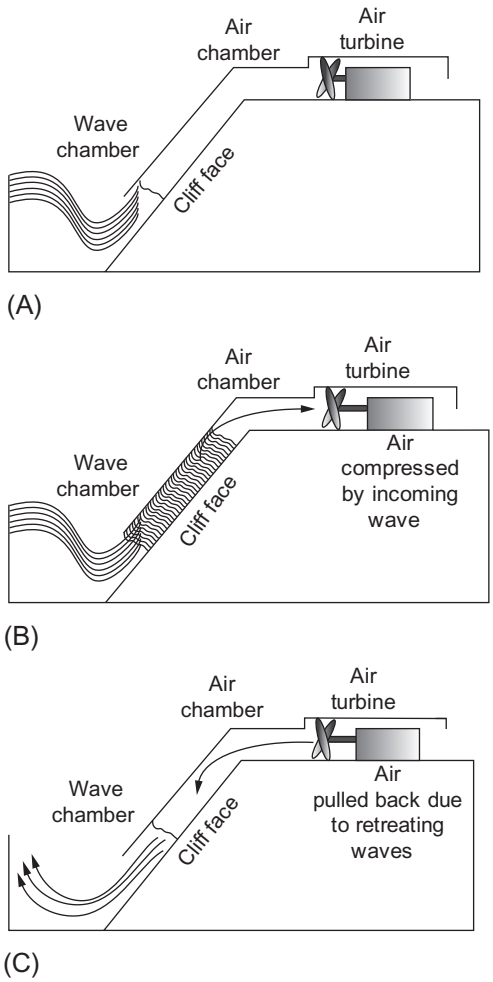

FIG. 23.38 Air-driven turbines using the wave power: (A) upcoming wave starts filling the chamber; (B) air is compressed by rising water; (C) air is pulled back by retreating waves [181].

shaft or pipe is another way to harness the wave energy. The air is driven into and out of the top of the shaft due to the rising and falling water, powering an air-driven turbine that is shown in Fig. 23.38.

The general structure of the nearshore air-driven turbine is shown in Fig. 23.38A. Waves push the air through the ventilator that drives the electric machine as shown in Fig. 23.38B. The wave retreats from the wave chamber inside the channel that decreases the pressure as shown in Fig. 23.38C. This method is advantageous because of the capability of using not only the wave power but also the power from the tidal motions. However, mechanical isolation should be provided within the wave and air chambers in order to obtain better efficiencies. This will also bring some more cost and design complexities to the system.

23.3.5.2 Ocean Tidal Energy

The generation of electric power from ocean tides is similar to the traditional hydroelectric generation. A dam, known as a barrage, across an inlet is required for the simplest tidal power plants. In a tidal power plant, usually, a tidal pond created by a dam and a powerhouse, which contains a turbo generator, and a sluice gate to allow the bidirectional tidal flow. During the flood tide, the rising tidal waters fill the tidal basin after opening the gate of the dam. When the dam is filled to capacity, the gates are closed. The tidal basin is released through a turbogenerator after the ocean waters have receded. Power can be generated during ebb tide, flood tide, or both. When the water is pulled back, ebb tide occurs, and when the water level increases near the shore, flood tide happens [183]. Tidal power can be economical at sites where mean tidal range exceeds 16 ft [183,184].

Tidal current is not affected by the climate change, the lack of rain, or a snowmelt. Therefore, tidal energy harvesting is practical since the tidal current is regular and predictable. Moreover, environmental and physical impacts and pollution issues are negligible. Tidal power can additionally be used for water electrolysis for hydrogen production applications and desalination. However, tidal power generation is an immature technology, which needs further investigations and developments.

Tidal turbines can be used for tidal energy harvesting, similar to the wind turbines. Tidal turbines can be located where there is a strong tidal flow. These turbines have to be much stronger than wind turbines since the water is about 800 times as dense as air. They will be heavier and more expensive; however, they will be able to capture more energy at much higher densities [181]. In Fig. 23.39, a typical tidal turbine is shown.

Usually, tidal fences having multiple turbines are mounted in the entrance of channels that are affected by ocean tides. Tidal water is forced to pass through a fence structure, which is called caisson in this fence application. Unlike barrage stations, basins are not required for fence applications, and they can be used in a channel between the mainland and a nearby offshore island or between two islands. Tidal fences can be mounted at the entrance of channels that ocean water gets inside the land via a bay (Fig. 23.40A), or between the main land and an island (Fig. 23.40B), or simply between two islands (as shown in Fig. 23.40C). Since they do not require flooding the basin, tidal

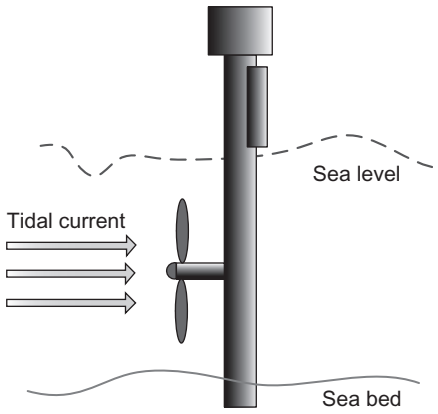

FIG. 23.39 Tidal turbine.

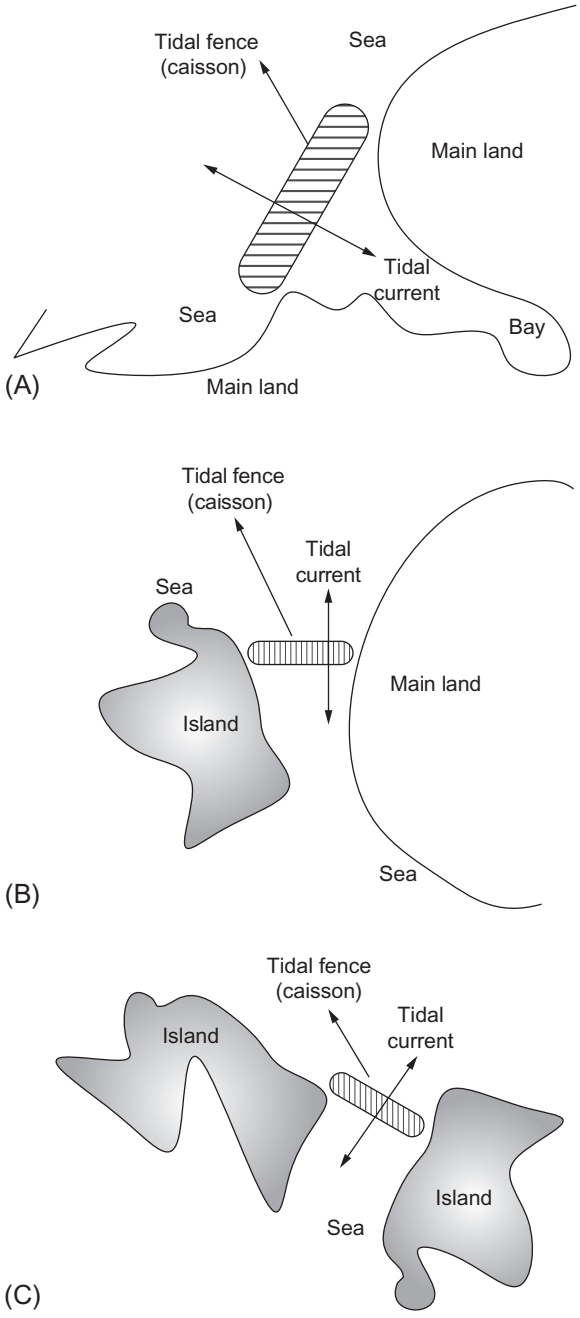

FIG. 23.40 Tidal fences can be mounted (A) at the entrance of bays, (B) between the main land and an island, and (C) between two islands.

fences have much less impact on the environment. In addition, they are significantly cheaper to install; however, the caisson may disrupt the movement of large marine animals and shipping [T4].

23.3.5.3 Power Electronic Interfaces for Ocean Energy Harvesting Applications

Both in ocean wave and ocean tidal energy harvesting applications, the generators may produce alternating currents and voltages that have varying magnitude and frequency. Therefore, output power of the ocean energy converters need further conditioning prior to the grid connection. In addition, the frequency of the output voltage should be regulated to be the same as grid frequency. Output power conditioning, amplitude, phase, and frequency of the conversion system can be regulated by utilizing power electronic converters.

Block diagram of a typical power conditioning system for a grid-connected ocean energy conversion system is shown in Fig. 23.41. Ocean wave or ocean tide potential and kinetic energies rotate the water turbine, or a power absorber directly drives a linear generator with up and down motions. The varying wave and tides result in variable frequency and amplitude of the generator output. The ac power produced by the generator is converted into dc power via three-phase bridge rectifiers followed by a dc/ac inverter. The output of the dc/ac inverter generally contains harmonics, which should be filtered. Finally, output power can be connected to grid and transmitted to consumers after its voltage is increased and isolated by a power transformer.

During the intermittencies, power cannot be generated. Therefore, an energy storage system should be connected to the generator output or output of a conversion stage in the power conditioning system. Stored energy can be supplied to the grid during the intermittency periods. Hence, it is ensured that continual power is supplied to the grid.

23.3.6 Geothermal Energy Systems

Geothermal energy is the thermal energy that is stored in the inner layers of the Earth composed of rocks and fluids. The temperature of the inner layers of the Earth gets hotter as the depth increases. In deeper layers, it is even extremely hotter due to the hot molten rock called magma [185,186].

Geothermal energy can be utilized by several methods. It can be used as direct heat for electric power generation. In the direct heat utilization, applications can be categorized as hydrothermal, agricultural, or industrial [187]. Hydrothermal resources have low to moderate temperatures between 20 and 150°C. These resources can be utilized to provide direct heating for residential, industrial, and commercial sectors [188]. These applications include but are not limited to water and space heating, greenhouse and agricultural heating, cleaning, textile processes, and food dehydration. Agricultural production is one of the utilization methods of direct use of geothermal energy. It is used to warm the greenhouses in order to provide cultivation. Industrial utilization examples can be food and cloth processing, manufacturing paper, pasteurizing milk, drying fish, vegetables and fruits, and even for refrigeration and air conditioning.

Other than the direct use of geothermal energy, it can be used as the heat and steam source for electric power plants. Instead of burning fossil fuels and generating heat for water boiling, geothermal power plants use the readily obtained heat or steam.

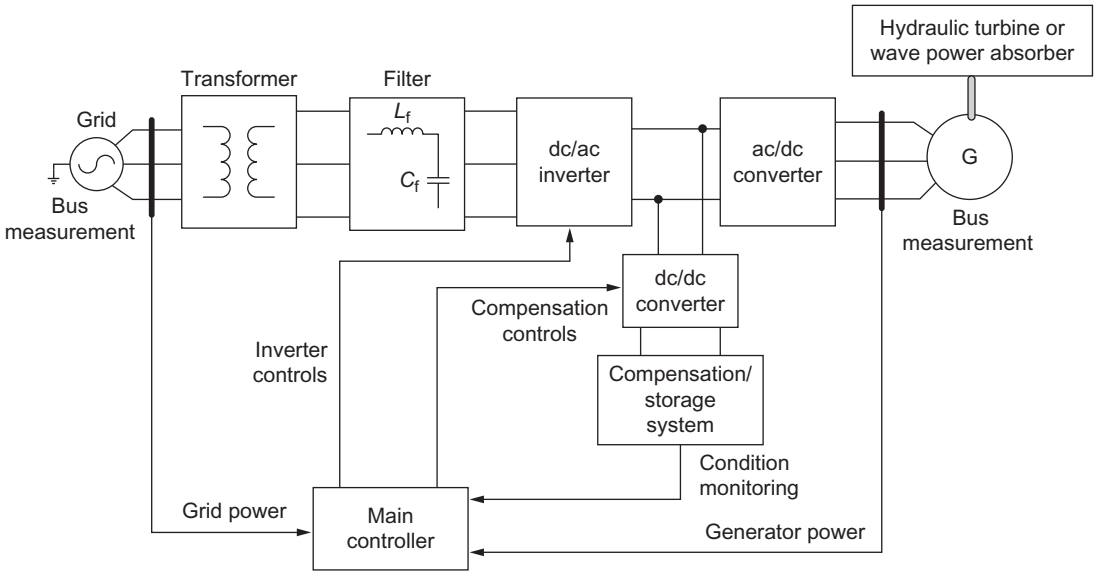

FIG. 23.41 Grid connection and controls of tidal current power conditioning system.

Natural hot water and/or steam from the inner layers of the Earth are used to drive the turbines and generators to produce electricity. Absolutely, no fuel firing is required for heating or steam generation for geothermal power plants. Therefore, geothermal power plants do not have emissions, and they are environmentally clean. Moreover, since the extracted heat is replaced by the thermal energy of the Earth's inner layers, geothermal energy is sustainable and renewable.

Schematic of a geothermal power plant is presented in Fig. 23.42.

The components of the geothermal power plant are described in Table 23.6.

The operating principle of a geothermal power plant is very similar to that of a coal-fired power plant. However, in geothermal power plants, hot steam and/or water is obtained from the deeper Earth layers instead of burning any fuel. Production well is used to draw hot water and/or steam from deeper layers. This mixture is separated by the separator in order to get the dry steam. Through a steam governor, a steam turbine is rotated by this high-pressure and high-temperature steam. Since the steam turbine is coupled to an electric generator, the mechanical steam power is converted into electric power. The output voltage of the generator is increased by a power transformer. The high voltage output of the power transformer can then be connected to the high-voltage transmission network. The steam loses its temperature and pressure after it goes through the steam turbine. Thus, the output flow of the steam turbine is condensed in the condensers. Condensed water is cooled down through the cooling tower, and cool water helps to condense the low-pressure/low-temperature steam in the condenser. The cooled water is then injected back to the inner Earth layers to get hot again. If the geothermal field is rich of hot water reservoirs, this cooled but still relatively warm water can be used for other heating purposes.

Geothermal energy is an abundant, secure, reliable, and renewable source of energy. It has high availability and capacity factor in comparison with other renewables. It is not a source of pollution for the environment; that is, their CO_2 emissions are less than 0.2% of the cleanest fossil-fuel-fired power plant, SO_2 emissions are less than 1%, and particulate emissions are less than 0.1%. It has an inherent energy storage capability and requires very small land area for establishment [186].

Geothermal power plants can be classified into three main generation technologies: dry-steam power plant, flash-steam power plant, and binary-cycle power plant.

Dry-steam power plants are the most common geothermal power plants since they are simple and cost-effective. These power plants are applicable to the geothermal fields where the geothermal steam is not mixed with water. In this method, production wells are drilled down to the aquifer to get superheated and pressurized steam. This steam is brought to the surface at high speeds. When the expanding steam passes through the turbine, the generator generates electricity [189,190]. The low-pressure steam output from the turbine is ventilated to the atmosphere in simple power plants. However, exhaust steam from the turbine is condensed in more complex power plants. The condensate can be reinjected to the reservoir by the injection wells, and/or it can be used as makeup cooling water.

Flash-steam power plants use a flash-steam technology where the hydrothermal source is in liquid form. This fluid is sprayed into a flash tank that is at a much lower pressure than the fluid. Therefore, the fluid immediately vaporizes rapidly into steam [189,191]. This generated steam is used to rotate the steam

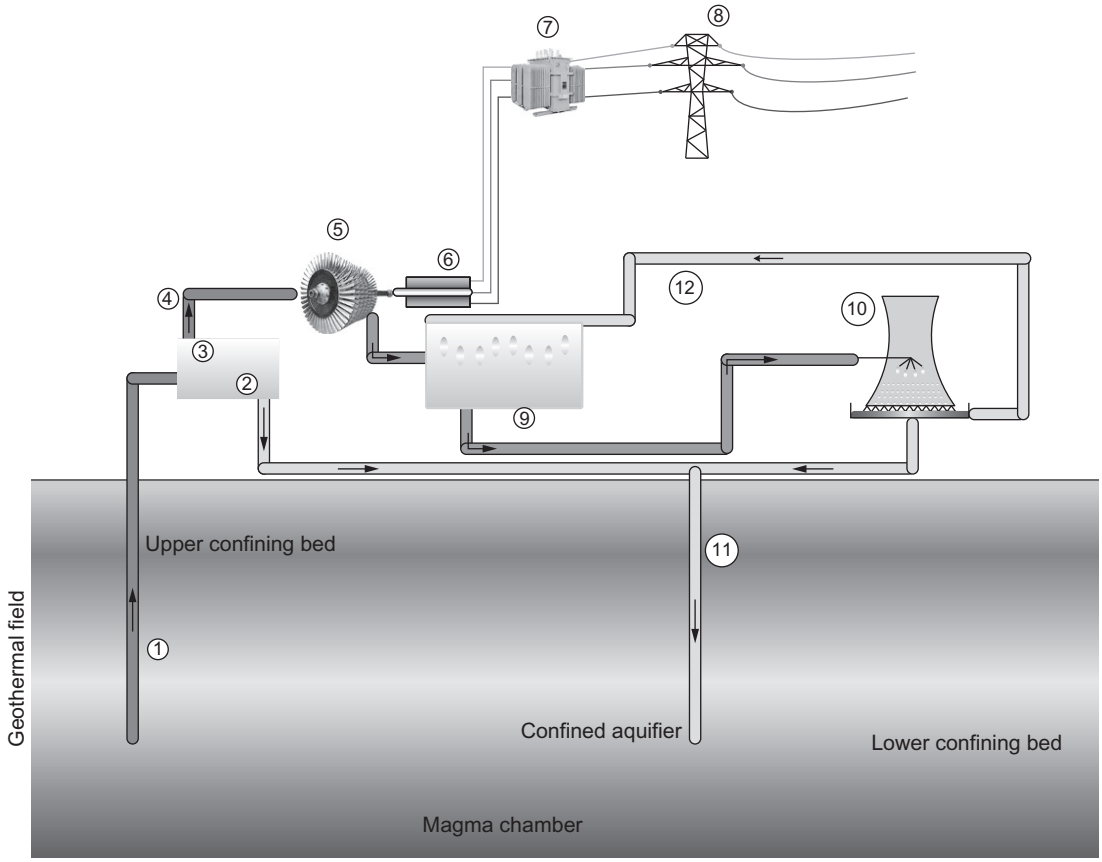

FIG. 23.42 A geothermal power plant.

turbines that are coupled to electric generators. The production well is kept under high pressure in order to prevent the geothermal fluid flashing inside the well [186]. Instead of using a single flashing system, dual-flashing systems are also used. The brine from the high-pressure steam is piped into a low-pressure separator/flash tank where the pressure is additionally reduced to generate lower-pressure steam in the dual-flash systems. In order to generate additional electric power, this lower-pressure steam is piped into a lower-pressure stage of the turbine. The steam exhaust from the high and low pressure turbines is condensed. Just like the dry-steam plants, the condensate is then used as makeup cooling water or reinjected to the reservoir.

Although the dual-flash power plants have higher capital cost, they have higher thermoelectric efficiency. Resource characteristics, power plant output, thermodynamic and economic factors, and equipment availability are the factors affecting the decision to build and operate a single-flash or dual-flash geothermal power plants [192]. Generally, dual-flash system is preferred if the fluid temperature is between 175 and 260°C, while single-flash systems are efficient enough for the fluid temperatures higher than 260°C.

Binary-cycle power plants are preferred when the geothermal resource is insufficiently hot to produce steam. Sometimes, the resource may have other chemical components causing impurities, and flashing may not become possible [186,193]. In these cases, binary-cycle power plants are preferred. In binary-cycle geothermal power plants, isobutene, isopentane, or pentane is used as the secondary fluid that has a lower boiling point than water. Since a separate working fluid is used, the cycle is called "binary." The geothermal fluid (water) is passed through a heat exchanger in order to heat up the secondary fluid. Secondary fluid vaporizes and expands through the turbines that are coupled to electric generators. After passing through the turbines, the working fluid is condensed and recycled for the next cycle. Moreover, the fluid remaining in the tank of flash-steam plants can be reutilized in binary-cycle plants. In a closed-cycle system, all of the geothermal fluid is injected back to the ground. Usually, binary-cycle plants are more efficient than the flash-steam plants in low to moderate temperatures of

geothermal fluids. Furthermore, corrosion problems are avoided since a pure working fluid is used.

23.3.7 Nuclear Power Plants

In nuclear power plants, energy is extracted from atomic nuclei by the controlled nuclear reactions. There are several available methods such as nuclear fission, nuclear fusion, and radioactive decay. The most common method is the nuclear fission. Similar to the conventional fossil-fuel-fired power plants, nuclear reactors generate heat in order to produce steam. However, unlike many conventional thermal power plants, nuclear power plants convert the energy released from the atoms' nucleus generally via nuclear fission, instead of burning fossil fuels. This energy is used for steam production that is utilized to operate the turbines that are coupled to electric generators. In this way, the mechanical work of the high-pressure steam is converted into electricity [194,195].

The fission of an atom occurs when a relatively large fissile atomic nucleus such as uranium-235 or plutonium-239 absorbs a neutron. The atom is then split by the fission into two or more smaller nuclei with kinetic energy, gamma radiation, and free neutrons [194]. Other fissile atoms may absorb a portion of these neutrons and create more fission, which release more neutrons, and so on [195]. By using neutron moderators and neutron poisons, this nuclear chain reaction can be controlled in order to adjust the potion of neutrons that will cause more fission. Manual or automatic control systems are used for this purpose or to shut down the reactor if unsafe conditions are detected [196].

Heat generation by the reactor core from fission involves several stages. The kinetic energy of the fission products is converted into thermal energy when a collision happens between the nuclei and nearby atoms. The reactor absorbs some of the gamma radiation produced during fission in the form of heat. Neutron absorption activates some materials, and the radioactive decay of fission products produces heat. Even after the reactor is shut down, this decay heat source may remain for some time. A nuclear reaction can generate heat power that is 1,000,000 times that of the equal mass of coal.

After the fission process, the heat released from the reactor is removed by a cooling system. This heat is conveyed to another part of the power plant, in which the thermal energy is utilized to generate electricity. The hot coolant in general is used as the heat source for a boiler. The boiler generates the pressurized steam that mechanically drives the steam turbines. The steam turbines rotate the electric generators [197]. A simple operating schematic of a nuclear power plant is depicted in Fig. 23.43.

By utilizing different coolants and fuels and integrating different control methodologies, many different reactor designs can be accomplished. In order to meet a specific need, some of these designs can be employed for various applications. Space and naval applications are some of these specific applications. In these applications, generally highly enriched uranium is used as the fuel that increases the reactor's power density and efficiency [198]. Currently, researchers are investigating new nuclear power generation techniques, known as the generation IV reactors. These new designs will have the possibility to offer cleaner and more secure fission reactors with less risk of the proliferation of nuclear weapons. New designs such as ESBWR offer passively safe plants, and other designs that are believed to be almost foolproof are being pursued or are available to be built [199]. In the near future, it is expected that the fusion reactors will be viable, which will reduce or eliminate many safety risks associated with nuclear fission [200].

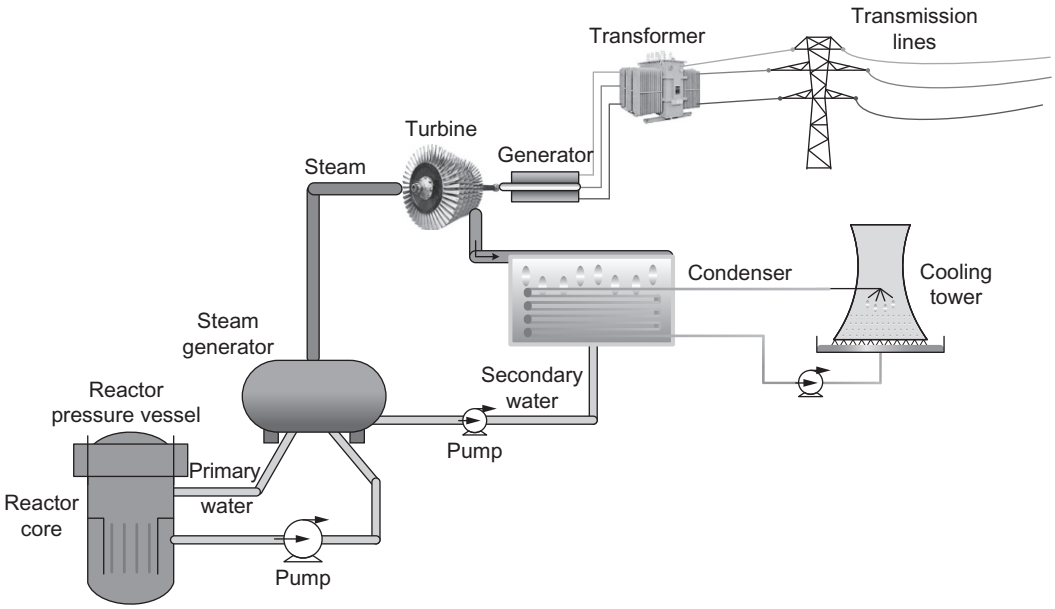

FIG. 23.43 A typical nuclear power plant.

23.3.8 Fuel Cell Power Plants

Since the beginning of twenty-first century, fuel-cell technology has been rapidly developed and has shown an invasive improvement for the applications ranging from portable electronic devices to vehicular power systems and MW size power plants [201–203]. Fuel cells are promising future energy conversion devices due to their high efficiency, excellent performance, low or zero emissions, and wide application area.

Fuel-cell power plants are electrochemical devices that produce electric energy directly from a chemical reaction. Fuel cells use fuel on the anode side and oxidant on the cathode side. The chemical reaction occurs on the electrolyte. The reactants, that is, fuel and oxidant, flow into the cell, while the reaction product (water) flows out of the cell. Many fuel and oxidant types can be used for fuel cells. Generally, hydrogen as the fuel and oxygen as the oxidant, from the air, can be used. On the other hand, alcohols and hydrocarbons can be other fuel types for different fuel cells, while other oxidants may be chlorine and chlorine dioxide [204–206].

Just like a battery, a fuel cell is composed of an electrolyte and a pair of electrodes. However, unlike the batteries, the reactants are continuously replenished during the operation; therefore, the cell is not required to be recharged. Ideally, fuel cells operate and continue to produce energy as long as the reactants are appropriately supplied to the anode and cathode sides.

There are many kinds of fuel cells categorized by their electrolyte type. Most common fuel-cell types are as follows:

- Proton exchange membrane fuel cells (PEMFCs)
- Phosphoric acid fuel cells (PAFCs)
- Direct methanol fuel cells (DMFCs)
- Solid oxide fuel cells (SOFC)
- Molten carbonate fuel cells (MCFCs)

PEMFCs are generally used for residential, vehicular, and portable applications. Solid electrolyte structure reduces the corrosion, they can operate at low temperature, and they have quick start-up and faster response times. PAFCs are typically used for transportation, heating, and electric utility applications. They may reach high efficiency points in electric cogeneration applications [207,208]. Currently, DMFCs are considered as a replacement alternative for batteries for small portable devices' power requirements. DMFC can be considered advantageous since methanol can be used directly without any reformer or fuel processor. However, they have relatively low efficiencies and slow response times since the reaction rate for the methanol is slow on presently available catalysts. On the other hand, DMFCs can be competitive with batteries since the simplicity, high storage density, and liquid methanol portability may compensate the relatively low efficiency [207]. MCFCs and SOFC are generally used as large power plants for electric utility applications. Both the technologies have higher efficiencies, fuel flexibility, and inexpensive catalysts [208]. However, they operate at really high temperatures generally between 600 and 1000°C. This high-temperature issue avoids these two fuel-cell technologies to be best candidates for portable or vehicular applications.

Especially, proton exchange membrane fuel cells are considered to be one of the most promising fuel-cell technologies among these next-generation fuel-cell power plants. This is due to their high efficiency and compact structure [209,210]. The operating principle of PEMFCs is focused in this section.

The operating principle along with the basic components of a PEMFC is presented in Fig. 23.44.

After the fuel is supplied to the anode side, the fuel is oxidized resulting in releasing electrons. The anode reaction for a fuel cell can be expressed as

$$2H_2 \rightarrow 4H^+ + 4e^- \tag{23.21}$$

These released electrons are transported to the cathode side through an external circuit. The hydrogen protons are traveled through the proton exchange membrane to the cathode side. The oxidant (i.e., oxygen) is reduced at the cathode side, using the electrons coming from the external circuit. Therefore, the cathode reaction is

$$O_2 + 4e^- \rightarrow 2O^{--}. \tag{23.22}$$

The hydrogen protons travel through the membrane and balance the flow of electrons through the external circuit. Therefore, the overall reaction equation becomes

$$2H_2 + O_2 \rightarrow 2H_2O + \text{Electric Power}. \tag{23.23}$$

A typical single fuel cell has a theoretical output voltage of 1.2 V. They generate ideally 0.6 A/cm^2. In order to reach higher voltage outputs from a fuel-cell system, cells are connected in series in the form of a string. For higher current outputs, the cells or the cell strings should be connected in parallel. Unfortunately, the output voltage of a fuel cell or a fuel-cell system decreases as the current drawn from the fuel cell is increased.

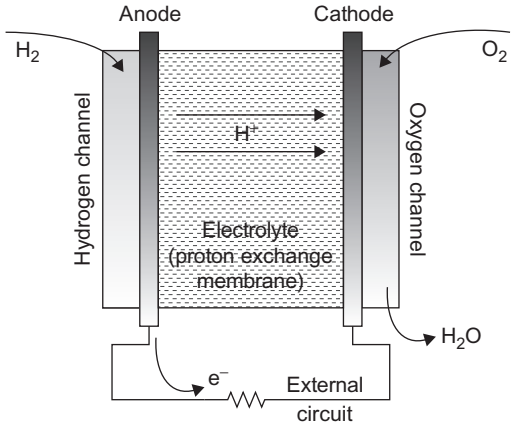

FIG. 23.44 Components of a PEM fuel cell and its operating principle.

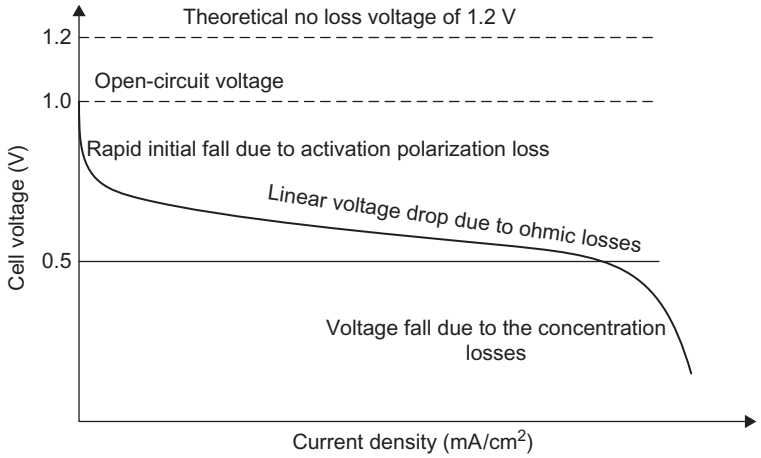

FIG. 23.45 Current-voltage characteristic of a fuel cell.

This voltage drop at the fuel-cell output is due to the ohmic, activation, and concentration losses [211].

A typical current-voltage characteristic curve of a fuel cell is shown in Fig. 23.45, which is also known as the polarization curve.

The output voltage of a fuel cell is less than its theoretical value even in the open-circuit conditions. This is due to the fact that the open-circuit voltage is calculated based on the ideal burning enthalpy of the hydrogen. The activation loss is generally effective at the low current densities. Activation loss is due to the electrode kinetics in which the electrochemical reaction of hydrogen and oxygen is slow. Activation loss causes a nonlinear voltage drop as the current starts to be drawn from the fuel cell. Ohmic losses are due to the electron flow through the electrolyte and electrodes and the equivalent resistance of the external circuit. Ohmic losses are directly proportional to the current density, and they increase linearly as the current increases. Concentration losses are due to the inability of maintaining the initial fuel concentration on the electrodes. Fuel and oxidant should be supplied sufficiently and continuously in order to meet sustained load demands. If the current is more than a certain value, a fuel cell fails to meet the new power demand, and the output voltage dramatically decreases. Therefore, this loss is quite severe at the high current densities.

Due to the polarization and current-voltage characteristics of the fuel cells, power conditioning devices such as dc/dc and/or dc/ac converters are required to maintain a fixed and stable dc voltage for the load bus. The power conditioning is also useful for converting the fuel-cell output to an appropriate magnitude and type. Power conditioning unit (PCU) not only controls the fuel-cell output voltage but also delivers a high power factor in grid-connected applications. PCU can reduce or eliminate the harmonics and help them operate effectively under all conditions. A fuel-cell power plant operating together with a PCU is presented in Fig. 23.46.

In the stationary or vehicular applications, a fuel-cell power plant may not be sufficient to satisfy all of the load demands [210]. Especially during transient load changes or peak demand periods, a fuel cell needs to be operated with an auxiliary power device such as battery packs or ultracapacitors. By operating fuel cell cascaded with batteries and/or ultracapacitors, steady-state, peak power demands, and transient load changes can be controlled more efficiently. In the topology of Fig. 23.47, the fuel-cell power plant is operated with auxiliary power devices.

23.4 Conclusions

In order to meet the future energy requirements, the energy should be generated and utilized wisely. Increasing the demand for energy, decreasing conventional fossil-fuel energy sources, and environmental concerns are driving forces toward renewable energy sources. However, the conventional sources will be utilized until modern, clean, and renewable technologies replace them. Therefore, a comprehensive strategy that supports a diversity of resources over the next century should be developed. Sustainable and long-term energy solutions in numerous forms are required to restructure the future's increasing energy demand.

24.1 Introduction

For many years, fossil fuels have been the primary source of energy. However, due to the limited supply, the rate of deployment of fossil fuels is more rapid than their rate of production, and hence, fossil fuels will eventually run out. Moreover, the threat of global climate change caused by carbon dioxide (CO_2) emissions from fossil fuels is one of the main reasons for the increasing consensus to reduce the consumption of such fuels. This reduction can be achieved by switching to renewable energy for many energy-requiring applications since it is "clean" and "green." Today, the global trend is to use a nondepletable clean source of energy for a healthier and greener environment to save the future generation. The most efficient and harmless energy source is probably solar energy, which is so technically straightforward to use in many applications. Almost, all renewable energy sources, except nuclear and geothermal, are the energy forms originating from the solar energy.

Solar energy is considered one of the most promising energy sources due to its infinite power. Thus, modern solar technologies have been penetrating the market at faster rates, and photovoltaic (PV) technology that has the greatest impact, not because of the amount of electricity it produces but because photovoltaic cells—working silently, not polluting—can generate electricity wherever the sun shines, even in places where no other form of electricity can be obtained. PV is a combination of the Greek word for light and the name of the physicist Alessandro Volta. PV is the direct conversion of sunlight into electricity by means of solar cells.

This chapter will highlight in brief how solar cells produce electricity and will discuss in detail the various techniques available to track the sun in order to maximize the output power generated by the PV array. Moreover, the components required to operate grid-connected and stand-alone PV systems will be described. Additionally, the affecting factors and design issues of PV systems will be presented.

24.2 Solar Cell Characteristics

Solar cells are composed of various semiconductor materials that become electrically conductive when supplied with heat or light. The majority of the first-generation solar cells produced are composed of silicon (Si), which exists in sufficient quantities. However, more than 95% of these cells have power conversion efficiency about 17%, whereas solar cells that developed over the last decade in laboratory environment have efficiency as high as 31%. All technologies related to capturing solar energy to be used as direct electricity generator are described as photovoltaic technology, which is subdivided into crystalline, thin film, and nanotechnology.

Doping technique is used to obtain an excess of positive charge carriers (p-type) or a surplus of negative charge carriers (n-type). When two layers of different doping are in contact, then a p-n junction is formed on the boundary.

An internal electric field is built up causing the separation of charge carriers released by light, freeing electrons within the electric field proximity, which then pull the electrons from the p-side to the n-side (Fig. 24.1). The primary solar cell equivalent circuit (Fig. 24.2) contains a current source with a parallel diode, in addition to parasitic series (R_s, normally small) and shunt (R_{sh}) resistances (relatively large). R_s is mainly affected by the factors such as the bulk resistance of the semiconductor material, metallic contacts, and interconnections, whereas R_{sh} is affected mainly by the p-n junction nonidealities and impurities near the junction.

A simplified equivalent circuit is shown in Fig. 24.3.

The diode current is given by the Shockley equation:

$$I_D = I_0 \left[\exp\left(\frac{qV}{nkT}\right) - 1 \right] \tag{24.1}$$

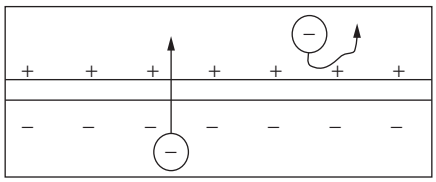

FIGURE 24.1 Effect of the electric field in a PV cell [1].

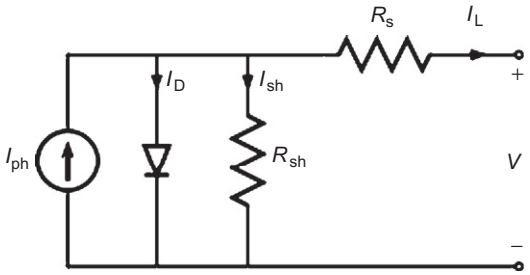

FIGURE 24.2 Solar cell equivalent circuit.

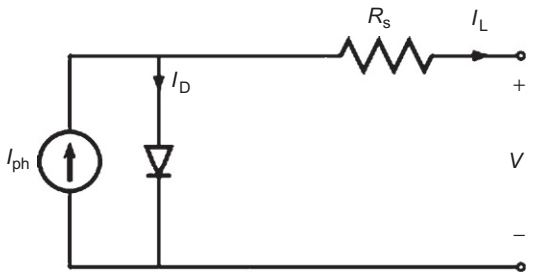

FIGURE 24.3 Model for a PV cell.

where I_0 is the reverse saturation current, q is the charge carrier, k is the Boltzmann constant, T is the cell temperature, and n is the ideality factor.

The PV module has two limiting components (Fig. 24.3): open-circuit voltage (V_{OC}) and short-circuit current (I_{sc}). To determine I_{sc}, set $V = 0$ and $I_{sc} = I_{ph}$, and this value changes proportionally to the cell irradiance. To determine V_{OC}, set the cell current $I_L = 0$; hence,

$$V_{OC} = \frac{nkT}{q} \ln\left[\frac{I}{I_0}\right] \tag{24.2}$$

The PV module can also be characterized by the maximum point when the product (V_{mp} (voltage, where power is maximum) $\times I_{mp}$ (current, where power is maximum)) is at its maximum value. The maximum power output is derived by

$$\frac{d(V \times I)}{dt} = 0 \tag{24.3}$$

and

$$V_{mp} = V_{OC} - \frac{kT}{q} \ln\left[\frac{V_{mp}}{nkT/q} + 1\right] \tag{24.4}$$

A PV module is normally rated using its W_p, which is normally 1 kW/m^2 under standard test conditions (STC), which defines the PV performance at an incident sunlight of 1000 W/m^2, a cell temperature of 25°C (77°F), and an air mass (AM) of 1.5. The product ($V_{mp} \times I_{mp}$) is related to the product generated by ($V_{OC} \times I_{SC}$) by a fill factor (FF) that is a measure of the junction quality and series resistance, and it is given by

$$FF = \frac{V_{mp} \times I_{mp}}{V_{OC} \times I_{SC}} \tag{24.5}$$

The closer the FF is to unity, the higher the quality of the PV module.

Finally, the last and most important factor of merit for a PV module is its efficiency (η), which is defined as

$$\eta = \frac{FF \times V_{OC} \times L_{OC}}{P_{in}} \tag{24.6}$$

P_{in} represents the incident power depending on the light spectrum incident on the PV cell.

To achieve the desired voltage and current levels, solar cells are connected in series (N_s) and parallel (N_p) combinations forming a PV module. The PV parameters are then affected as shown below:

$$I_{\text{ph total}} = N_p I_{\text{ph}} \tag{24.7}$$

$$I_{0\,\text{total}} = N_p I_0 \tag{24.8}$$

$$n_{\text{total}} = N_s n \tag{24.9}$$

$$R_{s\,\text{total}} = \frac{N_s}{N_p} R_s \tag{24.10}$$

This model is shown in Fig. 24.4.

In order to obtain the appropriate voltages and outputs for different applications, single solar cells are interconnected in series (for larger voltage) and in parallel (for larger current) to form the photovoltaic module. Then, several of these modules are connected to each other to form the photovoltaic array. This array is then fitted with aluminum or stainless steel frame and covered with transparent glass on the front side (Fig. 24.5).

The voltage generated by the array depends primarily on the design and materials of the cell, whereas the electric current depends primarily on the incident solar irradiance and the cell area. This current fluctuates since the path of the sun varies dramatically over the year, with winter and summer seasons being the two extreme excursions. The elevation angle of the sun ($\theta_{\text{sun}}^{\text{elevation}}$) is expressed in degrees above the horizon. Azimuth angle ($\phi_{\text{sun}}^{\text{azimuth}}$) of the sun is expressed in degrees from true north. Zenith angle ($\theta_{\text{sun}}^{\text{zenith}}$) of the sun equals 90 degrees less than the elevation angle of the sun, or

$$\theta_{\text{sun}}^{\text{zenith}} = 90\,\text{degrees} - \theta_{\text{sun}}^{\text{elevation}} \tag{24.11}$$

Azimuth, zenith, and elevation angles are illustrated in Fig. 24.6.

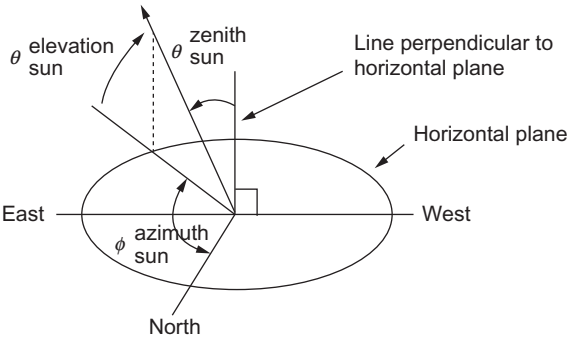

FIGURE 24.6 Azimuth, zenith, and elevation angles of a vector pointed toward the sun.

The output from a typical solar cell that is exposed to the sun, therefore, increases from zero at sunrise to a maximum at midday and then falls again to zero at dusk. The radiation of the sun varies when reaching the surface of the earth due to absorption and scattering effect in the earth's atmosphere. PV system designers require the estimate of the insolation expected to fall on a randomly tilted surface and hence need a good evaluation of global radiation on a horizontal surface, horizontal direct, and diffuse components, in order to estimate the amount of irradiation striking a tilted plane.

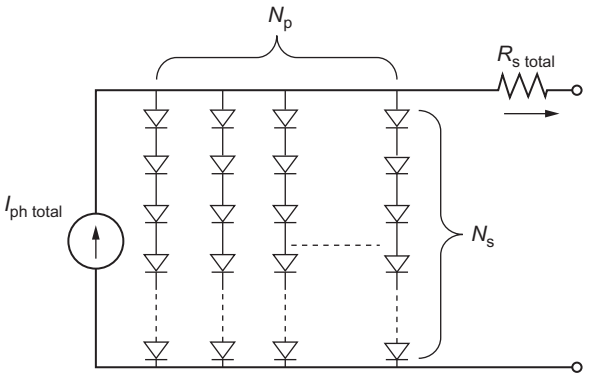

FIGURE 24.4 PV module circuit model.

24.3 Photovoltaic Technology Operation

Photovoltaic technology is used to produce electricity in areas where power lines do not reach. In developing countries, it helps improving living conditions in rural areas, especially in health care, education, and agriculture. In industrialized countries, such technology has been used extensively and integrated with the utility grid.

Photovoltaic arrays are usually mounted in a fixed position and tilted toward the south to optimize the noontime and the daily energy production. The orientation of fixed panel should

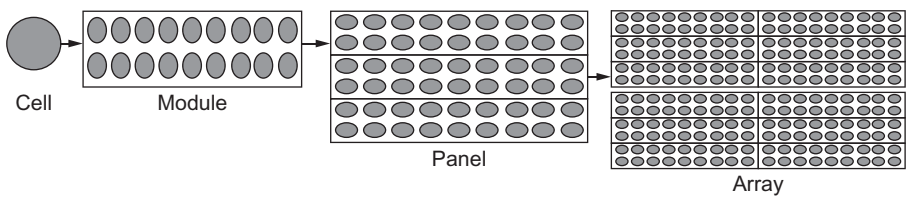

FIGURE 24.5 Photovoltaic cells, modules, panels, and array.

be carefully chosen to capture the most energy for the season or for a year. Photovoltaic arrays have an optimum operating point called the maximum power point (MPP) as shown in Fig. 24.7.

It is noted that power increases as voltage increases, reaching a peak value and decreases as the resistance increases to a point where current drops off. According to the maximum power transfer theory, this is the point where the load is matched to the solar panel's resistance at a certain level of temperature and insolation. The *I-V* curve changes as the temperature and insolation levels change as shown in Fig. 24.8, and thus, the MPP will vary accordingly.

It is shown that the open-circuit voltage increases logarithmically, while the short-circuit current increases linearly as the isolation level increases. Moreover, increasing the temperature of the cell decreases the open-circuit voltage and increases slightly the short-circuit current, causing a reduction in the efficiency of the cell.

The PV panels, usually mounted on the roof or at a near open area, are fixed to face the sun at an angle matching the country's latitude. If possible, seasonal adjustment of the module's direction toward the sun is done manually. Since solar power technology is relatively expensive, it is important to operate panels at their maximum power conditions. However, to collect as much solar radiation as possible, it is more convenient and efficient to use a sun tracking mechanism causing the module's surface to track the sun throughout the day.

The tracking can be along either one axis or two axes, whereby double axis tracking provides a higher power output. The energy yield can be thus increased by about 20%–30% depending on the seasonal climate and geographic location. Although some claim that a fixed system costs less and requires almost no maintenance, different tracking mechanisms that utilized to control the orientation of the PV panels have proved their superiority over fixed systems in terms of converted power efficiency.

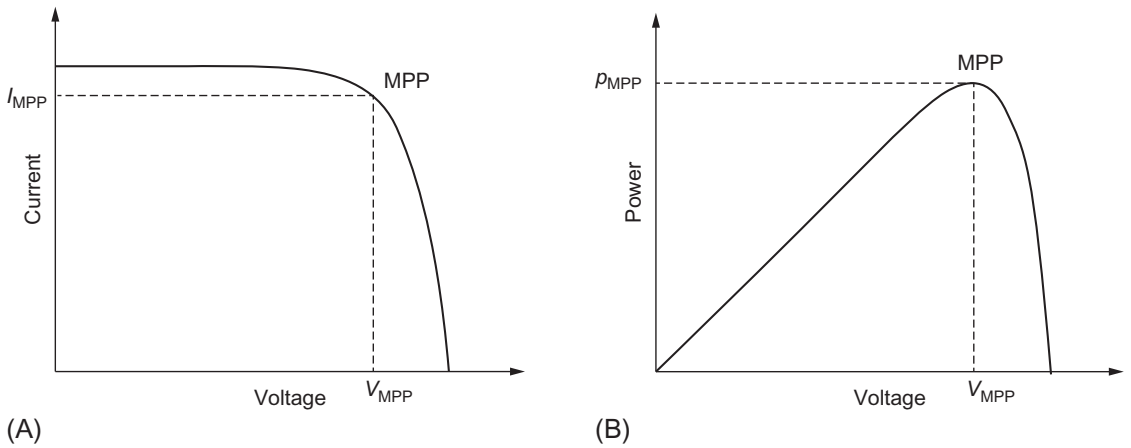

FIGURE 24.7 Typical PV module curves: (A) *I-V* characteristic of a solar cell showing maximum power point (MPP) and (B) *P-V* characteristic of a solar cell showing MPP.

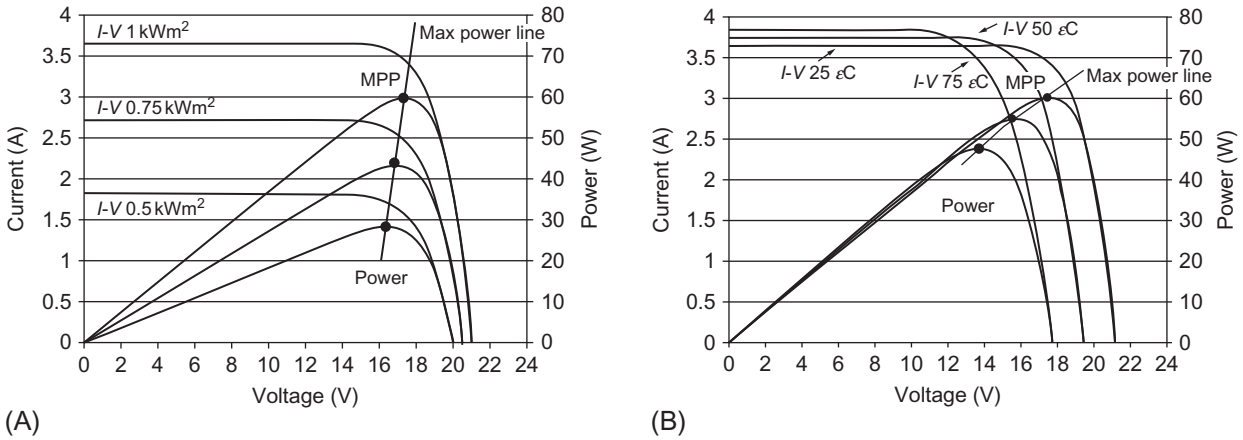

FIGURE 24.8 PV module characteristics: (A) PV panel insolation and (B) PV panel temperature.

To get maximum power from the PV panel at the prevailing temperature and insolation conditions, either the operating voltage or current should be controlled by a maximum power point tracker (MPPT) that should meet the following conditions:

- Operate the PV system close to the MPP irrespective of the atmospheric changes.
- Have low-cost and high-conversion efficiency.
- Provide an output interface compatible with the battery charging requirement.

24.4 Maximum Power Point Tracking Components

The MPPT increases the energy that can be transferred from the array to an electric system. The main function is to adjust the panel's output voltage to supply the maximum energy to the load. Most current designs consist of three basic components: switch-mode DC-DC converter, control system, and tracking component.

The switch-mode converter is the core of the entire supply because the energy drawn, stored as magnetic energy, is released at different potential levels. By setting up the switch-mode section in various topologies such as buck or boost converter, voltage converters are designed providing a fixed input voltage or current, which correspond to the maximum power point, allowing the output resistance to match the battery. To achieve the above-stated mechanism, a controller is essential to continuously monitor the PV system and ensure its operation at the PV maximum power point by tracking this MPP. The controller's aim is to continuously measure the voltage and current values generated from the PV and compare them with certain threshold values in order to apply either voltage controlled method or power feedback control.

24.4.1 Voltage Feedback Control

With the PV array terminal voltage being the controlled variable, voltage feedback controller forces the PV array to operate at its MPP by changing the array terminal voltage and neglecting the variation in the temperature and insolation level.

24.4.2 Power Feedback Control

In this method, the power delivered to the load is the controlled variable. To achieve maximum power, dp/dv should be zero. This control scheme is not affected by the characteristics of the PV array, yet it increases power to the load and not power from the PV array. Factors such as fast shadows may cause trackers to lose the MPP momentarily. It is very critical to ensure that the time lost in seeking MPP again, which equates the energy lost while the array is off power point, is very short. On the other hand, if lighting conditions do change, the tracker needs to respond within a short amount of time to the change avoiding energy loss. Therefore, the controller's most important feature is its capability to quickly adjust the system to operate back at the MPPT.

24.5 MPPT Controlling Algorithms

Several proposed algorithms to accomplish MPPT are described in the following sections.

24.5.1 Perturb and Observe

The perturb and observe (PAO) method has a simple feedback structure and few measured parameters. It operates by periodically perturbing (i.e., incrementing or decrementing) the duty cycle while controlling the array current as shown in Fig. 24.9 and comparing the PV output power with that of the previous perturbation cycle. It measures the derivative of power Δp and the derivative of voltage Δv to determine the movement of the operating point. If the perturbation leads to an increase (or decrease) in array power, the subsequent perturbation is made in the same (or opposite) direction. This cost-effective technique can be easily implemented and is characterized by continuously tracking and very efficiently extracting the maximum power from PV. However, such method may fail under rapidly changing atmospheric conditions due to its slow tracking speed.

24.5.2 Incremental Conductance Technique

The incremental conductance technique (ICT) process based on the fact that the derivative of the power with respect to the voltage (dp/dv) vanishes at the MPP because it is the maximum point on the curve as shown in Fig. 24.10.

The ICT algorithm detects the MPP by comparing di/dv with $\frac{-I}{V}$ till it attains the voltage operating point at which the incremental conductance is equal to the source conductance. The algorithm starts by measuring the present values of the I and V and then uses the corresponding stored value (I_b and V_b)

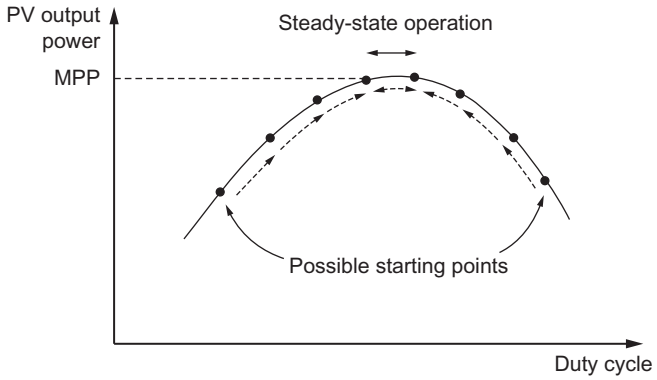

FIGURE 24.9 PAO technique.

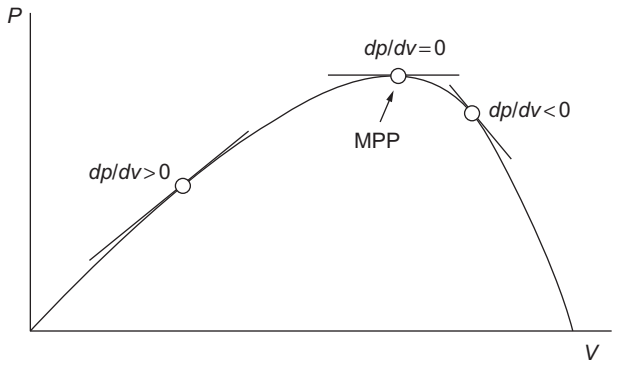

FIGURE 24.10 The slope "conductance" of the *P-V* curve.

measured during the preceding cycle to calculate the incremental changes as $dI = I - I_b$ and $dV = V - V_b$. Based on the result obtained, the control reference signal V_{ref} will be adjusted in order to move the array voltage toward the MPP voltage. At the MPP, $di/dv = \frac{-I}{V}$, no control action is needed; therefore, the adjustment stage will be bypassed, and the algorithm will update the stored parameters at the end of the cycle. In order to detect any changes in weather conditions, the algorithm detects whether a control action took place when the array was operating at the previous cycle MPP ($dv = 0$). This technique is accurate and well suited for rapid changes in atmospheric conditions; however, because the increment size approach is used to determine how fast the system is responding, ICT requires precise calculations of both instantaneous and increasing conductance.

24.5.3 Constant Reference

One very common MPPT technique is to compare the PV array voltage (or current) with a constant reference voltage (or current), which corresponds to the PV voltage (or current) at the maximum power point, under specific atmospheric conditions. The resulting difference signal (error signal) is used to drive a power conditioner, which interfaces the PV array to the load. Although the implementation of this method is simple, the method itself is not very accurate because it does not consider the effects of temperature and irradiation variations in addition to the difficulty in choosing the optimum point.

24.5.4 Current-Based Maximum Power Point Tracker

Current-based maximum power point tracker (CMPPT) is another MPPT technique that exists. Employed numerical methods show a linear dependence between the "cell currents corresponding to maximum power" and the "cell short-circuit currents." The current I_{MPP} operating at the MPP is calculated using the following equation:

$$I_{MPP} = M_C I_{SC} \tag{24.12}$$

where M_C is the "current factor" that differs from one panel to another and is affected by the panel surface conditions, especially if partial shading covers the panel. Although this method is easy to implement, an additional switch is added to the power converter to periodically short the PV array, increase the cost, and reduce the output power. This method also suffers from a major drawback due to periodic tuning requirement.

24.5.5 Voltage-Based Maximum Power Point Tracker

Similar to the above-mentioned method, voltage-based maximum power tracking (VMPPT) technique can also be applied. The MPP operating voltage is calculated directly from V_{OC}:

$$V_{MPP} = M_V V_{OC} \tag{24.13}$$

where M_V is the "voltage factor." The open-circuit voltage V_{OC} is sampled by an analog sampler, and then, V_{MPP} is calculated by Eq. (24.13). This operating V_{MPP} voltage is the reference voltage for the voltage control loop as shown in Fig. 24.11. This method always "results in a considerable power error because the output voltage of the PV module only follows the unchanged reference voltage during one sampling period" [2]. Albeit the implementation of this procedure is simple, it endures several disadvantages such as momentarily power converter shutdown causing power loss. Furthermore, such process depends greatly on the *I-V* characteristics and requires periodic tuning.

Other researchers argue that these two practices are considered to be "fast, practical, and powerful methods for MPP estimation of PV generators under all insolation and temperature conditions" [3].

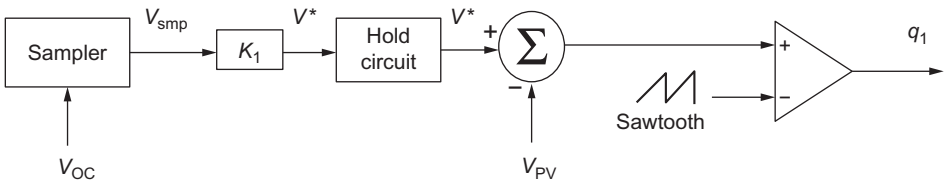

FIGURE 24.11 The conventional MPPT controller using open-circuit voltage V_{OC}.

24.5.6 Other Methods

Automated techniques such as Fibonacci line search, ripple correlation control method, neural network, and fuzzy logic have also been introduced for MPPT. In order to generate a clear understanding in determining the advantages and disadvantages of each algorithm, a comprehensive experimental comparison between different MPPT algorithms was made and run for the same PV setup at South Dakota State University, and results showed that the ICT method has the highest efficiency of 98% in terms of power extracted from the PV array, the PAO technique has the efficiency of 96.5%, and finally, the constant voltage method has the efficiency of 88%.

The ICT method provided good performance under rapidly changing weather conditions and provided the highest tracking efficiency, although four sensors were required to perform the measurements for computations and decision-making. If the system required more conversion time in tracking the MPP, a large amount of power loss would occur. On the contrary, under perturb and observe method, losses are reduced if the sampling and execution speed were increased. The main benefit of this procedure is that only two sensors are required, which resulted in the reduction of hardware requirements and cost.

24.6 Grid-Connected Photovoltaic System

Grid-connected photovoltaic systems are composed of PV arrays connected to the grid through a power conditioning unit (PCU) and are designed to operate in parallel with the electric utility grid. The power conditioning unit may include the MPPT, the inverter, the grid interface, and the control system needed for efficient system performance. There are two general types of electric designs for PV power systems: systems that interact with the utility power grid as shown in Fig. 24.12A and have no battery backup capability and systems that interact and include battery backup as well as shown in Fig. 24.12B. The latter type of system incorporates energy storage in the form of a battery to keep "critical load" circuits operating during utility outage. When an outage occurs, the unit disconnects from the utility and powers specific circuits of the load. If the outage occurs in daylight, the PV array is able to assist the load in supplying the loads.

The major component in both systems is the DC-AC inverter or also called the power conditioning unit (PCU). The inverter is the key to the successful operation of the system, but it is also the most complex hardware. The inverter requirements include operation over a wide range of voltages and currents and

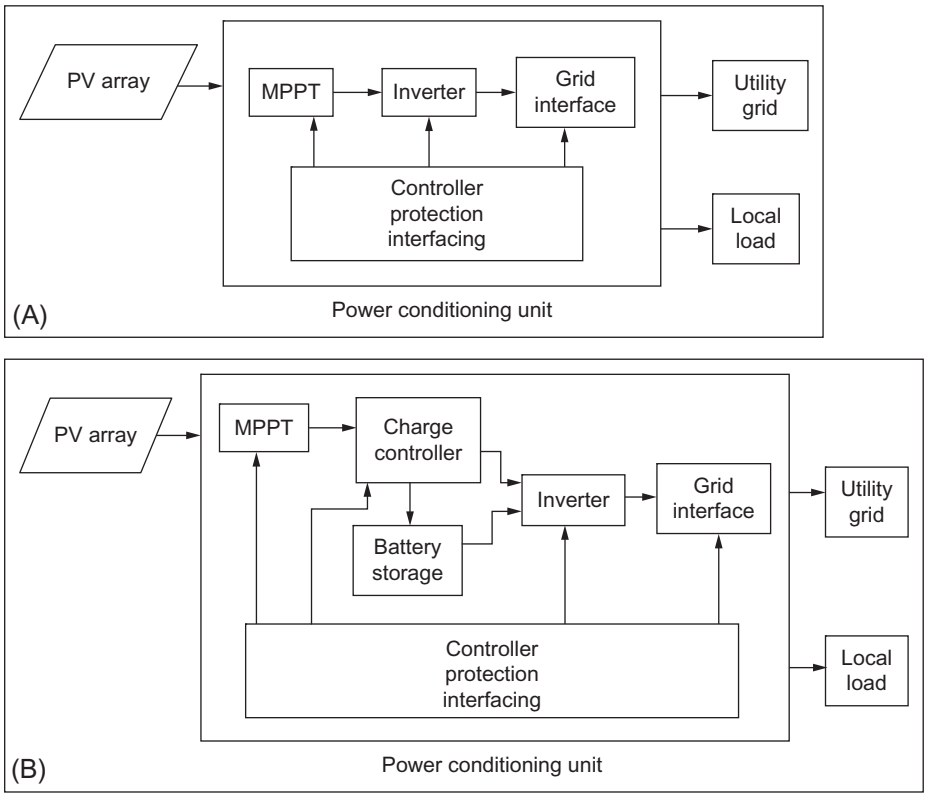

FIGURE 24.12 Block diagrams of grid-connected PV system: (A) without battery backup and (B) with battery storage.

regulated output voltage and frequency while providing AC power with good power quality that includes low total harmonic distortion and high power factor, in addition to highest possible efficiency for all solar irradiance levels. Inverters can be used in a centralized connection (Fig. 24.13A) for the whole array of PV, each PV module string is connected to a single inverter (Fig. 24.13B), and a single PV module is connected to a named microinverter (Fig. 24.13C).

The first circuit handled all the power, and the maximum power point is difficult to follow if there is voltage/current mismatching at the PV modules. The second option is more efficient than the first one since it minimizes the losses due to voltage/current mismatching and it enhances its modularity capability. The last circuit may perform a good tracking since each PV module is controlled independently; however, more stages and components are required.

For the last years, researchers have been working on developing different inverter topologies. The evolution of solid-state devices such as metal-oxide-semiconductor field-effect transistors (MOSFETs), insulated-gate bipolar transistors (IGBTs), microprocessors, and PWM-integrated circuits has allowed improvements on the inverter. Some research is being carried to ensure quality control, reliability, high efficiency, and lower cost since inverters are the key for a sustainable photovoltaic market.

24.6.1 Isolated Converters

For safety reasons, not only both the grid neutral line and the chassis of the PV modules must be grounded, but also the PCU may provide galvanic isolation. The first option is to place the isolation on the grid side, by using an AC low-frequency transformer (Fig. 24.14A), which makes the system big, heavy, and bulky. The second option is to include the isolation on the DC side, after the PV array, by using a high-frequency transformer (Fig. 24.14B), which is smaller and costs less than an AC transformer.

These options have different drawbacks: low efficiency, the size and weight are compromised, and the cost should be high due to the inclusion of the isolation. Therefore, researchers are developing the PCUs without isolation.

24.6.2 Transformerless Converters

A costless PCU is obtained if the isolation is removed, but then, a common-mode resonant circuit appears due to the grounding cable, which includes the filter, the inverter, the grid impedance, and the PV parasitic capacitance. This common mode generates a leakage current ($i_{leakage}$) that circulates through parasitic capacitances in PV array to the ground, as shown in Fig. 24.15. The common-mode voltage, the modulation

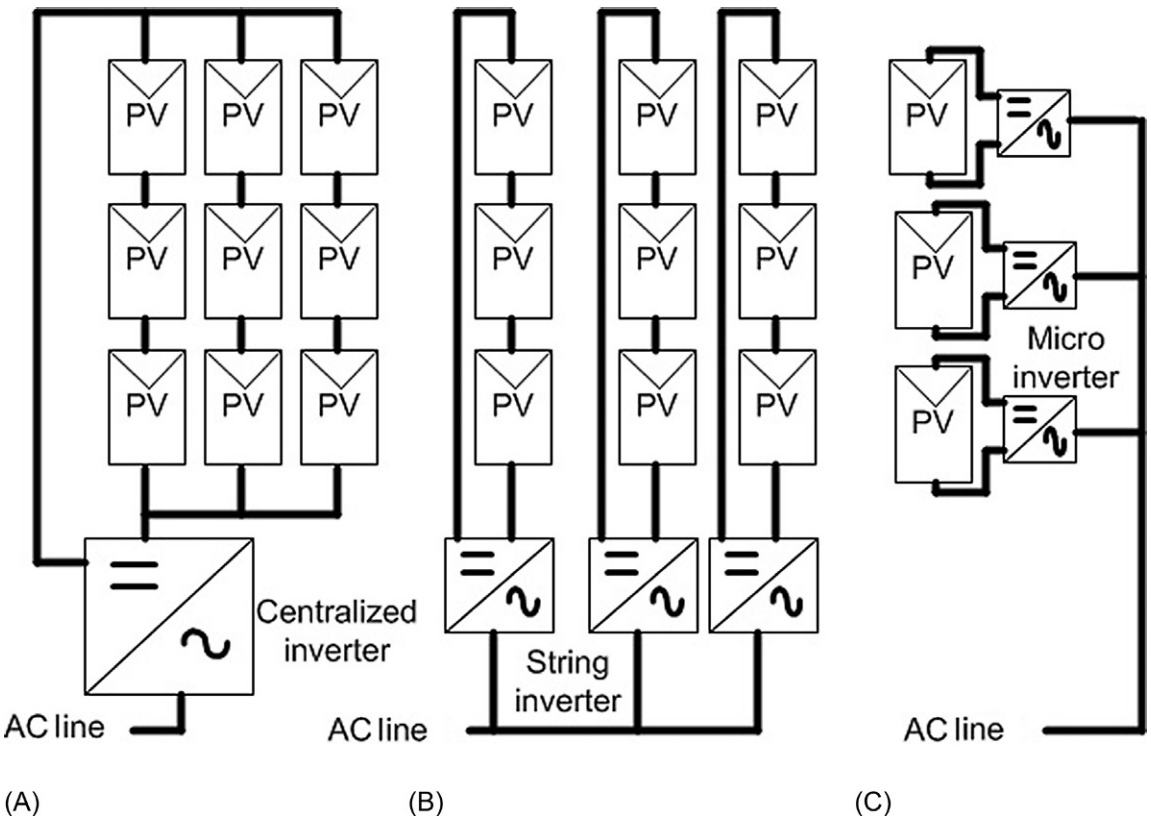

FIGURE 24.13 Grid-connected PV system: (A) centralized, (B) string connection, and (C) microinverter.

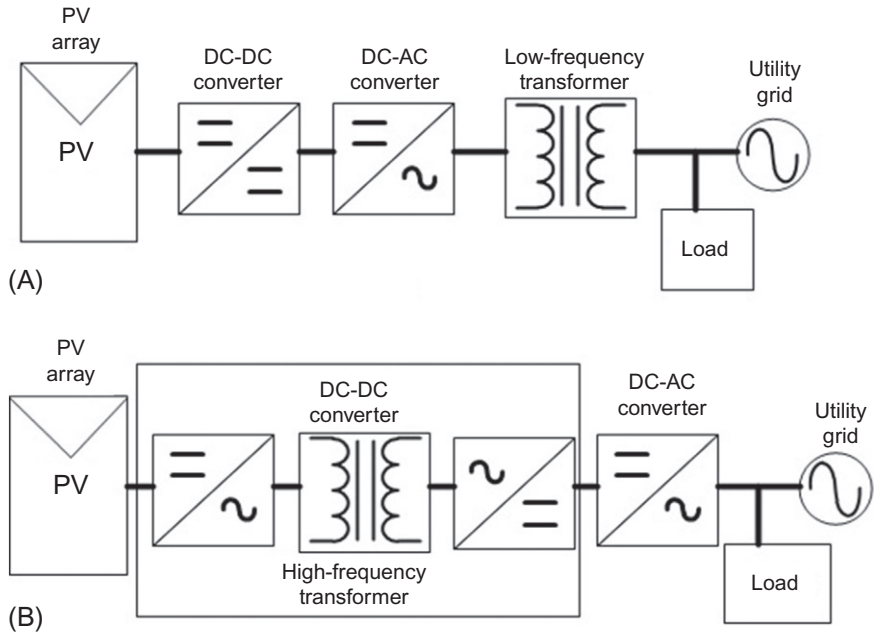

FIGURE 24.14 Grid-connected isolated PV system: (A) low-frequency transformer and (B) high-frequency transformer.

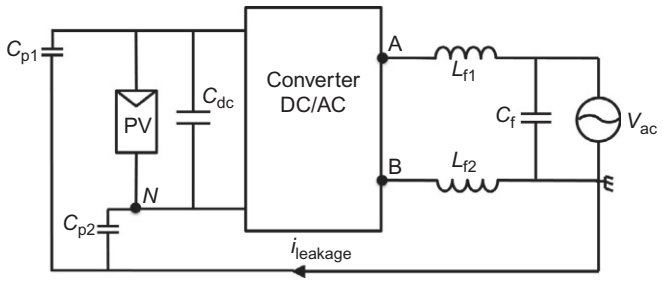

FIGURE 24.15 Block diagram to illustrate the leakage current.

strategy, and the value of the parasitic capacitance greatly affect the value of the leakage current.

The parasitic capacitance value depends on many factors such as the PV panel and frame structure, the surface of cells, the distance between cells, the weather conditions, and the type of EMC filter. In order to reduce this parasitic current, different PCUs have been reported: H-5, HERIC, and common-mode inverters, among others.

A. H-5 inverter

This DC/AC converter is similar to the traditional full-bridge inverter topology, where the upper switches operate at grid frequency and the lower ones work at a high frequency. It has incorporated an extra switch S_5 on the DC side that operates in both semicycles at a high frequency (Fig. 24.16A). The main characteristic of this configuration is that the PV array is decoupled from the grid when this extra switch is turned off.

Normally during active states, the current flows during freewheeling modes through two switches, but in active vectors, the current flows through three switches causing conduction losses, which become a disadvantage.

B. Heric inverter

This topology combines advantages from two alternatives: the three-level output voltage of the unipolar PWM, besides the reduced common-mode voltage as in the case of bipolar PWM. It consists of a full-bridge inverter plus two additional switches, as illustrated in Fig. 24.16B. Each group of diagonal switches of the full bridge operates at a high frequency during the half wave of the grid. One of the two additional switches is turned on during the half wave of the grid. S_5 or S_6 is used when the disconnection occurs between the grid and PV array, which reduces the leakage current. The main drawback of this topology is the pair of additional semiconductors.

C. Common mode converter

There are different schemes for this configuration; the main idea is that the neutral terminal of the grid is connected straight to the negative of the PV array. Shown in Fig. 24.16C is an alternative; this topology is composed of two power MOSFETs (S_1 and S_2), and just a single device is conducting in each switching state. The converter includes two capacitors and three inductors (C_f, C_{dc} and L_1, L_2, L_f).

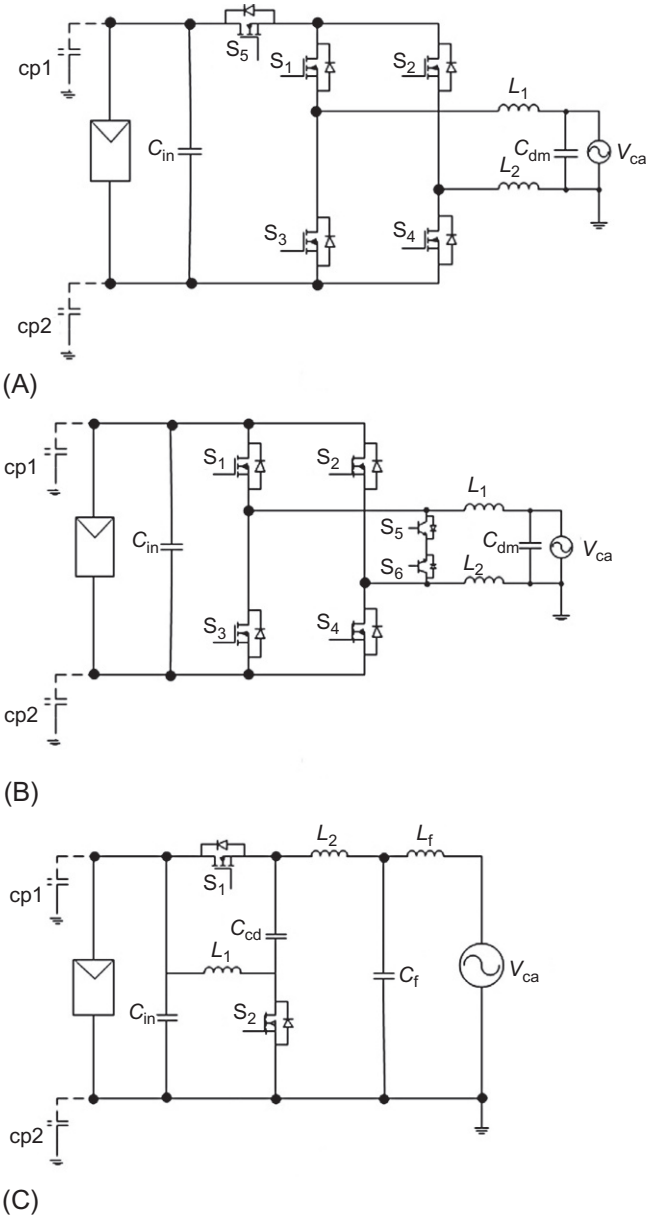

FIGURE 24.16 Transformerless inverters for PV systems: (A) H-5, (B) HERIC, (C) a common-mode topology.

Since the negative of the PV array is connected straight to the neutral line of the grid, the ground leakage current is very low, while the applied voltage to the parasitic capacitance is maintained almost constant.

24.6.3 Grid Synchronization

PV grid-connected converters need a phase and frequency tracking system to provide a reference signal in order to synchronize it with the grid voltage. It is critical in a synchronization system with a high degree of immunity to harmonics, unbalances, and power system disturbances as sags and swells.

There are several state-of-the-art techniques in detecting the phase angle of the grid voltages. A particular easy and simple to implement is the voltage zero-crossing technique. However, voltage sags and harmonics can disturb greatly the output signal. Digital schemes have improved zero-crossing method using filtering techniques: extended Kalman filters, low-pass filters, space vector, and recursive weighted least-square estimation.

Phase-locked-loop (PLL)-based algorithms can successfully reject harmonics, notches, voltage sags, and swells. At the same time, PLL algorithms provide the estimation of time-varying fundamental parameters from the distorted grid voltage waveform. Another representative technique in grid synchronization is the second-order generalized integrator frequency-locked loop (SOGI-FLL). SOGI-FLL-based techniques estimate important grid parameters for single- and three-phase systems, reducing undesirable frequency swing during phase-angle jumps.

24.6.4 Islanding Mode

For security reasons, the PV grid-connected inverters must be disconnected from the grid when the utility is disabled or out of operation. Once the grid is out, the PV system is operating in islanding mode, and this mode must be detected in order to shut off the system and separate it from the utility.

The islanding mode detector may be classified in local or remote techniques. The local techniques are based on the measurements of physical parameters at the common point of coupling, like voltage and current. The remote techniques are based on communication infrastructure between the electricity provider and the PV system. The local techniques may be subclassified in passive and active methods. These methods are briefly described as follows.

A. Passive methods

The passive method is based on not only the measurement of variables as voltage and current at common point of coupling but also obtaining parameters like *rms* voltage, *rms* current, frequency, phase, and total harmonic distortion. It established the range for the normal operation, and once the system is out of the specified range, the PV system is considered that is operating in islanding mode.

B. Active methods

The active methods also are based on the measurements of voltage and current, but additionally, these methods inject perturbations in order to accelerate the fastness of the detection. There are many methods.

One method is called the shift active frequency, during a small time, the injected current is zero (no sinusoidal current), and when the system is in islanding mode, the output frequency is naturally changed, and this will be detected fast.

A second method is called sandia voltage shift; in this scheme, a positive feedback is considered in the current loop; this loop tries to produce an instability at the

output voltage. If the system is operated normally, this loop will not cause a major trouble since the stability is determined by the grid. However, when the islanding mode occurs, this loop will produce an instability at the output voltage, and this is detected fast as an under or overvoltage.

24.7 Stand-Alone Photovoltaic System

The main advantage of PV systems is their flexibility to be implemented in remote locations where grid connection is either impossible or very expensive to execute. Such systems are called stand-alone PV systems and are described in this section.

Stand-alone photovoltaic systems are usually a utility power alternative. They generally include solar charging modules, storage batteries, and controls or regulators as shown in Fig. 24.17. Ground- or roof-mounted systems will require a mounting structure, and if AC power is desired, an inverter is also required. In many stand-alone PV systems, batteries are used for energy storage as they may account for up to 40% of the overall stand-alone PV system cost over its lifetime.

These batteries cause losses in the PV system due to limited availability of time and energy to recharge the battery in addition to the insufficient battery maintenance. Hence, a charge controller is then used to control the system and prevent the battery from overcharging and overdischarging. Overcharging shortens the battery life and may cause gassing, while undercharging may lead to sulfation and stratification, which result in the reduction in battery effectiveness and lifetime.

Batteries are often used in PV systems for storing energy produced by the PV array during daytime and supplying it to electric loads as needed (during nighttime or cloudy weather). Moreover, batteries are also needed in the tracker systems to operate at MPP in order to provide electric loads with stable voltages. Nearly, most of the batteries used in PV systems are deep-cycle lead-acid batteries. These batteries have thicker lead plates that make them tolerate deep discharges. The thicker the lead plates, the longer the lifespan of the batteries. The heavier the battery for a given group size, the thicker the plates and the better the battery will tolerate deep discharges.

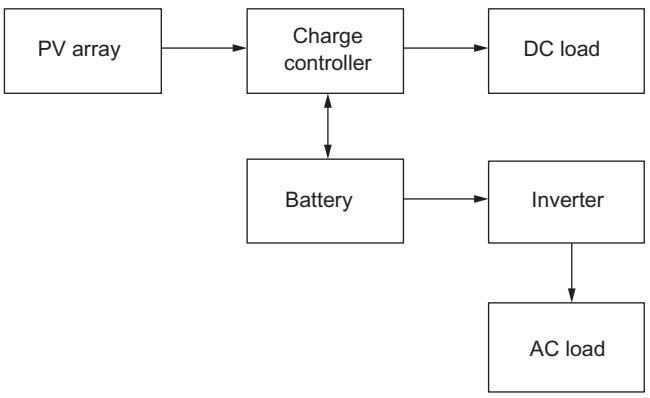

FIGURE 24.17 Diagram of stand-alone PV system with battery storage power DC and AC loads.

All deep-cycle batteries are rated in ampere-hour (AH) capacity, a quantity of the amount of usable energy it can store at nominal voltage. A good charge rate is approximately 10% of the total capacity of the battery per hour. This will reduce the electrolyte losses and the damage to the plates. A PV system may have to be sized to store a sufficient amount of power in the batteries to meet power demand during several days of cloudy weather, known as "days of autonomy." The Institute of Electrical and Electronics Engineers (IEEE) has set several guidelines and standards for sizing lead-acid batteries (IEEE Std 1013–1990), for selecting, charging, and testing in stand-alone PV systems (IEEE Std 1361–2003), and for installing and maintaining them (IEEE Std 937–2007).

Nickel-cadmium batteries are also used for PV stand-alone systems but are often expensive. However, their main advantage is they are not affected by temperature as other battery types, hence mostly recommended for industrial or commercial applications in cold locations. IEEE has also drafted some guidelines for installation and maintenance (IEEE Std 1145–1999).

To extend battery's lifetime and for efficient system's operation, a charge controller is needed to regulate the flow of electricity from the PV modules to the battery and the load. The controller keeps the battery fully charged without overcharging it. Many controllers have the ability to sense the excess of electricity drawn from batteries to the load and stop the flow until sufficient charge is restored to the batteries. The latter can greatly extend the battery's lifetime. However, controllers in the stand-alone photovoltaic system are more complex devices that depend on battery state of charge, which in turn depends on many factors and is difficult to measure. The controller must be sized to handle the maximum current produced. Several characteristics should be considered before selecting a controller such as adjustable set points including high-voltage and low-voltage disconnects, temperature compensation, low-voltage warning, and reverse current protection. Moreover, the controller should ensure that no current flows from the battery to the array at night.

24.7.1 Power Converters

There are different power converters for stand-alone systems, and they have different operating modes. They may be summarized as described below:

- Power delivered from the main voltage source

  The power converter may be able to deliver energy directly to the load form the main voltage source, without the use of the battery set. This mode in some converters is not considered, and the load is just fed by the battery set.

- Not energy available from the main voltage source
  It is possible to not have energy due to weather conditions, and then, the battery will deliver the energy to the load. This may be through a direct connection or by considering a power converter.
- Power delivered from main source and battery set
  When the photovoltaic system cannot provide all required energy by the load, but still there is available energy, then the system could be operated to demand energy from both sources: the photovoltaic system and the battery set. Not all the power converters may operate in this form.
- Charging the battery set
  Once the battery is empty, a charging mode must be considered. The battery is fed by the photovoltaic system through a power converter. This mode occurs if there is energy available from the renewable source.
- No energy available from any source
  It is possible to not have energy due to weather conditions and also when the battery is discharged; then, the system is turned off, until the system has the energy to operate.

For stand-alone applications, it is possible to consider more than one solar panel, besides the battery set. Then, power converter with multiple inputs should be considered. One of the most important issues in these converters is the power administration, that is, to determine when each source should be used, in order to have the best operation of the system.

24.8 Factors Affecting PV Output

PV systems produce power in proportion to the intensity of sunlight striking the solar array surface. Thus, there are some factors that affect the overall output of the PV system and are discussed below.

24.8.1 Temperature

The output power of a PV system decreases as the module temperature increases. An increasing cell temperature at constant irradiance causes a reduction in V_{OC} at a rate approximately of 2–2.5 mV/C. The short-circuit current, on the other hand, remains nearly constant. Since V_{mp} is normally about 80% of V_{OC} and the cells are series connected, it is important the combined effect on cell performance merit careful consideration. The temperature effect on monocrystalline solar cells is higher than polycrystalline silicon and thin-film solar cells; operating at temperatures higher than 25°C may reduce maximum output power by 15% in monocrystalline solar cells and by 5% in thin-film solar cells.

24.8.2 Dirt and Dust

Dirt and dust can accumulate on the solar module surface, also known as soiling. The soil layer blocks the sunlight and reduces the output power. Estimation of soiling loss is difficult due to the variations in the soil type, geographic locations, and climatic conditions. In general, there are two types of soil shading on PV modules, namely, hard shading and soft shading. Hard shading occurs when a solid such as accumulated dust blocks the sunlight in a clear and definable shape. On the other hand, soft shading takes place when some particles such as smog or some dust reduce the overall intensity of the solar irradiance.

For hard shading, the performance of the PV module depends on the portions shaded of the PV module. Soft shading affects the current of the PV module, but the voltage remains the same. To get better performance, the solar module surface must be clean. Manually hand cleaning element by water with detergent is suggested one time per week on the panel.

24.8.3 DC-AC Conversion

Because the power from the PV array is converted back to AC as shown earlier, some power is being lost in the conversion process, in addition to losses in the wiring. Common inverters used have peak efficiencies of about 90%–98%. Recently, the new devices based on gallium nitride (GaN) and silicon carbide (SiC) are recommended for these power converters.

24.9 PV System Design

The goal for a solar direct electricity generation system or photovoltaic system is to provide high-quality, reliable, and green electric power. Then, some suggestions may be followed.

24.9.1 Criteria for a Quality PV System

The criteria for quality PV system are as follows:

- Be properly sized and oriented to provide electric power and energy
- Good control circuit to reduce electric losses, overcurrent protection, switches, and inverters
- Good charge controller and battery management system, if the system contains batteries

24.9.2 Design Procedures

The first task in designing a PV system is to estimate the system's load. This is achieved by defining the power demand of all loads, the number of hours used per day, and the operating voltage. From the load ampere-hours and the given operating voltage for each load, the power demand is calculated. For a stand-alone system, the system voltage is the potential required by the largest load. When AC loads dominate, the DC system voltage should be chosen to be compatible with the inverter input.

24.9.3 Power-Conditioning Unit

The choice of the PCU has a great impact on the performance and economics of the system. It depends on the type of waveform produced, which in turn depends on the method used for conversion and the filtering techniques of unwanted frequencies. Several factors must be considered when selecting or designing the inverter:

- The power conversion efficiency
- Rated power
- Duty rating, the amount of time the inverter can supply maximum load
- Input voltage
- Voltage regulation
- Voltage protection
- Frequency requirement
- Power factor
- Islanding detection

24.9.4 Battery Sizing

PV system parameters need to be defined with the battery in mind. The amount of battery storage needed depends on the load energy demand and on weather patterns at the site. There is always a trade-off between keeping cost low and meeting energy demand. There are a number of basic battery characteristics that can have a significant impact on PV system performance.

Among the most important characteristics are temperature effects, recharge efficiency, charge voltage, and the number of days a PV battery will carry the load without energy from the PV array. It is important to clearly define battery charging requirements and meet those charging requirements with proper charge control voltage and array sizing.

25.1 Introduction

The Kyoto agreement on global reduction of greenhouse gas emissions has prompted renewed interest in renewable energy systems worldwide. Many renewable energy technologies today are well developed, reliable, and cost competitive with the conventional fuel generators. The cost of renewable energy technologies is on a falling trend and is expected to fall further as demand and production increases. There are many renewable energy sources (RES) such as biomass, solar, wind, minihydro, and tidal power. However, solar and wind energy systems make use of advanced power electronics technologies, and therefore, the focus in this chapter will be on solar photovoltaic and wind power.

One of the advantages offered by (RES) is their potential to provide sustainable electricity in areas not served by the conventional power grid. The growing market for renewable energy technologies has resulted in a rapid growth in the need of power electronics. Most of the renewable energy technologies produce DC power, and hence, power electronics and control equipment are required to convert the DC into AC power.

Inverters are used to convert DC to AC. There are two types of inverters: (a) stand-alone and (b) grid-connected. Both types have several similarities but are different in terms of control functions. A stand-alone inverter is used in off-grid applications with battery storage. With backup diesel generators (such as photovoltaic (PV)/diesel/hybrid power systems), the inverters may have additional control functions such as operating in parallel with diesel generators and bidirectional operation (battery charging and inverting). Grid-interactive inverters must follow the voltage and frequency characteristics of the utility generated power presented on the distribution line. For both types of inverters, the conversion efficiency is a very important consideration. Details of stand-alone and grid-connected inverters for PV and wind applications are discussed in this chapter.

Section 25.2 covers stand-alone PV system applications such as battery charging and water pumping for remote areas. This section also discusses power electronic converters suitable for PV-diesel hybrid systems and grid-connected PV for rooftop and large-scale applications. Of all the renewable energy options, the wind turbine technology is maturing very fast. A marked rise in installed wind power capacity has been noticed worldwide in the last decade. Per unit generation cost of wind power is now quite comparable with the conventional generation. Wind turbine generators are used in stand-alone battery charging applications, in combination with fossil-fuel

generators as part of hybrid systems and as grid-connected systems. As a result of advancements in blade design, generators, power electronics, and control systems, it has been possible to increase dramatically the availability of large-scale wind power. Many wind generators now incorporate speed control mechanisms like blade pitch control or use converters/inverters to regulate power output from variable-speed wind turbines. In Section 25.3, electric and power-conditioning aspects of wind energy conversion systems were included.

25.2 Power Electronics for Photovoltaic Power Systems

25.2.1 Basics of Photovoltaics

The density of power radiated from the sun (referred as "solar energy constant") at the outer atmosphere is 1.373 kW/m^2. Part of this energy is absorbed and scattered by the earth's atmosphere. The final incident sunlight on earth's surface has a peak density of 1 kW/m^2 at noon in the tropics. The technology of photovoltaics (PV) is essentially concerned with the conversion of this energy into usable electric form. Basic element of a PV system is the solar cell. Solar cells can convert the energy of sunlight directly into electricity. Consumer appliances used to provide services such as lighting, water pumping, refrigeration, telecommunication, and television can be run from PV electricity. Solar cells rely on a quantum-mechanical process known as the "photovoltaic effect" to produce electricity. A typical solar cell consists of a p-n junction formed in a semiconductor material similar to a diode. Fig. 25.1 shows a schematic diagram of the cross section through a crystalline solar cell [1]. It consists of a 0.2–0.3 mm thick monocrystalline or polycrystalline silicon wafer having two layers with different electric properties formed by "doping" it with other impurities (e.g., boron and phosphorous). An electric field is established at the junction between the negatively doped (using phosphorous atoms) and the positively doped (using boron atoms) silicon layers. If light is incident on the solar cell, the energy from the light

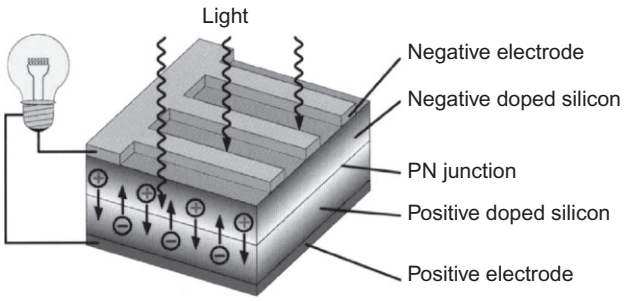

FIG. 25.1 Principle of the operation of a solar cell.

(photons) creates free charge carriers, which are separated by the electric field. An electric voltage is generated at the external contacts, so that current can flow when a load is connected. The photocurrent (I_{ph}), which is internally generated in the solar cell, is proportional to the radiation intensity.

A simplified equivalent circuit of a solar cell consists of a current source in parallel with a diode as shown in Fig. 25.2A. A variable resistor is connected to the solar cell generator as a load. When the terminals are short-circuited, the output voltage and also the voltage across the diode is zero. The entire photocurrent (I_{ph}) generated by the solar radiation then flows to the output. The solar cell current has its maximum (I_{sc}). If the load resistance is increased, which results in an increasing voltage across the p-n junction of the diode, a portion of the current flows through the diode, and the output current decreases by the same amount. When the load resistor is open-circuited, the output current is zero, and the entire photocurrent flows through the diode. The relationship between current and voltage may be determined from the diode characteristic equation:

$$I = I_{ph} - I_0\left(e^{qV/kT} - 1\right) = I_{ph} - I_d \qquad (25.1)$$

where q is the electron charge, k is the Boltzmann constant, I_{ph} is photocurrent, I_0 is the reverse saturation current, I_d is diode current, and T is the solar cell operating temperature (°K). The current versus voltage (I-V) of a solar cell is thus equivalent to an "inverted" diode characteristic curve shown in Fig. 25.2B.

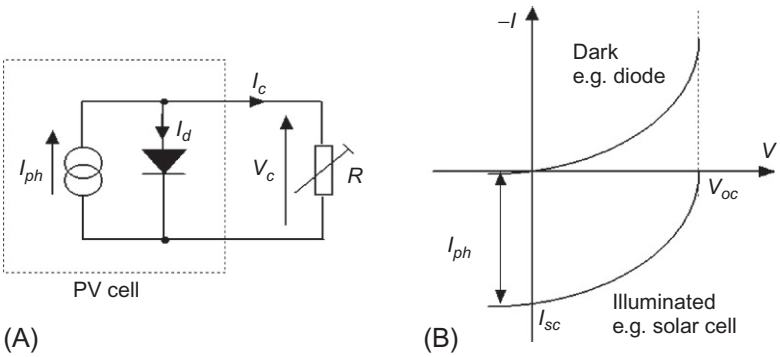

FIG. 25.2 Simplified equivalent circuit for a solar cell.

A number of semiconductor materials are suitable for the manufacturing of solar cells. The most common types using silicon semiconductor material (Si) are as follows:

- Monocrystalline Si cells
- Polycrystalline Si cells
- Amorphous Si cells

A solar cell can be operated at any point along its characteristic current-voltage curve, as shown in Fig. 25.3. Two important points on this curve are the open-circuit voltage (V_{oc}) and short-circuit current (I_{sc}). The open-circuit voltage is the maximum voltage at zero current, while short-circuit current is the maximum current at zero voltage. For a silicon solar cell under standard test conditions, V_{oc} is typically 0.6–0.7 V, and I_{sc} is typically 20–40 mA for every square centimeter of the cell area. To a good approximation, I_{sc} is proportional to the illumination level, whereas V_{oc} is proportional to the logarithm of the illumination level.

A plot of power (P) against voltage (V) for this device (Fig. 25.3) shows that there is a unique point on the I-V curve at which the solar cell will generate maximum power. This is known as the maximum power point (V_{mp} and I_{mp}). To maximize the power output, steps are usually taken during fabrication; the three basic cell parameters are open-circuit voltage, short-circuit current, and fill factor (FF)—a term describing how "square" the I-V curve is given by

$$\text{Fill Factor} = \left(V_{mp} \times I_{mp}\right)/\left(V_{oc} \times I_{sc}\right) \tag{25.2}$$

For a silicon solar cell, FF is typically 0.6–0.8. Because silicon solar cells typically produce only about 0.5 V, a number of cells are connected in series in a PV module. A panel is a collection of modules physically and electrically grouped together on a support structure. An array is a collection of panels (see Fig. 25.4).

The effect of temperature on the performance of silicon solar module is illustrated in Fig. 25.5. Note that I_{sc} slightly increases linearly with temperature, but V_{oc} and the maximum power, P_m, decrease with temperature [1].

Fig. 25.6 shows the variation of PV current and voltages at different insolation levels. From Figs. 25.5 and 25.6, it can be

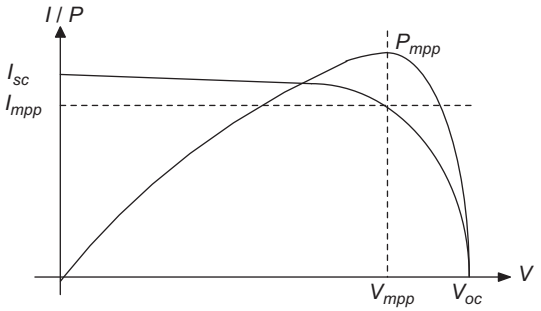

FIG. 25.3 Current versus voltage (I-V) and current power (P-V) characteristics for a solar cell.

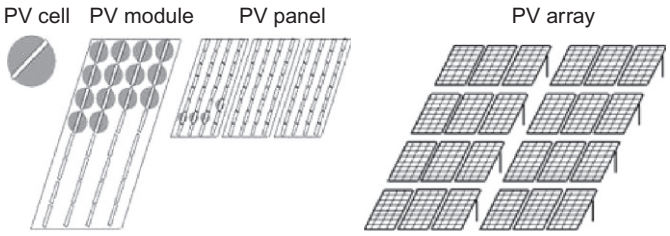

FIG. 25.4 PV generator terms.

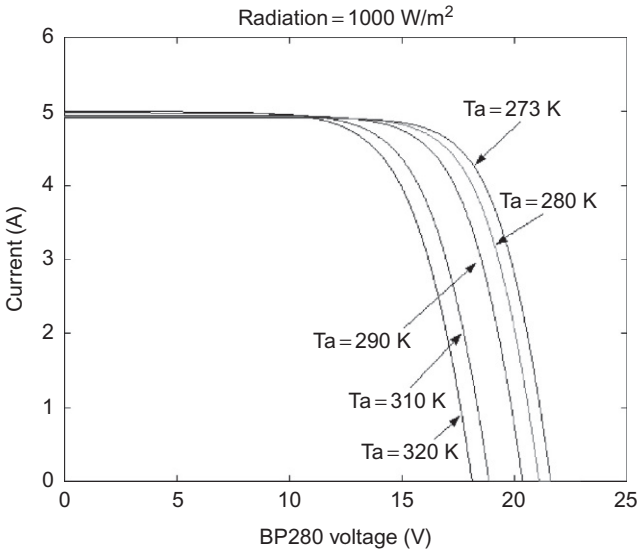

FIG. 25.5 Effects of temperature on silicon solar cells.

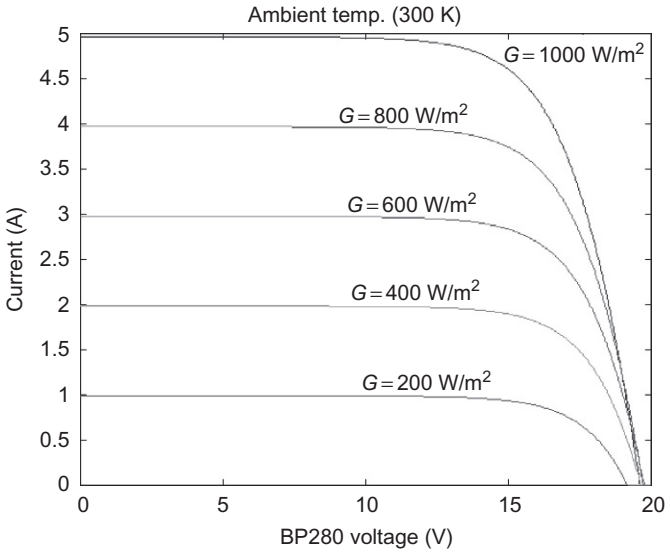

FIG. 25.6 Typical current/voltage (I-V) characteristic curves for different insolation.

seen that the *I-V* characteristics of solar cells at a given insolation and temperature consist of a constant voltage segment and a constant current segment [2]. The current is limited, as the cell is short-circuited. The maximum power condition occurs at the knee of the characteristic curve where the two segments meet.

25.2.2 Types of PV Power Systems

Photovoltaic power systems can be classified as follows:

- Stand-alone PV systems
- Hybrid PV systems
- Grid-connected PV systems

Stand-alone PV systems, shown in Fig. 25.7, are used in remote areas with no access to a utility grid. Conventional power systems used in remote areas often based on manually controlled diesel generators operating continuously or for a few hours. Extended operation of diesel generators at low load levels significantly increases maintenance costs and reduces their useful life. Renewable energy sources such as PV can be added to remote-area power systems using diesel and other fossil-fuel-powered generators to provide 24 h power economically and efficiently. Such systems are called "hybrid energy systems." Fig. 25.8 shows a schematic of a PV-diesel hybrid system. In grid-connected PV systems shown in Fig. 25.9, PV panels are connected to a grid through inverters without battery storage. These systems can be classified as small systems like the residential rooftop systems or large grid-connected systems. The grid-interactive inverters must be synchronized with the grid in terms of voltage and frequency.

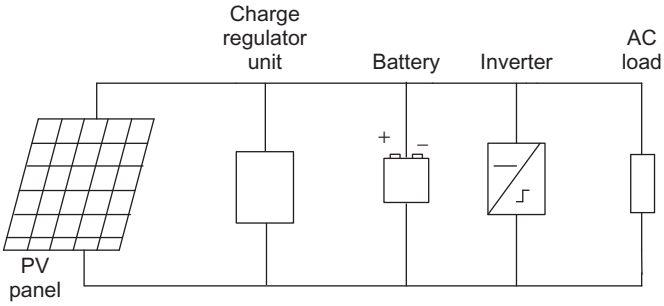

FIG. 25.7 Stand-alone PV system.

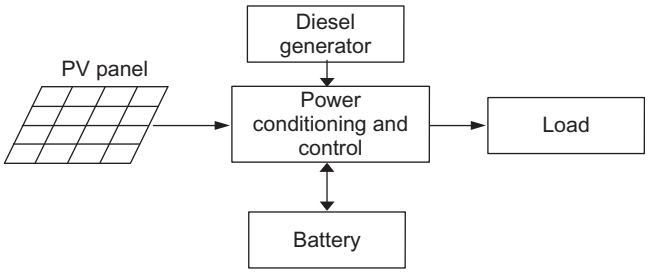

FIG. 25.8 PV-diesel hybrid system.

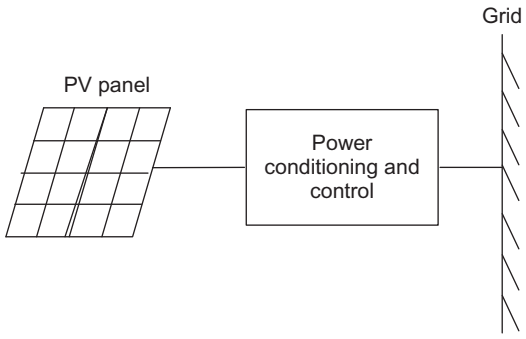

FIG. 25.9 Grid-connected PV system.

25.2.3 Stand-Alone PV Systems

The two main stand-alone PV applications are as follows:

- Battery charging
- Solar water pumping

25.2.3.1 Battery Charging

Batteries for PV systems

Stand-alone PV energy system requires storage to meet the energy demand during periods of low solar irradiation and nighttime. Several types of batteries are available such as the lead-acid, nickel-cadmium, lithium, zinc bromide, zinc chloride, sodium sulfur, nickel-hydrogen, redox, and vanadium batteries. The provision of cost-effective electric energy storage remains one of the major challenges for the development of improved PV power systems. Typically, lead-acid batteries are used to guarantee several hours to a few days of energy storage. Their reasonable cost and general availability has resulted in the widespread application of lead-acid batteries for remote-area power supplies despite their limited lifetime compared with other system components. Lead-acid batteries can be deep or shallow cycling gelled batteries, batteries with captive or liquid electrolyte, sealed and nonsealed batteries, etc. [3]. Sealed batteries are valve regulated to permit the evolution of excess hydrogen gas (although catalytic converters are used to convert as much evolved hydrogen and oxygen back to water as possible). Sealed batteries need less maintenance. The following factors are considered in the selection of batteries for PV applications [1]:

- Deep discharge (70%–80% depth of discharge)
- Low charging/discharging current
- Long duration charge (slow) and discharge (long duty cycle)
- Irregular and varying charge/discharge
- Low self-discharge
- Long lifetime

- Less maintenance requirement
- High-energy storage efficiency
- Low cost

Battery manufacturers specify the nominal number of complete charge and discharge cycles as a function of the depth of discharge (DOD), as shown in Fig. 25.10. While this information can be used reliably to predict the lifetime of lead-acid batteries in conventional applications, such as uninterruptable power supplies or electric vehicles, it usually results in an overestimation of the useful life of the battery bank in renewable energy systems.

Two of the main factors that have been identified as limiting criteria for the cycle life of batteries in PV power systems are incomplete charging and prolonged operation at a low state of charge (SOC). The objective of improved battery control strategies is to extend the lifetime of lead-acid batteries to achieve a typical number of cycles shown in Fig. 25.10. If this is achieved, an optimum solution for the required storage capacity and the maximum DOD of the battery can be found by referring to manufacturer's information. Increasing the capacity will reduce the typical DOD and therefore prolong the battery lifetime. Conversely, it may be more economic to replace a smaller battery bank more frequently.

PV charge controllers

Blocking diodes in series with PV modules are used to prevent the batteries from being discharged through the PV cells at night when there is no sun available to generate energy. These blocking diodes also protect the battery from short circuits. In a solar power system consisting of more than one string connected in parallel, if a short circuit occurs in one of the strings, the blocking diode prevents the other PV strings to discharge through the short-circuited string.

The battery storage in a PV system should be properly controlled to avoid catastrophic operating conditions like overcharging or frequent deep discharging. Storage batteries account for most PV system failures and contribute significantly to both the initial and the eventual replacement costs.

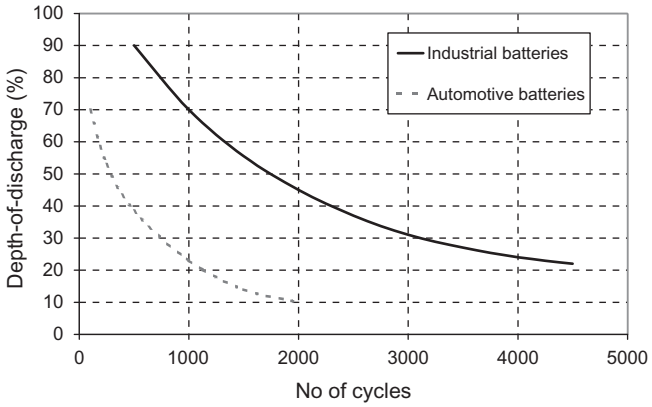

FIG. 25.10 Nominal number of battery cycles versus DOD.

Charge controllers regulate the charge transfer and prevent the battery from being excessively charged and discharged. Three types of charge controllers are commonly used:

- Series charge regulators
- Shunt charge regulators
- DC-DC converters

A series charge regulators: The basic circuit for the series regulators is given in Fig. 25.11. In the series charge controller, the switch S_1 disconnects the PV generator when a predefined battery voltage is achieved. When the voltage reduces below the discharge limit, the load is disconnected from the battery to avoid deep discharge beyond the limit. The main problem associated with this type of controller is the losses associated with the switches. This extra power loss has to come from the PV power, and this can be quite significant. Bipolar transistors, metal-oxide-semiconductor field-effect transistors (MOSFETs), or relays are used as the switches.

Shunt charge regulators: In this type, as illustrated in Fig. 25.12, when the battery is fully charged, the PV generator is short-circuited using an electronic switch (S_1). Unlike series controllers, this method works more efficiently even when the battery is completely discharged as the short-circuit switch need not be activated until the battery is fully discharged [1].

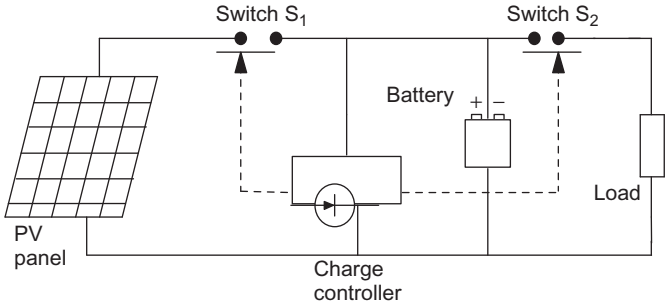

FIG. 25.11 Series charge regulator.

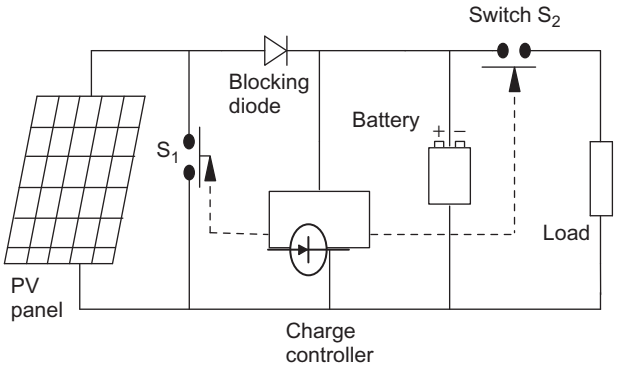

FIG. 25.12 Shunt charge regulator.

The blocking diode prevents short-circuiting of the battery. Shunt charge regulators are used for the small PV applications (less than 20 A).

Deep discharge protection is used to protect the battery against the deep discharge. When the battery voltage reaches below the minimum set point for deep discharge limit, switch S_2 disconnects the load. Simple series and shunt regulators allow only relatively coarse adjustment of the current flow and seldom meet the exact requirements of PV systems.

DC–DC converter type charge regulators: Switch-mode DC-to-DC converters are used to match the output of a PV generator to a variable load. There are various types of DC-DC converters such as the following:

- Buck (step-down) converter
- Boost (step-up) converter
- Buck-boost (step-down/step-up) converter

Figs. 25.13–25.15 show simplified diagrams of these three basic types of converters. The basic concepts are an electronic switch, an inductor to store energy, and a "flywheel" diode, which carries the current during that part of switching cycle when the switch is off. The DC-DC converters allow the charge current to be reduced continuously in such a way that the resulting battery voltage is maintained at a specified value.

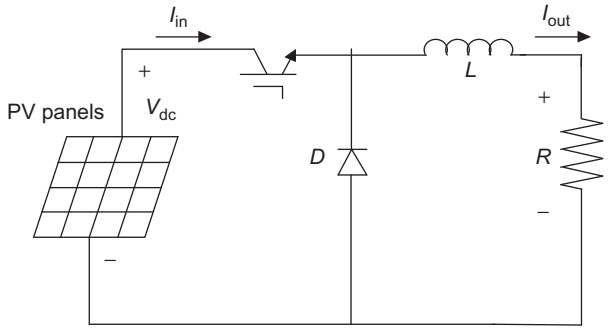

FIG. 25.13 Buck converter.

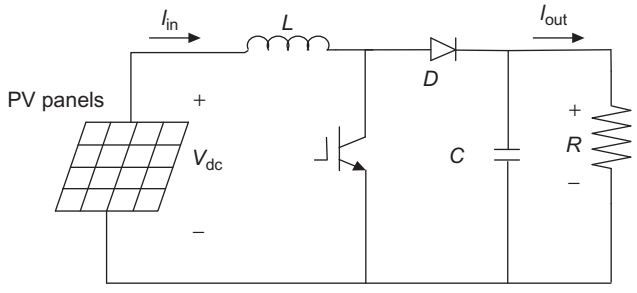

FIG. 25.14 Boost converter.

Maximum power point tracking (MPPT)

A controller that tracks the maximum power point locus of the PV array is known as the MPPT. In Fig. 25.16, the PV power output is plotted against the voltage for insolation levels from 200 to 1000 W/m^2 [4]. The points of maximum array power form a curve are termed as the maximum power locus. Due to high cost of solar cells, it is necessary to operate the PV array at its maximum power point (MPP). For overall optimal operation of the system, the load line must match the PV array's MPP locus.

Referring to Fig. 25.17, the load characteristics can be either curve OA or curve OB depending upon the nature of the load and its current and voltage requirements. If load OA is considered and the load is directly coupled to the solar array, the array will operate at point A1, delivering only power P1. The maximum array power available at the given insolation is P2. In order to use PV array power P2, a power conditioner coupled between array and the load is needed.

There are generally two ways of operating PV modules at maximum power point. These ways take advantage of analog and/or digital hardware control to track the MPP of PV arrays.

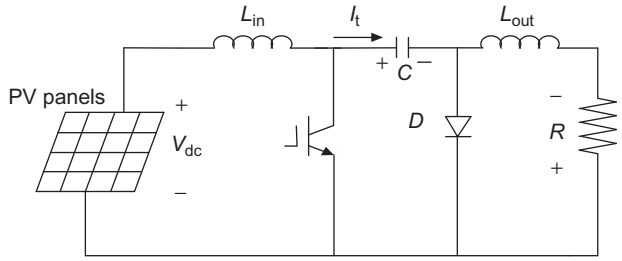

FIG. 25.15 Boost-buck converter.

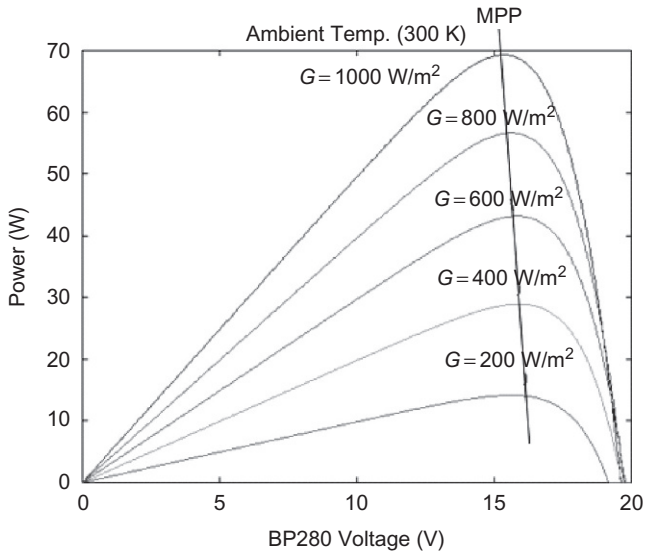

FIG. 25.16 Typical power/voltage characteristics for increased insolation.

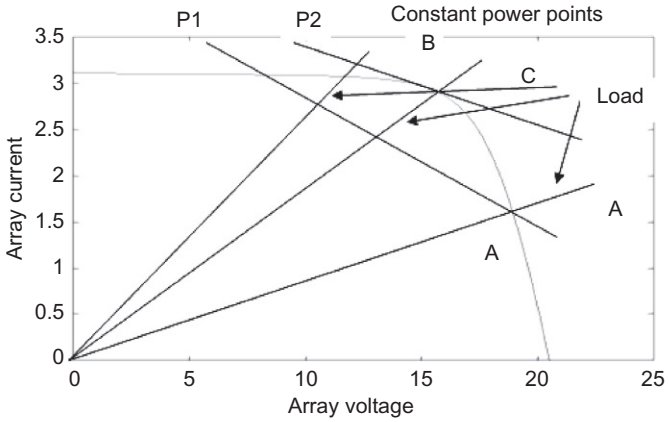

FIG. 25.17 PV array and load characteristics.

Analog control

There are many analog control mechanisms proposed in different articles, for instance, fractional short-circuit current (I_{SC}) [5–8], fractional open-circuit voltage (V_{OP}) [5,6,9–12], and ripple correlation control (RCC) [13–16].

Fractional open-circuit voltage (V_{OP}) is one of the simple analogue control methods. It is based on the assumption that the maximum power point voltage, V_{MPP}, is a linear function of the open-circuit voltage, V_{OC}. For example, $V_{MPP} = kV_{OC}$ where $k \asymp 0.76$. This assumption is reasonably accurate even for large variations in the cell short-circuit current and temperature. This type of MPPT is probably the most common type. A variation to this method involves periodically open-circuiting the cell string and measuring the open-circuit voltage. The appropriate value of V_{MPP} can then be obtained with a simple voltage divider.

Digital control

There are many digital control mechanisms that were proposed in different articles, for instance, perturbation and observation (P&O) or hill climbing [17–22], fuzzy logic [23–27], neural network [17,28–30], and incremental conductance (IncCond) [31–34].

The P&O or hill-climbing control involves around varying the input voltage around the optimum value by giving it a small increment or decrement alternately. The effect on the output power is then assessed, and a further small correction is made to the input voltage. Therefore, this type of control is called a hill-climbing control. The power output of the PV array is sampled at an every definite sampling period and compared with the previous value. In the event, when power is increased, then the solar array voltage is stepped in the same direction as the previous sample time, but if the power is reduced, then the array voltage is stepped in the opposite way and try to operate the PV array at its optimum/maximum power point.

To operate the PV array at the MPP, perturb and adjust method can be used at regular intervals. Current drawn is sampled every few seconds, and the resulting power output of the solar cells is monitored at regular intervals. When an increased current results in a higher power, it is further increased until power output starts to reduce. But if the increased PV current results in lesser amount of power than in the previous sample, then the current is reduced until the MPP is reached.

25.2.3.2 Inverters for Stand-Alone PV Systems

Inverters convert power from DC to AC, while rectifiers convert it from AC to DC. Many inverters are bidirectional, that is, they are able to operate in both inverting and rectifying modes. In many stand-alone PV installations, alternating current is needed to operate 230 V (or 110 V), 50 Hz (or 60 Hz) appliances. Generally, stand-alone inverters operate at 12, 24, 48, 96, 120, or 240 V DC depending upon the power level. Ideally, an inverter for a stand-alone PV system should have the following features:

- Sinusoidal output voltage.
- Voltage and frequency within the allowable limits.
- Cable to handle large variation in input voltage.
- Output voltage regulation.
- High efficiency at light loads.
- Less harmonic generation by the inverter to avoid damage to electronic appliances like television, additional losses, and heating of appliances.
- Photovoltaic inverters must be able to withstand overloading for short term to take care of higher starting currents from pumps, refrigerators, etc.
- Adequate protection arrangement for over-/undervoltage and frequency, short circuit, etc.
- Surge capacity.
- Low idling and no load losses.
- Low battery voltage disconnect.
- Low audio and radio frequency (RF) noise.

Several different semiconductor devices such as metal-oxide-semiconductor field-effect transistor (MOSFETs) and insulated-gate bipolar transistors (IGBTs) are used in the power stage of inverters. Typically, MOSFETs are used in units up to 5 kVA and 96 V DC. They have the advantage of low switching losses at higher frequencies. Because the on-state voltage drop is 2 V DC, IGBTs are generally used only above 96 V DC systems.

Voltage-source inverters are usually used in stand-alone applications. They can be single phase or three phase. There are three switching techniques commonly used: square-wave, quasi-square-wave, and pulse-width modulation. Square-wave or modified square-wave inverters can supply power tools, resistive heaters, or incandescent lights, which do not require a high-quality sine wave for reliable and efficient operation. However, many household appliances require low distortion sinusoidal waveforms. The use of true sine-wave inverters is recommended for remote-area power systems. Pulse-width modulated (PWM) switching is generally used for obtaining sinusoidal output from the inverters.

A general layout of a single-phase system, both half bridge and full bridge, is shown in Fig. 25.18. In Fig. 25.18A, single-phase half bridge is with two switches, S_1 and S_2; the capacitors C_1 and C_2 are connected in series across the DC source. The junction between the capacitors is at the midpotential. Voltage across each capacitor is $V_{dc}/2$. Switches S_1 and S_2 can be switched on/off periodically to produce AC voltage. Filter (L_f and C_f) is used to reduce high-switch-frequency components and to produce sinusoidal output from the inverter. The output of inverter is connected to load through a transformer. Fig. 25.18B shows the similar arrangement for full-bridge configuration with four switches. For the same input source voltage, the full-bridge output is twice, and the switches carry less current for the same load power.

The power circuit of a three-phase four-wire inverter is shown in Fig. 25.19. The output of the inverter is connected to load via three-phase transformer (delta/Y). The star point of the transformer secondary gives the neutral connection. Three phase or single phase can be connected to this system. Alternatively, a center tap DC source can be used to supply the converter, and the midpoint can be used as the neutral.

Fig. 25.20 shows the inverter efficiency for a typical inverter used in remote-area power systems. It is important to consider that the system load is typically well below the nominal inverter capacity P_{nom}, which results in low conversion efficiencies at loads below 10% of the rated inverter output power. Optimum overall system operation is achieved if the total energy dissipated in the inverter is minimized. The high conversion efficiency at low power levels of recently developed inverters for grid-connected PV systems shows that there is a significant potential for further improvements in efficiency.

Bidirectional inverters convert DC power to AC power (inverter) or AC power to DC power (rectifier) and are

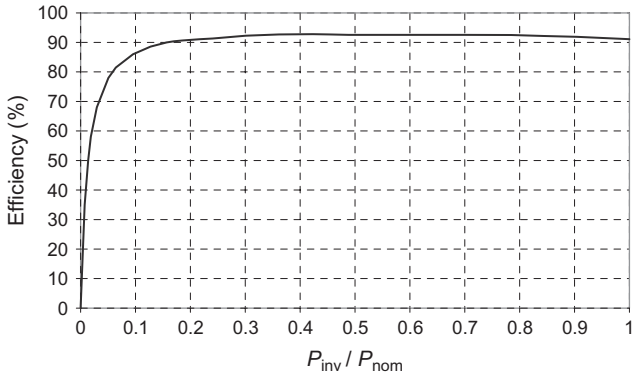

FIG. 25.20 Typical inverter efficiency curve.

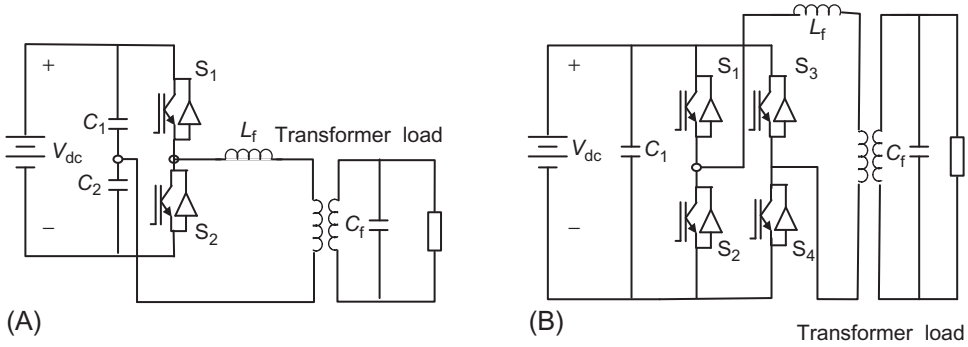

FIG. 25.18 Single-phase inverter: (A) half bridge and (B) full bridge.

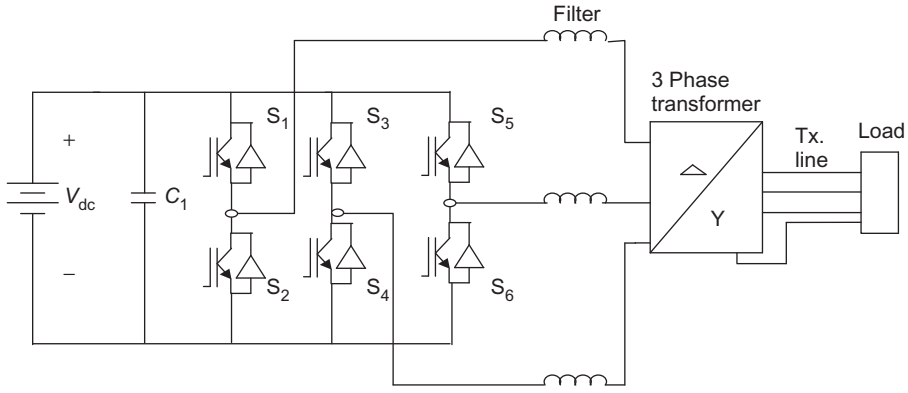

FIG. 25.19 A stand-alone three-phase four-wire inverter.

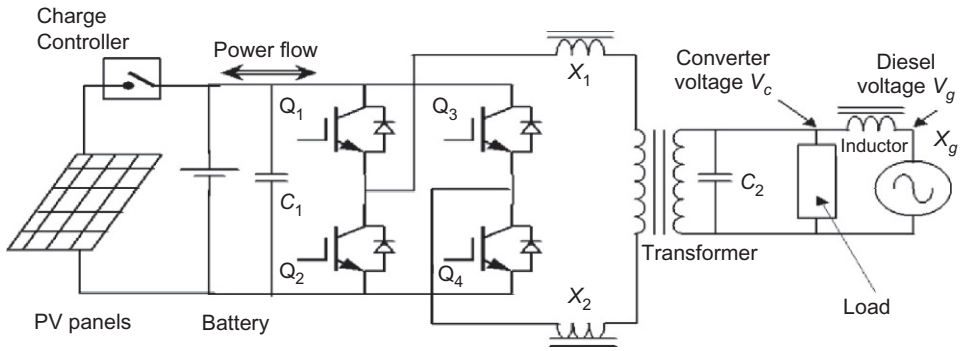

FIG. 25.21 Bidirectional inverter system.

becoming very popular in remote-area power systems [3,4]. The principle of a stand-alone single-phase bidirectional inverter used in a PV/battery/diesel hybrid system can be explained by referring Fig. 25.21. A charge controller is used to interface the PV array and the battery. The inverter has a full-bridge configuration realized using four power electronic switches (MOSFET or IGBTs) S_1–S_4. In this scheme, the diagonally opposite switches (S_1 and S_4) and (S_2 and S_3) are switched using a sinusoidally PWM gate pulses. The inverter produces sinusoidal output voltage. The inductors X_1, X_2, and the AC output capacitor C_2 filter out the high-switch-frequency components from the output waveform. Most inverter topologies use a low-frequency (50 or 60 Hz) transformer to step up the inverter output voltage. In this scheme, the diesel generator and the converter are connected in parallel to supply the load. The voltage sources, diesel and inverter, are separated by the link inductor X_m. The bidirectional power flow between inverter and the diesel generator can be established.

The power flow through the link inductor, X_m, is

$$S_m = V_m I_m^* \tag{25.3}$$

$$P_m = (V_m V_c \sin\delta)/X_m \tag{25.4}$$

$$Q_m = (V_m/X_m)(V_m - V_c \cos\delta) \tag{25.5}$$

$$\delta = \sin^{-1}[(X_m P_m)/(V_m V_c)] \tag{25.6}$$

where δ is the phase angle between the two voltages. From Eq. (25.4), it can be seen that the power supplied by the inverter from the batteries (inverter mode) or supplied to the batteries (charging mode) can be controlled by controlling the phase angle δ. The PWM pulses separately control the amplitude of the converter voltage, V_c, while the phase angle with respect to the diesel voltage is varied for power flow.

25.2.3.3 Solar Water Pumping

In many remote and rural areas, hand pumps or diesel-driven pumps are used for water supply. Diesel pumps consume fossil fuel, affect environment, need more maintenance, and are less reliable. Photovoltaic powered water pumps have received considerable attention recently due to major developments in the field of solar cell materials and power electronic systems technology.

Types of pumps

Two types of pumps are commonly used for the water pumping applications: positive and centrifugal displacement. Both centrifugal and positive displacement pumps can be further classified into those with motors that are (a) surface mounted and those that are (b) submerged into the water ("submersible").

Displacement pumps have water output directly proportional to the speed of the pump but almost independent of the head. These pumps are used for solar water pumping from deep wells or bores. They may be piston-type pumps or use diaphragm driven by a cam and rotary screw-type pumps or use progressive cavity system. The pumping rate of these pumps is directly related to the speed, and hence, constant torque is desired.

Centrifugal pumps are used for low-head applications especially if they are directly interfaced with the solar panels. Centrifugal pumps are designed for fixed-head applications, and the pressure difference generated increases in relation to the speed of the pump. These pumps are rotating impeller type, which throws the water radially against a casing, so shaped that the momentum of the water is converted into useful pressure for lifting [3]. The centrifugal pumps have relatively high efficiency, but it reduces at lower speeds, which can be a problem for the solar water pumping system at the time of low light levels. The single-stage centrifugal pump has just one impeller, whereas most borehole pumps are multistage types where the outlet from one impeller goes into the center of another and each one keeps increasing the pressure difference.

From Fig. 25.22, it is quite obvious that the load line is located relatively faraway from P_{max} line. It has been reported that the daily utilization efficiency for a DC motor drive is 87% for a centrifugal pump compared with 57% for a constant torque characteristic load. Hence, centrifugal pumps are more compatible with PV arrays. The system operating point is

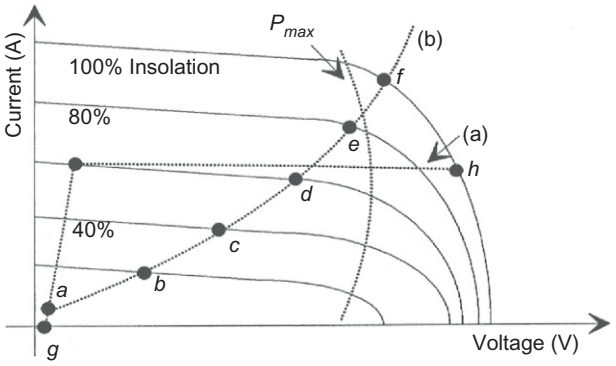

FIG. 25.22 *I-V* characteristics of a PV array and two mechanical loads: (A) constant torque and (B) centrifugal pump.

determined by the intersection of the *I-V* characteristics of the PV array and the motor as shown in Fig. 25.22. The torque-speed slope is normally large due to the armature resistance being small. At the instant of starting, the speed and the back emf are zero. Hence, the motor starting current is approximately the short-circuit current of the PV array. By matching the load to the PV source through MPPT, the starting torque increases.

The matching of a DC motor depends upon the type of load being used. For instance, a centrifugal pump is characterized by having the load torque proportional to the square of speed. The operating characteristics of the system (i.e., PV source, permanent magnet (PM) DC motor, and load) are at the intersection of the motor and load characteristics as shown in Fig. 25.23 (i.e., points a, b, c, d, e, and f for centrifugal pump). From Fig. 25.23, the system utilizing the centrifugal pump as its load tends to start at low solar irradiation (point a) level. However, for the systems with an almost constant torque characteristics in Fig. 25.22, the start is at almost 50% of one sum (full insolation) that results in short period of operation.

Types of motors

There are various types of motors available for the PV water pumping applications:

- DC motors
- AC motors

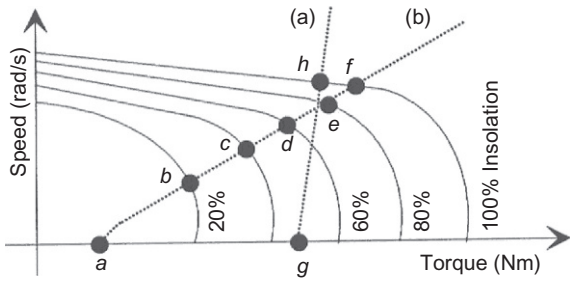

FIG. 25.23 Speed torque characteristics of a DC motor and two mechanical loads: (A) helical rotor and (B) centrifugal pump.

DC motors are preferred where direct coupling to PV panels is desired, whereas AC motors are coupled to the solar panels through inverters. AC motors in general are cheaper than the DC motors and are more reliable, but the DC motors are more efficient. The DC motors used for solar pumping applications are as follows:

- Permanent magnet DC motors with brushes
- Permanent DC magnet motors without brushes

In DC motors with the brushes, the brushes are used to deliver power to the commutator and need frequent replacement due to wear and tear. These motors are not suitable for submersible applications unless long transmission shafts are used. Brushless DC permanent magnet motors have been developed for submersible applications.

The AC motors are of the induction motor type, which is cheaper than DC motors and available worldwide. However, they need inverters to change DC input from PV to AC power. A comparison of the different types of motors used for PV water pumping is given in Table 25.1.

Power conditioning units for PV water pumping

Most PV pump manufacturers include power-conditioning units (PCU) that are used for operating the PV panels close to their MPP over a range of load conditions and varying insolation levels and also for power conversion. DC or AC motor-pump units can be used for PV water pumping. In its simplest form, a solar water pumping system is composed of PV array, PCU, and DC water-pump unit as shown in Fig. 25.24.

In case of lower light levels, high currents can be generated through power conditioning to help in starting the motor-pump units especially for reciprocating positive displacement type pumps with constant torque characteristics, requiring constant current throughout the operating region. In positive displacement type pumps, the torque generated by the pumps depends on the pumping head, friction, pipe diameter, etc. and needs certain level of current to produce the necessary torque. Some systems use electronic controllers to assist starting and operation of the motor under low solar radiation. This is particularly important when using positive displacement pumps. The solar panels generate DC voltage and current. The solar water pumping systems usually have DC or AC pumps. For DC pumps, the PV output can be directly connected to the pump through MPPT, or a DC-DC converter can also be used for interfacing for controlled DC output from PV panels. To feed the AC motors, a suitable interfacing is required for the power conditioning. These PV inverters for the stand-alone applications are very expensive. The aim of power-conditioning equipment is to supply the controlled voltage/current output from the converters/inverters to the motor-pump unit.

These power-conditioning units are also used for operating the PV panels close to their maximum efficiency for fluctuating solar conditions. The speed of the pump is governed by the

TABLE 25.1 Comparison of the different types of motor used for PV water pumping

Types of motor	Advantages	Disadvantages	Main features
Brushed DC	Simple and efficient for PV applications No complex control circuits is required as the motor starts without high-current surge These motors will run slowly but do not overheat with reduced voltage	Brushes need to be replaced periodically (typical replacement interval is 2000–4000 h or 2 years)	Requires MPPT for optimum performance Available only in small motor sizes Increasing current (by paralleling PV modules) increases the torque Increasing voltage (by series PV modules) increases the speed
Brushless DC	Efficient Less maintenance is required	Electronic computation adds to extra cost, complexity, and increased risk of failure/malfunction In most cases, oil cooled can't be submerged as deep as water cooled AC units	Growing trend among PV pump manufacturers to use brushless DC motors, primarily for centrifugal type submersible pumps
AC induction motors	No brushes to replace Can use existing AC motor/pump technology that is cheaper and easily available worldwide. These motors can handle larger pumping requirements	Needs an inverter to convert DC output from PV to AC adding additional cost and complexity Less efficient than DC motor-pump units Prone to overheating if current is not adequate to start the motor or if the voltage is too low	Available for single or three supply Inverters are designed to regulate frequency to maximize power to the motor in response to changing insolation levels

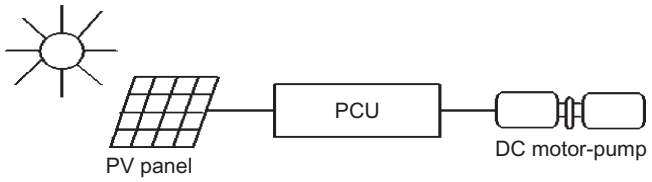

FIG. 25.24 Block diagram for DC motor-driven pumping scheme.

available driving voltage. Current lower than the acceptable limit will stop the pumping. When the light level increases, the operating point will shift from the MPP leading to the reduction of efficiency. For centrifugal pumps, there is an increase in current at increased speed, and the matching of *I-V* characteristics is closer for wide range of light intensity levels. For centrifugal pumps, the torque is proportional to the square of speed, and the torque produced by the motors is proportional to the current. Due to decrease in PV current output, the torque from the motor and consequently the speed of the pump are reduced, resulting in decrease in back emf and the required voltage of the motor. Maximum power point tracker can be used for controlling the voltage/current outputs from the PV inverters to operate the PV close to maximum operating point for the smooth operation of motor-pump units. The DC-DC converter can be used for keeping the PV panel output voltage constant and help in operating the solar arrays close to MPP. In the beginning, high starting current is required to produce high starting torque. The PV panels cannot supply this high starting current without adequate power-conditioning equipment like DC-DC converter or by using a starting capacitor. The DC-DC converter can generate the high starting currents by regulating the excess PV array voltage. DC-DC converter can be boost or buck converter.

Brushless DC motor (BDCM) and helical rotor pumps can also be used for PV water pumping [35]. Brushless DC motors are a self-synchronous type of motor characteristics by trapezoidal waveforms for back emf and air flux density. They can operate off a low-voltage DC supply that is switched through an inverter to create a rotating stator field. The current generations of BDCMs use rare-earth magnets on the rotor to give high air gap flux densities and are well suited to solar application. The block diagram of such an arrangement is shown in Fig. 25.25 that consists of PV panels, DC-DC converter, MPPT, and BDCM.

The PV inverters are used to convert the DC output of the solar arrays to the AC quantity so as to run the AC motor-driven pumps. These PV inverters can be variable frequency type, which can be controlled to operate the motors over wide range of loads. The PV inverters may involve impedance matching to match the electric characteristics of the load and array. The motor-pump unit and PV panels operate at their maximum efficiencies. Maximum power point tracker is also used in the power conditioning. To keep the voltage stable for the inverters, the DC-DC converter can be used. The inverter/converter has a capability of injecting high-switch-frequency components, which can lead to the overheating and the losses. So care shall be taken for this. The PV arrays are usually connected in series, parallel, or a combination of series-parallel configurations. The function of power electronic interface, as mentioned before, is to convert the DC power from

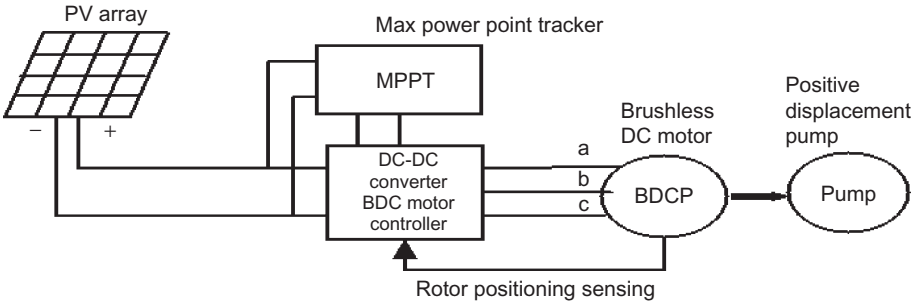

FIG. 25.25 Block diagram for BDCM for PV application.

the array to the required voltage and frequency to drive the AC motors. The motor-pump system load should be such that the array operates close to its MPP at all solar insolation levels. There are mainly three types of solar-powered water pumping systems as shown in Fig. 25.26.

The first system shown in Fig. 25.26A is an imported commercially available unit, which uses a specially wound low-voltage induction-motor-driven submersible pump. Such a low-voltage motor permits the PV array voltage to be converted to AC without using a step-up transformer. The second system, shown in Fig. 25.26B, makes use of a conventional "off-the-shelf" 415 V, 50 Hz induction motor [5]. This scheme needs a step-up transformer to raise inverter output voltage to high voltage. The third scheme as shown in Fig. 25.26C is composed of a DC-DC converter, an inverter that switches at a high frequency, and a mains voltage motor-driven pump. To get the optimum discharge (Q), at a given insolation level, the efficiency of the DC-DC converter and the inverter should be high. So the purpose should be to optimize the output from PV array, motor, and the pump. The principle used here is to vary the duty cycle of a DC-DC converter so that the output voltage is maximum. The DC-DC converter is used to boost the solar array voltage to eliminate the need for a step-up transformer and operate the array at the MPP. The three-phase inverter used in the interface is designed to operate in a variable frequency mode over the range of 20–50 Hz, which is the practical limit for most 50 Hz induction motor applications. Block diagram for frequency control is given in Fig. 25.27.

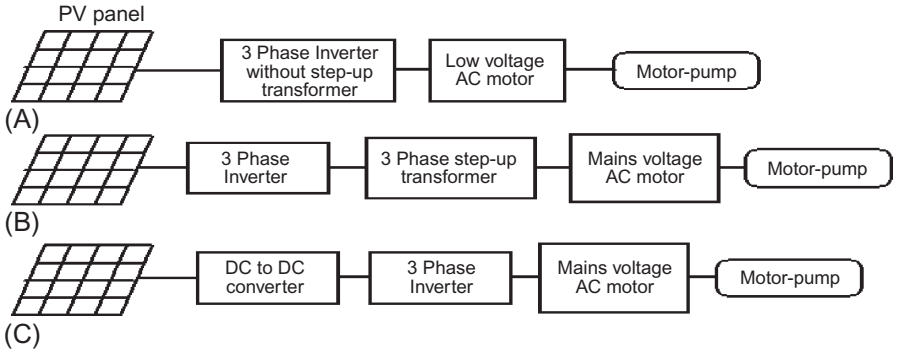

FIG. 25.26 Block diagrams for various AC motor-driven pumping schemes.

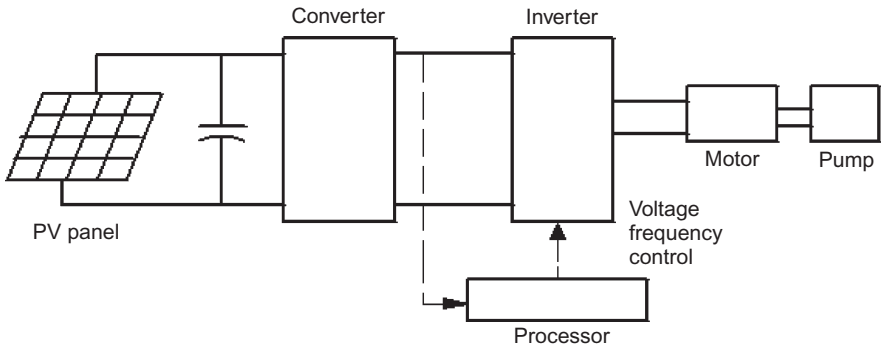

FIG. 25.27 Block diagram for voltage/frequency control.

This inverter would be suitable for driving permanent magnet motors by incorporating additional circuitry for position sensing of the motor's shaft. Also, the inverter could be modified, if required, to produce higher output frequencies for high-speed permanent magnet motors. The inverter has a three-phase full-bridge configuration implemented by MOSFET power transistors.

25.2.4 Grid-Connected PV Systems

The utility interactive inverters not only conditions the power output of the PV arrays but ensures that the PV system output is fully synchronized with the utility power. These systems can be batteryless or with battery backup. Systems with battery storage (or flywheel) provide additional power supply reliability. The grid connection of PV systems is gathering momentum because of various rebate and incentive schemes. This system allows the consumer to feed its own load utilizing the available solar energy, and the surplus energy can be injected into the grid under the energy by back scheme to reduce the payback period. Grid-connected PV systems can become a part of the utility system. The contribution of solar power depends upon the size of system and the load curve of the house. When the PV system is integrated with the utility grid, a two-way power flow is established. The utility grid will absorb excess PV power and will feed the house during nighttime and at instants while the PV power is inadequate. The utility companies are encouraging this scheme in many parts of the world. The grid-connected system can be classified as follows:

- Rooftop application of grid-connected PV system
- Utility-scale large system

For small household PV applications, a roof mounted PV array can be the best option. Solar cells provide an environmentally clean way of producing electricity, and rooftops have always been the ideal place to put them. With a PV array on the rooftop, the solar-generated power can supply residential load. The rooftop PV systems can help in reducing the peak summer load to the benefit of utility companies by feeding the household lighting, cooling, and other domestic loads. The battery storage can further improve the reliability of the system at the time of low insolation level, nighttime, or cloudy days. But the battery storage has some inherent problems like maintenance and higher cost.

For roof-integrated applications, the solar arrays can be either mounted on the roof or directly integrated into the roof. If the roof integration does not allow for an air channel behind the PV modules for ventilation purpose, then it can increase the cell temperature during the operation consequently leading to some energy losses. The disadvantage with the rooftop application is that the PV array orientation is dictated by the roof. In case, when the roof orientation differs from the optimal orientation required for the cells, then the efficiency of the entire system would be suboptimal.

Utility interest in PV has centered on the large grid-connected PV systems. In Germany, the United States, Spain, and in several other parts of the world, some large-scale PV plants have been installed. The utilities are more inclined with large-scale, centralized power supply. The PV systems can be centralized or distributed systems.

Grid-connected PV systems must observe the islanding situation, when the utility supply fails. In case of islanding, the PV generators should be disconnected from mains. PV generators can continue to meet only the local load, if the PV output matches the load. If the grid is reconnected during islanding, transient overcurrents can flow through the PV system inverters, and the protective equipments like circuit breakers may be damaged. The islanding control can be achieved through inverters or via the distribution network. Inverter controls can be designed on the basis of detection of grid voltage, measurement of impedance, frequency variation, or increase in harmonics. Protection shall be designed for the islanding, short circuits, over/under-voltages/currents, grounding, lightening, etc.

The importance of the power generated by the PV system depends upon the time of the day specially when the utility is experiencing the peak load. The PV plants are well suited to summer peaking, but it depends upon the climatic condition of the site. PV systems being investigated for use as peaking stations would be competitive for load management. The PV users can defer their load by adopting load management to get the maximum benefit out of the grid-connected PV plants and feeding more power into the grid at the time of peak load.

The assigned capacity credit is based on the statistical probability with which the grid can meet peak demand [3]. The capacity factor during the peaks is very similar to that of conventional plants, and similar capacity credit can be given for the PV generation except at the times when the PV plants are generating very less power unless adequate storage is provided. With the installation of PV plants, the need of extra transmission lines, transformers can be delayed or avoided. The distributed PV plants can also contribute in providing reactive power support to the grid and reduce burden on VAR compensators.

25.2.4.1 Inverters for Grid-Connected Applications

Power conditioner is the key link between the PV array and mains in the grid-connected PV system. It acts as an interface that converts DC current produced by the solar cells into utility grade AC current. The PV system behavior relies heavily on the power-conditioning unit. The inverters shall produce good quality sine-wave output. The inverter must follow the frequency and voltage of the grid, the inverter has to extract maximum power from the solar cells with the help of MPPT, and the inverter input stage varies the input voltage until the MPP on the *I-V* curve is found. The inverter shall monitor all the phases of the grid. The inverter output shall be controlled in terms of voltage and frequency variation. A typical grid-connected inverter may use a PWM scheme and operates in the range of 2–20 kHz.

25.2.4.2 Inverter Classifications

The inverters used for the grid interfacing are broadly classified as follows:

- Voltage-source inverters (VSI)
- Current-source inverters (CSI)

The inverters based on the control schemes can be classified as follows:

- Current controlled (CC)
- Voltage controlled (VC)

The source is not necessarily characterized by the energy source for the system. It is a characteristic of the topology of the inverter. It is possible to change from one source type to another source type by the addition of passive components. In the voltage-source inverter (VSI), the DC side is made to appear to the inverter as a voltage source. The VSIs have a capacitor in parallel across the input, whereas the CSIs have an inductor in series with the DC input. In the CSI, the DC source appears as a current source to the inverter. Solar arrays are fairly good approximation to a current source. Most PV inverters are voltage source even though the PV is a current source. Current-source inverters are generally used for large motor drives though there have been some PV inverters built using a current-source topology. The VSI is more popular with the PWM VSI dominating the sine-wave inverter topologies.

Fig. 25.28A shows a single-phase full-bridge bidirectional VSI with (A) voltage control and phase-shift (δ) control—voltage-controlled voltage-source inverter (VCVSI). The active power transfer from the PV panels is accomplished by controlling the phase angle δ between the converter voltage and the grid voltage. The converter voltage follows the grid voltage. Fig. 25.28B shows the same VSI operated as (B) current controlled (CCVSI). The objective of this scheme is to control active and reactive components of the current fed into the grid using PWM techniques.

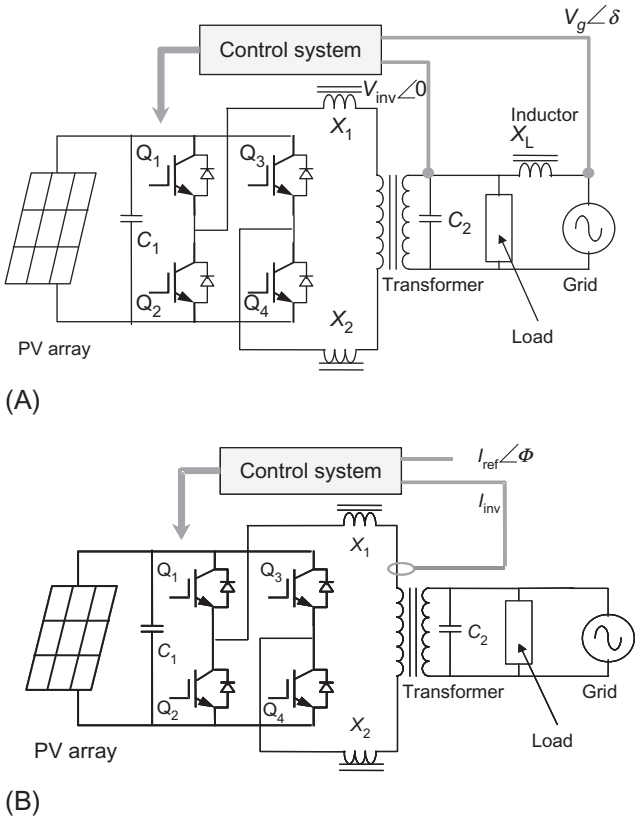

FIG. 25.28 Voltage-source inverter: (A) voltage control and (B) current control.

25.2.4.3 Inverter Types

Different types are being in use for the grid-connected PV applications such as the following:

- Line-commutated inverter
- Self-commutated inverter
- Inverter with high-frequency transformer

Line-commutated inverter

The line-commutated inverters are generally used for the electric motor applications. The power stage is equipped with thyristors. The maximum power tracking control is required in the control algorithm for solar application. The basic diagram for a single-phase line-commutated inverter is shown in Fig. 25.29 [2].

The driver circuit has to be changed to shift the firing angle from the rectifier operation ($0 < \phi < 90$) to inverter operation ($90 < \phi < 180$). Six-pulse or twelve-pulse inverters are used for the grid interfacing, but twelve-pulse inverters produce less harmonics. The thysistor-type inverters require a low-impedance grid interface connection for commutation purpose. If the maximum power available from the grid connection is less than twice the rated PV inverter power, then the line-commutated inverter should not be used [2]. The line-commutated inverters are cheaper but inhibits poor power quality. The harmonics injected into the grid can be large unless taken care of by employing adequate filters. These line-commutated inverters also have poor power factor, poor power quality, and need additional control to improve the power factor. Transformer can be used to provide the electric isolation. To suppress the harmonics generated by these inverters, tuned filters are employed, and reactive power compensation is required to improve the lagging power factor.

Self-commutated inverter

A switch-mode inverter using pulse-width modulated (PWM) switching control can be used for the grid connection of PV systems. The basic block diagram for this type of inverter is shown in Fig. 25.30. The inverter bridges may consist of bipolar transistors, MOSFET transistors, IGBTs, or gate turn-off thyristors (GTOs), depending upon the type of application. GTOs are

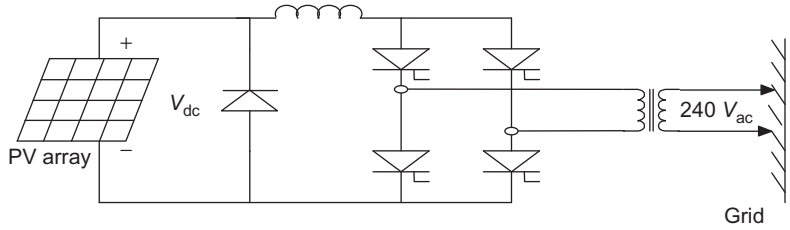

FIG. 25.29 Line-commuted single-phase inverter.

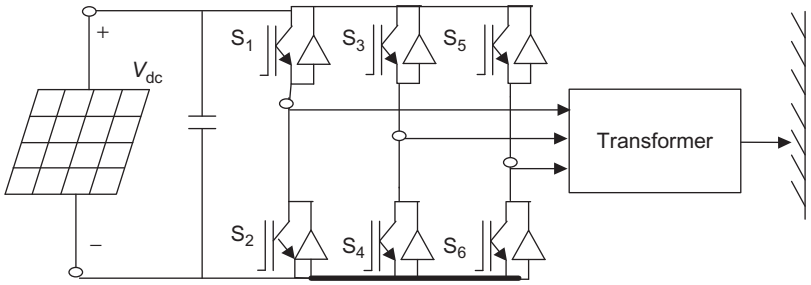

FIG. 25.30 Self-commutated inverter with PWM switching.

used for the higher-power applications, whereas IGBTs can be switched at higher frequencies, that is, 16 kHz, and are generally used for many grid-connected PV applications. Most of the present day inverters are self-commutated sine-wave inverters.

Based on the switching control, the voltage-source inverters can be further classified based on the switching control as follows:

- PWM (pulse-width modulated) inverters
- Square-wave inverters
- Single-phase inverters with voltage cancellations
- Programmed harmonic elimination switching
- Current-controlled modulation

Inverter with high-frequency transformer

The 50 Hz transformer for a standard PV inverter with PWM switching scheme can be very heavy and costly. While using frequencies more than 20 kHz, a ferrite core transformer can be a better option [2]. A circuit diagram of a grid-connected PV system using high-frequency transformer is shown in Fig. 25.31.

The capacitor on the input side of high-frequency inverter acts as the filter. The high-frequency inverter with PWM is used to produce a high-frequency AC across the primary winding of the high-frequency transformer. The secondary voltage of this transformer is rectified using high-frequency rectifier. The DC voltage is interfaced with a thyristor inverter through a low-pass inductor filter and hence connected to the grid. The line current is required to be sinusoidal and in phase with the line voltage. To achieve this, the line voltage (V_1) is measured to establish the reference waveform for the line current I_L*. This reference current I_L* multiplied by the transformer ratio gives the reference current at the output of a high-frequency inverter. The inverter output can be controlled using current control technique [36]. These inverters can be with low-frequency transformer isolation or high-frequency transformer isolation. The low-frequency (50–60 Hz) transformer of a standard

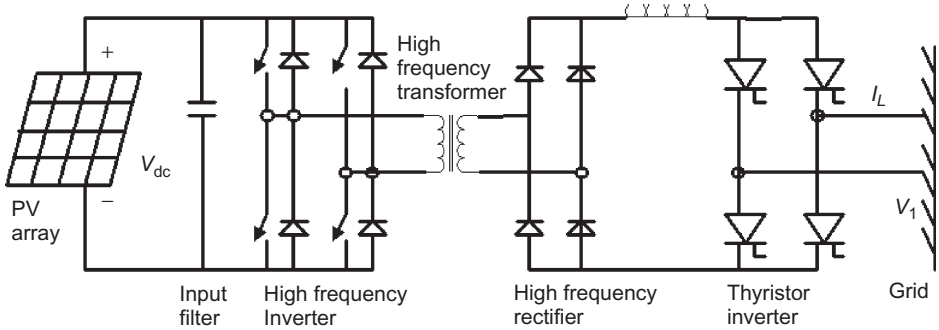

FIG. 25.31 PV inverter with high-frequency transformer.

inverter with PWM is a very heavy and bulky component. For residential grid-interactive rooftop inverters below 3 kW rating, high-frequency transformer isolation is often preferred.

Other PV inverter topologies

In this section, some of the inverter topologies discussed in various research papers have been discussed.

Multilevel converters: Multilevel converters can be used with large PV systems where multiple PV panels can be configured to create voltage steps. These multilevel voltage-source converters can synthesize the AC output terminal voltage from different level of DC voltages and can produce staircase waveforms. This scheme involves less complexity and needs less filtering. One of the schemes (half-bridge diode-clamped three-level inverter [37]) is given in Fig. 25.32. There is no transformer in this topology. Multilevel converters can be beneficial for large systems in terms of cost and efficiency. Problems associated with shading and malfunction of PV units need to be addressed.

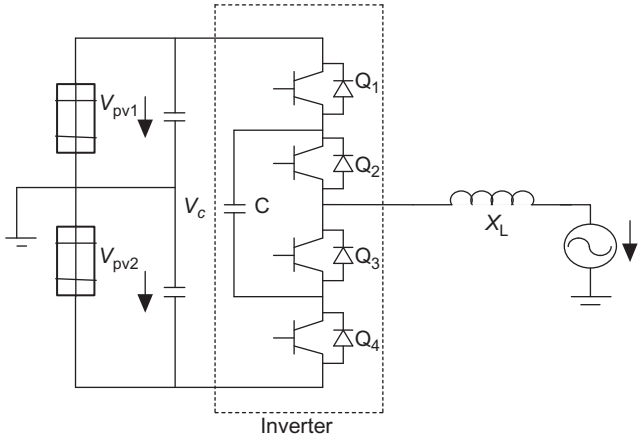

FIG. 25.32 Half-bridge diode-clamped three-level inverter.

The utilization of cascaded multilevel inverter (CMLI) in high-voltage and high-power PV energy conversion has been recently increased [38–40]. CMLI consists of a number of inverter units that are fed by isolated PV array [38]. Each unit utilizes low-voltage components, and the final output voltage is synthesized by combining all units in series. This topology has modular characteristic, since all the units are similar and have the same control strategy. This modularity feature makes it very easy to replace any faulty unit. Without discontinuing the load, it is also possible to bypass the faulty module by adopting a proper control technique [41].

Fig. 25.33 shows a five-level cascaded H-bridge inverter. Each inverter arm consists of a number of H-bridge units whose outputs are connected in series. Each unit comprises four switches (S_1–S_4) and one DC input supply ($\mathbf{V_{dc}}$). The basic H-bridge unit shown in Fig. 25.34 is able to produce three voltage levels ($-\mathbf{V_{dc}}$, 0, and $\mathbf{V_{dc}}$). The output voltage and switching logic of this H-bridge unit is shown in Table 25.2.

In Fig. 25.34, each phase arm contains two series-connected units. The output line voltages comprises five levels ($-2\,\mathbf{V_{dc}}$, $-\mathbf{V_{dc}}$, 0, $\mathbf{V_{dc}}$, and $2\,\mathbf{V_{dc}}$). If the number of units in each phase arm is "u," then the number of levels in the line voltage is ($l = 2u + 1$). All possible switching combinations for a five-level H-bridge inverter are presented in Table 25.3.

A three-phase "l"-level CHB MLI needs $6(l-1)$ switching devices. No additional diodes are needed, except the anti-parallel diodes in the switches. The current and voltage ratings of all switching devices are similar in case of symmetrical condition. In case of PV energy conversion, the input DC supplies of the H-bridge units are replaced by the PV arrays [42–45].

Non-insulated voltage source: In this scheme [46], string of low-voltage PV panels or one high-voltage unit can be coupled with the grid through DC-to-DC converter and voltage-source inverter. This topology is shown in Fig. 25.35. PWM switching scheme can be used to generate AC output. Filter has been used to reject the switching components.

Non-insulated current source: This type of configuration is shown in Fig. 25.36. Noninsulated current-source inverters [46] can be used to interface the PV panels with the grid. This topology involves low cost, which can provide better efficiency. Appropriate controller can be used to reduce current harmonics.

Buck converter with half-bridge transformer link: PV panels are connected to grid via buck converter and half bridge as shown in Fig. 25.37. In this, high-frequency PWM switching has been used at the low-voltage PV side to generate an attenuated rectified 100 Hz sine-wave current waveform

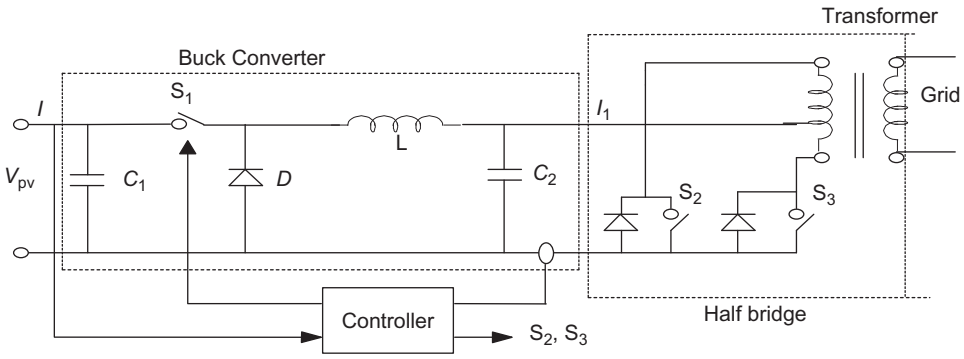

FIG. 25.37 Buck converter with half-bridge transformer link.

[47]. Half-wave bridge is utilized to convert this output to 50 Hz signal suitable for grid interconnection. To step up the voltage, the transformer has also been connected before the grid connection point.

Flyback converter: This converter topology steps up the PV voltage to DC bus voltage. Pulse-width-modulation-operated converter has been used for grid connection of PV system (Fig. 25.38). This scheme is less complex and has less number of switches. Flyback converters can be beneficial for remote areas due to less complex power-conditioning components.

Interface using paralleled PV panels: Low-voltage AC bus scheme [48] can be comparatively efficient and cheaper option. One of the schemes is shown in Fig. 25.39. A number of smaller PV units can be paralleled together and then connected to combine single low-frequency transformer. In this scheme, the PV panels are connected in parallel rather than series to avoid problems associated with shading or malfunction of one of the panels in series connection.

25.2.4.4 Power Control through PV Inverters

The system shown in Fig. 25.40 shows control of power flow onto the grid [49]. This control can be an analog or a

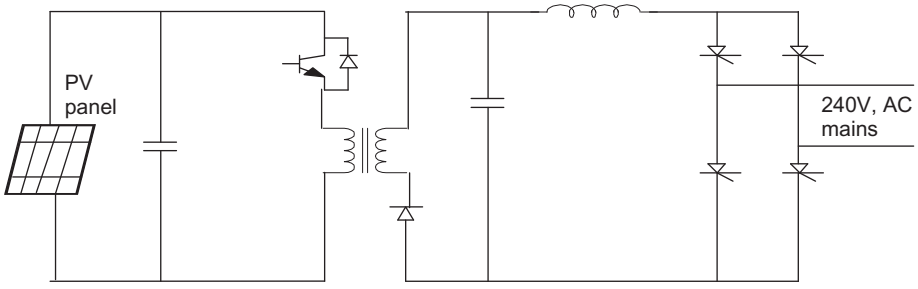

FIG. 25.38 Flyback converter.

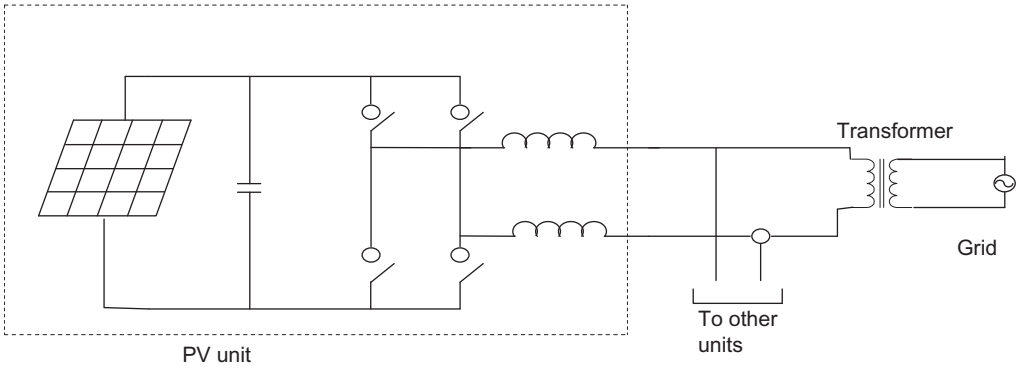

FIG. 25.39 Converter using parallel PV units.

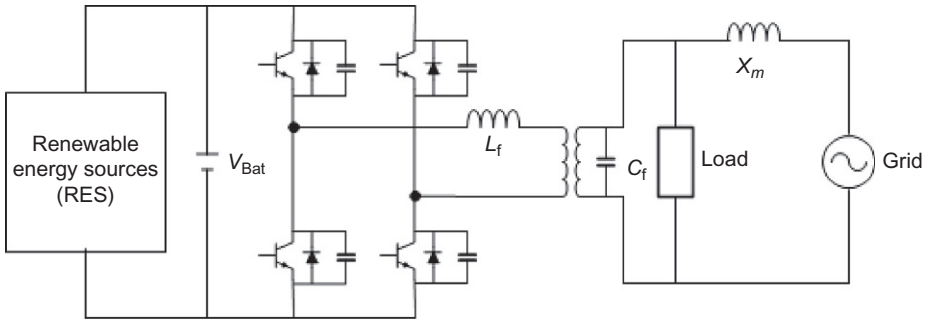

FIG. 25.40 Schematic diagram of a parallel processing DGS.

microprocessor system. This control system generates the waveforms and regulates the waveform amplitude and phase to control the power flow between the inverter and the grid. The grid-interfaced PV inverters, voltage-controlled VSI (VCVSI), and current-controlled VSI (CCVSI) have the potential of bidirectional power flow. They not only can feed the local load but also can export the excess active and reactive power to the utility grid. An appropriate controller is required in order to avoid any error in power export due to errors in synchronization, which can overload the inverter.

There are advantages and limitations associated with each control mechanism. For instance, VCVSIs provide voltage support to the load (here, the VSI operates as a voltage source), while CCVSIs provide current support (here, the VSI operates as a current source). The CCVSI is fast in response compared with the VCVSI, as its power flow is controlled by the switching instant, whereas in the VCVSI the power flow is controlled by adjusting the voltage across the decoupling inductor. Active and reactive powers are controlled independently in the CCVSI but are coupled in the VCVSI. Generally, the advantages of one type of VSI are considered as a limitation of the other type [50].

Fig. 25.41 shows the simplified/equivalent schematic diagram of a VCVSI. For the following analysis, it is assumed that the output low-pass filters (L_f and C_f) of VSIs will filter out high-order harmonics generated by PWMs. The decoupling inductor (X_m) is an essential part of any VCVSI as it makes the power flow control possible. In a VCVSI, the power flow of the distributed generation system (DGS) is controlled by adjusting the amplitude and phase (power angle (δ)) of the inverter output voltage with respect to the grid voltage. Hence, it is important to consider the proper sizing of the decoupling inductor and the maximum power angle to provide the required power flow when designing VCVSIs. The phasor diagram of a simple grid-inverter interface with a first-order filter is shown in Fig. 25.42.

Referring to Fig. 25.41, the fundamental grid current (I_g) can be expressed by Eq. (25.7):

$$I_g = \frac{V_g < 0 - V_c < \delta}{jX_m} = -\frac{V_c \sin\delta}{X_m} - j\frac{V_g - V_c \cos\delta}{X_m} \tag{25.7}$$

where V_g and V_c are, respectively, the grid and the VCVSI's fundamental voltages and X_m is the decoupling inductor impedance. Using per-unit values ($S_{base} = V_{base}^2/Z_{base}$, $V_{base} = V_c$, and $Z_{base} = X_m$) where V_{base}, Z_{base}, and S_{base} are the base voltage, impedance, and complex power values, respectively, the grid apparent power can be expressed as Eq. (25.8):

$$S_{gpu} = -V_{gpu} \sin\delta + j\left(V_{gpu}^2 - V_{gpu} \cos\delta\right) \tag{25.8}$$

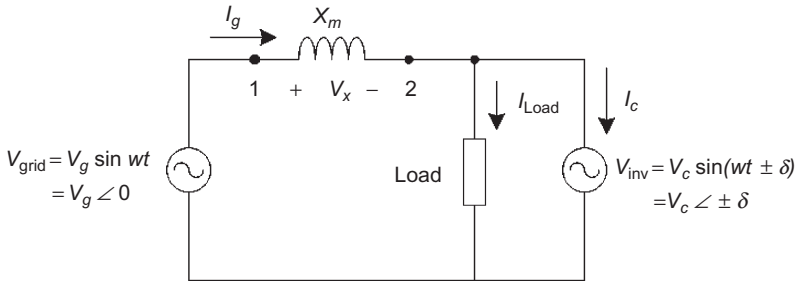

FIG. 25.41 The equivalent circuit diagram of a VCVSI.

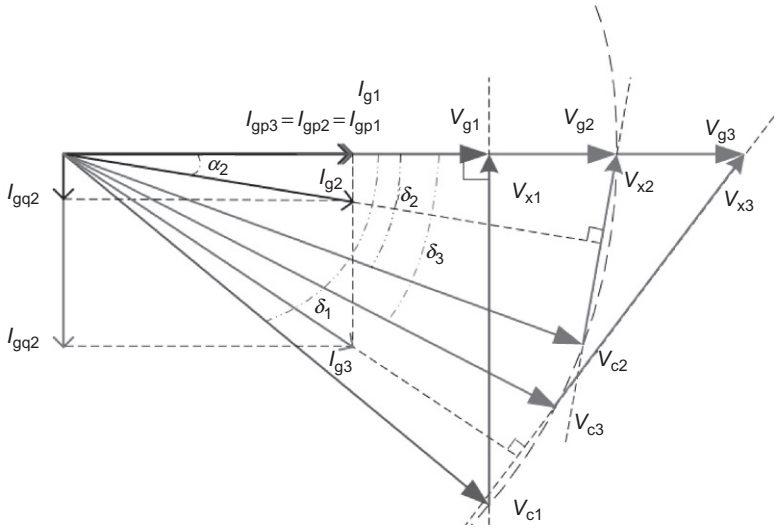

FIG. 25.42 Phasor diagram of a VCVSI with resistive load and assuming the grid is responsible for supplying the active power [50].

Using per-unit values, the complex power of the VCVSI and decoupling inductor are

$$S_{cpu} = -V_{gpu}\sin\delta + j\left(V_{gpu}\cos\delta - 1\right) \tag{25.9}$$

$$S_{xpu} = j\left(V_{gpu}^2 - 2V_{gpu}\cos\delta + 1\right) \tag{25.10}$$

where S_{gpu}, S_{cpu}, and S_{xpu} are per-unit values of the grid, VCVSI, and decoupling inductor apparent power, respectively, and V_{gpu} is the per-unit value of the grid voltage.

Fig. 25.43 shows the equivalent schematic diagram of a CCVSI. As a CCVSI controls the current flow using the VSI switching instants, it can be modeled as a current source, and there is no need for a decoupling inductor (Fig. 25.43). As the current generated from the CCVSI can be controlled independently from the AC voltage, the active and reactive power controls are decoupled. Hence, unity power factor operation is possible for the whole range of the load. This is one of the main advantages of CCVSIs.

As the CCVSI is connected in parallel to the DGS, it follows the grid voltage. Fig. 25.44 shows the phasor diagram of a CCVSI-based DGS in the presence of an inductive load (considering the same assumption as VCVSI section). Fig. 25.44 shows that when the grid voltage increases, the load's active power consumption, which is supplied by the grid, increases and the CCVSI compensates the increase in the load reactive power demand. In this case, the CCVSI maintains grid supply

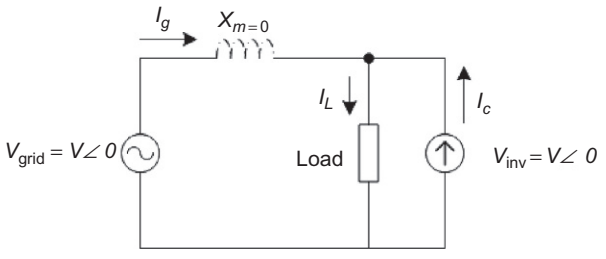

FIG. 25.43 The equivalent circuit of a CCVSI.

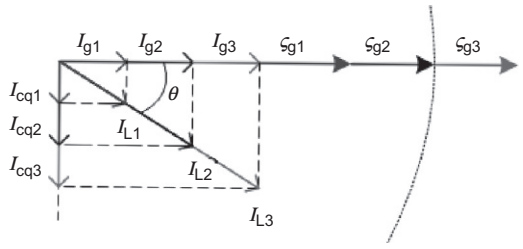

FIG. 25.44 Phasor diagram of a CCVSI with inductive load and assuming grid is responsible for supplying the active power [50].

at unity power factor, keeping the current phase delay with respect to the grid voltage at a fixed value (θ). Therefore, the CCVSI cannot maintain the load voltage in the presence of a DGS without utilizing extra hardware and control mechanisms. This limitation on load voltage stabilization is one of the main drawbacks of CCVSI-based DGS.

Assuming the load active current demand is supplied by the grid (reactive power support function), the required grid current can be rewritten as follows:

$$I_g^* = \mathrm{Re}[I_L] = \mathrm{Re}\left[\frac{S_L}{V_g}\right] \tag{25.11}$$

where S_L is the demanded load apparent power. For grid power conditioning, it is preferred that the load operate at unity power factor. Therefore, the CCVSI must provide the remainder of the required current in Eq. (25.12):

$$I_c = I_L - I_g^* \tag{25.12}$$

For demand side management (DSM), it is desirable to supply the active power by the RES, where excess energy from the RES is injected into the DGS. The remaining load reactive power will be supplied by the CCVSI. Hence, Eq. (25.12) can be rewritten as Eq. (25.13):

$$I_g^* = \mathrm{Re}[I_L] - \mathrm{Re}[I_c] = \mathrm{Re}\left[\frac{S_L - P_{RES}}{V_g}\right] \tag{25.13}$$

When using a voltage controller for grid-connected PV inverter, it has been observed that a slight error in the phase of synchronizing waveform can grossly overload the inverter whereas a current controller is much less susceptible to voltage phase shifts [49]. Due to this reason, the current controllers are better suited for the control of power export from the PV inverters to the utility grid since they are less sensitive to errors in synchronizing sinusoidal voltage waveforms.

A prototype current-controlled-type power-conditioning system has been developed by the first author and tested on a weak rural feeder line at Kalbarri in Western Australia [51]. The choice may be between additional conventional generating capacities at a centralized location and adding smaller distributed generating capacities using RES like PV. The latter option can have a number of advantages like as follows:

- The additional capacity is added wherever it is required without adding additional power distribution infrastructure. This is a critical consideration where the power lines and transformers are already at or close to their maximum ratings.
- The power-conditioning system can be designed to provide much more than just a source of real power, for minimal extra cost. A converter providing real power needs only a slight increase in ratings to handle significant amounts of reactive or even harmonic power. The same converter that converts DC PV power to AC power can simultaneously provide the reactive power support to the week utility grid.

The block diagram of the power-conditioning system used in the Kalbarri project has been shown in Fig. 25.45. This CCVSI operates with a relatively narrow switching frequency band near 10 kHz. The control diagram indicates the basic operation of the power-conditioning system. The two outer control loops operate to independently control the real and reactive power flow from the PV inverter. The real power is controlled by an outer MPPT algorithm with an inner DC link voltage control loop providing the real current magnitude request I_P*, and hence, the real power export through PV converter is controlled through the DC link voltage regulation. The DC link voltage is maintained at a reference value by a PI control loop, which gives the real current reference magnitude as its output. At regular intervals, the DC link voltage is scanned over the entire voltage range to check that the algorithm is operating on the absolute MPP and is not stuck around a local MPP. During the night, the converter can still be used to regulate reactive power of the grid-connected system although it cannot provide active power. During this time, the PI controller maintains a minimum DC link voltage to allow the power-conditioning system to continue to operate, providing the necessary reactive power.

The AC line voltage regulation is provided by a separate reactive power control, which provides the reactive current magnitude reference I_Q*. The control system has a simple transfer function, which varies the reactive power command in response to the AC voltage fluctuations. Common to the

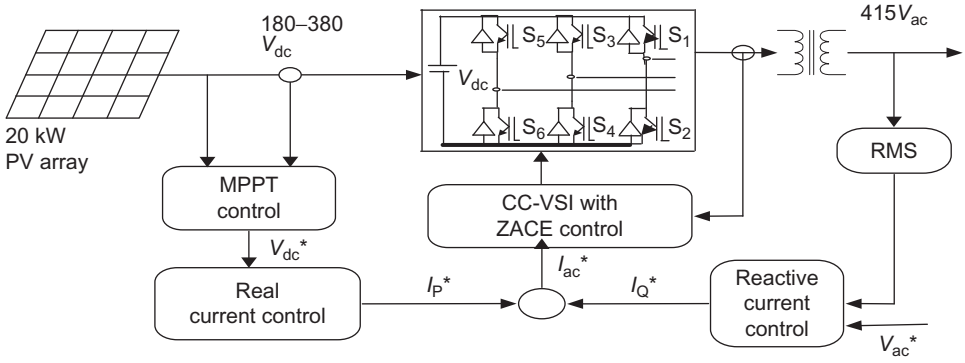

FIG. 25.45 Block diagram of Kalbarri power-conditioning system.

outer real and reactive power control loops is an inner higher bandwidth zero average current error (ZACE) current control loop. I_p* is in phase with the line voltages, and I_Q* is at 90° to the line voltage. These are added together to give one (per phase) sinusoidal converter current reference waveform (I_{ac}*). The CCVSI control consists of analog and digital circuitry that acts as a ZACE transconductance amplifier in converting I_{ac}* into AC power currents [52].

25.2.4.5 System Configurations

The utility compatible inverters are used for power conditioning and synchronization of PV output with the utility power. In general, four types of batteryless grid-connected PV system configurations have been identified:

- Central plant inverter
- Multiple string DC/DC converter with single-output inverter
- Multiple string inverter
- Module-integrated inverter

Central plant inverter

In the central plant inverter, usually a large inverter is used to convert DC power output of PV arrays to AC power. In this system, the PV modules are serially stringed to form a panel (or string), and several such panels are connected in parallel to a single DC bus. The block diagram of such a scheme is shown in Fig. 25.46.

Multiple string DC/DC converter

In multiple string DC/DC converter, as shown in Fig. 25.47, each string will have a boost DC/DC converter with transformer isolation. There will be a common DC link, which feeds a transformerless inverter.

Multiple string inverters

Fig. 25.48 shows the block diagram of multiple string inverter system. In this scheme, several modules are connected in series on the DC side to form a string. The output from each string is converted to AC through a smaller individual inverter. Many such inverters are connected in parallel on the AC side. This arrangement is not badly affected by the shading of the panels. It is also not seriously affected by inverter failure.

Module integrated inverter

In the module-integrated inverter system (Fig. 25.49), each module (typically 50–300 W) will have a small inverter. No cabling is required. It is expected that high volume of small inverters will bring down the cost.

25.2.4.6 Grid-Compatible Inverters Characteristics

The characteristics of the grid-compatible inverters are as follows:

- Response time
- Power factor
- Frequency control
- Harmonic output
- Synchronization
- Fault current contribution
- DC current injection
- Protection

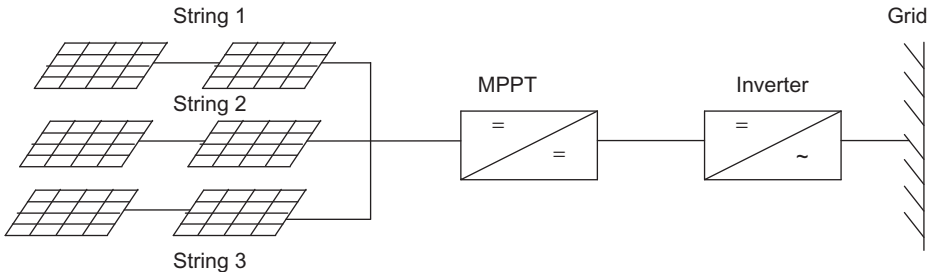

FIG. 25.46 Central plant inverter.

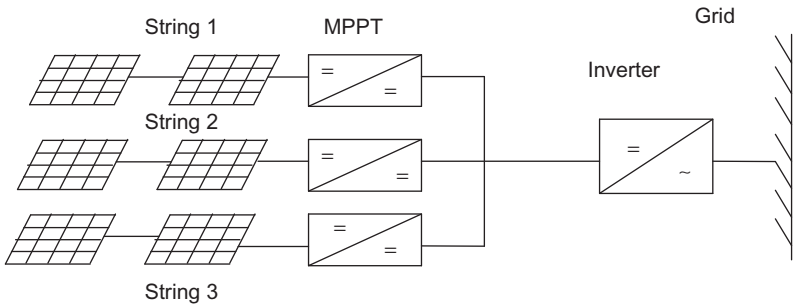

FIG. 25.47 Multiple string DC/DC converter.

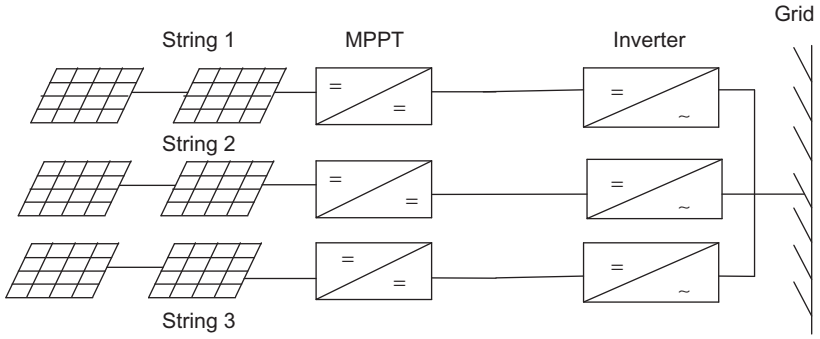

FIG. 25.48 Multiple string inverter.

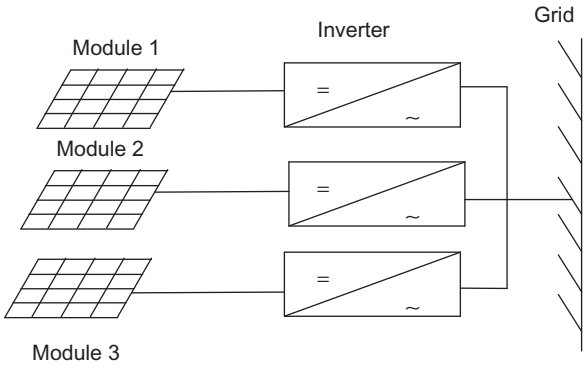

FIG. 25.49 Module-integrated inverter.

The response time of the inverters shall be extremely fast and governed by the bandwidth of the control system. The absence of rotating mass and use of semiconductor switches allow inverters to respond in millisecond time frame. The power factor of the inverters is traditionally poor due to displacement power factor and the harmonics. But with the latest development in the inverter technology, it is possible to maintain the power factor close to unity. The converters/inverters have the capability of creating large voltage fluctuation by drawing reactive power from the utility rather than supplying [53]. With proper control, inverters can provide voltage support by importing/exporting reactive power to push/pull toward a desired set point. This function would be of more use to the utilities as it can assist in the regulation of the grid system at the domestic consumer level.

Frequency of the inverter output waveshape is locked to the grid. Frequency bias is where the inverter frequency is deliberately made to run at 53 Hz. When the grid is present, this will be pulled down to the nominal 50 Hz. If the grid fails, it will drift upward toward 53 Hz and trip on overfrequency. This can help in preventing islanding.

Harmonics output from the inverters have been very poor traditionally. Old thyristor-based inverters are operated with slow switching speeds and could not be pulse-width modulated. This resulted in inverters known as 6-pulse or 12-pulse inverters. The harmonics so produced from the inverters can be injected into the grid, resulting in losses, heating of appliances, tripping of protection equipments, and poor power quality. The number of pulses is being the number of steps in a sine-wave cycle. With the present advent in the power electronics technology, the inverter controls can be made very well. Pulse-width-modulated inverters produce high-quality sine waves. The harmonic levels are very low and can be lower than the common domestic appliances. If the harmonics are present in the grid voltage waveform, harmonic currents can be induced in the inverter. These harmonic currents, particularly those generated by a voltage-controlled inverter, will in fact help in supporting the grid. These are good harmonic currents. This is the reason that the harmonic current output of inverters must be measured onto a clean grid source so that the only harmonics being produced by the inverters are measured.

Synchronization of inverter with the grid is performed automatically and typically uses zero-crossing detection on the voltage waveform. An inverter has no rotating mass and hence has no inertia. Synchronization does not involve the acceleration of a rotating machine. Consequently, the reference waveforms in the inverter can be jumped to any point required within a sampling period. If phase-locked loops are used, it could take up a few seconds. Phase-locked loops are used to increase the immunity to noise. This allows the synchronization to be based on several cycles of zero-crossing information. The response time for this type of locking will be slower.

Photovoltaic panels produce a current that is proportional to the amount of light falling on them. The panels are normally rated to produce 1000 W/m^2 at 25°C. Under these conditions, the short-circuit current possible from these panels is typically only 20% higher than the nominal current, whereas it is extremely variable for wind. If the solar radiation is low, then the maximum current possible under short circuit is going to be less than the nominal full-load current. Consequently, PV systems cannot provide the short-circuit capacity to the grid. If a battery is present, the fault current contribution is limited by the inverter. With the battery storage, it is possible for the battery to provide the energy. However, inverters are typically limited between 100% and 200% of nominal rating under current limit conditions. The inverter needs to protect itself against the short circuits because the power electronic components will

typically be destroyed before a protection device like circuit breaker trips.

In case of inverter malfunction, inverters have the capability to inject the DC components into the grid. Most utilities have guidelines for this purpose. A transformer shall be installed at the point of connection on the AC side to prevent DC from entering into the utility network. The transformer can be omitted when a DC detection device is installed at the point of connection on the AC side in the inverter. The DC injection is essentially caused by the reference or power electronic device producing a positive half cycle that is different from the negative half cycle resulting in the DC component in the output. If the DC component can be measured, it can then be added into the feedback path to eliminate the DC quantity.

Protection requirements

A minimum requirement to facilitate the prevention of islanding is that the inverter energy system protection operates and isolates the inverter energy system from the grid if

- Overvoltage,
- Undervoltage,
- Overfrequency,
- Underfrequency exist.

These limits may be either factory set or site programmable. The protection voltage operating points may be set in a narrower band if required, for example, 220–260 V. In addition to the passive protection detailed above and to prevent the situation where islanding may occur because multiple inverters provide a frequency reference for one another, inverters must have an accepted active method of islanding prevention following grid failure, for example, frequency drift and impedance measurement. Inverter controls for islanding can be designed on the basis of detection of grid voltage, measurement of impedance, frequency variation, or increase in harmonics. This function must operate to force the inverter output outside the protection tolerances specified previously, thereby resulting in isolation of the inverter energy system from the grid. The maximum combined operation time of both passive and active protections should be 2 s after grid failure under all local load conditions. If frequency shift is used, it is recommended that the direction of shift be down. The inverter energy system must remain disconnected from the grid until the reconnection conditions are met. Some inverters produce high-voltage spikes, especially at light load, which can be dangerous for the electronic equipment. IEEE P929 gives some idea about the permitted voltage limits.

If the inverter energy system does not have the above frequency features, the inverter must incorporate an alternate anti-islanding protection feature that is acceptable to the relevant electricity distributor. If the protection function above is to be incorporated in the inverter, it must be type tested for compliance with these requirements and accepted by the relevant electricity distributor. Otherwise, other forms of external protection relaying are required that have been type tested for compliance with these requirements and approved by the relevant electricity distributor. The inverter shall have adequate protection against short circuit, other faults, and overheating of inverter components.

25.3 Power Electronics for Wind Power Systems

In the rural United States, the first windmill was commissioned in 1890 to generate electricity. Today, large wind generators are competing with utilities in supplying clean power economically. The average wind turbine size has been 300–600 kW until recently. The new wind generators of 1–3 MW have been developed and are being installed worldwide, and prototype of even higher capacity is under development. Improved wind turbine designs and plant utilization have resulted in significant reduction in wind energy generation cost from 35 cents/kWh in 1980 to less than 5 cents/kWh in 1999, in locations where wind regime is favorable. At this generation cost, wind energy has become one of the least cost power sources. Main factors that have contributed to the wind power technology development are as follows:

- High-strength fiber composites for manufacturing large low-cost blades
- Variable-speed operation of wind generators to capture maximum energy
- Advancement in power electronics and associated cost
- Improved plant operation and efficiency
- Economy of scale due to the availability of large wind generation plants
- Accumulated field experience improving the capacity factor
- Computer prototyping by accurate system modeling and simulation

Table 25.4 is for wind sites with average annual wind speed of 7 m/s at 30 m hub height. Since the 1980s, wind technology capital costs have reduced by 80% worldwide. Operation and maintenance costs have declined by 80%, and the availability factor of grid-connected wind plants has increased to 95%. At present, the capital cost of wind generator plants has dropped to about $600/kW, and the electricity generation cost has reduced to 6 cents/kWh. It is expected to reduce the

TABLE 25.4 Wind power technology developments

	1980	1999	Future
Cost per kilowatt-hour	$0.35–0.40	$0.05–0.07	<$0.04
Capital cost per kilowatt	$2000–3000	$500–700	<$400
Operating life	5–7 years	20 years	30 years
Capacity factor (average)	15%	25%–30%	>30%
Availability	50%–65%	95%	>95%
Wind turbine unit size range	50–150 kW	300–1000 kW	500–2000 kW

generation cost below 4 cents/kWh. Keeping this in view, the wind generation is going to be highly competitive with the conventional power plants. In Europe, the United States, and Asia, the wind power generation is increasing rapidly, and this trend is going to continue due to economic viability of wind power generation.

The technical advancement in power electronics is playing an important part in the development of wind power technology. The contribution of power electronics in control of fixed-speed/variable-speed wind turbines and interfacing to the grid is of extreme importance. Because of the fluctuating nature of wind speed, the power quality and reliability of the wind-based power system needs to be evaluated in detail. Appropriate control schemes require power conditioning.

25.3.1 Basics of Wind Power

The ability of a wind turbine to extract power from wind is a function of three main factors:

- Wind power availability
- Power curve of the machine
- Ability of the machine to respond to wind perturbations

The mechanical power produced by a wind turbine is given by

$$P_m = 0.5\rho C_p A U^3 \text{ W} \tag{25.14}$$

The power from the wind is a cubic function of wind speed. The curve for power coefficient C_p and λ is required to infer the value of C_p for λ based on wind speed at that time.

Where tip-speed ratio, $\lambda = \frac{r\omega_A}{U}$, ρ = air density, Kg m^{-3}, C_p = power coefficient, A = wind turbine rotor swept area, m^2, and U = wind speed in meters per second.

The case of a variable-speed wind turbine with a pitch mechanism that alters the effective rotor dynamic efficiency can be easily considered if an appropriate expression for C_p as a function of the pitch angle is applied. The power curve of a typical wind turbine is given in Fig. 25.50 as a function of wind speed.

The C_p–λ curve for 150 kW windmaster machine is given in Fig. 25.51, which has been inferred from the power curve of the machine. The ratio of shaft power to the available power in the wind is the efficiency of conversion, known as the power coefficient C_p:

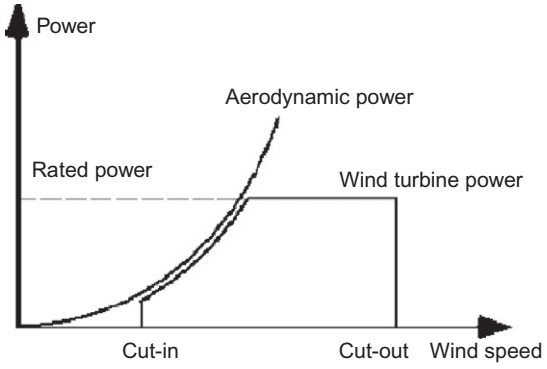

FIG. 25.50 Power curve of wind turbine as a function of wind speed [54].

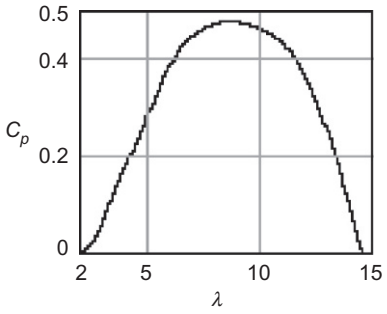

FIG. 25.51 Cp–λ curve of wind machine [54].

$$C_p = \frac{P_m}{(1/2\rho A U^3)} \tag{25.15}$$

The power coefficient is a function of turbine blade tip-speed to wind-speed ratio (β). A tip-speed ratio of 1 means the blade tips are moving at the same speed as the wind, and when β is 2, the tips are moving at twice the speed of the wind and so on [55]. Solidity (σ) is defined as the ratio of the sum of the width of all the blades to the circumference of the rotor. Hence,

$$\sigma = Nd/(2\pi R) \tag{25.16}$$

where N = number of blades and d = width of the blades.

The power from a wind turbine doubles as the area swept by the blades doubles. But doubling of the wind speed increases the power output eight times. Fig. 25.52 gives a family of power curves for a wind turbine. If the loading of the turbine is controlled such that the operating point is along the maximum power locus at different wind speeds, then the wind energy system will be more efficient.

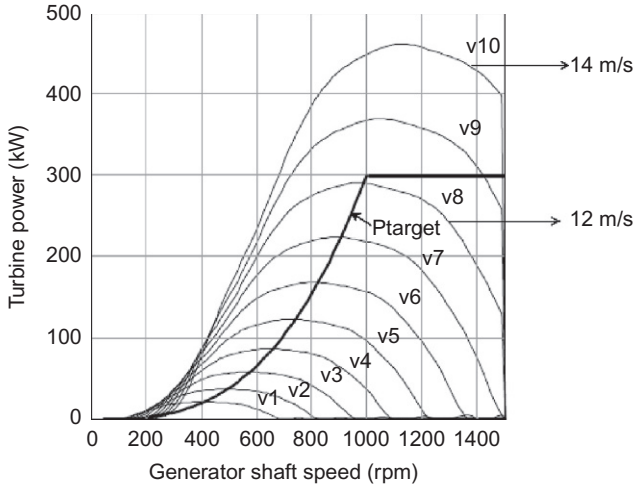

FIG. 25.52 Turbine power vs shaft speed curves.

25.3.1.1 Types of Wind Turbines

There are two types of wind turbines available Fig. 25.53:

- Horizontal-axis wind turbines (HAWTs)
- Vertical-axis wind turbines (VAWTs)

Vertical-axis wind turbines (VAWTs) have an axis of rotation that is vertical, and so, unlike the horizontal wind turbines, they can capture winds from any direction without the need to reposition the rotor when the wind direction changes (without a special yaw mechanism). Vertical-axis wind turbines were also used in some applications as they have the advantage that they do not depend on the direction of the wind. It is possible to extract power relatively easier. But there are some disadvantages such as no self-starting system, smaller power coefficient than obtained in the horizontal-axis wind turbines, strong discontinuation of rotations due to periodic changes in the lift force, and the regulation of power that is not yet satisfactory.

The horizontal-axis wind turbines are generally used. Horizontal-axis wind turbines are, by far, the most common design. There are a large number of designs commercially available ranging from 50 W to 4.5 MW. The number of blades ranges from one to many in the familiar agriculture windmill. The best compromise for electricity generation, where high rotational speed allows the use of a smaller and cheaper electric generator, is two or three blades. The mechanical and aerodynamic balance is better for three-bladed rotor. In small wind turbines, three blades are common. Multiblade wind turbines are used for water pumping on farms.

Based on the pitch control mechanisms, the wind turbines can also be classified as follows:

- Fixed-pitch wind turbines
- Variable-pitch wind turbines

Different manufacturers offer fixed-pitch and variable-pitch blades. Variable pitch is desirable on large machines because the aerodynamic loads on the blades can be reduced and when used in fixed-speed operation they can extract more energy. But necessary mechanisms require maintenance, and for small machines, installed in remote areas, fixed pitch seems more desirable and economical. In some machines, power output regulation involves yawing blades so that they no longer point into the wind. One such system designed in Western Australia has a tail that progressively tilts the blades in a vertical plane so that they present a small surface to the wind at high speeds.

The active power of a wind turbine can be regulated either by designing the blades to go into an aerodynamic stall beyond the designated wind speed or by feathering the blades out of the wind, which results in reducing excess power using a mechanical and electric mechanism. Recently, an active stall has been used to improve the stability of wind farms. This stall mechanism can prevent power deviation from gusty winds to pass through the drivetrain [56].

Horizontal-axis wind turbines can be further classified into fixed speed (FS) or variable speed (VS). The FS wind turbine (FSWT) generator is designed to operate at maximum efficiency while operating at a rated wind speed. In this case, the optimum tip-speed ratio is obtained for the rotor airfoil

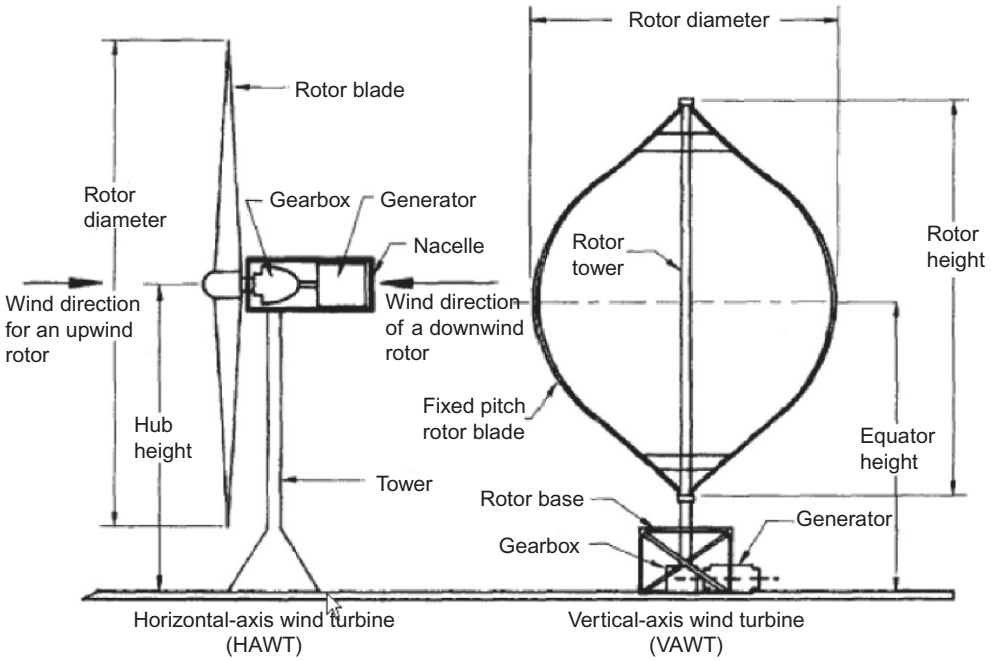

FIG. 25.53 Typical diagram of HAWTs and VAWTs.

at a rated wind speed. For a VS wind turbine (VSWT) generator, it is possible to obtain optimum wind speed at different wind speeds. Hence, this enables the VS wind turbine to increase its energy capture. The general advantages of a VSWT are summarized as follows:

- VSWTs are more efficient than the FSWTs.
- At low wind speeds, the wind turbines can still capture the maximum available power at the rotor, hence increasing the possibility of providing the rated power for wide speed range.

25.3.1.2 Types of Wind Generators

Schemes based on permanent magnet synchronous generators (PMSG) and induction generators are receiving close attention in wind power applications because of their qualities such as ruggedness, low cost, manufacturing simplicity, and low-maintenance requirements. Despite many positive features over the conventional synchronous generators, the PMSG was not being used widely [22]. However, with the recent advent in power electronics, it is now possible to control the variable voltage, variable frequency output of PMSG. The permanent magnet machine is generally favored for developing new designs, because of higher efficiency and the possibility of a rather smaller diameter. These PMSG machines are now being used with variable-speed wind machines.

In large power system networks, synchronous generators are generally used with fixed-speed wind turbines. The synchronous generators can supply both the active and reactive power, and their reactive power flow can be controlled. The synchronous generators can operate at any power factor. For the induction generator, driven by a wind turbine, it is a well-known fact that it can deliver only active power while consuming reactive power.

Synchronous generators with high power rating are significantly more expensive than induction generators of similar size. Moreover, direct-connected synchronous generators have the limitation of rotational speed being fixed by the grid frequency. Hence, fluctuation in the rotor speed due to wind gusts leads to higher torque in high power output fluctuations and the derived train. Therefore, in grid-connected application, synchronous generators are interfaced via power converters to the grid. This also allows the synchronous generators to operate wind turbines in VS, which makes gearless operation of the VSWT possible.

The squirrel-cage induction generators are widely used with the fixed-speed wind turbines. In some applications, wound rotor induction generators have also been used with adequate control scheme for regulating speed by external rotor resistance. This allows the shape of the torque-slip curve to be controlled to improve the dynamics of the drivetrain. In case of PMSG, the converter/inverter can be used to control the variable voltage, variable frequency signal of the wind generator at varying wind speed. The converter converts this varying signal to the DC signal, and the output of converter is converted to AC signal of desired amplitude and frequency.

The induction generators are not locked to the frequency of the network. The cyclic torque fluctuations at the wind turbine can be absorbed by very small change in the slip speed. In case of the capacitor-excited induction generators, they obtain the magnetizing current from capacitors connected across its output terminals [55,57,58].

To take advantage of VSWTs, it is necessary to decouple the rotor speed and the grid frequency. There are different approaches to operate the VSWT within a certain operational range (cut-in and cut-out wind speed). One of the approaches is dynamic slip control, where the slip is allowed to vary up to 10% [59]. In these cases, doubly-fed induction generators (DFIG) are used (Fig. 25.54). One limitation is that DFIG require reactive power to operate. As it is not desired that the grid supply this reactive power, these generators are usually equipped with capacitors. A gearbox forms an essential component of the wind turbine generator (WTG) using induction generators. This results in the following limitations:

- Frequent maintenance
- Additional cost
- Additional losses

With the emergence of large wind power generation, increased attention is being directed toward wound rotor induction generators (WRIG) controlled from the rotor side for variable-speed constant-frequency (VSCF) applications. A wound rotor induction generator has a rotor containing a three-phase winding. These windings are made accessible to the outside via slip rings. The main advantages of a wound rotor induction generator for VSCF applications are as follows:

- Easier generator torque control using rotor current control.
- Smaller generator capacity as the generated power can be accessed from the stator and from the rotor. Usually, the rotor power is proportional to the slip speed (shaft speed-synchronous speed). Consequently, smaller rotor power converters are required. The frequency converter in the rotor (inverter) directly controls the current in the rotor winding, which enables the control of the whole generator output. The power electronic converters generally used are rated at 20%–30% of the nominal generator power.
- Fewer harmonics exist because control is in the rotor while the stator is directly connected to the grid.

If the rotor is short-circuited (making it the equivalent of a cage rotor induction machine), the speed is primarily determined by the supply frequency, and the nominal slip is within 5%. The mechanical power input ($P_{TURBINE}$) is converted into stator electric power output (P_{STATOR}) and is fed to the AC supply. The rotor power loss, being proportional to the slip speed, is commonly referred to as the slip power (P_{ROTOR}).

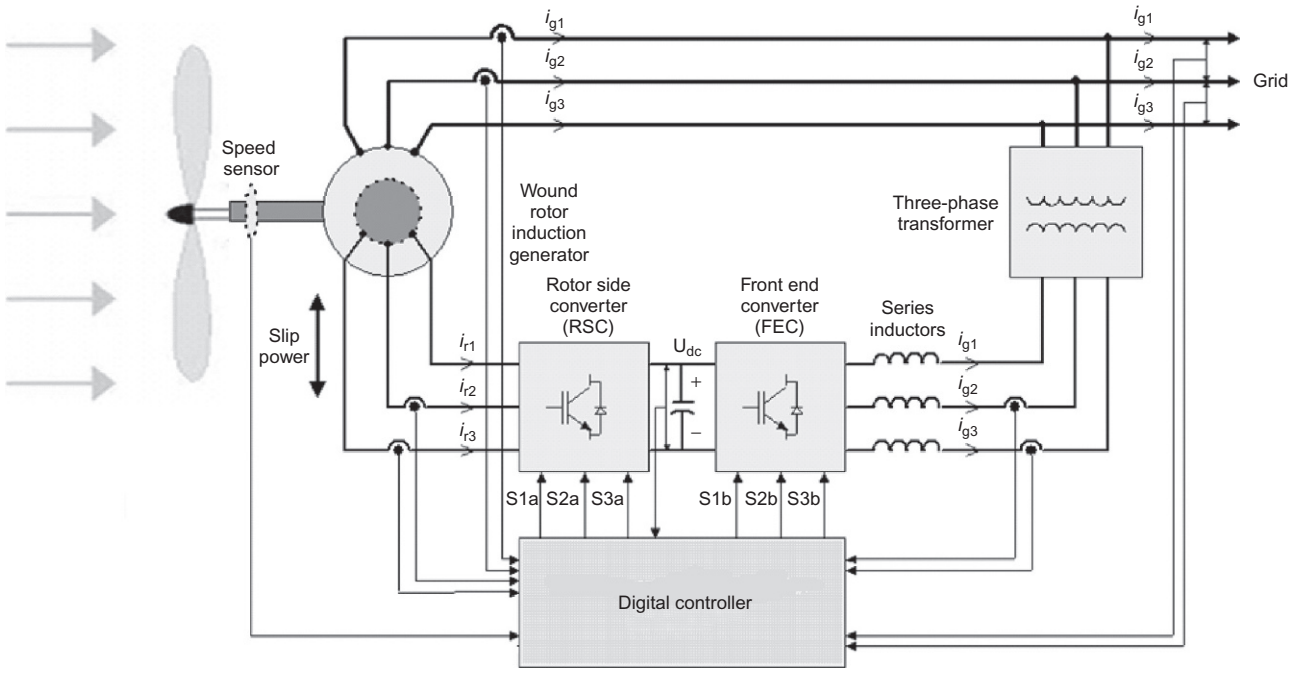

FIG. 25.54 Variable-speed doubly-fed induction generator (VSDFIG) system.

The possibility of accessing the rotor in a doubly fed induction generator makes a number of configurations possible. These include slip power recovery using a cycloconverter, which converts the ac voltage of one frequency to another without an intermediate DC link [60–62], or back-to-back inverter configurations [63,64].

Using voltage-source inverters (VSIs) in the rotor circuit, the rotor currents can be controlled at the desired phase, frequency, and magnitude. This enables reversible flow of active power in the rotor, and the system can operate in subsynchronous and supersynchronous speeds, both in motoring and generating modes. The DC link capacitor acts as a source of reactive power, and it is possible to supply the magnetizing current, partially or fully, from the rotor side. Therefore, the stator-side power factor can also be controlled. Using vector control techniques, the active and reactive powers can be controlled independently, and hence, fast dynamic performance can also be achieved.

The converter used at the grid interface is termed as the line-side converter or the front-end converter (FEC). Unlike the rotor-side converter, this operates at the grid frequency. Flow of active and reactive powers is controlled by adjusting the phase and amplitude of the inverter terminal voltage with respect to the grid voltage. Active power can flow either to the grid or to the rotor circuit depending on the mode of operation. By controlling the flow of active power, the DC bus voltage is regulated within a small band. Control of reactive power enables unity power factor operation at the grid interface. In fact, the FEC can be operated at a leading power factor, if it is so desired. It should be noted that, since the slip range is limited, the DC bus voltage is less in this case when compared with the stator side control. A transformer is therefore necessary to match the voltage levels between the grid and the DC side of the FEC. With a PWM converter in the rotor circuit, the rotor currents can be controlled at the desired phase, frequency, and magnitude. This enables reversible flow of active power in the rotor, and the system can operate in subsynchronous and supersynchronous speeds, both in motoring and generating modes (Fig. 25.55).

25.3.2 Types of Wind Power Systems

Wind power systems can be classified as follows:

- Stand-alone
- Hybrid
- Grid-connected

25.3.3 Stand-alone Wind Power Systems

Stand-alone wind power systems are being used for the following purposes in remote-area power systems:

- Battery charging
- Household power supply

25.3.3.1 Battery Charging with Stand-alone Wind Energy System

The basic elements of a stand-alone wind energy conversion system are as follows:

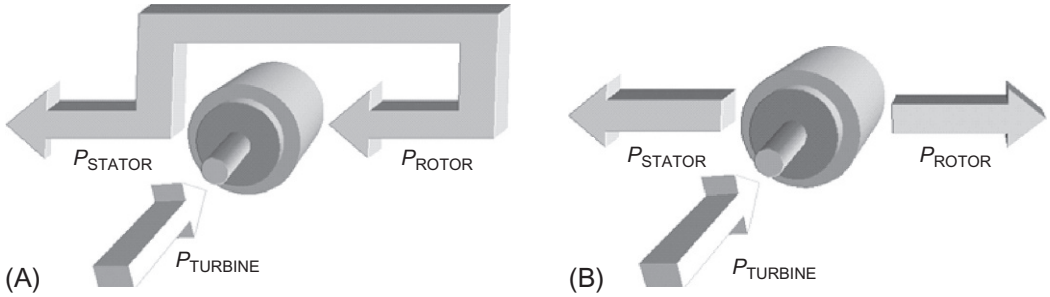

FIG. 25.55 Doubly fed induction generator power flow in generating mode: (A) subsynchronous and (B) supersynchronous.

- Wind generator
- Tower
- Charge control system
- Battery storage
- Distribution network

In remote-area power supply, an inverter and a diesel generator are more reliable and sophisticated systems. Most small isolated wind energy systems use batteries as a storage device to level out the mismatch between the availability of the wind and the load requirement. Batteries are a major cost component in an isolated power system.

25.3.3.2 Wind Turbine Charge Controller

The basic block diagram of a stand-alone wind generator and battery charging system is shown in Fig. 25.56.

The function of charge controller is to feed the power from the wind generator to the battery bank in a controlled manner. In the commonly used permanent magnet generators, this is usually done by using the controlled rectifiers [65]. The controller should be designed to limit the maximum current into the battery, reduce charging current for high battery SOC, and maintain a trickle charge during full SOC periods.

25.3.4 Wind-Diesel Hybrid Systems

The details of hybrid systems are already covered in Section 25.2.4. Diesel systems without batteries in remote areas are characterized by poor efficiency, high maintenance, and fuel costs. The diesel generators must be operated above a certain minimum load level to reduce cylinder wear and tear due to incomplete combustion. It is a common practice to install dump loads to dissipate extra energy. More efficient systems can be devised by combining the diesel generator with a battery-inverter subsystem and incorporating RES, such as wind/solar where appropriate. An integrated hybrid energy system incorporating a diesel generator, wind generator, battery or flywheel storage, and inverter will be cost-effective at many sites with an average daily energy demand exceeding 25 kWh [66]. These hybrid energy systems can serve as a minigrid as a part of distributed generation rather than extending the grid to the remote rural areas. The heart of the hybrid system is a high-quality sine-wave inverter, which can also be operated in reverse as battery charger. The system can cope with loads ranging from zero (inverter only operation) to approximately three times greater capacity (inverter and diesel operating in parallel).

Decentralized form of generation can be beneficial in remote-area power supply. Due to high cost of PV systems, problems associated with storing electricity over longer periods (like maintenance difficulties and costs), wind turbines can be a viable alternative in hybrid systems. Systems with battery storage provide better reliability. Wind power penetration can be high enough to make a significant impact on the operation of diesel generators.

High wind penetration also poses significant technical problems for the system designer in terms of control and transient stability [29]. In earlier stages, wind-diesel systems were installed without assessing the system behavior due to the lack

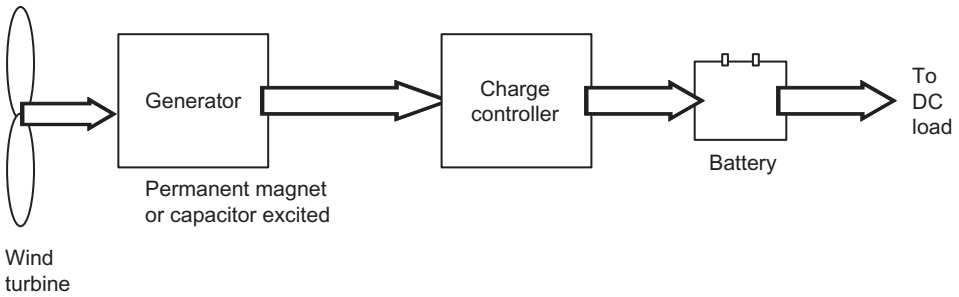

FIG. 25.56 Block diagram for a stand-alone wind generator and battery charging system.

of design tools/software. With the continual research in this area, there is now software available to assist in this process. Wind-diesel technology has now matured due to research and development in this area. Now, there is a need to utilize this knowledge into cost-effective and reliable hybrid systems [67]. In Western Australia, dynamic modeling of wind-diesel hybrid system has been developed in Curtin/MUERI, supported by the Australian Cooperative Research Centre for Renewable Energy (ACRE) program 5.21.

25.3.5 Grid-Connected Wind Energy Systems

Small-scale wind turbines, connected to the grid (weak or strong grid), have been discussed here. Wind-diesel systems have been getting attention in many remote parts of the world lately. Remote-area power supplies are characterized by low inertia, low damping, and poor reactive power support. Such weak power systems are more susceptible to sudden change in network operating conditions [68]. In this weak grid situation, the significant power fluctuations in the grid would lead to reduced quality of supply to users. This may manifest itself as voltage and frequency variations or spikes in the power supply. These weak grid systems need appropriate storage and control systems to smooth out these fluctuations without sacrificing the peak power tracking capability. These systems can have two storage elements. The first is the inertia of the rotating mechanical parts, which includes the blades, gearbox, and the rotor of the generators. Instead of wind speed fluctuation causing large and immediate change in the electric output of the generator as in a fixed-speed machine, the fluctuation will cause a change in shaft speed and not create a significant change in generator output. The second energy storage element is the small battery storage between the DC-DC converter and the inverter. The energy in a gust could be stored temporarily in the battery bank and released during a lull in the wind speed, thus reducing the size of fluctuations.

In larger-scale wind turbines, the addition of inverter control further reduces fluctuation and increases the total output power. Thus, the total output of the wind energy system can be stabilized or smoothed to track the average wind speed and can omit certain gusts. The system controller should track the peak power to maximize the output of the wind energy system. It should monitor the stator output and adjust the inverter to smooth the total output. The amount of smoothing would depend on SOC of the battery. The nominal total output would be adjusted to keep the battery bank SOC at a reasonable level. In this way, the total wind energy system will track the long-term variations in the wind speed without having fluctuations caused by the wind. The storage capacity of the battery bank needs only be several minutes to smooth out the gusts in the wind, which can be easily handled by the weak grid. In the cases, where the weak grid is powered by diesel generators, the conventional wind turbine can cause the diesel engines to operate at low capacity. In case of strong wind application,

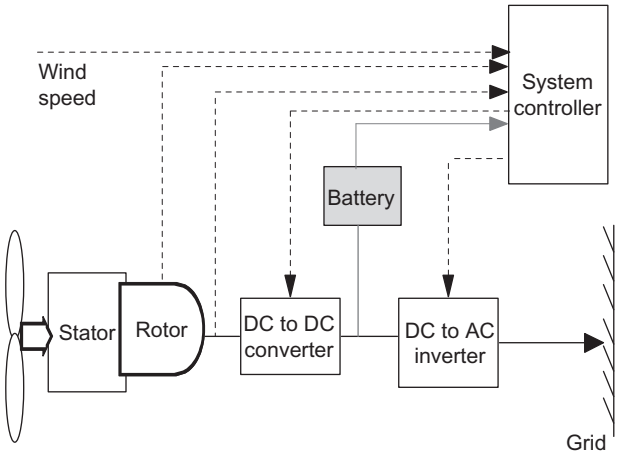

FIG. 25.57 System block diagram of grid-connected wind energy system.

the fluctuations in the output of the wind energy generator system can be readily absorbed by the grid. The main aim here is to extract the maximum energy from the wind. The basic block layout of such a system [69] is shown in Fig. 25.57.

The function of the DC-DC converter will be to adjust the torque on the machine and hence ensure by measurement of wind speed and shaft speed that the turbine blades are operating so as to extract optimum power. The purpose of the inverter is to feed the energy gathered by the rotor and DC-DC converter, in the process of peak power tracking, to the grid system. The interaction between the two sections would be tightly controlled so as to minimize or eliminate the need for a battery bank. The control must be fast enough so that the inverter output power set point matches the output of the DC-DC converter. For a wound rotor induction machine operating over a two-to-one speed range, the maximum power extracted from the rotor is equal to the power rating of the stator. Thus, the rating of the generator from a traditional point of view is only half that of the wind turbine [69]. Since half the power comes from the stator and half from the rotor, the power electronics of the DC-DC converter and inverter need to handle only half the total wind turbine output, and no battery would be required.

Power electronics technology also plays an important role in both system configurations and in control of offshore wind farms [70]. Wind farms connect in various configurations and control methods using different generator types and compensation arrangements. For instance, wind farms can be connected to the AC local network with centralized compensation or with a HVDC transmission system and DC local network. Decentralized control with a DC transmission system has also been used [71].

25.3.5.1 Soft Starters for Induction Generators

When an induction generator is connected to a load, a large inrush current flows. This is something similar to the direct online starting problem of induction machines. It has been

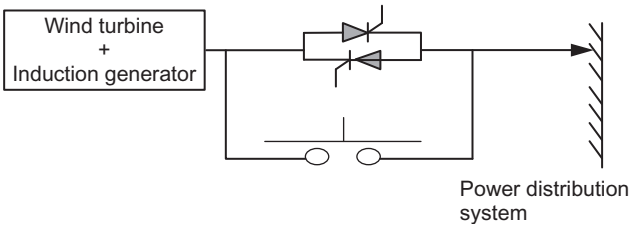

FIG. 25.58 Soft starting for wind turbine coupled with induction generator.

observed that the initial time constants of the induction machines are higher when it tries to stabilize initially at the normal operating conditions. There is a need to use some type of soft-starting equipment to start the large induction generators. A simple scheme to achieve this is shown in Fig. 25.58.

Two thyristors are connected in each phase, back to back. Initially, when the induction generator is connected, the thyristors are used to control the voltage applied to the stator and to limit the large inrush current. As soon as the generator is fully connected, the bypass switch is used to bypass the soft-starter unit.

25.3.6 Control of Wind Turbines

Theory indicates that operation of a wind turbine at fixed tip-speed ratio (C_{pmax}) ensures enhanced energy capture [54]. The wind energy systems must be designed so that above the rated wind speed, the control system limits the turbine output. In normal operation, medium- to large-scale wind turbines are connected to a large grid. Various wind turbine control policies have been studied around the world. Grid-connected wind turbines generators can be classified as follows:

- Fixed-speed wind turbines
- Variable-speed wind turbines

25.3.6.1 Fixed Speed Wind Turbines

In case of a fixed-speed wind turbine, synchronous or squirrel-cage induction generators are employed and are characterized by the stiff power train dynamics. The rotational speed of the wind turbine generator in this case is fixed by the grid frequency. The generator is locked to the grid, thereby permitting only small deviations of the rotor shaft speed from the nominal value. The speed is very responsive to wind speed fluctuations. The normal method to smooth the surges caused by the wind is to change the turbine aerodynamic characteristics, either passively by stall regulation or actively by blade pitch regulation. The wind turbines often subjected to very low (below cut-in speed) or high wind speed (above rated value). Sometimes, they generate below rated power. No pitch regulation is applied when the wind turbine is operating below rated speed, but pitch control is required when the machine is operating above rated wind speed to minimize the stress. Fig. 25.59 shows the effect of blade pitch angle on the torque-speed curve at a given wind speed.

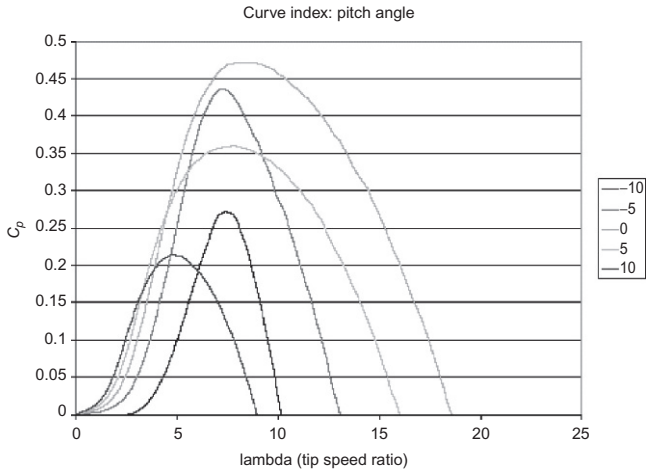

FIG. 25.59 C_p/λ curves for different pitch settings.

Blade pitch control is a very effective way of controlling wind turbine speed at high wind speeds, hence limiting the power and torque output of the wind machine. An alternative but cruder control technique is based on airfoil stall [54]. A synchronous link maintaining fixed turbine speed in combination with an appropriate airfoil can be designed so that, at higher than rated wind speeds, the torque reduces due to airfoil stall. This method does not require external intervention or complicated hardware, but it captures less energy and has greater blade fatigue.

The aims of variable-pitch control of medium- and large-scale wind turbines were to help in start-up and shutdown operation, to protect against overspeed and to limit the load on the wind turbine [72]. The turbine is normally operated between a lower and an upper limit of wind speed (typically 4.5–26 m/s). When the wind speed is too low or too high, the wind turbine is stopped to reduce wear and damage. The wind turbine must be capable of being started and run up to speed in a safe and controlled manner. The aerodynamic characteristics of some turbines are such that they are not self-starting. The required starting torque may be provided by motoring or changing the pitch angle of the blade. In case of grid-connected wind turbine system, the rotational speed of the generator is locked to the frequency of the grid. When the generator is directly run by the rotor, the grid acts like an infinite load. When the grid fails, the load rapidly decreases to zero resulting in the turbine rotor to accelerate quickly. Overspeed protection must be provided by rapid braking of the turbine. A simple mechanism of one of blade pitch control techniques is shown in Fig. 25.60.

In this system, the permanent magnet synchronous generator (PMSG) has been used without any gearbox. Direct connection of generator to the wind turbine requires the generator to have a large number of poles. Both induction generators and wound-filed synchronous generators of high pole number require a large diameter for efficient operation. Permanent

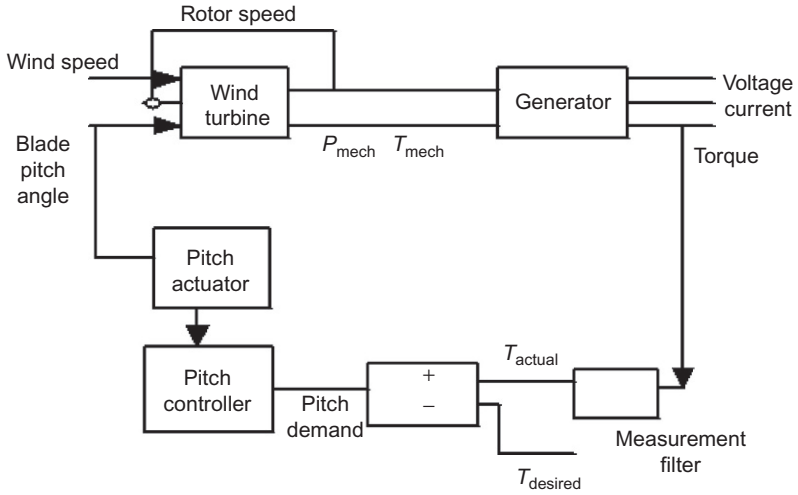

FIG. 25.60 Pitch control block diagram of a PMSG.

magnet synchronous generators allow a small pole pitch to be used [73]. The power output, P_{mech}, of any turbine depends mainly upon the wind speed, which dictates the rotational speed of the wind turbine rotor. Depending upon the wind speed and rotational speed of turbine, tip-speed ratio λ is determined. Based on computed λ, the power coefficient C_p is inferred. In the control strategy above, the torque output, T_{actual}, of the generator is monitored for a given wind speed and compared with the desired torque, T_{actual}, depending upon the load requirement. The generator output torque is passed through the measurement filter. The pitch controller then infers the modified pitch angle based on the torque error. This modified pitch angle demand and computed λ decides the new C_p, resulting in the modified wind generator power and torque output. The controller will keep adjusting the blade pitch angle till the desired power and torque output are achieved.

Some of the wind turbine generator includes the gearbox for interfacing the turbine rotor and the generator. The general drivetrain model [72] for such a system is shown in Fig. 25.61. This system also contains the blade pitch angle control provision.

The drivetrain converts the input aerodynamic torque on the rotor into the torque on the low-speed shaft. This torque on the low-speed shaft is converted to high-speed shaft torque using the gearbox and fluid coupling. The speed of the wind turbine here is low, and the gearbox is required to increase the speed so as to drive the generator at rated rpm, for example, 1500 rpm. The fluid coupling works as a velocity-in-torque-out device and transfers the torque [72]. The actuator regulates the tip angle based on the control system applied. The control system here is based on a pitch regulation scheme where the blade pitch angle is adjusted to obtain the desired output power.

25.3.6.2 Variable Speed Wind Turbines

The variable-speed constant-frequency turbine drivetrains are not directly coupled to the grid. The power-conditioning device is used to interface the wind generator to the grid. The output of the wind generator can be variable voltage and variable frequency, which is not suitable for grid integration, and appropriate interfacing is required. The wind turbine rotor in this case is permitted to rotate at any wind speed by power-generating unit.

A number of schemes have been proposed in the past that allow wind turbines to operate with variable rotor speed while feeding the power to a constant-frequency grid. Some of the benefits that have been claimed for variable-speed constant-frequency wind turbine configuration are as follow [69]:

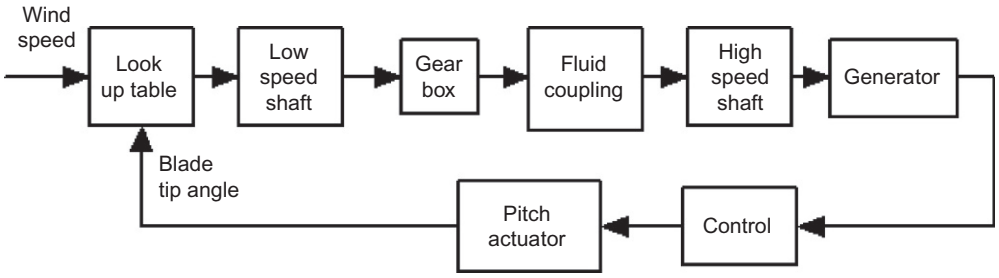

FIG. 25.61 Block diagram of drivetrain model.

- The variable-speed operation results in increased energy capture by maintaining the blade tip speed to wind-speed ratio near the optimum value.
- By allowing the wind turbine generator to run at variable speed, the torque can be fixed, but the shaft power allowed to increase. This means that the rated power of the machine can be increased with no structural changes.
- A variable-speed turbine is capable of absorbing energy in wind gusts as it speeds up and gives back this energy to the system as it slows down. This reduces turbulence-induced stresses and allows capture of a large percentage of the turbulent energy in the wind.
- More efficient operation can be achieved by avoiding aerodynamic stall over most of operating range.
- Better grid quality is due to the support of grid voltage.

Progress in the power electronic conversion system has given a major boost to implementing the concept of variable-speed operation. The research studies have shown that the most significant potential advancement for wind turbine technology was in the area of power electronic controlled variable-speed operation. There is much research underway in the United States and Europe on developing variable-speed wind turbine as cost-effective as possible. In the United States, the NASA MOD-0 and MOD-5B were operated as variable-speed wind turbines [69]. Companies in the United States and Enercon (Germany) made machines incorporate a variable-speed feature. Enercon variable-speed wind machine is already in operation in Denham, Western Australia.

The ability to operate at varying rotor speed effectively adds compliance to the power train dynamics of the wind turbine. Although many approaches have been suggested for variable-speed wind turbines, they can be grouped into two main classes: (a) discretely variable speed and (b) continuously variable speed [69,74].

25.3.6.3 Discretely Variable Speed Systems

The discretely variable-speed category includes electric system where multiple generators are used, either with different number of poles or with different ratio gearing connected to the wind rotor. It also includes those generators, which can use different number of poles in the stator or can approximate the effect by appropriate switching. Some of the generators in this category are those with consequent poles, dual winding, or pole amplitude modulation. A brief summary of some of these concepts is presented below.

Pole changing type induction generators

These generators provide two speeds, a factor of two apart, such as four pole/eight pole (1500/750 rpm at a supply frequency of 50 Hz or 1800/900 rpm at 60 Hz). They do this by using one-half the poles at the higher speed. These machines are commercially available and cost about 50% more than the corresponding single-speed machines. Their main disadvantage, in comparison with other discretely variable machines, is that the two-to-one speed range is wider than the optimum range for a wind turbine [75].

Dual stator winding two speed induction generators

These machines have two separate stator windings, only one of which is active at a time. As such, a variety of speed ranges can be obtained depending on the number of poles in each winding. As in the consequent pole machines, only two speeds may be obtained. These machines are significantly heavier than single-machines, and their efficiency is less, since one winding is always unused, which leads to increased losses. These machines are commercially available. Their cost is approximately twice that of single-speed machines [75].

Multiple generators

This configuration is based on the use of a multiple generator design. In one case, there may simply be two separate generators (as used on some European wind turbines). Another possibility is to have two generators on the same shaft, only one of which is electrically connected at a time. The gearing is arranged such that the generators reach synchronous speed at different turbine rotor speeds.

Two speed pole amplitude modulated induction generator (PAM)

This configuration consists of an induction machine with a single stator, which may have two different operating speeds. It differs from conventional generators only in the winding design. Speed is controlled by switching the connections of the six stator leads. The winding is built in two sections that will be in parallel for one speed and in series for the other. The result is the superposition of one alternating frequency on another. This causes the field to have an effectively different number of poles in the two cases, resulting in two different operating speeds. The efficiency of the PAM is comparable with that of a single-speed machine. The cost is approximately twice that of conventional induction generators.

The use of a discretely variable-speed generator will result in some of the benefits of continuously variable-speed operation, but not all of them. The main effect will be in increased energy productivity, because the wind turbine will be able to operate close to its optimum tip-speed ratio over a great range of wind speeds than will a constant speed machine. On the other hand, it will perform as single-speed machine with respect to rapid changes in wind speed (turbulence). Thus, it could not be expected to extract the fluctuating energy as effective from the wind as would be continuously variable-speed machine. More importantly, it could not use the inertia of the rotor to absorb torque spikes. Thus, this approach would not result in improved fatigue life of the machine, and it could not be an integral part of an optimized design such as one using yaw/speed control or pitch/speed control.

25.3.6.4 Continuously Variable Speed Systems

The second main class of systems for variable-speed operation is those that allow the speed to be varied continuously. For the continuously variable-speed wind turbine, there may be more than one control, depending upon the desired control action [76–80]:

- Mechanical control
- Combination of electric/mechanical control
- Electric control
- Electric/power electronics control

The mechanical methods include hydraulic and variable ratio transmissions. An example of an electric/mechanical system is one in which the stator of the generator is allowed to rotate. All the electric category includes high-slip induction generators and the tandem generator. The power electronic category contains a number of possible options. One option is to use a synchronous generator or a wound rotor induction generator, although a conventional induction generator may also be used. The power electronics is used to condition some or all the power to form an appropriate to the grid. The power electronics may also be used to rectify some or all the power from the generator, to control the rotational speed of the generator or to supply reactive power. These systems are discussed below.

Mechanical systems

Variable speed hydraulic transmission: One method of generating electric power at a fixed frequency while allowing the rotor to turn at variable speed is the use of a variable-speed hydraulic transmission. In this configuration, a hydraulic system is used in the transfer of the power from the top of the tower to ground level (assuming a horizontal-axis wind turbine). A fixed displacement hydraulic pump is connected directly to the turbine (or possibly gearbox) shaft. The hydraulic fluid is fed to and from the nacelle via a rotary fluid coupling. At the base of the tower is a variable displacement hydraulic motor, which is governed to run at constant speed and drive a standard generator.

One advantage of this concept is that the electric equipment can be placed at ground level making the rest of the machine simpler. For smaller machines, it may be possible to dispense with a gearbox altogether. On the other hand, there are a number of problems using hydraulic transmissions in wind turbines. For one thing, pumps and motors of the size needed in wind turbines of greater than about 200 kW are not readily available. Multiples of smaller units are possible, but this would complicate the design. The life expectancy of many of the parts, especially seals, may well be less than 5 years. Leakage of hydraulic fluid can be a significant problem, necessitating frequent maintenance. Losses in the hydraulics could also make the overall system less efficient than conventional electric generation. Experience over the last many years has not shown great success with the wind machines using hydraulic transmission.

Variable ratio transmission: A variable ratio transmission (VRT) is one in which the gear ratio may be varied continuously within a given range. One type of VRT suggested for wind turbines is using belts and pulleys, such as are used in some industrial drives [69,81]. These have the advantage of being able to drive a conventional fixed-speed generator while being driven by a variable-speed turbine rotor. On the other hand, they do not appear to be commercially available in larger sizes, and those, which do exist, have relatively high losses.

Electrical/mechanical variable speed systems – rotating stator induction generator

This system uses a conventional squirrel-induction generator whose shaft is driven by a wind turbine through a gearbox [54,81]. However, the stator is mounted to a support that allows bidirectional rotation. This support is in turn driven by a DC machine. The armature of the DC machine is fed from a bidirectional inverter, which is connected to the fixed frequency AC grid. If the stator support allowed to turn in the same direction as the wind turbine, the turbine will turn faster. Some of the power from the wind turbine will be absorbed by the induction generator stator and fed to the grid through the inverter. Conversely, the wind turbine will turn more slowly when the stator support is driven in the opposite direction. The amount of current (and thus the torque) delivered to or from the DC machine is determined by a closed loop control circuit whose feedback signal is driven by a tachometer mounted on the shaft of the DC machine.

One of the problems with this system is that the stator slip rings and brushes must be sized to take the full power of the generator. They would be subjected to wear and would require maintenance. The DC machine also adds to cost, complexity, and maintenance.

Electrical variable speed systems

High slip induction generator: This is the simplest variable-speed system, which is accomplished by having a relatively large amount of resistance in the rotor of an induction generator. However, the losses increase with increased rotor resistance. Westwind Turbines in Australia investigated such a scheme on a 30 kW machine in 1989.

Tandem induction generator: A tandem induction generator consists of an induction machine fitted with two magnetically independent stators, one fixed in position and the other able to be rotated, and a single squirrel-cage rotor whose bars extend to the length of both stators [69,81]. Torque control is achieved by physical adjustment of the angular displacement between the two stators, which causes a phase shift between the induced rotor voltages.

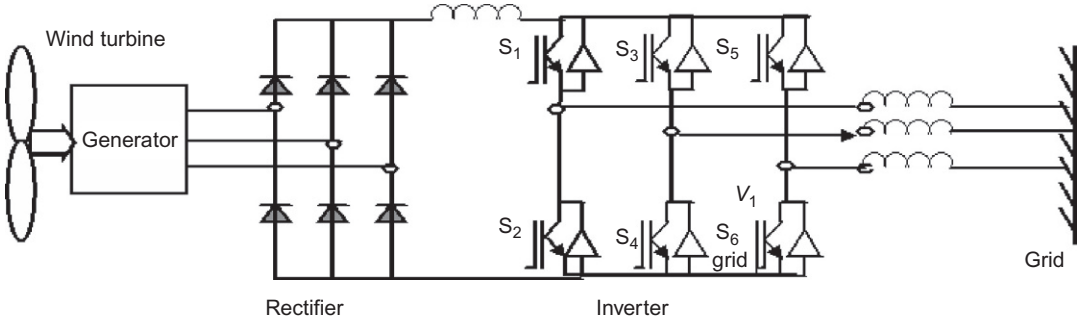

FIG. 25.62 Grid-connected wind energy system through AC/DC/AC converter.

Electrical/power electronics

The general configuration is shown in Fig. 25.62. It consists of the following components:

- Wind generator
- Rectifier
- Inverter

The generator may be DC, synchronous (wound rotor or permanent magnet type), squirrel-cage wound rotor, or brushless doubly fed induction generator. The rectifier is used to convert the variable voltage variable frequency input to a DC voltage. This DC voltage is converted into AC of constant voltage and frequency of desired amplitude. The inverter will also be used to control the active/reactive power flow from the inverter. In case of DC generator, the converter may not be required or when a cycloconverter is used to convert the AC directly from one frequency to another.

25.3.6.5 Types of Generator Options for Variable Speed Wind Turbines Using Power Electronics

Power electronics may be applied to four types of generators to facilitate variable-speed operation:

- Synchronous generators
- Permanent magnet synchronous generators
- Squirrel-cage induction generators
- Wound rotor induction generators

Synchronous generator

In this configuration, the synchronous generator is allowed to run at variable speed, producing power of variable voltage and frequency. Control may be facilitated by adjusting an externally supplied field current. The most common type of power conversion uses a bridge rectifier (controlled/uncontrolled), a DC link, and inverter as shown in Fig. 25.62. The disadvantage of this configuration includes the relatively high cost and maintenance requirements of synchronous generators and the need for the power conversion system to take the full power generated (as opposed to the wound rotor system).

Permanent magnet synchronous generators

The permanent magnet synchronous generator (PMSG) has several significant advantageous properties. The construction is simple and does not required external magnetization, which is important especially in stand-alone wind power applications and also in remote areas where the grid cannot easily supply the reactive power required to magnetize the induction generator. Similar to the previous externally supplied field current synchronous generator, the most common type of power conversion uses a bridge rectifier (controlled/uncontrolled), a DC link, and inverter as shown in Fig. 25.63 [82–84].

Fig. 25.64 shows a wind energy system where a PMSG is connected to a three-phase rectifier followed by a boost converter. In this case, the boost converter controls the electromagnetic torque, and the supply side converter regulates the DC link voltage and controls the input power factor. One drawback of this configuration is the use of diode rectifier that increases the current amplitude and distortion of the PMSG. As a result, this configuration has been considered for small size wind energy conversion systems (smaller than 50 kW).

The advantage of the system in Fig. 25.63 with regardant to the system showed in Fig. 25.64 is it allows the generator to operate near its optimal working point in order to minimize the losses in the generator and power electronic circuit.

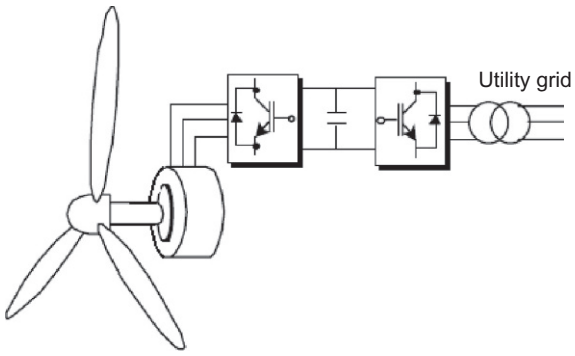

FIG. 25.63 Grid-connected PMSG wind energy system through DC/AC converter.

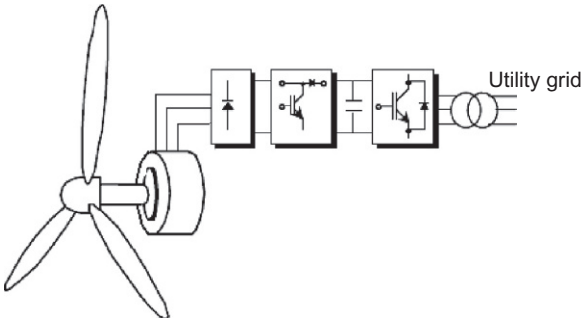

FIG. 25.64 Grid-connected PMSG wind energy system through DC/AC converter with a boost chopper.

However, the performance is dependent on the good knowledge of the generator parameter that varies with temperature and frequency. The main drawbacks, in the use of PMSG, are the cost of permanent magnet that increase the price of machine, demagnetization of the permanent magnet material, and it is not possible to control the power factor of the machine.

To extract maximum power at unity power factor from a PMSG and feed this power (also at unity power factor) to the grid, the use of back-to-back connected PWM voltage-source converters are proposed [85]. Moreover, to reduce the overall cost, reduced switch PWM voltage-source converters (four switches) instead of conventional (six-switch) converters for variable-speed drive systems can be used. It is shown that by using both rectifier and inverter current control or flux-based control, it is possible to obtain unity power factor operation both at the WTG and the grid. Other mechanisms can also be included to maximize power extraction from the VSWT (i.e., MPPT techniques) or sensorless approaches to further reduce cost and increase reliability and performance of the systems.

Squirrel-cage induction generator

Possible architecture for systems using conventional induction generators that have a solid squirrel-cage rotor has many similarities to those with synchronous generators. The main difference is that the induction generator is not inherently self-exciting, and it needs a source of reactive power. This could be done by a generator side self-commutated converter operating in the rectifier mode. A significant advantage of this configuration is the low-cost and low-maintenance requirements of induction generators. Another advantage of using the self-commutated double converter is that it can be on the ground, completely separate from the wind machine. If there is a problem in the converter, it could be switched out of the circuit for repair, and the wind machine could continue to run at constant speed. The main disadvantage with this configuration is that, as with the synchronous generator, the power conversion system would have to take the full power generated and could be relatively costly compared with some other configurations. There would also be additional complexities associated with the supply of reactive power to the generator.

Wound rotor induction generator

A wound rotor induction rotor has three-phase winding on the rotor, accessible to the outside via slip rings. The possibility of accessing the rotor can have the following configurations:

- Slip power recovery
- Use of cycloconverter
- Rotor resistance chopper control

Slip power recovery (static Kramer system): The slip power recovery configuration behaves similarly to a conventional induction generator with very large slip, but in addition, energy is recovered from the rotor. The rotor power is first carried out through slip rings and then rectified and passed through a DC link to a line-commutated inverter and into the grid. The rest of the power comes directly from the stator as it normally does. A disadvantage with this system is that it can only allow super-synchronous variable-speed operation. Its possible use in the wind power was reported by Smith and Nigim [86].

In this scheme shown in Fig. 25.65, the stator is directly connected to the grid. Power converter has been connected to the rotor of wound rotor induction generator to obtain the

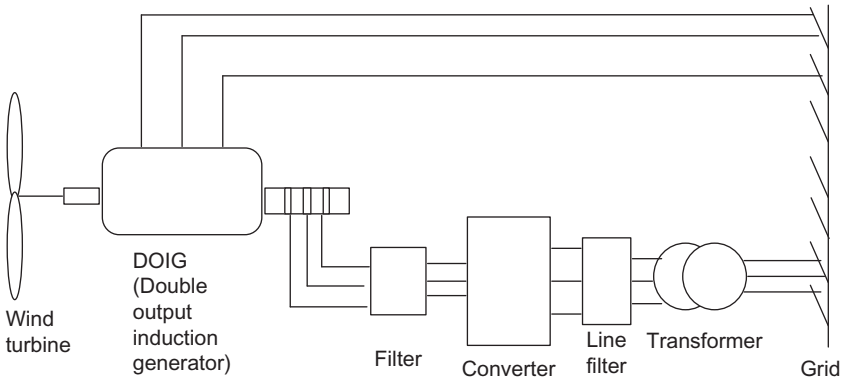

FIG. 25.65 Schematic diagram of doubly fed induction generator.

optimum power from variable-speed wind turbine. The main advantage of this scheme is that the power-conditioning unit has to handle only a fraction of the total power so as to obtain full control of the generator. This is very important when the wind turbine sizes are increasing for the grid-connected applications for higher penetration of wind energy and the smaller size of converter can be used in this scheme.

Cycloconverter (static Scherbius system): A cycloconverter is a converter that converts AC voltage of one frequency to another frequency without an intermediate DC link. When a cycloconverter is connected to the rotor circuit, sub- and supersynchronous operation variable-speed operation is possible. In supersynchronous operation, this configuration is similar to the slip power recovery. In addition, energy may be fed into the rotor, thus allowing the machine to generate at subsynchronous speeds. For that reason, the generator is said to be doubly fed [87]. This system has a limited ability to control reactive power at the terminals of the generator, although as a whole it is a net consumer of reactive power. On the other hand, if coupled with capacitor excitation, this capability could be useful from the utility point of view. Because of its ability to rapidly adjust phase angle and magnitude of the terminal voltage, the generator can be resynchronized after a major electric disturbance without going through a complete stop/start sequence. With some wind turbines, this could be a useful feature.

Rotor resistance chopper control: A fairly simple scheme of extracting rotor power as in the form of heat has been proposed in [48].

25.3.6.6 Isolated Grid Supply System with Multiple Wind Turbines

The isolated grid supply system with a wind park is shown in Fig. 25.66. Two or more wind turbines can be connected to this system. A diesel generator can be connected in parallel. The converters, connected with wind generators, will work in parallel, and the supervisory control block will control the output of these wind generators in conjunction with the diesel generator. This type of decentralized generation can be a better option where high penetration of wind generation is sought. The individual converter will control the voltage and frequency of the system. The supervisory control system will play an important part in coordination between multiple power generation systems in a remote-area power supply having weak grid.

25.3.6.7 Power Electronics Technology Development

To meet the needs of future power generation systems, power electronics technology will need to evolve on all levels, from devices to systems. The development needs are as follows:

- There is a need for modular power converters with plug-and-play controls. This is particularly important for high-power utility systems, such as wind power. The power electronic equipment used today is based on industrial motor drive technology. Having dedicated, high power density, modular systems will provide flexibility and efficiency in dealing with different energy sources and large variation of generation systems architectures.
- There is a need for new packaging and cooling technologies, and integration with PV and fuel cell will have to be addressed. The thermal issues in integrated systems are

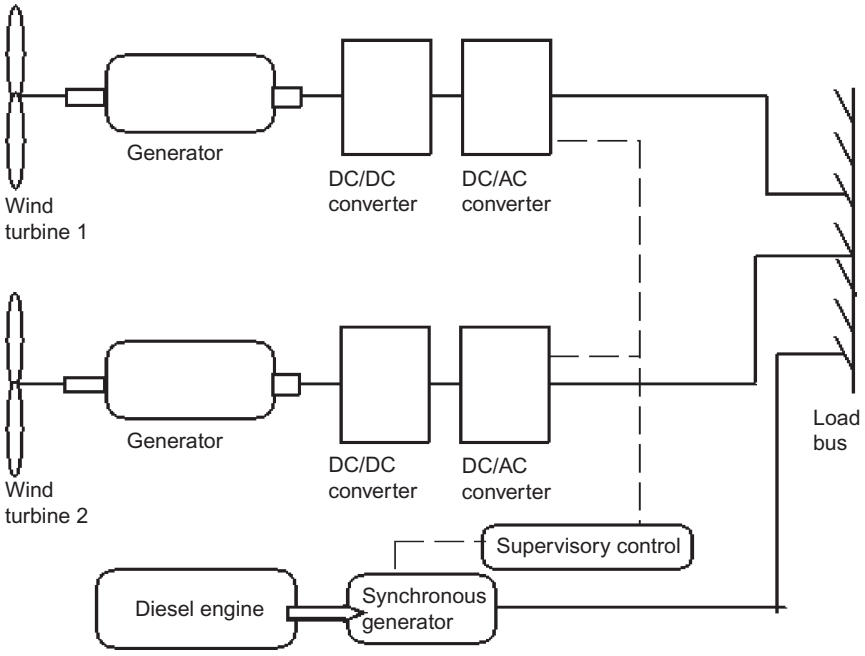

FIG. 25.66 Schematic diagram of isolated grid system having a wind park.

complex, and new technologies such as direct fluid cooling or microchannel cooling may find application in future systems. There is large potential for advancement in this area.
- There is a need for new switching devices with higher temperature capability, higher switching speed, and higher current density/voltage capability. The growth in alternative energy markets will provide a stronger pull for further development of these technologies.

25.4 Power Electronics for Hybrid Energy Systems

The combination of RES, such as PV arrays or wind turbines, with engine-driven generators and battery storage, is widely recognized as a viable alternative to conventional remote-area power supplies (RAPS). These systems are generally classified as hybrid energy systems (HES). They are used increasingly for electrification in remote areas where the cost of grid extension is prohibitive and the price for fuel increases drastically with the remoteness of the location. For many applications, the combination of renewable and conventional energy sources compares favorably with fossil-fuel-based RAPS systems, in regard to both their cost and technical performance. Because these systems employ two or more different sources of energy, they enjoy a very high degree of reliability as compared with single-source systems such as a stand-alone diesel generator or a stand-alone PV or wind system. Applications of hybrid energy systems range from small power supplies for remote households, providing electricity for lighting and other essential electric appliances, to village electrification for remote communities have been reported [88].

Hybrid energy systems generate AC electricity by combining RES such as PV array with an inverter, which can operate alternately or in parallel with a conventional engine-driven generator. They can be classified according to their configuration as follows [89]:

- Series hybrid energy systems
- Switched hybrid energy systems
- Parallel hybrid energy systems

The parallel hybrid systems can be further divided to DC or AC coupling. An overview of the three most common system topologies is presented by Bower [90]. In the following, a comparison of typical PV-diesel system configurations is described.

25.4.1 Series Configuration

In the conventional series hybrid systems shown in Fig. 25.67, all power generators feed DC power into a battery. Each component has therefore to be equipped with an individual charge controller and in the case of a diesel generator with a rectifier.

To ensure reliable operation of series hybrid energy systems, both the diesel generator and the inverter have to be sized to meet peak loads. This results in a typical system operation where a large fraction of the generated energy is passed through the battery bank, therefore resulting in increased cycling of the battery bank and reduced system efficiency. AC power delivered to the load is converted from DC to regulated AC by an inverter or a motor generator unit. The power generated by the diesel generator is first rectified and subsequently converted back to AC before being supplied to the load, which incurs significant conversion losses.

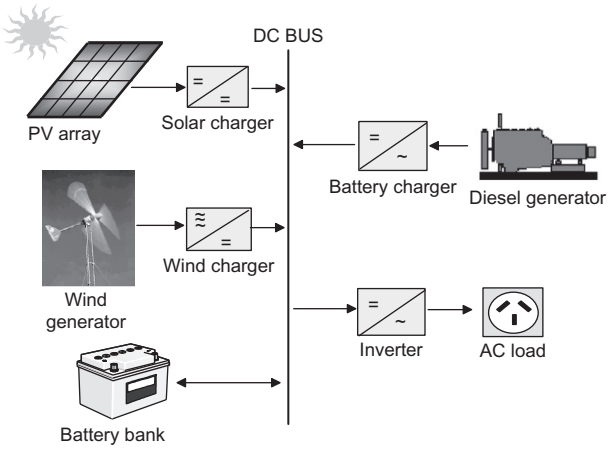

FIG. 25.67 Series hybrid energy system.

The actual load demand determines the amount of electric power delivered by the PV array, the wind generator, the battery bank, or the diesel generator. The solar and wind charger prevents overcharging of the battery bank from the PV generator when the PV power exceeds the load demand and the batteries are fully charged. It may include MPPT to improve the utilization of the available PV energy, although the energy gain is marginal for a well-sized system. The system can be operated in manual or automatic mode, with the addition of appropriate battery voltage sensing and start/stop control of the engine-driven generator.

Advantages are as follows:

- The engine-driven generator can be sized to be optimally loaded while supplying the load and charging the battery bank, until a battery SOC of 70%–80% is reached.
- No switching of AC power between the different energy sources is required, which simplifies the electric output interface.
- The power supplied to the load is not interrupted when the diesel generator is started.
- The inverter can generate a sine wave, modified square wave, or square wave depending on the application.

Disadvantages are as follows:

- The inverter cannot operate in parallel with the engine-driven generator; therefore, the inverter must be sized to supply the peak load of the system.
- The battery bank is cycled frequently, which shortens its lifetime.

- The cycling profile requires a large battery bank to limit the depth of discharge (DOD).
- The overall system efficiency is low, since the diesel cannot supply power directly to the load.
- Inverter failure results in complete loss of power to the load, unless the load can be supplied directly from the diesel generator for emergency purposes.

25.4.2 Switched Configuration

Despite its operational limitations, the switched configuration remains one of the most common installations in some developing countries. It allows operation with either the engine-driven generator or the inverter as the AC source, yet no parallel operation of the main generation sources is possible. The diesel generator and the RES can charge the battery bank. The main advantage compared with the series system is that the load can be supplied directly by the engine-driven generator, which results in a higher overall conversion efficiency. Typically, the diesel generator power will exceed the load demand, with excess energy being used to recharge the battery bank. During periods of low electricity demand, the diesel generator is switched off, and the load is supplied from the PV array together with stored energy. Switched hybrid energy systems can be operated in manual mode, although the increased complexity of the system makes it highly desirable to include an automatic controller, which can be implemented with the addition of appropriate battery voltage sensing and start/stop control of the engine-driven generator (Fig. 25.68).

Advantages are as follows:

- The inverter can generate a sine wave, modified square wave, or square wave, depending on the particular application.
- The diesel generator can supply the load directly, therefore improving the system efficiency and reducing the fuel consumption.

Disadvantages are as follows:

- Power to the load is interrupted momentarily when the AC power sources are transferred.
- The engine-driven alternator and inverter are typically designed to supply the peak load, which reduces their efficiency at part load operation.

25.4.3 Parallel Configuration

The parallel hybrid system can be further classified as DC and AC couplings as shown in Fig. 25.69. In both schemes, a bidirectional inverter is used to link between the battery and an AC source (typically the output of a diesel generator). The bidirectional inverter can charge the battery bank (rectifier operation) when excess energy is available from the diesel generator or by the renewable sources and act as a DC-AC converter (inverter operation). The bidirectional inverter may also provide "peak shaving" as part of a control strategy when the diesel engine is overloaded. In Fig. 25.69A, the renewable energy sources (RES) such as photovoltaic and wind are coupled on the DC side. DC integration of RES results in "custom" system solutions for individual supply cases requiring high costs for engineering, hardware, repair, and maintenance. Furthermore, power system expandability for covering the needs of growing energy and power demand is also difficult. A better approach would be to integrate the RES on the AC side rather than on the DC side as shown in Fig. 25.69B.

Parallel hybrid energy systems are characterized by two significant improvements over the series and switched system configuration.

The inverter and the diesel generator capacity rather than their individual component ratings limit the maximum load that can be supplied. Typically, this will lead to a doubling of the system capacity. The capability to synchronize the inverter with the diesel generator allows greater flexibility to optimize the operation of the system. Future systems should be sized with a reduced peak capacity of the diesel generator, which results in a higher fraction of directly used energy and hence higher system efficiencies.

By using the same power electronic devices for both inverter and rectifier operation, the number of system components is minimized. Additionally, wiring and system installation costs are reduced through the integration of all power-conditioning

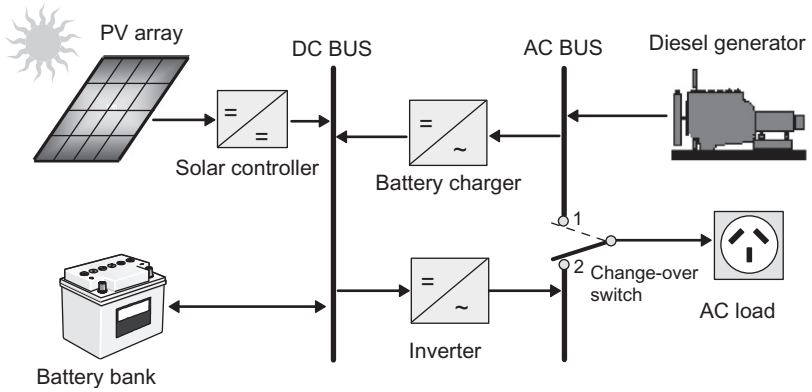

FIG. 25.68 Switched PV-diesel hybrid energy system.

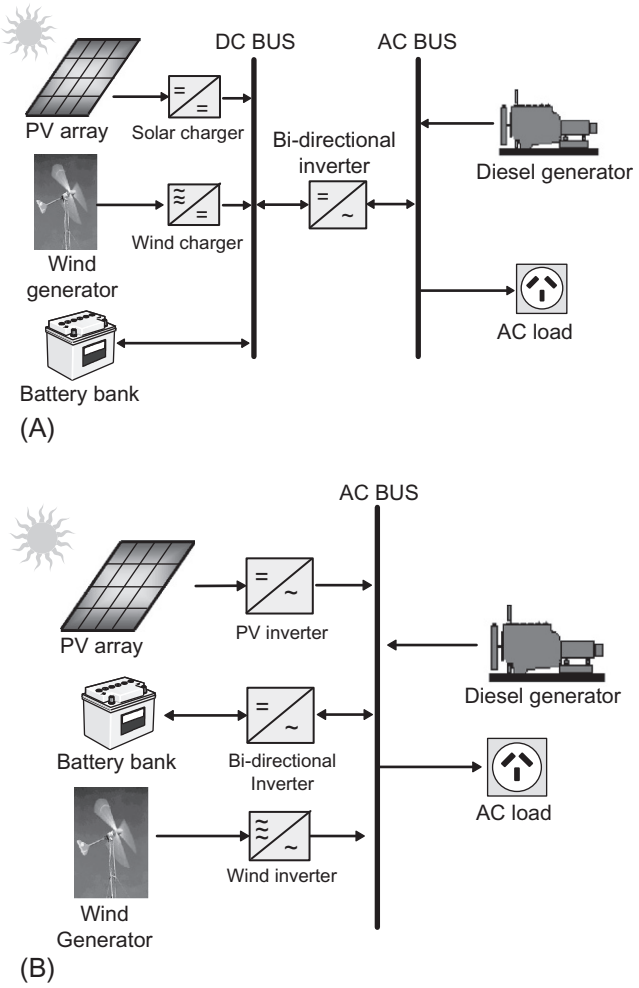

FIG. 25.69 Parallel PV-diesel hybrid energy system: (A) DC decoupling and (B) AC coupling.

devices in one central power unit. This highly integrated system concept has advantages over a more modular approach to system design, but it may prevent convenient system upgrades when the load demand increases.

The parallel configuration offers a number of potential advantages over other system configurations. These objectives can only be met if the interactive operation of the individual components is controlled by an "intelligent" hybrid energy management system. Although today's generation of parallel systems includes system controllers of varying complexity and sophistication, they do not optimize the performance of the complete system. Typically, both the diesel generator and the inverter are sized to supply anticipated peak loads. As a result, most parallel hybrid energy systems do not utilize their capability of parallel, synchronized operation of multiple power sources.

Advantages are as follows:

- The system load can be met in an optimal way.
- Diesel generator efficiency can be maximized.
- Diesel generator maintenance can be minimized.
- A reduction in the rated capacities of the diesel generator, battery bank, inverter, and renewable resources is feasible while also meeting the peak loads.

Disadvantages are as follows:

- Automatic control is essential for the reliable operation of the system.
- The inverter has to be a true sine-wave inverter with the ability to synchronize with a secondary AC source.
- System operation is less transparent to the untrained user of the system.

25.4.4 Control of Hybrid Energy Systems

The design process of hybrid energy systems requires the selection of the most suitable combination of energy sources, power-conditioning devices, and energy storage system together with the implementation of an efficient energy dispatch strategy. System simulation software is an essential tool to analyze and compare possible system combinations. The objective of the control strategy is to achieve optimal operational performance at the system level. Inefficient operation of the diesel generator and "dumping" of excess energy is common for many RAPS, operating in the field. Component maintenance and replacement contributes significantly to the life-cycle cost of systems. These aspects of system operation are clearly related to the selected control strategy and have to be considered in the system design phase.

Advanced system control strategies seek to reduce the number of cycles and the DOD for the battery bank, run the diesel generator in its most efficient operating range, maximize the utilization of the renewable resource, and ensure high reliability of the system. Due to the varying nature of the load demand, the fluctuating power supplied by the photovoltaic generator, and the resulting variation of battery SOC, the hybrid energy system controller has to respond to continuously changing operating conditions. Fig. 25.70 shows different operating modes for a PV single-diesel system using a typical diesel dispatch strategy:

Mode (I). The base load, which is typically experienced at nighttime and during the early morning hours, is supplied by energy stored in the batteries. Photovoltaic power is not available, and the diesel generator is not started.

Mode (II). PV power is supplemented by stored energy to meet the medium load demand.

Mode (III). Excess energy is available from the PV generator, which is stored in the battery. The medium load demand is supplied from the PV generator.

Mode (IV). The diesel generator is started and operated at its nominal power to meet the high evening load. Excess energy available from the diesel generator is used to recharge the batteries.

Mode (V). The diesel generator power is insufficient to meet the peak load demand. Additional power is supplied from the batteries by synchronizing the inverter AC output voltage with the alternator waveform.

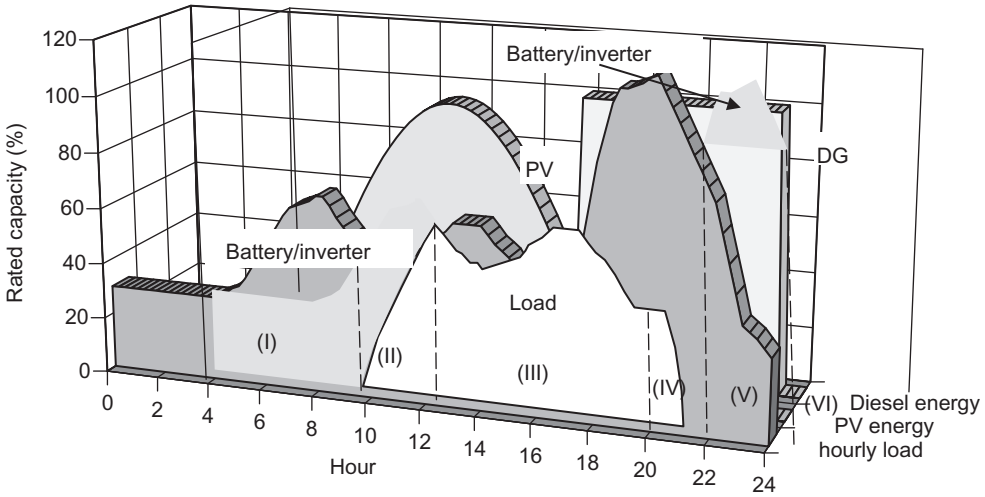

FIG. 25.70 Operating modes for a PV single-diesel hybrid energy system.

Mode (VI). The diesel generator power exceeds the load demand, but it is kept operational until the batteries are recharged to a high SOC level.

In principle, most efficient operation is achieved if the generated power is supplied directly to the load from all energy sources, which also reduces cycling of the battery bank. However, since diesel generator operation at light loads is inherently inefficient, it is common practice to operate the engine-driven generator at its nominal power rating and to recharge the batteries from the excess energy. The selection of the most efficient control strategy depends on fuel, maintenance and component replacement cost, the system configuration, environmental conditions, and constraints imposed on the operation of the hybrid energy system.

25.4.5 Grid-Connected Hybrid Energy Systems

Grid-connected hybrid renewable energy systems (RES), such as PV arrays or wind turbines, engine-driven generators, and battery storage, increase the reliability of the renewable energy supply to the grid [91]. Different RES are connected to a common DC or AC bus, as illustrated in Section 25.4.1. Usually, a power transformer is required to step up the inverter output voltage to a medium-/high-voltage grid. Such power transformer is subjected to a high initial cost, regular maintenance cost, and large physical size [40]. The application of a suitable dielectric material enables the power conditioning of RES to be cheaper, more efficient, and lighter in weight. In [40], a high-frequency, 10–20 kHz magnetic linked cascaded multilevel inverter (CMLI) is proposed, which eliminates the necessity of using a step-up power transformer to interface the CMLI to the grid. The block diagram of such grid-connected hybrid energy systems is shown in Fig. 25.71. Various RES are connected in a common DC bus through suitable converter and high-frequency magnetic link (HFML) that is energized by the common DC bus. The HFML facilitates isolated DC supplies for the three-phase CMLI as shown in Fig. 25.72. The HFML converts the DC bus voltage into 10–20 kHz square-wave

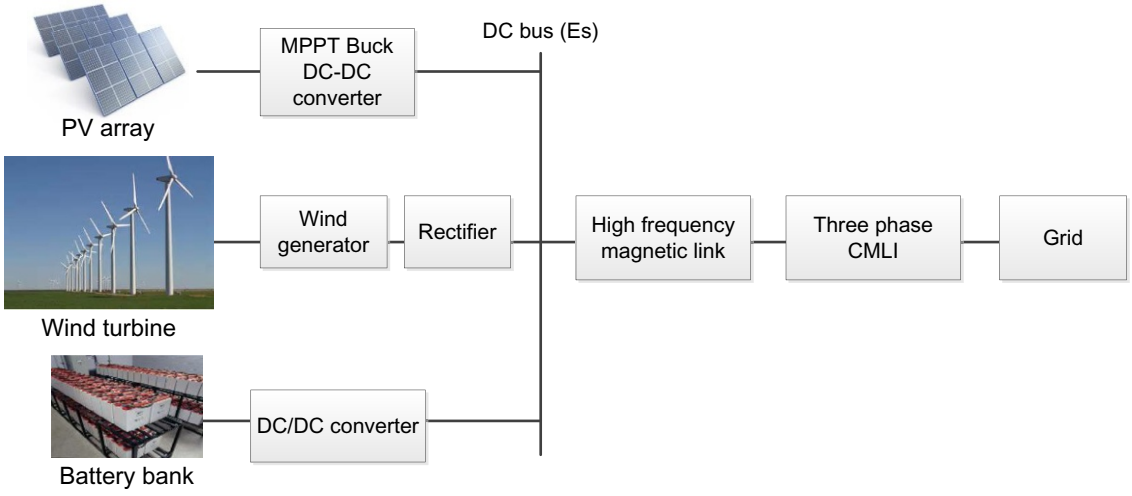

FIG. 25.71 Block diagram of a typical Grid-connected RES hybrid energy system.

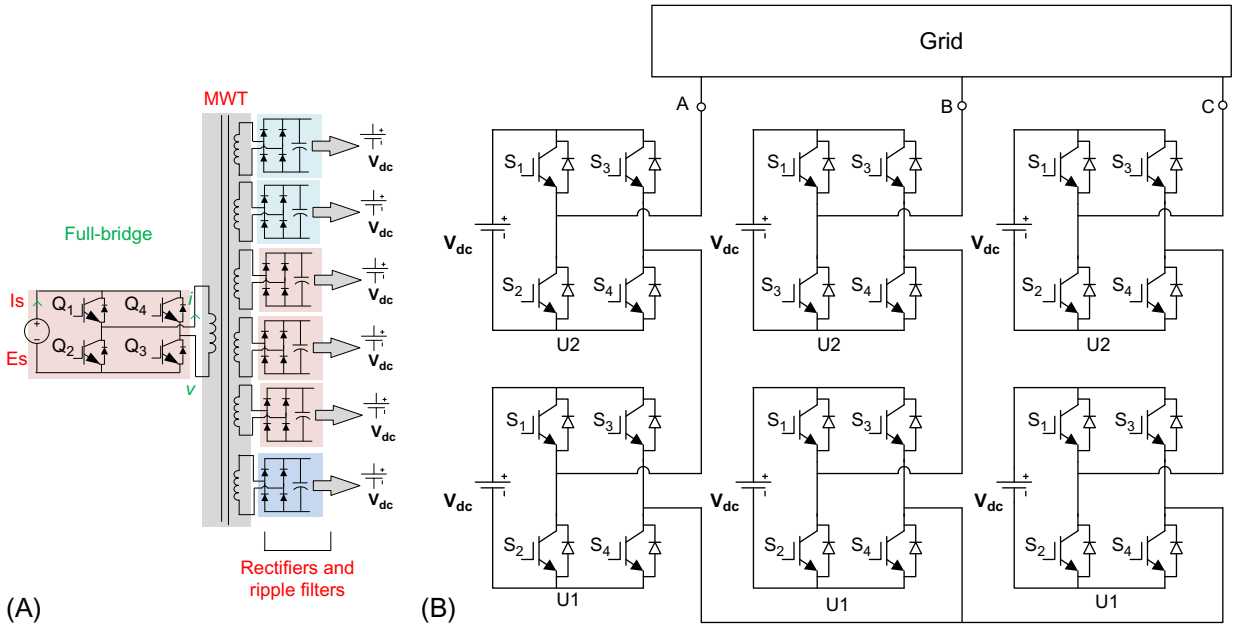

FIG. 25.72 Circuital diagram of the Grid-connected hybrid energy systems. (A) High frequency magnetic link, (B) Grid connected CMLI..

voltage using a full bridge. This high-frequency square-wave voltage is fed to the primary of a multiwinding transformer (MWT), which involves full-bridge diode rectifier connected to the MWT secondary windings as shown in Fig. 25.72A. The output terminals of the rectifiers are connected to the cascaded units of the CMLI as shown in Fig. 25.72B. The CMLI inverter output terminals are connected to the grid. The main reasons of utilizing high-frequency voltage for the MWT are to reduce the transformer core size and to create galvanic isolation between the PV panels and the grid [92]. It is possible to reduce the size of harmonic filter at the inverter output as CMLI generates output voltage with inherently low harmonic contents. Moreover, the cost of the overall conversion system can be reduced by the elimination of the step-up transformer [93,94].

26.1 Elements of Power System

The growth of electricity production and usage in the world is at an all-time high. It is the fastest growing form of end-use energy worldwide. The world net electricity generation in the year 2006 is estimated at 18 trillion kWh. It is forecasted to be 23.2 trillion kWh in the year 2015 and 31.8 trillion in the year 2030 [1]. Electricity production from fossil fuels raises concern on climate change, and hence, alternative energy sources such as solar, geothermal, wind, wave, tidal, and biomass are being developed rapidly around the world.

Modern electric power system consists of complex interconnected network of components generally divided into generation, transmission, distribution, and load. The invention of the transformer at the end of the nineteenth century enables electric energy to be transmitted at higher voltages and hence higher capacity. In this chapter, the components that make up the modern power system are briefly reviewed, namely, generators, transformers, and transmission line. The chapter will focus on the transmission of electric power and how to optimize its power transfer capability. The chapter will also discuss the phenomena of overvoltages and the insulation requirement of transmission lines. The use of power electronics in electric power transmission is covered in Chapters 31 and 32, respectively, such as high-voltage direct current (HVDC) system and flexible AC transmission system (FACTS) (Fig. 26.1).

26.2 Generators and Transformers

Generators are the starting point in a power system where electricity is generated. The most commonly used type of generator is the synchronous generator, driven by a prime mover. In a thermal power station, the prime mover is powered by steam turbines using coal, gas, nuclear, or oil as the fuel. Steam turbines usually operate at high speed to optimize its power output. For a 60 Hz system, the speed of rotation is 3600 (two-pole machine) or 1800 rpm (four-pole machine). For a 50 Hz system, the speed of rotation is 3000 (two-pole machine) or 1500 rpm (four-pole machine). Hydropower station uses the potential

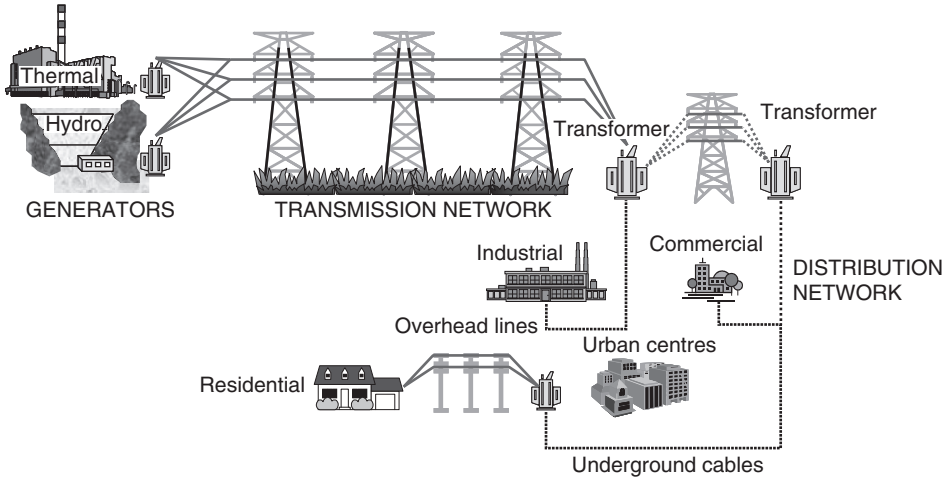

FIG. 26.1 Illustration of the basic components of a power system.

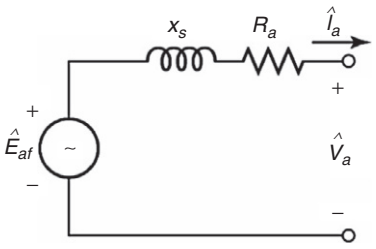

FIG. 26.2 Equivalent circuit of a synchronous generator.

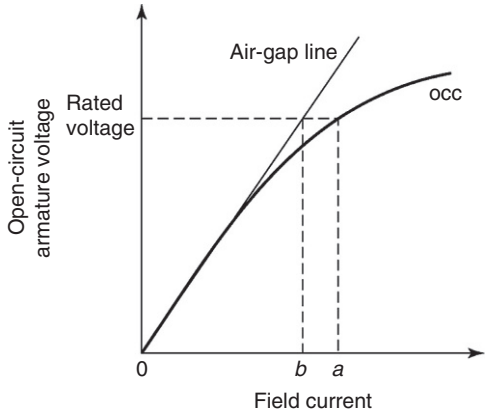

FIG. 26.3 Open-circuit characteristic (occ) of a synchronous generator.

energy of water to power the hydraulic turbines. The hydraulic turbines usually operate at relatively low speed, coupled to generators with salient-type rotor with many poles. In power-generating stations, the electric power is generated at high voltages typically between 10 and 30 kV, while the size of the generators varies from 50 to 1500 MW (Fig. 26.2).

A synchronous generator produces alternating current in the armature winding (usually a three-phase winding on the stator) with dc excitation supplied to the field winding (usually on the rotor). The per-phase equivalent circuit of a synchronous generator is shown below where the armature voltage, V_a, can be written as

$$V_a = R_a I_a + jX_s I_a + E_{af}$$

where

V_a is the armature voltage
R_a is the armature resistance
I_a is the armature current
X_s is the synchronous reactance
E_{af} is the internal generated voltage

The open-circuit characteristic (occ) of a synchronous generator as shown below represents the relationship between the field current I_f and the internal generated voltage E_{af}. Note that with the armature winding open-circuited, the armature voltage V_a is equal to the internal generated voltage E_{af}. As the field current I_f is increased from zero, the armature voltage V_a increases linearly. Near the rated voltage, the saturation effect is clearly seen with the departure of the occ from the straight line (air-gap line) (Fig. 26.3).

Another characteristic of the synchronous generator is illustrated by the V curve shown in Fig. 26.4. For a constant real-power loading, the field current and hence excitation can be adjusted to vary the reactive power VAr generated, hence power factor (pf).

The voltage output of the generator is transformed to a higher voltage before transmitting the power over a long distance to reduce the transmission losses, I^2R losses. Transformers are used to step up or step down the voltage (Fig. 26.5).

Transmission system voltages vary from country to country. For example, in Britain, they are 400 and 275 kV; in the United States, they are 765, 500, and 345 kV, while in Malaysia, they are 500 and 275 kV. The subtransmission network is at 115 kV in the United States, while it is 132 kV in Britain and Malaysia. This network in turn supplies the distribution network to the customers in a given area. In Britain and Malaysia, the distribution

network operates at 33 and 11 kV supplying the customer's feeders at 400 V three-phase and 230 V per-phase. Transformer used in the power system ranges from small 500 kVA distribution transformers to 1000 MVA supergrid transformers.

Detailed theoretical analysis of transformers has been covered in numerous textbooks. It is suffice to show here the equivalent circuit of a transformer to appreciate its electric circuit representation. The component R_c represents the core losses that consist of eddy current losses and hysteresis losses, while the component X_m represents the flow of the magnetization current. Core losses also known as no-load losses are essentially the power required to energize the core. It depends primarily on the voltage and frequency and does not vary much with system operation variations. On the other hand, R_{eq} and X_{eq} represent the primary and secondary winding of the transformer where the load losses originate. Load losses consist of the I^2R losses mainly in the windings and stray losses that include winding eddy losses and the effect of leakage flux entering internal metallic structures (Fig. 26.6).

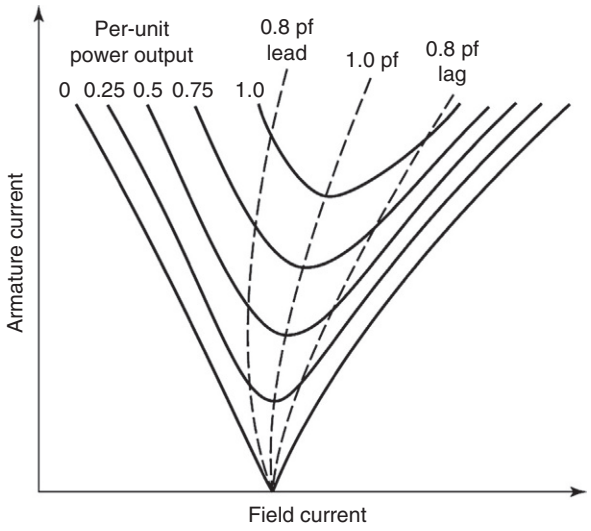

FIG. 26.4 A typical V curve of a synchronous generator.

26.3 Transmission Line

The bulk transfer of electric energy from generating power plants to substations located near population centers is achieved through high-voltage transmission lines. Interconnected transmission lines are referred to as high-voltage transmission networks. Electricity is transmitted at high voltage to reduce the energy lost in long-distance transmission. It is important to understand the characteristic of the important component, which is the conductor, to appreciate the limiting factors to the power transfer capability of the transmission line. The power transfer can then be optimized using latest sensor and communication technology.

FIG. 26.5 Transmission lines out of Connaught Bridge Power Station, Malaysia.

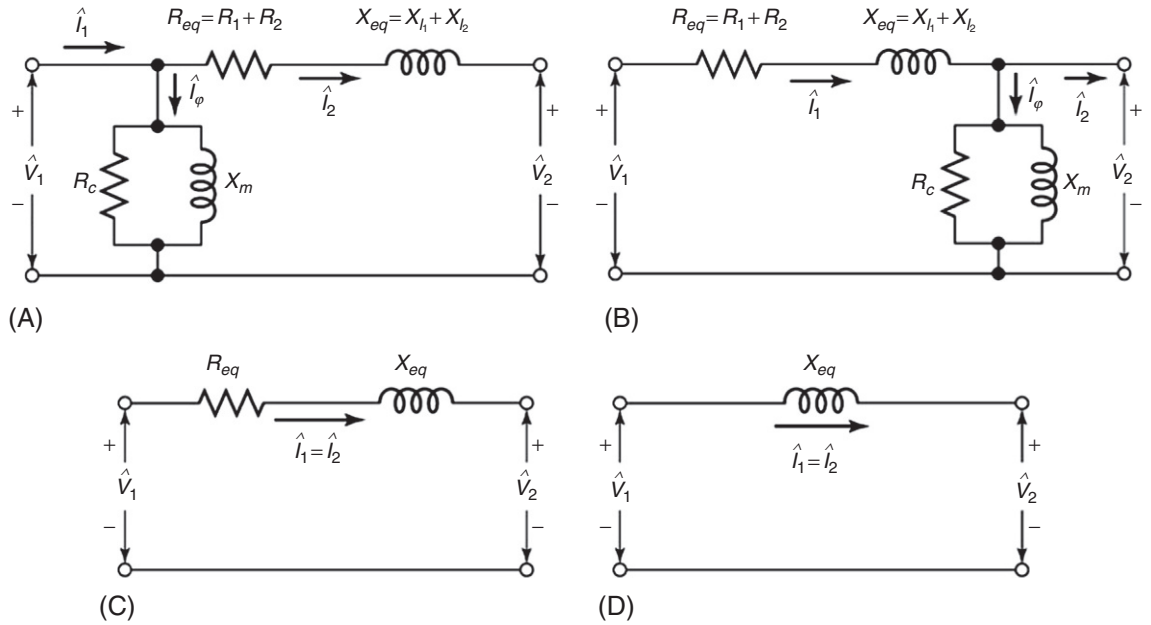

FIG. 26.6 Equivalent circuit representation of a transformer from a comprehensive representation to most simplified. (A) Core-loss at the input side, (B) lose-loss at the output side, (C) core-loss neglected, (D) resistive loss neglected.

The conductor is one of the major components of a transmission line design. It is essential that the most appropriate conductor type and size be selected for optimum operating efficiency. There are four common types of conductors used for many years in electric utilities: (i) all-aluminum conductor (AAC), (ii) aluminum conductor steel reinforced (ACSR), (iii) aluminum conductor alloy reinforced (ACAR), and (iv) all-aluminum alloy conductor (AAAC). Regardless of the type of metal used in the makeup of the conductor, the strands are always round and have a concentric lay.

26.3.1 Aluminum Conductor Steel-Reinforced

Electric utility companies have utilized ACSR as a common choice of conductor in transmission lines for many years. ACSR is used extensively on long spans as both ground and phase conductors because of its high mechanical strength-to-weight ratio and good current-carrying capacity. ACSR consists of solid or stranded coated steel core surrounded by one or more layers of 1350-H19 aluminum. Because of the presence of the 1350 aluminum in the construction, ACSR has equivalent or higher thermal ratings to equivalent sizes of AAC [2] (Fig. 26.7).

The cross-sectional area of ACSR is specified according to the cross-sectional area of aluminum to be contained in the construction. For example, a 428 mm^2 54/7 ACSR has 428 mm^2 of aluminum, the equivalent aluminum area content of 428 mm^2 AAC. The steel content of ACSR typically ranges from 11% to 18% by weight for the conductor stranding of 18/1, 45/7, 72/7, or 84/19. However, it can vary up to 40% depending on the desired tensile strength. It is desirable for ground wires in extra-long spans crossing rivers, for example, to have a stranding of 8/1, 12/7, or 16/19, giving them higher tensile strength. Fig. 26.8 shows the standard stranding of ACSR [3].

The high tensile strength combined with the good conductivity gives ACSR several advantages such as the following:

- The high tensile strength of ACSR allows it to be installed in areas subject to extreme wind loading.
- Because of the presence of the steel core, lines designed with ACSR elongate less than other standard conductors, yielding less sag at a given tension. Therefore, the maximum allowable conductor temperature can be increased to allow a higher thermal rating when replacing other standard conductors with ACSR.
- ACSR is less likely to be broken by falling tree limbs.

26.4 Factors That Limit Power Transfer in Transmission Line

Factors that limit the power transfer are voltage drop, voltage stability, and thermal rating. For short transmission line, which is approximately less than 80 km, the power transfer is limited by the thermal rating. The thermal rating is limited by the maximum operating temperature of the conductor. This maximum operating temperature is limited by the maximum line sag limit and maximum allowable operating temperature of the conductor material.

FIG. 26.7 Steel lattice structure of a transmission line tower.

26.4.1 Static and Dynamic Thermal Rating

Static thermal rating of the overhead transmission line is a fix rating in terms of current-carrying capacity. It is a conservative rating where worse case weather for contributing for maximum heat onto the conductor is assumed.

Dynamic thermal rating of the overhead transmission line is a time-dependence rating where the actual weather and loading of the conductor are measured and the thermal rating is calculated in real time.

26.4.2 Thermal Rating

Bare overhead conductor is normally exposed to environment when it is in service. Due to this reason, the conductor temperature is normally influenced by weather condition and the electric current loading of the conductor. In thermal rating calculation, meteorologic parameters such as wind speed and direction, solar radiation, and ambient temperature are required for the calculation where the calculation is based on heat balance energy equation; in steady-state condition, the conductor heat gain is equal to the heat loss (no heat energy is stored in the conductor). The mathematical representation of the heat balance energy equation as in Eq. (26.1) and by reorganizing the equation as in Eq. (26.2), the thermal rating can be calculated [4]. The heating elements are solar radiation and internal heating by the electric current flow through the conductor resistance or ohmic loss (I^2R). The heat loss is due to convection and radiation:

$$q_c + q_r = q_s + I^2 \cdot R(T_c) \tag{26.1}$$

$$I_{rating} = \sqrt{\frac{q_c + q_r - q_s}{R}} \tag{26.2}$$

where

q_s heat input due to solar, W/m

$I^2R(T_c)$ heat input due to line current (R is a function of conductor temperature)

q_c heat output due to convection (a function of wind, air temperature, and conductor temperature), W/m

q_r heat output due to radiation (a function of wind, air temperature, and conductor temperature), W/m

26.4.3 Convection Heat Loss

Convection heat-loss calculation can be grouped into natural convection and forced convection. The natural convection heat loss, q_{cn}, is calculated in the condition where there is no wind. This happens in all thermal systems where there is a thermal gradient. Heat will migrate from the hotter region to the cooler region until the temperature is uniform across the entire system. The natural convection heat loss (watt per unit length, W/m) for the bare-stranded overhead conductor is a function of air density, ρ_f; conductor diameter, D; and temperature difference between conductor and ambient, $(T_c - T_a)$, as given by Eq. (26.3) [4]:

$$q_{cn} = 0.0205\rho_f^{0.5} D^{0.75} (T_c - T_a)^{1.25} \tag{26.3}$$

In conditions where there is wind, wind blowing against the bare overhead conductor introduces cooling effect where the heat

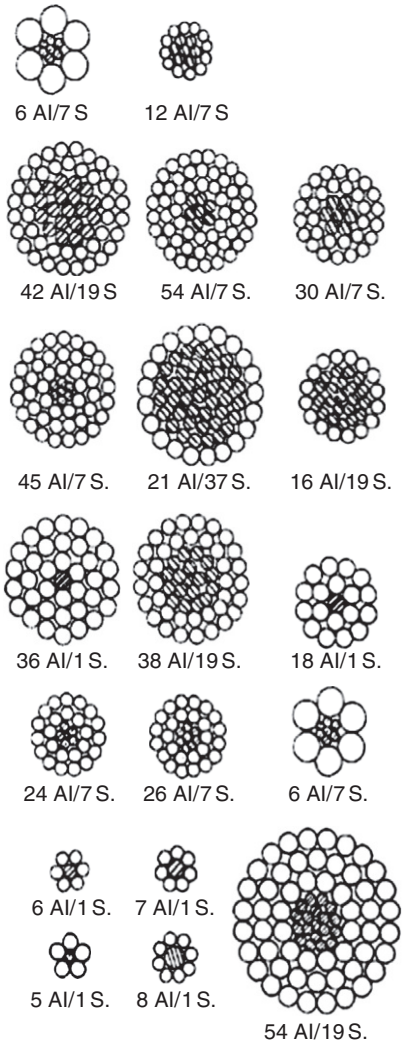

FIG. 26.8 Standard stranding of ACSR conductor.

from the conductor will be transferred over the temperature gradient, from high to low, to the moving air; this is called forced convection heat loss. There are two equations used in the calculation for the forced convection heat loss. One is used for low wind speed, q_{c1}, and another for high wind speed, q_{c2} [4]. The reason that there are two similar, yet independent, equations is because the correction factors incorporated into the equations are proprietary to a certain band of conditions. Eq. (26.4) is for low wind speed, and Eq. (26.5) is for high wind speed:

$$q_{c1} = \left[1.01 + 0.0372\left(\frac{D\rho_f V_w}{\mu_f}\right)^{0.52} \cdot k_f \cdot k_{angle} \cdot (T_c - T_a)\right] \text{W/m} \tag{26.4}$$

$$q_{c2} = \left[0.0119\left(\frac{D\rho_f V_w}{\mu_f}\right)^{0.6} \cdot k_f \cdot k_{angle} \cdot (T_c - T_a)\right] \text{W/m} \tag{26.5}$$

where air density, ρ_f; air viscosity, μ_f; and coefficient of thermal conductivity of air, k_f, are calculated using Eqs. (26.8), (26.9), and (26.10), respectively, at T_{film} where

$$T_{film} = \frac{T_c + T_a}{2} \tag{26.6}$$

At any wind speed, the highest of the two calculated forced convection heat-loss rates is used. The angle at which the wind is blowing relative to the conductor's axis is also considered. The convective heat-loss rate is multiplied by the wind direction factor, K_{angle}, where ϕ is the angle between the wind direction and the conductor axis. This modifying factor is used to create a modified forced convective heat-loss value. The maximum heat loss will occur when the wind is perfectly perpendicular. The wind direction factor is calculated using Eq. (26.7):

$$K_{angle} = 1.194 - \cos(\phi) + 0.194\cos(2\phi) + 0.368\sin(2\phi) \tag{26.7}$$

$$\rho_f = \frac{1.293 - 1.525 \times 10^{-4} H_e + 6.379 \times 10^{-9} H_e^2}{1 + 0.00367 T_{film}} \text{kg/m}^3 \tag{26.8}$$

$$\mu_f = \frac{1.458 \times 10^{-6} (T_{film} + 273)^{1.5}}{T_{film} + 383.4} Pa.s \tag{26.9}$$

$$k_f = 2.424 \times 10^{-2} + 7.477 \times 10^{-5} T_{film} - 4.407 \times 10^{-9} T_{film}^2 \, W/m^\circ C \tag{26.10}$$

26.4.4 Radiative Heat Loss

Radiative heat loss is usually a small fraction of the total heat loss. It is depending on conductor diameter, D; emissivity, ε; conductor temperature, T_c; and ambient temperature, T_a, as given by Eq. (26.11) [4]. If the ambient temperature is kept constant, for example, at 28°C, the radiative heat loss increases exponentially with conductor temperature as shown in Fig. 26.9. Emissivity, ε, is dependent on the conductor surface and varies from 0.27 for new stranded conductor to 0.95 for industrial weathered conductors [5]. It is equal to the ratio of the heat radiated by the conductor and to the heat radiated by a perfect blackbody of the same shape and orientation. Typical values for new bare overhead conductor are between 0.2 and 0.3. The solar emissivity of a new bare overhead conductor increases with age. A typical value for a conductor that has been in use for more than 5 (in industrial environments) to 20 years (in rural clean environments) is 0.7. A value of 0.5 is used if nothing is known about the conductor emissivity [4]:

$$q_r = 0.0178 D\varepsilon \left[\left(\frac{T_c + 273}{100}\right)^4 - \left(\frac{T_a + 273}{100}\right)^4\right] \text{W/m} \tag{26.11}$$

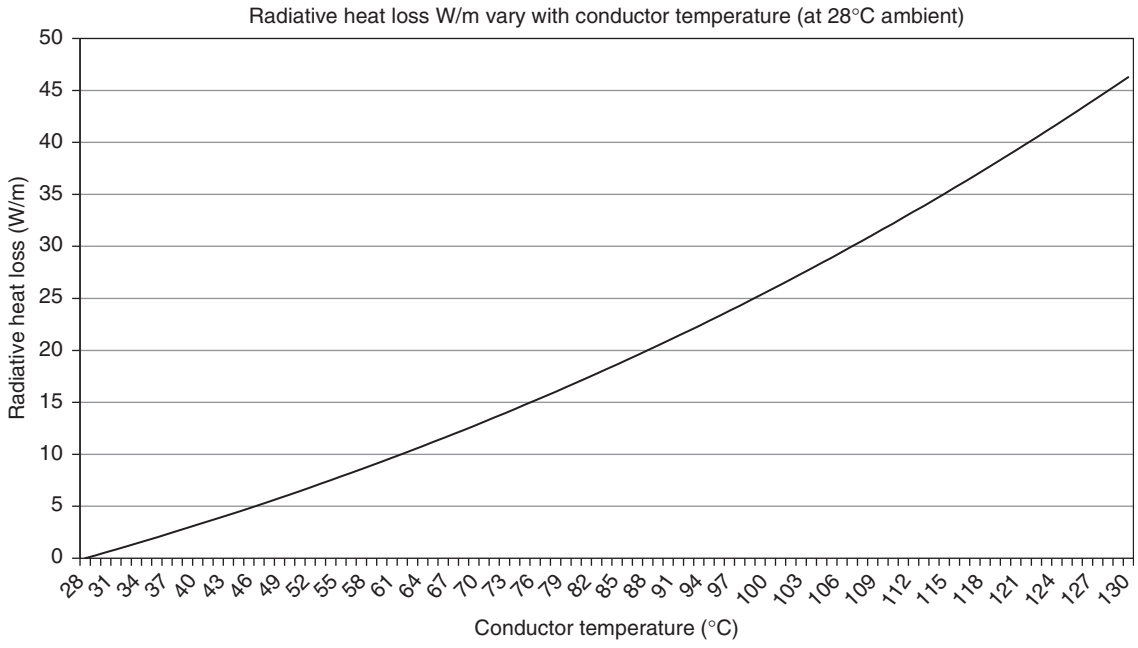

FIG. 26.9 Radiative heat loss (W/m) as function of conductor temperature.

26.4.5 Solar Heat Gain

The solar heat gain, q_s, depends on the conductor diameter, D; absorptivity, α; and global solar radiation, S, as given by Eq. (26.12):

$$q_s = \alpha SD \tag{26.12}$$

The conductor solar absorptivity, α, is a number that varies between 0.27 for bright stranded aluminum conductor and 0.95 for weathered conductor in industrial environment. It is equal to the ratio of the solar heat absorbed by the conductor to the solar heat absorbed by a perfect blackbody of the same shape orientation. Typical values for new conductor are between 0.2 and 0.3. The solar absorptivity of an overhead conductor increases with age. A typical value for a conductor that has been in use for more than 5 (in industrial environments) to 20 years (in rural clean environment) is 0.9. A value of 0.5 is often used if nothing is known about the conductor absorptivity [4].

26.4.6 Ohmic Losses ($I^2R(T_c)$) Heat Gain

The ohmic loss of the bare overhead conductor is depending on the amount of current flows and conductor electric resistance, whereas the conductor electric resistance is depending on conductor temperature. For all bare overhead conductors, controlled lab tests have been carried out; high and low temperature and electric resistance values have been established. This is then published as a guide for electric utilities to use as a reference in their estimation of their system's performance. As upper and lower limits have been defined, it is merely a matter of interpolation to obtain values between the given temperatures. For values outside the envelope, extrapolation can be readily used to obtain the result with reasonable accuracy. For example, lab tests conducted for 1350-H19 aluminum show that for entry resistance values at temperatures of 25°C and 75°C, the errors are negligible [6]. For entry resistance values at temperatures of 25°C and 175°C, the errors are approximately 3% too low at 500°C but 0.5% too high at 75°C. It is concluded that the use of resistance data for temperatures of 25°C and 75°C is adequate for rough calculation of steady-state and transient thermal rating for conductor temperature up to 175°C. The formula that is used to obtain the resistance of the conductor, per unit length, based on the established lab test results is given in Eq. (26.13):

$$R(T_c) = \left[\frac{R(T_{High}) - R(T_{Low})}{T_{High} - T_{Low}}\right] \cdot (T_c - T_{Low}) + R(T_{Low}) \tag{26.13}$$

26.5 Effect of Temperature on Conductor Sag or Tension

26.5.1 Conductor Temperature and Sag Relationship

The relationship of the sag to the temperature of a homogenous conductor is almost linear. A third-degree equation gives a very close approximation of the temperature as a function of the sag, Eq. (26.14) [7]:

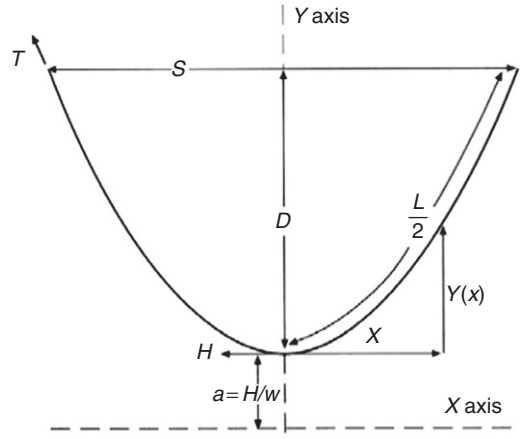

FIG. 26.10 Catenary sag model—level span [7,8].

$$\text{Temperature} = T_0 + A(S - S_0) + B(S - S_0)^2 + C(S - S_0)^3 \tag{26.14}$$

The line sag can be determined from the measured tension or direct measured ground clearance. For practical purposes, the sag can be considered to be inversely proportional to the tension in most spans. For a higher degree of accuracy, the sag/tension relationship can be determined to any desired degree of accuracy based on catenary equations. For level conductor spans as in Fig. 26.10, the low point is in the center of the total sag, D, given by Eq. (26.15):

$$D = \frac{H}{w}\left[\cosh\left(\frac{ws}{2H}\right) - 1\right] \tag{26.15}$$

The horizontal component of tension, H, is located at the point in the span where the conductor slope is horizontal or at the midpoint for level spans. The conductor tension, T, is found at the ends of the spans at the point of attachment and is calculated using Eq. (26.16), and it corresponds to a conductor length, L, given by Eq. (26.17):

$$T = H + wD \tag{26.16}$$

$$L = \left(\frac{2H}{w}\right)\sinh\left(\frac{Sw}{2H}\right) \tag{26.17}$$

Eq. (26.17) describes the behavior of ideal (with perfectly elastic stress and strain characteristics) concentric-lay-stranded conductors [6]. The actual conductors such as ACSR conductors exhibit nonlinear behavior when loaded from initial tension to some final value due to wind or temperature loading. Permanent elongation from creep and heavy loading also affects the resulting sag. Also, high-temperature operations result in thermal elongation of the steel and aluminum strands, thus affecting sag. Therefore, in order to calculate the correct sag, it is necessary to separate the effects of conductor elongation due to tensile loading and thermal loading. This process requires an iterative procedure in which the mathematical formulas describing the conductor elongation caused by the temperature change are solved simultaneously with the tension and conductor length relationship. To calculate the change in length due to temperature loading, Eq. (26.18) is used:

TABLE 26.1 Coefficients of thermal expansion for bare-stranded conductors [8]

Conductor	α (per °C)
AAC	23.0×10^{-6}
36/1 ACSR	22.0×10^{-6}
18/1 ACSR	21.1×10^{-6}
45/7 ACSR	20.7×10^{-6}
54/7 ACSR	19.5×10^{-6}
26/1 ACSR	18.9×10^{-6}
30/7 or 30/19 ACSR	17.5×10^{-6}

$$L_T = L_{T_{REF}}\left[1 + \alpha_{AS}\left(T - T_{rRef}\right)\right] \tag{26.18}$$

where

L_T = final length of conductor
$L_{T_{REF}}$ = reference length of the conductor
α_{AS} = coefficient of linear thermal elongation for AL/SW strands, given in Table 26.1
$\left(T - T_{rRef}\right)$ = change in temperature

For inclined spans, the length of the conductor between the supports is divided into two separate sections as in Fig. 26.11. The same equation in (26.15) can be used for the calculation of the height of the conductor. In each part of the span, the sag is dependent upon the vertical distance between support points and can be described by Eqs. (26.19) and (26.20) [7]:

$$D_R = D\left(1 - \frac{h}{4D}\right)^2 \tag{26.19}$$

$$D_L = D\left(1 + \frac{h}{4D}\right)^2 \tag{26.20}$$

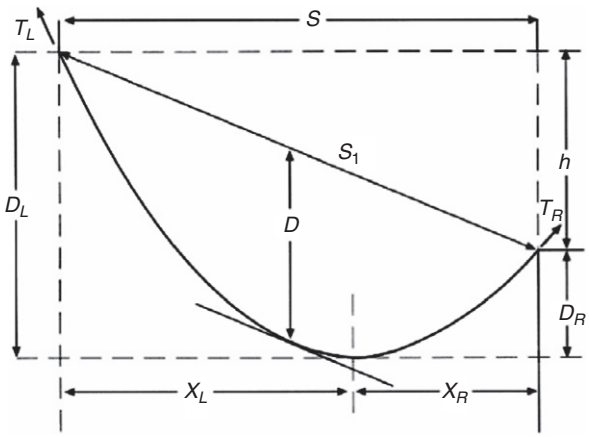

FIG. 26.11 Catenary sag model—inclined span [7,8].

Most of the sag and tension calculations are typically performed with line rating software, for example, PLS-CADD software from Power Line Systems, Inc., the Unites States. To demonstrate the process on how sags and tensions occur for overhead line, simplified sag calculations and conductor length can be done by using Eqs. (26.21) and (26.22), respectively [6]:

$$D = \frac{H}{w}\left[\cosh\left(\frac{ws}{2H}\right) - 1\right] \asymp \frac{wS}{8H} \tag{26.21}$$

$$L = \left(\frac{2H}{w}\right)\sinh\left(\frac{Sw}{2H}\right) \asymp S + \frac{8D^2}{3S} \tag{26.22}$$

The example of the relationship between conductor temperature and conductor sag can be describe by the following example [8].

A transmission line with ACSR conductor 795 kcmil (405 mm^2) and a 1000 ft level span. The conductor weight per unit length is 1.094 lb/ft (1.6 kg/m), ambient temperature is 77°F (25°C), and horizontal tension component, H, is 25% of the ultimate tension strength (31,500 lb):

$$H = 0.25 \times 31{,}500\text{lbs} = 7875\text{lbs}(35{,}196\text{N})$$

Conductor sag, D, is calculated by using Eq. (26.21):

$$D = \frac{wS^2}{8H} = \frac{1.094(1000)^2}{(8)7875} = 17.37\text{ft}(5.29\text{m})$$

Conductor length, L, is calculated by using Eq. (26.22):

$$L = S + \frac{8D^2}{3S} = 1000 + \frac{8(17.37)^2}{3(1000)} = 1000.8\text{ft}(305.05\text{m})$$

Eq. (26.18) is used to calculate the conductor length when the conductor temperature increases from ambient to 50°C (122°F) and then to 150°C (302°F). The coefficient of linear thermal expansion is $10.7 \times 10^{-6}/°\text{F}$:

$$\begin{aligned} L_T &= L_{T_{REF}}[1 + \alpha_{AS}(T - T_{rRef})] \\ L_{(122)} &= 1000.80[1 + 10.7 \times 10^{-6}(122 - 77)] \\ &= 1001.28\text{ft}(305.2\text{m}) \\ L_{(302)} &= 1000.80[1 + 10.7 \times 10^{-6}(302 - 77)] \\ &= 1003.21\text{ft}(305.8\text{m}) \end{aligned}$$

The conductor sag is calculated by rearranging Eq. (26.22):

$$\begin{aligned} D &= \sqrt{\frac{3S(L-S)}{8}} \\ D_{(122)} &= \sqrt{\frac{3(1000)(1.28)}{8}} = 21.9\text{ft}(6.68\text{m}) \\ D_{(302)} &= \sqrt{\frac{3(1000)(3.21)}{8}} = 34.7\text{ft}(10.58\text{m}) \end{aligned}$$

The relationship of the conductor temperature and the conductor sag for the above example can be summarized in Table 26.2.

TABLE 26.2 Relationship between conductor temperature and conductor sag for the ACSR conductor 405 mm^2 for a 1000 ft level span [6]

Conductor temperature (°C)	Conductor sag, D (m)
25	5.29
50	6.68
150	10.58

The conductor temperature corresponds to the measured sag given by Eq. (26.14), since the current conductor temperature is known; the dynamic thermal rating for the maximum conductor temperature, for example, at 75°C can be calculated by using Eq. (26.2).

From the known conductor temperature, the value of q_r can be calculated by the thermal rating Eq. (26.11). The value of q_s can be calculated by Eq. (26.12); the conductor resistance at the known temperature can be calculated by Eq. (26.13). By rearranging the thermal balance equation and with the known value of conductor current, the convective heat loss q_c can be calculated using Eq. (26.23):

$$q_c = I^2R(t) + q_s - q_r \tag{26.23}$$

From the known value of q_c, the equivalent perpendicular wind speed can be calculated by Eq. (26.4) or (26.5). Assuming the equivalent perpendicular wind speed is constant, then the thermal rating at the maximum conductor temperature can be calculated.

26.6 Standard and Guidelines on Thermal Rating Calculation

Reference standard for thermal rating calculation is published by IEEE; the first standard is IEEE Std 738-1993, IEEE Standard for Calculation of Bare Overhead Conductor Temperature and Ampacity Under Steady-State Conditions. Later, the new revision of this standard is published, IEEE Std 738-2006. The revised standard has additional information that addresses fault current and transient rating calculation, SI units were used throughout, and the solar heating calculation was extensively revised to cater for most part of the world instead of only 20 degrees north and above in the first standard IEEE Std 738-1993. The IEEE standard presents a method of calculating the current-temperature relationship of overhead lines given the weather conditions. The heat balance energy equation used for thermal rating calculation is described in details in this standard. The equation relating electric current to conductor temperature described in this standard can be used in two ways:

- To calculate the conductor temperature when the electric current is known
- To calculate the current that yields a given maximum allowable conductor temperature

Other guidelines on thermal rating calculation were developed by CIGRE working group WG 22.12, published in Electra No. 144 in October 1992, The thermal behavior of overhead conductors, Sections 1 and 2: Mathematical model for evaluation of conductor temperature in the steady state and the application thereof. And another one was published in Electra No. 174 in October 1997, The thermal behavior of overhead conductors, Section 3: Mathematical model for evaluation of conductor temperature in the unsteady state. In these guidelines, the heat balance energy equation is discussed in more details compared with in IEEE standard where other addition elements are added in the heat balance energy equation such as magnetic heating, corona heating, and evaporating cooling.

26.7 Optimizing Power Transmission Capacity

26.7.1 Overview of Dynamic Thermal Current Rating of Transmission Line

Real-time thermal rating methods can be classified into two basic types: weather model (WM) and conductor temperature model (CTM) [4]. The difference between the two models is the method by which the conductor convective heat-transfer coefficient is calculated. The WM approach calculates the convective heat-transfer coefficient using ambient temperature, wind speed, and wind direction data together with empirical expressions for convective heat transfer for airflow past cylindrical objects. The CTM computes the convective heat-transfer coefficient directly using the conductor heat balance energy equation, conductor temperature, air temperature, and conductor current. There are five main dynamic thermal rating techniques in WM and CTM, that is, weather monitoring, line tension monitoring, sag monitoring, line temperature monitoring, and conductor replica technique. The most appropriate technique depends upon a particular application and is based on various issues including accuracy, cost, and ease of installation [8].

In general, the overview of DTCR system is as shown in Fig. 26.12. There are three main components that form the dynamic thermal current rating (DTCR) system: remote monitoring station, communication system, and the system computer. Remote monitoring station gathers information on the environment in which the transmission lines are located and also information on the line sag/clearance or tension or conductor temperature. The remote monitoring station is normally placed at a critical location along the transmission line where the wind cooling is minimal or where there is an increased probability of contact between the conductor and objects on the ground.

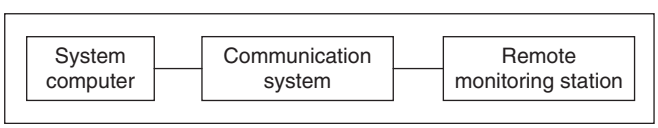

FIG 26.12 Dynamic thermal current rating (DTCR) system block diagram.

The communication system used in this real-time thermal rating system can be wireless or wired system. Normally, wireless communication system is more suitable for the thermal rating system compared with wired system due to connectivity issues and cost. The wireless system is easy to be implemented; it is robust and suitable for use in the outdoor environment. Data transfer from the remote monitoring station to the system computer can be based on dial-up connection at certain time intervals.

The system computer normally consists of two software modules, thermal rating calculation module and thermal rating display module. It has two primary functions, namely, to process the weather and line clearance data then calculate the thermal rating of the line and to display the thermal rating in real time.

As electric current in an overhead conductor increases, the line temperature increases, and therefore, the line sags. Each line has a minimum clearance to ground, which must never be violated for safety reasons. The thermal rating is the maximum current that results in the line sagging down exactly to the minimum clearance. Any additional current would result in too much sag and therefore breaches the safety requirement [9].

There are a few methods of transmission line sag monitoring that has been developed. One of the methods proposed is based on global positioning system (GPS). The method is known as differential GPS [10]. This mode consists of the use of two GPS receivers, the base and the rover as shown in Fig. 26.13. The actual position of the base is known (e.g., by precise surveying) and compared with the readings received at the same base point. With the estimated error, the readings obtained at the rover can be compensated by simple subtraction.

Another method to monitor the line sag is by using smart camera. This method is developed by Electric Power Research Institute (EPRI), the United States [4]. The system uses an imaging system to monitor the location of the conductor or a target attached to it as shown in Fig. 26.14. The imaging system is installed on either a transmission line structure or any other structure with a view of the span being monitored. The field of view of the imaging system remains the same at all time, and the location of the conductor or the target in the view changes as the conductor moves up, down, or horizontally. Image-processing technique is used to determine the location of the conductor or the target attached to the conductor in the camera's field of view. The search algorithm uses a preselected subimage of the target and searches the image to determine the most likely location of the target in the camera image. The key for the success of this approach is to have a target with unique features that cannot be easily found in the background. The change in vertical position of the conductor in the image is

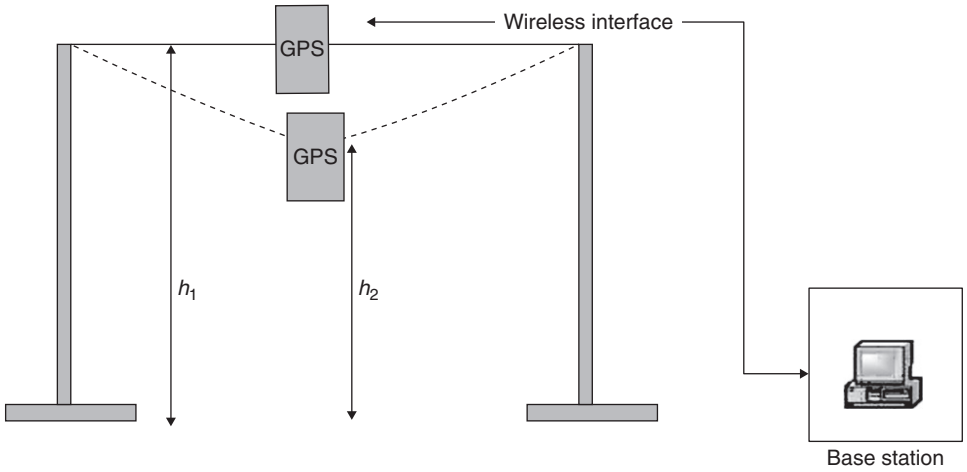

FIG. 26.13 Line sag measurement using differential GPS technique [6].

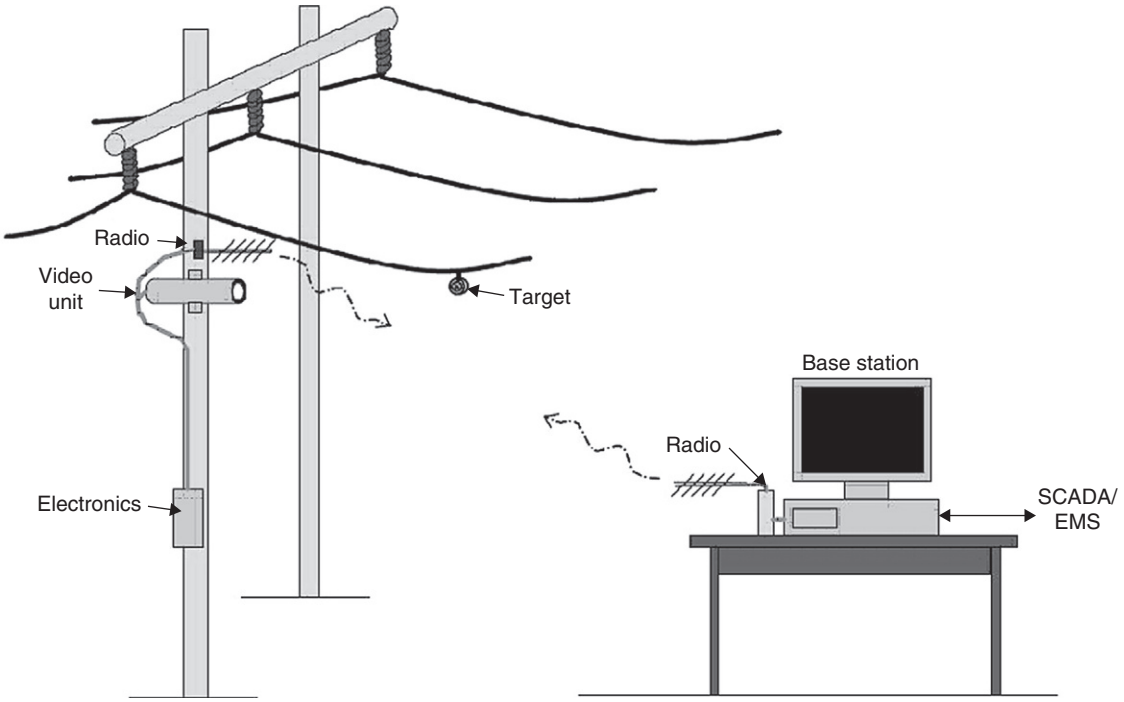

FIG. 26.14 Line sag measurement using smart camera [11].

directly related to the change in ground clearance or sag. At the time of installation, location of the conductor or the target attached to the conductor in the imaging system's field of view is calibrated to the measured ground clearance/sag. Ground clearance or sag at any later time is obtained from the measured change in location of the conductor using calibration constants obtained at the time of system calibration. The resulting clearance information may be made available on a real-time basis using telemetry and/or logged in a data logger for historical study. An effective conductor temperature is calculated using sag-tension routines of line rating software such as PLS-CADD software from Power Line Systems, Inc., the United States, and the real-time ratings is calculated using IEEE standard 738 [4].

Tension monitors consist of solar-powered line tension monitoring system located along the transmission line that communicate the measured data via spread-spectrum radios to receiving units at substations that are further linked to the utility's EMS/SCADA systems. The conductor tension is measured using load cell installed at the dead-end insulators.

There are also sensors that measure the ambient temperature and the net radiation at the conductor. All data are transmitted to the center processor computer for the line thermal rating calculation. The calibration of the system allows determination of the conductor temperature based on the measured tension [2].

Direct measurement of conductor temperature method uses temperature sensor that is directly attached to the conductor. It uses solid-state thermoelectric sensors, and it is powered up using line-current transformer. The system was developed by Niagara Mohawk in the 1980s, and the temperature sensor was called Power Donut. This method can provide conductor temperature data in real time. Power Donut has ambient and conductor temperature measurement accuracy of $\pm 2°C$ over a range of $-40°C$ to $125°C$ [12]. The advantage of this method is that the user has a direct measurement of conductor temperature. If the line rating is intended to limit the loss of conductor strength at high temperature, then this method is mostly appropriate.

Ground clearance has direct relationship with line sag as they depend on conductor temperature. Therefore, thermal rating can also be determined by monitoring the ground clearance. Laser distance measurement sensor can be used to measure the distance between the transmission line and ground. The installation of the laser distance measurement sensor must be at the middle of the span on the ground directly under the transmission line as shown in Fig. 26.15.

To enable continuous monitoring of the line clearance, the sensor can be set to operate in automatic mode that will take measurement continuously for a certain time interval. The line thermal rating can be calculated based on the conductor temperature determined by the clearance measurement.

A number of studies have shown that it is possible to calculate the thermal rating of an overhead conductor in a single span if the weather conditions in the span are known. This can be done using historical weather data records in order to select appropriately conservative static ratings, or it can be done in real time as a basis to dynamically rate the line. By accounting for variations in span orientation along a transmission line, it was found that the weather data from a single weather station as far as 20 mi away could be used to predict the statistical distribution of thermal ratings for that line [5]. For a real-time monitoring, the dynamic thermal rating of the line is calculated using real-time value of the line load current and the weather data. Example of a weather station installation at the transmission line is shown in Fig. 26.16.

FIG. 26.16 Weather monitoring using a weather station for transmission line in Malaysia.

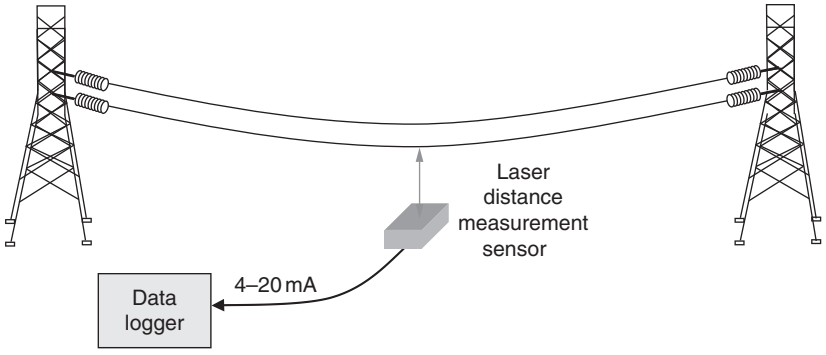

FIG. 26.15 Laser distance measurement sensor installation.

26.7.2 Example of Dynamic Thermal Current Rating of Transmission Line

The dynamic rating profile as shown in Fig. 26.17 is based on DTCR calculations using weather data recorded by a weather station for one of the transmission lines in Malaysia [13]. The figure shows three curves:

- Measured load on the line
- Static rating
- Calculated dynamic rating from DTCR software

It is important to note that

- the dynamic rating is almost always greater than the static rating,
- the measured load is always significantly lower than the static rating.

For statistical representation of the thermal rating, the thermal rating data for certain duration, for example, 6 months, can be represented using probability density plot. The probability density plot shows the frequency of the thermal rating in a certain period of time. It can be used as a guide for operating the transmission line or revising the static rating. Example of the probability density plot is shown in Fig. 26.18.

The graphs show that the load is always below the static rating. Only during emergencies, the load would exceed the normal static rating. The dynamic thermal rating is mostly 20% higher than the static rating that is shown at the tip of the dynamic thermal rating probability density graph in Fig. 26.18. This is the available potential extra capacity ready to be utilized when DTCR system is used to monitor the line rating.

26.8 Overvoltages and Insulation Requirements of Transmission Lines

The considerations for insulation requirements of transmission lines are critical because overvoltages can occur as a result of lightning strokes, switching, faults, load failure, and others. Overvoltages are transitory phenomena. It is defined as any transitory voltage between phase and ground or between phases with a crest value higher than the crest value of maximum system voltage [14]. These overvoltages are often expressed in per unit values, with maximum system voltage as per unit base.

For example, the phase-to-ground per unit overvoltage is

$$V_{\text{pu}} = \frac{V_{\text{L-G}}\sqrt{3}}{V_{\text{m}}\sqrt{2}}$$

where

V_{pu} = per unit phase-to-ground overvoltage

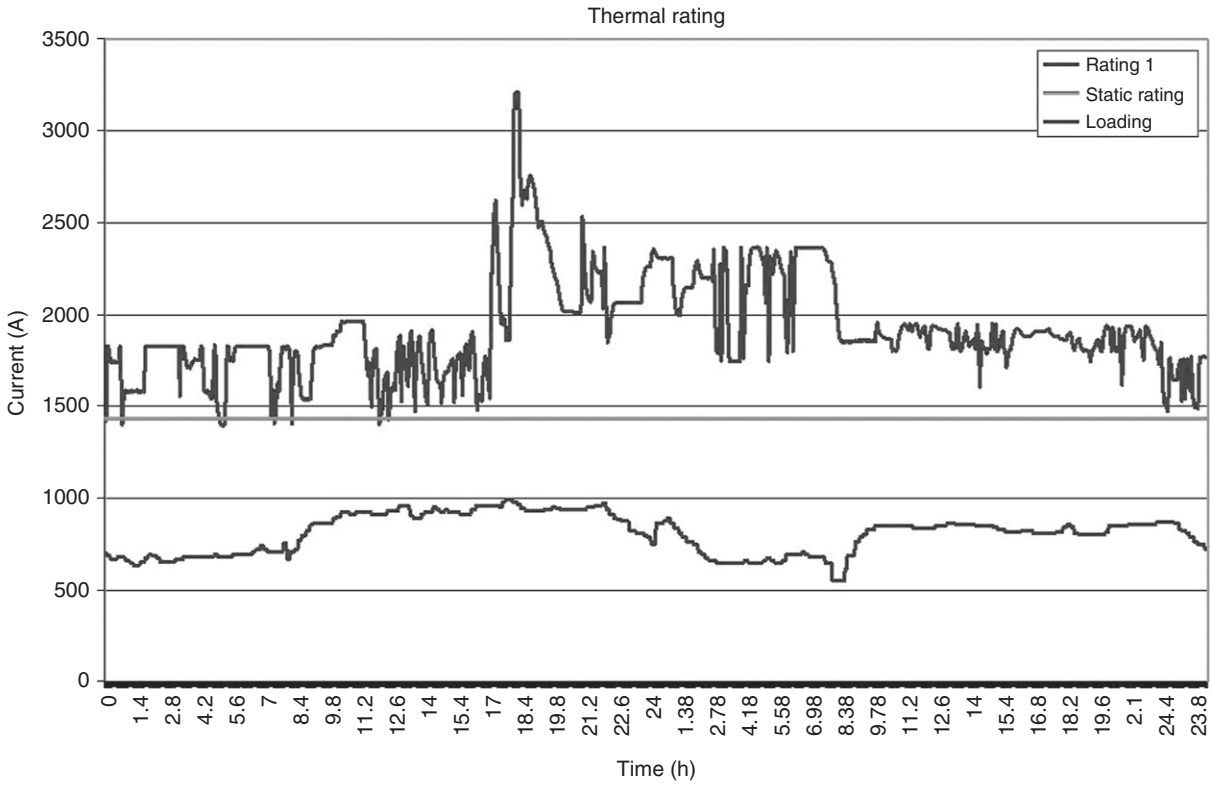

FIG. 26.17 Dynamic thermal rating profile of a transmission line in Malaysia.

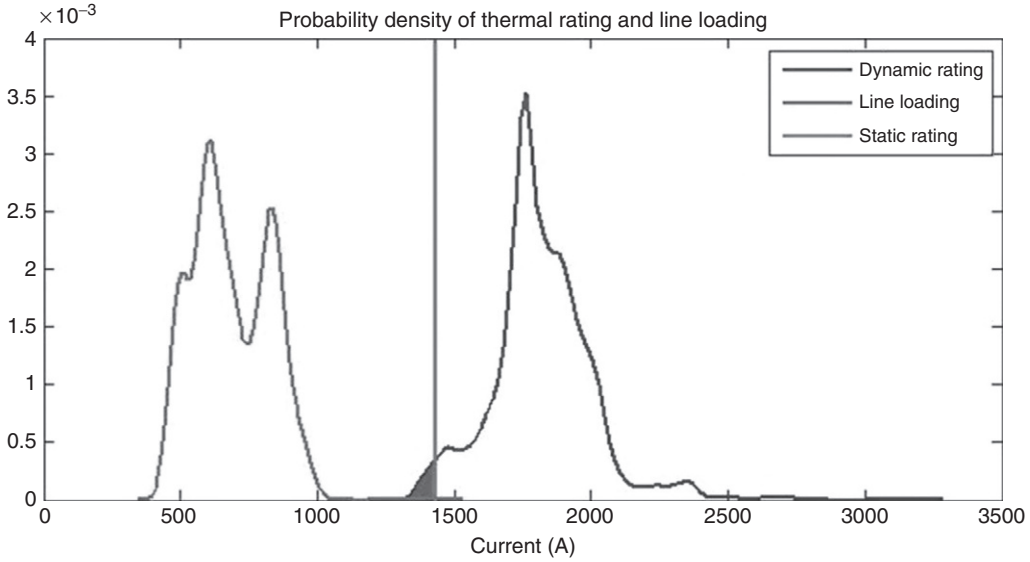

FIG. 26.18 Probability density plot of the dynamic thermal rating and line loading of a transmission line in Malaysia.

V_{L-G} = crest value of phase-to-ground overvoltage
V_m = maximum rms system voltage

This condition can be transient or permanent depending on its duration. Understanding overvoltage behavior including power-frequency phenomena and switching and lightning surges is important prerequisite condition in determining insulation coordination in a power system network.

The overvoltage phenomena are classified into four major classes [15]:

(a) Power-frequency overvoltages (also known as temporary overvoltages) that include Ferranti effect, self-excitation generator, overvoltage of unfaulted phases due to single-line-to-ground fault, and sudden load failure.
(b) Lower frequency harmonic resonant overvoltages that include lower order frequency resonance and local area resonant overvoltages.
(c) Switching surges that include breaker closing overvoltages, breaker tripping overvoltages, and switching surges by line switches
(d) Overvoltages by lightning strikes direct to phase conductors (direct flashover) and direct stroke to overhead shield wire or to tower structure (back flashover) or induced flashovers.
(e) Overvoltages due to abnormal conditions such as interrupted ground fault of cable, overvoltages induced on cable sheath, or touching of different kilovolts line.

In this chapter, the emphasis is given on overvoltages due to lightning strikes and switching surges and temporary overvoltages that have great impact in the selection of insulation requirements for transmission lines.

26.8.1 Overvoltage Phenomena by Lightning Strikes

By definition, lightning is an electric discharge. It is the high-current discharges of an electrostatic electricity accumulation between thundercloud and ground (cloud-to-ground discharges) or within the thundercloud (intracloud discharges). Other types of discharges such as cloud-to-cloud lightning and cloud-to-air lightning also exist but not very frequent. The thunderclouds contain ice crystals that are positively charged upper portion and water droplets that are negatively charged, usually located at lower portion of the thundercloud. The vertical circulation in terms of updrafts and downdrafts due to height and temperature effects caused disposition of charges in the thunderclouds (Fig. 26.19).

The mechanism of a lightning stroke is typically explained as follows. As the negative charges build up in the cloud base, positive charges are induced on the ground. When the voltage gradient within the cloud build up to the order of $5-10\text{kV/cm}$, the ionized air breaks down and creates an ionized path (leader) moving from thundercloud to ground. This initial leader progresses by series of jumps called a stepped leader. As this stepped leader (or downward leader) nears the ground, the upward leader (or return stroke) is initiated that meets the downward leader. This return stroke propagates upward from the ground to the thundercloud following the same path, at the speed of 10%–30% that of light, which is visible to the naked eye. The current involved may exceed 200 kA and lasting about 100 μs The second leader called dart leader may stroke following the same path taken by the first leader, about 40 μs later. The process of dart leader and return stroke can be repeated several times. The complete process of successive strokes are called lightning flash.

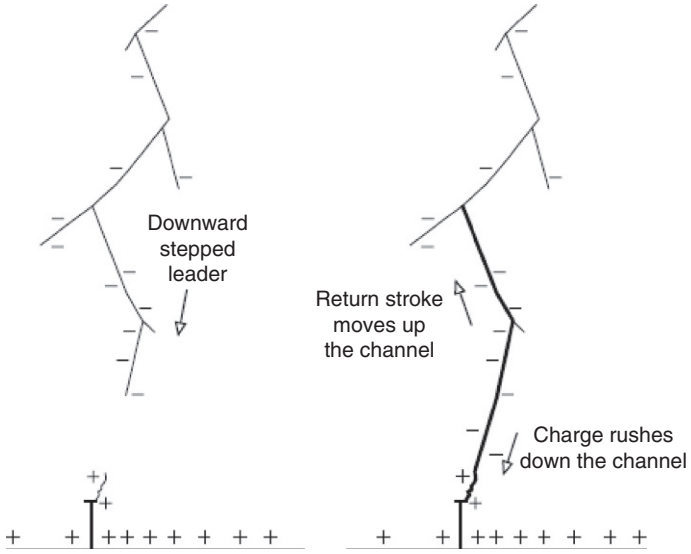

FIG. 26.19 Cloud-to-ground lightning.

Lightning surge phenomena can be classified into three different stroke modes: (a) direct strike on phase conductors (direct flashover), (b) direct strike on shield wire or tower structure, and (c) induced strokes.

In the case of direct strike, the lightning current path is directly from the thundercloud to the line. This will cause the voltage to rise at stroke termination point, on either one phase or more phase conductors. The stroke current propagates in the form of a traveling wave in both directions and raises potential of the line to the voltage of the downward leader. Overvoltage may exceed the line-to-ground withstand voltage of line insulation and cause insulation failure, if not properly protected.

In the case of direct strike on shield wire or tower structure, a lightning stroke directly strikes the shield wire or tower structure. If lightning strikes a tower top, some of the current may flow through the shield wires, and the remaining current flows through the tower to the earth. For stroke with average current magnitude and rate of rise, the current may flow into the ground provided the tower and its footing resistance are low. Otherwise, the lightning current will raise the tower to a high voltage above the ground, causing flashover from the tower over the line insulators to one or more phase conductors.

In induced strokes, lightning strokes terminate at some point on the Earth at a short distance from a transmission line. This can be considered as a virtual wire connected to a cloud and an earth point and a surge current $I(t)$ flowing along the virtual wire. This wire has mutual capacitances and mutual inductances across the line conductors and the shield wires of the neighborhood transmission lines. In this regard, the capacitive induced voltages and inductive induced voltage appear on the phase conductors and on the shield wires [15].

The insulation for lines is composed of air and solid dielectric insulators. The geometry of the insulators and their insulation strengths is selected to ensure that if an insulation failure occurs, the failure will be a flashover in air. This flashover produces a low-impedance path through which 50 Hz power current will flow. Generally, these arcs are not self-extinguishing. To interrupt the power fault, a protective device (circuit breaker) operating to de-energize the circuit will be required. Four types of lightning-caused flashover can occur on transmission lines: back flashover, shielding failure, induced, or midspan.

A back flashover event can occur when lightning strikes a grounded conductor or structure. In this case, a flashover proceeds backward from tower metal to the insulated conductor. A lightning stroke, terminating on an overhead ground wire or shield wire, produces waves of current and voltage that travel along the shield wire. At the tower/pole, these waves are reflected back toward the struck point and are transmitted down the tower/pole toward the ground and outward onto the adjacent shield wires. Riding along with these surge voltages are other surge voltages coupled onto the phase conductors. These waves continue to be transmitted and reflected at all points of impedance discontinuity. The surge voltages are built up at the tower/pole, across the phase-ground insulation, across the air insulation between phase conductors, and along the span across the air insulation from the shield wire to the phase conductor. If this surge voltage exceeds the insulation strength, flashover occurs. The parameters that affect the line back flashover rate (BFR) are the following:

- Ground flash density
- Surge impedances of the shield wires and tower/pole
- Coupling factors between conductors
- Power-frequency voltage

- Tower and line height
- Span length
- Insulation strength
- Footing resistance and soil composition

Sometimes, the design engineer can vary the shield wire surge impedance and the coupling factors, for example, using two shield wires instead of one. Normally, only insulation and footing impedance can be varied to improve back flashover performance. Reducing the footing impedance directly reduces the voltage stress across the insulator for a given surge current down the tower.

A shielding failure is defined as a lightning stroke that terminates on a phase conductor. For an unshielded line, all strokes to the line are shielding failures. For a transmission line with overhead shield wires, most of the lightning strokes that terminate on the line hit the shield wire and are not considered shielding failures.

The calculated number of shielding failures for a particular transmission line model depends on a number of factors, including the model's electrogeometric parameters, the stroke current distribution, and natural shielding from trees, terrain, or buildings. Not all shielding failures will result in insulator flashover. The critical current is defined as the lightning stroke current that, injected into the conductor, will result in flashover. The critical current for a particular transmission line conductor is calculated by

$$I_c = \frac{2^*(CFO)}{Z}$$

where CFO is the lightning impulse negative polarity critical flashover voltage and Z is the conductor surge impedance.

Severe transient overvoltage can be induced on overhead power lines by nearby lightning strikes. On lower voltage distribution power lines, indirect lightning strikes cause the majority of lightning-related flashovers. Estimation of indirect lightning effects is crucial for proper protection and insulation coordination of overhead lines. The problem of induced flashovers from nearby lightning strikes has received a great deal of scientific attention in the past 20 years, and the result has been the development of more accurate estimation models of lightning-induced overvoltages.

Important points to remember when dealing with induced flashovers from nearby lightning strokes include the following:

- Insulator CFO voltages above approximately 400 kV prevent nearly all induced flashovers.
- The presence of an effectively grounded overhead shield wire or neutral on the line will reduce insulator voltages by 30%–40%, depending on the line configuration.
- Line surge arresters installed every few spans can improve induced flashover performance for distribution voltage lines (spacing line arresters in this manner will seldom improve direct stroke lightning performance, only induced flashovers, and it is not recommended for transmission lines).

Power line flashovers caused by lightning strokes near midspan are unusual for most line configurations. Midspan flashovers become more likely when midspan conductor spacing is small, such as on-distribution lines, or when span lengths are very long (304.8 m or more). The voltage on a conductor follows the equation presented for a shielding failure. If the voltage rises to approximately 610 kV/m in the air gap between conductors, a long, relatively slow breakdown process might occur that might take many microseconds to complete.

26.8.2 Switching Surges

Switching surges can occur during the operation of circuit breaker and line switch opening (tripping) and closing at the same substation. In general, switching surges occur in the vicinity of non-self-restoring insulation equipment such as generators, transformers, breakers, and cables. Overvoltages caused by switching surges are a concern since they can damage insulation or cause insulation flashover. Damage and flashovers often lead to power system outage that is highly undesirable. The amplitude of a typical switching surge is about 1.5 pu with duration of about one power-frequency cycle [16].

26.8.3 Temporary Overvoltage

A temporary overvoltage is an oscillatory phase-to-ground overvoltage that is of relatively long duration and is undamped or only weakly damped. These types of overvoltages usually originate from faults, sudden changes of load, Ferranti effect, linear resonance, ferroresonance, open conductors, induced resonance from couple circuits, and others (e.g., backfeeding and stuck pole). In general, temporary overvoltage has two important characteristics: They are determinable, and they persist for many cycles. The magnitudes of these voltages may be calculated by steady-state analysis, assuming the physical conditions on the system are known.

26.9 Methods of Controlling Overvoltages

There are several means for controlling the overvoltages that occur on transmission system. Overvoltages due to switching surges can be controlled by modifying the operation of a circuit breaker or other switching device in various ways. The overvoltage may be limited to an acceptable level with the installation of surge arresters at the specific locations to be protected. The transmission system may be changed to minimize the effect of switching operations.

It is clear that if the source of the overvoltage is a random event such as lightning or fault initiation, the only sure method of controlling overvoltage will be the use of surge arresters or similar protective devices. In lightning protection

design, two aspects are important to consider: (i) diversion and shielding, mainly for structural protection that also provides reduction of electric and magnetic fields within the structure, and (ii) limiting the currents and voltages on electronic, power, and communication systems through surge protection. For the latter, the protection must include the control of currents and voltages from direct strikes to the structure and from lightning-induced current and voltage surges propagating into the structure from aerial or buried conductors from outside. Four general types of current- and voltage-limiting technique are commonly used [17] which are as follows:

(a) Voltage crowbar devices such as gas-tube arresters, silicon-controlled rectifiers (SCRs), and triacs that limit overvoltages to values smaller than operating voltages and short-circuit the current to ground.
(b) Voltage clamps such as metal oxide varistors (MOVs), Zener diodes, and p-n junction transistors. These solid-state nonlinear devices reflect and absorb energy while clamping the applied voltage across terminals to 30%–50% above the system operating voltage.
(c) Circuit filters that are linear circuits that both reflect and absorb the frequencies contained in the lightning transient pulses.
(d) Isolating devices such as optical isolators and isolation transformers suppress relatively large transients.

Reduction of basic impulse insulation levels of transmission equipment is possible with the use of surge arresters. Arresters are primarily used to protect the system insulation from the effects of lightning. Nowadays, modern arresters can also control many other system surges that may be caused by switching or faults. Arresters provide indispensable aid to insulation coordination in electric power system. It has basically a nonlinear resistor so that its resistance decreases rapidly as the voltage across it rises. At the surge ends and the voltage across the arrester returns to the normal line-to-neutral voltage level, the resistance becomes high enough to limit the arc current to a value that can be quenched by the series gap of the arrester.

Surge arresters may be used to control temporary overvoltages, such as due to a fault. It may be able to protect the equipment for the short time it takes to clear the applicable breakers. Similarly, surge arresters may be used to control switching surge overvoltages along a transmission line and thus reduce the length of required insulator strings. For example, the use of metal oxide arresters at the receiving end of a 280 km line can reduce the switching overvoltage along the line from a maximum of 2.2 to 1.8 pu.

26.10 Insulation Coordination

Insulation coordination is the selection of the insulation strength [18]. The strength is selected on the basis of some quantitative or perceived degree of reliability. It is also important to know the stress placed on the insulation and methods to reduce the stress, be it through surge arresters or other means. There are three different voltage stresses to consider when determining insulation and electric clearance requirements for the design of high-voltage transmission lines: (i) the power-frequency voltage, (ii) lightning surge, and (iii) switching surge. In general, lightning surges have the highest value and the highest rates of voltage rise. Properly done insulation coordination provides assurance that the insulation used will withstand all normal discharge and a majority of abnormal discharges. Several terms used in insulation coordination are defined as follows.

The basic lightning impulse insulation level (BIL) is defined as the electric strength of insulation expressed in terms of the crest value of the "standard lightning impulse" [18]. The BILs are universally for dry conditions. It is determined by tests made using impulses of a 1.2/50-μs waveshape. Several tests are performed, and a number of flashovers are noted.

The basic lightning impulse insulation level (BSL) is the electric strength of insulation expressed in terms of the crest value of a standard switching impulse. BSLs are universally for wet conditions.

Withstand voltage is the highest voltage that the insulation can withstand without failure or disruptive discharge, under specified test conditions. It is a common practice to assign a specific testing waveshape and duration of its application to each category of overvoltage.

There are two major categories of insulation: external insulation is the distances in open air or across the surfaces of solid insulation in contact with open air that is subjected to dielectric stress and to the effects of the atmosphere. Most transmission line insulation is external insulation. Internal insulation is the internal solid, liquid, or gaseous parts of the insulation of equipment that are protected by the equipment enclosures from the effects of the atmosphere such as in a transformer.

Insulation can also be divided into self-restoring and non-self-restoring categories. Self-restoring insulation completely recovers its insulating properties after a disruptive discharge. Non-self-restoring insulation loses insulation properties or does not recover completely after a disruptive discharge. Most external insulation, such as external air gap, is self-restoring insulation, and most internal insulation, such as solid insulation in a transformer, is non-self-restoring insulation. Insulation failure consequences are different for the different categories. Failure of non-self-restoring internal insulation is catastrophic, while failure of external self-restoring insulation may only be a nuisance. Testing may be done after a disruptive discharge for self-restoring internal insulation that provides statistical data for examination.

Insulation coordination involves the following processes: (i) determination of line insulation, (ii) selection of BIL and insulation levels of other equipment, and (iii) selection of lightning arresters. To assist this process, standard insulation levels

are recommended such as in IEC Publication 71.1 "Insulation Coordination Part 1, Definitions, Principles and Rules," 1993–12.

Knowledge of the overvoltages that the system will be exposed may be gained in two general ways: by measurement on the real system or by analysis on related models. Field measurement on a real system can only be done after the system is built. Analytic method can be used to determine the magnitude of overvoltages. The transient behavior of a complex transmission system must be studied through models either analog or digital. Transient network analyzer is an example on an analog model. For transmission lines below 345 kV, the line insulation is determined by lightning flashover rate. At 345 kV, the line insulation may be dictated either by switching surge or by lightning flashover rate. Above 345 kV, switching surges become a major factor in flashover considerations. The probability of flashover due to a switching surge is a function of the line characteristics and the magnitude of the surges expected. The number of insulators may be selected to keep the probability of flashovers due to switching surge very low.

In the design of substation, the maximum switching surge level used is either the maximum surge that can take place in the system or the protective level of arresters. In this case, the insulation coordination in a substation involves the selection of the minimum arrester rating applicable to withstand the power-frequency voltage and the equipment insulation level to be protected by arresters.

27.1 Introduction

High-voltage direct current (HVDC) transmission [1–3] is a major user of power electronics technology. HVDC technology first made its mark in the early undersea cable interconnections of Gotland (1954) and Sardinia (1967) and then in long-distance transmission with the Pacific Intertie (1970) and Nelson River (1973) schemes using mercury-arc valves. A significant milestone development occurred in 1972 with the first back-to-back (BB) asynchronous interconnection at Eel River between Quebec and New Brunswick; this installation also marked the introduction of thyristor valves to the technology and replaced the earlier mercury-arc valves.

Until 2005, a total of 70,000 MW HVDC transmission capacity is installed in some 95 projects all over the world. To understand the rapid growth of DC transmission (Table 27.1) [4] in the past 50 years, it is first necessary to compare it to conventional AC transmission.

27.1.1 Comparison of AC-DC Transmission

Making a planning selection between either AC or DC transmission is based on an evaluation of transmission costs, technical considerations, and reliability/availability offered by the two power transmission alternatives.

27.1.1.1 Evaluation of Transmission Costs

The cost of a transmission line comprises the capital investment required for the actual infrastructure (i.e., right of way (RoW), towers, conductors, insulators, and terminal equipment) and costs incurred for operational requirements (i.e., losses). Assuming similar insulation requirements for peak voltage levels for both AC and DC lines, a DC line can carry as much power with two conductors (having positive/negative polarities with respect to ground) as an AC line with three conductors of the same size. Therefore, for a given power level, a DC line requires a smaller RoW, simpler and cheaper towers, and reduced conductor and insulator costs. As an example, Fig. 27.1 shows the comparative case of AC and DC systems carrying 2000 MW.

With the DC option, since there are only two conductors (with the same current capacity of three AC conductors), the power transmission losses are also reduced to about two-thirds of the comparable AC system. The absence of skin effect with DC is also beneficial in reducing power losses marginally, and the dielectric losses in the case of power cables are also very much less for DC transmission.

Corona effects tend to be less significant on DC than for AC conductors. The other factors that influence line costs are the costs of compensation and terminal equipment. DC lines do not require reactive power compensation, but the terminal equipment costs are increased due to the presence of converters and filters.

Fig. 27.2 shows the variation of infrastructure costs with distance for AC and DC transmission. AC tends to be more economical than DC for distances less than the "break-even distance" but is more expensive for longer distances. This is due to a combination of the terminal equipment costs and line costs for the two types of transmission. The break-even distances can vary from about 500 to 800 km in overhead lines depending on the per unit line costs. With a cable system, this break-even distance approaches 50 km.

27.1.1.2 Evaluation of Technical Considerations

Due to its fast controllability, a DC transmission system has full control over transmitted power, an ability to enhance transient and dynamic stability in associated AC networks and can limit fault currents in the DC lines. Furthermore, DC transmission overcomes some of the following problems associated with AC transmission:

- Stability limits

  The power transfer in an AC line is dependent on the angular difference between the voltage phasors at the two line ends. For a given power transfer level, this angle increases with distance. The maximum power transfer is limited by the considerations of steady state and transient stability. The power-carrying capability of an AC line is inversely proportional to transmission distance, whereas the power-carrying ability of DC lines is unaffected by the distance of transmission.
- Voltage control

  Voltage control in AC lines is complicated by line-charging requirements and voltage drops. The voltage profile in an AC line is relatively flat only for a fixed level of power transfer, corresponding to its surge impedance loading (SIL). The voltage profile varies with the line loading. For constant voltage at the line ends, the midpoint voltage is reduced for line loadings higher than SIL and increased for loadings less than SIL.

  The maintenance of constant voltage at the two ends requires reactive power control as the line loading is

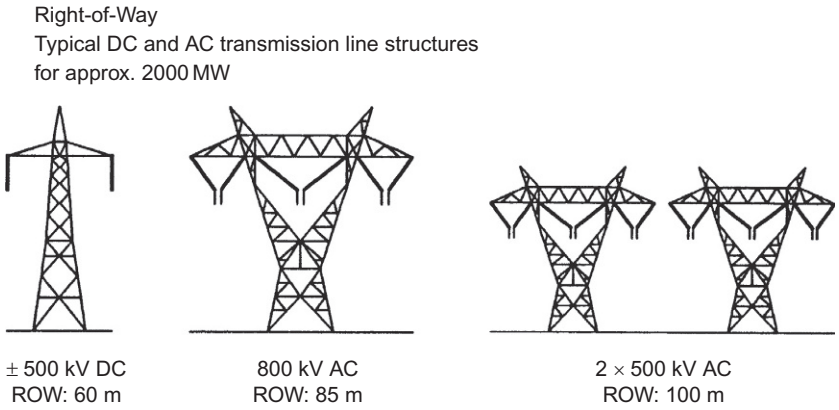

FIG. 27.1 Comparison of RoW for AC and DC transmission systems.

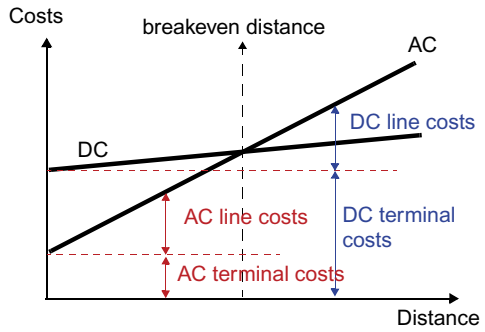

FIG. 27.2 Comparison of AC-DC transmission system costs.

increased. The reactive power requirements increase with line length.

Although DC converter stations require reactive power related to the power transmitted, the DC line itself does not require any reactive power.

The steady-state charging currents in AC cables pose serious problems and make the break-even distance for cable transmission around 50 km.

- Line compensation

  Line compensation is necessary for long-distance AC transmission to overcome the problems of line charging and stability limitations. The increase in power transfer and voltage control is possible through the use of shunt inductors, series capacitors, static var compensators (SVCs), and, lately, the new-generation static compensators (STATCOMs).

  In the case of DC lines, such compensation is not needed.

- Problems of AC interconnection

  The interconnection of two power systems through AC ties requires the automatic generation controllers of both systems to be coordinated using tie line power and frequency signals. Even with coordinated control of interconnected systems, the operation of AC ties can be problematic due to (i) the presence of large power oscillations that can lead to frequent tripping, (ii) increase in fault level, and (iii) transmission of disturbances from one system to the other.

  The fast controllability of power flow in DC lines eliminates all of the above problems. Furthermore, the asynchronous interconnection of two power systems can only be achieved with the use of DC links.

- Ground impedance

  In AC transmission, the existence of ground (zero sequence) current cannot be permitted in steady state due to the high magnitude of ground impedance that will not only affect efficient power transfer but also result in telephonic interference.

  The ground impedance is negligible for DC currents, and a DC link can operate using one conductor with ground return (monopolar operation). The ground return is objectionable only when buried metallic structures (such as pipelines) are present and are subject to corrosion with DC current flow. It is to be noted that even while operating in the monopolar mode, the AC network feeding the DC converter station operates with balanced voltages and currents. Hence, single-pole operation of DC transmission systems is possible for extended periods, while in AC transmission, single-phase operation or any unbalanced operation is not feasible for more than a second.

- Problems of DC transmission

  The application of DC transmission is limited by factors such as

  (1) high cost of conversion equipment,
  (2) inability to use transformers to alter voltage levels,
  (3) generation of harmonics,
  (4) requirement of reactive power,
  (5) complexity of controls.

  Over the years, there have been significant advances in DC technology, which have tried to overcome the disadvantages listed above, except for item (2). These are the following:

  (1) Increase in the ratings of a thyristor cell that makes up a valve
  (2) Modular construction of thyristor valves
  (3) Twelve-pulse operation of converters
  (4) Use of forced commutation
  (5) Application of digital electronics and fiber optics in the control of converters.

  Some of the above advances have resulted in improving the reliability and reduction of conversion costs in DC systems.

27.1.2 Evaluation of Reliability and Availability Costs

Statistics on the reliability of HVDC links are maintained by CIGRE and IEEE working groups. The reliability of DC links has been very good and is comparable with AC systems. The availability of DC links is quoted in the upper 90%.

27.1.3 Applications of DC Transmission

Due to their costs and special nature, most applications of DC transmission generally fall into one of the following four categories:

- Underground or underwater cables

  In the case of long cable connections over the break-even distance of about 40–50 km, DC cable transmission system has a marked advantage over AC cable connections. Examples of this type of applications were the Gotland (1954) and Sardinia (1967) schemes.

  The recent development of voltage-source converters (VSC) and the use of rugged polymer DC cables, with

the so-called "HVDC Light" option, are being increasingly considered. An example of this type of application is the 180-MW Directlink connection (2000) in Australia.

- Long-distance bulk power transmission

  Bulk power transmission over long distances is an application ideally suited for DC transmission and is more economical than AC transmission whenever the break-even distance is exceeded. Examples of this type of application abound from the earlier Pacific Intertie to the recent links in China and India.

  The break-even distance is being effectively decreased with the reduced costs of new compact converter stations possible due to the recent advances in power electronics (discussed in a later section).
- Asynchronous interconnection of AC systems

  In terms of an asynchronous interconnection between two AC systems, the DC option reigns supreme. There are many instances of BB connections where two AC networks have been tied together for the overall advantage to both AC systems. With recent advances in control techniques, these interconnections are being increasingly made at weak AC systems. The growth of BB interconnections is best illustrated with the example of N. America where the four main independent power systems are interconnected with 12 BB links.

  In the future, it is anticipated that this BB connection will also be made with VSCs offering the possibility of full four-quadrant operation and the total control of active/reactive power coupled with the minimal generation of harmonics.
- Stabilization of power flows in integrated power system

  In large interconnected systems, power flow in AC ties (particularly under disturbance conditions) can be uncontrolled and lead to overloading and stability problems, thus endangering system security. Strategically placed DC lines can overcome this problem due to the fast controllability of DC power and provide much needed damping and timely overload capability. The planning of DC transmission in such applications requires detailed study to evaluate the benefits. Examples are the IPP link in the United States and the Chandrapur-Padghe link in India.

Presently, the number of DC lines in a power grid is very small compared with the number of AC lines. This indicates that DC transmission is justified only for specific applications. Although advances in technology and introduction of multi-terminal DC (MTDC) systems are expected to increase the scope of application of DC transmission, it is not anticipated that the AC grid will be replaced by a DC power grid in the future. There are two major reasons for this. First, the control and protection of MTDC systems is complex, and the inability of voltage transformation in DC networks imposes economic penalties. Second, the advances in power electronics technology have resulted in the improvement of the performance of AC transmissions using FACTS devices, for instance, through introduction of static var systems, static phase shifters, etc.

27.1.4 Types of HVDC Systems

Three types of DC links are considered.

27.1.4.1 Monopolar Link

A monopolar link (Fig. 27.3A) has one conductor and uses either ground or sea return. A metallic return can also be used where concerns for harmonic interference and/or corrosion exist. In applications with DC cables (i.e., HVDC Light), a cable return is used. Since the corona effects in a DC line are substantially less with negative polarity of the conductor as compared with the positive polarity, a monopolar link is normally operated with negative polarity.

27.1.4.2 Bipolar Link

A bipolar link (Fig. 27.3B) has two conductors, one positive and the other with negative polarity. Each terminal has two sets of converters of equal rating, in series on the DC side. The junction between the two sets of converters is grounded at one or both ends by the use of a short electrode line. Since both poles operate with equal currents under normal operation, there is zero-ground current flowing under these conditions. Monopolar operation can also be used in the early stages of the development of a bipolar link. Alternatively, under faulty converter conditions, one DC line may be temporarily used as a metallic return with the use of suitable switching.

27.1.4.3 Homopolar Link

In this type of link (Fig. 27.3C), two conductors having the same polarity (usually negative) can be operated with ground or metallic return.

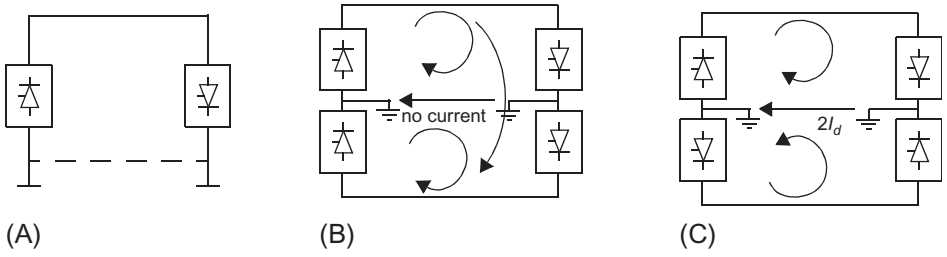

FIG. 27.3 Types of HVDC links: (A) monopolar link, (B) bipolar link, and (C) homopolar DC link.

Due to the undesirability of operating a DC link with ground return, bipolar links are mostly used. A homopolar link has the advantage of reduced insulation costs, but the disadvantages of earth return outweigh the advantages.

27.2 Main Components of HVDC Converter Station

The major components of an HVDC transmission system are the converter stations at the ends of the transmission system. In a typical two-terminal transmission system, both a rectifier and an inverter are required. The role of the two stations can be reversed as controls are usually available for both functions at the terminals. The major components of a typical 12-pulse bipolar HVDC converter station (Fig. 27.4) are discussed below.

27.2.1 Converter Unit

This usually consists of two three-phase converter bridges connected in series to form a 12-pulse converter unit. The design of valves is based on a modular concept where each module contains a limited number of series-connected thyristor levels. The valves can be packaged as either a single-valve, double-valve, or quadruple-valve arrangement. The converter is fed by converter transformers connected in star/star and star/delta arrangements to form a 12-pulse pair.

The valves may be cooled by air, oil, water, or Freon. However, the cooling using deionized water is more modern and considered efficient and reliable. The ratings of a valve group are limited more by the permissible short-circuit currents than by the steady-state load requirements.

Valve firing signals are generated in the converter control at ground potential and are transmitted to each thyristor in the valve through a fiber-optic light guide system. The light signal received at the thyristor level is converted to an electric signal using gate drive amplifiers with pulse transformers. Recent trends in the industry indicate that direct optical firing of the valves with LTT thyristors is also feasible.

The valves are protected using snubber circuits, protective firing, and gapless surge arrestors.

27.2.1.1 Thyristor Valves

Many individual thyristors are connected in series to build up an HVDC valve. To distribute the off-state valve voltage uniformly across each thyristor level and protect the valve from di/dt and dv/dt stresses, special snubber circuits are used across each thyristor level (Fig. 27.5).

The snubber circuit is composed of the following components:

- A saturating reactor is used to protect the valve from *di*/*dt* stresses during turn-on. The saturating reactor offers a high inductance at low current and a low inductance at high currents.
- A DC grading resistor R_G distributes the direct voltage across the different thyristor levels. It is also used as a voltage divider to measure the thyristor level voltage.
- RC snubber circuits are used to damp out voltage oscillations from power frequency to a few kHz.
- A capacitive grading circuit C_{FG} is used to protect the thyristor level from voltage oscillations at a much higher frequency.

A thyristor is triggered on by a firing pulse sent via a fiber-optic cable from the valve base electronics (VBE) unit at earth potential. The fiber-optic signal is amplified by a gate electronic unit (GEU) that receives its power from the RC snubber circuit during the valve's off period.

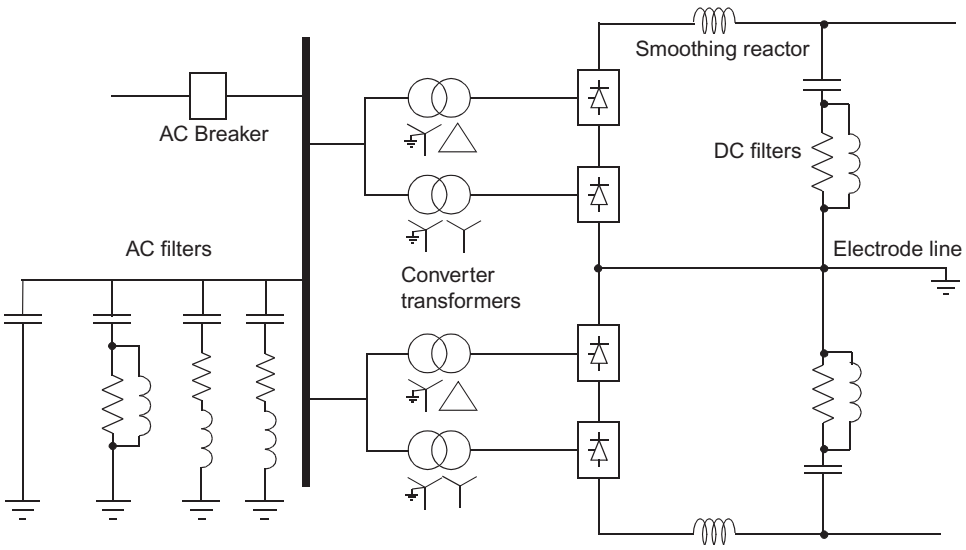

FIG. 27.4 Typical HVDC converter station equipment.

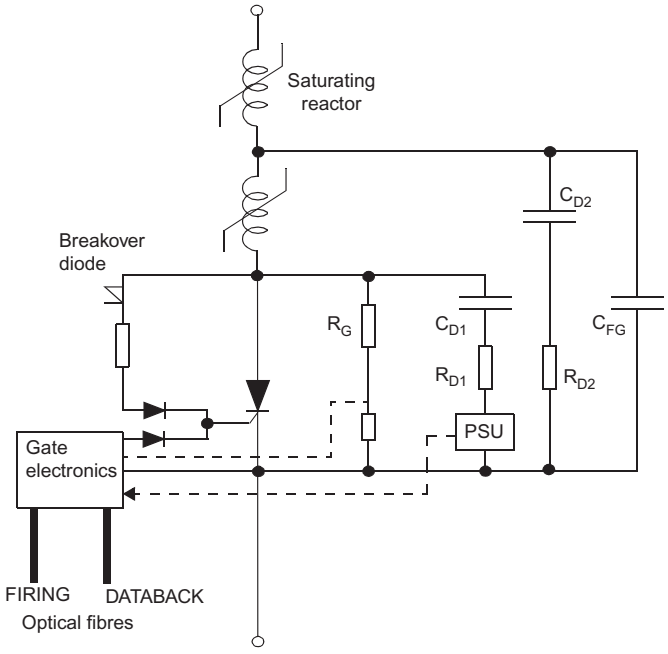

FIG. 27.5 Electric circuit of the thyristor level [2].

The GEU can also effect the protective firing of the thyristor independent of the central control unit. This is achieved by a breakover diode (BOD) via a current-limiting resistor that triggers the thyristor when the forward voltage threatens to exceed the rated voltage for the thyristor. This may arise in a case when some thyristors may block forward voltage, while others may not.

It is normal to include some extra redundant thyristor levels to allow the valve to remain in service after the failure of some thyristors. A metal oxide surge arrestor is also used across each valve for overvoltage protection.

The thyristors produce considerable heat loss, typically 24–40 W/cm^2 (or over 1 MW for a typical quadruple valve), and so, an efficient cooling system is essential.

27.2.2 Converter Transformer

The converter transformer (Fig. 27.6) can have different configurations: (i) three phase, two winding; (ii) single phase, three winding; and (iii) single phase, two winding. The valve-side windings are connected in star and delta with neutral point ungrounded. On the AC side, the transformers are connected in parallel with the neutral grounded. The leakage impedance of the transformer (typical value between 15% and 18%) is chosen to limit the short-circuit currents through any valve.

The converter transformers are designed to withstand DC voltage stresses and increased eddy current losses due to harmonic currents. One problem that can arise is due to the DC magnetization of the core due to unsymmetrical firing of valves.

27.2.3 Filters

Due to the generation of characteristic and noncharacteristic harmonics by the converter, it is necessary to provide suitable filters on the AC-DC sides of the converter to improve the

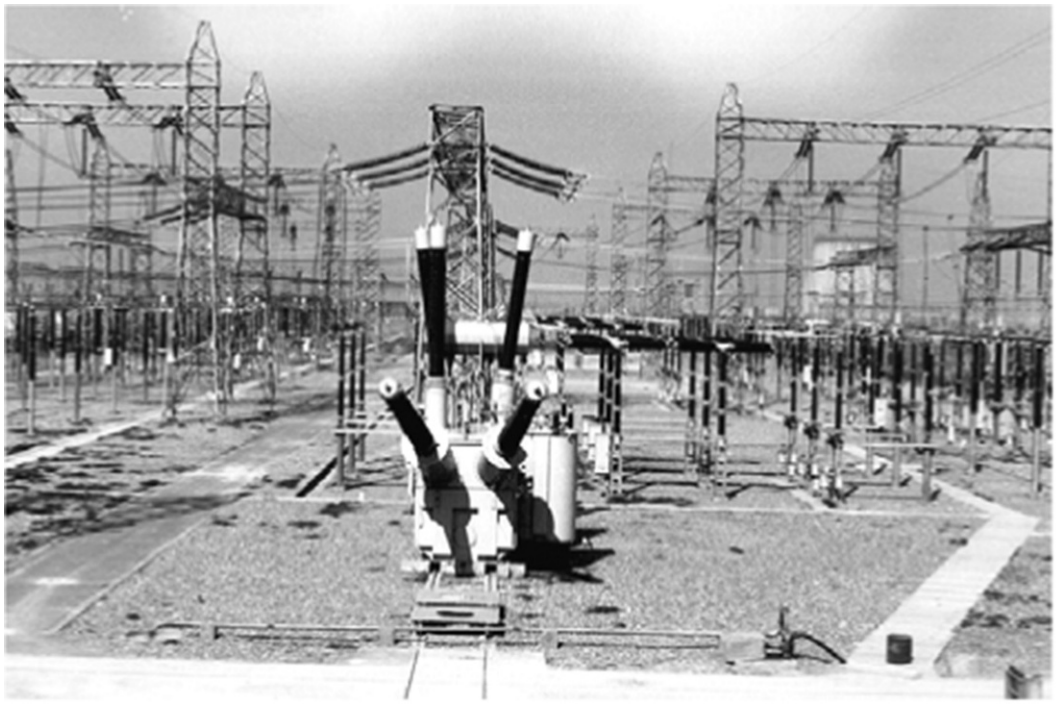

FIG. 27.6 Spare converter for multilevel convertertransformer in the switchyard of an HVDC station.

power quality and meet telephonic and other requirements. Generally, three types of filters are used for this purpose:

27.2.3.1 AC Filters

AC filters (Fig. 27.7) are passive circuits used to provide low impedance, shunt paths for AC harmonic currents. Both tuned and damped filter arrangements are used. In a typical 12-pulse station, filters at eleventh and thirteenth harmonics are required as tuned filters. Damped filters (normally tuned to the twenty-third harmonic) are required for the higher harmonics. In recent years, C-type filters have also been used since they provide more economic designs. Double- or even triple-tuned filters exist to reduce the cost of the filter (see application example system).

The availability of cost-effective active AC filters will change the scenario in the future.

27.2.3.2 DC Filters

These are similar to AC filters and are used for the filtering of DC harmonics. Usually, a damped filter at the twenty-fourth harmonic is utilized. Modern practice is to use active DC filters (see also the application example system presented later). Active DC filters are increasingly being used for efficiency and space-saving purposes.

27.2.3.3 High Frequency (RF/PLC) Filters

These are connected between the converter transformer and the station AC bus to suppress any high-frequency currents. Sometimes, such filters are provided on the high-voltage DC bus connected between the DC filter and DC line and also on the neutral side.

27.2.4 Reactive Power Source

Converter stations consume reactive power that is dependent on the active power loading (typically about 50%–60% of the active power). Part of this reactive power requirement is provided by the AC filters. In addition, shunt (switched) capacitors and static var systems are also used.

27.2.5 DC Smoothing Reactor

A sufficiently large series reactor is used on the DC side of the converter to smooth the DC current and for the converter protection from line surges. The reactor (Fig. 27.8) is usually

FIG. 27.7 Installation of an AC filter in the switchyard.

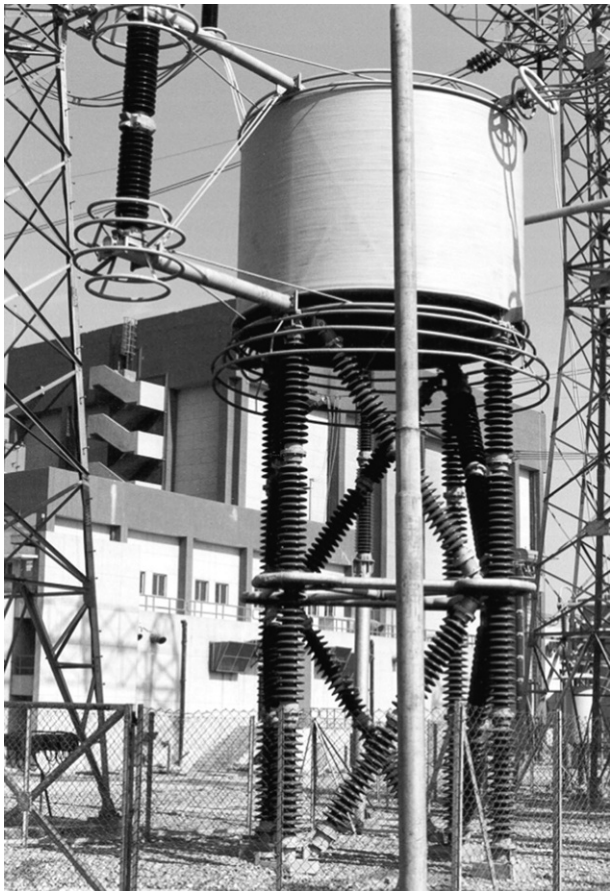

FIG. 27.8 Installation of an air-cooled smoothing reactor.

designed as a linear reactor and may be connected on the line side, on the neutral side, or at an intermediate location. Typical values of the smoothing reactor are in the 240–600 mH range for long-distance transmission and about 24 mH for a BB connection.

27.2.6 DC Switchgear

This is usually modified AC equipment and used to interrupt only small DC currents (i.e., employed as disconnecting switches). DC breakers or metallic return transfer breakers (MRTB) are used, if required, for the interruption of rated load currents.

In addition to the equipment described above, AC switchgear and associated equipment for protection and measurement are also part of the converter station.

27.2.7 DC Cables

Contrary to the use of AC cables for transmission, DC cables do not have a requirement for continuous charging current. Hence, the length limit of about 50 km does not apply. Moreover, DC voltage gives less aging and hence a longer lifetime for the cable. The new design of HVDC Light cables from ABB is based on extruded polymeric insulating material instead of classic paper-oil insulation that has a tendency to leak. Due to their rugged mechanical design, flexibility, and low weight, polymer cables can be installed underground cheaply with a plowing technique or, in submarine applications, can be laid in very deep waters and on rough sea bottoms. Since DC cables are operated in bipolar mode, one cable with positive polarity and one cable with negative polarity, very limited magnetic fields result from the transmission. HVDC Light cables have successfully achieved operation at a stress of 20 kV/mm.

27.3 Analysis of Converter Bridge

To consider the theoretical analysis of a conventional six-pulse bridge (Fig. 27.9), the following assumptions are made:

- DC current I_d is considered constant.
- Valves are ideal switches.
- AC system is strong (infinite).

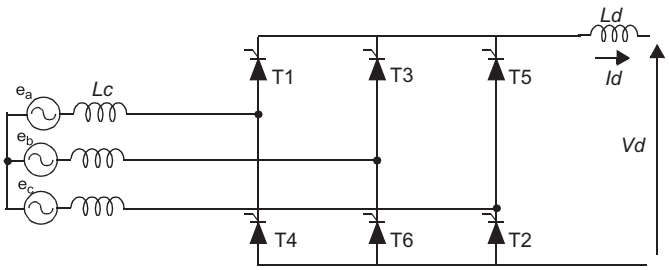

FIG. 27.9 Six-pulse bridge circuit.

Due to the leakage impedance of the converter transformer, commutation from one valve to the next is not instantaneous. An overlap period is necessary, and depending on the leakage, either two, three, or four valves may conduct at any time. In the general case, with a typical value of converter transformer leakage impedance of about 13%–18%, either two or three valves conduct at any one time.

The analysis of the bridge gives the following DC output voltages:

For a rectifier:

$$V_{dr} = V_{dor} \cdot \cos\alpha - R_{cr} \cdot I_d \tag{27.1}$$

where $V_{dor} = \frac{3}{\pi} \cdot \sqrt{2} \cdot V_{LL}$ and $R_{cr} = \frac{3}{\pi} \cdot wL_{cr}$.

For an inverter:

There are two options possible depending on choice of the delay angle or extinction angle as the control variable:

$$-V_{di} = V_{doi} \cdot \cos\beta + R_{ci} \cdot I_d \tag{27.2}$$

$$-V_{di} = V_{doi} \cdot \cos\gamma - R_{ci} \cdot I_d \tag{27.3}$$

where

V_{dr} and V_{di}—DC voltage at the rectifier and inverter, respectively
V_{dor} and V_{doi}—open-circuit DC voltage at the rectifier and inverter, respectively
R_{cr} and R_{ci}—equivalent commutation resistance at the rectifier and inverter, respectively
L_{cr} and L_{ci}—leakage inductance of converter transformer at rectifier and inverter, respectively
I_d—DC current
α—delay angle
β—advance angle at the inverter ($\beta = \pi - \alpha$)
γ—extinction angle at the inverter ($\gamma = \pi - \alpha - \mu$)

27.4 Controls and Protection

In a typical two-terminal DC link connecting two AC systems (Fig. 27.10), the primary functions of the DC controls are to

- control power flow between the terminals,
- protect the equipment against the current/voltage stresses caused by faults,

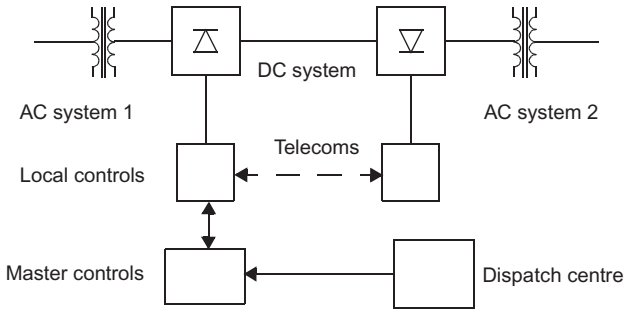

FIG. 27.10 Typical HVDC system linking two AC systems.

- stabilize the attached AC systems against any operational mode of the DC link.

The DC terminals each have their own local controllers. A centralized dispatch center will communicate a power order to one of the terminals that will act as a master controller and has the responsibility to coordinate the control functions of the DC link. Besides the primary functions, it is desirable that the DC controls have the following features:

- Limit the maximum DC current
  Due to a limited thermal inertia of the thyristor valves to sustain overcurrents, the maximum DC current is usually limited to less than 1.2 pu for a limited period of time.
- Maintain a maximum DC voltage for transmission
  This reduces the transmission losses and permits optimization of the valve rating and insulation.
- Minimize reactive power consumption
  This implies that the converters must operate at a low firing angle. A typical converter will consume reactive power between 50% and 60% of its MW rating. This amount of reactive power supply can cost about 15% of the station cost and comprise about 10% of the power loss.

The desired features of the DC controls are indicated below:

1. Limit maximum DC current—Since the thermal inertia of the converter valves is quite low, it is desirable to limit the DC current to prevent failure in the valves.
2. Maintain maximum DC voltage for transmission purposes to minimize losses in the DC line and converter valves.
3. Keep the AC reactive power demand low at either converter terminal. This implies that the operating angles at the converters must be kept low. Additional benefits of doing this are to reduce the snubber losses in the valves and reduce the generation of harmonics.
4. Prevent commutation failures at the inverter station and hence improve the stability of power transmission.
5. Other features, that is, the control of frequency in an isolated AC system or enhanced power system stability.

In addition to the above desired features, the DC controls will have to cope with the steady-state and dynamic requirements of the DC link, as shown in Table **27.2**.

TABLE 27.2 Requirements of the DC link

Steady-state requirements	Dynamic requirements
Limit the generation of noncharacteristic harmonics	Step changes in DC current or power flow
Maintain the accuracy of the controlled variable, that is, DC current and/or constant extinction angle	Start-up and fault-induced transients
Cope with the normal variations in the AC system impedances due to topology changes	Reversal of power flow
	Variation in frequency of attached AC system

TABLE 27.3 Choice of control strategy for two-terminal DC link

Condition No.	Desirable features	Reason	Control implementation
1	Limit the maximum DC current, I_d	For the protection of valves	Use constant current control at the rectifier
2	Employ the maximum DC voltage, V_d	For reducing power transmission losses	Use constant voltage control at the inverter
3	Reduce the incidence of commutation failures	For stability purposes	Use minimum extinction angle control at inverter
4	Reduce reactive power consumption at the converters	For voltage regulation and economic reasons	Use minimum firing angles

27.4.1 Basics of Control for a Two-Terminal DC Link

From converter theory, the relationship between the DC voltage V_d and DC current I_d is given by Eqs. (27.1)–(27.3). These three characteristics represent straight lines on the V_d-I_d plane. Notice that Eq. (27.2), that is, beta characteristic, has a positive slope, while the Eq. (27.3), that is, gamma characteristic, has a negative slope. The choice of the control strategy for a typical two-terminal DC link is made according to conditions in Table **27.3**.

Condition (27.1) implies the use of the rectifier in constant current control mode. And condition (27.3) implies the use of the inverter in constant extinction angle (CEA) control mode. Other control modes may be used to enhance the power transmission during contingency conditions depending upon applications. This control strategy is illustrated in Fig. 27.11.

The rectifier characteristic is composed of two control modes: alpha-min (line AB) and constant current (line BC). The alpha-min mode of control at the rectifier is imposed by the natural characteristics of the rectifier AC system and the ability of the valves to operate at alpha equal to zero, that is, in the limit, the rectifier acts as a diode rectifier. However, since a minimum positive voltage is desired before firing of the valves to ensure conduction, an alpha-min limit of about 2–5 degrees is typically imposed.

The inverter characteristic is composed of two modes: gamma-min (line PQ) and constant current (line QR). The operating point for the DC link is defined by the crossover point X of the two characteristics. In addition, a constant

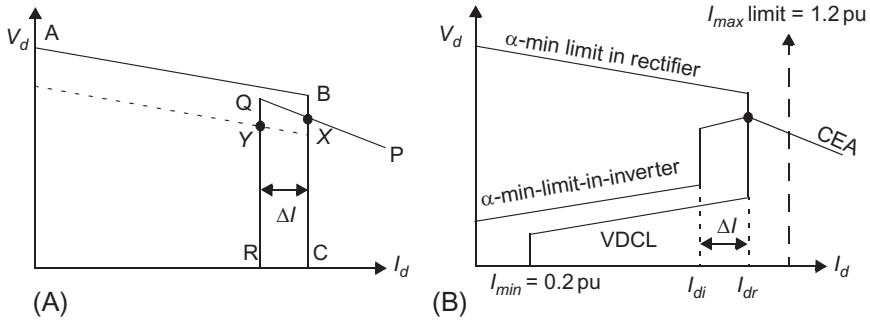

FIG. 27.11 Static V_d-I_d characteristic for a two-terminal link: (A) unmodified and (B) modified.

current characteristic is also used at the inverter. However, the current demanded by the inverter I_{di} is usually less than the current demanded by the rectifier I_{dr} by the current margin ΔI that is typically about 0.1 pu; its magnitude is selected to be large enough so that the rectifier and inverter constant current modes do not interact due to any current harmonics that may be superimposed on the DC current. This control strategy is termed the current margin method.

The advantage of this control strategy becomes evident if there is a voltage decrease at the rectifier AC bus. The operating point then moves to point Y. This way, the current transmitted will be reduced to 0.9 pu of its previous value, and voltage control will shift to the rectifier. However, the power transmission will be largely maintained near to 90% of its original value.

The control strategy usually employs the following other modifications to improve the behavior during system disturbances:

At the rectifier:

1. Voltage-dependent current limit, VDCL
   This modification is made to limit the DC current as a function of either the DC voltage or, in some cases, the AC voltage. This modification assists the DC link to recover from faults. Variants of this type of VDCL do exist. In one variant, the modification is a simple fixed value instead of a sloped line.
2. I_d-min limit
   This limitation (typically 0.2–0.3 pu) is to ensure a minimum DC current to avoid the possibility of DC current extinction caused by the valve current dropping below the hold-on current of the thyristors, an eventuality that could arise transiently due to harmonics superimposed on the low value of DC current. The resultant current chopping would cause high overvoltages to appear on the valves. The magnitude of I_d-min is affected by the size of the smoothing reactor employed.

At the inverter:

1. Alpha-min limit at inverter
   The inverter is usually not permitted to operate inadvertently in the rectifier region, that is, a power reversal occurring due to, say, an inadvertent current margin sign change. To ensure this, an alpha-min limit in inverter mode of about 100–110 degrees is imposed.
2. Current error region
   When the inverter operates into a weak AC system, the slope of the CEA control mode characteristic is quite steep and may cause multiple crossover points with the rectifier characteristic. To avoid this possibility, the inverter CEA characteristic is usually modified into either a constant beta characteristic or a constant voltage characteristic within the current error region.

27.4.2 Control Implementation

27.4.2.1 Historical Background

The *equidistant pulse firing control* systems used in modern HVDC control systems were developed in the mid-1960s [5,6]; although improvements have occurred in their implementation since then, such as the use of microprocessor-based equipment, their fundamental philosophy has not changed much. The control techniques described in Refs. [5,6] are of the *pulse frequency control* (PFC) type as opposed to the now-out-of-favor *pulse phase control* (PPC) type. All these controls use an independent *voltage-controlled oscillator* (VCO) to decouple the direct coupling between the firing pulses and the commutation voltage, V_{com}. This decoupling was necessary to eliminate the possibility of harmonic instability detected in the converter operation when the AC system capacity became nearer to the power transmission capacity of the HVDC link, that is, with the use of weak AC systems. Another advantage of the equidistant firing pulse controls was the elimination of noncharacteristic harmonics during steady-state operation. This was a prevalent feature during the use of the earlier *individual phase control* (IPC) system where the firing pulses were directly coupled to the commutation voltage, V_{com}.

27.4.2.2 Firing Angle Control

To control the firing angle of a converter, it is necessary to synchronize the firing pulses emanating from the ring counter to the AC commutation voltage that has a frequency of 60 Hz in steady state. However, it was noted quite early on (the early 1960s) that the commutation voltage (system) frequency is

not a constant, neither in frequency nor amplitude, during a perturbed state. However, it is the frequency that is of primary concern for the synchronization of firing pulses. For strong AC systems, the frequency is relatively constant and distortion free to be acceptable for most converter type applications. But as converter connections to weak AC systems became required more often than not, it was necessary to devise a scheme for synchronization purposes that would be *decoupled* from the commutation voltage frequency for durations when there were perturbations occurring on the AC system. The most obvious method is to utilize an *independent oscillator* at 60 Hz, which can be *synchronously locked* to the AC commutation voltage frequency. This oscillator would then provide the (phase) reference for the generation of firing pulses to the ring counter during the perturbation periods and would use the steady-state periods for locking in step with the system frequency. The advantage of this independent oscillator would be to provide an ideal (immunized and clean) sinusoid for synchronizing and timing purposes. There are two possibilities for this independent oscillator:

- Fixed-frequency operation
- Variable frequency operation

Use of a fixed-frequency oscillator (although feasible and called the pulse phase control oscillator) is not recommended, since it is known that the system frequency does drift, between say 55 and 65 Hz, due to the rotating machines used to generate electricity. Therefore, it is preferable to use a variable frequency oscillator (called the pulse frequency control oscillator) with a locking range of between 50 and 70 Hz and the center frequency of 60 Hz. This oscillator would then need to track the variations in the system frequency, and a control loop of some sort would be used for this tracking feature; this control loop would have its own gain and time parameters for steady-state accuracy and dynamic performance requirements.

The control loop for frequency tracking purposes would also need to consider the mode of operation for the DC link. The method widely adopted for DC-link operation is the so-called current margin method.

27.4.3 Control Loops

Control loops are required to track the following variables:

(a) The ordered current I_{or} at the rectifier and the inverter
(b) The ordered extinction angle (γ_o) at the inverter

27.4.3.1 Current Control Loops

In conventional HVDC systems, a PI regulator is used (Fig. 27.12) for the rectifier current controller. The rectifier plant system is inherently nonlinear and has a relationship given in Eq. (27.1). For constant I_d and for small changes in α, we have

$$\frac{\Delta V_d}{\Delta \alpha} = -V_{dor} \cdot \sin \alpha. \tag{27.4}$$

It is obvious from Eq. (27.4) that the maximum gain ($\Delta V_d/\Delta\alpha$) occurs when $\alpha = 90$ degrees. Thus, the control loop must be stabilized for this operation point, resulting in slower dynamic properties at normal operation with α within the range 12–18 degrees. Attempts have been made to linearize this gain and have met with some limited success. However, in practical terms, it is not always possible to have the DC link operating with the rectifier at 90 degrees due to harmonic generation and other protection elements coming into operation also. Therefore, optimizing the gains of the PI regulator can be quite arduous and take a long time. For this reason, the controllers are often pretested in a physical simulator environment to obtain approximate settings. Final (often very limited) adjustments are then made on-site.

Other problems with the use of a PI regulator are listed below:

- It is mostly used with fixed gains, although some possibility for gain scheduling exists.
- It is difficult to select optimal gains, and even then, they are optimal over a limited range only.
- Since the plant system is varying continually, the PI controller is not optimal.

A similar current control loop is used at the inverter (Fig. 27.13). Since the inverter also has a gamma controller, the selection between these two controllers is made via a MINIMUM SELECT block. Moreover, in order to bias the inverter current controller off, a current margin signal ΔI is subtracted from the current reference I_{or} received from the rectifier via a communication link.

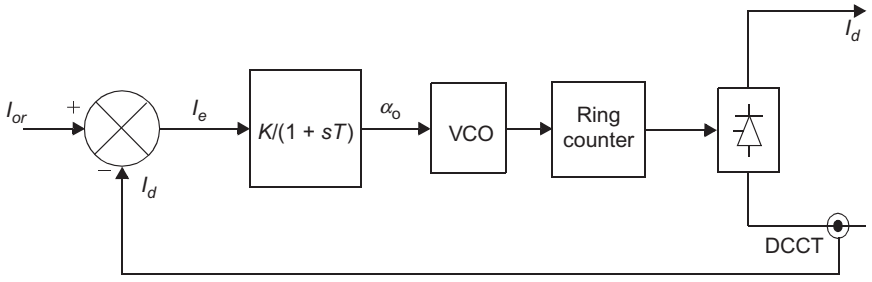

FIG. 27.12 Control loop for the rectifier.

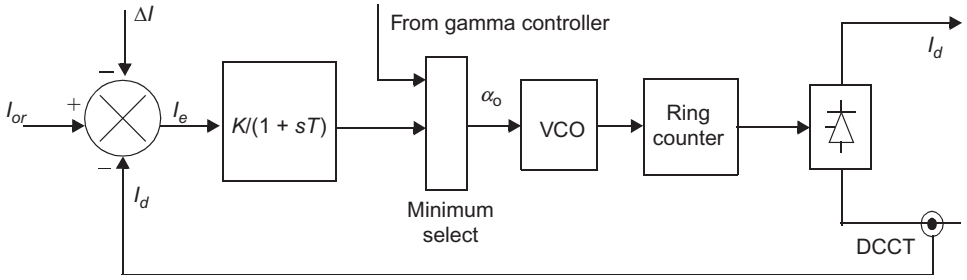

FIG. 27.13 Current controller at the inverter.

Telecommunication requirements

As was discussed above, the rectifier and inverter current orders must be coordinated to maintain a current margin of about 10% between the two terminals at all times; otherwise, there is a risk of loss of margin, and the DC voltage could run down. Although, it is possible to use slow voice communication between the two terminals and maintain this margin, the advantage of fast control action possible with converters may be lost for protection purposes. For maintaining the margin during dynamic conditions, it is prudent to raise the current order at the rectifier first followed by the inverter; in terms of reducing the current order, it is necessary to reduce at the inverter first and then at the rectifier.

27.4.3.2 Gamma Control Loop

At the inverter end, there are two known methods for the gamma control loop. The two variants are different only due to the method of determining the extinction angle:

- Predictive method for the indication of extinction angle (gamma)
- Direct method for actual measurement of extinction angle (gamma)

In either case, a delay of one cycle occurs from the indication of actual gamma and the reaction of the controller to this measurement. Since the avoidance of a commutation failure often takes precedence at the inverter, it is normal to use the minimum value of gamma measured for the 6 or 12 inverter valves for the converter(s).

1. *Predictive method of measuring gamma*

   The predictive measurement tries to maintain the commutation *voltage-time area after commutation* larger than a specified minimum value. Since the gamma prediction is only approximative, the method is corrected by a slow feedback loop that calculates the error between the predicted value and actual value of gamma (one cycle later) and feeds it back.

   The predictor calculates continuously, by a triangular approximation, the total available voltage-time area that remains after commutation is finished. Since an estimate of the overlap angle μ is necessary, it is derived from a well-known fact in converter theory that the overlap commutation voltage-time area is directly proportional to direct current and leakage impedance (assumed constant and known) value of the converter transformer.

   The prediction process is inherently of an individual phase firing character. If no further measures are taken, each valve would fire on the minimum margin condition. To counteract this undesired property, a special firing symmetrizer is used; when one valve has fired on the minimum margin angle, the following two or five valves fire equidistantly. (The choice of either two or five symmetrized valves is mainly a stability question.)

2. *Direct method of measuring gamma*

   In this method, the gamma measurement is derived from a measurement of the actual valve voltage. Waveforms of the gamma measuring circuit are shown in Fig. 27.13. An internal timing waveform, consisting of a ramp function of fixed slope, is generated after being initiated from the instant of anode current zero. This value corresponds to a direct voltage proportional to the last value of gamma. From the gamma values of all (either 6 or 12) valves, the smallest value is selected to produce the indication of measured gamma for use with the feedback regulator (Fig. 27.14).

   This value is compared with a gamma-ref value, and a PI regulator defines the dynamic properties for the controller. Inherently, this method has an individual phase control characteristic. One version of this type of control

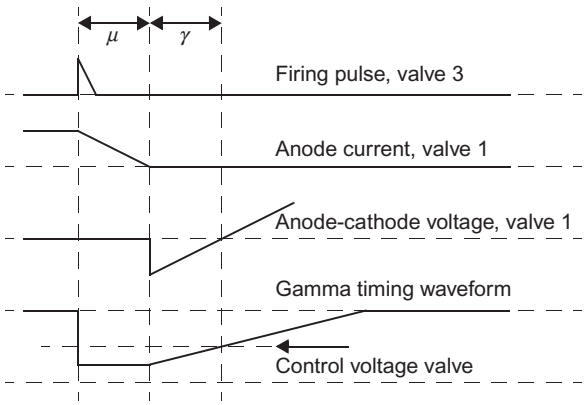

FIG. 27.14 Waveforms for the gamma measuring circuit [5].

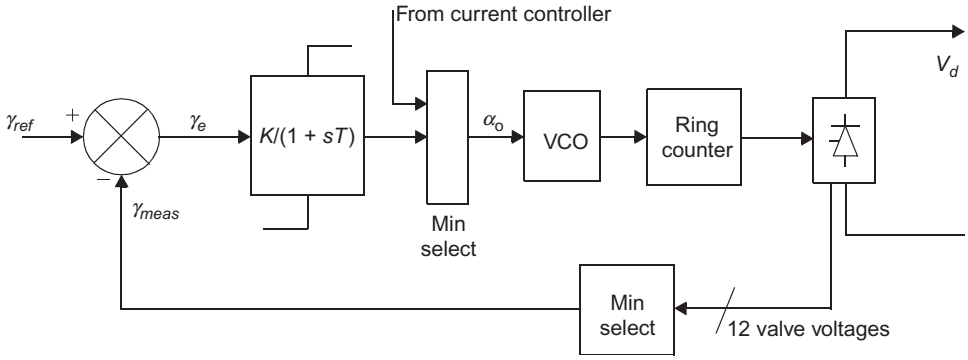

FIG. 27.15 Gamma feedback controller.

implementation overcomes this problem by using a symmetrizer for generating equidistant firing pulses. The 12-pulse circuit generates 12 gamma measurements; the minimum gamma value is selected and then used to derive the control voltage for the firing pulse generator with symmetrical pulses (Fig. 27.15).

27.4.4 Hierarchy of DC Controls

Since HVDC controls are hierarchical in nature, they can be subdivided into blocks that follow the major modules of a converter station (Fig. 27.16). The main control blocks are as follows:

1. The bipole (master) controller is usually located at one end of the DC link and receives its power order from a centralized system dispatch center. The bipole controller derives a current order for the pole controller using a local measurement of either AC or DC voltage. Other inputs may also be used by the bipole controller such as frequency control for damping or modulation purposes. A communication to the remote terminal of the DC link is also necessary to coordinate the current references to the link.
2. The pole controller then derives an alpha order for the next level. This alpha order is sent to both the positive and negative poles of the bipole.
3. The valve group controllers generate the firing pulses for the converter valves. Controls also receive measurements of DC current, DC voltage, and AC current into the converter transformer. These measurements assist in the rapid alteration of firing angle for protection of the valves during perturbations. A slow loop for control of tap-changer position as a function of alpha is also available at this level.

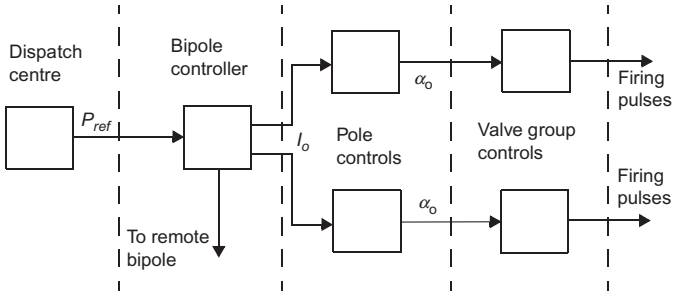

FIG. 27.16 Hierarchy of controllers.

27.4.5 Monitoring of Signals

As described earlier, monitoring of the following signals is necessary for the controls (Fig. 27.17) to perform their functions and assist in the protection of the converter equipment:

V_d and I_d—DC voltage and DC current, respectively,
I_{AC} and I'_{AC}—AC current on line side and converter side of the converter transformer, respectively,
V_{AC}—AC voltage at the AC filter bus.

27.4.6 Protection Against Over-Currents

Faults and disturbances can be caused by malfunctioning equipment or insulation failures due to lightening and pollution. First, these faults need to be detected with the help of monitored signals. Second, the equipment must be protected by control or switching actions. Since DC controls can react within one cycle, control action is used to protect equipment against overcurrent and overvoltage stresses and minimize loss of transmission. In a converter station, the valves are the most critical (and most expensive) equipment that need to be protected rapidly due to their limited thermal inertia.

The basic types of faults that the converter station can experience are the following:

- Current extinction (CE)

  CE can occur if the valve current drops below the holding current of the thyristor. This can happen at low-current operation accompanied by a transient leading to current extinction. Due to the phenomena of current chopping of an inductive current, severe overvoltages may result. The size of the smoothing reactor and the rectifier minimum current setting I_{min} helps to minimize the occurrence of CE.
- Commutation failure (CF) or misfire

  In line-commutated converters, the successful commutation of a valve requires that the extinction angle

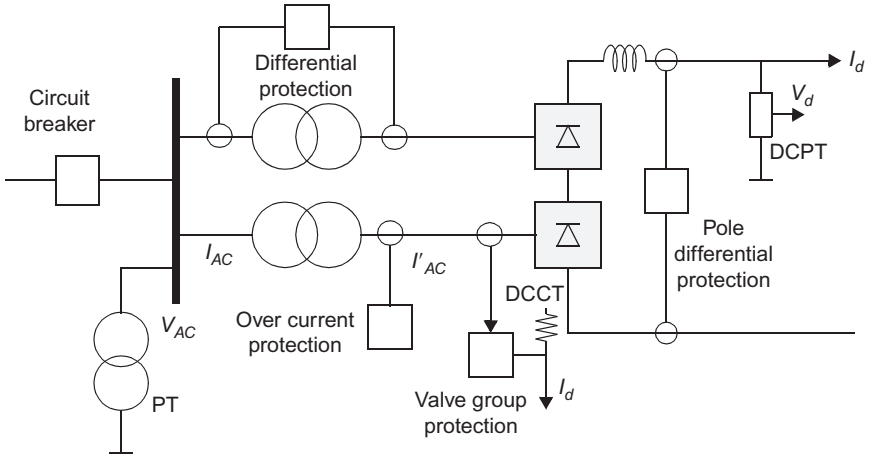

FIG. 27.17 Monitoring points for the protection circuits.

γ-nominal be maintained more than the minimum value of the extinction angle γ-min. Note that γ-nominal $= 180 - \alpha - \mu$. The overlap angle μ is a function of the commutation voltage and the DC current. Hence, a decrease in commutation voltage or an increase in DC current can cause an increase in μ, resulting in a decrease in γ-nominal. If γ-nominal $< \gamma$-min, a CF may result. In this case, the outgoing valve will continue to conduct current, and when the incoming valve is fired in sequence, a short circuit of the bridge will occur.

A missing firing pulse can also lead to a misfire (at a rectifier) or a CF (at an inverter). The effects of a single misfire are similar to those of a single CF. Usually, a single CF is self-clearing, and no special control actions are necessary. However, a multiple CF can lead to the injection of AC voltages into the DC system. Control action may be necessary in this case.

The detection of a CF is based on the differential comparison of DC current and AC currents on the valve side of the converter transformer. During a CF, the two valves in an arm of the bridge are conducting. Therefore, the AC current goes to zero, while the DC current continues to flow.

The protection features employed to counteract the impact of a CF are indicated in Table **27.4**.

- Short circuits—internal or DC line

  An internal bridge fault is rare as the valve hall is completely enclosed and is air-conditioned. However, a bushing can fail, or valve cooling water may leak resulting in a short circuit. The AC breaker may have to be tripped to protect against bridge faults.

  The protection features employed to counteract the impact of short circuits are indicated in Table **27.4**.

The fast-acting HVDC controls (which operate within one cycle) are used to regulate the DC current for protection of the valves against AC and DC faults.

The basic protection (Fig. 27.18) is provided by the VGP differential protection that compares the rectified current on the valve side of the converter transformer with the DC current measured on the line side of the smoothing reactor. This method is applied because of its selectivity possible due to high impedances in the smoothing reactor and converter transformer.

TABLE 27.4 Protection against overcurrents

Fault type	Occurrence	Fault current level	Protection method
Internal faults	Infrequent	10 pu	Valve is rated to withstand this surge
DC line faults	Frequent	2–3 pu	– Forced retard of firing angle – Dynamic VDCL deployment – Trip AC breaker CB after third attempt
Commutation failures (single or multiple)	Very frequent	1.5–2.5 pu	Single CF: – Self-clearing Multiple CF: – Beta angle advanced in stages – Static VDCL deployment

The OCP is used as a backup protection in case of malfunction in the VGP. The level of overcurrent setting is set higher than the differential protection.

The pole differential protection (PDP) is used to detect ground faults, including faults in the neutral bus.

27.4.7 Protection Against Over-Voltages

The typical arrangement of metal oxide surge arrestors for protecting equipment in a converter pole is shown in Fig. 27.18. In general, overvoltages entering from the AC bus are limited by the AC bus arrestors; similarly, overvoltages entering the converter from the DC line are limited by the DC arrestor. The AC and DC filters have their respective arrestors also. Critical

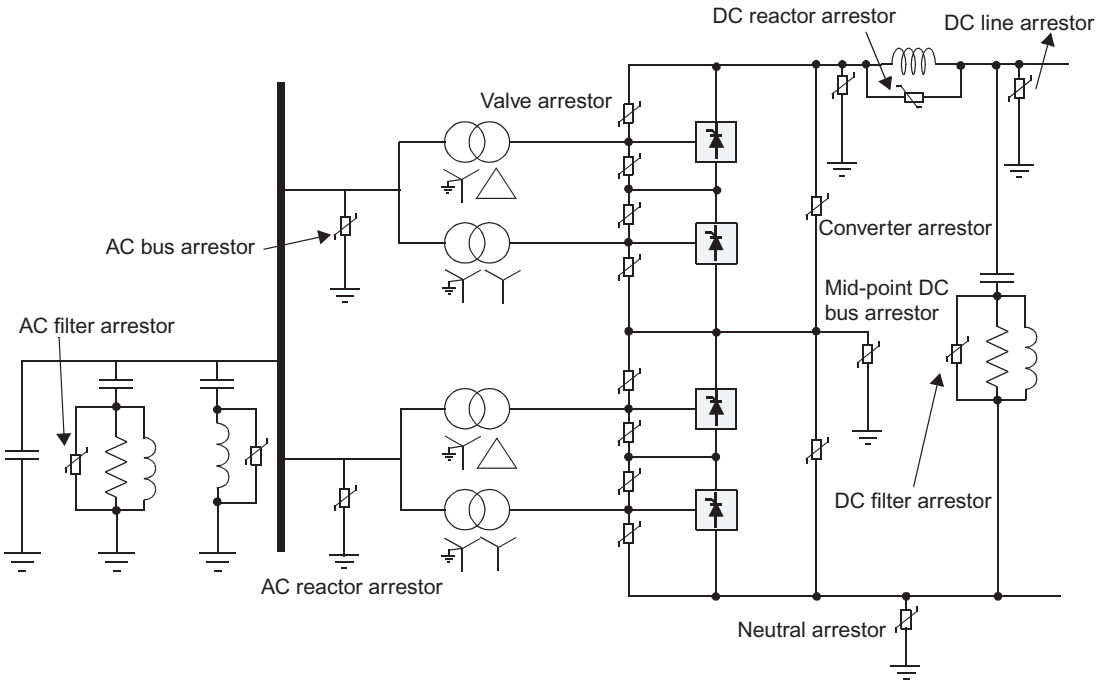

FIG. 27.18 Typical arrangement of surge arrestors for a converter pole.

components such as the valves have their own arrestors placed close to these components. The protective firing of a valve is used as a backup protection for overvoltages in the forward direction. Owing to their varied duty, these arrestors are rated accordingly for the location used. For instance, the converter arrestor for the upper bridge is subjected to a higher energy dissipation than for the lower bridge.

Since the evaluation of insulation coordination is quite complex, detailed studies are often required with DC simulators to design an appropriate insulation coordination strategy.

27.5 MTDC Operation

Most HVDC transmission systems are two-terminal systems. A multiterminal DC system (MTDC) has more than two terminals, and there are two existing installations of this type. There are two possible ways of tapping power from an HVDC link, that is, with series or parallel taps.

27.5.1 Series Tap

A monopolar version of a three-terminal series DC link is shown in Fig. 27.19. The system is grounded at only one suitable location. In a series DC system, the DC current is set by one terminal and is common to all terminals; the other terminals are operated at a constant delay angle for a rectifier and constant extinction angle for inverter operation with the help of transformer tap changers.

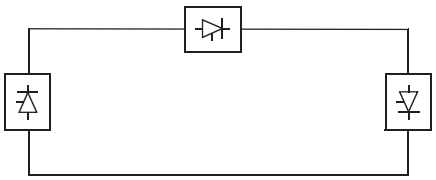

FIG. 27.19 Series tap.

Power reversal at a station is done by reversing the DC voltage with the aid of angle control.

No practical installation of this type exists in the world at present. From an evaluation of ratings and costs for series taps, it is not practical for the series tap to exceed 20% of the rating for a major terminal in the MTDC system.

27.5.2 Parallel Tap

A monopolar version of a three-terminal parallel DC link is shown in Fig. 27.20. In a parallel MTDC system, the system voltage is common to all terminals. There are two variants possible for a parallel MTDC system: radial or mesh. In a radial system, disconnection of one segment of the system will interrupt power from one or more terminals. In a mesh system, the removal of one segment will not interrupt power flow providing the remaining links are capable of carrying the required power.

Power reversal in a parallel system will require mechanical switching of the links as the DC voltage cannot be reversed.

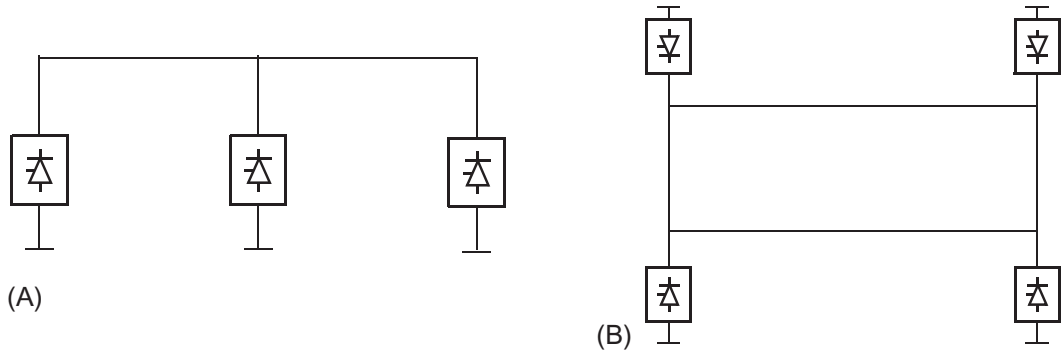

FIG. 27.20 Parallel tap: (A) radial type and (B) mesh type.

From an evaluation of ratings and costs for parallel taps, it is not practical for the parallel tap to be less than 20% of the rating for a major terminal in the MTDC system.

There are two installations of parallel taps existing in the world. The first is the Sardinia-Corsica-Italy link where a 50 MW parallel tap at Corsica is used. Since the principal terminals are rated at 200 MW, a commutation failure at Corsica can result in very high overcurrents (typically 7 pu); for this reason, large smoothing reactors (2.5 H) are used in this link.

The second installation is the Quebec-New Hampshire 2000 MW link where a parallel tap is used at Nicolet. Since the rating of Nicolet is at 1800 MW, the size of the smoothing reactors was kept to a modest size.

27.5.3 Control of MTDC System

Although several control methods exist for controlling MTDC systems, the most widely utilized method is the so-called current margin method that is an extension of the control method used for two-terminal DC systems.

In this method, the voltage setting terminal (VST) operates at the angle limit (minimum alpha or minimum gamma), while the remaining terminals are controlling their respective currents. The control law that is used sets the current reference at the voltage setting terminal according to

$$\Sigma \cdot I_j ref = \Delta I \tag{27.5}$$

where ΔI is known as the current margin.

The terminal with the lowest voltage ceiling acts as the VST.

An example of the control strategy is shown in Fig. 27.21 for a three-terminal DC system with one rectifier REC and two inverters, INV1 at 40% and INV2 at 60% rating. The REC1 and INV2 terminals are maintained in current control, while INV1 is the VST operating in CEA mode.

Due to the requirement to maintain current margin for the MTDC system at all times, a centralized current controller, known as the current reference balancer (CRB) (Fig. 27.22), is required. With this technique, reliable two-way telecommunication links is required for current reference coordination

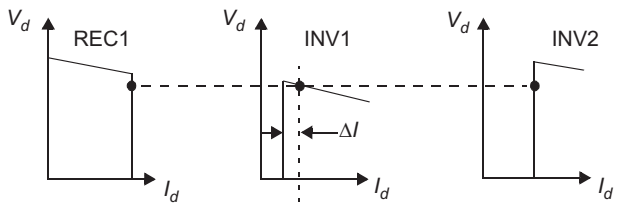

FIG. 27.21 Current margin method of control for MTDC system.

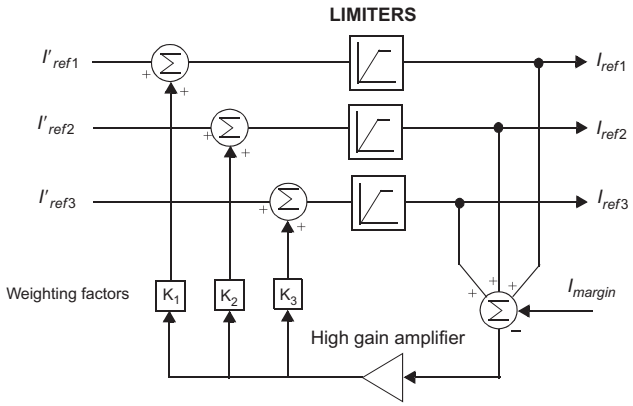

FIG. 27.22 Current reference balancer.

purposes. The current orders, I_{ref1}–I_{ref3}, at the terminals must satisfy the control law according to Eqs. (27.5) and (27.6). The weighting factors (K_1, K_2, and K_3) and limits are selected as a function of the relative ratings of the terminals.

27.6 Application

27.6.1 HVDC Interconnection at Gurun (Malaysia)

The 240/600 MW HVDC interconnection between Malaysia and Thailand is a major first step in implementing electric power network interconnections in the ASEAN region. It is jointly undertaken by two utilities, Tenaga Nasional Berhad (TNB) of Malaysia and Electricity Generating Authority of

Thailand (EGAT). This will be the first HVDC project for both these utilities. The HVDC interconnection consists of a 110 km HVDC line (85 km owned by TNB and 25 km owned by EGAT) with the DC converter stations at Gurun on the Malaysian side and Khlong Ngae on the Thailand side. The scheme entered into commercial operation in July 2000. The interconnection provides a range of diverse benefits such as

- spinning reserve sharing,
- economic power exchange-commercial transactions,
- emergency assistance to either AC system,
- damping of AC system oscillations,
- reactive power support (voltage control),
- deferment of generation plant up.

27.6.1.1 Power Transmission Capacity

The converter station is presently constructed for monopolar operation for power transfer of 240 MW in both directions with provisions for future extensions to a bipole configuration giving a total power-transfer capability of 600 MW. The HVDC line is constructed with two pole conductors to cater for the second 240 MW pole. Full-length neutral conductors are used instead of ground electrodes because of high land costs and inherently high values of soil resistivity.

The monopole is rated for a continuous power of 240 MW (240 kV and 1000 A) at the DC terminal of the rectifier station. In addition, there is a 10 min overload capability of up to 450 MW, which may be utilized once per day when all redundant cooling equipment is in service.

The HVDC interconnection scheme is capable of continuous operation at a reduced DC voltage of 210 kV (70%) over the whole load range up to the rated DC current of 1000 A with all redundant cooling equipment in service.

27.6.1.2 Performance Requirements

A high degree of energy availability was a major design objective (Fig. 27.23). Guaranteed targets for both stations are the following:

- Energy availability: >99.5%
- Forced energy unavailability: <0.43%
- Forced outage rate: <5.4 outages per year

27.6.1.3 Technical Information

See Table **27.6**.

27.6.1.4 Major Technical Features

The station incorporates the latest state-of-the-art technology in power electronics and control equipment. The features include the following:

- A fully decentralized control and protection system
- Active DC filter technology
- Hybrid DC current shunt measuring devices
- Triple-tuned AC filter

27.7 Modern Trends

27.7.1 Converter Station Design of the 2000s

The 1500 MW, ±500 kV Rihand-Delhi HVDC transmission system (commissioned in 1991) serves as an example of a

Pole conductor	
Neutral conductor	Hen ACSR 298 mm^2

typical design of the last decade. Its major design aspects were the following:

- Stations employ water-cooled valves of indoor design with the valves arranged as three quadruple valves suspended from the ceiling of the valve hall.
- Converter transformers are one-phase, three-winding units situated close to the valve hall with their bushings protruding into the valve hall.
- AC filtering is done with conventional, passive, double-tuned, and high-pass units employing internally fused capacitors and air-cored reactors; these filters are mechanically switched for reactive power control.
- DC filtering is done with conventional, passive units employing a split smoothing reactor consisting of both an oil-filled reactor and an air-cored reactor.
- DCCT measurement is based on a zero-flux principle.
- Control and protection hardware is located in a control room in the service building between the two valve halls. The controls still employed some analog parts, particularly for the protection circuits. The controls were duplicated with an automatic switchover to hot standby for reliability reasons.

This design was done in the 1980s to meet the requirements of the day for increased reliability and performance requirements, that is, availability, reduced losses, higher overload capability, etc. However, these requirements led to increased costs for the system.

The next-generation equipment is now being spearheaded by a desire to reduce costs and make HVDC as competitive as AC transmission. This is being facilitated by the major developments of the past decade that have taken place in power electronics. Therefore, the next-generation HVDC equipment will be influenced by the following.

27.7.1.1 Thyristor Development

HVDC thyristors are now available with a diameter of 150 mm at a rating of 8–9 kV and power handling capacity of 1500 kW that will lead to a dramatic decrease in the number of series-connected components for a valve with consequential cost reductions and improvement in reliability.

The development of the light-triggered thyristor (LTT) (Figs. 27.24 and 27.25) is likely to eliminate the electronic unit (with their high number of electronic components) for generating the firing pulses for the thyristor (Fig. 27.26). The

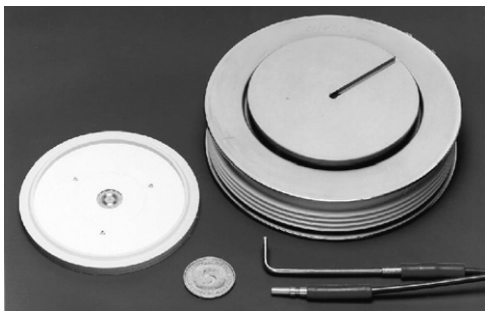

FIG. 27.24 Silicon wafer and construction of the LTT. The light guides appear in the bottom right-hand corner.

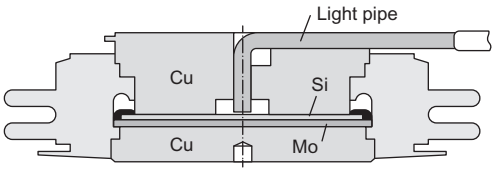

FIG. 27.25 Cross section of the LTT with the light pipe entry.

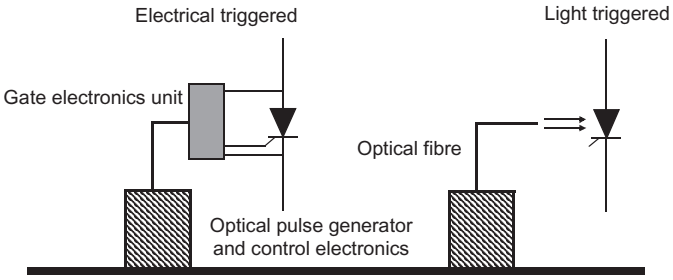

FIG. 27.26 Conventional firing versus light-triggered firing.

additional functional requirements of monitoring and protection of the device are being incorporated also.

Both of the above developments present the possibility of achieving compact valves that can be packaged for outdoor construction, thereby reducing the overall cost and reliability of the station.

27.7.1.2 Higher DC Transmission Voltages

For long-distance transmission, there is a tendency to use a high voltage to minimize the losses. The typical transmission voltage has been ±500 kV, although the Itaipu project in Brazil uses 600 kV. The transmission voltage has to balance against the cost of insulation. The industry is considering raising the voltage to ±800 kV.

27.7.1.3 Controls

It is now possible to operate an HVDC scheme into an extremely weak AC system, even with short-circuit capacity down to unity.

Using programmable DSPs has resulted in a compact and modular design that is low cost; furthermore, the number of control cubicles has decreased by a factor of almost 10 times in the past decade. Now, all control functions are implemented on digital platforms. The controls are fully integrated having monitoring, control, and protection features. The design incorporates self-diagnostic and supervisory characteristics. The controls are optically coupled to the control room for reliable operation. Redundancy and duplication of controls is resulting in very high reliability and availability of the equipment.

27.7.1.4 Outdoor Valves

The introduction of air-insulated, outdoor valves will reduce costly requirements for a valve hall. The use of a modular, compact design that will be preassembled in the manufacturing plant will save installation time and provide for a flexible station layout. This design has been feasible because of development of a composite insulator for DC applications that is used as a communication channel for fiber optics, cooling water, and ventilation air between the valve unit and ground.

27.7.1.5 Active DC Filters

This development, made possible due to advances in power electronics and microprocessors, has resulted in a more efficient DC filter operating over a wide spectrum of frequencies and provides a compact design (Fig. 27.27).

27.7.1.6 AC Filters

Conventional AC filters used passive components for tuning out certain harmonic frequencies. Due to the variations in frequency and capacitance, physical aging, and thermal

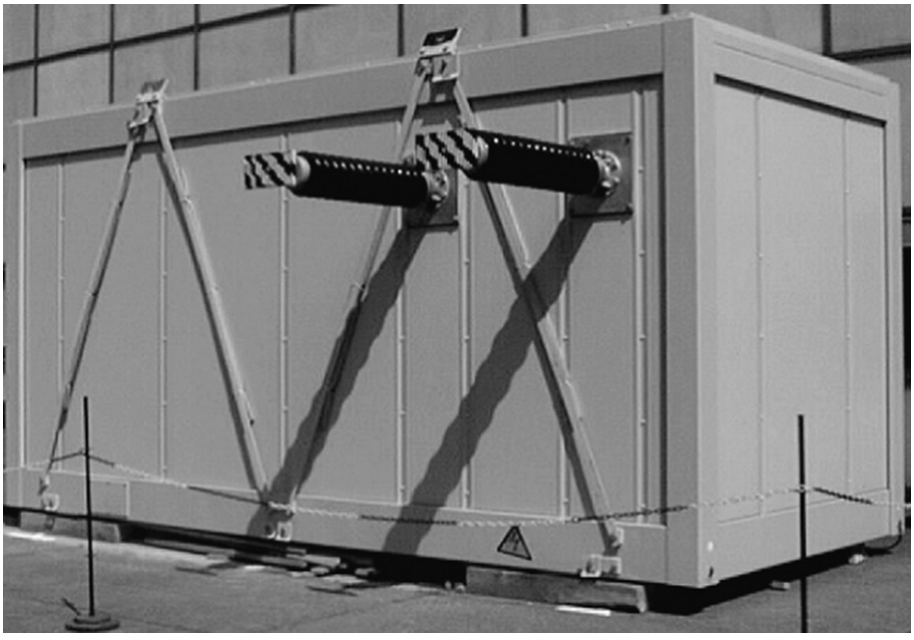

FIG. 27.27 Compact outdoor container with an active DC filter.

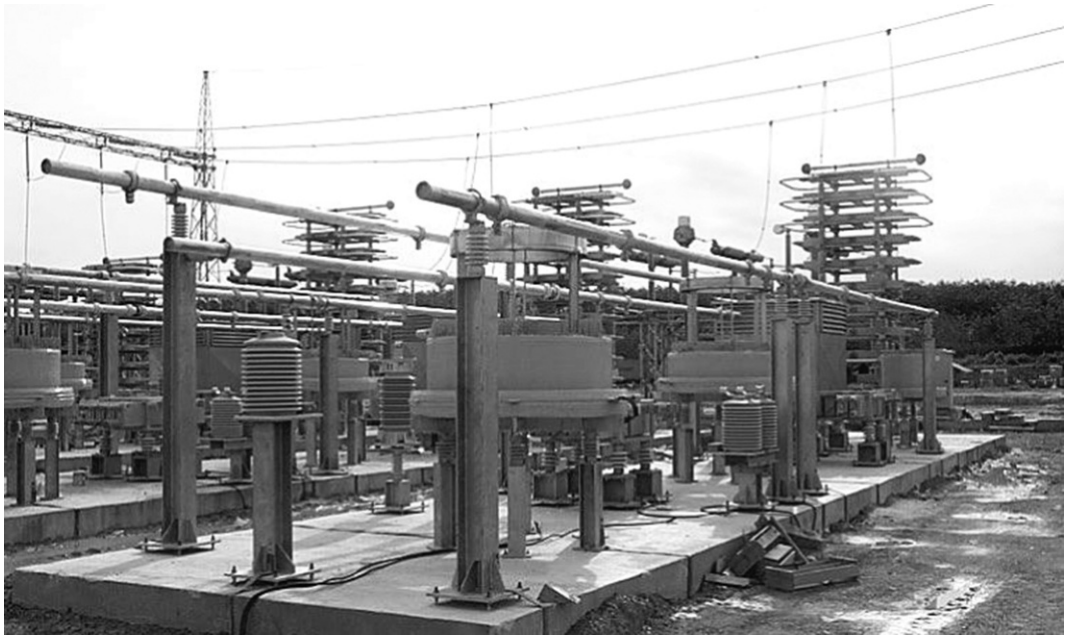

FIG. 27.28 Installation of the triple-tuned filter at the Gurun station in Malaysia.

characteristics of these tuned filters, the quality factors for the filters were typically about 100–125, which meant that the filters could not be too sharply tuned for efficient harmonic filtering. The advent of electronically tunable inductors, based on the transductor principle, means that the *Q*-factors can now approach the natural one of the inductor. This will lead to much more enhanced filtering capacities (Fig. 27.28).

27.7.1.7 AC-DC Current Measurements

The new optical current transducers utilize a precision shunt at high potential. A small optical fiber link between ground and high potential is utilized resulting in a lower probability of a flashover. The optical power link transfers power to high potential for use in the electronic equipment. The optical data link transfers data to ground potential. This transducer results in high reliability, compact design, and efficient measurement (Fig. 27.29).

FIG. 27.29 The optical current transducer.

27.7.1.8 New Topologies

Two new topological changes to the converter design will impact greatly on future designs:

1. Series-compensated commutation:

   There are two variants to this topology: the capacitor-commutated converter (CCC) (Fig. 27.30A) and the controlled series capacitor converter (CSCC) (Fig. 27.30B). Essentially, the behavior of the two variants is very similar. The insertion of a capacitor in series with the converter transformer leakage reactance causes a major reduction in the commutation impedance of the converter resulting in a reduction in the reactive power requirement of the converter. An increase in the size of the series capacitor can even result in the converter operation at a leading power factor if so desired. However, the negative impact of a lower commutation impedance results in additional stresses on the valves and transformers and additional cost implications [7].

   The first CCC back-to-back converter station (rated at 2×550 MW) has been put into service at Garabi, on the

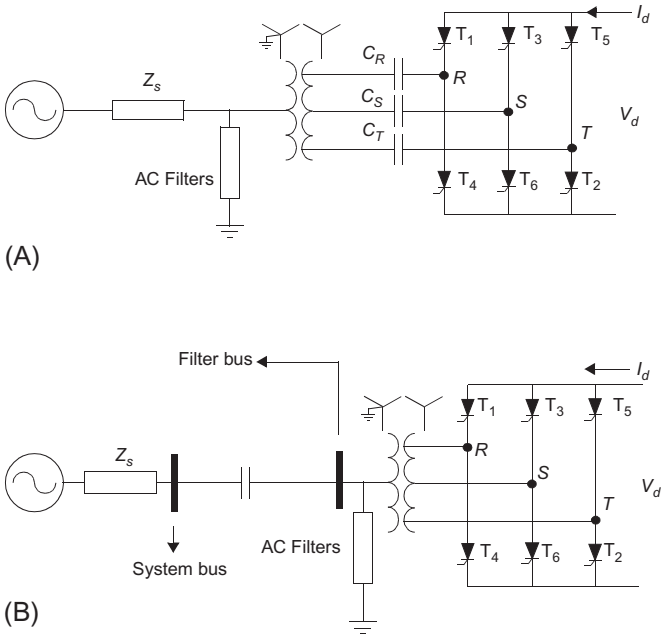

FIG. 27.30 (A) Capacitor-commutated converter circuit and (B) controlled series capacitor converter circuit.

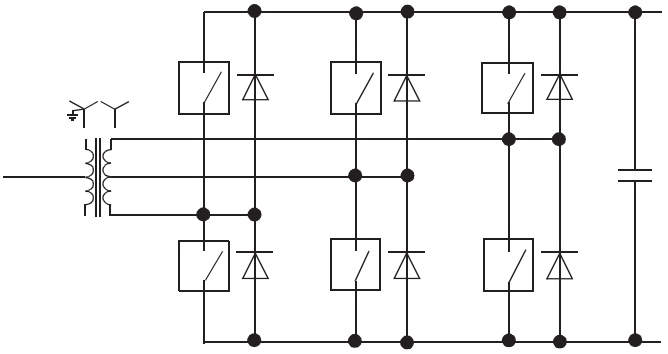

FIG. 27.31 Voltage-source converter topology.

Brazilian side of the Uruguay River. The system interconnects the electric systems of Argentina and Brazil.

2. Voltage-source converters (VSC): The use of self-commutation with the new-generation switching devices (i.e., GTOs and IGBTs) has resulted in the topology of a voltage-source converter (VSC) (Fig. 27.31) as opposed to the conventional converter using line-commutated thyristors and current source converter (CSC) topology. The VSC, being self-commutated, can control active/reactive power and, with PWM techniques, control harmonic generation as well. The application of such circuits is presently limited by the switching losses and ratings of available switching devices. The ongoing advances in power electronic devices are expected to have a major impact on the future application of this type of converter in HVDC transmission. New application areas, particularly in distribution systems, are being actively investigated with this topology. Table **27.5** provides a partial list of the HVDC links in operation using this technique.

One major difficulty for the use of the VSC is the threat posed to the valves from a short circuit on the DC line. Unlike the CSC where the valves are inherently protected against short-circuit currents by the presence of the smoothing reactor, the VSC is relatively unprotected. For this reason, the VSC applications are almost always used with DC cables where the risk of a DC line short circuit is greatly reduced (Table **27.7**).

27.7.1.9 Compact Station Layout

The advances discussed above have resulted in marked improvement of the footprint requirement of the compact station [8] of the year 2000 that has about 24% space requirement of the comparable HVDC station designed in the past decade (Fig. 27.32).

27.8 VSC-HVDC System

27.8.1 Introduction

The existing power transmission networks in most developed countries are heavily loaded that has created the risk of system instability and power quality deterioration. Furthermore, these countries have the problem of obtaining right of ways and face environmental issues for the construction of new transmission lines. The necessity for a new technology by which increased power transmission can be achieved using the existing network infrastructure is clear. As explained earlier, the VSC-HVDC transmission system can take the place of this technology to solve the problem to some extent. The VSC-HVDC system is a relatively mature technology that comprises the high-power, high-frequency semiconductor switches (i.e., IGBTs and GTOs). These devices incorporated with antiparallel diodes make one complete unit. Several units are connected in series to build a valve to get the required voltage level and to increase the redundancy in the converter. The control of these switches is done by using pulse-width modulation (PWM) techniques by which it is possible to control the magnitude and phase angle of the generated fundamental (60 Hz) voltage component. This high controllability of VSC results in a wide range of power system applications like VSC-HVDC, static synchronous compensator (STATCOM), static synchronous series compensator (SSSC), unified power flow controller (UPFC), interline power flow controller (IPFC), and active filters. In addition to bulk power transmission, strategically located VSC-HVDC system in an existing AC power system network augments the network stability and reliability during disturbances and contingencies.

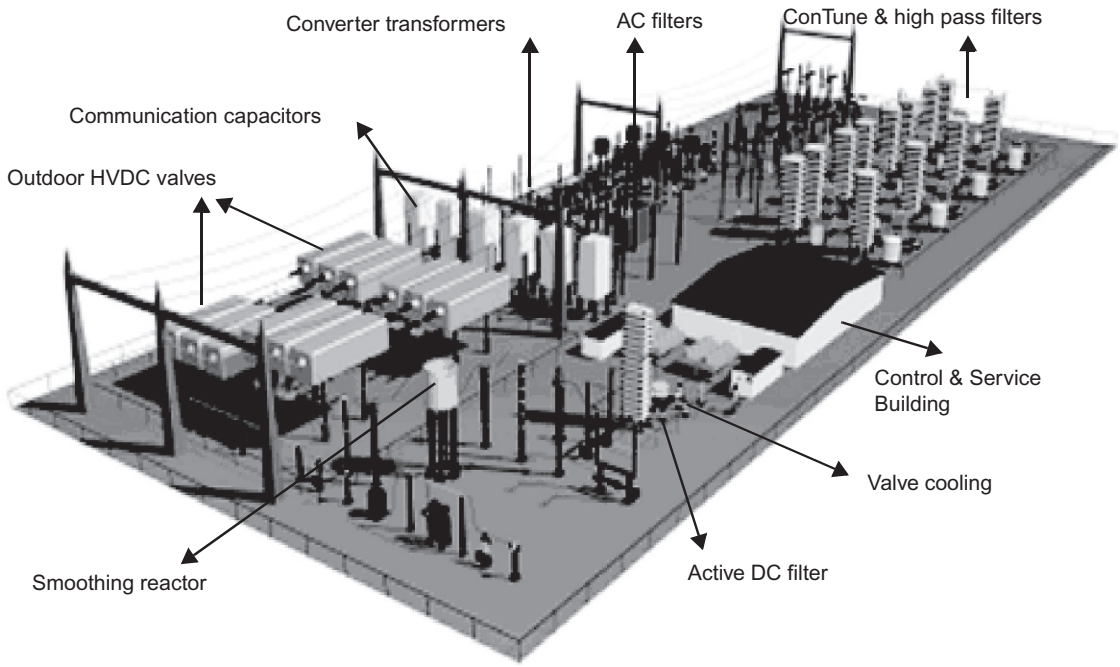

FIG. 27.32 Layout of a compact HVDC.

27.8.2 VSC-HVDC System

Fig. 27.33 shows the single-line diagram of a VSC-HVDC system that interconnects two AC networks of same operating frequency for power transmission and stability improvement during contingencies. The system consists of different equipments, such as shunt-connected RLC filters, interfacing transformers, VSCs and their control systems, DC overhead or underground cables, and DC capacitors. The following subsections provide explanations regarding the function of each apparatus comprising the VSC-HVDC.

27.8.2.1 AC Shunt RLC-Filters

Switching of high-power, high-frequency switches generates harmonics in the converter output voltages and currents. The order of harmonics generated is directly related to the PWM switching frequency of the semiconductor switches.

Single- or double-tuned low-pass and high-pass damped RLC filters are connected to suppress these harmonics. The frequency modulation index is defined as m_f that is defined as the ratio of the switching frequency of the converter to the fundamental frequency of the AC voltage. In the case of three-phase VSC, the harmonics in the line-to-line voltages are present. The odd harmonics exist as sidebands, centered around the m_f and its multiples where m_f is odd. The value of m_f is chosen such that it should be an odd integer to eliminate the even harmonics; also, if it is a multiple of 3, then most of the triplen harmonics are canceled out in the line-to-line voltage.

27.8.2.2 Converter Transformer

A converter transformer interfaces the VSC AC terminals to AC network with suitable voltage level at both sides. It provides electric isolation and operates as a filter between converter and AC networks and provides the appropriate AC voltage level to optimize the available converter valve voltage rating. Configuration and rating of the transformer can be decided from the total system power rating, converter topology, and specified requirements.

27.8.2.3 Voltage Source Converter

The VSC is the main building block of the VSC-HVDC system. The number of switches employed depends on the operating characteristic and voltage level required. The series-connected IGBT switches, connected with antiparallel diodes, make up a valve. Two valves are connected in series to make up the converter leg for one phase. VSC can operate as a rectifier or an inverter at either end depending on the current flow direction. Two converters can be connected as a back-to-back system to connect two different AC grids, DC transmission line, or overhead cables for bulk power transmission or underground cables for connection of offshore oil rigs, islands, or offshore wind farms. The six-switch converter comprises a group of six valves. Different types of PWM techniques are used to operate and control the converter switches. Typical IGBT has rating of 6.5 kV and 2.4 kA. The voltage across the IGBT switch in the ON state is typically in the range of 1–3 V that creates the ON state losses. The switching losses are the second major loss mechanism and are due to fact that, during the turn ON and turn OFF transition, current is still flowing while voltage is present across the device. In order to minimize the switching losses, the maximum switching frequency needs to be carefully considered. VSC is equipped with the RC snubbers and series R-L elements to reduce the dv/dt and di/dt stresses on the switches during ON/OFF transitions.

27.8.2.4 DC Transmission

The DC system can be in the form of a transmission line, with underground or overhead cables. The overhead cables can be used with a moderate size of towers. The extruded polymer cable is a newly developed technique in which the insulation is highly resistant to the DC voltage.

The DC transmission system adopted here is a bipolar transmission system in which the power can flow in both the overhead poles and ground is used as a return path in case of monopolar operation. In case of failure or preplanned maintenance of one pole, reduced power can still be transmitted using the other pole. Two smoothing inductors are connected on DC transmission system to reduce the ripples in the DC current.

27.8.2.5 DC Capacitors

As shown in Fig. 27.33, two series-connected DC capacitors of same size are employed across the DC terminals of converter with grounded midpoint. The size of the capacitor depends on the required DC voltage level and the acceptable DC ripple.

The DC voltage should be adequate for the generation of sinusoidal voltages on AC side of the converter. For the system to

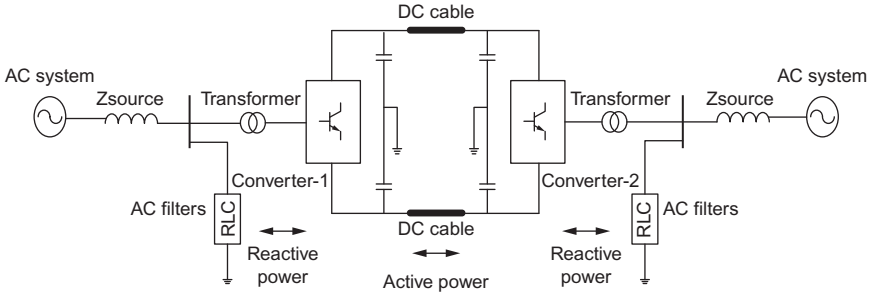

FIG. 27.33 Single-line diagram of VSC-HVDC system.

operate in the linear range of the PWM, the DC voltage should be 1.634 times the value of root mean square (RMS) AC voltage.

The PWM switching of high-power high-frequency switches generates the harmonics in the DC current flowing in the transmission line. This generates the harmonics in the DC voltage that is strongly related to the converter AC voltage. By evaluation of the magnitude of ripple and the switching frequency of the semiconductor switches, the DC side capacitor ratings can be finalized.

The value of DC capacitor C_{DC} used here can be small, which may result in a faster converter response. The energy stored in the capacitor is released during transients that will help to stabilize the power flow on the DC transmission system. The DC capacitor size is characterized with a time constant τ, which can be defined as the ratio between the energy stored in the capacitor at the rated DC voltage V_{DC} and the apparent power rating of the converter SC:

$$\tau = \frac{\frac{1}{2} C_{DC} V^2_{DC}}{S_C} \tag{27.6}$$

The time constant is equal to the time needed to charge the capacitor from zero to rated voltage V_{DC} if the converter is supplied with a constant active power equal to SC. The time constant τ can be selected to be small to satisfy ripple and transient overvoltage requirement on the DC voltage. A relatively small time constant allows fast control of active power and reactive power.

27.8.3 Topologies of the VSC

VSC can be divided into topologies according to the number of levels for converter output AC voltage, either two level or multilevel. These are explained in following subsections.

27.8.3.1 Two-Level Voltage Source Converter

A two-level bridge is the simplest circuit configuration that can be used to construct a three-phase VSC. It has been widely used in many applications for a range of power levels. As shown in Fig. 27.34, the converter can generate DC voltage waveform of only two values, $\pm V_{DC}/2$, where V_{DC} is the total DC voltage. Relatively simple power and control circuitry, small DC capacitor size, small footprint environmentally, and same semiconductor duty ratio are some of the advantages related to a two-level VSC.

27.8.3.2 Multi-level Voltage Source Converter VSC

Converter topologies with more than two-level voltages are known as multilevel converters. In this type of VSC, the output AC voltage waveform has different level according to the construction of the VSC. The main requirement for multilevel converters is to synthesize a sinusoidal voltage from several voltage levels that are obtained from the DC side capacitor voltages. Multilevel VSCs are divided into different types according to their application. The multilevel VSC found various

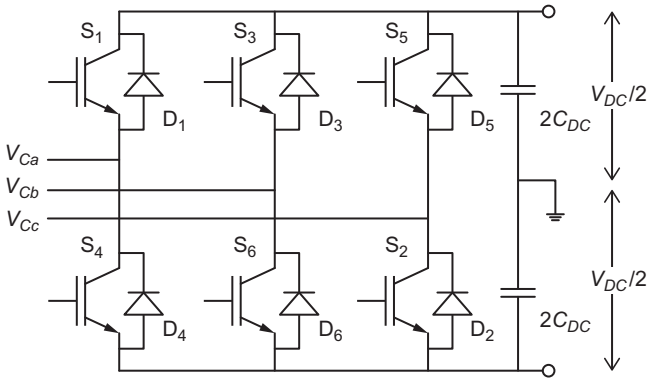

FIG. 27.34 Two-level, six-switch, three-phase converter topology.

applications in power systems due to its high power density, excellent performance, and high reliability. Various multilevel topologies are explained next.

27.8.3.3 Neutral Point Diode Clamped VSC

Neutral-point diode-clamped VSC topology is shown in Fig. 27.35. As shown, this topology uses clamping diodes to limit the dynamic and static overvoltages of switching devices. The clamping diodes are connected to the center point of the DC bus capacitor.

The advantages of this topology include reasonable small size of the DC capacitors, small footprint environmentally, and good quality AC output waveform. An n-level diode-clamp converter typically consists of (n-1) capacitors on the DC bus and produces n-levels of the converter output AC voltage. With a higher number of levels, harmonics generation is very low that can even avoid the need for filters in some cases. The disadvantages are related to voltage balancing across the DC capacitors, uneven loss distribution between devices, and excessive clamping diodes necessity in higher levels.

27.8.3.4 Flying Capacitor VSC

Fig. 27.36 shows the three-level flying-capacitor-type VSC topology. This topology uses capacitors instead of diodes in

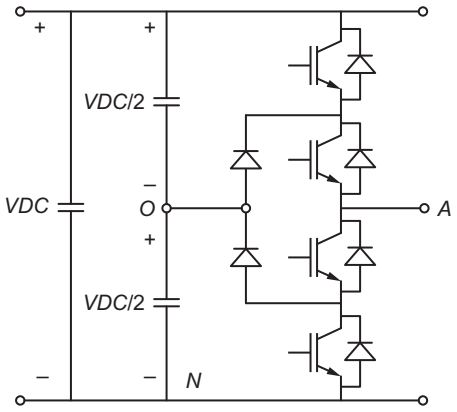

FIG. 27.35 Three-level, NPC converter topology.

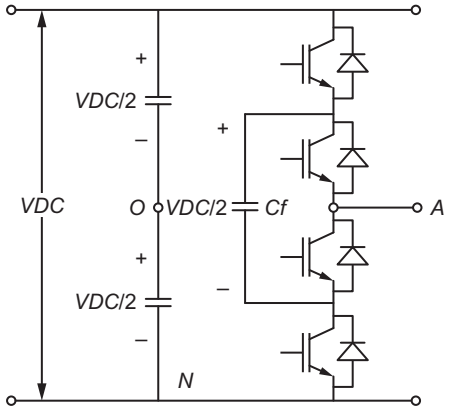

FIG. 27.36 Three-level, flying-capacitor converter topology.

the diode-clamped topology. For an n-level converter, $(n-1)$ numbers of DC capacitors at DC bus and $(n-1)\times(n-2)/2$ number of auxiliary capacitors per phase leg are required. These capacitors are known as floating capacitors.

The AC waveform synthesized by this topology is better than the diode-clamped topology. The advantages of this topology are the extra ride through capabilities during power outage and severe disturbances due to large number of storage capacitors, switch combination redundancy for balancing different voltage levels, and avoidance of harmonic filters in higher-level applications. The requirement of an excessive number of storage capacitors on DC side and across the semiconductor switches in higher number of levels makes this topology very expensive. The converter control system is complex, and switching losses are higher compared with diode-clamped topology.

27.8.3.5 ANPC (Actively Neutral Point Clamped) converter

Fig. 27.37 shows the three-level ANPC converter topology in which the clamping diodes are replaced by semiconductor switches. The disadvantage of uneven loss distribution across various devices in the neutral-point diode-clamped converter topology is mitigated by this newly developed topology.

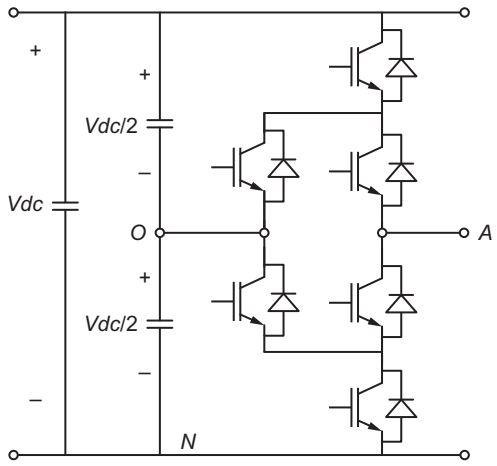

FIG. 27.37 Three-level, actively neutral-point-clamped converter topology.

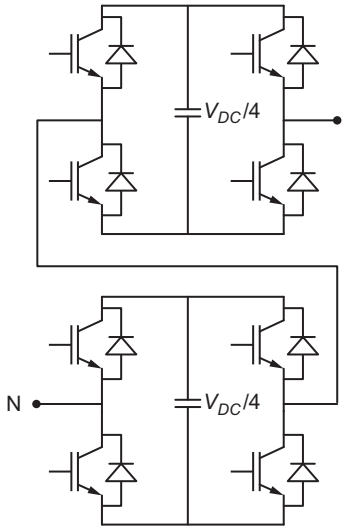

FIG. 27.38 Five-level, cascaded H-bridge converter topology.

27.8.3.6 Cascaded H-Bridge Converter

This VSC topology (Fig. 27.38) is a cascaded structure that consists of full-bridge inverter units connected in series.

Each unit is fed by a separate DC capacitor, and no other circuit to balance the voltage matching of the switching devices is necessary. There is no need to add the clamping diodes or voltage-balancing capacitors in this topology that results in a relatively simple construction. Main drawback of this topology is the requirement of several independent DC power supplies.

27.8.3.7 Multi-pulse Topologies

In a six-switch converter, the commutation of current takes place six times per cycle. In the case of 12-switch converter, two six-switch converters are connected in series to form a 12-switch converter topology. By using the six-switch converter, the additional multiswitch topologies in multiples of six can be created to form the required pulse level. The 24-switch and 48-pulse converters are implemented in some research papers for application as a STATCOM in power system. The main purpose of using these topologies is to reduce the voltage and current harmonics in the system. As the number of switches increases, the harmonic distortion in the system decreases proportionally.

27.8.4 PWM for VSC

PWM is the most accepted switching technique in which the comparison between a fundamental frequency modulating waveform and a fixed carrier frequency triangular waveform generates the firing pulses for VSC. The magnitude and phase

angle of the generated fundamental frequency component of the converter output AC voltage can be controlled by varying the magnitude and phase angle of the modulating waveform. In this technique, the converter output AC voltage contains harmonic frequency components in addition to fundamental frequency component located around the multiples of the triangular waveform carrier frequency.

27.8.4.1 Sinusoidal PWM

The PWM technique used for switching of the semiconductor devices of converter decides the frequency and nature of the converter output AC voltage. So to get the sinusoidal waveform as an output, sinusoidal PWM technique is used. The sinusoidal modulating waveform of 60 Hz system frequency is compared with a high-frequency triangular waveform to generate the pulse-width modulated firing pulses for converter. Two different SPWM methods can be implemented to get the required output.

(a) Bi-polar SPWM

In the case of bipolar sinusoidal PWM method, a single fundamental frequency modulating waveform per phase is compared with the high-frequency triangular waveform. The output voltage switches between $-V_{DC}/2$ and $+V_{DC}/2$ voltage levels where V_{DC} is the total DC voltage. It is the reason why this type of switching is called a bipolar PWM switching. As shown in Fig. 27.39, during comparison, when the sinusoidal waveform is greater than the triangular waveform, the PWM trigger signal is high, otherwise at lower level.

(b) Uni-polar SPWM

In the case of unipolar sinusoidal PWM technique, two same phase fundamental frequency modulating waveforms with opposite polarity are compared with the high-switching-frequency triangular waveforms. The output voltage switches between $+V_{DC}/2$ and 0 or between 0 and $-V_{DC}/2$. For this reason, this type of PWM scheme is called a PWM with a unipolar voltage switching.

27.8.5 VSC-HVDC Operation

The VSC-HVDC operation can be explained by considering its operating principle, four-quadrant operation in P-Q diagram, and capability to operate in either rectifier or inverter modes.

27.8.5.1 Operating Principle of VSC-HVDC

The VSC-HVDC operating principle can be explained from the SLD shown in Fig. 27.40, where two AC networks are connected by a VSC-HVDC transmission system.

The converter transformer connecting AC network and converter can be modeled as an equivalent series resistance and reactance. The transformer resistance is very small compared

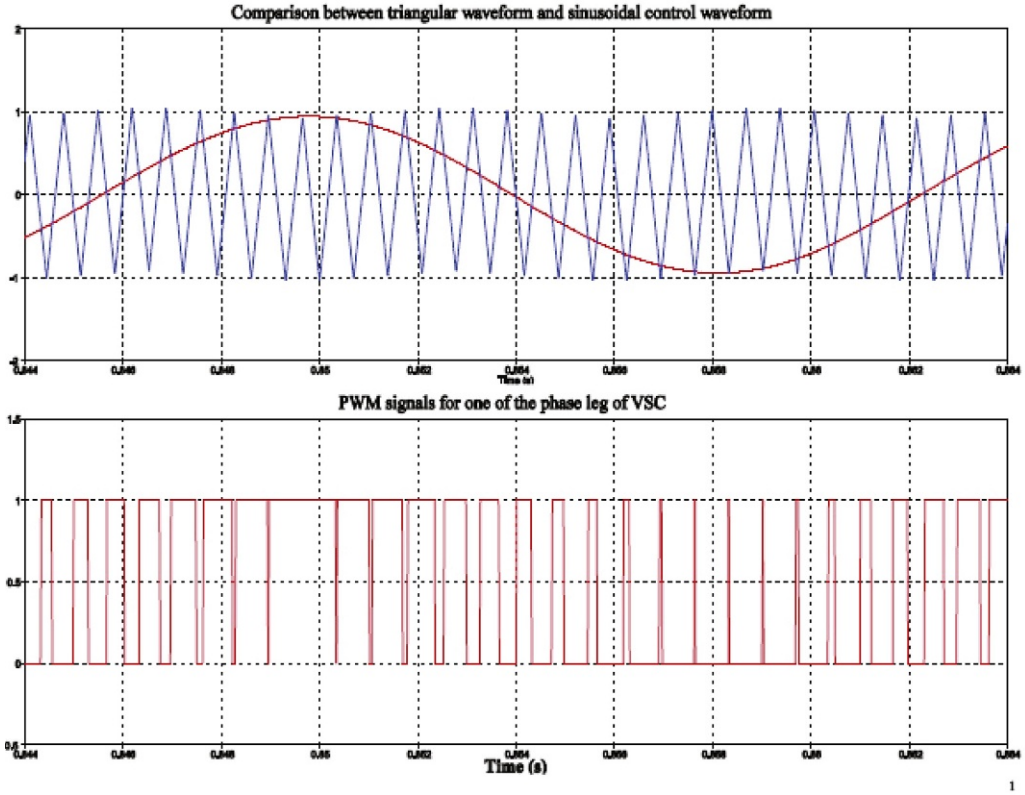

FIG. 27.39 Comparison between sinusoidal and triangular waveform and PWM signals.

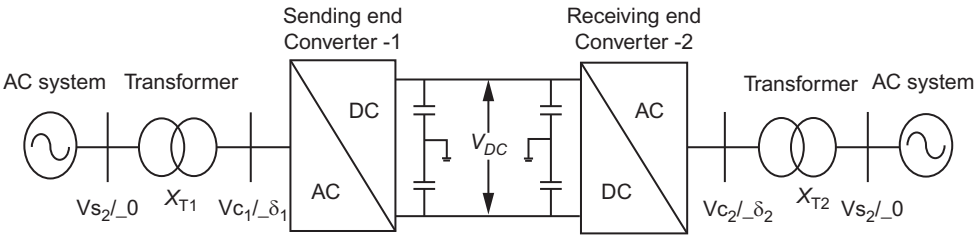

FIG. 27.40 Single-line diagram for VSC-HVDC operating principle.

with the transformer reactance, so it can be neglected in power calculations. The phase shift between both sides' voltages due to transformer reactance is responsible for active power flow. At sending end, the voltage V_{S1} at AC bus is considered as a reference, so the converter output AC voltage V_{C1} has phase shift δ_1 with respect to the bus voltage V_{S1}. The magnitude and phase angle of converter output AC voltage V_{C1} is controlled by the VSC control system. The active and reactive power flow between the AC system and the converter depends on the magnitude of the voltages at both sides of the transformer, the transformer reactance X_{T1} and the phase angle δ_1 between them. The active and reactive power flow between AC bus and converter AC terminals can be expressed as follows: the active power at sending end and receiving end is given by

$$P_S = \frac{|V_{S_1}||V_{C_1}| \times \sin\delta_1}{X_{T_1}},\ P_R = \frac{|V_{S_2}| \times |V_{C_2}| \times \sin\delta_2}{X_{T_2}} \tag{27.7}$$

The reactive power at sending end and receiving end is given by

$$\begin{aligned} Q_S &= \frac{|V_{S_1}|^2}{X_{T_1}} - \frac{|V_{S_1}| \times |V_{C_1}| \times \cos\delta_1}{X_{T_1}}, \\ Q_R &= \frac{|V_{S_2}| \times |V_{C_2}| \times \cos\delta_2}{X_{T_2}} - \frac{|V_{S_2}|^2}{X_{T_2}} \end{aligned} \tag{27.8}$$

The amplitude, phase angle, and frequency of fundamental component of converter output AC voltage V_{C1} and V_{C2} can be controlled using the SPWM technique. If the voltage at the DC side of the converter is V_{DC} that is assumed to be constant, then the fundamental frequency component of converter output AC voltage can be derived from the following equation:

$$Vc(t) = \frac{1}{2} V_{DC} M_i \sin(\omega t + \delta) \tag{27.9}$$

where V_{DC} is the voltage on DC side, ω is the angular frequency, M_i is modulation index, and δ is the phase angle between the converter output AC voltage and the AC bus voltage. *Mi* can be defined as the ratio of peak value of voltage of modulating waveform (fundamental frequency sinusoidal waveform) to the peak value of voltage of carrier waveform (switching-frequency triangular waveform). From Eq. (27.9), it is seen that the fundamental component of converter voltage depends on the variables *Mi*, angle δ, and frequency that are independently controlled by VSC controllers. The active and reactive power can be controlled by controlling the phase angle δ and the amplitude of the fundamental frequency component of converter AC output voltage V_C, respectively.

In a VSC-HVDC, the polarity of DC voltage is constant, so the power reversal is done by current reversal in the DC link. The current in DC link flows from higher to lower DC voltage level. For stable VSC operation and flow of active power, the DC-link voltage is maintained at a desired reference value by using a feedback control loop. The power flow to and from the AC source can be controlled according to the DC-link voltage requirements. The voltage V_{DC} is measured and controlled in such manner that the DC current flow can be in either direction depending on the requirement of active power flow direction.

27.8.5.2 Four Quadrant Operation of VSC

Active power flow direction for rectifier or inverter operation and reactive power flow direction for inductive or capacitive operating mode of VSC can be explained by a P-Q circle diagram shown in Fig. 27.41. The diagram explains the ability of VSC to operate in all four quadrants of P-Q circle and to achieve the independent control of active and reactive power.

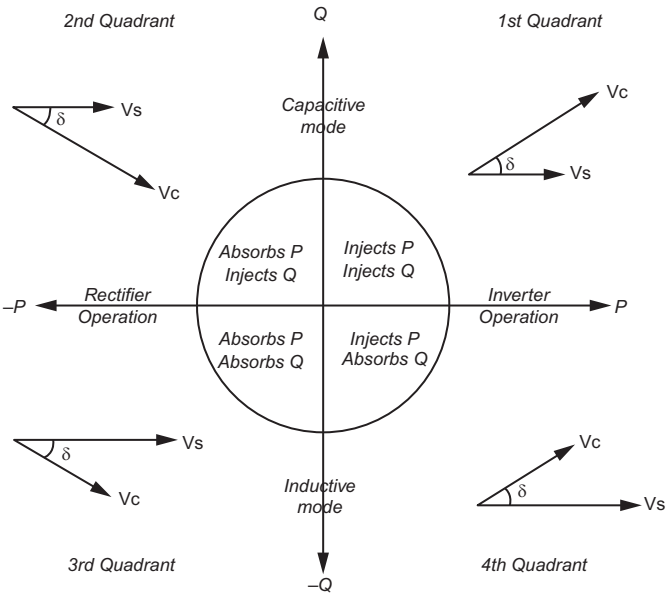

FIG. 27.41 P-Q circle diagram for VSC operation.

The direction of current flow and hence active power flow decides the rectifier or inverter operation of converter.

In the first quadrant, both the active and reactive powers are positive, which means that the converter injects both powers to AC system that shows the capacitive mode of inverter operation. The converter output AC voltage magnitude is higher than AC bus voltage and leads AC bus voltage by an angle δ.

In the second quadrant, the active power is negative, and the reactive power is positive, which explains the capacitive mode of rectifier operation. In this case, the converter output AC voltage amplitude is higher than AC bus voltage, but it lags the AC bus voltage by an angle δ.

Both the powers in the third quadrant are negative that means the converter absorbs both powers from the AC system, which explains the inductive mode of rectifier operation. In this case, the AC bus voltage magnitude is higher than the converter output AC voltage, and it leads by an angle δ.

In the fourth quadrant, the active power is positive, and the reactive power is negative, which explains the inductive mode of inverter operation. Here, the converter output AC voltage leads the AC bus voltage, but its magnitude is less than the AC bus voltage.

According to the converter MVA capacity and system requirements, converter can operate in any mode (i.e., capacitive or inductive) of rectifier or inverter operation.

27.8.5.3 Rectifier-Inverter Operation of VSC

The rectifier or inverter operation of VSC can be explained by considering Fig. 27.42. AC bus voltage V_S can be taken as a reference, and V_C is the converter AC output voltage with phase shift δ. The converter transformer can be represented by an equivalent resistance R_T and reactance X_T. Two capacitors of same rating $2C_{DC}$ are connected in series across the DC terminals of the converter. The direction of current flow decides the operation of VSC as a rectifier or inverter.

As shown in Fig 27.43, the AC system voltage V_S leads the converter AC output voltage V_C by an angle δ. The active power flows from the AC system to the converter, so the converter operates as a rectifier. As shown in the figure, ΔV is the voltage drop across the transformer impedance that is controlled in order to control the angle δ. In the rectifier mode of operation, the current I_{DC} is considered positive, and the capacitor C_{DC} is discharged through the DC transmission system. The error signal demands the control circuit for more power from the AC supply. The control circuit thereby generates the appropriate PWM signals for the switching devices, and accordingly, more current flows from the AC to DC side, and the capacitor voltage recovers its predefined value.

As shown in Fig. 27.44, the AC system voltage V_S lags the converter AC output voltage by an angle δ. In this case, the active power flows from the converter to AC system, so the converter operates as an inverter. In the inverter mode of operation, I_{DC} becomes negative, and the capacitor C_{DC} is overcharged. The error signal demands the controls to discharge the capacitor C_{DC} and return power to the AC system. The PWM can control both the active power and reactive power independently. Thus, this type of converter can be used for power factor correction also in addition to power transmission.

Depending on the control strategy, VSC can be operated as either inverter or rectifier; therefore, it is often referred to as a converter. Two such converters are often cascaded to control the power flow between two AC networks. The first converter converts AC voltage to variable DC-link voltage, and the second converter converts the DC voltage to variable AC voltage with fixed or variable frequency.

27.8.6 Summary

In this chapter, the VSC-HVDC system construction, its principle of operation, and operational function of each component are explained in detail. The different topologies of VSC and PWM techniques are explained. The principle of operation for the VSC-HVDC is explained regarding the active and reactive power flow. P-Q circle diagrams are explained regarding the rectifier/inverter operation and capacitive or inductive mode of operation.

27.9 Control of VSC-HVDC System

27.9.1 Introduction

VSC-HVDC transmission system has flexibility in terms of controlled quantities offering two degrees of freedom at each end to provide stable and robust control. As described in Section **27.8.5**, VSC-HVDC system has advantage of independent control of active and reactive power. The direction of active power flow can be changed without changing the DC voltage polarity. The reactive power can be controlled independently at either converter station by controlling converter AC output voltage.

Although both current and voltage control schemes are possible, current control is generally preferred for its excellent dynamic characteristics and inherent overcurrent limitation capabilities. When current control is used, the rectifier input current and inverter output currents are measured and compared with reference signals; the current errors are used as inputs to the PWM modulator, which then provides the required switching signals. The requirements for the control system to operate the VSC-HVDC system are the following:

- It must be capable of controlling the desired active power in either direction.
- The reactive power of system must be controlled independently at both ends.
- The DC voltage must be maintained at desired level for power transfer.

The control modes are chosen according to the application and requirement of the given power system. The rectifier and inverter controllers take the control of any two of above-mentioned four control strategies according to the system requirements and operating conditions. VSC_1 controllers operate on active power and reactive power control, whereas VSC_2 controllers deal with DC voltage and reactive power control (Fig. 27.45).

27.9.2 Direct Control Method

Direct control method is a simple method for the control of VSC-HVDC. The angle *d* and modulation index *Mi* are controlled directly by using PI controllers. The measured values are compared with the reference values, and the resultant errors are fed to the PI controllers. The output of which is used as either modulation index or angle delta. The modeling of direct control system is provided in Section **27.9.5.3**. Though this method is not used in practical applications, it is useful in comparative studies of operation and performance of VSC-HVDC.

27.9.3 Vector Control Method

The P and Q controlled quantities of VSC-HVDC are coupled to each other such that any change in one quantity strongly affects the other. The vector control method removes the coupling between these quantities to ensure the independent

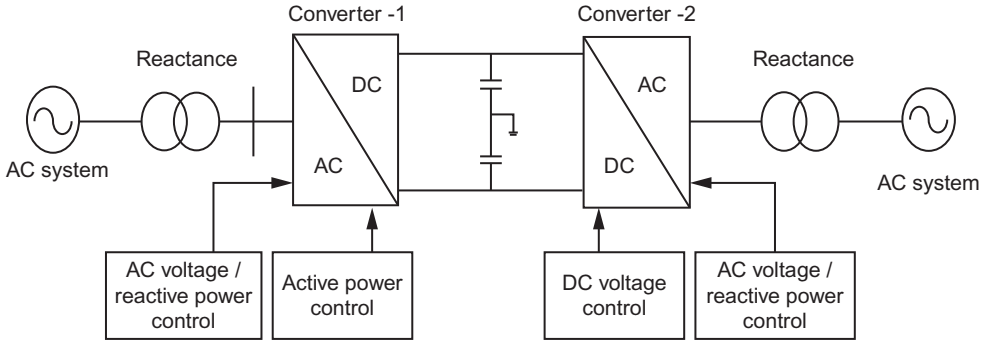

FIG. 27.45 VSC-HVDC control system.

control of each quantity. The vector control strategy consists of a cascade control system with faster inner controllers. The vector controller is accomplished by additional outer current controller that provides the reference values for inner controller. The outer controllers include active power controller, reactive power controller, AC voltage controller, DC voltage controller, or frequency controller where the implementation of particular control strategy depends on the application and operating conditions of VSC-HVDC system. It is not possible to implement all the control strategies at the same time and requires an extensive system operation and performance studies for implementation of particular control method.

For feeding the passive system at receiving end without any local voltage source, it is necessary to control the frequency and AC voltage, whereas the active power and reactive power control is required in active AC system. However, since the active power flow into the DC link must be balanced, the DC voltage controller is necessary in any case to achieve active power balance. On the DC side, the active power input to the DC link must equal the active power output from the DC link plus the losses in the DC link. Any difference would result in a change in the DC voltage.

In order to understand the vector control technique of the VSC-HVDC transmission system, the mathematical model for VSC-HVDC system needs to be derived. The vector control strategy can be derived from the mathematical modeling of the system shown in Fig. 27.46.

The AC filters connected to the VSC-HVDC system behave as pure capacitors at fundamental frequencies. Hence, in the mathematical model presented here, the filter resistances and inductances can be neglected. From the single-line diagram (Fig. 27.46), the voltage across the transformer, the current to the filter, and the voltage across the source impedance can be obtained in three-phase instantaneous form as follows:

The voltage across the source impedance is

$$Vac(t)_{abc} - Vs(t)abc = Rsi_S(t)_{abc} + Ls\frac{d}{dt}i_S(t)_{abc} \tag{27.10}$$

The current through the filters is

$$i_S(t)_{abc} - i_t(t)_{abc} = C_f\frac{d}{dt}Vs(t)_{abc} \tag{27.11}$$

The voltage across the transformer is

$$Vs(t)_{abc} - Vc(t)_{abc} = R_T i_t(t)_{abc} + L_T\frac{d}{dt}i_S(t)_{abc} \tag{27.12}$$

From Eqs. (27.10)–(27.12), the following differential equations can be derived:

$$\frac{d}{dt}i_S(t)_{abc} = -\frac{Rs}{L_S}i_S(t)_{abc} + \frac{1}{Ls}\left\{Vac(t)_{abc} - Vs(t)_{abc}\right\} \tag{27.13}$$

$$\frac{d}{dt}Vs(t)_{abc} = \frac{1}{C_f}i_S(t)_{abc} - \frac{1}{C_f}i_t(t)_{abc} \tag{27.14}$$

$$\frac{d}{dt}is(t)_{abc} = -\frac{R_T}{L_T}i_t(t)_{abc} + \frac{1}{L_T}\left\{Vs(t)_{abc} - Vc(t)_{abc}\right\} \tag{27.15}$$

By using Clarke's transformation matrix, quantities from ABC frame can be converted to αβ reference frame as follows:

$$\begin{bmatrix} x_\alpha \\ x_\beta \end{bmatrix} = \frac{2}{3}\begin{bmatrix} 1 & \cos\gamma & \cos 2\gamma \\ 0 & \sin\gamma & \sin 2\gamma \end{bmatrix}\begin{bmatrix} x_a \\ x_b \\ x_c \end{bmatrix} \tag{27.16}$$

where $\gamma = 2\pi/3$.

Eqs. (27.13)–(27.15) can be converted in to αβ frame as follows:

$$\frac{d}{dt}i_S(t)_{\alpha\beta} = -\frac{Rs}{L_S}i_S(t)_{\alpha\beta} + \frac{1}{Ls}\left\{Vac(t)_{\alpha\beta} - Vs(t)_{\alpha\beta}\right\} \tag{27.17}$$

$$\frac{d}{dt}Vs(t)_{\alpha\beta} = \frac{1}{C_f}i_S(t)_{\alpha\beta} - \frac{1}{C_f}i_t(t)_{\alpha\beta} \tag{27.18}$$

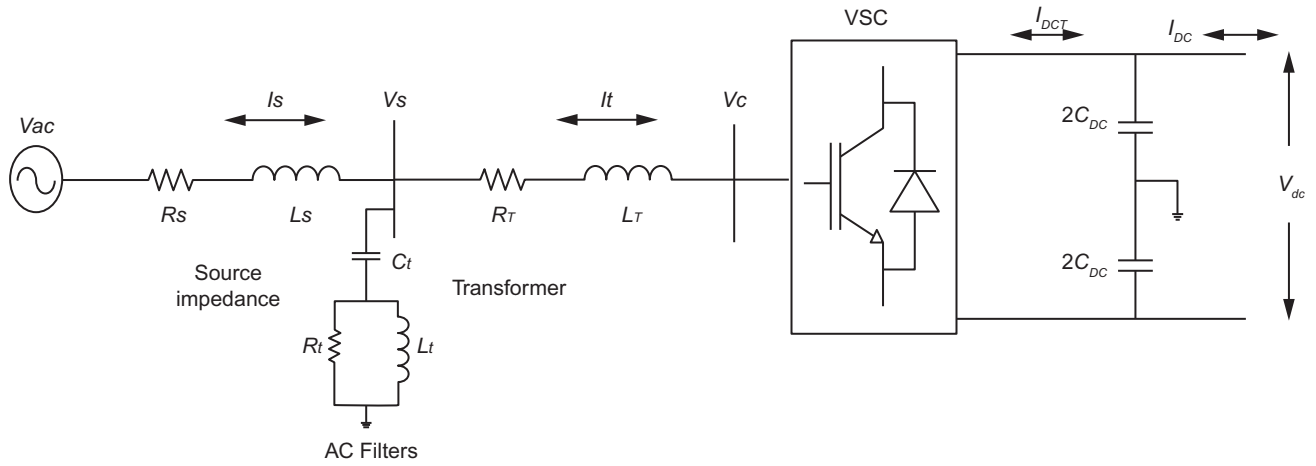

FIG. 27.46 Vector control system of VSC-HVDC system.

$$\frac{d}{dt}is(t)_{\alpha\beta} = -\frac{R_T}{L_T}i_t(t)_{\alpha\beta} + \frac{1}{L_T}\left\{Vs(t)_{\alpha\beta} - Vc(t)_{\alpha\beta}\right\} \quad (27.19)$$

By using the transformation angle θ derived from a phase-locked loop (PLL), the above equations are further transferred to the synchronously rotating dq reference frame, using Park's transformation, as follows:

$$\begin{bmatrix} x_d \\ x_q \end{bmatrix} = \begin{bmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{bmatrix} \begin{bmatrix} x_\alpha \\ x_\beta \end{bmatrix} \quad (27.20)$$

$$\frac{d}{dt}i_S(t)_{dq} = -\frac{Rs}{L_S}i_S(t)_{dq} - j\omega i_S(t)_{dq} + \frac{1}{L_S}\left\{Vac(t)_{dq} - Vs(t)_{dq}\right\} \quad (27.21)$$

$$\frac{d}{dt}Vs(t)_{dq} = \frac{1}{C_f}i_S(t)_{d_q} - \frac{1}{C_f}i_t(t)_{dq} - j\omega Vs(t)_{dq} \quad (27.22)$$

$$\frac{d}{dt}is(t)_{dq} = -\frac{R_T}{L_T}i_t(t)_{dq} - j\omega i_t(t)_{dq} + \frac{1}{L_T}\left\{Vs(t)_{dq} - Vc(t)_{dq}\right\} \quad (27.23)$$

The AC filter voltage, the current through the transformer, and the AC side voltage of VSC can be expressed as

$$Vs(t)_{dq} = -L_S\frac{d}{dt}i_S(t)_{dq} - R_S i_S(t)_{d_q} - j\omega L_S i_S(t)_{dq} + Vac(t)_{dq} \quad (27.24)$$

$$i_t(t)_{dq} = i_S(t)dq = C_f\frac{d}{dt}Vs(t)_{dq} - j\omega C_f Vs(t)_{dq} \quad (27.25)$$

$$Vc(t)_{dq} = -L_S\frac{d}{dt}i_t(t)_{dq} - R_T i_S(t)_{dq} - j\omega L_T i_S(t)_{dq} + Vs(t)_{dq} \quad (27.26)$$

From Eq. (27.26), the dq current component through the transformer can be given as

$$\frac{d}{dt}i_t(t)_d = \omega i_t(t)_q + \frac{Vs(t)_d - Vc(t)_d}{L_T} - \frac{R_T}{L_T}i_t(t)_d \quad (27.27)$$

$$\frac{d}{dt}i_t(t)_q = \omega i_t(t)_d + \frac{Vs(t)_q - Vc(t)_q}{L_T} - \frac{R_T}{L_T}i_t(t)_q \quad (27.28)$$

Eqs. (27.27) and (27.28) present the relationship between input reference current and converter output AC voltage in dq reference frame.

27.9.4 Limitations

The VSC-HVDC link with its semiconductor switches has a limited overload capacity. Large transient currents due to system disturbances can stress or damage the converter valves. Therefore, a current limit must be implemented in the control system. Moreover, since the maximum voltage amplitude out of the VSC is limited by the VSC voltage capability, the produced reference voltage from the vector controller must be appropriately limited. The current limit I_{lim} is compared with the current magnitude computed from the active and reactive reference currents. When the current limit is exceeded, both the active and reactive reference currents have to be limited. The choice of how to limit both reference currents will depend on the application. For instance, if the converter is connected to a strong system, the active component of the reference current will be given priority, when the current limit is exceeded, to produce more active power. The produced active power is estimated from the equation:

$$P_{max} = \sqrt{{V_c}^2 {I_{lim}}^2} \quad (27.29)$$

If the converter is connected to a weak system or used to supply a bulk industrial user (or island), the VSC will give priority to the reactive component of the reference current to maintain the AC voltage when the current limit is exceeded. The remaining capacity is then available for active power production. The produced reactive and active power may be estimated from the following equations:

$$Q_{max} = V_c {I_{lim}}^{(q)}, P_{max} = \sqrt{{V_c}^2 {I_{lim}}^2 - {Q^2}_{max}} \quad (27.30)$$

where $I_{lim}^{(q)}$ is the preset maximum reactive reference current.

27.9.5 Outer Controller

The outer controller consists of the DC voltage controller, active power controller and reactive power controller. The proposed simulation model consists of active power and reactive power controllers at VSC_1 and DC voltage and reactive power controllers at VSC_2. The outer controller creates the reference values of the dq current components for inner current controllers. The outer controller gains are smaller when compared with the inner controller to ensure the stability of the complete system.

27.9.5.1 DC Voltage Controller

As shown in Fig. 27.46, the instantaneous active and reactive powers in dq reference frame at the AC side of the VSC and the power P_{DC} transmitted on the DC side of the VSC are expressed as

$$P = \frac{3}{2}\left(Vs_d \cdot i_d + Vs_q \cdot i_q\right) \quad (27.31)$$

$$Q = \frac{3}{2}\left(Vs_d \cdot i_d - Vs_q \cdot i_q\right) \quad (27.32)$$

$$P_{DC} = V_{DC} I_{DCT} \quad (27.33)$$

where I_{DCT} is the current flowing in the DC terminals of the VSC.

During steady-state operation, the dq components of voltages are constant at the rated values. Therefore, the voltage Vs_d is rated voltage Vs, and Vs_q is zero. By considering the above assumptions, the active and reactive powers are expressed as follows:

$$P=\frac{3}{2}(V_S i_d), Q=\frac{3}{2}(V_S i_q) \tag{27.34}$$

If the losses in the converter transformer and converter are neglected, the power at the AC and DC sides can be considered equal, that is,

$$\frac{3}{2}(V_s i_d) = V_{DC} I_{DCT} \tag{27.35}$$

Hence,

$$I_{DCT} = \frac{3}{2}\frac{(Vsi_d)}{V_{DC}} \tag{27.36}$$

The current in the DC line of the VSC is given as

$$I_{DCT} = C_{DC}\frac{dV_{DC}}{dt} + I_{DC} \tag{27.37}$$

Any imbalance between the AC and DC powers leads to a change in voltage at the DC-link capacitors, which is given as

$$C_{DC}\frac{dV_{DC}}{dt} = I_{DCT} - I_{DC} \tag{27.38}$$

where I_{DCT} is the current in the DC terminals of the VSC, C_{DC} is the total DC side capacitance, V_{DC} is the DC voltage across the capacitor, and I_{DC} is the DC current flowing through the transmission line. The value of DC current from Eq. (27.37) can be used in Eq. (27.35), that is,

$$\frac{3}{2}(V_S i_d) = V_{DC}\left(C_{DC}\frac{dV_{DC}}{dt} + I_{DC}\right) \tag{27.39}$$

$$C_{DC}\frac{dV_{DC}}{dt} = \frac{3}{2}\frac{Vsi_d}{V_{DC}} - I_{DC} \tag{27.40}$$

From Eq. (27.39), the value of the reference current $i_d{}^*$ is derived as follows:

$$i_d{}^* = \frac{2}{3}\frac{V_{DC}}{V_S}\left(C_{DC}\frac{dV_{DC}}{dt} + I_{DC}\right) \tag{27.41}$$

The d-component of the current derived Eq. (27.41) gives the reference current for the inner current controller for DC voltage control.

27.9.5.2 Active Power Controller

The active current reference is obtained from Eq. (27.34):

$$i_d{}^* = \frac{2}{3}\frac{P_{ref}}{V_S} \tag{27.42}$$

where P_{ref} is the reference active power. For accurate control of the active power, a combination of a feedback loop and an open loop is used:

$$i_d{}^* = \frac{2}{3}\frac{P_{ref}}{V_S} + \left(K_{p1} + \frac{K_{i1}}{s}\right)\left(P_{ref} - P_{actual}\right) \tag{27.43}$$

where K_{p1} and K_{i1} are the proportional and integral gains, respectively, of the active power controller.

27.9.5.3 Reactive Power Controller

A reactive power controller similar to the active power controller is obtained from Eq. (27.34) as

$$i_q{}^* = \frac{2}{3}\frac{Q_{ref}}{V_S} \tag{27.44}$$

where Q_{ref} is reference reactive power. Again, same method is used to combine a feedback loop with an open loop:

$$i_q{}^* = \frac{2}{3}\frac{Q_{ref}}{V_S} + \left(K_{p2} + \frac{K_{i2}}{s}\right)\left(Q_{ref} - Q_{actual}\right) \tag{27.45}$$

where Kp_2 and Ki_2 are the proportional and integral gains, respectively, of the reactive power controller.

Fig. 27.47 shows active and reactive power control system for VSC_1. The control block of PLL is shown from which the synchronization angle θ is derived and fed to the ABC to dq block.

27.9.6 Summary

This chapter deals with the control system of VSC-HVDC transmission system. Two different control systems, direct control and vector control, are explained. The VSC-HVDC mathematical model is provided in this chapter. Block diagram of active power and reactive power control systems in vector control technique is also provided here.

27.10 HVDC System Simulation Techniques

Modern HVDC systems incorporate complex control and protection features. The testing and optimization of these features require powerful tools that are capable of modeling all facets of the system and have the flexibility to do the evaluation in a rapid, effective, and cost-efficient manner.

27.10.1 DC Simulators and TNAs [9]

For decades, this has been achieved with the aid of physical power system simulators or transient network analyzers (TNAs) that incorporate scaled physical models of all power

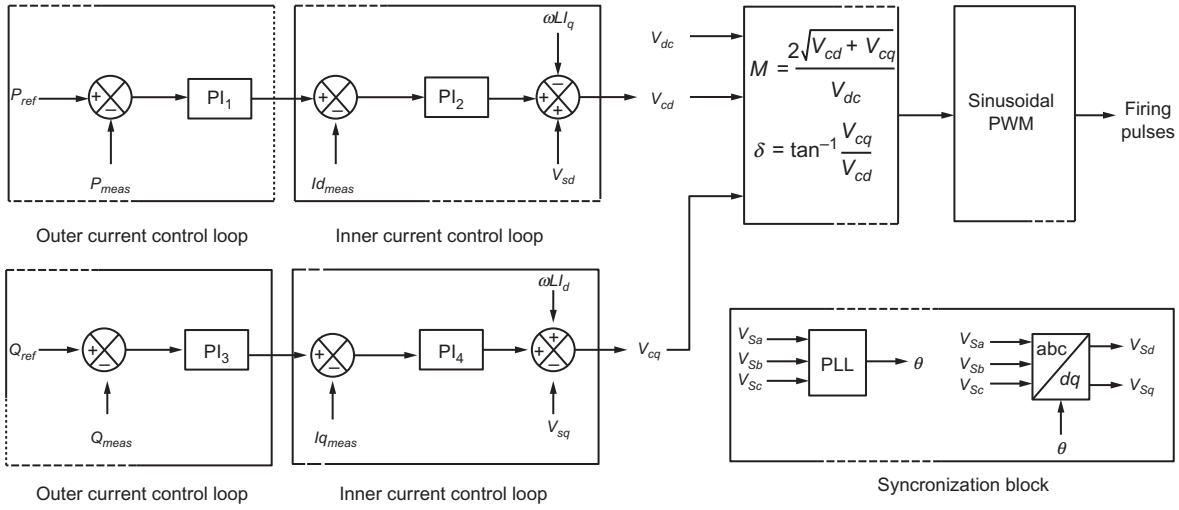

FIG. 27.47 Active and reactive power control system.

system elements (three-phase DC network lines/cables, sources as emf behind reactances, model circuit breakers for precisely timed AC system disturbances, transformers (system and convertor transformers with capacity to model saturation characteristics), filter capacitors, reactors, resistors, arrestors, and machines). Until the 1970s, these were built with analog components. However, with the developments in microprocessors, it is now feasible to utilize totally digital simulators operating in real time for even the most complex HVDC system studies. Most simulator operating scale are in the range 20–100 V DC and 0.2–1 A AC and at power frequency of 50 or 60 Hz. The stray capacitances and inductances are, however, not normally represented since the simulator is primarily used to assess control system behavior and temporary overvoltages of frequencies below 1000 Hz. Due to the developments of flexible AC transmission system (FACTS) application, most modern simulators now include similarly scaled models of HVDC converters, static compensators, and other thyristor-controlled equipment. The controls of these equipments are usually capable of realistic performance during transients such as the AC faults and commutation failure. The limited availability of adequate models of some of the system elements restricts the scope of the studies that can be completed entirely by means of the simulator. Due to the scaling problems, the losses in the simulator may be disproportionately high and need to be partly compensated by electronic circuits (negative resistances) to simulate appropriate damping of overvoltages and other phenomena.

27.10.2 Digital Computer Analysis

The main type of program employed for studies is an electromagnetic transient program (EMTP) that solves sets of differential equations by step-by-step integration methods. The digital program must allow for modeling of both the linear and nonlinear components (single and three phase) and of the topological changes caused, for example, by valve firing or by circuit-breaker operation. Detailed modeling of the converter control system is necessary depending on the type of study.

EMTP has become an industry standard analysis tool for power systems and is widely used. The program has had a checkered history, and numerous variants have appeared. Initially, the development of the program was supported by the Bonneville Power Administration (BPA). Some of the drawbacks in the capabilities of EMTP became more pronounced as the modeling of flexible AC transmission system (FACTS) with power electronic switches and voltage-source converters became more desirable.

Some of the drawbacks of the original EMTP version were the following:

1. The use of a fixed timestep that did not take into account the relatively long periods of inaction during nonswitching events. This results in unnecessarily long simulation times and huge amounts of data to be manipulated. This is particularly problematic for simulating power electronic converters.
2. The use of a fixed timestep results in the modeled switches chopping inductive currents that causes numerical oscillations. The use of artificial RC "snubbers" helped to alleviate some of these problems. The choice of the snubber capacitor was a function of the magnitude of the current to be chopped and the timestep size.
3. The use of the trapezoidal integration method results in numerical oscillations when the network admittance matrix to be inverted becomes singular. This is the direct result of modeling switches as truly either ON or OFF without representation of their intermediate nonlinear characteristics.

4. The requirement of a one timestep delay between the main program and the TACS subroutine for control simulation.
5. The use of new voltage-source converters with multiple switchings per cycle made the problem of switching "jitter" much more evident.
6. The lack of user-friendly input and output processors.

In recent years, considerable effort has been made by the EMTP Development Coordination Group (DCG) to restructure the program. This has resulted in the latest version called the EMTP restructured version (RV) (see www.emtp.com). The entire code of the program has been rewritten, and graphic input and output processors have been added. A sample of the graphic input file is shown in Fig. 27.48.

The main advantage of digital studies is the possibility of correct representation of the damping present in the system. This feature permits more accurate evaluation of the nature and rate of decay of transient voltages following their peak levels in the initial few cycles and also a more realistic assessment of the peak current and total energy absorption of the surge arrestors. The digital program also allows modeling of stray inductances and capacitances and can be used to cover a wider frequency range of transients than the DC simulator.

The main disadvantage of the digital studies is the lack of adequate representation of commutation failure phenomena with the use of power electronic converters. However, with the increasing capacity of computers, this is likely to be overcome in the future.

The models used in the simulators and digital programs depend on the assumptions made and on the proper understanding of the component and system characteristics; therefore, they require care in their usage to avoid unrealistic results in inexperienced hands.

27.11 Concluding Remarks

HVDC technology is now mature, reliable, and accepted all over the world. From its modest beginning in the 1950s, the technology has advanced considerably and maintained its leading edge image. The encroaching technology of flexible AC transmission systems (FACTS) has learned and gained from the technological enhancements made initially by HVDC systems. FACTS technology may challenge some of the traditional roles for HVDC applications since the deregulation of the electric utility business will open up the market for increased interconnection of networks [7]. HVDC transmission has unique characteristics that will provide it with new opportunities.

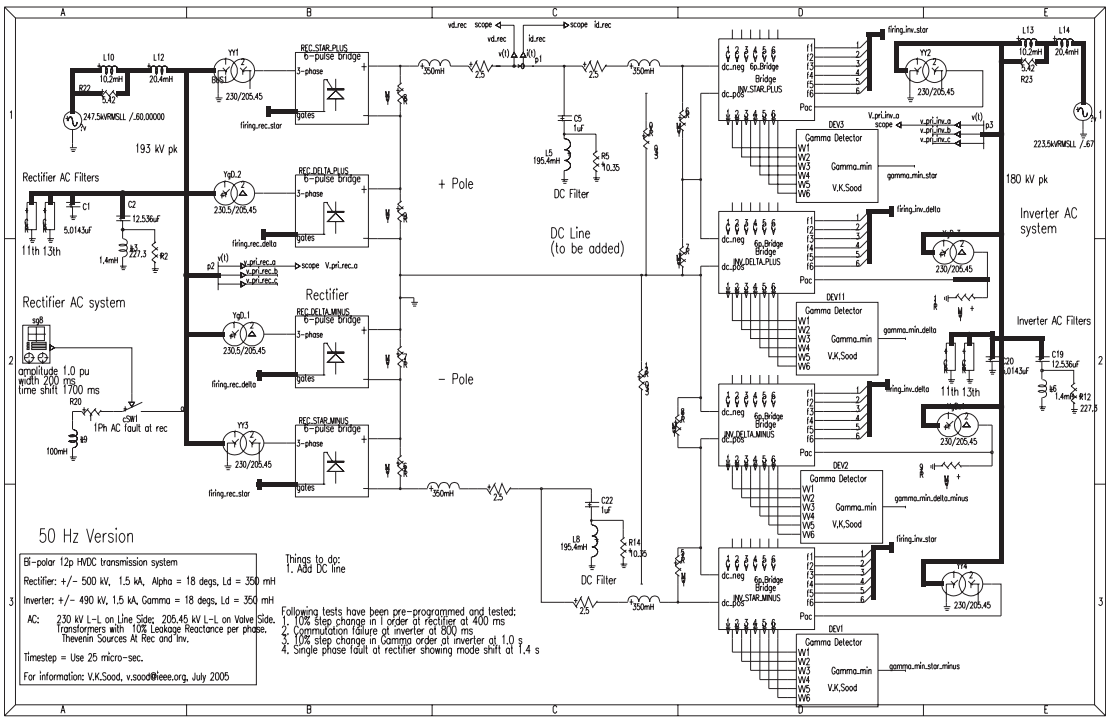

FIG. 27.48 A sample of the graphic input file of EMTP RV.

Although the traditional applications of HVDC transmission will be maintained for bulk power transmission in places like China, India, S. America, and Africa, the increasing desire for the exploitation of renewable resources will provide both a challenge and an opportunity for innovative solutions in the following applications:

- Connection of small dispersed generators to the grid
- Alternatives to local generation
- Feeding to urban city centers

Acknowledgments

The author pays tribute to the many pioneers whose vision of HVDC transmission has led to the rapid evolution of the power industry. It is not possible here to name all of them individually.

A number of photographs of equipment have been included in this chapter, and I thank the suppliers (Mr. P. Lips of Siemens and Mr. R. L.Vaughan from ABB) for their assistance in getting clearances.

I also thank my wife Vinay for her considerable assistance in the preparation of this manuscript.

28.1 Introduction

In 1988, Hingorani [1] published a paper entitled "Power Electronics in Electric Utilities: Role of Power Electronics in Future Power Systems," proposing the extensive use of power electronics for the control of ac systems, which resulted in the flexible ac transmission system or the FACTS concepts [2]. The basic idea was to obtain ac systems with a high level of control flexibility, as in high-voltage direct current (HVDC) systems [3] based on the use of the thyristor and the self-commutated (controllable turn-on and turn-off) silicon (Si) semiconductor devices, such as gate turn-off thyristors (GTOs), insulated gate bipolar transistors (IGBTs), and integrated gate-controlled thyristors (IGCTs) [4,5], or silicon carbide (SiC)-based devices [6], which were not yet developed at that time.

The switching characteristics of thyristors—controlled turn-on and natural turn-off—are appropriate for using in line-commutated converters, such as in conventional HVDC transmission systems with a current source in the dc side. In this application, the technology for series connection of thyristors is very important due to the high-voltage characteristics of the transmission voltage. This is a well-known technology.

Copyright © 2018 Elsevier Inc. All rights reserved.
http://dx.doi.org/10.1016/B978-0-12-811407-0.00031-3

Maximum breakdown voltage and current conduction capabilities are around 8 kV and 4 kA, respectively. These are some features that make thyristors important for very high-power applications, although they present some serious drawbacks, such as the lack of controlled turn-off capability and low switching speeds.

Self-commutated switches are adequate for use in converters where turn-off capability is necessary. The device with highest ratings in this group was, for a long time, the GTO with maximum switching capability of 6 kV and 6 kA. At present, there are IGBTs with ratings in the range of 6.5 kV to 3 kA and IGCTs with switching capability of about 6 kV and 4 kA. The GTOs and IGCTs are devices that normally need small inductor for limiting the rate of change of turn-on current (di/dt). Normally, GTOs also need a snubber circuit for limiting the rate of change of voltage (dv/dt).

The GTOs, IGCTs, and IGBTs are the most used options for self-commutated high-power converters. Because the switching time of these devices is in the microsecond range (or below), their series connection is more complicated than in the case of thyristors. However, there are examples of series connections of various GTOs or IGCTs, and in the case of IGBTs, the number of series connected devices can go as high as 32 [7]. It is worth to note that GTOs are not used in new projects anymore.

Because of the commutation nature of the thyristors, the converters used in HVDC systems are of the current source type [8]. On the other hand, the force-commutated converters using the self-commutated devices are basically of the voltage source type. More details about current source and voltage source converters can be found in many power electronics books, for example, Refs. [3,8].

28.2 Ideal Shunt Compensator

A simple and lossless ac system is composed of two ideal generators, and a short transmission line, as shown in Fig. 28.1, is considered as basis to the discussion of the operating principles of a shunt compensator [9]. The transmission line is modeled by an inductive reactance X_L. In the circuit, a continuously controlled voltage source is connected in the middle of the transmission line. It is assumed that the voltage phasors V_S and V_R have the same magnitude, V, and are phase-shifted by δ. The subscript "S" stands for "source" and "R" stands for "receptor." Fig. 28.2 shows the phasor diagram of the system given in Fig. 28.1 in which the compensation voltage phasor V_M has also the same magnitude as V_S and V_R, and its phase is exactly $(-\delta/2)$ with respect to V_S and $(+\delta/2)$ with respect to V_R.

In this situation, the current I_{SM} flows from the source and the current I_{MR} flows into the receptor. The phasor I_M is the resulting current flowing through the ideal shunt compensator; Fig. 28.2 shows that this current I_M, in this case, is orthogonal to the voltage V_M, which means that the ideal shunt compensator voltage source does not have to generate or absorb active power and have only reactive power in its terminals.

From Fig. 28.2 and knowing that no active power flows to or from the ideal shunt compensator, it is possible to calculate the power transferred from V_S to V_R that is given by

$$P_S = \frac{2V^2}{X_L}\sin(\delta/2) \tag{28.1}$$

where P_S is the active power flowing from the source.

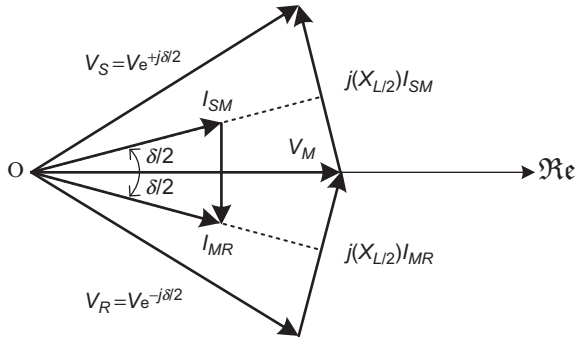

FIG. 28.2 Phasor diagram of the system with shunt reactive power compensation.

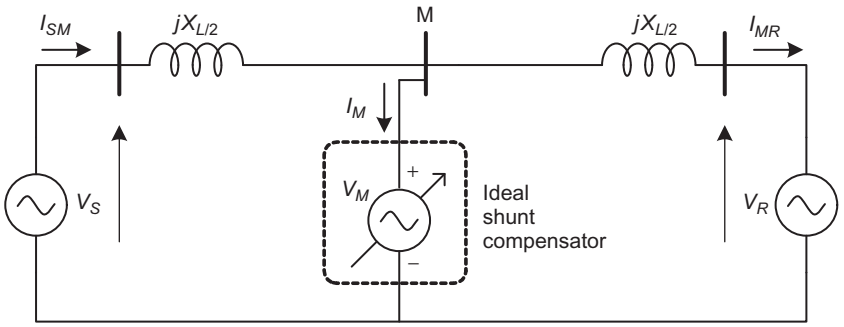

FIG. 28.1 Ideal shunt compensator connected in the middle of a transmission line.

If the ideal shunt compensator were not present, the transferred power would be given by

$$P_S = \frac{V^2}{X_L}\sin\delta \tag{28.2}$$

Since $2\sin(\delta/2)$ is always greater than $\sin\delta$ for δ in the range of $[0, 2\pi]$, the ideal shunt compensator does improve the power transfer capability of the transmission line. This voltage source is in fact operating as an ideal reactive power shunt compensator.

If the phase angle between V_M and V_S is different from $\delta/2$ (as shown in Fig. 28.3), the power flowing through V_M has both active and reactive components.

With the characteristics of the ideal shunt compensator, presented above, it is possible to synthesize power electronic-based devices to operate as active or reactive power compensators. This is discussed in the following sections. It will be seen that the requirements of the device synthesis with actual semiconductor switches for the situations of reactive or active power compensation are different because of the need of energy storage element or energy source if active power is to be drained or generated by the shunt compensator.

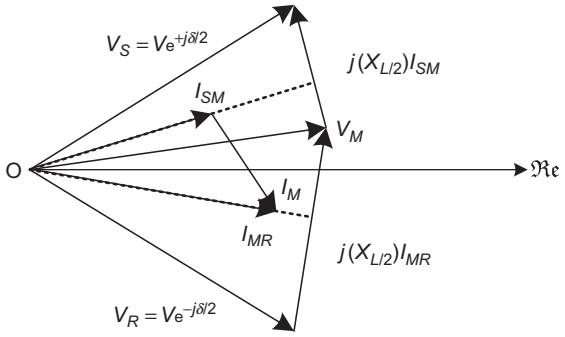

FIG. 28.3 Phasor diagram of the system with shunt reactive and active power compensation.

28.3 Ideal Series Compensator

Similar to the previous section, the ideal series compensator is modeled by a voltage source for which the phasor is V_C connected in the middle of a lossless transmission line as shown in Fig. 28.4

The current flowing through the transmission line is given by

$$I = (V_{SR} - V_C)/jX_L \tag{28.3}$$

where $V_{SR} = V_S - V_R$.

If the ideal series compensator voltage is generated in such a way that its phasor V_C is in quadrature with line current I, this series compensator neither supplies nor absorbs active power. As discussed earlier, power at the series source is only reactive, and the voltage source may, in this particular case, be replaced by capacitive or inductive equivalent impedance. Then, the equivalent impedance is given by

$$X_{eq} = X_L(1+s) \tag{28.4}$$

where

$$s = \frac{X_{Comp}}{X_L};\ \ (0 \le |s| \le 1) \tag{28.5}$$

is the compensation factor and X_{Comp} is the series equivalent compensation reactance, negative if capacitive and positive if inductive. In this case, the compensation voltage is given by

$$V_C = jX_{eq}I_L \tag{28.6}$$

and the transmitted power is equal to

$$P_s = \frac{V^2}{X_L(1-s)}\sin\delta \tag{28.7}$$

Eq. (28.7) shows that the transmitted power can be considerably increased by series compensation, choosing a proper

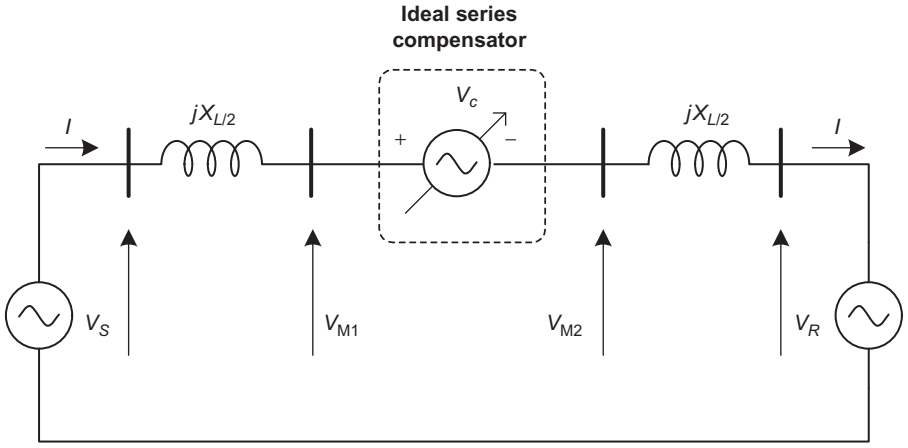

FIG. 28.4 Ideal series compensator connected in the middle of a transmission line.

compensation factor s. The reactive power at the series source is given by

$$Q_{CS} = \frac{2V^2}{X_L}\frac{s}{(1-s)^2}(1-\cos\delta) \tag{28.8}$$

The left-hand side of Fig. 28.5A shows the phasor diagram of the system shown in Fig. 28.4 without the ideal series compensator. On the right-hand side of the Fig. 28.5A, the voltage phasor V_L on the line reactance X_L and the compensator voltage phasor V_C are shown for a given compensation level, assuming that this voltage V_C corresponds to a capacitive compensation. In this case, the line current phasor leads voltage phasor V_C by 90 degrees, and the total voltage drop in the line $V_Z = V_S - V_R - V_C$ is larger than the original voltage drop V_L. The current flowing in the line is larger after compensation than before. This situation shows the case where the series compensator is used to increase power flow.

The left-hand side of the Fig. 28.5B shows the same noncompensated situation as in the previous case. On the right-hand side, the case of an equivalent inductive compensation is shown. In this case, the compensation voltage V_C is in phase with the line drop voltage V_L, producing an equivalent total voltage drop V_Z smaller than in the original case. As a result, the current phasor I flowing in the line is smaller than before compensation. This kind of compensation might be interesting in the case that the power flowing through the line has to be decreased. In either capacitive or inductive compensation modes, no active power is absorbed or generated by the ideal series compensator.

Fig. 28.6 shows an ac system with an ideal generic series compensation voltage source V_C for the general case where it may not be in quadrature with the line current. In this case, the compensator can fully control the phase difference between the two systems, thus controlling the active and reactive power exchanged between them. However, in this case, the compensation voltage source V_C may have to absorb or generate active power (P_C) and control the reactive power (Q_C).

Fig. 28.7 shows the phasor diagram of this ideal generic series compensator. This figure also shows a dashed-line circle with the locus of all possible positions that the compensation voltage V_C could take, assuming that the magnitude shown for this voltage

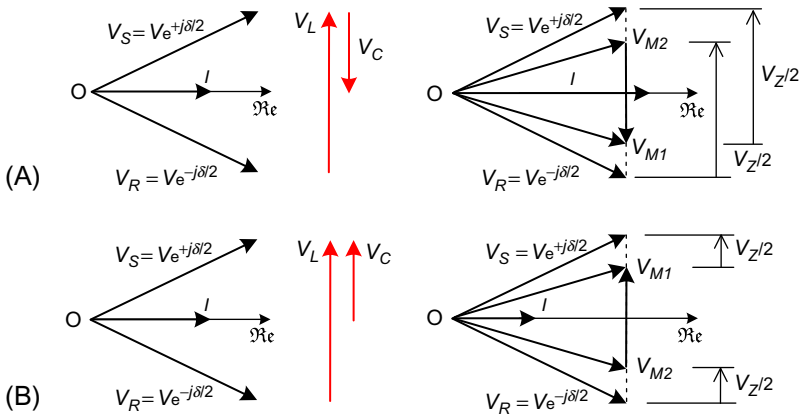

FIG. 28.5 Phasor diagram of the series reactive compensator: (A) capacitive and (B) inductive mode.

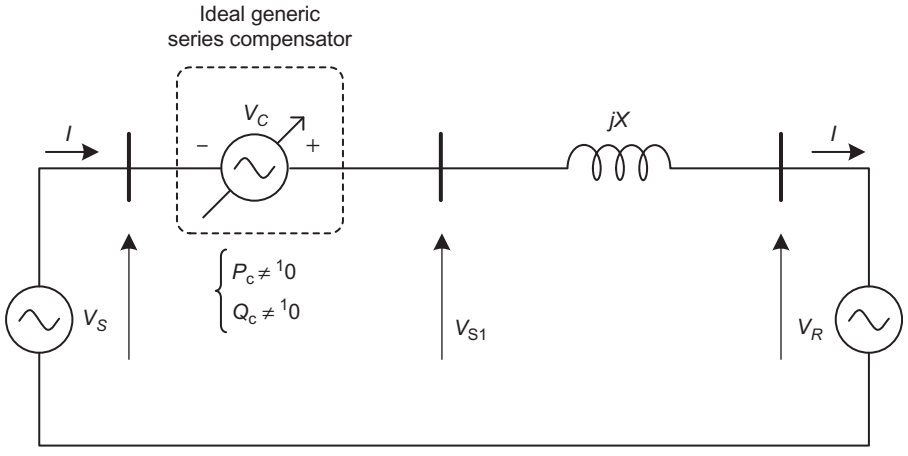

FIG. 28.6 Ideal generic series compensator.

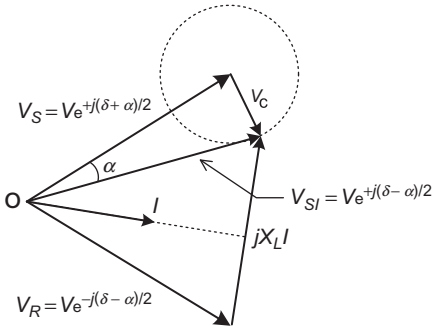

FIG. 28.7 Phasor diagram of the ac system compensated with an ideal generic series compensator.

is its maximum. Naturally, if the sum of the compensation voltage and the source voltage V_S is on the circle, the magnitude of V_{SI} may be smaller or larger than the magnitude of V_S.

The compensation voltage V_C can be added to the V_S in a way that the resultant voltage V_{S1} has the same magnitude of V_S but with a phase shifted by an angle α. In this case, the series compensator can be called as a phase-shifter compensator, and the power flowing through the transmission line (see Fig. 28.6) is expressed below:

$$P_S = \frac{V^2}{X_L}\sin(\delta - \alpha) \tag{28.9}$$

Eq. (28.9) shows that transmitted power increases as the phase difference $(\delta - \alpha)$ reaches 90 degrees. However, its maximum value is the same as in the case of no compensation. The difference is that with this compensator, the system power angle, and angle difference between the two voltage sources at the terminals of the line can be controlled faster than the conventional way, that is, by controlling the synchronous generator.

In Fig. 28.7, voltage V_C may have any phase angle with respect to line current. Therefore, it may have to supply or absorb active power and control reactive power. As in the case of the shunt device, this feature must also be taken into account in the synthesis of the actual devices. As a first approximation, when the goal is to control active power flowing through the medium- or short-length transmission lines, compensator location seems to be a question of convenience.

Fig. 28.8 summarizes the active power transfer characteristics in a transmission line as a function of the power angle, δ, as shown in Figs. 28.1 and 28.2, for the cases of the line without compensation, line with series or shunt reactive power compensation, and line with phase-shift compensation (generic series compensation). These characteristics are drawn on the assumption that the source voltages V_S and V_R (see Fig. 28.2) have the same magnitude. A 50% series compensation ($s = 0.5$) as defined in Eq. (28.4) presents a significant increase in the line power transfer capability.

As shown in Fig. 28.8, in general, series compensation is the best choice for increasing power transfer capability. The phase-shifter compensator is important to connect two systems with excessive or uncontrollable phase difference. It does not increase power transfer capability significantly; however, it may allow the adjustment of large or highly variable phase differences. The shunt compensator does not increase power transfer capability in a significant way in its normal operating region, where the angle δ is naturally below 90 degrees and in general around or less than 30 degrees. The great importance of the shunt compensator is the increase in the stability margin, as explained in Fig. 28.9.

Fig. 28.9 shows the power transfer characteristics $(P_\delta \times \delta)$ of a transmission line, which is first assumed to be transmitting power P_{S0} at phase angle δ_0. If a problem happens in the line (e.g., a fault), the turbine that drives the generator cannot change its mechanical power input immediately even if there

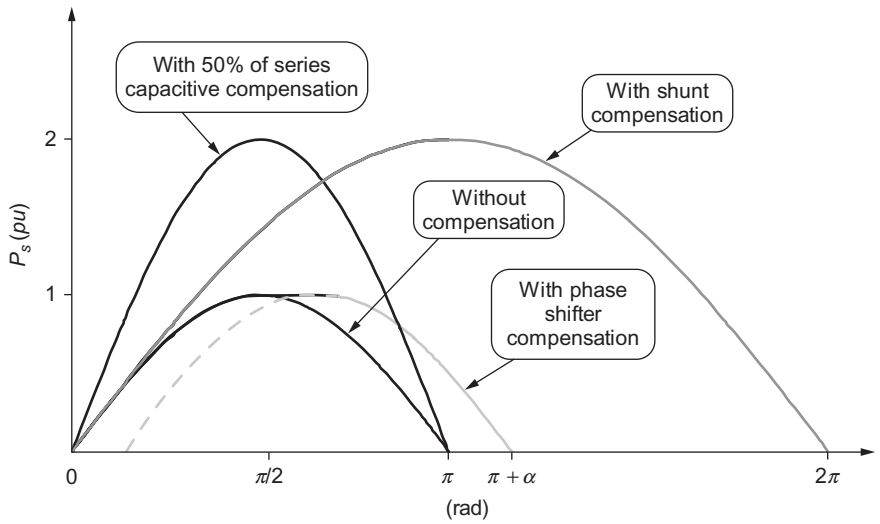

FIG. 28.8 Power transfer characteristics for the case of shunt, series, phase shift, and no compensation.

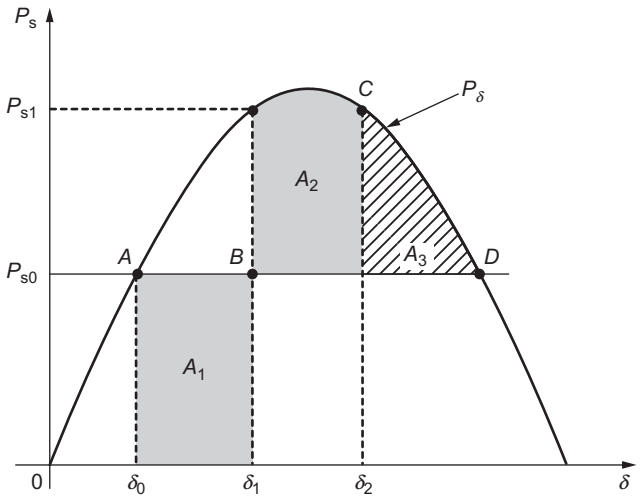

FIG. 28.9 Stability margin characteristics—stable situation.

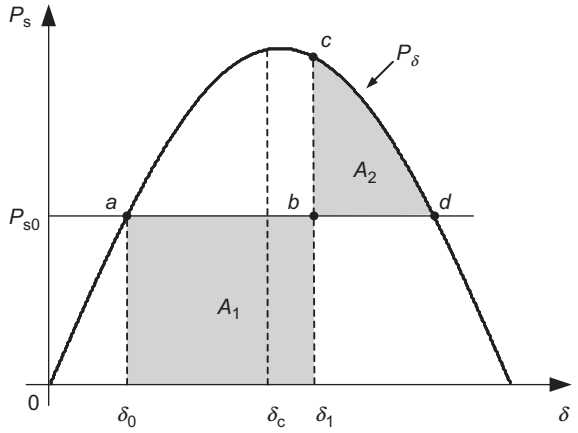

FIG. 28.10 Stability margin characteristics—unstable situation.

is no power transmission for a short time. This situation accelerates the generator, increasing its frequency and leading to an increase of the phase angle δ to δ_1. If the line restarts operation at the instant corresponding to this phase angle δ_1, the transmitted power will be P_{S1}, which is larger than P_{S0} and decelerates the turbine or generator. The area A_1 corresponds to the energy that accelerated the turbine. As the frequency gets higher than the rated frequency at (P_{S1}, δ_1), the phase angle will increase up to δ_2, where the area A_2 is equal to the area A_1. If the area given by the A_2 plus A_3 is larger than A_1, the system is said to be dynamically stable. On the contrary, if it is not possible to have an area A_2 equal to A_1, the system is said to be unstable. An unstable situation is shown in Fig. 28.10 in which the system is the same as in Fig. 28.9 but assuming a longer interval with no power transmission. In this case, the turbine or generator accelerates more than that in Fig. 28.9, and the phase angle δ increases above its critical value δ_c, which is slightly less than 90 degrees reaching δ_1. Therefore, the area below the $Px\delta$ curve to decelerate the system is not enough leading to an unstable system because A_2 is smaller than A_1 and the frequency does not return to its original value.

Looking at Fig. 28.8, it is possible to see that depending on the operating point, all three compensation methods increase the stability margin as the area under the curve of transmitted power $P\delta$ versus phase angle δ is increased. The ideal shunt compensator is the one that most increases this area, and thus, it is said to be the best option to increase the stability margin.

28.4 Synthesis of FACTS Controllers

It has been stated that the synthesis of the compensators presented in Sections 28.2 and 28.3 can be achieved with thyristors or self-commutated switches. Each type of switches (thyristor or self-commutated) leads to controllers with different operating principles and synthesis concepts, and hence, they should be discussed separately. Terms and definitions for most of the FACTS controllers are given in Ref. [10].

Thyristor-based FACTS controllers use line or natural commutation together with large passive energy storage elements (capacitors or reactors). On the other hand, controllers based on self-commutating switches use gate-controlled commutation. In general, it is said that the first generation of FACTS devices is based on conventional line-commutated thyristors, and the subsequent generations are based on gate-controlled devices or self-commutated switches. The most important FACTS controllers based on thyristors and self-commutating controllers are presented in the following sections.

28.4.1 Thyristor-Based FACTS Controllers

28.4.1.1 Thyristor-Controlled Reactor

The most used thyristor-based FACTS controller is the thyristor-controlled reactor (TCR) as shown in Fig. 28.11A. This is a shunt compensator that produces an equivalent continuous variable inductive reactance by using phase-angle control. Fig. 28.11B shows the voltage and current waveforms of the TCR. The current is controlled by the firing angle α; the magnitude of the fundamental current component can be larger or smaller depending on the angle α, which can vary from 90 to 180 degrees measured from the zero crossing of the voltage. At $\alpha = 90$ degrees, the reactor is fully inserted in the circuit, and for $\alpha = 180$ degrees, the reactor is completely out of the circuit. Fig. 28.12 shows the equivalent admittance of the TCR as function of the firing angle α. Naturally, this admittance is always inductive.

28.4.1.2 Thyristor-Switched Capacitor

Fig. 28.13 shows the thyristor-switched capacitor (TSC). The word "controlled" used in the case of the reactor is substituted by "switched" because the thyristor is turned on only when zero-voltage switching (ZVS) condition is possible. This means that the voltage across the thyristor terminals has to be zero at

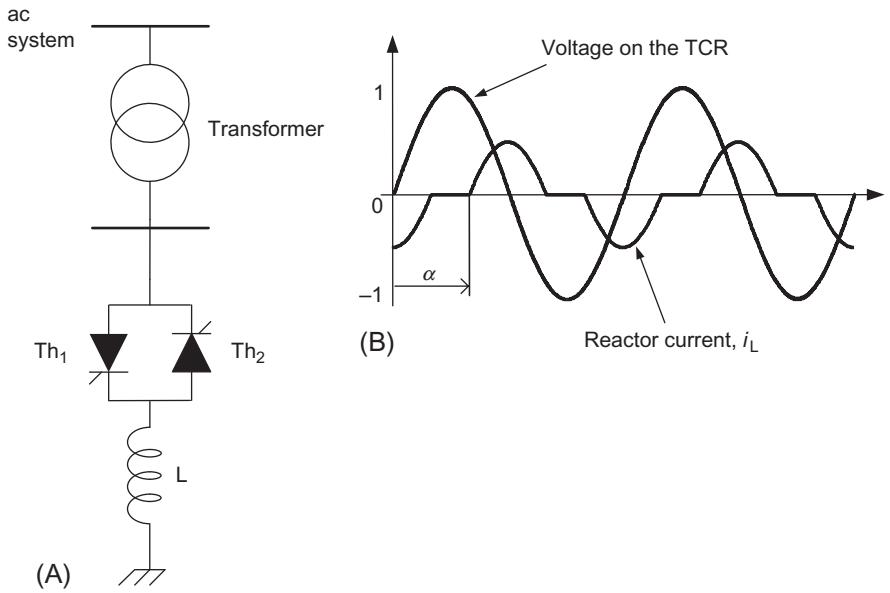

FIG. 28.11 (A) TCR and (B) its voltage and current waveforms.

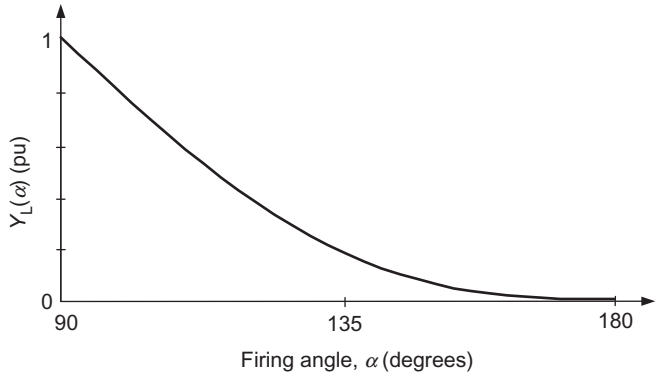

FIG. 28.12 Equivalent admittance of a TCR as a function of the firing angle α.

the turn-on instant. In practical cases, it may be slightly positive because thyristors need positive anode-cathode voltages to be triggered (positive anode-cathode voltage during turn-on); however, if this voltage is too high, it can produce a large current spike that can damage the thyristors. Therefore, due to this switching characteristic, the thyristors can only connect the capacitor to the grid or disconnect it. Consequently, only step-like control is possible, and a continuous control is not possible. The capacitor connection to or disconnection from the grid is normally performed at very low frequencies, and the harmonics, when they appear, are not a serious concern.

28.4.1.3 Static Var Compensator

The use of the TCR shown in Fig. 28.11 or the TSC shown in Fig. 28.13 allows only continuous inductive compensation or discontinuous capacitive compensation. However, in most applications, it is desirable to have continuous capacitive or inductive compensation. The static var compensator (SVC)

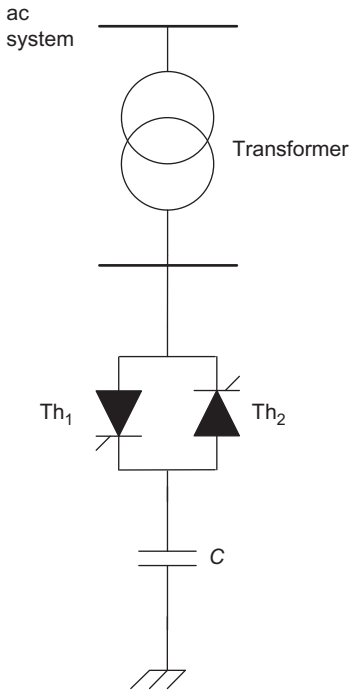

FIG. 28.13 Thyristor-switched capacitor (TSC).

is generally designed to operate in both inductive and capacitive continuous compensation [11,12]. It may be used for reactive power compensation for either voltage regulation or power factor correction. The basic three-phase SVC scheme is comprised of a three-phase TCR parallel connected to a capacitor bank. The TCR serves as the controller basis for the conventional SVC.

Fig. 28.14 shows a single-line diagram of an SVC, where the TCRs are Δ connected and the capacitors are Y connected. The

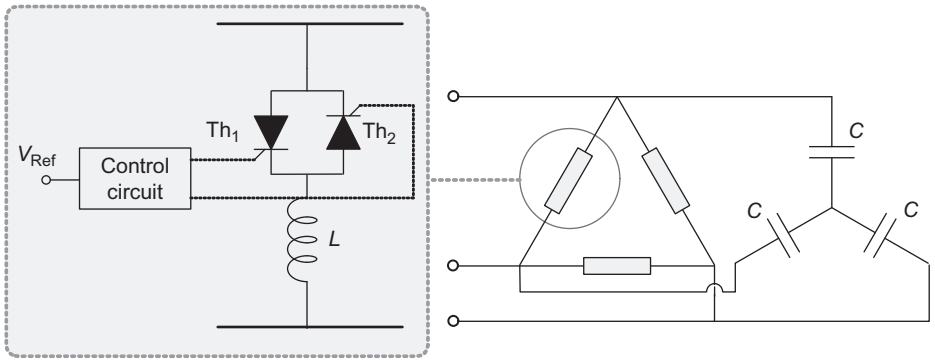

FIG. 28.14 Six-pulse SVC.

circuit does not show the filters that are normally needed due to the switching-generated harmonics. In some cases, the capacitor bank can be a fixed capacitor parallel connected to a TSC in order to get more flexibility in terms of control range.

The capacitance of the SVC is calculated in such a way as to generate the maximum capacitive reactive power that it has to control. This condition is achieved when the thyristors are turned off ($\alpha = 180$ degrees). On the other hand, the maximum reactive power of the TCR inductor has to be greater than the reactive power of the capacitor bank. In this way, the SVC can control the reactive power from capacitive to inductive. The maximum inductive reactive power is given for the case when the thyristors are turned on at minimum firing angle ($\alpha = 90$ degrees). The SVC can control reactive power from maximum capacitive for $\alpha = 180$ degrees to maximum inductive for $\alpha = 90$ degrees. Thus, the SVC represents an adjustable fundamental frequency susceptance to the ac network, controlled by the firing angle of the TCR thyristors (90 degrees $< \alpha <$ 180 degrees).

The SVC is well known, and many examples of successful applications can be found around the world.

Due to the once-per-cycle thyristor firing with phase-angle control, current with low-order harmonic components appears and Y-Δ transformers and passive filters may be needed to eliminate part of them. Three sets of TCRs connected in the Δ side of Y-Δ transformers form a conventional six-pulse TCR. To minimize harmonic generation, it is common to have two sets of transformers connected in Y-Δ and Δ-Δ with the TCR connected in the Δ side forming a 12-pulse TCR.

28.4.1.4 Thyristor-Switched Series Capacitor

Fig. 28.15 shows the thyristor-switched series capacitor (TSSC). In this controller, the thyristors should be kept untriggered so as to connect the capacitors in series with the transmission line. If the thyristors are turned on, the capacitor is bypassed. Thyristors must be turned on at a zero-voltage condition (ZVS), as it occurs in the case of the TSC, to avoid current spikes in the switches. An example of an application based on this concept is presented in Ref. [13].

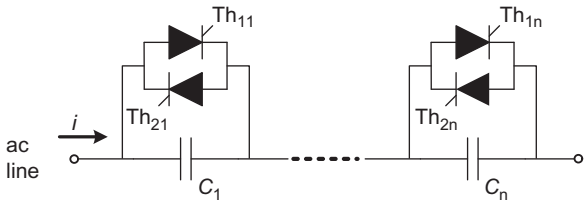

FIG. 28.15 Thyristor-switched series capacitors (TSSC).

This compensation system has the advantage of being very simple. However, it does not allow continuous control. If the connection or disconnection of the capacitors is to be made at sporadic switching, it can be said that no harmonic problem occurs. Depending on the frequency the thyristors are switched, harmonic or subharmonics may appear. In this arrangement, it is interesting to choose a number of capacitors in such a way that many different combinations can be achieved. For example, if the total number of capacitors is three, they could have impedance proportional to 1, 2, and 3. Therefore, by combining these values, it is possible to obtain equivalent capacitive impedance proportional to 1, 2, 3, 4, 5, and 6.

28.4.1.5 Thyristor-Controlled Series Capacitor

Fig. 28.16 shows the thyristor-controlled series capacitor (TCSC). In this figure, the transmission line and the voltage

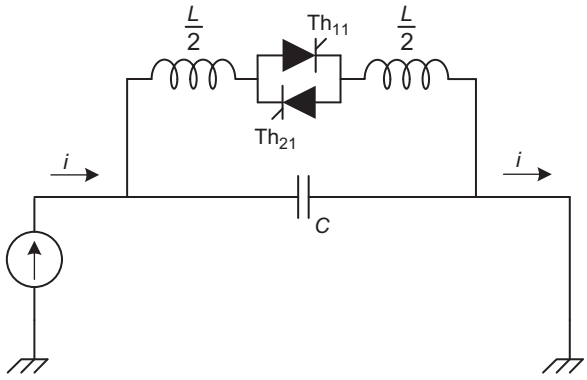

FIG. 28.16 Thyristor-controlled series capacitors (TCSC).

sources at its ends are represented by a current source because this is the actual behavior of most of the transmission system. This compensator is also based on the TCR that was first developed for shunt connection. When the TCR is used connected in series with the line, it has to be always connected in parallel with a capacitor because it is not possible to control the current if the equivalent of the transmission line and the sources is a current source. This circuit is similar to the conventional SVC with the difference that the TCSC is connected in series with the line. In this compensator, the equivalent value of the series connected reactor can be continuously controlled by adjusting the firing angle of the thyristors. As a consequence, this device presents a continuously controllable series capacitor. Various practical systems based on this concept are under operation around the world [13–15]. This device has been used for power flow control and power oscillation damping.

Fig. 28.17 presents the current and voltage waveforms in the TCSC, showing that although there is a large amount of harmonics in the capacitor and reactor currents, capacitor voltage is almost sinusoidal. In actual applications, these harmonics are not a serious concern, and they are filtered by the capacitor itself and by the transmission line impedance.

Fig. 28.18 shows the equivalent impedance of the TCSC as a function of the firing angle α. This figure shows that this controller has both capacitive and inductive characteristic regions divided by a resonant region. In the example shown in this figure, the resonance happens for α around 145 degrees. In normal operation, the TCSC is controlled in the capacitive compensation region where its impedance varies from its minimum value Z_{min} for firing angle $\alpha = 180$ degrees and its maximum safe value Z_{max} for α around 150 degrees. Operation with α close to the resonance region is not safe. This device can operate also in the inductive region, but in this case, normally, it is used only when $\alpha = 90$ degrees to decrease power transfer capability of the transmission line.

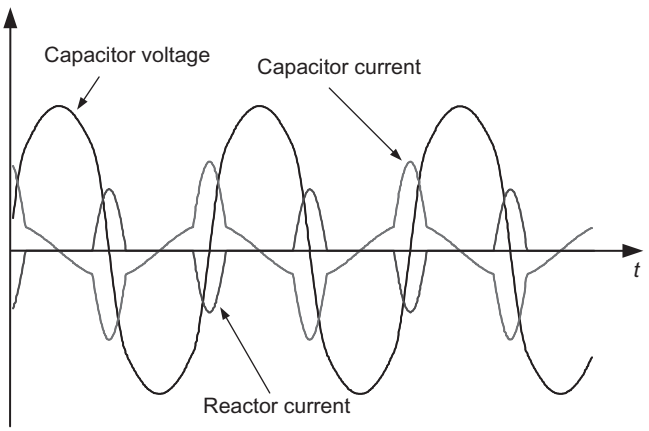

FIG. 28.17 TCSC voltage and current waveforms.

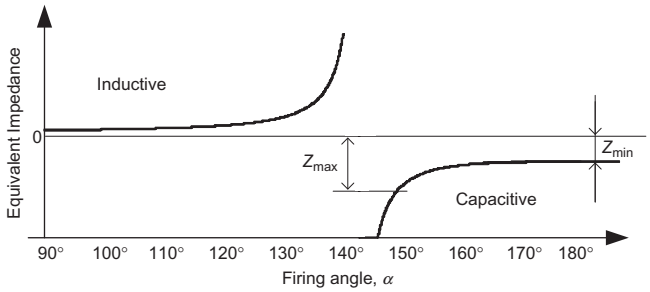

FIG. 28.18 TCSC equivalent reactance.

28.4.1.6 Thyristor-Controlled Phase Angle Regulator

The thyristor-controlled phase-angle regulator (TCPAR), shown in Fig. 28.19 as an example, may improve considerably the controllability of a utility of power transmission system. In this figure, only the control of phase "a" is detailed. The series voltage generated in phase "a" comes from three secondary windings of a transformer whose primary side is connected between phases "b" and "c." Each of the three secondary windings can be connected in series with the line through the thyristors' switching. The thyristors are connected in antiparallel, forming bidirectional naturally commutated switches. By turning on a set of thyristors, a voltage whose magnitude can be controlled by phase control is connected in series with the transmission line. The number of secondary windings is chosen as to decrease harmonic content of the series compensation voltage (Fig. 28.17).

The TCPAR in Fig. 28.19 has some peculiarities that should be pointed out. One of them is that active power can only flow from the shunt to the series windings. The compensation voltage phasor, as shown in Fig. 28.20, has a limited range of

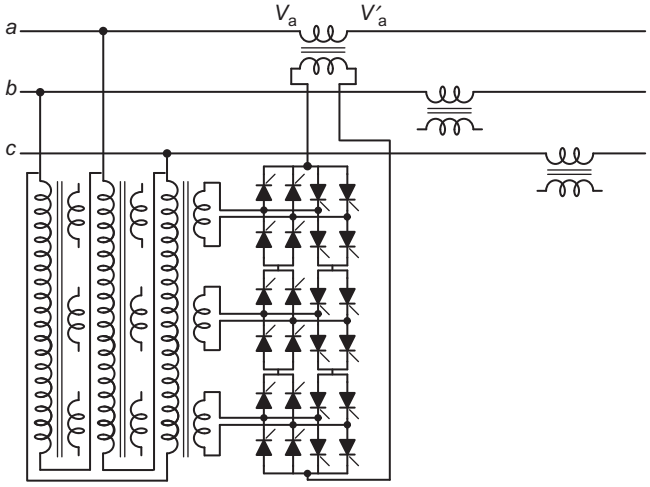

FIG. 28.19 Thyristor-controlled phase-angle regulator (TCPAR).

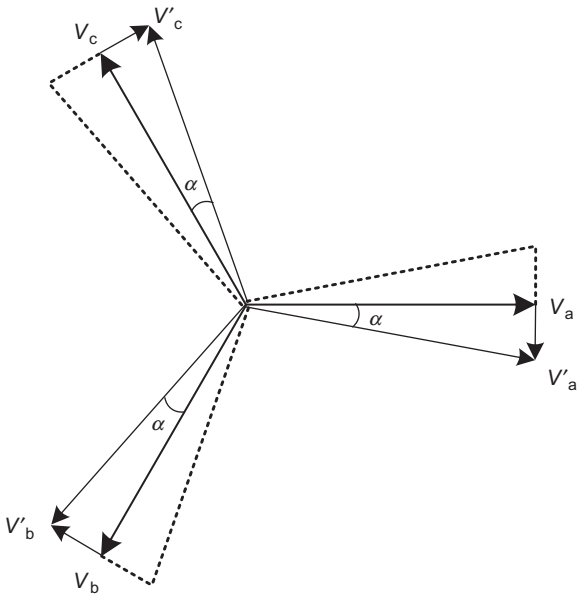

FIG. 28.20 Phasor diagram of the TCPAR in Fig. 28.19.

variation; in the case of phase "a," its locus is along a line orthogonal to V_a because the injected voltage is in phase with the voltage $(V_b - V_c)$. As a consequence, it is not possible for the TCPAR to generate a compensating voltage phasor whose locus is a circle, as shown in Fig. 28.7, for the case of an ideal generic series compensator.

Other configuration of phase shifters can be found in the literature, for example [16,17].

28.4.2 FACTS Controllers Based on Self-Commutated Switches

There are various different types of FACTS controllers based on self-commutated switches, and the names used here are in accordance with the names published in Ref. [10]. Some of them are newer controllers and are not in that reference. In this case, the name used is the same as it appears in the literature. In Ref. [2], it is possible to find most of the details of FACTS controllers.

The development of high-power self-commutated devices has led to the development of high-power voltage source converters (VSC), such as the six-pulse two-level VSC shown in Fig. 28.21A [4] or the three-level neutral point clamped VSC shown in Fig. 28.21B [18]. In the figures, the generic switches could be IGBTs, IGCTs, or other self-commutating switches or even the recently developed SiC switches, with an antiparallel connected diode. This set of self-commutated switch and antiparallel diode operates with a unidirectional voltage-blocking capability and a bidirectional current flow. In contrast, the current source converters (CSC) used in HVDC transmission systems use switches (thyristors) operating with unidirectional current flow and bidirectional voltage-blocking capabilities.

In a conventional VSC, for industrial applications, a voltage source is connected at the converter dc side. However, in the case that only reactive power has to be controlled, the dc voltage source may be replaced by a capacitor. If active power has to be absorbed or generated by the compensator, an energy storage system has to be connected at the dc side of the VSC.

In practical applications, small reactors (L) are necessary to connect the VSC to the ac network. This is necessary to avoid current peaks during switching transients. In most cases, these reactors are the leakage inductance of the coupling transformers.

28.4.2.1 Static Synchronous Compensator (STATCOM)

The first high-rating STATCOM started operation in 1991 [19] in Japan and uses three single-phase VSCs to form one

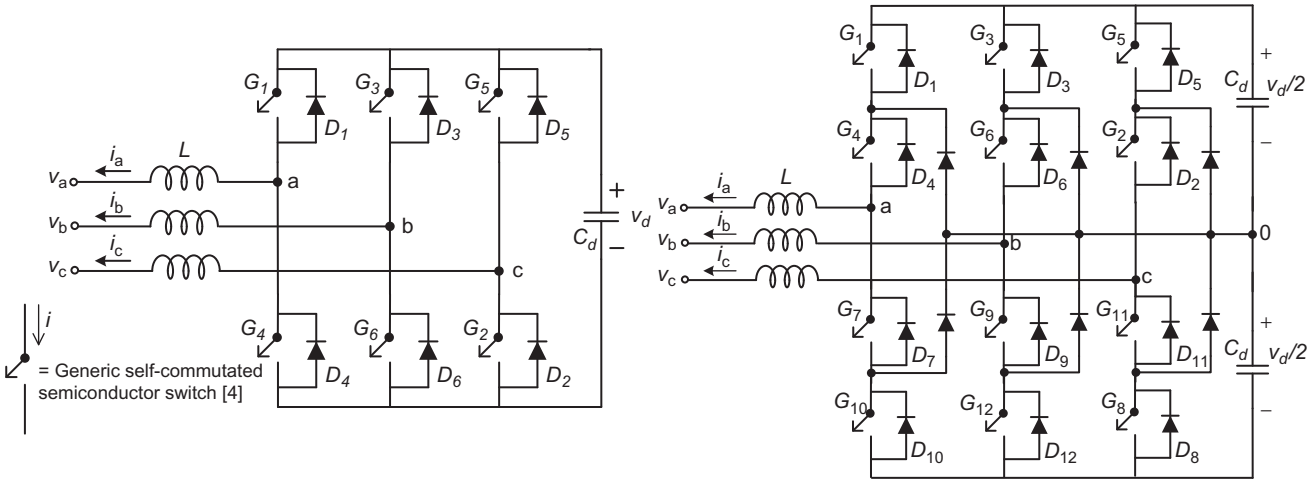

FIG. 28.21 (A) Basic six-pulse VSC two-level var compensator and (B) basic three-level var compensator.

three-phase, six-pulse, 10 MVA converter. To guarantee low losses, the switching frequency is equal to the line frequency, and a total of eight sets of three-phase converters are used to form a 48-pulse converter. All the converters have a common dc capacitor in their dc side. In the ac side, the converters are connected in series through a zigzag transformer to eliminate low-frequency voltage harmonics. The device with compensation capability of 80 MVA was developed to increase the transient stability margin of the system, and it has allowed a 20% increase of the transmitted power above the previous stability limit. Since it was developed for improving transient stability margin, it normally operates in standby mode without reactive compensation and, consequently, low losses. During transient situation, this STATCOM operates for a short time until the system is stable.

The development of the first high-power (±100 Mvar) STATCOM in the United States was reported in Ref. [20]. It is based on eight sets of three-phase bridge converters, similar to that shown in Fig. 28.21A; it was developed for reactive power control, so it can operate continuously with acceptable losses. The switching frequency is equal to line frequency, and the number of pulses is 48; therefore, the output voltage waveform is almost sinusoidal, and harmonic filters are not used in both cases referred in Refs. [19,20].

Basic switching control techniques

In FACTS applications, the power ratings of the converters are in the range of some MW to hundreds of MW, and the switching frequency is lower than the switching frequency used in industrial application converters to avoid excessive switching losses. However, there are various switching control types. The most known so far are as follows:

- Multipulse converters switched at line frequency, as in Refs. [19,20]
- Pulse-width modulation (PWM) with harmonic elimination technique [21]
- Sinusoidal PWM [7]
- Cascade converters [22], including the multilevel modular converter (MMC) [23]

Multipulse converters switched at line frequency

The multipulse converter was the first choice for STATCOM application because it presents low losses and low harmonic content [19,20]. Fig. 28.22 shows a 24-pulse converter based on three-phase, two-level six-pulse converters. In this case, the zigzag transformers are connected in such a way as to produce phase differences of 15, 30, 45, and 60 degrees. With this arrangement, the resulting output voltage and its harmonic spectrum are as shown in Fig. 28.23. The first two harmonic components are the twenty-third- and twenty-fifth-order harmonics. Fig. 28.24 shows the voltage waveform for a 48-pulse converter and its respective harmonic spectrum. In this case, the first two harmonic components are the forty-seventh-

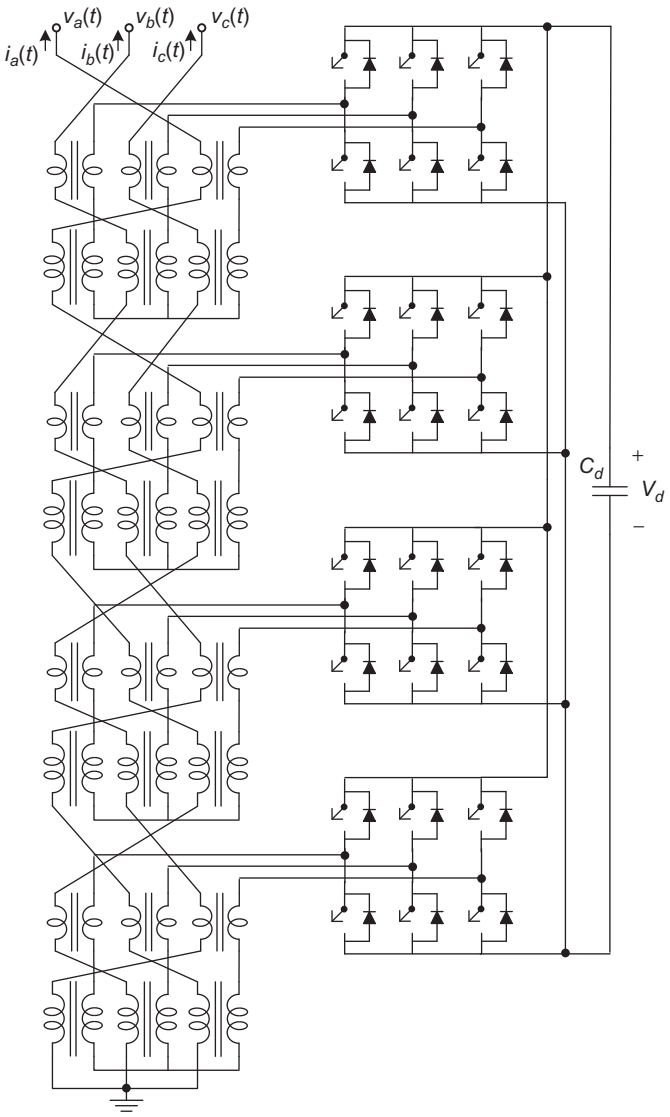

FIG. 28.22 Six-pulse 2-level VSC-based 24-pulse static var compensator (STATCOM).

and forty-ninth-order harmonics. The total harmonic distortions (THD) for the 24-pulse and 48-pulse converters are 7% and 3.3%, respectively. These converters can also be built by using three-level converters. However, one drawback of the multipulse converter is the complexity, weight, and cost of the transformers, which have to operate with high harmonic content in their voltage and various different turns ratio.

PWM with harmonic elimination technique

One way to avoid the complexity of the multipulse converters is to use PWM with harmonic elimination technique [21]. With this approach, it is possible to use relatively low switching frequency and, consequently, have low switching losses. The PWM modulation is obtained by off-line calculation of the switches at "on" and "off" instants in order to eliminate the low-frequency harmonics. Fig. 28.25A shows an example of

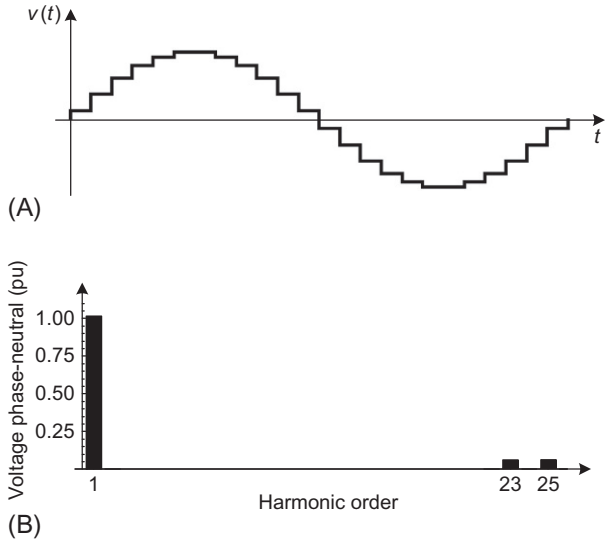

FIG. 28.23 (A) 24-pulse converter voltage waveform and (B) its harmonic spectrum.

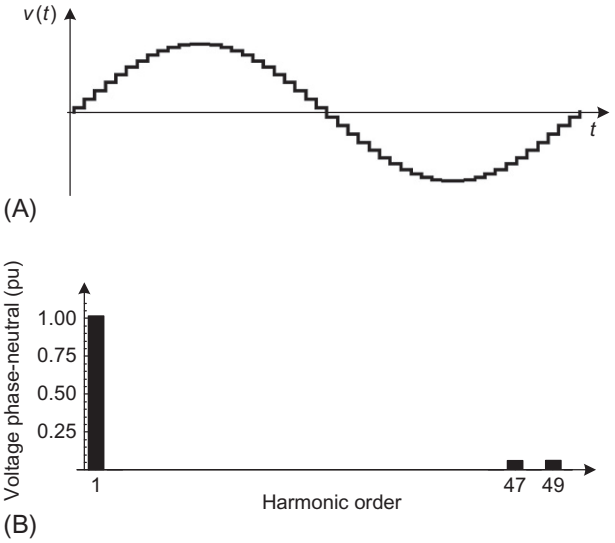

FIG. 28.24 (A) 48-pulse converter voltage waveform and (B) its harmonic spectrum.

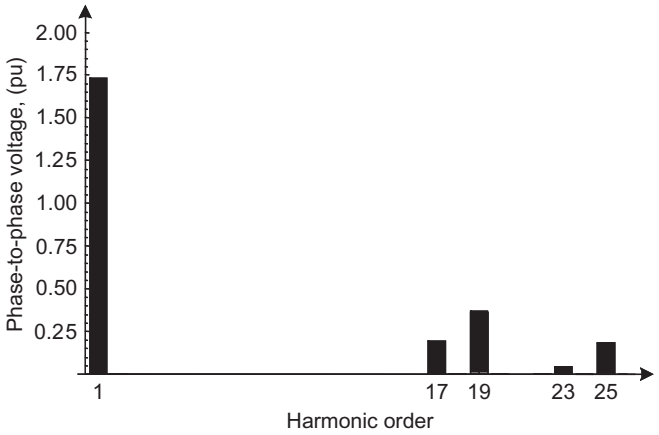

FIG. 28.26 Line voltage harmonic spectrum for the voltage waveform in Fig. 28.25A.

voltage waveform with "on" and "off" instants calculated in such a way as to eliminate the fifth-, seventh-, eleventh-, and thirteenth-order harmonics. This voltage corresponds to the voltage between one phase of the converter and the negative terminal of the dc side. Fig. 28.25B shows the control angle as a function of the modulation index m_a. Fig. 28.26 shows the harmonic spectrum for the phase-to-phase voltage waveform corresponding to that shown in Fig. 28.25A. Here, it is considered that the rms value of the fundamental component of the voltage in Fig. 28.25 is equal to unity. In Fig. 28.26, the magnitude of the fundamental component is equal to $\sqrt{3}$ pu. The higher-order harmonics in the voltage waveform can be eliminated by a relatively small passive filter, so the voltage and the current at the converter terminals are practically harmonic-free; therefore, the transformer that connects a PWM-controlled STATCOM to the grid may be a conventional transformer designed for sinusoidal operation.

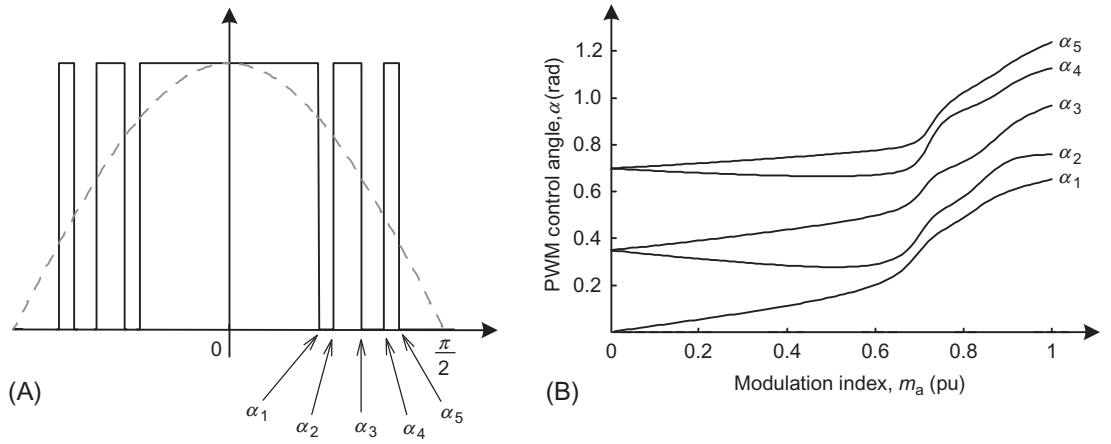

FIG. 28.25 (A) Example of one-phase voltage with the harmonic elimination technique and (B) the control angle as function of the modulation index.

Sinusoidal PWM

The sinusoidal PWM control technique is possibly the simplest to implement and can be synthesized by comparing a sinusoidal reference voltage with a triangular carrier [4]. This switching control method needs a relatively high switching frequency, which is in the range of 1–2 kHz and consequently produces higher switching losses than multipulse STATCOM. The harmonic content at low frequencies is negligible; however, there is a relatively high harmonic content at the switching frequency, which is eliminated by a passive filter.

Cascade converter

The basic cascade converter [22] topology is shown in Fig. 28.27. Only two single-phase full-bridge converters are shown, the first and the *n*th. However, in actual application, several of them are connected in series and switched at line frequency. The resulting voltage waveform can be similar to the multipulse converter waveform with the advantage that there is no need of transformers to sum up the converter output voltage. Due to the line frequency switching, the switching losses are very low. The resulting voltage waveform can be almost sinusoidal depending on the number of series converters, and the transformer used to connect them to the grid can be a conventional sinusoidal waveform transformer, if necessary. The need to have one dc capacitor for each single-phase converter has two consequences: the number of capacitors is equal to the number of single-phase converters, and the capacitance of each capacitor has to be much higher than three-phase converters. This is because the instantaneous power in each single-phase converter has a large oscillating component at double of the line frequency, and it would force a large voltage ripple in the capacitors if they were small.

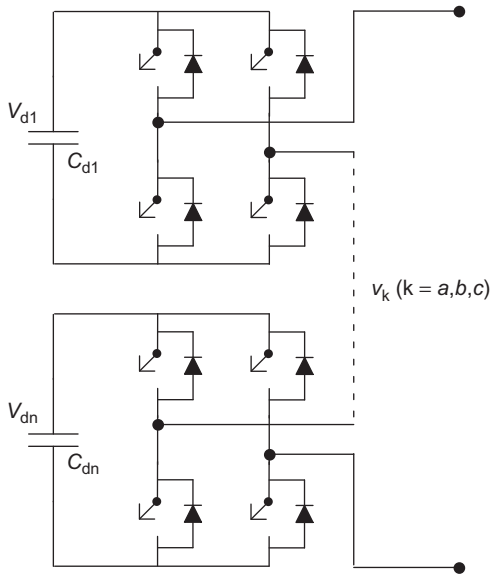

FIG. 28.27 Cascade converter basic topology.

Multilevel modular converter: The MMC is an emerging topology for high-power and high-voltage VSC application [23]; it is suitable for either HVDC transmission or FACTS applications [24,25]. For very high-power applications, an MMC is also an alternative, and potentially preferable, to a multilevel converter [26]. The MMC is being presented as the preferred potential candidate for VSC-HVDC system applications [27]. Features like modularity and capability of a multimodule VSC to handle high power or high voltage indicate that a MMC may also be an option to high-power STATCOM and other FACTS compensator such as SSSC, UPFC, or IPFC.

Fig. 28.28 shows the basic topology of a three-phase MMC. Each leg is comprised of *n* submodules, which are composed of two self-commutated switches and a storage capacitor. Depending on the application, a full-bridge submodule might be necessary instead of the half bridge shown in this figure. A semi-full-bridge submodule topology is an alternative option for blocking short-circuit current in the dc link of the converter [28]. The submodule can be seen as a voltage source with two possible stages 0 or V_C where V_C is the voltage over the submodule capacitor. Thus, each arm can be understood as a controllable voltage with *n* possible voltage steps, and the higher the number of submodules, the more approximated sine waveform can be achieved at the ac side. The main advantages of the MMC are low switching losses, low *dv/dt* over individual switch, modularity, reconfigurable design, and increased energy storage [26]. Beyond that, the MMC can also be directly connected to the power system, that is, without any power transformer [29], which can reduce the overall substation footprint and cost, resulting in a compact-area HVDC substation.

STATCOM control techniques

The control of reactive power in the STATCOM is done by controlling its terminal voltage. Fig. 28.29 shows a simplified circuit in which the ac grid is represented by a voltage source V_S behind an impedance jX_L and the STATCOM is represented by its fundamental voltage component V_I. Fig. 28.30A shows the case when the ac grid phasor voltage V_S is in phase with the STATCOM voltage V_I and both have the same magnitude. In this case, the line current I_L is zero. Fig. 28.30B shows the case when V_S is little larger than V_I. In this case, the line current I_L, which lags the impedance voltage V_L by 90 degrees, is also lagging the ac grid phasor voltage V_S, and therefore, the STATCOM produces an inductive reactive power. On the other hand, Fig. 28.30C shows the case when V_S is little smaller than V_I. Hence, the line current I_L, which lags the voltage V_L by 90 degrees, leads the voltage V_S, and therefore, the STATCOM produces a capacitive reactive power. In summary, the STATCOM reactive power can be controlled if the magnitude of its V_I voltage is controlled, assuming that it is in phase with V_S:

- If $|V_S|$ is equal to $|V_I|$, there is no reactive power and no active power in the STATCOM.

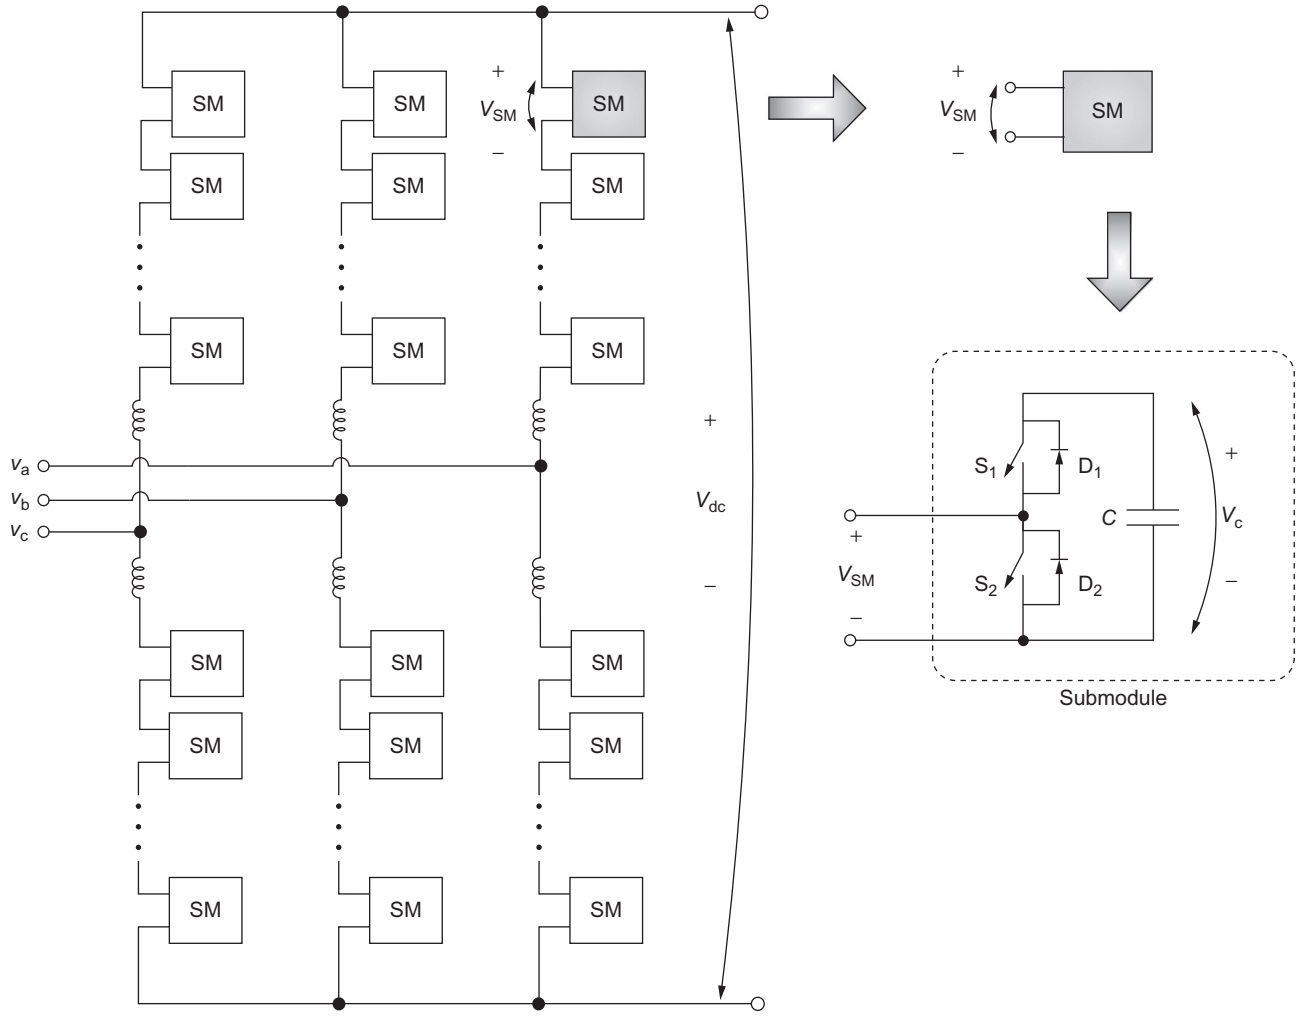

FIG. 28.28 Modular multilevel converter topology.

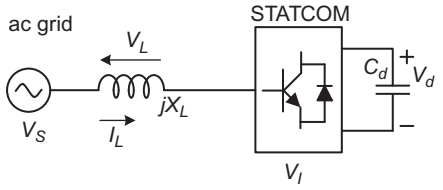

FIG. 28.29 Simplified circuit for the ac grid and the STATCOM.

- If $|V_S|$ is larger than $|V_I|$, the STATCOM reactive power is inductive.
- If $|V_S|$ is smaller than $|V_I|$, the STATCOM reactive power is capacitive.

Therefore, the reactive power control in a STATCOM is a problem of how to control the magnitude of its voltage V_I. There are two basic principles: (*i*) in the case of multipulse converters, the output voltage magnitude can only be controlled by controlling the dc-side voltage that is the dc capacitor voltage, and (*ii*) in the case of PWM control, the dc capacitor voltage can be kept constant, and the voltage can be controlled by PWM controller.

Fig. 28.31A shows the phasor diagram for the case when a phase difference δ between V_S and V_I is positive. The resulting line current is in such a way that produces an active power flowing into the converter, charging the dc capacitor. Fig. 28.31B shows the phasor diagram for a negative phase angle δ. In this case, the dc capacitor is discharged. Therefore, by controlling the phase angle δ, it is possible to control the dc capacitor voltage.

In general, STATCOM based on multipulse converter without PWM has to control its voltage by charging or discharging the dc capacitor, and this voltage has to be variable. On the other hand, STATCOM based on a PWM-controlled converter has to control dc-side capacitor voltage only to maintain it constant. In both cases, the principle shown in Fig. 28.31 is valid.

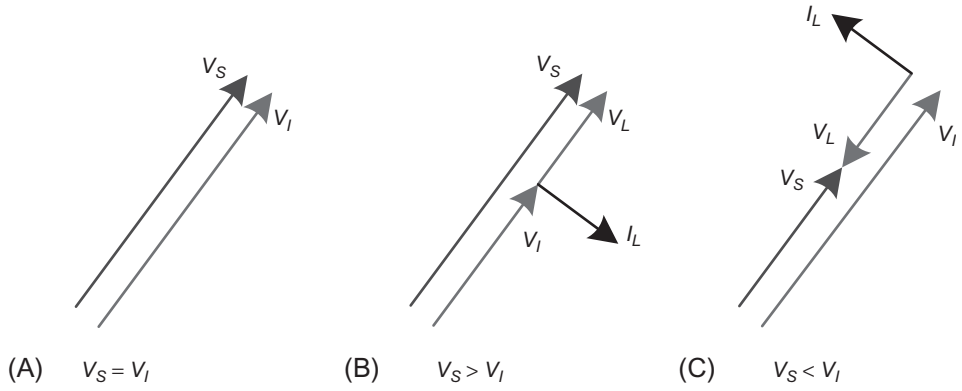

FIG. 28.30 Reactive power control in a STATCOM.

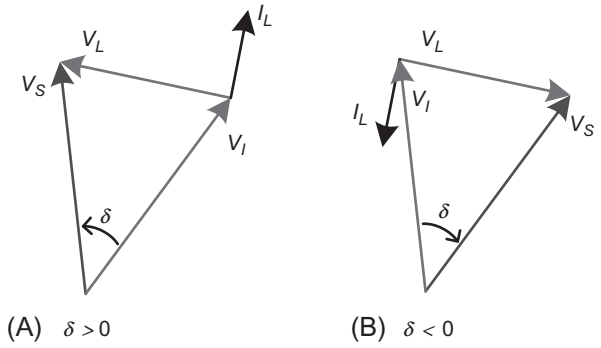

FIG. 28.31 Active power control in a STATCOM.

The STATCOM control technique presented previously illustrates the basic scalar control concepts. However, this compensator can be also controlled by a vector technique [30].

Fig. 28.32 shows a basic control structure for the STATCOM. In this diagram, the vector control technique is implemented in dq synchronous reference frame. This technique is called voltage-oriented control (VOC), in which the grid voltage vector is aligned with the d-axis through the phase-locked loop (PLL) block. This means that the q-axis component of the grid voltage, in steady state, is zero.

The dc-link and grid voltages are controlled through the d- and q-axes, respectively. For the dc voltage control, the voltage across the capacitor is sensed by Hall effect sensor and compared with its reference value. For the grid voltage control, the voltage at the PCC is sensed by Hall effect sensor too, and these signals are transformed to *dq* components in synchronous reference frame. The next step is to compute the aggregate value for this quantity. The aggregate value is an instantaneous quantity, and it results from the square root of the sum of the squared instantaneous values of currents or voltages. This means that the aggregate value is a constant if and only if the voltages (or currents) in all phases are perfectly sinusoidal and balanced [31,32]. The LPF block is a low-pass filter to eliminate any oscillating components in the signal of the aggregate value. Error signals are generated and are input in proportional-integral (PI) controllers, for both cases, as shown in Fig. 28.32, and the current references are generated. From

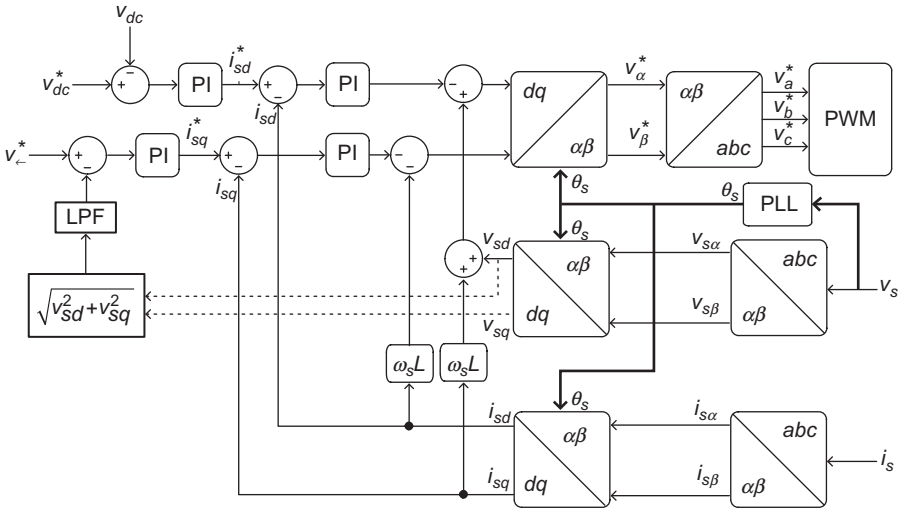

FIG. 28.32 Block diagram of STATCOM based on voltage-oriented control (VOC).

these, reference currents are in *dq* synchronous reference frame. In the inner control loop, the current references are compared with measured values of these same variables. Thus, error signals resulting from this operation excite PI controllers that generate voltage references in the controllers' outputs. Nevertheless, these values must be compensated to avoid coupling between *d*- and *q*-axes [33–35].

Another detail, for this diagram, is that there is an intermediate transformation block from abc to αβ instead of the direct transformation abc-dq, because dc values can be present in αβ component signals caused by the acquisition and/or signal conditioning systems or even by the modulation system, in some cases. Thus, they can be eliminated through the installation of high-pass filters (not present in the figure) just after those intermediate blocks, which would not be possible in the case of direct transformation from abc to dq.

Another way to control the STATCOM is by using the instantaneous power theory [36,37], where only the imaginary power is controlled.

STATCOM DC side capacitor

Theoretically, the dc-side capacitor of a STATCOM based on three-phase converters operating in a balanced system and controlling only the reactive power could have a capacitance equal to zero farad, once the three-phase instantaneous reactive power does not contribute to the energy transfer between the dc and ac side [38]. However, in actual STATCOM, a finite capacitor has to be used with the objective of keeping constant or controlled dc voltage as it tends to vary due to the converter switching. One parameter commonly used in synchronous machine is the inertia constant *H* defined by

$$H = \frac{J\omega^2/2}{S} \tag{28.10}$$

where *J* and ω are the rotor moment of inertia and angular speed and *S* is the machine apparent power. A similar parameter for the STATCOM, H_{ST}, can be defined by

$$H_{ST} = \frac{CV_d^2/2}{S} \tag{28.11}$$

where *C* and V_d are the dc capacitance and its voltage, respectively, and *S* is the STATCOM apparent power.

In both cases, the constants *H* and H_{ST} are values in time units corresponding to the relation of the amount of energy stored in the rotor inertia, or in the capacitor, and the machine, or STATCOM, apparent power, respectively. In the case of synchronous machines, the value of *H* is in the range of few seconds (generally, in the range of 1–3 s), and in the case of the STATCOM, H_{ST} value is in the range of milliseconds or below (0.5–50 ms) if only reactive power is to be controlled. These numbers show that the STATCOM based on three-phase converters and designed only for reactive power control (which is the general case) has almost no stored energy in its dc capacitor. On the other hand, STATCOM based on single-phase converters without a common dc link may have larger capacitors as in the case of cascade converters due to the power oscillations at double of the line frequency.

There are STATCOM (in some cases with different names) that are designed for operation with unbalanced loads. In this case, the dc capacitor has to be also much larger than in the case of balanced systems to avoid large voltage ripple on the dc voltage due to power oscillations at twice the line frequency, which appears naturally in unbalanced systems [33,39] or unbalanced voltages [34] or system with flicker problem [35,40]. In this case, the STATCOM compensates reactive power and the instantaneous oscillating active power due to the negative sequence current components. In fact, this is an extension of the shunt active power filter application where the goal is the current harmonic compensation, which includes negative sequence currents even at the fundamental frequency. If subharmonics are present, the device is able to filter them out as well.

STATCOM with energy storage

In general, the STATCOM is designed for reactive power compensation, and it does not need large energy storage elements. However, there are some applications where it may be interesting to have some energy stored in the dc side, for example, to compensate for active power for a short time. In these applications, the dc-side capacitor has to be substituted by a voltage source energy storage device like a battery [41] or a double-layer capacitor (super capacitor). Another possibility is to store energy in superconducting magnetic energy storage (SMES) systems [42,43]. A natural solution for the use of the superconducting reactor would be the connection to the ac grid through a current source converter (CSC) instead of the voltage source converter. However, this has not been the case found in the literature. Fig. 28.33 shows a block diagram of a typical STATCOM/SMES system, where the SMES is

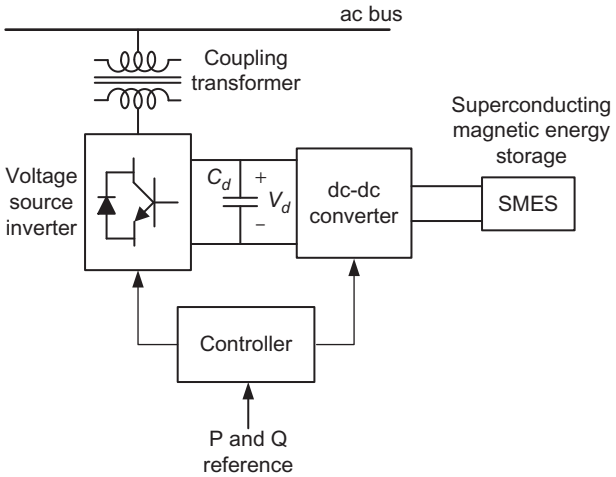

FIG. 28.33 STATCOM with SMES.

connected to the dc side of the STATCOM through a dc-dc converter, which converts the direct current in the superconductor magnet to dc voltage in the STATCOM dc side and vice versa. This STATCOM can control reactive power continuously and active power for a short time, normally up to few seconds, depending on the amount of energy stored in the superconducting magnet.

Comparison between SVC and STATCOM

Fig. 28.34A shows the steady-state volt-ampere characteristics for the SVC shown in Fig. 28.14, whereas Fig. 28.34B shows the same characteristics for a STATCOM. For operation at rated voltage, both devices can present similar characteristics in terms of control range. However, current compensation capability of SVC for lower voltages becomes smaller, whereas in the STATCOM, it does not change significantly for voltages lower than rated value (but approximately above 0.2 pu). This is explained by the fact that the SVC is based on impedance control, whereas the STATCOM is based on current controlled voltage source control. Therefore, in the SVC, the current decreases with a corresponding voltage decrease, whereas in the STATCOM, the current capability of the converters depends only on the switching device used, so the maximum current can be kept unchanged even for a low voltage condition. This is an important characteristic, especially in applications where the voltage may drop (as in most cases), where the STATCOM presents a better performance.

28.4.2.2 Adjustable Speed Synchronous Condenser (ASSC)

The adjustable speed synchronous condenser is not exactly a FACTS compensator, as it contains an electric machine. However, it may be an interesting shunt device to compensate reactive power continuously and relatively large amounts of active power for a short time. The basic topology of this compensator is shown in Fig. 28.35. It is based on a double-fed machine with a conventional three-phase winding in the stator and a three-phase winding in the rotor. The latter is supplied by a three-phase converter connected back-to-back to a second converter, which is connected to the grid.

This configuration allows the generation of a rotating magnetic flux in the rotor, which depends on the rotor converter frequency. When the machine is rotating at synchronous speed, the rotor converter operates at zero frequency and the magnetic flux in the rotor is stationary with respect to the rotor itself. In this case, the compensator operates as a conventional synchronous condenser.

However, when the rotor speed is lower or higher than the synchronous speed (normally during transients), the rotor converter generates a field current with the necessary frequency to keep the stator and rotor fluxes synchronized—if the synchronous frequency is 60 Hz and the rotor is running, for instance, at 58 Hz, the rotor converter has to supply voltage or current at 2 Hz so as to synchronize the fluxes. Naturally, it would be more interesting to use field-oriented control [44] instead of scalar control to get a better performance.

This hybrid compensator may supply energy to the ac system, if rotor speed is decreased. This machine is designed to have relatively large rotor inertia so as to present a large inertia constant (which may be in the range of more than 10 s). It is also called adjustable speed rotary condenser [45]. Operation at speeds higher than the synchronous speed is also possible, if it is necessary to absorb energy from the grid.

One of the advantages of this device is that a compensator with power in the range of 400 MVA may be synthesized with power electronics converter rated at a small fraction of this power and with a large capability to supply both active (for a few seconds) and reactive power (continuously) [45].

28.4.2.3 Static Synchronous Series Compensator

In contrast to the STATCOM, which is a shunt FACTS compensator, it is possible to build a converter-based compensator for series compensation. Fig. 28.36 shows the basic diagram of a static synchronous series compensator (SSSC) based on voltage

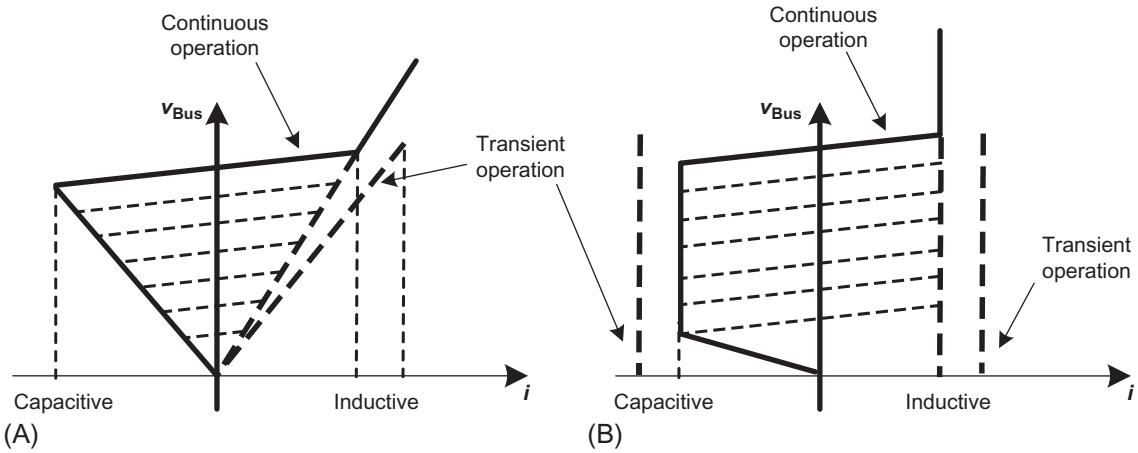

FIG. 28.34 Comparison between volt-ampere characteristics of (A) SVC and (B) STATCOM.

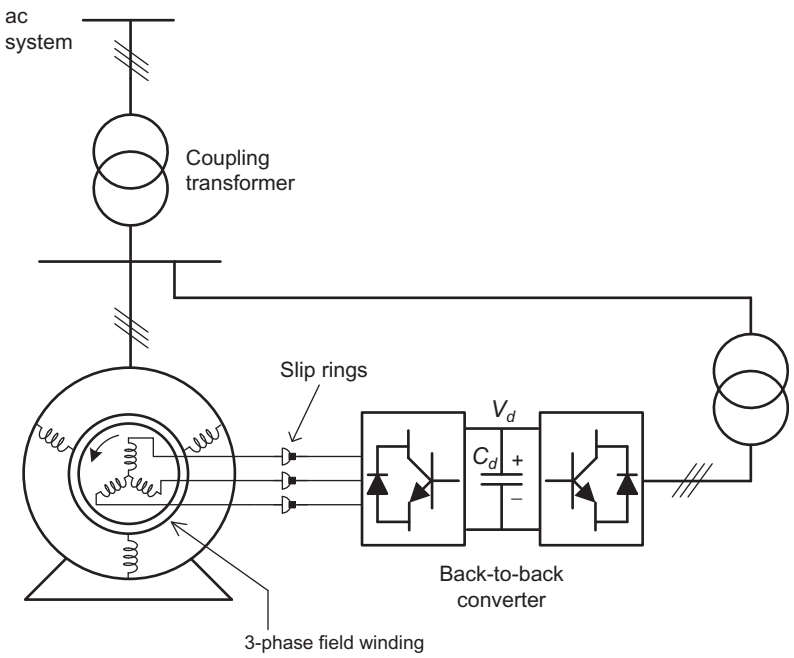

FIG. 28.35 Adjustable speed synchronous condenser (ASSC).

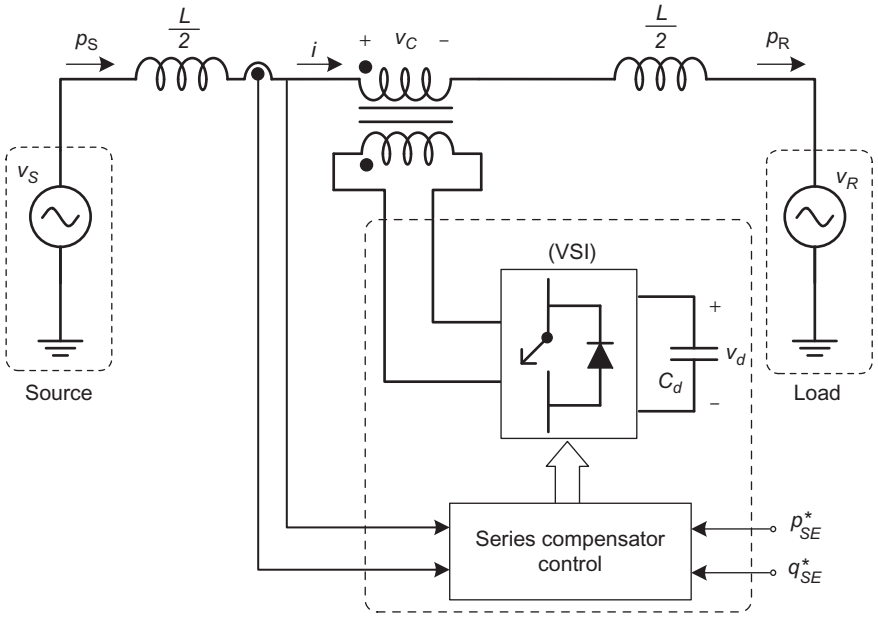

FIG. 28.36 Static synchronous series compensator (SSSC).

source converter (VSC) with a capacitor in its dc side and connected in series with the transmission line through a transformer [46]. The inputs to the SSSC controller shown in this figure are the line current and voltage and the active and reactive power references p^*_{SE} and q^*_{SE}, respectively. In general, only reactive power is compensated, and in this case, the active power reference p^*_{SE} is zero and q^*_{SE} is chosen so as to control power flow. Naturally, in the case of power flow control, it is necessary to have another control loop for this purpose and this is not shown in the figure.

One should note that if current is flowing in the transmission line, the SSSC controls reactive power by generating voltage v_C in quadrature with the line current. The device then shows capacitive or inductive equivalent impedance by increasing or decreasing the power flow, respectively. The compensation characteristic is as shown in Fig. 28.8, for the case of series

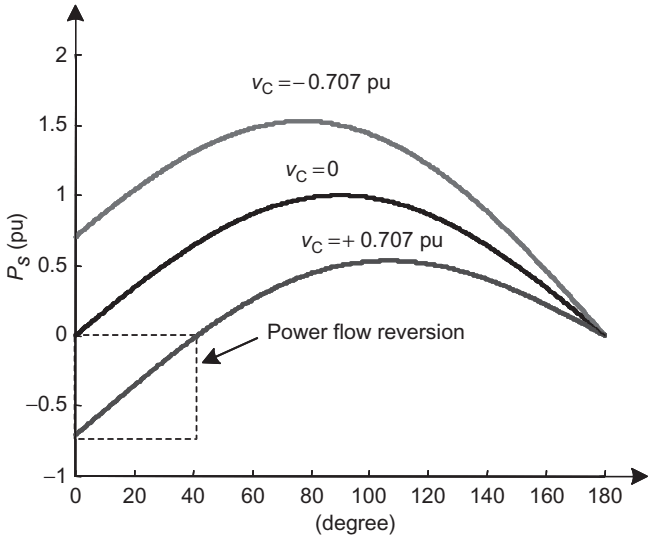

FIG. 28.37 Power flow characteristics for voltage-controlled SSSC.

compensation where the transmitted power is always positive for $0 < \delta < 180$ degrees. That is, with reactive power control, it is only possible to transmit in one direction. However, if instead of controlling q^*_{SE}, voltage v_C is controlled, it is possible to have power flow reversion. Fig. 28.37 shows the power flow characteristics of a transmission line with an SSSC using constant voltage control. The voltage is in quadrature with the current, and its magnitude is kept constant. The figure shows that it is possible to have power flow reversion for small values of δ with a constant compensation voltage v_C.

It should be noted that the discussion presented with respect to the converters topologies and controllers for the case of the STATCOM is also valid for the case of the SSSC. The SSSC can be used for power flow control and for power oscillation damping as well.

28.4.2.4 Gate-Controlled Series Capacitor

Fig. 28.16 shows the TCSC, which is basically a TCR in parallel with a capacitor and both connected in series with a transmission line. The combination is effective in continuously controlling the equivalent capacitive reactance presented to the system, mainly for power flow control and power oscillation damping purposes. It was also pointed out that the device has the disadvantage of a resonant condition due to the parallel association of capacitor and TCR (see Fig. 28.18).

In [47], the continuously regulated series capacitor using GTO thyristors to directly control capacitor voltage is presented. Fig. 28.38 shows this new device that is called gate-controlled series capacitor (GCSC) [48], hereafter renamed as the gate-controlled series capacitor (GCSC) because it may also be built using other self-commutated switches such as IGBTs or IGCTs.

The GCSC circuit consists of a capacitor and a pair of self-commutated switches in antiparallel connection. As the

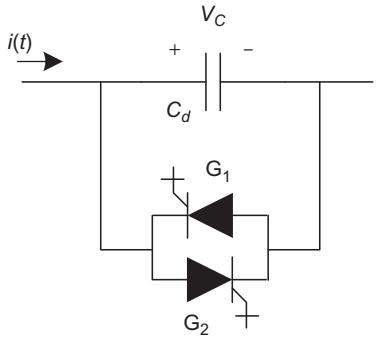

FIG. 28.38 Gate-controlled series capacitor.

switches operate under ac voltage, they must be able to block both direct and reverse voltages and allow current control in both directions.

Fig. 28.39 shows the voltage and current waveforms for the GCSC, where the current in the transmission line is assumed to be sinusoidal. If the switches are kept turned on, the capacitor is bypassed and does not present any compensation effect. If they are kept off, the capacitor is fully inserted in the line. On the other hand, if the switches are conducting and are turned off at a given blocking angle γ counted from the zero crossings of the line current, the capacitor voltage v_C appears as a result of the integration of the line current passing through it. The next time the capacitor voltage crosses zero, the switches are turned on again, to be turned off at the next turn-off angle γ. With this switching control sequence, it must be clear that the switches always switch at zero voltage. This is an interesting feature for the series connection of the switches under high-voltage operation [49].

The GCSC has some advantages when compared with the TCSC—the blocking angle can be continuously varied, which in turn varies the fundamental component of the voltage v_C. Also, it can be smaller than the TCSC [50]. Moreover, the dynamic response of the GCSC is generally better than that of the TCSC [51].

The impedance of the GCSC at the fundamental frequency, as a function of the blocking angle γ, is shown in Fig. 28.40.

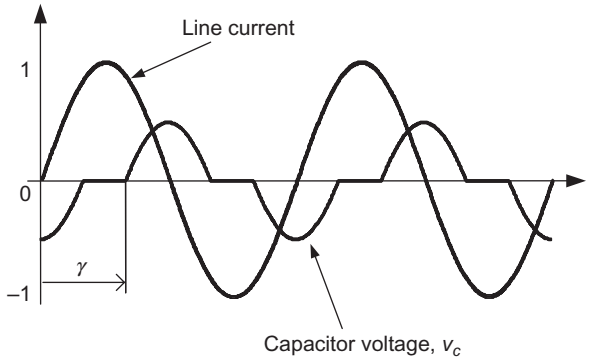

FIG. 28.39 GCSC voltage and current waveforms.

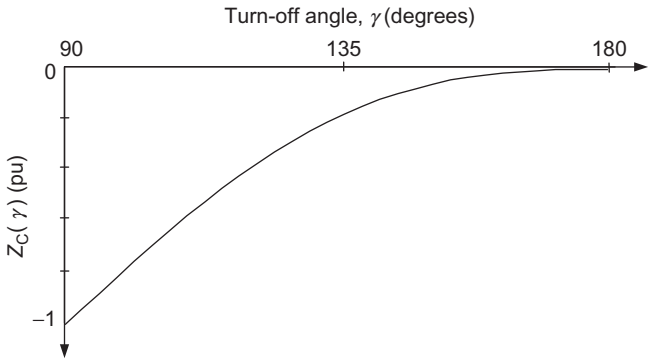

FIG. 28.40 GCSC equivalent fundamental impedance.

A blocking angle of 90 degrees means the capacitor is fully inserted in the circuit, whereas a value of 180 degrees corresponds to a situation where the capacitor is bypassed and no compensation occurs.

28.4.2.5 Unified Power Flow Controller

The unified power flow controller (UPFC) is a more complete transmission line compensator [52], shown as a simplified block diagram in Fig. 28.41. This device can be understood as a STATCOM and an SSSC with a common dc link. The energy storing capacity of the DC capacitor is generally small, and so the shunt converter has to drain (or inject) active power from the grid in exactly the same amount as the active power being injected (or drained) by the series converter. If this is not followed, the dc-link voltage may increase or decrease with respect to the rated voltage, depending on the net power being absorbed or delivered by both converters. On the other hand, the reactive power in the shunt or series converter can be controlled independently, giving a great flexibility to the power flow control.

The phasor diagram in Fig. 28.42 shows that the UPFC can be controlled in such a way as to produce any voltage phasor in series with the transmission line that fits inside the dashed-line

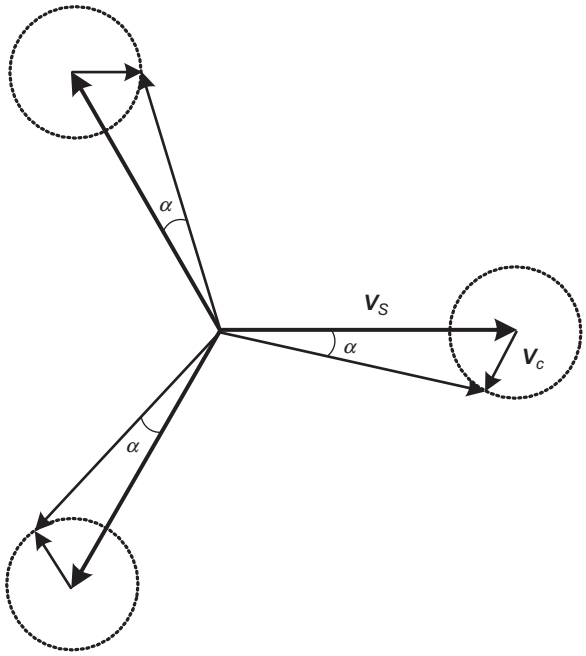

FIG. 28.42 Phasor diagram for a system with a UPFC.

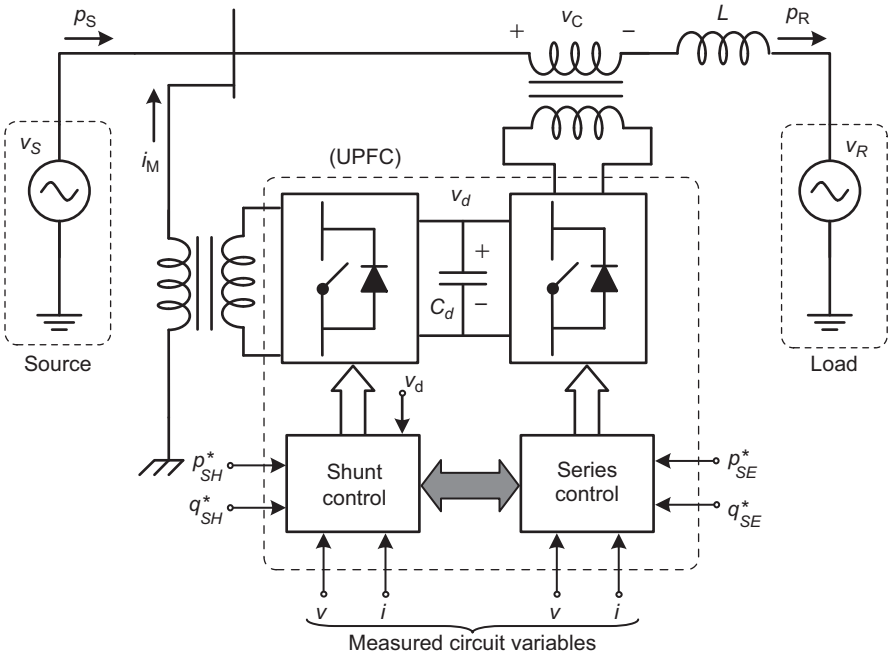

FIG. 28.41 UPFC block diagram.

circle on top of the phase voltage phasors. The maximum radius of the circle is limited by the voltage limitation of the series converter. The fact that the locus of v_c is a circle is one of the greatest advantages of the UPFC when compared with the thyristor-based phase shifter. If the UPFC presents capacitive or inductive reactive power in parallel with the system, the magnitude of voltage V_S is increased or decreased, respectively. This extra characteristic increases the locus of the series voltage v_c. Of course, this effect is only possible if an inductive impedance is present in series with the voltage source V_S, which is normally the case.

The shunt compensator of the UPFC is normally used with two objectives. The first is to control the reactive power in the point of connection, therefore controlling the voltage at this point. The second is to control active power in such a way as to control the dc-link voltage. The control technique to be used can be similar to the one used in STATCOM. The series compensator can be controlled in the same way as the SSSC, with the difference that in this case, it may control active and reactive power. Naturally, the active power control in the series compensator would change the capacitor voltage that should be controlled by the shunt compensator.

The UPFC can also be used to regulate directly the voltage in distribution feeder or transmission line. In the case that the UPFC is based on single-phase converter units (UPFC-1ϕ) [53,54], it can control unbalanced voltage. This application is named as direct voltage control (DVC) [55], and it is a promising solution for power quality issues in distribution grid with high penetration of intermittent generation sources, such as wind or solar power. Since this grid has a resistive characteristic, the indirect voltage control, based on shunt reactive compensator, could be ineffective [56]. Moreover, the use of single-phase converters permits the direct voltage control even under unbalanced operation, and each phase voltage can be controlled independently to balance the grid voltage.

Fig. 28.43 shows the basic line diagram of the UPFC based on single-phase back-to-back VSC unit for phase *a*. In each phase, one converter (VSC 1a) is shunt connected to the grid through a transformer (T_{sh}), and the other converter (VSC 2a) is directly connected in series at the point that voltage should be controlled (PCC). In Fig. 28.43, each VSC is connected in series with the secondary windings of the grid transformer (T_{grid}), avoiding a coupling transformer. The series converter of each UPFC 1ϕ is controlled to synthesize a compensation voltage (V_{comp}) to keep the PCC voltage regulated at a reference value, that is,

$$\dot{V}_{PCC_j} = \dot{V}_{T2_j} + \dot{V}_{comp_j} \tag{28.12}$$

where $\dot{V}_{T2_j}$ ($j = a, b, c$) is the phasor of voltage phase "j" in secondary wind of the transformer and $\dot{V}_{comp_j}$ is the phasor of the compensation voltage synthetized by the series VSC connected to phase "j." The compensation voltage can be represented as

$$\dot{V}_{comp_j} = \dot{k}\,\dot{V}_{2_j} \tag{28.13}$$

where $\dot{k}$ is the complex compensation factor, which means that both the magnitude and the phase of the compensation voltage can be controlled independently in each phase. This feature is suitable for grids with unbalanced voltage issues. If only the magnitude of the voltage in each phase should be compensated, the compensation factor is a real number, which means that the compensation voltage, $\dot{V}_{comp_j}$, is in phase to the secondary phase voltage of the grid transformer, $\dot{V}_{T2_j}$, and a simple control strategy can be applied as shown in Fig. 28.44. This figure shows the control block diagram of the series VSC for direct voltage magnitude compensation for one phase. The rms value of the PCC phase voltage ($V_{PCC\,rms_j}$) is compared with the reference value ($V_{rms\ ref}$); the output error is processed by a PI controller, generating the compensation voltage magnitude. This signal is multiplied by a sinusoidal signal, sin(θ_{PLL}), in phase with secondary phase voltage of the grid transformer, $\dot{V}_{T2_j}$, obtained from the synchronizing circuit (phase locked loop (PLL)).

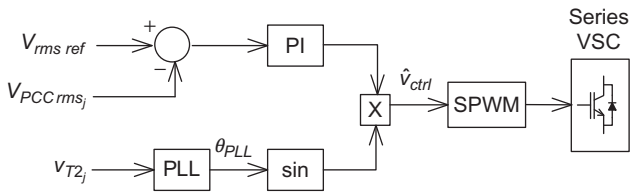

FIG. 28.44 Voltage control block diagram for the series VSC (magnitude compensation only).

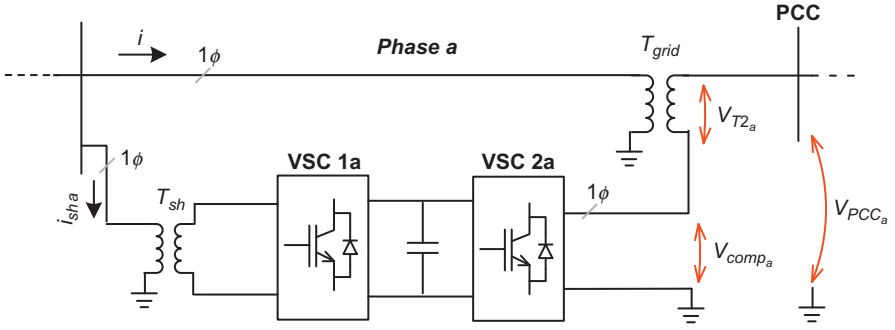

FIG. 28.43 Direct voltage control using UPFC 1ϕ units.

28.4.2.6 Interline Power Flow Controller

The interline power flow controller (IPFC) [53] is a UPFC-derived device with the objective of controlling power flow between two lines instead of one line as in the UPFC. Fig. 28.45 shows a basic block diagram of an IPFC with two converters to control the power flow in lines 1 and 2. The minimum number of converters connected back-to-back is two, but there may be more. Each converter should be connected in series with a different transmission line and should control power flow in this line with the following conditions:

- The reactive power control can be totally independent in each converter.
- The active power flowing into or out of each converter has to be coordinated in such a way that the dc-link voltage is kept controlled.

The dc-link voltage control can be achieved in a similar way as in the case of the UPFC. In this case, one of the series converters can control the compensation voltage freely, and it may produce active power flowing into or from the dc link, which would charge or discharge the dc-link capacitor. Therefore, the other converter has to be controlled to regulate this dc voltage. If there are n converters with n greater than two, $(n-1)$ converters can absorb or generate active power, whereas one converter has to control the dc-link voltage. Anyway, all n converters can control reactive power freely. For instance, this concept allows the control of the power flow in n lines, and it is possible to transfer active power from one line to another to balance power flow in n parallel transmission lines.

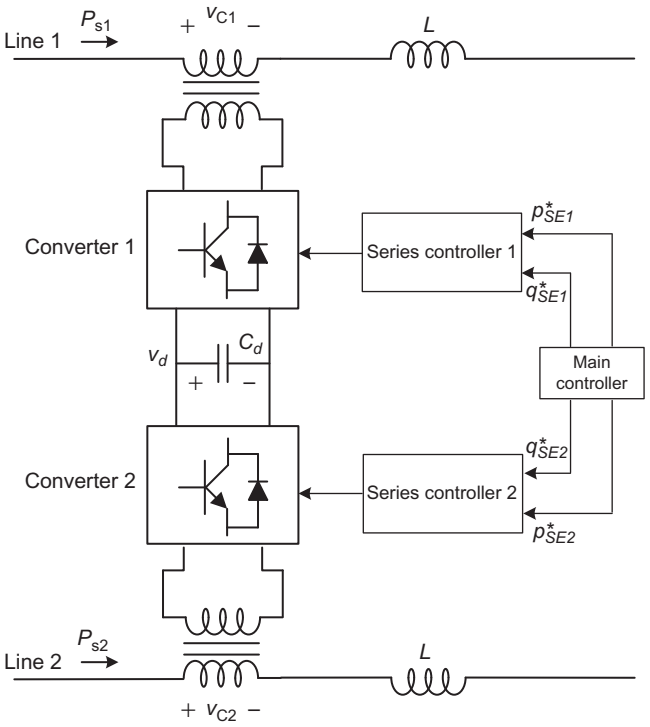

FIG. 28.45 Block diagram of IPFC with two converters.

28.4.2.7 Convertible Static Converter

Following the IPFC, a more generic concept is the convertible static converter (CSC) [57,58], which is based on the connection of a voltage source converter in various different topologies. Considering one simple case of two transmission lines and two converters with apparent power each equals to S, it is possible to have the following topologies:

- Two converters connected in shunt operating as a STATCOM rated at $2S$ apparent power
- Two converters connected in series with one transmission line forming an SSSC with $2S$ apparent power
- One converter connected in shunt and the other in series forming a UPFC
- One converter connected in series with one line and the other connected in series with the other line forming an IPFC

Other topologies are possible depending on how the converters are connected in the system. The basic control of each converter depends on how it is being used if, as a STATCOM, SSSC, UPFC, or IPFC.

28.5 Ancillary Services

Ancillary services are essential for grid reliability, including these services that can facilitate wind farms obtaining connection permits in some countries. Thus, taking advantage of the current scenario with high penetration of wind turbines in the distribution and transmission systems in several regions throughout the world, more and more, these services are being incorporated into the modern wind farms. These services include voltage and reactive power support, frequency-active power control, and fault ride through capability. This is all possible thanks to the ability of modern wind turbines to make use of FACTS controller features. Nowadays, most of wind farms are based on doubly fed induction generator (DFIG) or permanent magnet synchronous generator (PMSG). However, solar photovoltaic power plants can also contribute to these services, since they are connected to the grid via power inverters [59]. So, photovoltaic and wind turbine power plants can contribute to increase the reliability of distribution and transmission systems, as indicated in Fig. 28.46.

Modern grid codes define a range of technical requirements that generation power plants must fulfill. For example, it is very common in the voltage support through reactive current injection during fault operation and the voltage support of the power system in normal operation through the

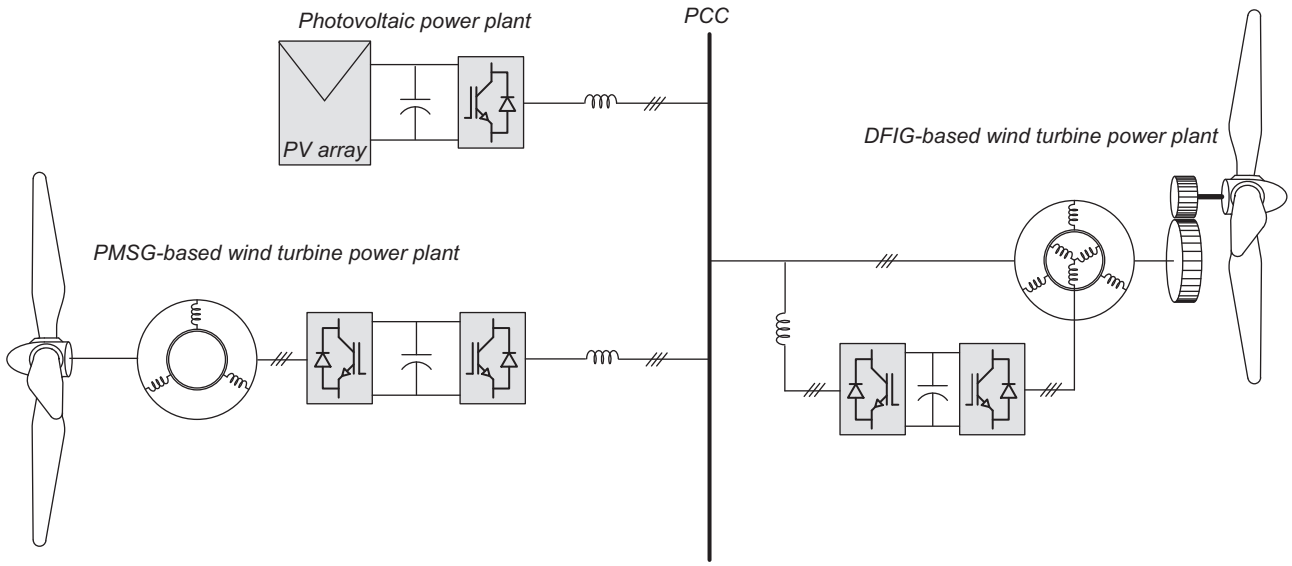

FIG. 28.46 Photovoltaic and wind turbine power plants connected to the grid.

reactive power control. Advanced control designs associated with power electronics converters are responsible to provide these ancillary services [59,60].

Wind turbines connected to the grid through a static power converter can provide an adequate inertial response to the system. The idea behind that is that the converter control system ensures a resistant torque to the wind turbine shaft during a frequency disturbance to extract energy. Thus, the behavior of synchronous generator with large inertia can be emulated [61–65].

Generally, a photovoltaic power plant has no energy storage; therefore, it cannot emulate an inertia, so it cannot contribute by itself to increasing the inertia of the system. Unless it uses other components like a flywheel or a battery to allow this service [61].

29.1 An Overview

29.1.1 Introduction

In every industry, there are industrial processes of some form, which require adjustments for either normal operation or optimum performance. Such adjustments are usually accomplished with a variable speed drive (VSD) system. They are an important part of automation. They help to optimize the process, reduce investment costs, energy consumption, and energy cost.

There are three basic types of VSD systems: electric drives, hydraulic drives, and finally mechanical drives. This chapter focuses mainly on electric drives.

A typical electric VSD system consists of three basic components: the electric motor, the power converter, and the control system, as illustrated in Fig. 29.1. The electric motor is connected directly or indirectly (through gears) to the load. The power converter controls the power flow from an AC supply (often via a supply transformer) to the motor by appropriate control of power semiconductor switches (part of the power converter).

With recent advances of power semiconductor and converter topologies, electric VSDs are witnessing a revolution in applications including computer peripheral drives, machine tools and robotic drives, test benches, fan pumps and compressors, paper mill drives, automation, traction and ship propulsion, and cement mill and rolling mill drives.

For a proper control system, the VSD system variables, both mechanical and electric, are required for control and protection. Signals are usually derived from sensors, whose outputs are very much dependent on the control strategy employed and the functionality required.

This chapter introduces electric VSDs and briefly describes their benefits. It examines their classifications from different perspectives. Their specification requirement to meet

applications of different industries is briefly outlined. Various VSD topologies have been carefully examined and compared with each other. A selection of modern VSD applications are examined and briefly commented upon.

29.1.2 Historical Review

In order to appreciate electric VSDs, significant dates in the evolution of electric drives are summarized in Table 29.1 [1].

The increased popularity of electric VSD systems, witnessed in recent years, may be explained by the many advantages a VSD can offer. Such advantages include operation at speeds significantly different from the synchronous speed, energy saving, reduced mechanical shock, improved process performance, improved efficiency, reduced mechanical wear, increased plant life, reduced total ownership costs, reduced system fault levels, and reduced AC disturbances in certain applications. Furthermore, modern electric drives are equipped with many features, including serial communication, remote control, diagnostics, and trip history. In the low-voltage low-power arena, packaged electric drives are becoming a commodity product. The disadvantages of such a system are also recognized. They include the need for extra space to accommodate the equipment, cooling, capital cost, noise, and power system harmonic effects. The following is a brief review of some of the benefits and drawbacks of VSDs.

TABLE 29.1 Historical review

Year	Key advancement
1886	The birth of the electric variable speed drive system represented by Ward-Leonard system
1889	The invention of squirrel cage induction motor
1890	The slip-ring induction motor drive—speed control via rotor resistance control
1904	Kramer drives—introduce a DC link between the slip rings and the AC supply
1911	Variable speed system based on induction motor with a commutator on the rotor
1923	Ignitron made controlled rectification possible
1928	The invention of thyratron and grid-controlled mercury-arc rectifiers
1930	DC-to-AC power inversion
1931	AC-to-AC power conversion by cycloconverters
1950	Silicon-based power switches
1960	Thyristors (SCRs) became available, and variable speed drives began
1961	Back-to-back reversing DC drive introduced
1960s	Power semiconductor voltage and current ratings grew and performance characteristics improved
1970	The concept of packaging industrial drives was introduced
1972	First integrated motors with DC converter
1973	Isolated thyristors packages
1970s	The principle of vector control (field-oriented control) evolved
1983	Plastic molding made their first significant impact on VSDs
1985	Direct torque control as a concept
1990	Integrated power modules
1992	A new packaging trend emerged
1996	Universal drives (a general purpose open-loop vector drive, a closed-loop flux vector drive, and a servo drive)
1998	Complete AC/AC integral converter up to 15 kW
1998	Medium-voltage pulse-width-modulated voltage-source inverter drives—became a commercial product

29.1.3 Advantages of VSD

The author suggests that VSDs benefit most industrial processes with some form of drive. The challenge has often been how to quantify these benefits. The energy saving potential of VSD can be easily quantified, particularly for fan and pump drive applications.

29.1.3.1 Energy Saving

Electric VSD provides savings in two ways: (a) directly by consuming less energy and (b) indirectly by improving the product quality. The latter is often more difficult to quantify.

Direct energy saving is possible only with centrifugal loads such as centrifugal pumps and fans. Such loads are often run at fixed speeds. Traditionally, an automatic valve, or some other mechanical means, is used to vary fluid flow rates in pumps. However, if a VSD is used, then the motor speeds can be controlled electronically to obtain a desired flow rate and can result in significant energy savings.

On the basis of the laws of affinity for centrifugal loads,

- the volume of flow is directly proportional to speed,
- pressure is proportional to the square of the speed,
- input power is proportional to the cube of the speed.

The affinity law states that the power consumption is proportional to the cube of the motor speed. This implies that if the speed is halved, then the power consumption is reduced to one-eighth. So, energy savings occur as the requirement for volume decreases. If, for example, a cooling system calls for operation at 50% airflow volume, it requires only 12.5% of the power needed to run the system at 100% volume. Because power requirements decrease faster than the reduction in volume, there is a potential for significant energy reduction at lower volume.

Generally, centrifugal pumps and fans are sized to handle peak volume requirements that typically occur for short periods. As a result, centrifugal pumps and fans mostly operate at reduced volumes.

Opening or closing of a damper allows the airflow of fans to be controlled. Restricting the airflow causes the motor to work hard even with a low throughput.

With a VSD, the speed of the fan can be reduced, thus giving the opportunity to reduce energy consumption. Adjusting the speed of the motor regulates the airflow. The control can be achieved by monitoring humidity, temperature, flow, etc. The lower the required throughput, the greater the energy saved.

It has been estimated that the payback period of a 50 kW fan or pump VSD equipment operating 2000 h/year is 1.9 years for operation at 75% speed and 1.23 years for 50% speed. It has been assumed that the cost of the VSD is £5.5 k and the cost of power is £0.05/kW.

29.1.3.2 Improved Process Control

Using VSDs to improve process control results in more efficient operating systems. The throughput rates of most industrial processes are functions of many variables. For example, throughput in continuous metal annealing depends on, among other factors, the material characteristics, the cross-sectional area of the material being processed, and the temperature of one or more heat zones. If constant speed motors are used to run conveyors on the line, it must either run without material during the time required to change the temperature in a heat zone or produce scrap during this period. Both choices waste energy or material.

With VSDs, however, the time needed to change speed is significantly less than the time it takes to change heat-zone temperature. By adjusting the material flow continuously to match the heat-zone conditions, a production line can operate continuously. The results are less energy use and less scrap metal.

29.1.3.3 Reduced Mechanical Stress (Soft Starts)

Starting a motor on line power increases stress on the mechanical system, for example, belts and chains. Direct on-line start-up of an induction motor is always associated with high inrush current with poor power factor.

VSD can improve the operating conditions for a system by giving a smooth, controlled start and by saving some energy during starting and running. Smoother start-up operation will prolong life and reduce maintenance, but it is difficult to do more than make an estimate of the cost advantages of these. The benefits of soft start, inherent in VSD, are that it eliminates the uncontrolled inrush of current that occurs when stationary motor is connected to full line voltage, and also the inevitable suddenly applied high start-up torque. Benefits are that the power wasted by current inrush is eliminated and that the life of the motor and the driven machine are prolonged by the gentle, progressive application of torque.

29.1.3.4 Improved Electrical System Power Factors

When a diode supply bridge is used for rectification, electric VSDs operate at near-unity power factor over the whole speed range (the supply delivers mostly real power). When a fully controlled thyristor supply bridge is used (as in DC, cyclo, and current source drives), the power factor starts at around 0.9 at full speed and proportionately worsens as speed declines due to front-end thyristors (typically 0.45 at 50% speed and 0.2 at 25% speed).

Modern pulse-width modulated (PWM) drives convert the three phases AC line voltage to a fixed-level DC voltage. They do this regardless of inverter output speed and power. The PWM inverters, therefore, provide a constant power factor regardless of the power factor of the load machine and the controller installation configuration, for example, by adding a reactor or output filter between the VSD and the motor.

29.1.4 Disadvantages of VSD

The cost of VSD is generally space, cooling, and capital cost. Some of the drawbacks are the following:

- Acoustic noise
- Motor derating
- Supply harmonics

The PWM voltage-source inverter (VSI) drives, equipped with fast-switching devices, add other possible problems such as (a) premature motor insulation failures, (b) bearing/earth current, and (c) electromagnetic compatibility (EMC).

29.1.4.1 Acoustic Noise

In some installations, placing a VSD on a motor increases the motor's acoustic noise level. The noise occurs when the drive's nonsinusoidal (current and voltage) waveforms produce vibration in the motor's laminations. The nonsinusoidal current and voltage waveforms produced by the VSD are the result of the transistor switching frequency and modulation in the DC-to-AC inverter. The switching frequency, fixed or variable, determines the audible motor noise. In general, the higher the carrier frequency, the closer the output waveform is to a pure sine wave. One method of reducing audible motor noise is full-spectrum switching (random switching frequency). The VSD manufacturers accomplish full-spectrum switching by an algorithm within the VSD controller. The motor performance is optimized by evaluating motor characteristics, including motor current, voltage, and the desired output frequency. The resulting frequency band, though audible to humans, produces a family of tones across a wide frequency band. So, the perceived motor noise is considerably less than it would be with a single switching frequency.

Motor noise may not present a problem. Relevant factors include motor locations and the amount of noise produced by other equipment. Traditionally, motor noise level is reduced by adding an LC filter between the VSD and the motor, that is, reducing the high-frequency component of the motor voltage waveform. Modern PWM inverter drives run at very high switching frequency and with random switching frequency thus reducing the noise level too. Various methods have been proposed to reduce the magnetically generated noise, which is radiated from inverter-fed induction motors.

29.1.4.2 Motor Heating

Most motor manufacturers design their products according to NEMA standards to operate on utility-supplied power. Designers base their motors' heating characteristics and cooling methods on power supplied at fixed voltage and frequency.

For many drive applications, particularly those requiring relatively low power, inverters with a high switching speed can produce variable voltage and variable frequency with little significant harmonic content. With these, either standard or high-efficiency induction motors can be used with little or no motor derating. However, the inverters used in larger drives have limits on switching rate that cause their output voltages to contain substantial harmonics of orders 5, 7, 11, 13, and so on. These, in turn, cause harmonic currents and additional heating (copper and iron losses) in the stator and rotor windings. These harmonic currents are limited mainly by the leakage inductance. For simple six-step inverters, the additional power losses, particularly those in the rotor, may require derating of the motor by 10%–15%.

Existing constant speed drives often have an oversized induction motor. These can usually be converted to variable speed operation using the original induction motor. Most of the subsequent operation will be at lower load and lower loss than that for which the motor was designed.

Modern PWM-VSI drives produce a voltage wave with negligible lower-order harmonics. The wave consists of pulses formed by switching at relatively high frequency between the positive and negative sides of the DC link voltage supply. With larger motors that operate from AC supplies up to 6600 V, the rapid rate of change of the voltage applied to the winding may cause deterioration and failure in the insulation on the entry turns of standard motors.

On self-ventilated (fan-cooled) motors, reducing the motor shaft speed decreases the available cooling airflow. Operating a motor at full torque and reduced speed results in inadequate airflow. This consequently results in increased motor insulation temperature. This potentially can be damaging and can reduce the life of the motor's insulation or cause the motor to fail. One potential solution is to add a constant speed, separately driven cooling fan to the motor. This approach ensures adequate stator cooling over the whole speed range. However, the rotor will run hotter than designed as internal airflow remains a function of speed. As there are no windings in the rotor, insulation failure is not an issue, but bearings may run hotter and require more frequent lubrication.

Fan-cooled motors with centrifugal loads present less of a problem. Pumps and fans, for example, do not require full torque at reduced speeds. So, in these cases, there is less thermal stress on motors at reduced speeds. Centrifugal load does not cause the motor to exceed thermal limits defined by the insulation system.

29.1.4.3 Supply Harmonics

Current and voltage harmonics in the AC supply are created by VSD (as a nonlinear load) connected on the power distribution system. Such harmonics pollute the electric plant, which could cause problems if harmonic level increases beyond a certain level. The effect of harmonics can be overheating of transformers, cables, motors, generators, and capacitors connected to the same power supply with the devices generating the harmonics.

The IEEE 519 recommends practices and requirements for harmonic control in electric power systems. The philosophy of such regulations is to limit the harmonics injection from customers so that they will not cause unacceptable voltage distortion levels for normal system characteristics and to limit the overall total harmonic distortion of the system voltage supplied by the utility.

In order to reduce supply harmonics that are generated by VSDs equipped with a 6-pulse diode bridge rectifier, VSD equipment manufacturers adopt various techniques. Table 29.2 summarizes the most common methods and their advantages and disadvantages [2].

Ref. [2] quantifies the cost of these options as a percentage of the cost of a basic system with 6-pulse diode bridge. For low-power VSDs, the cost of a drive with a line reactor is estimated to be 120% of that without. A VSD with a 12-pulse diode bridge with a polygon transformer is 200% while for a double-wound transformer is 210%. The most expensive solution is that with active front end, estimated at 250%.

For 6-pulse converter, $n6p \pm 1$ (5, 7, 11, 13, 17, 19, etc) order harmonics are generated. To minimize the effects on the supply network, recommendations are laid down by IEEE 519 as to the acceptable harmonic limits. For higher drive powers, therefore, either harmonic filtering or use of a higher converter pulse number is necessary. It is generally true that the use of a higher pulse number is the cheaper alternative. Ref. [2] also quantifies the harmonic levels generated by each of the above method; refer to Table 29.3 for a direct comparison.

29.2 Drives Requirements and Specifications

29.2.1 General Market Requirements

Some of the most common requirements of VSDs are high reliability, low initial and running costs, high efficiency across speed range, compactness, satisfactory steady-state and dynamic performance, compliance with applicable national and international standards (e.g., EMC, shock, and vibration), durability, high availability, ease of maintenance, and repairs.

The order and priority of such requirements may vary from one application to another and from one industry to another.

TABLE 29.2 Techniques used to reduce supply harmonics

Topology	Advantage	Disadvantage
6-Pulse bridge with a choke	• Least expensive—low cost • Known technology • Simple to apply	• Bulky • Too large a value can reduce available torque • Only applies to the drive • Least effective method of filtering
12-Pulse bridge	• Eliminates the 5, 7, 17, and 19 harmonics • Known technology • Simple to apply	• Bulky and expensive • Only applies to the drive • A lot of 12-pulse drives on one site will shift the problem to the eleventh and thirteenth harmonics
6-Pulse, fully controlled active front end	• Comprehensive filtering for the drive • Cancels all low-order harmonics	• Very expensive • Not widely available • New technology
Harmonic filters	• Filters the installation • Reduces the harmonics at the point of common coupling • Least expensive filter to install	• Needs a site survey • Only sized to the existing load
Active filter	• Intelligent filter • Extremely efficient • Can be used globally or locally • More than one device can be installed on the same supply	• Very expensive

TABLE 29.3 Supply harmonics for different supply bridge configurations

Harmonic order number	Fifth (%)	Seventh (%)	Eleventh (%)	Thirteenth (%)	Seventeenth (%)	Nineteenth (%)
6-Pulse	54	36	10	6.7	7	5
6-Pulse with inductor	30	12	9	6	4	4
12-Pulse with polygon transformer	11	6	6	5	2	1
12-Pulse with double-wound transformer	4	3	8	5	1	1
24-Pulse 250% cost	4	3	1	1	1	1
Active front end	3	3	3	0	2	2

For example, for low-performance drives such as fans and pumps, the initial cost and efficiencies are paramount, as the main reason for employing VSDs is energy saving. However, in other industries such as marine, the compactness of the equipment (high volumetric power densities) is a priority requirement due to shortage in space. In such environments, direct raw water cooling is the preferred choice as water is plentiful, and forced water cooling results in a more compact drive solution.

In critical VSD applications, such as military marine propulsion, reliability, availability, and physical size are very critical requirements. Cost is relatively less critical. However, achieving these requirements adds to the cost of the basic drive unit. Series and parallel redundancy of components enable the VSD equipment to continue operation even with failed components. These are usually repaired during regular maintenance. In other critical applications (such as hot mill strips or subsea drives), the cost of drive failures could be many times more expensive than the drive itself. For example, accessing a drive down on the seabed, many kilometers below the seawater level, could be very difficult.

This section identifies the VSD requirements in various drive applications in different industries.

29.2.1.1 The Mining Industry

The majority of early-generation large mine winders are DC drives. Modern plants and retrofits generally employ cycloconverters with AC motors. However, small mine winders (below 1 MW) tend to remain DC.

The main requirements are the following:

- High reliability and availability
- Fully regenerative
- Small number requiring single-quadrant operation
- High range of speeds
- High starting torque required
- High torque required continuously during slow-speed running
- Low-torque ripple required
- Low supply harmonics
- Low audible noise emissions
- Flameproof packaging

29.2.1.2 The Marine Industry

The requirements of this industry are the following:

- Initial purchase price
- Reliability
- Ease of maintenance, that is, minimum component count and simple design
- Size and weight of equipment
- Transformerless, water-cooled VSD equipment is always preferred

Other desirable features include the following:

- A requirement for the integration of power management functions
- High volumetric power density (the smallest possible)
- Remote diagnostics, to allow faultfinding by experts onshore in critical situations

Drive powers are commonly in the range of 0.75–5.8 MW for thrusters and 6–24 MW for propulsion. The evolution in the commercial market is toward powers from 1 to 10 MW for propulsion. Higher powers are required for naval applications. The package drive efficiency must be equal to or better than 96%. Noise and harmonics problems are to be considered when using PWM inverters. The supply side harmonics produced must be capable of being filtered. Above 1 MW, power converters are usually equipped with a 12-pulse supply bridge, given today's technology.

Two-quadrant operation is required in general; hence, a diode supply bridge is adequate. Occasional requirement for crash stops forces the use of dynamic brake chopper. DC bus can be advantageous for supply to wharf loading equipment, but the drive power ranges are such that commercially available products already adequately serve this application.

The use of standard AC machines is desirable; however, if motors matched to the inverter prove to be cheaper, their use could be preferred. Low-noise emission (acoustic and electromagnetic) is very important. There is no requirement for high torque at low speed. Programming and expanded input and output capabilities are required to avoid the need for additional programmable logic control (PLC).

29.2.1.3 The Process Industries

The main requirements of this market are the following:

- Initial purchase price (long-term cost of ownership does not generally influence purchasing decision)
- Efficiency in continuous processes
- Reliability
- Ease of maintenance
- Bypass facility

The industry preference is for air-cooled drives. It is perceived that air-cooled drives are less costly than their water-cooled equivalents. Customers often have the belief that water and electricity does not mix well and are wary of problems with leaks. The exception is the offshore industry where equipment size is paramount, and therefore, water cooling is standard. In general, there is no perceived requirement for space saving in majority of process plants. The desirable features often requested by customers are ease of maintenance and good diagnostic facilities.

The market requirement is for cost-effective, stand-alone drives at various power levels from a fraction of a kW up to 30 MW. The use of standard AC machines is desirable. However, if nonstandard but simpler and cheaper machines can be offered, an advantage could be gained:

- Two-quadrant operation for fans, pumps, and compressors.
- Four-quadrant operation for some test benches.
- Control must allow additional functions such as temperature protection, motor bearing temperature, and flow and pressure control.
- There is no requirement, in general, for field weakening.
- The harmonics produced by the drive, imposed on the power system, should not require a harmonic filter. Harmonics must be minimized.

In the low-voltage (LV) arena, the PWM-VSI is dominating the market. In the medium-voltage (MV) arena, there are a number of viable drive solutions—load-commutated inverters (LCIs) and cycloconverters. However, there is a developing market for MV PWM-VSI drives.

29.2.1.4 The Metal Industries

The requirements of this industry are the following:

- Reliability—high availability.
- Efficiency of the equipment—long-term costs of ownership.
- Low maintenance costs—this has been a key factor in the move from DC to AC.
- Power supply system distortion—more onerous regulations from the supply authorities.
- Initial purchase cost—very competitive market and large drive costs have a big impact on total project costs.
- Confidence in the supplier and their solution.

The following is a list of desirable features:

- Programmable system drives with powerful programming tools.
- Preference for air-cooled stacks but water-cooled is acceptable if a water-to-air heat exchanger is used.
- Powerful maintenance and diagnostic tools.
- Low EMC noise signature.
- Ability to interface to existing automation system via network, fieldbus, or serial link.
- Physical size of equipment is often not an important consideration.
- Fire protection systems integral to drive equipment.

The main market concerns are (a) EMC regulations, (b) effects on motor insulation of higher voltage levels, and (c) cooling with "dirty" mill water is not acceptable. The maintenance of deionized water circuits is a big issue.

29.2.2 Drive Specifications

Failure to properly specify an electric VSD can result in a conflict between the equipment's supplier and the end user. Often, the cost can be delayed project completion and/or the loss of revenue.

In order to avoid such a problem, requirement specifications should reflect the operating and environmental conditions (Table 29.4). The equipment supplier and the customer need to work as partners and cooperate from the beginning of the project until successful commissioning and hand over. It is advisable that the end user procures the complete drive system, including system engineering, commissioning, and engineering support, from one competent supplier.

It is one of the first priorities to identify applicable national and international standards on issues related to EMC, harmonics, safety, noise, and smoke emissions during faults, dust, and vibration. Overspecifying the requirements could often result in a more expensive solution than necessary. Underspecifying the requirements result in poor performance and disappointment.

As far as the end user is concerned, they need to specify the drive interfaces—the AC input voltage, shaft mechanical power, and shaft speed. The torque and current are calculated from these. Frequency and power factor depend on the choice of motor.

For a high-power drive, it is always recommended to carry out a "harmonic survey." Such a survey will reveal the existing level of harmonics and quantify the impact of the new drive on the harmonic levels.

TABLE 29.4 Typical example of VSD specifications

Variable	Specification
Application	Dynamometer application for a test bench
Motor type	Induction motor
Duty cycle	Continuous at full rating. 150% overload for 1 min every 60 min
Power rating	100 kW
Supply voltage	690 V ± 5%
Supply frequency	50 ± 0.05 Hz
Speed range	1000:1
Accuracy	0.1%
Min/max speed	0/1500 rpm
Torque dynamic response	<10 ms from 100% positive torque to 100% negative torque
Power factor	>96% lagging at all speeds
Efficiency	>98% at full load
Performance	Fully regenerative Full torque at zero speed
Ambient temperature	0–40°C
Supply harmonics	G5/3, IEEE519
Life expectancy	>5 years
MTBF	>50,000 h
MTTR	<2 h
IP rating	IP45
IEEE 519	IEEE recommended practices and requirements for harmonic control in electric power systems
IEC 60146	Semiconductor converters. Specifications of basic requirements
IEC 61800	Adjustable speed electric power drives systems

29.3 Drive Classifications and Characteristics

Table 29.5 illustrates the most commonly used classifications of electric VSDs. In this section, particular emphases will be given to classification by applications and by converter types.

Other classifications, not listed in Table 29.5, include the following:

- Working voltage: low voltage <690 V or medium voltage (MV) 2.4–11 kV
- Current type: unipolar or bipolar drive
- Mechanical coupling: direct (via a gearbox) or indirect mechanical coupling
- Packaging: integral motors as opposed to separate motor inverter
- Movement: rotary movement, vertical, or linear
- Drive configuration: stand-alone system and DC link bus
- Speed: high speed and low speed
- Regeneration mode: regenerative or nonregenerative
- Cooling method: direct and indirect air and direct water (raw water and deionized water)

Section 29.2 deals with the subject of drives requirement and specification from applications point of view, while Section 29.5 deals with drive topologies from the point of view of motor classifications.

29.3.1 Classification by Applications

Under this classification, there are four main groups:

- Appliances (white goods)
- General purpose drives
- System drives
- Servo drives

Table 29.6 describes the main features of these groups and lists typical applications.

TABLE 29.5 Classifications of electric VSD

By application	By devices	By converter	By motors	By industry	By rating
• Appliances	• Thyristor	• AC/DC (chopper)	• DC	• Power generation	• Fraction kW power <1 kW
• Low performance (2Q) ($1 < P < 5$ kW)	• Transistor	• AC/AC direct (cyclo- and matrix converter)	• Induction motor (squirrel cage and wound rotor)	• Metal	• Low power
• High performance (4Q)	• Gate turn-off thyristor (GTO)				
• Integrated gate-commutated thyristor (IGCT) power < 500 kW	• AC/AC via a DC link voltage source	• Synchronous motor	• Petrochemical	• Medium	
• Servo	• Insulated-gate bipolar transistor (IGBT)	• AC/AC via a DC link current source	• *Special motors*: SRM, BDCM, stepper, actuators, linear motor	• Process industry	• High power 1–50 MW
• MOSFET				• Mining • Marine	

TABLE 29.6 Classification of electric VSD by application

Type of drive	Appliances	General purpose	System	Servo
Performance	Low	Low	High	Very high
Power rating	Very low	Whole range	Whole range	Low
Motor	Universal and induction motor. Recently, PM and SRM are being used	DC motor, induction motor, and synchronous motor	DC motors, induction motors, and synchronous motors	DC motors, brushless DC motors, induction motor, stepper motors, and actuators
Converter	Simple, low cost	AC and DC drives with open-loop controller	PWM drives with DC bus, cycloconverter, good quality control with closed-loop control, and needs encoder or an observer	DC drive, AC drive, and special motor drives. Tendency toward brushless DC motors
Typical industry	Home	Process	Metal	Automation
Feature	Mass production, low cost, price-sensitive, and very low power	Nonregenerative, cost-sensitive, low or no overload, low start-up, low performance, and stand-alone	Accuracy with encoders $\lll 0.1\%$ in steady state and dynamic, good precision and linearity of I/O and control, flexible with operation capability, and setup and configuration communication and feedback	Closed loop, PM motor, >1000 Hz torque response, precise and rapid response, and frequent full speed reversal high precision and linearity of I/Os
Applications	Home appliances, for example, washing machines, dishwasher, temple dryers, and freezers	Fans, pumps, compressors, mixers, and simple elevator	Test benches, winders, sectional process line, elevator, cranes, and hoists	Positioning, pick and place, robotics, coordinate control, and machine tools

29.3.2 Classification by Type of Power Device

The silicon-controlled rectifier (SCR), also known as the thyristor, is the oldest controllable solid-state power device and still the most widely used power device for MV—AC voltages between 2.4 and 11 kV—high-power drive applications. Such devices are available at high voltages and currents, but the maximum switching frequency is limited and requires a complex commutation circuit for VSI drive. The SCRs are therefore most popular in applications where natural commutation is possible (e.g., cycloconverters and LCI current source converters).

The gate turn-off thyristor (GTO) has made PWM-VSI drives viable in LV drive applications. The traction industry was one of the first to benefit from such a device on a large scale.

Complex gate drive and limited switching performance, combined with the need for a snubber circuit, limited this device to high-performance applications where the SCR-based drives could not give the required performance.

The main power devices available in the market can be divided into two groups as shown in Table 29.7.

Bipolar-/MOSFET-type transistors have witnessed significant popularity in the late 1980s; however, they have been replaced by the IGBT that combines the characteristics of both devices—the current handling capability of the bipolar transistor and the ease of drive of the MOSFET.

Traction inverters are designed for DC link voltages between 650 V DC and 3 kV DC with ratings up to 3 MW. The first generation of widely used traction inverter equipment was GTO-based, while the latest generation is almost exclusively IGBT-based. Conversion to IGBT has enabled a 30%–50% reduction in cost, weight, and volume of the equipment.

Early attempts to use GTOs in MV applications failed because of their high cost, snubber requirements, and associated snubber energy loss, which is proportional to the square of the supply voltage. Energy-recovery circuitry enables recovery of most of the snubber energy but adds to the cost and complexity of the converter. With high-voltage IGBT and IGCT, MV PWM-VSI has become commercially available with supply voltage up to 6.6 kV and power rating in excess of 19 MW.

29.3.3 Classification by the Type of Converter

The power converter is capable of changing both its output voltage magnitude and frequency. However, in many applications, these two functions are combined into a single converter by the use of the appropriate switching function, for example, PWM. By appropriate control of the stator frequency of AC machines, the speed of rotation of the magnetic field in the machine's air gap and thus output speed of the mechanical drive shaft can be adjusted. As the magnetic flux density in the machine must be kept constant under normal operation, the ratio of motor voltage over stator frequency must be kept constant.

The input power of the majority of VSD systems is obtained from sources with constant frequency (e.g., AC supply grid or AC generator). In order to achieve a variable-frequency output energy, an AC/AC converter is needed. Some converters achieve direct power conversion from AC/AC without an intermediate step (e.g., cycloconverters and matrix converters). Other converters require DC link (as current source or voltage source).

In all AC VSDs, the direction of shaft rotation is reversed by simply changing the phase rotation of the inverter through the sequence of driving the switches.

29.3.3.1 DC Static Converter

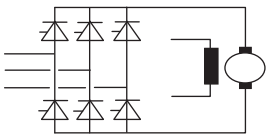
This drive employs the simplest static converter. It is easily configured to be a regenerative drive with a wide speed range. Table 29.8 summarizes its key features.

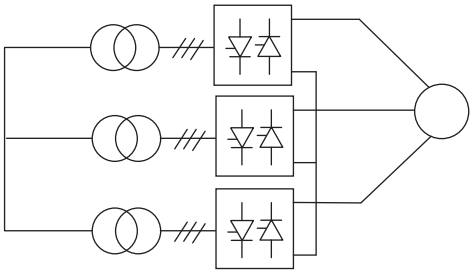
High torque is available throughout the speed range with excellent dynamic performance. Unfortunately, the motor requires regular maintenance, and the top speed often is a limiting factor. Commutator voltage is limited to around 1000 V, and this limits the maximum power available. The continuous stall torque rating is very limited due to the motor's commutator.

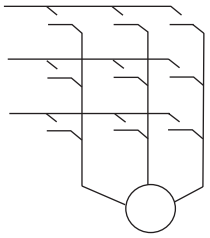
29.3.3.2 Direct AC/AC Converters

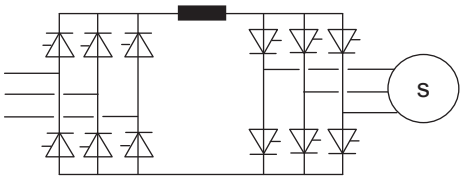
Cyclo-converter

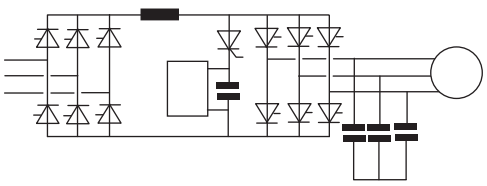
A typical cycloconverter comprises the equivalent of three anti-parallel 6-pulse bridges (for regenerative converter) whose output may be operated in all four quadrants with natural commutation. The main features of cycloconverters are listed in Table 29.8. This type of drive is best suited for high-performance high-power >2 MW drives where the maximum motor frequency is <33% of the mains frequency.

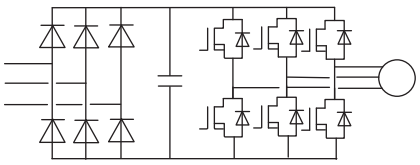


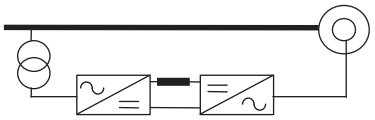












Matrix-converter

The force-commutated cycloconverter (better known as a matrix converter) represents possibly the most advanced state of the art at present, enabling a good input and output current waveform and eliminating the DC link components with very

TABLE 29.7 Power devices used in the VSD converters

Group 1: thyristors	Group 2: transistors
This group covers devices having a four-layer, three-junction monolithic structure. They are characterized by low conduction losses and high surge and current-carrying capabilities. They operate as an on/off switch. The most popular types of devices listed under this group	Switches listed under this group are basically three-layer two-junction structure devices, which operate in switching and linear modes. They are best recognized for ruggedness of their turn-off capabilities
• Silicon-controlled rectifier (SCR) • Gate turn-off thyristor (GTO) • MOSFET-controlled thyristor (MCT) • Field-controlled thyristor (FCT) • Emitter-switched thyristor (EST) • MOS turn-Off thyristor (MTO) • Integrated gate-commutated thyristor (IGCT)	• Bipolar junction transistor (BJT) • Darlington transistor • MOSFET • Injection-enhanced gate transistor (IEGT) • Carrier stored trench-gate bipolar transistor (CSTBT) • Insulated-gate bipolar transistor (IGBT)

TABLE 29.8 Converter topologies

Converter	Schematic	Features
(a) Controlled rectifier		• DC motor • Fully controlled SCR converter • Controlled DC voltage • Simple converter topology • Power factor is a function of speed
(b) Cyclo		• Induction motor and synchronous motor • Direct AC/AC power conversion • 3 × 6-pulse SCR-based fully controlled converters—APT for fully regenerative • Natural commutation • Low supply harmonics, 18-pulse • Power factor is a function of speed
(c) Matrix		• Squirrel-cage induction motor • Synchronous motor • Direct AC/AC power conversion • Forced commutated, reverse conducting switches • Four-quadrant operation inherent PWM in/PWM out • Controlled power factor
(d) LCI		• Synchronous motor • Simple converter arrangement • Power factor is a function of speed • Load-commutated SCRs • Synchronous motor requires excitation • Suffer from torque pulsation at low speeds
(e) FCI		• Squirrel-cage induction motor • Similar to LCI • Requires output capacitors for commutation • Requires a diverter commutation circuit for commutation at low speeds • Torque pulsation and resonance
(f) VSI		• Synchronous and squirrel-cage induction motors • 6-pulse diode front end • Good power factor across speed range • DC link voltage source • PWM output voltage
(g) Kramer		• Wound-rotor induction motor with slip rings • Small energy recovery converter • Any type of converter may be used between slip ring and AC input

little limitation in input-to-output frequency ratio. This type of converter is still at its early stages of development. The main advantage of this drive is the ability to convert AC fixed-frequency supply input to AC output without DC bus. It is ideal for integrated motor drives with relatively low power ratings. Major drawbacks include (a) the increased level of silicon employed (bidirectional switches), (b) its output voltage is always less than its input voltage, and (c) complexity of commutation and protection.

Matrix converters provide direct AC/AC power conversion without an intermediate DC link and the associated reactive components. They have substantial benefits for integrated drives as outlined below:

- Reduced volume due to the absence of DC link components.
- Ability to operate at the higher thermal limit imposed by the power devices.
- Reduced harmonic input current compared with diode bridge.
- Ability to regenerate into the supply without dumping heat in dynamic braking resistors.
- Matrix converters have not been commercially exploited because of voltage ratio limitation, device count, and difficulties with current commutation control and circuit protection.

29.3.3.3 Current Source Inverter

The output of this inverter is rectangular blocks of current from the motor bridge supplied from a supply converter whose output is kept at constant current by a DC link reactor and current servo. This type of inverter is typically based on fast thyristors.

Load commutated inverter

Natural commutations of thyristors are usually achieved with synchronous machines at speeds >10%. Natural commutation is induced as a result of the presence of the motor's electromotive force (EMF); this is called load commutation hence the drives' other name of LCI. At low speeds, the motor voltage is too low to give motor bridge commutations. This is achieved by using the supply converter. Induction-motor LCI drives can be supplied by adding a large capacitor on the motor terminals.

The LCI drive covers a wider speed range (up to 10,000 rpm) with power rating up to 100 MW. It gives full load torque throughout the speed range with moderate dynamic performance. Its simple converter design combined with a maintenance-free motor design (both induction and synchronous) has increased the popularity of these drives. It is still a popular solution for high-power drives (e.g., conveyors, pumps, fans, compressors, and marine propulsion).

The LCI drive has limited performance at low speeds. It also suffers from torque pulsation at 6 and 12 times the motor's frequency and beat frequencies. Critical speeds can excite mechanical resonance. Its AC power factor varies with speed. Torque pulsations can be reduced in 12-pulse systems if required.

Forced commutated inverter

Externally commutated current source converters with an induction motor are also a viable solution. To compensate for the inductive component in the motor current, a bank of capacitors are usually used at the motor terminals. The capacitor current is proportional to the motor voltage and frequency. Load commutation at high speed where the compensation current is high enough. Forced commutation at lower speed where the capacitive current is too low for compensation. Forced commutation is achieved using various techniques. The one shown above is based on DC link diverter that consists of a GTO, loading equipment in parallel with the diverting/compensating capacitor. Modern drives employ forced commutated devices, such as reverse-blocking GTOs and IGCTs.

29.3.3.4 Slip Power Recovery (Kramer)

In this type of converter, which is described in Table 29.8, the rotor current of a slip-ring wound-rotor induction motor is rectified and the power then reconverted to AC at fixed frequency and fed back into the supply network. For traditional designs, the low-frequency slip-ring currents are rectified with a diode bridge, and the DC power is then inverted into AC power at mains frequency.

The traditional designs had poor AC mains dip immunity, high torque pulsation, and high levels of low-frequency AC supply harmonics. The latest generation of this type of drive is called the rotor drive and uses PWM-VSI inverters for the rotor and AC supply bridges.

This keeps sine-wave currents in the AC rotor circuits, and the drive has many advantages over traditional circuits including the following:

- No torque pulsation
- Low AC harmonics
- Very high immunity to AC supply dips
- Very cost-effective if a limited speed range is required but still requires a separate starter
- Inherent ability to run at rated speed without electronic circuits
- Converter cost reduced by 2:1 if it uses the ± speed ability to give a speed range

29.3.3.5 PWM-VSI Converter

The availability of power electronic switches with turn-off capability; for example, FETs, BJTs, IGBTs, and GTOs have currently favored drives with voltage-fed PWM converters on induction.

The PWM-VSI drives offer the highest possible performance of all VSDs; refer to Table 29.9. Recent improvements

TABLE 29.9 Drive features

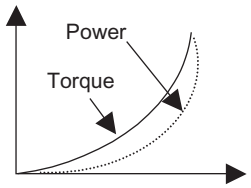
	DC drive			AC drive		
Type	DC	Cyclo	CSI (FCI)	CSI (LCI)	Kramer	PWM-VSI
Motor type	• DC motor	• Induction and synchronous motors	• Induction motor	• Synchronous motor	• Slip-ring wound-rotor induction motor	• Induction or synchronous
Power • Speed range • Accuracy • Maximum speed	• Up to 10 MW • 1000:1 • 0.01% • Limited by motor capability	• 2–30 MW • 1000:1 • ±0.01% • 1000 rpm	• 1–10 MW • 10:1 • ±1% • 6000 rpm	• 1–100 MW • 10:1 • ±0.01% • 10,000 rpm	• 0.5–50 MW • 0.8:1.2 • 0.1% • <1200 rpm	• 0.5–2 MW • 1000:1 • 0.01% • 10,000 rpm
Performance	• High torque over speed range • High dynamic performance	• High torque over speed range • High dynamic performance	• Poor dynamic response • Low starting torque	• High torque over speed range • Reasonable dynamic performance	• High torque over speed range • High dynamic performance	• High torque over speed range • High dynamic performance
Advantages	• Simple regenerative	• High stall torque (induction) • Inherently regenerative • Robust motors • Low maintenance motor • High overload capacity	• Standard robust maintenance-free motor • Minimal derating	• Simple • Inherently regenerative • Maintenance-free motor	• Regenerative (new) • Robust • Slip ring wound rotor • High overload capacity	• Good power factor • Tolerant to supply dips • Standard robust maintenance-free motor • Minimal derating
Disadvantages	• Stall torque rating • Motor maintenance • Custom motor design	• Motor custom design • Low AC supply power factor	• Complex • Poor dynamic performance • Torque pulsation and resonance	• Motor custom design • Torque pulsation	• Complex • Motor custom design	• Complex • Expensive • Regeneration at extra cost
Applications	• Mill drives (ball and sag) • Marine propulsion • Mine winders • Process lines • Conveyors	• Mill drives (ball and sag) • Marine propulsion • Mine winders • Conveyors	• Pumps, fans, and compressors • Soft starter	• Pumps, fans, and compressors • Soft starter • Marine propulsion • Conveyors • Mill drives	• Pumps, fans, and compressors • Power generation • Mills (ball and sag)	• Process lines • Paper machines • Traction

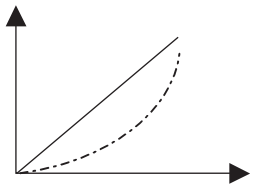
in switching technology and the use of microcontrollers have greatly advanced this type of drive. The inverters are now able to operate with an infinite speed range. The supply power factor is always near unity. Additional hardware is easily added if there is a requirement to regenerate power back into the mains supply. Motor ripple current is related to the switching frequency, and in large drives, the motor may be derated by <3%.

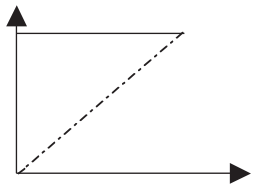
29.3.3.6 Comparison

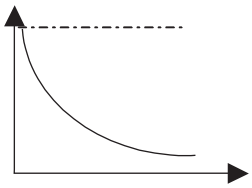
Table 29.9 summarizes the main features of all types of converter drives discussed above and assesses their merits and drawbacks. It also illustrates typical applications.

29.4 Load Profiles and Characteristics









The way the drive performs is very much dependent on the load characteristics. Here are four load characteristics described.

29.4.1 Load Profile Types

In the literature, four different load profiles have been described, for example, Ref. [3] (Table 29.10). These are the following:

1. Torque proportional to the square of the shaft speed (variable torque)
2. Torque linearly proportional to speed (linear torque)

TABLE 29.10 Load characteristics

Type I	Type II	Type III	Type IV
• $T=f(n^2)$ • $P=f(n^3)$ • Low start-up torque • Best suited for energy saving • Torque-speed curve is required when specifying a drive • Axial and centrifugal pumps • Axial and centrifugal ventilators • Screw and centrifugal compressors • Centrifugal mixers • Agitators	• $T=f(n)$ • $P=f(n^2)$ • Information about process is needed (e.g., density, consistency, viscosity, and temperature) • Mixers • Stirrers	• $T=$ constant • $P=f(n)$ • At start-up, the torque may be higher than nominal. Examples are static friction with conveyor belts. Vertical and horizontal forces need to be taken into consideration for inclined conveyors • Extrusions, draw benches • Paper and printing continuous machines • Volumetric gear pumps/pistons pumps, etc. • Piston compressors • Conveyor machines • Lift machines	• $T=f(1/n)$ • $P=$ constant • Mostly dominated by DC drives but modern PWM-VSI is taking over. Certain loads such as winding and reeling machinery require closed-loop controls • Lift machine • Reciprocating rolling mill • Winding machines • Lathes • Winders • Reelers • Wire drawers • Web-feed printing machines
			

3. Torque independent of speed (constant torque)
4. Torque inversely proportional to speed (inverse torque)

29.4.2 Motor Drive Duty

29.4.2.1 Duty Cycle

The size of the driven motors is generally chosen for continuous operation at rated output, yet a considerable proportion of motor drives is used for duties other than continuous. As the output attainable under such deviating conditions may differ from the continuous rating, fairly accurate specification of the duty is an important prerequisite for proper planning. There is hardly a limit to the number of possible duty types.

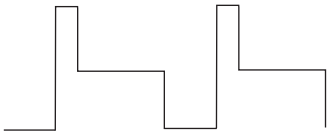
In high-performance applications, such as traction and robotics, the load and speed demands vary with time. During acceleration of traction equipment, a higher start-up torque (typically twice the nominal torque) is required; this is usually followed by cruising and deceleration intervals. As the torque varies with time so does the motor current (and motor flux linkage level). The electric, magnetic, and thermal loading of the motor and the electric and thermal loading of the power electronics converter are definite constraints in a drive specification.

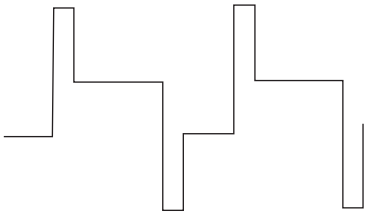
Table Table 29.11 categorizes operating duties into eight major types (Ref. [4]).

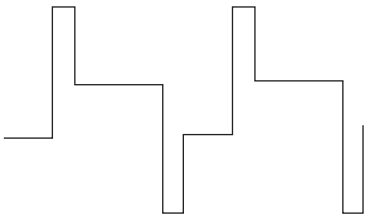
29.4.2.2 Mean Output

Variation of the required motor output during the periods of loaded operation is among the most frequent deviations from the duty types defined in Table Table 29.11. In such cases, the load (defined as current or torque) is represented by the mean load. This represents the root-mean-square (RMS) value, calculated from the load versus time characteristics. The maximum torque must not exceed 80% of the breakdown torque of an induction motor.

If the ratio of the peak torque to the minimum power requirements is greater than 2:1, the error associated with using the RMS output becomes excessive, and the mean current has to be used instead. No such mean value approximation is possible with duty type S2, which therefore necessitates special inquiry.







Careful assessment of duty types S2–S8 reveals that there exist two distinct groups:

1. Duties S2, S3, and S6 permit uprating of motors relative to the output permissible in continuous running duty (S1).
2. Duties S4, S5, S7, and S8 requiring derating relative to the output permissible in continuous running duty (S1).

29.4.2.3 Thermal Cycling

The drive duty cycle also affects the reliability and the life expectancy of power devices. Repetitive load cyclic duty results in additional thermal stresses on power devices. Frequent acceleration and deceleration of drives results in repetitive junction temperature rise and falls at the cyclic duty. The life expectancy of devices is often determined by the maximum allowed number of cycles for a given power device junction temperature rise.

TABLE 29.11 Definition of load cyclic duties—VDE0530, in accordance with IEC 34-1

Duty type	Representation	Description
S1: Continuous running duty		Operation at constant load of sufficient duration for the thermal equilibrium to be reached. Specify by indicating "S1" and required output
S2: Short-time duty		Operation at constant load during a given time, less than required to reach thermal equilibrium, followed by a rest and deenergized period of sufficient duration to reestablish machine temperatures within 2°C of the coolant
S3: Intermittent periodic duty with a high start-up torque		A sequence of identical duty cycles, each including a period of operation at constant load and a rest and deenergized period. In this duty type, the cycle is such that the starting current does not significantly affect the temperature rise
S4: Intermittent periodic with a high start-up torque		A sequence of identical duty cycles, each cycle including a significant period of starting, a period of operation at constant load, and a rest and deenergized period
S5: Intermittent periodic duty with high start-up torque and electric braking		A sequence of identical cycles, each cycle consisting of a period of starting, a period of operation at constant load, a period of rapid electric braking, and a rest and deenergized period
S6: Continuous-operation periodic duty		A sequence of identical duty cycles, each cycle consisting of a period of operation at constant load and a period of operation at no load. There is no rest and deenergized period
S7: Continuous-operation periodic duty with high start-up torque and electric braking		A sequence of identical duty cycles, each cycle consisting of a period of starting, a period of operation at constant load, and a period of electric braking. There is no rest and deenergized period
S8: Continuous-operation periodic duty with related load/speed changes		A sequence of identical duty cycles, each cycle consisting of a period of operation at constant load corresponding to a predetermined speed of rotation, followed by one or more periods of operation at other constant loads corresponding to different speeds of rotation. There is no rest and deenergized period

Although this is true for all types of power devices, it is more critical for IGBTs where wire bonds and solder layers are used.

In modern IGBT-based converter design, the maximum junction temperature rise of the IGBTs is limited to a level, which ensures a conservative number of thermal cycles over the lifetime of the drive. Typical junction temperature rise is 30°C for a repetitive cyclic duty (e.g., steel mill) and 40°C for nonrepetitive cyclic duty (e.g., fan pumps).

29.4.2.4 Multiquadrant Operation

Fully regenerative electric VSDs offer a rapid regenerative dynamic braking in both forward and reverse directions. Operation in motoring implies that torque and speed are in the same direction (QI, III). In regenerative braking, the torque is opposite to the speed direction (QII and IV), and the electric power flow in the motor is reversed. (See Fig. 29.2.)

Positive power flow of electric energy means that electric power is drawn from the power supply via the power

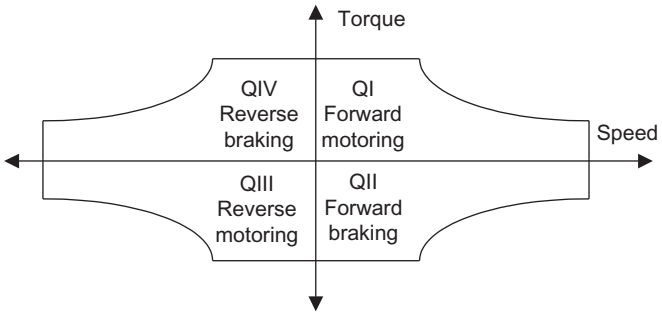


FIGURE 29.2 Operating regions of electric VSD.

electronics converter by the motor, while negative power flow refers to electric power delivered by the motor in the generator mode to the power electronics converter. This could be regenerated back to the supply or dissipated as a heat in the dynamic brake dissipative mechanism.

For regenerative drive, the power electronics converter has to be designed to be able to handle bidirectional power flow. In low and medium power converter (say <500 kW) with slow dynamic braking demands, the generated power during the braking period is interchanged with the strong filter capacitor of power electronics converter, or DC (dynamic) braking is used.

29.4.2.5 Dynamic Braking Energy

There exist two types of energy stored in VSD, which need to be dealt with during dynamic braking:

- *Inertia or kinetic energy loads*: Typically moving (rotating or linear) machines. These would decelerate naturally to rest. Braking can speed up the process cycle for the sake of productivity.
- *Mass or potential energy loads*: Typically hoists or lifts—which would run on or even accelerate. Braking must apply full power to maintain constant speed while the load is lowered.

The drive losses, mechanical resistance, and the transmission efficiency, work in favor of deceleration, reducing the braking power demand. The energy regenerated by potential energy loads depends on maximum power and both the overrun time and the decelerating time.

The braking time and the duty cycle time are decided by the requirements of the process system, but note particularly the effect of varying the braking duty cycle time and the deceleration time.

For DC injection braking, the kinetic energy of the motor-load system is converted to heat in the motor rotor. For fast and frequent generator braking, the power electronics converter has to handle the generated power either by a controlled dynamic brake chopper (with braking resistor) or through bidirectional power flow. The power losses in the converter can assist in dynamic braking.

For a fast speed response, modern VSDs may develop a maximum transient torque up to the base speed and maximum transient power up to a maximum speed, provided that both the motor and the power electronics converter can handle these powers. For a 200 kW dynamometer drive application, a rapid change of torque from full positive torque to full negative torque is required in <10 ms.

29.5 VSD Topologies

In this section, drive topologies are classified according to the motor they employ. Various publications dealt with this subject, for example, Refs. [3,5]. The most common motors are illustrated in Fig. 29.3.

29.5.1 DC Motor Drives

Until recently, the DC motor drive was the most commonly used type of electric VSD, with only very few exceptions, and is the least expensive. The mechanical commutator is an electromechanical DC-to-AC bidirectional power flow power converter, as the currents in the rotor armature coils are AC while the brush current is DC. The DC drive is well-known, well proved, and widely applied; yet, its popularity is in relative decline due to the emergence of the more robust, lower cost squirrel-cage induction motor drive.

Unfortunately, the mechanical commutator though not bad in terms of losses and power density has serious commutation current and speed limits and thus limits the power per unit to 1–2 MW at 1000 rpm and may not be accepted at all in chemically aggressive or explosion-prone environments. The application of the DC drive has been restricted to hazardous areas due to the very limited availability of flameproof DC machines. Commutator and brush maintenance is difficult in such

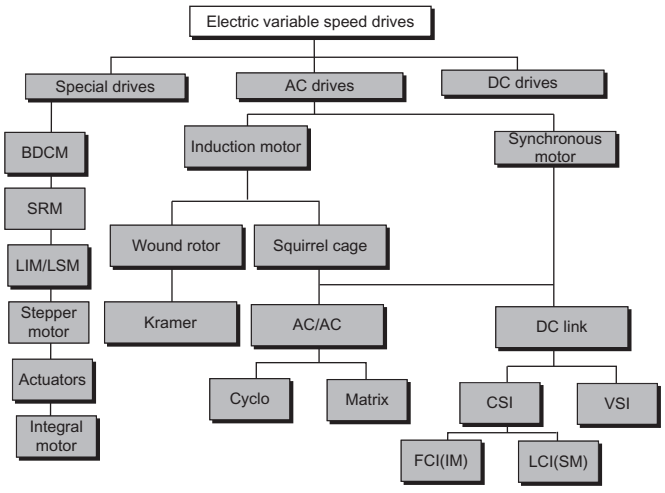

FIGURE 29.3 Classification of electric VSD.

environments. Furthermore, continuous sparking at the brushes is virtually inevitable at full load output.

Due to the inherent ease of speed control of the separately excited DC machine, DC drives found popularity in early electric drive applications, by varying the applied armature voltage. This variable armature voltage is simply generated by phase-controlled rectification, and this technique has now almost entirely replaced the Ward-Leonard systems previously used.

The AC/DC converter offers a variable DC voltage, which is capable of four-quadrant operation (positive and negative DC voltage and DC current output). Permanent magnet-excited brushed motors have been used in numerous applications for some time, particularly in nonregenerative drive applications.

Motor output torque is approximately proportional to armature current, and motor speed is approximately proportional to converter output voltage. Speed control by sensing armature voltage is therefore feasible giving an accuracy of around 5%.

Provided the motor excitation is kept constant, the DC drive power factor is proportional to motor speed. Since most pumps, compressors, and fans demand a torque proportional to the square of speed, constant excitation systems are used and so the above relationship applies.

A typical power factor, at maximum rated speed for a DC drive, is 0.85. This relationship applies to many other types of electric drives.

If a slow dynamic response is satisfactory, regeneration to the mains supply is achieved either by reversing the motor field or armature connection. Alternatively, regeneration with faster response is achieved by connecting another thyristor bridge in antiparallel with the main bridge. In this case, fast response is possible with changeover time of <15 ms between full torque motoring to full torque regenerating. The 6-pulse drive configuration is acceptable for powers up to 1 MW. This limitation arises not from any semiconductor device limitation but is due to AC line current harmonics the converter generates.

A force-commutated or "chopper" converter for DC motors uses the principle of variable mark-space control using a thyristor or transistor solid-state switch. With a diode front-end converter, a fixed, smoother DC supply is derived from the mains by uncontrolled rectification and rapidly applied, removed, and reapplied to the machine for adjustable intervals, thus applying a variable mean DC voltage to the DC motor; refer to Fig. 29.4B.

This type of DC drive has the advantage of high (near unity) power factor at all motor speeds and much reduced harmonic spectrum.

29.5.2 Induction Motor Drive

29.5.2.1 Squirrel Cage Induction Motor

Squirrel-cage induction motors are simpler in structure than DC motors and are most commonly used in the VSD industry. They are robust and reliable. They require little maintenance and are available at very competitive prices. They can be designed with totally enclosed motors to operate in dirty and explosive environments. Their initial cost is substantially less than that of commutator motors, and their efficiency is comparable. All these features make them attractive for use in industrial drives.

The three-stator windings develop a rotating magnetic flux rotating at synchronous speed. This speed depends on the motor pole number and supply frequency: the rotating flux intersects the rotor windings and induces an EMF in the rotor winding, which in turn results in circulating current. The rotor currents produce a second magnetic flux, which interacts with the stator flux to produce torque to accelerate the machine. As the rotor accelerates, the induced rotor voltage falls in magnitude and frequency until an equilibrium speed is reached. At this point, the induced rotor current is sufficient to produce the torque demanded by the load. The rotor speed is slightly lower than the synchronous speed by the slip frequency, typically 3%.

In order to ensure constant excitation of the machine, and to maximize torque production up to the base speed, the ratio of stator voltage to frequency needs to be kept approximately constant.

Induction motor drive has three distinct operating regions:

(a) *Constant torque*: The inverter voltage is controlled up to a maximum value limited by the supply voltage. As the motor speed and the voltage are increased in proportion, constant V/F, the rated flux linkage is maintained up to the base speed. Values of torque up to the maximum value can be produced at speeds up to about this base value. The maximum available torque is proportional to the square of the flux linkage. Typically, the induction

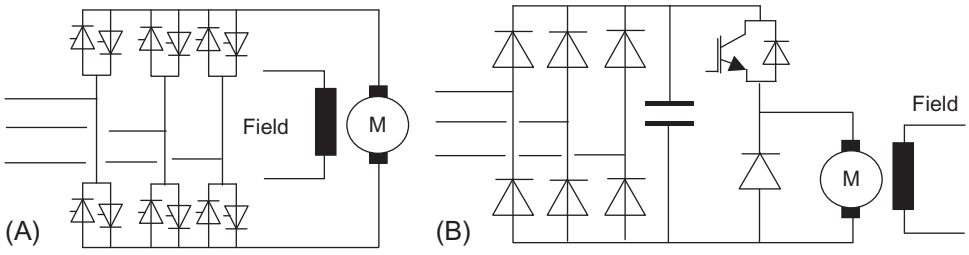

FIGURE 29.4 DC drive: (A) with fully controlled antiparallel supply bridge and (B) diode rectifier with DC chopper.

motor is designed to provide a continuous torque rating of about 40%–50% of its maximum torque.

(b) *Constant power*: For higher speed, the frequency of the inverter can be increased, but the supply voltage has to be kept constant at the maximum value available in the supply. This causes the stator flux linkage to decrease in inverse proportion to the frequency. Constant power can be achieved up to the speed at which the peak torque available from the motor is just sufficient to reach the constant power curve. A constant power speed range of 2–2.5 can usually be achieved. Within this range, the motor frequency is increased until at maximum speed.

(c) *Machine limit (pullout torque)*: Once the machine limit has been reached, the torque falls off in proportion to the square of motor frequency. Operation at the higher end of this speed range may not be feasible as the motor power factor worsens. This in turn results in a higher stator current than the rated value. The motor heating may be excessive unless the duty factor is low.

Induction motors are used in applications requiring fast and precise control of torque, speed, and shaft position.

The control method widely used in this type of application is known as vector control, a transient response at least equivalent to that of a commutator motor can be achieved.

The voltage, current, and flux linkage variables in this circuit are space vectors from which the instantaneous values of the phase quantities can be obtained by projecting the space vector on three radial axes displaced 120 degrees from each other. The real and imaginary components of the space vectors are separated, resulting in separate direct and quadrature axis equivalent circuits but with equal parameters in the two axes.

Changes in the rotor flux linkage can be made to occur only relatively slowly because of the large value of the magnetizing inductance of the induction motor. Vector control is based on keeping the magnitude of the instantaneous magnetizing current space vector constant so that the rotor flux linkage remains constant. The motor is supplied from an inverter that provides an instantaneously controlled set of phase currents that combine to form the space vector, which is controlled to have constant magnitude to maintain constant rotor flux linkage. The second component is a space vector, which is in space quadrature with the instantaneous magnetizing current space vector. This component is instantaneously controlled to be proportional to the demand torque.

To the extent that the inverter can supply instantaneous stator currents meeting these two requirements, the motor is capable of responding without time delay to a demand for torque. This feature, combined with the relatively low inertia of the induction motor rotor, makes this drive attractive for high-performance control systems.

Vector control requires a means of measuring or estimating the instantaneous magnitude and angle of the space vector of the rotor flux linkage. Direct measurement is generally not feasible. Rapid advances are being made in devising control configurations that use measured electric terminal values for estimation.

29.5.2.2 Slip-Ring (Wound-rotor) Induction Motor Drive

Wound-rotor induction motors with three rotor slip rings have been used in adjustable speed drives for many years. In an induction motor, torque is equal to the power crossing the air gap divided by the synchronous mechanical speed. In early slip-ring induction motor drives, power was transferred through the motor to be dissipated in external resistances, connected to the slip-ring terminals of the rotor. This resulted in an inefficient drive over most of the speed ranges. More modern slip-ring drives use an inverter to recover the power from the rotor circuit, feeding it back to the supply system.

The speed of slip-ring induction motor can be controlled by the following:

- Stator frequency control as with a cage rotor machine.
- Rotor frequency control.
- Rotor resistance control.
- Slip energy recovery (Kramer system). For capital cost reasons, the last two are commonly used.

Addition of rotor resistance especially for starting large induction motors is well-known. The basic effect produced by adding rotor resistance is to alter the speed at which maximum motor torque is developed. Unfortunately, power dissipation as heat in the rotor resistance bank takes place; earlier means to overcome this shortcoming were to convert the rotor power to DC and feed a DC motor on the same shaft. The rotor slip energy, when running at reduced speed, is therefore reconverted to mechanical power. This is the "Kramer" system. The disadvantages of this approach were the extra maintenance and capital costs.

The static Kramer system overcomes these shortcomings by replacing the DC machine with a line-commutated inverter that returns the slip energy directly to the AC line, either directly (on lower power systems) or via a transformer. A key advantage of the Kramer drive system is that the slip-energy recovery equipment (DC machines or static inverter) needs only be rated for a fraction of the maximum motor rating. This is true when a small speed range is required and provided that a separate means is provided of starting the motor. This is because the motor rotor current is proportional to torque and the rotor voltage inversely proportional to speed.

Naturally, if the slip-energy recovery network can be rated to withstand full rotor voltage (developed at standstill), a controlled speed range of zero to maximum could be achieved. However, this is generally only feasible on smaller motors (below 2000 kW) where the rotor voltage is sufficiently low for an economic inverter package. Secondly, if a full speed range is needed, the slip-energy recovery network has to be

rated at full motor power, so static Kramer drives become uneconomic for wide speed ranges. The overall system power factor would be very low for a wide speed range system.

For the above reasons, Kramer drives are very suitable for high-power drives (>200 kW) where a small speed range is required. Pump and fan drives present therefore good economic applications. Kramer drives have also been used for low-speed-range endurance dynos using the recovery system to control torque of induction generator. As with all line-commutated converters and inverters, current harmonics are produced, and these can be reduced to acceptable values. However, as the slip-energy recovery network is only power-rated in direct proportion to the speed reduction required (assuming constant load torque), the magnitudes of the harmonic currents generated are proportionally less than with drives where the solid-state converters have to handle the whole drive power. Harmonics of the rotor rectifiers are transmitted through the rotor and appear as noninteger harmonics in the main supply.

The main disadvantages of the slip-ring induction motor drive are (a) the increased cost of the motor in comparison with a squirrel cage, (b) the need for slip-ring maintenance, (c) difficulty in operating in hazardous environments, (d) the need for switchable start-up resistors, and (e) the poor power factor compared with other types of drive.

29.5.3 Synchronous Motor Drives

To understand the way the synchronous machine operates, let us assume that the induction motor were to rotate at the synchronous speed by an external means. Under this condition, the frequency and magnitude of the rotor currents would become zero. If an external DC power supply were connected to the rotor winding, then the rotor would become polarized in a similar way to a permanent magnet. The rotor would pull into step with the air-gap-rotating magnetic field, generated by the stator but lagging it by a small constant angle referred to as the load angle. The load angle is proportional to the torque applied to the shaft, and the rotor keeps rotating at synchronous speed, provided that the DC supply is maintained to the rotor field winding. The magnetic flux produced by the rotor winding intersects the stator windings and generates a back EMF, which makes the synchronous motor significantly different from the induction motor.

As with the induction motor drive, the requirement is to keep the ratio V/F constant (i.e., varies both the stator frequency and applied voltages in proportion to the desired motor speed).

The supply bridge converter is phase-controlled generating an adjustable DC current in the DC link choke. To generate maximum torque from the synchronous motor, this current is switched into the motor stator windings at the correct phase position with respect to rotor angular position as detected by the position sensor by the inverter bridge. When running above about 10% speed, the back EMF generated by the synchronous motor is sufficient to commutate the current into the next arm of the inverter bridge. So, as this type of inverter is machine (motor)-commutated, the inverter configuration is merely that of a conventional DC drive. The complexity, expense, and limited power capability of the force-commutated circuitry is therefore avoided.

The motor back EMF is insufficient for thyristor commutation at low speeds. The technique here, therefore, is to rapidly phase back the supply converter bridge to reduce the DC link current to zero and after a short delay (to ensure that all thyristors in the machine bridge are turned off) reapply DC current when the correct thyristor trigger pattern has been reestablished. As the motor speed and thus back EMF increase to a value sufficient for machine commutation, changeover to continuous DC link current operation is effected.

During the starting mode, the correct inverter bridge firing instant is determined by rotor position sensor, which is mounted on the motor shaft whose angular position is detected by opto or magnetic probes. When in the machine-commutated mode, sensing of stator voltage is used. To develop maximum torque in the low speed or pulsed mode, angular rotor position sensing is necessary. However, if less than full load torque availability at low speed can be tolerated, the inverter system can be set to produce a low fixed frequency in the pulsed mode. This frequency is then increased, as motor rotation is detected (either in steps or on a preset ramp rate) until sufficient back EMF is generated to facilitate changeover to the voltage-sensing mode.

As previously stated, the key advantage of this type of drive is that all thyristor devices are line- or machine-commutated. Expensive and complex forced commutation circuitry is avoided, and fast turn-off thyristors are unnecessary. Inverter systems of this type can therefore be built at very high powers, up to 100 MW. Also, as a result of avoiding force commutation, converter efficiency is high.

The thyristors in the machine inverter bridge must be triggered at such an angle to give sufficient time for commutation from one device to the next. This results in the synchronous motor operating at a high leading power factor of around 0.85. However, as far as the mains supply is concerned, the total drive has the characteristics of a DC drive where power factor is proportional to speed.

Another important characteristic of this type of drive is that it is inherently reversible and regenerative. For regenerative operation, the inverter bridge is triggered in the fully advanced position, so in effect, it becomes a plain diode bridge. A DC output voltage, approximately proportional to motor speed, is therefore generated at the DC side of the supply converter bridge. This converter bridge is now triggered in the regenerative mode thus returning power to the supply system. Reversing operation is achieved by altering the sequence in which the thyristors in the inverter bridge are triggered.

This type of drive is widely applied over a wide power range as it embodies an efficient brushless motor and relatively simple

and efficient converter. At lower powers, say below 30 kW, permanent-magnet synchronous motors are more common.

Unlike the induction motor, the synchronous type requires two types of converter: the first for main power conversion while the second is low power for field excitation. The field converter feeds the rotor exciter winding through slip rings and brushes, or alternatively, a brushless exciter can be used. A coordinated control of the two converters provides for active power and reactive power control and for efficient wide speed range control in high-power applications.

For high-power applications, synchronous motors are preferred because of the ability to control reactive power flow through appropriate control of excitation. Synchronous motors tend to have wider speed range and higher efficiency. However, synchronous motors are generally more expensive than induction motors.

With modern high-power PWM-VSI drives, synchronous motor can be driven for same inverter with vector control methods.

29.5.4 Special Motors

Motors under this category employ power electronics converters for normal operation. Generally, this type of motor has a large number of phases in order to limit torque pulsation and self-start from any rotor initial position. This is a new breed of motors, which can be fed through a unipolar or bipolar current. Also they have singly salient or doubly salient magnetic structures with or without permanent magnets on the rotor.

29.5.4.1 Brushless DC Motor Drive

This type of machine has a similar construction to a standard synchronous machine, but the rotor magnetic field is produced by permanent magnet material. A position sensor is used to ensure synchronism between the rotor position and the stator magnetomotive force (MMF) via drive signals to the inverter. The use of new magnet materials characterized by high coercive force levels has reduced magnet sizes and largely overcome the demagnetization problem. The absence of the field copper losses improves the machine efficiency.

As the permanent magnet is the source for excitation, the brushless DC motor (BDCM) can be viewed as a constant flux motor. A limited amount of flux weakening can be achieved by increasing the load angle of the stator current. Achieving a useful constant power range is not usually practical with this type of motor. A large demagnetizing component of stator current would be required to produce a significant reduction in magnet flux, and this would increase the stator loss substantially.

The required base torque determines the motor size, and the losses are essentially independent of the number of stator turns. At speeds up to the base speed of the constant power range, the efficiency of the motor is essentially the same as for one designed for rated voltage at base speed. For operation above base speed, the stator current from the inverter is reduced in inverse proportion to the speed. This mode of operation in the high-speed range reduces the dominant stator winding losses relative to a machine in which the flux is reduced and the current kept constant. The losses in the inverter are, however, increased due to its higher current rating. For an electric road vehicle that must carry its energy store, the net energy saving may be sufficiently valuable to overcome the additional cost of the larger inverter. A further advantage of this approach is that, if the DC supply to the inverter is lost, the open-circuit voltage applied to the inverter switches will be within their normal ratings.

The BDCM has higher volumetric power density compared with other types of motors (induction or synchronous). They are particularly suited for the high values of acceleration required in drives (e.g., machine tools). They are often operated with high acceleration for a short time followed by a longer period of low torque. At such low values of load factor, the cooling capability is frequently not a limitation. The major interest is in obtaining the maximum acceleration from the motor. The short-term stator current of a BDCM is limited to the value required for magnet protection. These values of acceleration are significantly higher than that can be achieved with either induction or DC motors of similar maximum torque rating.

29.5.4.2 Switched Reluctance Motor Drive

This motor can be regarded as a special case of a salient synchronous machine in which the field MMF is zero and the torque is produced by reluctance or saliency action only. The rotor has no winding. The switched reluctance motor (SRM) drive needs an inverter whose frequency is locked to the shaft speed, but since the torque is linearly proportional to the square of the stator current, the use of unidirectional current involves little sacrifice in performance.

Generally, the use of position sensors in the SRM and BDCM is something of a disadvantage in both cases. The SRM does not require permanent magnets, which can cost and may involve demagnetization risks and limit top speeds due to centrifugal forces. The SRM hence has a simpler construction and is more robust. However, the need to magnetize the motor from the AC side adds to inverter costs and may increase peak current levels significantly, hence raising stator copper losses.

Switched-reluctance synchronous motors have a cylindrical stator with three AC windings and a solid rotor (without any winding) with a moderate orthogonal axis magnetic saliency up to 4 (6) to 1. High magnetic saliency is obtained with multiple flux barriers. The conventional SRMs are to some extent (up to 100 kW) used in low-dynamics VSDs with open-loop speed control, as the speed does not decrease with load. Consequently, the control is simpler than with induction motors.

The main drawback of the conventional SRD is the low motor power factor and the relatively poor torque density, which leads to a higher kVA rating of the power converter ($\sim$20%). The main advantage of the synchronous reluctance motor over the induction motor of similar rating is the higher

efficiency. Compared with the squirrel-cage induction motor, the rotor loss is small or negligible in synchronous reluctance machines. If the saliency ratio is sufficient to produce a power factor equal to that of the induction motor, the stator winding loss will be the same. Also, the stator iron losses will be similar for the two motors.

The reluctance motor is capable of operation in the constant power mode of operation. As for all AC drives, when the supply voltage limit is reached above the base speed, the flux linkage is reduced in inverse proportion to the shaft speed, and the torque is inversely proportional to speed squared.

29.5.4.3 Linear Motors

There are applications in which linear motion, as opposed to rotational, is required. A linear machine has the same operating principles as those applied to all other rotating machines. The PWM-VSI converters and motor control principles discussed in this chapter are also applicable to this type of motor.

There are two types of linear motors:

- LIM—linear induction motor
- LSM—linear synchronous motor with permanent magnetic excitation

The LSM type has the following advantages over the LIM:

- Better power factor
- More responsive control
- Higher efficiency

The disadvantages of LSM are the following:

- Very accurate position feedback is required.
- The use of PM—expensive and heavy.

Transport, material handling, and extrusion processes are a few examples in which linear motors have successfully been employed.

29.5.4.4 Stepper Motors

Stepper motors are either built in a similar manner to BDCM, with permanent magnets embedded in or bonded to the rotor or a rotor with no magnets. The latter type is made of a ferrite magnetic material, and its circumference is cut to form a number of slots, forming teeth lengthwise to the rotor axis.

Torque production can be based on (a) magnetic reluctance (as in SRM), (b) magnetic attraction (as in BDCM), or (c) both magnetic reluctance and attraction.

Stepper drives do not offer dynamic speed control, and the main action is to accelerate at full torque to full speed, maintain the speed, and decelerate at full torque. In comparison with the reluctance-type stepper motor, the permanent magnet type offers greater torque for a given speed, particularly at start and low speeds.

Most drives incorporate controllers with connections for a communications link for supervisory control by PLC, hard-wiring connectors for analog/digital inputs and outputs, and some are equipped with software for communications with a computer or handheld keypad. Table 29.12 lists typical options.

Unlike above motor drives, the stepper motor can achieve precise position control without the need for any external feedback.

29.5.4.5 Actuators

Actuators are widely used in industry, primarily for positioning tasks. Their designs are based on all sorts of force-producing principles. Ref. [7] describes several types of direct drive electric actuators, including (a) the DC actuator (moving coil type), (b) induction actuators, (c) synchronous actuators (moving magnet DC type), (d) reluctance actuators, and (e) inductor actuators (polarized reluctance type).

Electric actuators are used increasingly in control systems and automated electromechanical equipment. Typical specification factors include range of motion, type of motion (linear

TABLE 29.12 Control features for servo and stepper motor drives (Ref. [6])

Control features	Servo drive	Stepper drive
Acceleration/deceleration time	Adjustable	Accelerate at maximum torque, time is dependent on maximum torque and inertia
Maximum speed	Part of the motor specification	Part of the motor specification
Speed control	Permit a range of speed settings	Not necessarily available
Torque control	Many offer speed and torque control	Always operate at maximum torque
Auto-tuning	A feature of some servo drive	Not applicable
Reversing	Commonly available by digital control signal	Commonly available by digital control signal
Zero speed clamp	Applies full torque to hold the position constant	Applies full torque to hold the position constant
Dynamic braking	Controlled deceleration, may require dissipative brake resistor	Usually standard
Regenerative braking	Dedicated circuit for controlled braking	Not applicable
Travel limits	Definition of travel limits in the forward and reverse directions	Standard
Jog or inch	Digital command to "jog" one step (with defined distance)	Optional feature
Closed-loop configuration	Most drives accept external signals for closed-loop control	Most drives accept external signals for closed-loop control
Programming functions	Many drives incorporate programming functions as in PLCs, reset all functions to default states, return to a home position, enable or disable repetition or a preset sequence, select a particular set of control inputs, increased or decreased speed, change the torque boost, etc.	

or rotary and stepwise or continuous), resolution needs, speed of response, environmental conditions, supply conditions, allowable electromagnetic noise emission level, need for integrated position and velocity sensors, maintenance needs, eligibility, cost, peak, and continuous torque.

The main demands of industry for high-performance systems are the following:

(a) A convenient supply and low power consumption
(b) Reliability and robustness
(c) Low initial cost and maintenance
(d) Fast response
(e) Linear "torque-excitation" characteristics

29.5.4.6 Integrated Motors

The integral motor consists of a standard AC motor with an integrated frequency inverter and EMC filter. It is robust and specified for reliable operation and often designed to handle rough working conditions, including ambient temperature −25°C to −40°C and dusty, corrosive, and humid environments (enclosure IP55). This type of drive uses a standard induction motor with the AC/AC converter integrated in the motor frame often as a separate converter box mounted directly above the motor frame in place of the terminal box. The power popularity of this type of drive is limited to 0.5–7.5 kW.

This type of motor offers the following advantages:

- Save space by eliminating the need for a separate controller
- Reduce installed costs because cabling between motor and converter is eliminated
- Eliminate motor problems caused by high voltage transient due to output cable capacitance
- Minimize EMC due to high dV/dt

The integrated drive includes most features including start, stop, forward, reverse, speed and torque controls, and controlled acceleration and deceleration.

29.6 PWM-VSI DRIVE

In recent years, the popularity of PWM-VSI has increased beyond recognition. Its dynamic performance and controllability is better than the DC drive. Its power range has extended to areas dominated for years by traditional solutions such as the cycloconverter and LCI drives.

29.6.1 Drive Comparison

Table 29.13 shows a direct comparison between the cycloconverter, LCI, and PWM-VSI drives. The DC drive and the slip-power recovery converter type are not listed because AC drives have already replaced DC drives in most applications due to low maintenance and better reliability of AC motors. Slip recovery is only suitable for applications with a limited speed range and requires a slip-ring wound rotor.

TABLE 29.13 Drive comparison

Control features	Cyclo	LCI	PWM-VSI	Matrix
Speed	Limited	Wide	Wide	Wide
Dynamic response	Excellent	Good	Excellent	Excellent
Torque pulsation	Low	High	Very low	Very good
Power factor at low speed	Poor	Poor	Very good	Very good
Stability	Good	Moderate	Very good	Very good
Motor	Custom	Custom	Standard	Standard[a]
Regeneration	Inherent	Inherent	Needs extra hardware	Inherent
Volumetric power density	Moderate	Good	Very good	Excellent

[a]The AC output voltage of the matrix converter is always less than the input voltage—derating is expected, or a larger frame size is required.

In comparison with the cycloconverter and LCI current-source converter drives, the PWM-VSI drive offers the following advantages:

- Excellent dynamic response
- Smooth torque/speed control over full speed range (0–200 Hz)
- High volumetric power density
- Ride through of dips in supply voltage
- Use of standard motors (squirrel-cage induction motor or synchronous motor)
- Improved AC supply power factor over full speed range
- Reduced cabling and transformer size and cost in comparison with cycloconverters
- No significant torque pulsation
- Lower noise level
- Low maintenance

29.6.2 Medium Voltage PWM-VSI

The maximum power rating of LV VSD is limited by practical current ratings of power components such as motor, cable, and transformer (typically 1500 A), giving a limit of about 2 MVA at 600 V. At this rating, motor manufacturers always prefer an MV machine design—significant saving and improved thermal performance of power components can be achieved by operating at medium voltages instead of low voltages. Many VSD applications will benefit from the availability of economic MV alternatives.

When adequately rated high blocking voltage devices are available, a simple two-level inverter or alternatively three-level neutral-point clamp (NPC) has always been the choice to meet required output voltages. These topologies offer a simple and cost-effective solution.

Series connection of power devices is the traditional solution for high-power high-voltage thyristor-based drives. This approach is perceived to be complex with fast-switching IGBTs because of simultaneous switching and correct static and dynamic voltage sharing of series devices.

The "multilevel" inverter drive is seen to offer a better solution for high-power, high-voltage inverter drive. The output waveform is high quality, even at very high modulation frequencies, which inherently results in lower harmonic content in the output voltage waveform (less losses, less torque pulsation, and lower insulation voltage stresses).

Ref. [8] and Fig. 29.5 categorize MV converter topologies as follows:

(A) Series-connected two level (SC2L)
(B) Three-level neutral-point clamp (3LNPC)
(C) Multilevel: diode-clamped multilevel (DCML) and capacitor-clamped multilevel (CCML)
(D) Isolated series H-bridge (ISHB) (Table 29.14)

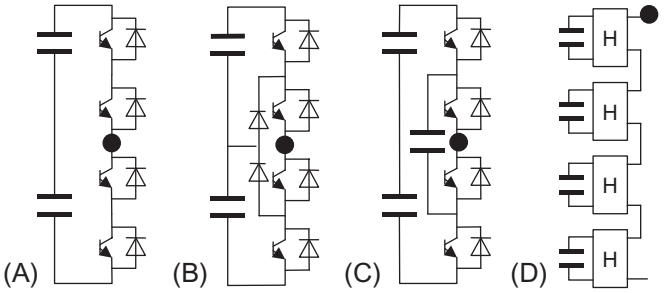

FIGURE 29.5 MV stack topologies.

29.6.3 Control Strategies

Several control techniques can be found in the VSD industry; refer to Fig. 29.6. These are the following:

- Open-loop inverter with fixed V/Hz control
- Open-loop inverter with flux vector control

TABLE 29.14 Comparison between different MV converter stack topologies

Topologies	Advantages	Disadvantages
Two-level with series devices (SC2L)	• Simple and proved technology • Same converter design over supply voltage range • Standard fully developed PWM control • Provision for series redundancy of power switches per inverter phase arm ($n+1$)	• Static and dynamic voltage sharing of series devices • High dV/dt due to synchronous commutation of series devices • High switching frequency harmonic content in inverter output voltage
Three-level NPC (3LNPC)	• Well proved • Reduced harmonic content • Better utilization of switches • Reduced dV/dt (half the SC2L equivalent)	• Series redundancy is difficult to achieve • More complex PWM control is needed than two level • Requires extra clamping diodes • Requires split DC link • Requires midpoint voltage balance control • Even number of power devices per arm is always needed • Switches require snubbers
Diode-clamped multilevel (DCML)	• Reduced harmonic contents • Reduced dV/dt	• Series redundancy is very difficult to achieve • Very complex PWM control is needed • Requires many steering diodes • Requires split DC link • Requires voltage balance control of split DC link capacitors • Uneven current stresses on power devices • Requires snubbers
Capacitor-clamped multilevel (CCML)	• This configuration has all the advantages of a multilevel converter plus simpler arrangement, modular building block • Less components • Snubberless operation is possible • Easier capacitor voltage balance than 3LNPC	• Possible parasitic resonance between decoupling capacitors • Complex to provide series redundancy • More complex PWM control strategy than for two level • Voltage redistribution of capacitors during supply voltage surges • Too many capacitors (bulky stack design and poor capacitor utilization at high ratings) • Complex converter arrangement (for low stray inductance) • Inverter rating is limited by the load current flowing through the capacitors
Series-connected isolated H-bridges (ISHB)	• Modular design of the converter power modules • The basic building block is based on a DC supply bridge, decoupling capacitor, and an H-bridge arrangement • In the AC supply, the combined diode bridge rectifiers act like a multipulse bridge (18p for four level and 24p for five level), reducing harmonic injection into the AC supply. • Its output has very low harmonic contents in spite of the low switching frequency	• Employs a special (bulky and expensive) transformer • Complex to achieve series redundancy • Different supply transformer designs are required for applications operating at different AC line voltages • Power pulsation for poor power factor loading • Poor utilization of capacitors • Not suitable for common DC bus applications • Dynamic braking is difficult

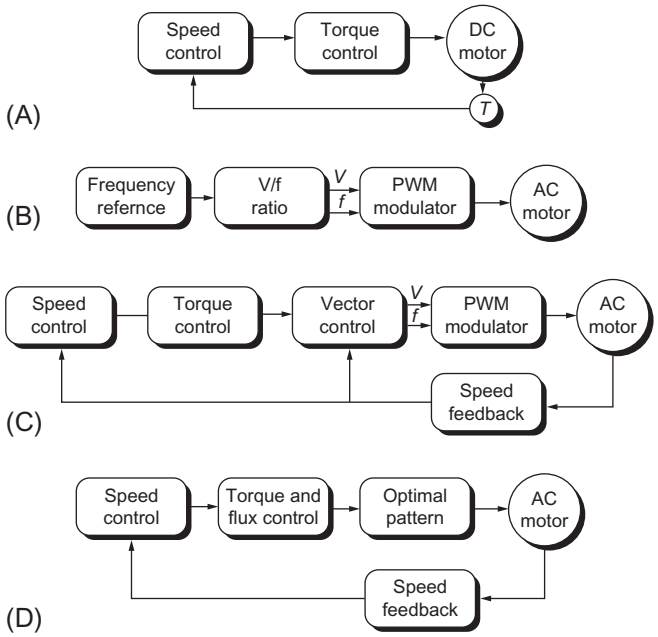

FIGURE 29.6 Electric drive control techniques. (A) DC drive, (B) frequency control (PWM scalar control), (C) flux vector control (field-oriented control), and (D) direct torque control.

- Closed-loop inverter with flux vector control (induction motor)

Table 29.15 summarizes the main features, advantages, and disadvantages of each technique.

29.6.4 Communication in VSDs

The use of a high-speed advanced digital communication (fieldbus) to build industrial automation system for real-time control or simply for data logging has become well established in modern industries. Digital communication resulted in replacing wiring looms with a digital serial network; this resulted in a lower cost installation and a more reliable solution. Over the last few years, many industrial fieldbuses emerged, and end users, system integrators, and original equipment manufacturers (OEMs) chose the optimum system for their applications.

A fieldbus is a digital communication system that allows a control system to exchange data with remote sensors, actuators, and drives using a single communication link. The major benefits seen are (a) reduced installation and cabling cost and better overall immunity of the system. Both factors result in a more reliable operation and reduced maintenance costs.

There exist two main types of network:

(a) Centralized network—requires a network master controller, typically a PLC. The master device is entirely responsible for controlling communications over the network, while the slave devices tend to be "dumb" devices with no local intelligence.
(b) Decentralized network—which requires some local intelligence at each node but no overall master device. This is ideal for real-time application environment, as all nodes are effectively running in parallel.

Most modern VSDs are equipped with hardware and software, which enable local and remote communication with plant

TABLE 29.15 Comparison between various control methods used in VSD

Drive type	DC drive		AC drive	
Control method	• Field oriented	• Frequency control	• Flux vector control	• Direct torque control
Features	• Field orientation via mechanical commutator • Controlling variables are armature current and field current • Torque control is direct • Typical response 10–20 ms	• Voltage and frequency control • Simulation of variable speed drive using modulator • Flux provided with a constant *V*/*F* ratio • Open-loop drive • Load dictate torque level • Typical torque dynamic response 100 ms	• Field-oriented control—similar to DC drive • Motor electric characteristics are modeled (observer) • Closed-loop drive • Torque controlled indirectly • Typical torque dynamic response 10–20 ms	• Use advance control theory • Controlled variables are magnetizing flux and motor control • Typical torque dynamic response is <5 ms
Advantages	• Accurate and fast torque control • High dynamic speed response • Simple to control	• Low cost • No feedback devices are required • Simple	• Good torque response • Accurate speed control • Full torque at zero speed • Performance approaching DC drive	• Simple • No feedback requirements • No need for an observer
Disadvantages	• Reduced motor reliability • Regular maintenance • Motor costly to purchase • Needs encoder for feedback	• Field orientation not used • Motor status ignored • Torque is not controllable • Delaying modulator used	• Feedback is needed • Costly • Modulator is needed	

automated system via a fieldbus system. The most popular fieldbuses are Profibus, Interbus, Ctnet, Sercos, Worldfib, and DeviceNet.

29.6.5 PWM Techniques

Different PWM techniques have been employed in PWM-VSD converters. Fig. 29.7 identifies the most commonly used techniques.

29.6.6 Impact of PWM Waveform

29.6.6.1 PWM Voltage Waveform

Fast switching of IGBTs (typically <1 μs) results in high *dV/dt*, typically 3–5 kV/μs, and possible voltage overshoot at turn-off that can last for a few microseconds. The fast rate of rise/fall of voltage combined with high peak voltage at the turn-off results in a premature failure of motors and EMC. Refs. [9–11] deal with the effect of PWM waveforms of VSD.

The following is a brief summary of the effect of the unfiltered waveforms.

29.6.6.2 Effect on Motor

- Premature insulation failure due to partial discharge as a result of peak voltage, high *dV/dt*, and high frequency.
- Motor shaft voltage that forces current into the shaft bearing, leading to early bearing failure.
- Motor stray capacitance (between windings and earthed frame) leads to earth-current flow caused by high *dV/dt*.
- High *dV/dt* creates nonuniform distribution of voltage across the winding, with high voltage drop across the first few turns and consequential failures.
- In a large motor, voltage differential on the frame is likely to develop in spite of protective earthing of the motor. More than one earthing point is needed.

29.6.6.3 Effect on Cables

- Voltage-doubling effect at the rising/falling edges of voltage waveform due to wave propagation in long cables [9].
- Earth-current flows in cable stray capacitance due to *dV/dt*.
- Restriction on cable type used and earthing methods employed.
- Cable type (armored, screen, and multicore).
- Likelihood of cross talk with other surrounding cables running in parallel.
- For PWM drives, the cost of cabling is likely to be significant due to special requirements of cables and termination methods employed.

29.6.6.4 Effect on EMC/Insulation/Earthing

- Inductive and capacitive couplings between live components and earth result in common-mode and differential-mode noise. This could lead to malfunctioning of nearby sensitive equipment.
- The voltage to earth applied on drive components pulsates at the switching frequency, adding voltage stresses (worst at low speeds and low modulation index). This poses

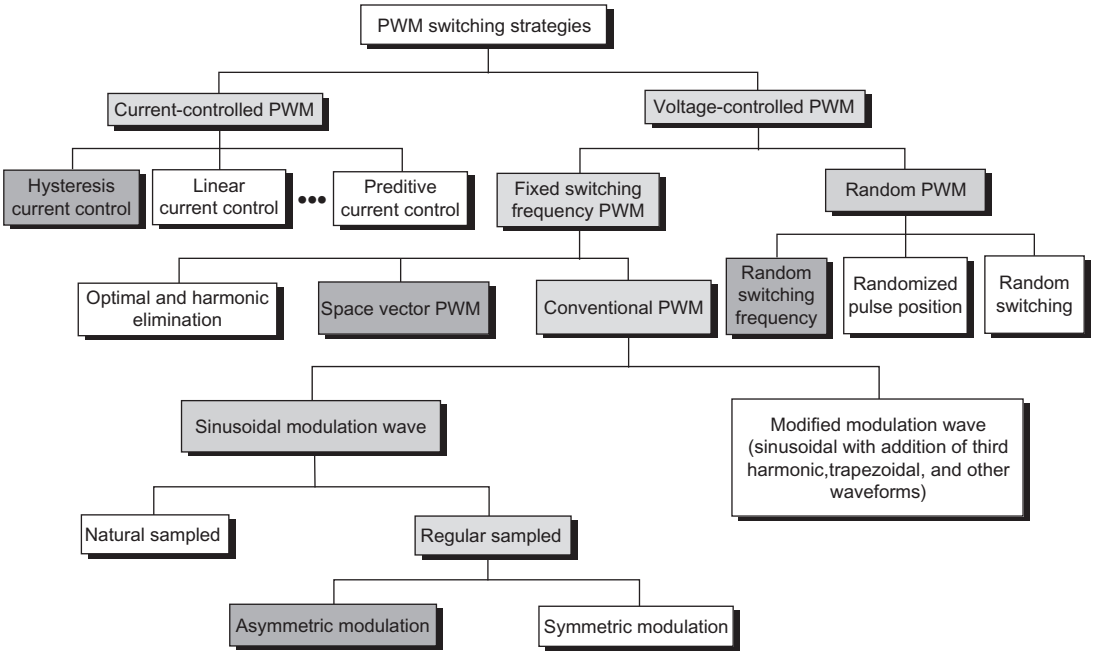

FIGURE 29.7 Classifications of PWM techniques.

additional insulation requirements on main power components (motor, cable, output filter, and transformer).
- A fourth wire may be required between the motor frame and the converter virtual earth so that a low impedance path is provided for the motor earth current.
- Strict rules must be observed when cabling and earthing.

29.6.6.5 Motor Insulation

High peak voltages can be experienced at the motor terminals especially when long cable is employed (10–100 m depending on the size of motor). This is usually caused by voltage-doubling phenomena of a transmission line with unequal line and load impedance. Motor line voltage can reach twice the DC link voltage with long cables.

Fast voltage rise times of 5000 V/μs can be measured at the motor terminals. Under this condition, the motor insulation becomes stressed and can lead to a premature breakdown of a standard motor insulation. When motor fails due to insulation stress caused by high peak voltage and fast voltage rise times, failure occurs in the first turn as phase-to-phase short or phase-to-stator short. The highest voltage is normally seen by the first turn of the winding.

Standard motor capabilities, established by the National Electrical Manufacturers Association (NEMA) and expressed in the MG-I standard (part 30), indicate that standard NEMA type B motors can withstand 1000 V peak at a minimum rise time of 2 μs (500 V/μs). Ref. [10] describes the effect of PWM inverter waveform on motor insulation in more detail.

Partial discharge

The phenomena that starts deterioration of the motor insulation is called partial discharge (PD). When electric stresses in insulation voids exceed the breakdown voltage of the air, a partial discharge occurs. Successive PDs destroy the insulation slowly.

Voltage strength between phase to phase and phase to frame

Both NEMA and IEC are proposing (a) maximum 1000 V at rise time <2 μs and (b) a maximum rate of rise of 500 V/μs. It is believed that low-voltage standard motors can withstand a lot larger voltage stresses than specified by NEMA and IEC, possibly up to 1300 V, almost regardless of the rise time.

Voltage strength between turn to turn

In low-voltage AC motors, the conductor insulation is designed for 245 V RMS (350 V peak). The insulation strength is however higher depending on the impregnation method.

29.6.6.6 Bearing Current

Bearing current and shaft voltages under 50/60 Hz sine-wave operation has been recognized since 1924. The bearing impedance characteristics largely determine the resulting bearing current that will flow for a given shaft voltage [11].

The rotating machines have three basic sources of shaft voltage. These are the following:

- Electromagnetic induction from the stator winding to the rotor shaft (due to small asymmetries of the magnetic field in the air gap that is inherent in a practical machine design). The design limit is <1 V RMS.
- Electrostatic coupled from internal sources: such as voltage in motors where rotor charge accumulation may occur (belt-driven coupling and ionized air passing over rotor fan blades).
- Electrostatic coupled from external sources such as PWM inverter. The presence of high *dV/dt* across the stator neutral to frame ground causes a portion of the voltage to ground due to capacitor divider action. The presence of PWM-related voltage components is undesirable and leads to a premature bearing failure.
- The fundamental cause of the shaft voltage is magnetic asymmetry between the stator and the rotor or possibly a phase shift of the motor voltage waveform. System ground may also contribute to this condition through unbalance system voltage.
- NEMA-500 recommends the consideration of insulated bearing for motor frame of certain sizes.

29.6.6.7 Electromagnetic Compatibility

The main sources of electromagnetic emission of PWM-VSI drives are described in [12] as follows:

AC/DC converter: Supply harmonics caused by supply bridge rectifier (from 100 Hz to 2.5 kHz): as already explained, the input bridge circuit with an SCR or diode bridge is a source of supply harmonics in the input current.

DC/AC inverter: Harmonics caused by the switching of the inverter bridge (from 3 kHz to 20 MHz): the inverter bridge uses fast-switching devices to create PWM voltage output. The inverter is a source of a wide band of frequencies, typically extending from the basic switching frequency (usually several kilohertz) to the radio high-frequency bands at 20 MHz. The radio frequency current spreads out into both the supply and motor connections. An EMC filter is often used to limit the spread of high-frequency harmonics into the supply.

Control electronics: The control circuit employs a microprocessor with clock frequency of several megahertz, typically 20 MHz. The clock wave produces frequencies, which are multiple of 20 MHz up to 300 MHz (Table 29.16).

29.6.7 Techniques Used to Reduce the Effect of PMP Voltage Waveform

29.6.7.1 Output Line Reactor

A reactor increases the rise time, but the benefit of its connection may be negated as follows:

- Beneficial connection if cable length is short enough for reflections to be superimposed within rise time, that is,

TABLE 29.16 An overview of techniques used as a counter measure to EMI

Effect	Frequency range (f)	Counter measure	
		At source	At load
Mains	$\leq$100 Hz	• Avoid circulating currents	• Balanced signal circuits • Avoid earth loops in signal paths • Screening (electric field only)
Mains harmonics	$100 < f \leq 2.5$ kHz	• Line and/or DC link reactor on rectifiers. • Higher pulse number rectifier (e.g., 12, 18, or 24) • Low impedance supply • Harmonic filters	• Balanced signal circuits • Avoid earth loops in signal paths • Filtering
Intermediate	$2.5 < f \leq 150$ kHz	• Filters	• Filtering • Screening • Balanced signal circuits
Low frequency	150 kHz $< f \leq$ 30 MHz	• Filters—one per apparatus • Cable screening	• Filtering • Screening
High frequency	30 MHz $< f \leq$ 1 GHz	• Screening • Internal filtering	• Screening

if rise time is increased beyond critical value of cable length.
- Harmful connection if cable length is too long; the reactor may have negligible effect on peak voltage (theoretically, its presence is insignificant in this case) or ringing period, but it will increase the duration of each overshoot, thus increasing the probability of partial discharge.

Adding a series line reactor between the motor and inverter is not as simple as illustrated above because the reactor adds or adjusts other resonant modes where the reactor rings with lumped capacitance. These resonant modes are pure transmission line modes and can double voltage. Some line inductance helps short-circuit protection. If earth current is limited by other means, then the coupled reactors may be helpful.

29.6.7.2 Sine-Wave Filter

This mechanism filters the PWM carrier frequency; thus, the converter output voltages are sinusoidal. This type of filter is best suited for low-performance drives and/or retrofit applications (old or standard motors). Ref. [13] and Table 29.17 illustrate the filtering options for high-power VSDs.

Employing a filter at the inverter output has some practical consequences:

- Cost and weight of filter
- Filter power losses and voltage drop
- A small derating of power switches due to circulating current between filter L, C, and DC link capacitor
- Reduced torque response due to time delay in the filter, sine-wave type
- Potential oscillations that have to be electronically dampened
- Potential induction motor self-excitation

29.6.7.3 PWM (dV/dt) Filter

This reduces the dV/dt seen by the motor to a level, which does not compromise the motor or EMC. It is ideal for high-performance drives with custom-built motors.

29.6.7.4 RC Filter at Motor Terminals

A simple RC network is used at the motor terminal; the capacitor would represent a short circuit for the high-frequency components (sharp dV/dt). Wave reflection will not happen if the resistor value is similar to the cable characteristic impedance. Resistor losses are generally small, as current flow will only occur at the rising and falling edges of the PWM waveform.

29.6.7.5 Common Mode Reactor

The presence of capacitive current due to the high dV/dt can be improved by employing a common-mode reactor. It is well established that such a choke is not effective to reduce the RMS and mean values of the leakage current but only effective to reduce the peak value. The presence of such a choke in the circuit increases the inductance and resistance of the zero sequence impedance.

29.6.8 Supply Front-End for PWM-VSI Drives

There are many types of PWM voltage-source drive depending on the supply front-end type and regenerative technique employed (Table 29.18):

(i) PWM-VSI with a diode supply front end
(ii) As above but with a dynamic brake chopper
(iii) Fully controlled thyristor front end
(iv) As above but with a dynamic brake chopper
(v) Fully controlled antiparallel thyristor supply bridge
(vi) PWM supply front end

TABLE 29.17 Filtering options for PWM-VSI drives (Ref. [13])

Option	No filter	*dV/dt* filter	Sine-wave filter
Motor *dV/dt*	High	Acceptable	Low
Motor insulation	Must be increased	Normal	Normal
EMC ground noise	Very high	Low	Very low
PWM carrier at motor	100%	100%	Very low
Motor audible noise	Higher	Decreased a little	Minimum
Motor derating	Approx. 13%	Approx. 3%	0%
Torque response	Fast	Fast	Suits most applications
Motor cost	Typically +10% cost	Normally no extra cost	No extra cost
Conclusions	Impractical	Suitable only for high dynamic torque response	Best choice for most drives

The use of a higher pulse number than 6-pulse would necessitate the use of a supply transformer. This is always considered to be an unnecessary "evil" because of additional cost, losses, and the need for extra space to accommodate this component. For MV applications, this is considered to be a necessity for isolation and protection.

29.6.8.1 Regenerative Braking

Several techniques are usually used for regenerative braking.

A simple diode front-end supply bridge will operate in two quadrants (positive and negative speeds). There is no regenerative power capability as any regeneration of power would result in an increase in the DC link voltage, and the drive will trip on overvoltage.

If a small amount of regeneration is required, during stopping, or speed reversal, then a dynamic brake chopper may be used. This is a simple chopper with a dynamic brake resistor. The size of the resistor is very much dependent on the regenerative brake energy, its magnitude, and repetition rate.

Full power regeneration is possible by employing a fully controlled antiparallel thyristor front end. This is similar to that used on DC drives or cycloconverters.

A more modern approach is to use pulse converter front end (fully controlled bridge). This is a four-quadrant converter with the ability to control the power factor and the DC link. Such an option necessitates the use of a precharge circuit for the DC link and smoothing inductance on the AC side.

For fully regenerative drives, the supply needs to be receptive.

By using a PWM rectifier as a primary converter in this composite structure, both the problems of regeneration and line current distortion are successfully solved—with the penalty of having a much more complicated converter structure and control system.

With the modern PWM-VSI VSD controller, the supply bridge can be fully controlled. Such an option offers the following benefits:

- Fully regenerative drive
- Unity power factor all time
- Sine-wave input voltage and current
- Can operate with controlled power factor (e.g., leading power factor)

TABLE 29.18 Types of supply front-end bridges of PWM-VSI drives

Type	Power device	Motor speed reversal	Regenerative capability	Regenerative with AC supply loss	Comment
I	Diode	Yes	No	No	• Good power factor across speed range • Needs precharge circuit • The lack of protection
II	Diode	Yes	Dissipative	Yes	• Ditto
III	SCR	Yes	No	No	• Power factor is function of speed • Fully controlled DC link • Phase back when (a) supply voltage rises, (b) fault on DC bus side • Needs gate drivers for SCRs
IV	SCR	Yes	Dissipative	Yes	• Ditto
V	SCR	Yes	Regenerative into supply	No	• Ditto
VI	Forced commutated devices (e.g., IGBT/IGCT)	Yes	Regenerative into supply	No	• Can operate with controlled power factor (unity, lagging, leading) • High-frequency harmonics • DC link voltage higher than the crest of the supply voltage • Fully controlled DC link, even during a supply dip • Output voltage equals to input voltage • Requires a precharge circuit

- Can operate as an active filter while supplying power to the load. Possible elimination of low-order supply harmonics (fifth and seventh)
- Output voltage equals the input voltage

29.7 Applications

29.7.1 VSD Applications

Table 29.19 summarizes main industries and applications.

Present solution of drives and electric drive application examples from various industries have been described in this section.

29.7.2 Applications by Industry

29.7.2.1 Deep Mining

Ref. [14] lists various high-power MV VSI inverter drive applications for the mining industry. In deep mine conveyor belt applications, a PWM-VSI drive offers significant advantages over other conventional alternatives. The following benefits have been identified for deep mine conveyor belts applications:

- Improved drive starting and stopping
- Improved reliability
- Matching belt speed to production
- Easier belt inspection
- Reduced belt wear and increased belt life
- Lower specification belt material may be used
- Low speed running to reduce coal removal by windage
- Manpower saving—less coal spillage
- Unity power factor with low harmonic content
- Reduced AC supplies disturbances

For hoist applications, the PWM-VSI drives can also be used to replace DC and cycloconverter drives for mine hoist applications. The benefits are the following:

- Improved drive control, with 100% continuous stall torque available with induction motors
- Reduced AC supplies disturbances
- Very unlikely to need reactive MVAR correction even at high ratings
- Improved immunity to AC supplies dips

The use of electrically coupled mine hoist systems has many advantages especially for deep mines and set to become an essential feature of many new mine shaft systems. The circuit is shown in Fig. 29.8.

The power flows naturally from motor 1 to motor 2 such that at the point of balance, the AC supply current is virtually zero and at near-unity power factor.

This technology is the natural successor to the DC electrically coupled winders and totally solves the poor AC power factor that would result if twin drive cyclo motors were used.

29.7.2.2 Industrial Processes

In this industry, there are a number of viable drive solutions available for the major market power ranges, from LCIs to FCI. However, there is a developing market for MV variable speed drives. The PWM-VSI using new high-power IGBTs or IGCTs appears to be the best solution for the future. Benefits include better power factor, no limit on frequency, and higher voltages.

PWM-VSI converter cost is likely to be higher than equivalent other well-established technologies (e.g., LCI). Hence, the

TABLE 29.19 Application analysis of VSDs

Industry	Current drive topology	Preferences	Applications
Power generation	Direct on line (DOL) Soft start CSI3	• 6.6–11 kV	Boiler feed pump, start-up converter, coal mills
Petrochemical	LCI DOL CSI3	• Air-cooled, stand-alone • Induction motors up to 10 MW • Synchronous above 10 MW	Petrochemical and derivatives, gas liquefaction, pipelines and storage, oil on/offshore and pipelines
Mining	Cycloconverters	• Low maintenance • Reliability • Low power supply distortion	Mine winders, conveyor belts, coal mills, ventilation fans, underground machinery
Stand-alone and process industries		• Low cost • Efficiency • Ease of repair and maintenance	Water and sewage pumps, wind mills, material handling (extruders), test benches, paper and plastic machines
Metals	Mill drives—cycloconverters	• Air-cooled • High dynamic performance • Low maintenance motor	Hot mills, medium section mills, finishing section mills, cold mills
Marine	LCI cycloconverters	• Small size • Low maintenance • Water-cooled	Warships, drilling vessels (mono hulls), chemical tankers, shuttle tankers, cruise liners, icebreakers, semisubmersibles, fishing vessels, cable layers, floating exploration rigs, ferries, research vessels, container vessels

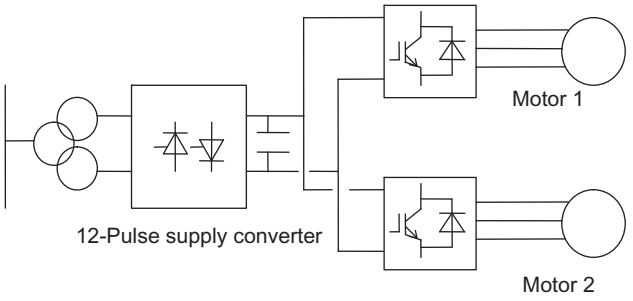

FIGURE 29.8 PWM-VSI electrically coupled mine hoist drive.

flexibility in choice of motors and improved control must be exploited. The advantage of offering an MV solution may prove significant. Possible means of reducing motor costs are the following:

1. Higher frequencies are achievable, allowing the use of high-speed motors and gearboxes.
2. Higher pole number machines can be used, giving a cost saving.
3. Better power factor over the speed range giving power supply saving.
4. Induction motors with rotors adapted for use with VSDs can be used with resultant cost savings over standard DOL, fixed speed motors.
5. Higher voltages and smaller conductors.
6. However, at low powers, the relative cost of the machines is less significant versus the cost of the converters. Hence, the viability of this technology in this market requires close examination.

The cycloconverter drive with a synchronous motor is used when four-quadrant operation is required. Particularly for high power rating with high torque at low speed and at standstill but with a rather low maximum speed are drive requirements. Gearless cement mill drives were the first applications of cycloconverters. The mill tube is driven from low-speed wraparound motor with a high number of poles.

29.7.2.3 Metal Industry

The majority of installed hot mill drives are cycloconverters. A few LCI drives have been used, but applications are limited for such technology on mill main drives. Most early-generation plants are equipped with DC drives. The trend is to replace DC with AC.

Direct current drive applications were universally used in the first generation of rolling mills. The market for new mills requiring this technology is declining as the steel industry moves to AC as a preference. On early-generation mills where motors are retained, DC drives are likely to be required. Customers in their inquiries, some requesting AC alternatives, are still requesting DC drive solutions.

DC drives are probably still the most economic for the power range of 750–1500 kW. The number of manufacturers however, producing DC motors, is declining, particularly in the case of large DC motor manufacture. The lower price of DC solutions is offset by the advantage of the use of AC motors in AC solutions, making AC the more popular choice.

Current-source inverter LCI can be applied to roughing stands of rod and bar mills. Technical limitations include the risk of torque pulsation and a minimum drive output frequency of 8 Hz.

Cycloconverter is the solution most often used. However, it is relatively expensive compared with alternative technology. Major cost penalties arise from supply transformers, cabling, and bridge configuration. In some cases, active power supply compensation equipment may be required, taking the costs even higher. Cycloconverter solutions will still be cost-effective for medium-to-high power, low-speed, low-frequency (say below 21 Hz maximum operating frequency) applications. This would include hot reversing mills, with direct drive, for the primary rolling processes, albeit a declining application area, and possibly for direct-drive, low-speed, high-torque roller-table applications. Technical limitations include limited output frequency (typically 29 Hz for 12-pulse at 60 Hz supplies), which can necessitate the use of two-pole motors to reach application speeds.

The high-power PWM-VSI using new power devices (IGBT/IGCT) appears to be the best solution for the future. Benefits include better power factor, no limit on frequency, and higher voltages. Potentially, either the two-level or the multilevel solution will meet the market requirements.

In some applications, like coilers/uncoilers, the system is composed of several drives, which have different power cycles; when some drives are furnishing power, others are braking. A common DC bus system will allow that the energy fed from drives operating in the regenerative braking mode will be utilized by other drives connected to the same DC bus but operating in the motoring mode. The supply bridge, that is, rectifier, feeding the DC bus system will only be rated for the total system power.

The benefits of the DC bus systems include the following:

- Good operating power factor
- Low harmonics (lowest when using 12-pulse or 18-pulse front ends)
- Possibility of energy transfer on the common DC link solutions (reducing front-end converter and transformer sizes with attendant energy saving, possibility of using kinetic energy to allow controlled stopping)

29.7.2.4 Marine and Offshore

Drive powers are commonly in the range of 0.75–5.8 W for thrusters and 6–24 MW for propulsion. The evolution in the commercial market is toward powers from 1 to 10 MW for propulsion. Higher powers are required for naval applications with package drive efficiency better than 96%.

The PWM inverters at these powers would allow the use of induction machines, rather than the more expensive

synchronous alternatives required for LCI drive. This could give savings in the price of the motor.

Current source inverter (CSI) drive LCI is used for all applications except for icebreakers where cycloconverter drives are used. The PWM (voltage source) inverter using new force-commutated drive appears to be the best solution for the future. Benefits include better power factor, no limit on frequency, and higher voltages. Many icebreakers and some other ships are equipped with diesel-generator-fed cycloconverter synchronous motors with power ratings up to about 20 MW per unit.

29.7.3 Examples of Modern VSD Systems

29.7.3.1 Integrated Power System for All Electric Ship

This is a full-scale main propulsion drive for the US Navy [15]. It consists of a main propulsion 19 MW induction motor drive system. The power converter consists of three 6-pulse rectifier stages, three 6 kV DC links, and 15 IGBT-based H-bridges feeding a 15-phase induction motor (Fig. 29.9).

This drive demonstrates the potential of modern power electronics over more traditional solutions such as cycloconverter and LCI. The volumetric power density of the new converter is reported to be 905 kW/m^3, compared with 455 kW/m^3 for cyclo and 313 kW/m^3 for LCI.

29.7.3.2 Subsea Separation and Injection System

This is a full-scale pilot plant developed to increase recovery and improve the economics of offshore oil and gas fields. The system comprises several VSD units, typically 500 kW oil pump, 1 MW multiphase booster and 1–2.5 MW water injection drive unit, and such a system is called "SUBSIS" [16]. The main task for such a system is to separate the bulk water from the well stream and treat it either for discharge into the sea or reinjection into the reservoir.

This system employs subsea-based rotating machinery for pumping, boosting, and compression. The subsea electric power distribution system (SEPDIS) is an innovative and cost-effective subsea processing (Fig. 29.10). The pump motors are mounted in a pressurized vessel and positioned on the seabed. Ref. [16] identifies the benefits of subsea drives as follows:

- 3%–6% increase in oil and gas recovery
- Improved pipeline transportation conditions by removing water from the well stream
- Reduced environmental impact due to lower energy consumption and reduction in chemicals used to inhibit corrosion
- Reduced size and cost of new platforms
- Cost-effective development of marginal fuels through reuse of existing infrastructure

29.7.3.3 Shaft-Generator for Marine Application

During cruising at sea, up to 3.5 MW of electric power is extracted from the ship's main diesel engine/propeller shaft (90,000 hp per ship) via a salient pole shaft generator, which is fitted to the main propeller shaft. The converter output voltage (set at 60 Hz) is stepped up to 6.6 kV [17].

The converter is based on 24-pulse converter (LCI) technology, which is traditionally used as main ship propulsion. The shaft generator output frequency varied between 14 and 25.7 Hz; six-phase generator and the output stage are configured as 24-pulse, via a step-up transformer. At the output, a passive LC filter is employed, with a synchronous condenser started by a pony motor.

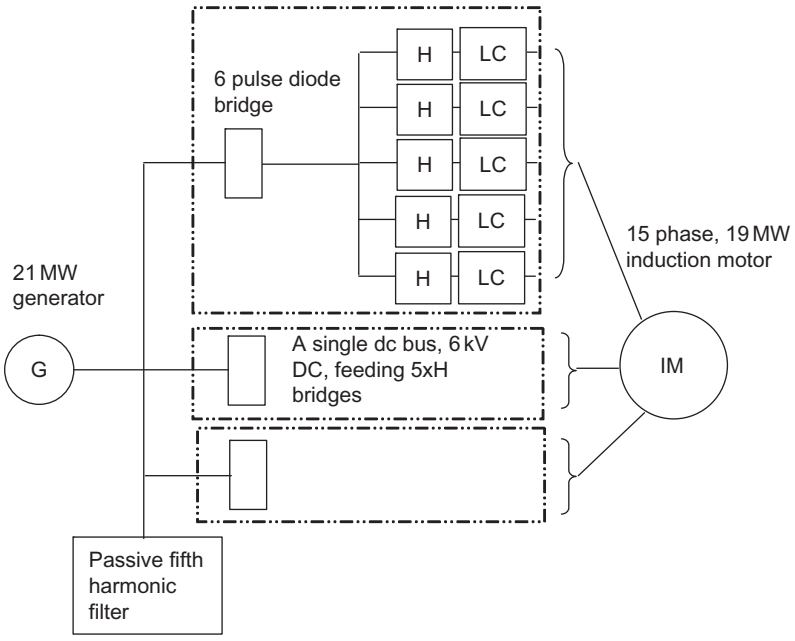

FIGURE 29.9 Schematic diagram of the IPS drive system [15].

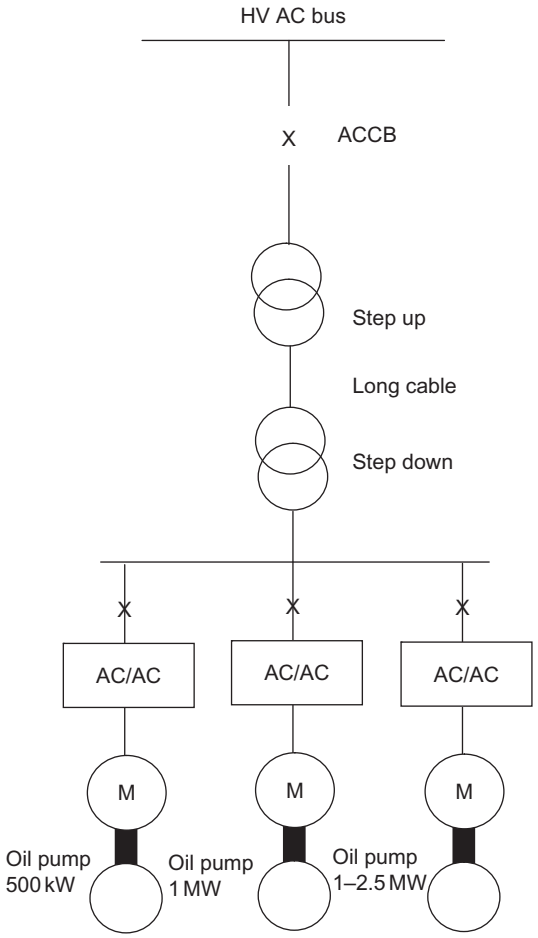

FIGURE 29.10 Schematic diagram of SEPDIS.

This type of application is likely to significantly benefit from the higher volumetric power density of the PWM-VSI with fully controlled front-end. Such a system will eliminate the need for a passive filter at the output stage and use a standard three-phase generator.

The same technology is also applicable to high-speed generators and windmill energy. The ability of the active front end to sustain fixed DC link voltage over a relatively wide shaft speed range results in a very good control of the output voltage, irrespective of the shaft speed.

In wind power plants, the optimal efficiency of the wind turbine depends on the speed when the wind conditions change. It is, therefore, advantageous to vary the speed of the generator and link it via a frequency converter to the AC system.

For high-speed generators, driven by diesel engine or gas turbine, the fully controlled converters enable direct power conversion from AC high frequency (hundreds of Hz) to fixed power frequency (50/60) Hz fixed output voltage. The magnitude of the output voltage is kept constant irrespective of speed variation of the generator (Fig. 29.11).

29.7.3.4 Linear Motor Drive for Roller Coaster

This drive involves a fully regenerative PWM-VSI. The supply front end is made of antiparallel thyristor front end, while the machine bridge is based on PWM IGBT VSI. "Superman" has been developed for Six Flags California at Magic Mountain. The inverter output frequency is 0–230 Hz and 525 V AC RMS. The power rating is 1.8 MW. The duty cycle is 1.8 MW for 7 s, followed by 16 s at zero power, and 1.3 MW for 5 s and a stop period of 32 s. This ride involves acceleration at 4.5 g, speed and free fall (6.5 s of weightlessness, during which a height of 415 ft is achieved [18]).

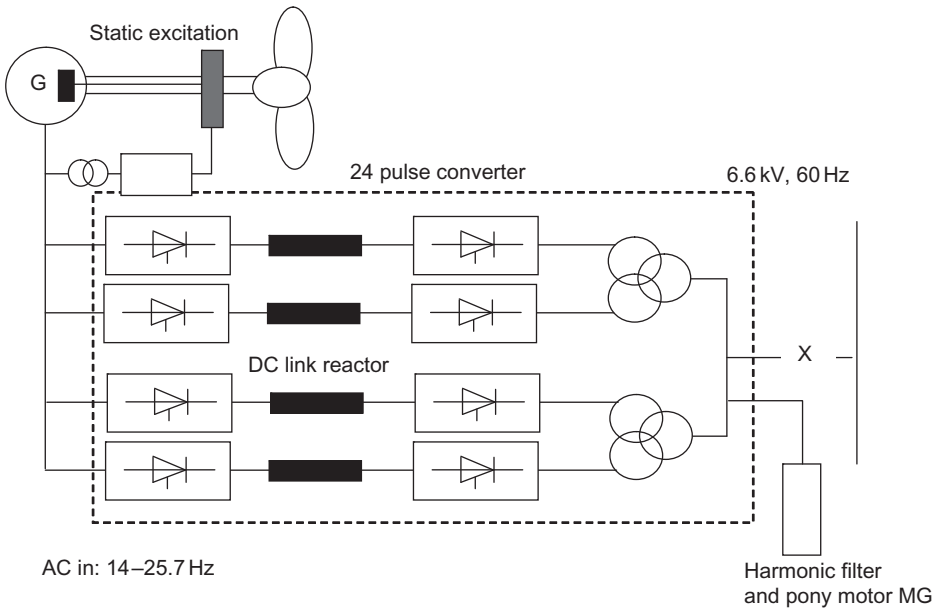

FIGURE 29.11 Schematic diagram of shaft generator.

The same concept employed in this application could be used for aeroplane launcher on aircraft carriers, instead of the conventional catapult.

29.8 Summary

The benefits of VSD are there to be quantified, and energy saving has been the prime reason for employing a VSD in standalone drive applications. Other benefits such as improved process control or increase life expectancy are often difficult to quantify in real terms.

There is a large selection of VSD systems to meet a wide range of applications. In the low and medium power, the induction motor and PWM-VSI are supreme. At higher power ratings, MV PWM-VSIs are gaining popularity, but LCI and cycloconverter drives would remain key technologies with very high power applications.

Modern drives are becoming more available at competitive prices with good reliability record. However, there are concerns with regard to the impact of fast switching on the motor and the environment.

To ensure successful implementation of a VSD system, both the supplier and end users need to work in partnership. Ideally, one competent supplier should supply the full drive package, with some after-sale service support. Understanding the nature of the load plays an important role in specifying the power rating of VSD correctly to meet performance requirements and required life expectancy.

New areas of VSD applications are emerging as the power electronics advances and become more reliable at affordable prices. Packaged drives up to several hundred kWs are becoming a commodity product, and end users do not need to involve a third party during specification, installation, and commissioning. Integrated motors are likely to increase their popularity, possibly with new types of power converters, for example, matrix.

30.1 Introduction

The widespread proliferation of power electronics and ancillary control circuits into motor control systems in the past several decades have led to a situation where motor drives, which process about two-thirds of the world's electric power into mechanical power, are on the threshold of processing all of this power via power electronics. The days of driving motors directly from the fixed ac or dc mains via mechanical adjustments are truly over. Table 30.1 indicates application areas where various types of power electronic converter-driven motor drives are routinely used.

The widespread incorporation of power, control, and signal electronics in motor drives has meant that processes can now be driven much more efficiently with a much greater degree of flexibility than previously possible. Of course, certain processes are more favorable to certain types of motors, because of the more favorable match between their characteristics. Historically, this situation was brought about by the demands of the industry. Increasingly, however, power electronic devices and control hardware are easily tailoring the rigid characteristics of the motor (when driven from a fixed dc or ac supply source) to the requirements of the load. Development of novel forms of machines and control techniques therefore has not abated, as recent trends would indicate.

It should be expected that just as power electronics equipment has tremendous variety, depending on the power level of the application, motors also come in many different types, depending on the requirements of application and power level. Often, the choice of a motor and its power electronic drive circuit for application is forced by these realities, and the application engineer therefore needs to have a good understanding of the application, the available motor types, and the suitable power electronic converter and its control techniques. Table 30.1 gives a rough guide of combinations of suitable motors and power electronic converters for a few typical applications.

For many years, the brushed dc motor had been the natural choice for applications requiring high dynamic performance. Drives of up to several hundred kilowatts have used this type of motor. In contrast, the induction motor was considered for low-performance, adjustable-speed applications at low and medium power levels. At very high power levels, the slip-ring induction motor or the synchronous motor drive was the natural choice. These boundaries are increasingly becoming blurred, especially at the lower power levels, especially for AC motor drives.

Another factor for motor drives was the consideration for servo performance. The ever-increasing demand for greater productivity or throughput and higher quality of most of the industrial products that we use in our everyday lives means that all aspects of dynamic response and accuracy of motor drives have to be increased. Issues of energy efficiency and harmonic proliferation into the supply grid are also increasingly affecting the choices for motor-drive circuitry.

A typical motor-drive system is expected to have some of the system blocks indicated in Fig. 30.1. The load may be a conveyor system, a traction system, the rolls of a mill drive, the cutting tool of a numerically controlled machine tool, the compressor of an air conditioner, a ship propulsion system, a control valve for a boiler, a robotic arm, and so on. The power electronic converter block may use diodes, metal oxide semiconductor field-effect transistors (MOSFETS), gate turnoff thyristors (GTOs), insulated gate bipolar transistors (IGBTs), or thyristors. The controllers may consist of several control loops, for regulating voltage, current, torque, flux, speed, position, tension, or other desirable conditions of the load. Each of these may have their limiting features purposely placed in order to protect the motor, the converter, or the load. The input

TABLE 30.1 Typical motor, converter, and application guides

Motor	Type of converter	Type of control	Applications
Brushed dc motor	Thyristor ac-dc converter	Phase control, with inner current loop	Process rolling mills, winders, locomotives, large cranes, extruders, and elevators
	GTO/IGBT/MOSFET chopper	Pulse-width modulator (PWM) control with inner current loop	Drives for transportation, machine tools, and office equipment
Induction motor (cage)	Back-back thyristor	Phase control	Pumps and compressors
	IGBT/GTO inverter/ cycloconverter	PWM *V-f* control	General-purpose industrial drive such as for cranes, pumps, fans, elevators, material transport and handling, extruders, and subway trains
	IGBT/GTO	Vector control	High-performance ac drives in transportation, motion control, and automation
Induction motor (slip ring)	Thyristor ac-dc converter	Phase control with dc-link current loop	Large pumps, fans, and cement kilns
Synchronous motor (excited)	Thyristor ac-dc converter	DC-link current loop	Large pumps, fans, blowers, compressors, and rolling mills
Synchronous motor (PM)	IGBT/MOSFET inverter	PWM current control	High-performance ac servo drives for office equipment, machine tools, automotive traction drives and motion control

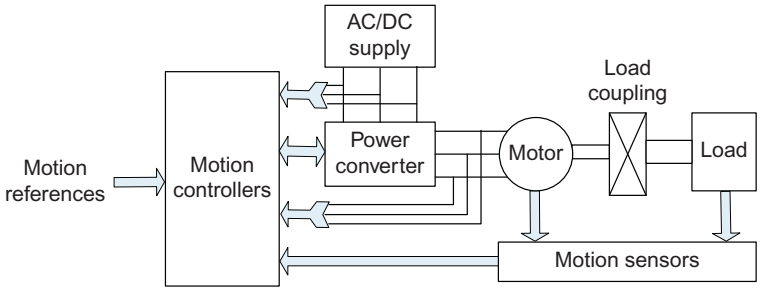

FIG. 30.1 Block diagram of a typical motor-drive system.

commands and the limiting values to these controllers would normally come from the supervisory control systems that produce the required references for a drive. This supervisory control system is normally more concerned with the overall operation of the process rather than the drive.

Consequently, a vast array of choices and technologies exist for a motor-drive application. Against this background, this chapter gives a brief description of the dominant forms of motor drives in current usage. The interested reader is expected to consult further reading material listed at the end of this chapter for more detailed coverage.

30.2 DC Motor Drives

30.2.1 Introduction

Direct-current motors are extensively used in variable-speed drives and position-control systems where good dynamic response and steady-state performance are required. Examples are in robotic drives, printers, machine tools, process rolling mills, paper and textile industries, and many others. Control of a dc motor, especially of the separately excited type, is very straightforward, mainly because of the incorporation of the commutator within the motor. The commutator brush allows the motor-developed torque to be proportional to the armature current if the field current is held constant. Classical control theories are then easily applied to the design of the torque and other motion loops of a drive system.

The mechanical commutator limits the maximum applicable voltage to about 1500 V and the maximum power capacity to a few hundred kilowatts. Series or parallel combinations of more than one motor are used, when dc motors are applied in applications that handle larger loads. The maximum armature current and its rate of change are also limited by the commutator.

30.2.2 DC Motor Representation and Characteristics

The dc motor has two separate sources of fluxes that interact to develop torque. These are the field and the armature circuits. Because of the commutator action, the developed torque is given by

$$T = Ki_f i_a \tag{30.1}$$

where i_f and i_a are the field and the armature currents, respectively, and K is a constant relating motor dimensions and parameters of the magnetic circuits.

The dynamic and the steady-state responses of the motor and load are given by

$$\text{Dynamic} \qquad \text{Steady} - \text{state}$$

$$v_a = R_a i_a + L_a \frac{di_a}{dt} + e \qquad V_a = R_a I_a + E \tag{30.2}$$

$$v_f = R_f i_f + L_f \frac{di_f}{dt} \qquad V_f = R_f I_f \tag{30.3}$$

$$e = Ki_f \omega \qquad E = KI_f \omega \tag{30.4}$$

$$T = J\frac{d\omega}{dt} + D\omega + T_L \qquad T = J\omega + T_L \tag{30.5}$$

where J, D and T_L are the moment of inertia, damping factor, and load torque, respectively, referred to the motor, and the subscripts a and f refer to the armature and field circuits, respectively. R, L, I, and E refer to resistance, inductance, current, and back emf of the motor in associated circuits referred by the subscripts.

Small servo-type dc motors normally have permanent-magnet (PM) excitation for the field, whereas larger size motors tend to have separate field supply, V_f, for excitation. The separately excited dc motors represented in Fig. 30.2A have fixed field excitation, and these motors are very easy to control via the armature current control, which are easily designed using classical linear control theory. Thyristor ac-dc converters with phase-angle control are popular for the larger size motors, whereas the duty-cycle-controlled pulse-width-modulated switching dc-dc converters are popular for servo-motor drives. The series-excited dc motor has its field circuit in series with the armature circuit as shown in Fig. 30.2B. Such a connection gives high torque at a low speed and low torque at a high

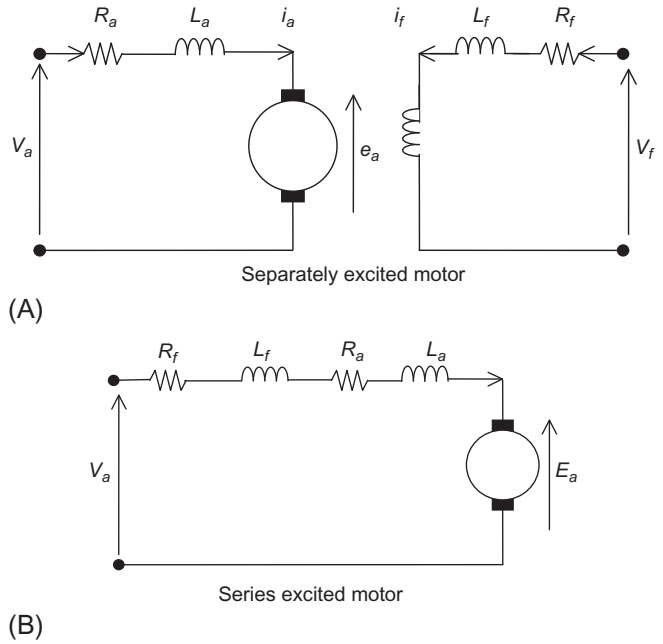

FIG. 30.2 Representation of the separately excited and series-excited motor circuits: (A) separately excited dc motor circuit and (B) series-excited dc motor circuit.

speed—a pseudo constant-power-like characteristic that may match traction-type loads well.

Torque-speed characteristics of the separately excited and series-excited dc motors are indicated in Fig. 30.3A and B, respectively. The speed of the separately excited dc motor drops with load, the net drop being about 5%–10% of the base speed at full load. The voltage drop across the armature resistance and the armature reaction are responsible for this. Operation of the motor above the base speed at which the armature voltage reaches for the rated field excitation is by means of field

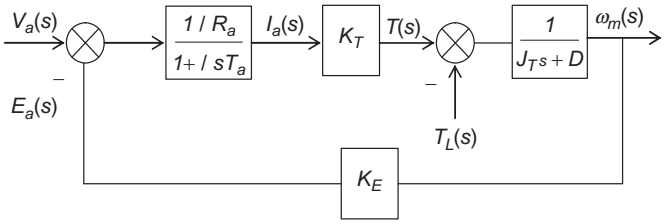

FIG. 30.4 Transfer characteristic block diagram of a separately excited motor.

weakening, whereby the field current is reduced in order to increase speed beyond the base speed. The armature voltage is now maintained at the rated value actively, by overriding the field control if required. Note that the range of field control is limited because of the magnetic nonlinearity of the field circuit and the problem of good commutation at weak field. Usually, the top speed is limited to about three times the base speed. Note also that field weakening results in reduced torque production per ampere of armature current. Depending on the type of load, the armature current, and speed change as dictated by Eqs. (30.1)–(30.5).

For the separately excited dc motor, assuming that the field excitation is held constant, the transfer characteristic between the shaft speed and the applied voltage to the armature can be expressed as indicated in the block diagram of Fig. 30.4. If we ignore the load torque T_L, the transfer characteristic is given by

$$\frac{\omega_m}{V_a} = \frac{K_T}{(sL_a + R_a)(Js + D) + K_E K_T} \tag{30.6}$$

the characteristic roots of which are given by

$$\left(s + \frac{1}{T_a}\right)\left(s + \frac{D}{J}\right) + \frac{1}{T_a T_m} = 0 \tag{30.7}$$

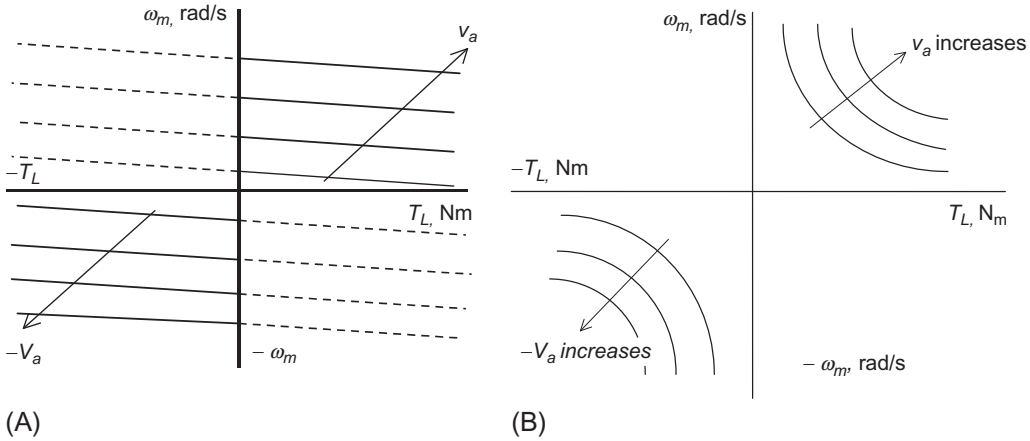

FIG. 30.3 Torque-speed characteristics of the (A) separately excited and (B) series-excited motors.

If we compare this with a standard second-order system, the undamped natural frequency and damping factor are given by

$$\omega_n = \sqrt{\frac{1}{T_a}\left(\frac{1}{T_m} + \frac{D}{J}\right)} \tag{30.8}$$

and

$$\sigma = \xi\omega_n = \frac{1}{2}\left[\frac{1}{T_a} + \frac{D}{J}\right] \tag{30.9}$$

where T_m = mechanical time constant = $\frac{R_a J}{K_E K_T}$ in which $K_E = Ki_f = K_T$ in SI units and T_a = electric time constant = $\frac{L_a}{R_a}$.

The speed response of the motor around an operating speed to the application of load torque on the shaft is given by

$$\frac{\Delta\omega_m}{\Delta T_L} = \frac{1 + sT_a}{(1 + sT_a)(Js + D) + \frac{K_E K_T}{R_a}} \tag{30.10}$$

30.2.3 Converters for DC Drives

Depending on the application requirements, the power converter for a dc motor may be chosen from a number of topologies. For example, a half-controlled thyristor converter or a single-quadrant pulse-width-modulated (PWM) switching converter may be adequate for a drive that does not require controlled deceleration with regenerative braking. On the other hand, a full four-quadrant thyristor or transistor converter for the armature circuit and a two-quadrant converter for the field circuit may be required for a high-performance drive with a wide speed range.

The frequency at which the power converter is switched, for example, 100 Hz for a single-phase thyristor bridge converter supplied from a 50 Hz ac source (or 300 Hz for a three-phase thyristor bridge converter), 20 kHz for a PWM MOSFET H-bridge converter, and so on, has a profound effect on the dynamics achievable with a motor drive. Low-power switching devices tend to have faster switching capability than high-power devices. This is convenient for low-power motors since these are normally required to be operated with high dynamic response and accuracy.

30.2.3.1 Thyristor Converter Drive

Consider the dc drive of Fig. 30.5 for which the armature supply voltage v_a to the motor is given by

$$v_a = \frac{2V_{\max}}{\pi}\cos\alpha \tag{30.11}$$

where V_{max} is the peak value of the line-line ac supply voltage to the converter and α is the firing angle. The dc output voltage v_a is controllable via the firing angle α, which in turn, is controlled by the control voltage e_c as the input to the firing control circuit (FCC). The FCC is synchronized with the mains ac supply and drives individual thyristors in the ac-dc converter according to the desired firing angle. Depending on the load and the speed of operation, the conduction of the current may become discontinuous as indicated in Fig. 30.6A. When this happens, the converter output voltage does not change with the control voltage as proportionately as with the continuous conduction. The motor speed now drops much more with the load as indicated by Fig. 30.6B. The consequent loss of gain of the converter may have to be avoided or compensated if good control over speed is desired.

The output voltage of the simple, two-pulse ac-dc converter of Fig. 30.5 is rich in ripples of frequency nf, where n is an even integer starting with two and f is the frequency of the ac supply. Such low-frequency ripple may derate the motor considerably. Converters with higher pulse number, such as the 6- or 12-pulse converters deliver much smoother output voltage and may be desirable for more demanding applications.

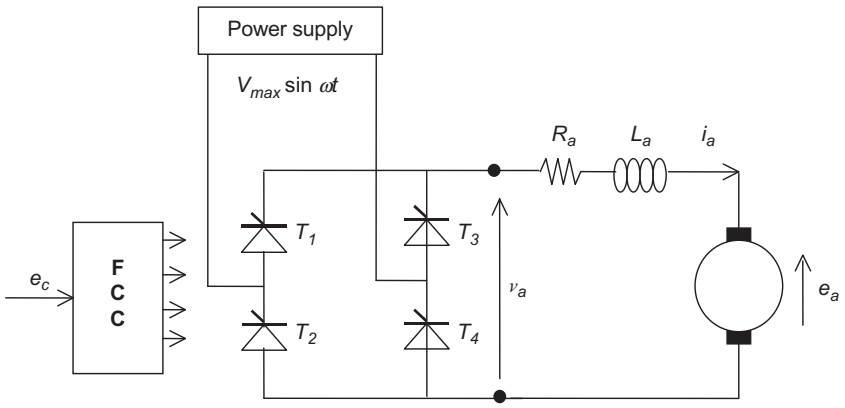

FIG. 30.5 A two-quadrant single-phase thyristor bridge converter drive.

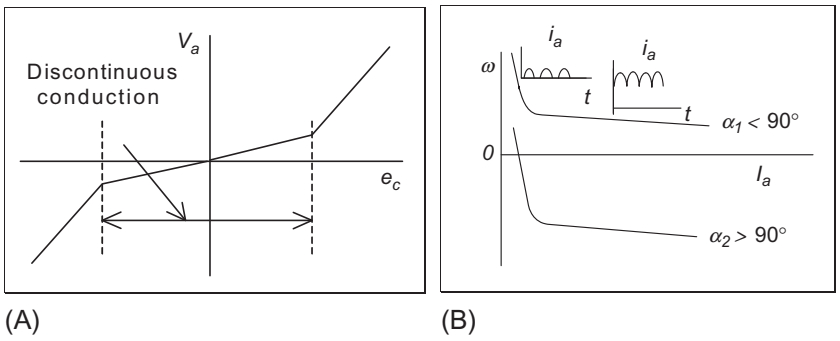

FIG. 30.6 Converter output voltage and motor torque-speed characteristic with discontinuous conduction.

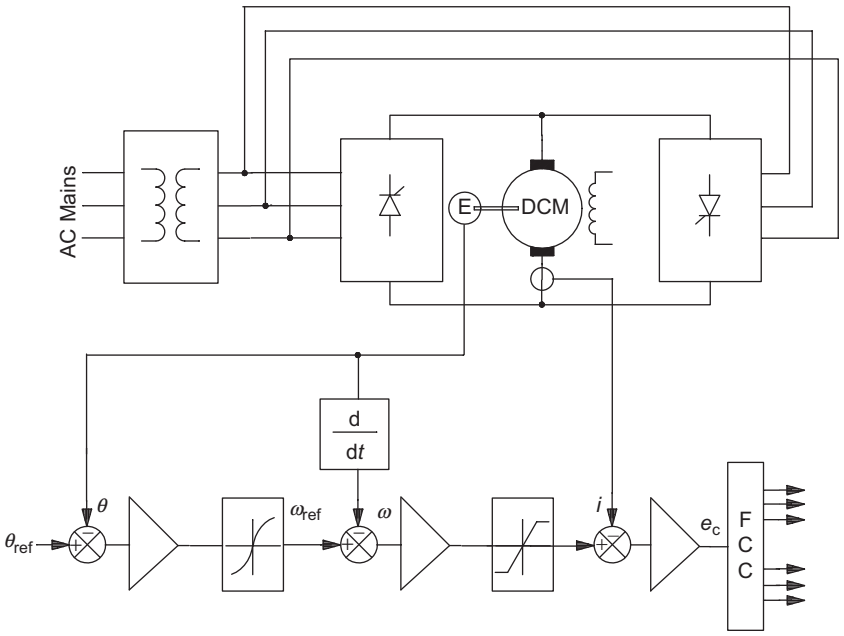

FIG. 30.7 Bidirectional speed- and position-control system with a back-to-back (dual) thyristor converter.

A high-performance dc drive for a rolling mill drive may consist of such converter circuits connected for bidirectional operation of the drive, as indicated in Fig. 30.7. The interfacing of the FCC to other motion-control loops, such as speed and position controllers, for the desired motion is also indicated

Two fully controlled bridge ac-dc converter circuits are used back-to-back from the same ac supply. One is for forward, and the other is for reverse driving of the motor. Since each is a two-quadrant converter, either may be used for regenerative braking of the motor. For this mode of operation, the braking converter, which operates in the inversion mode, sinks the motor current aided by the back emf of the motor. The energy of the overhauling decelerating motor now returns to the ac source.

It may be noted that the braking converter may be used to maintain the braking current at the maximum allowable level right down to zero speed. A complete acceleration-deceleration cycle of such a drive is indicated in Fig. 30.8. During braking, the firing angle is maintained at an appropriate value at all times so that the controlled and predictable deceleration takes place at all times.

The innermost control loop indicated in Fig. 30.7 is for torque, which translates to an armature current loop for a dc drive. Speed- and position-control loops are usually designed as hierarchical control loops. Operation of each loop is sufficiently decoupled from each other so that each stage can be designed in isolation and operated with its special limiting features.

30.2.3.2 PWM Switching Converter Drive

Pulse-width-modulated switching converters have traditionally been referred to as choppers in many traction and forklift-type drives. These are essentially PWM dc-dc converters operating from rectified dc or battery mains. These converters can also operate in one, two, or four quadrants, offering a few choices to meet application requirements. Servo-drive systems normally use the full four-quadrant converter of Fig. 30.9 that allows the bidirectional driving and regenerative braking capabilities.

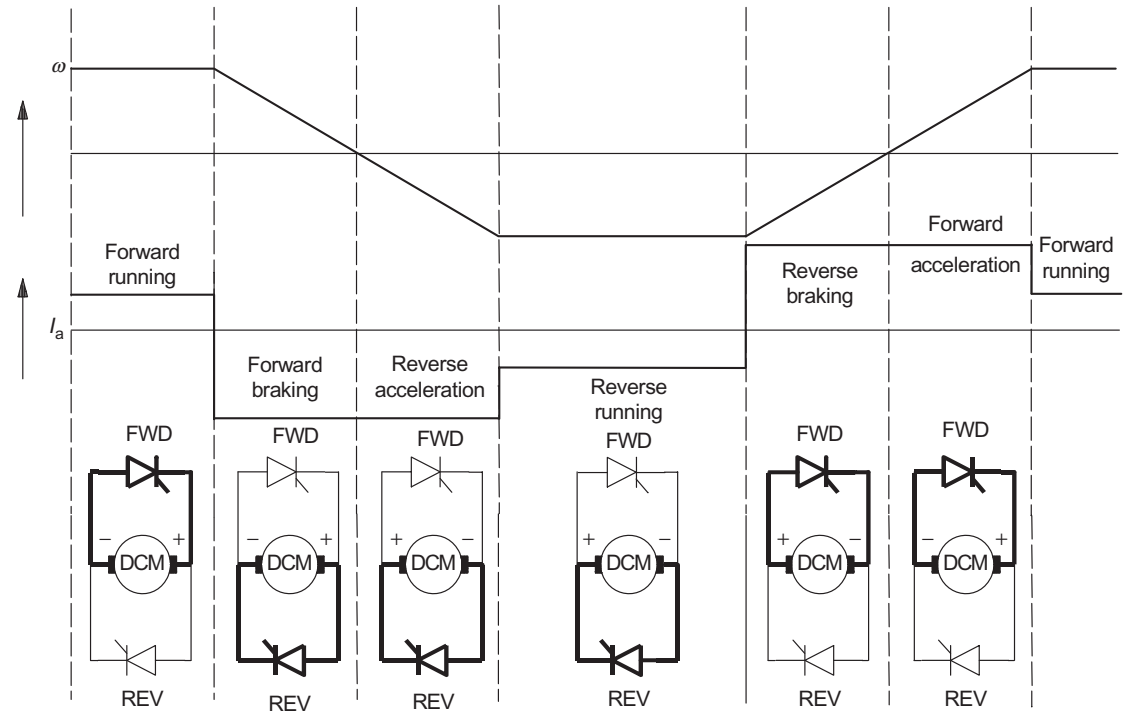

FIG. 30.8 Converter conduction and operating duty of a bidirectional drive.

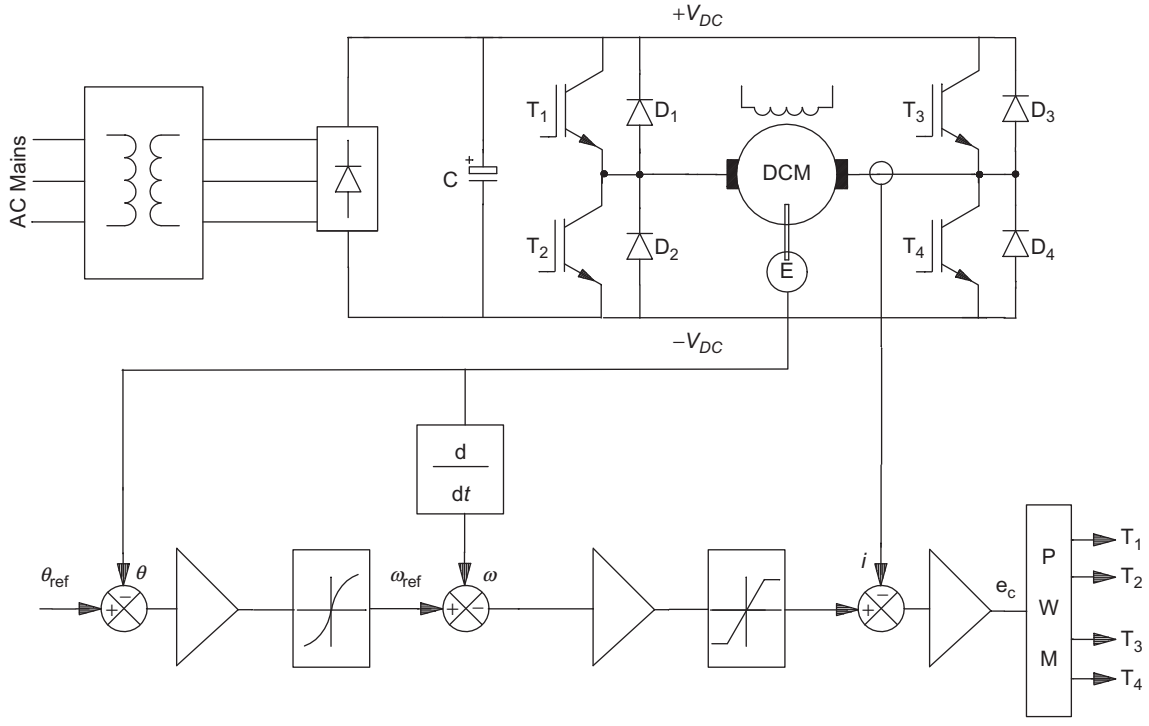

FIG. 30.9 Bidirectional speed- and position-control system with a PWM transistor bridge drive.

For forward driving, the transistors T_1 and T_4 and diode D_2 are used as a buck converter that supplies a variable voltage, v_a, to the armature given by

$$v_a = \delta V_{DC} \tag{30.12}$$

where V_{DC} is the dc supply voltage to the converter and δ is the duty cycle of the transistor T_1.

The duty cycle δ is defined as the duration of the ON-time of the modulating (switching transistor) as a fraction of the switching period. The switching frequency is normally dictated

by the application and the type of switching devices selected for the application.

During regenerative braking in the forward direction, transistors T_2 and diode D_4 are used as a boost converter that regulates the braking current through the motor by automatically adjusting the duty cycle of T_2. The energy of the overhauling motor now returns to the dc supply through the diode D_1, aided by the motor back emf and the dc supply. Again, note that the braking converter, comprising T_2 and D_1, may be used to maintain the regenerative braking current at the maximum allowable level right down to zero speed.

Fig. 30.10 shows a typical acceleration-deceleration cycle of such a drive under the action of the control loops indicated in Fig. 30.9.

Four-quadrant PWM converter drives such as that in Fig. 30.10 are widely used for motion-control equipment in the automation industry. Because of the significant development of power switching devices, switching frequencies of 10–20 kHz are easily attainable. At such frequencies, virtually, no derating of the motor is necessary.

In order to satisfy the requirements of a drive application, simpler versions of the drive circuits indicated in Figs. 30.7 and 30.9 may be used. For instance, for a unidirectional drive, half of the converter circuits indicated earlier may be used. Further simplification of the drive circuit is possible, if regenerative braking is not required.

30.2.4 Drive System Integration

A complete drive system has a torque controller (armature current controller for a dc drive) as its innermost loop, followed by a speed controller as indicated in Fig. 30.11.

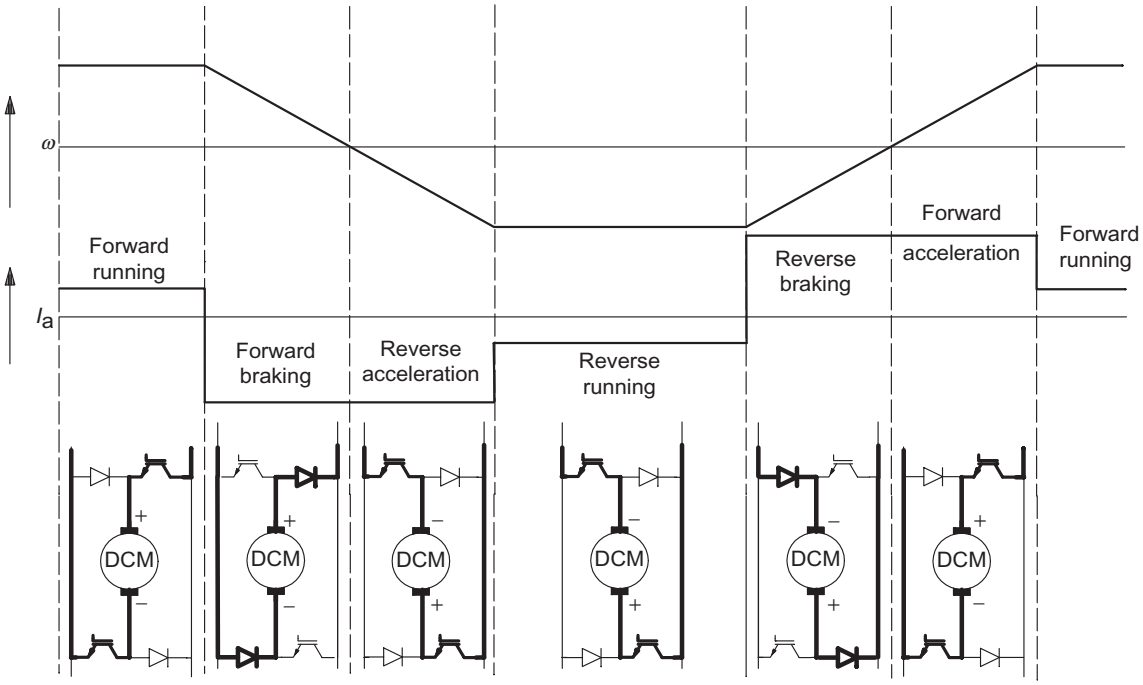

FIG. 30.10 Converter conduction and operating duty with a PWM bridge transistor drive.

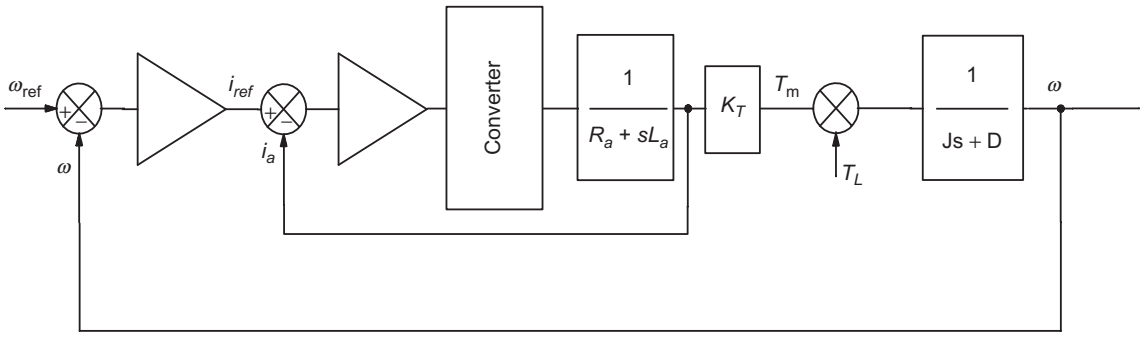

FIG. 30.11 Structure of a closed-loop speed-control system with a dc drive.

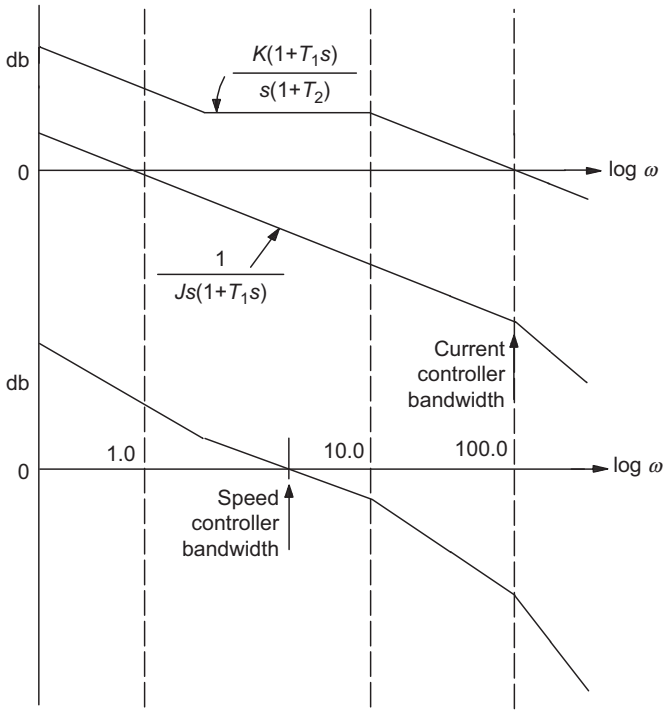

FIG. 30.12 Typical current and speed-control-loop designs for the system of Fig. 30.11.

The inner current loop is often regulated with a proportional-plus-integral (PI)-type controller of high gain. The rest of the inner loop consists of the converter, the motor armature, which is essentially an R-L circuit with the armature back emf as disturbance and the current sensor. The current sensor is typically an isolated circuit, such as a Hall sensor or a direct-current transformer (DCT). A well-designed torque (armature current) loop behaves essentially as a first-order lag system. Together with the mechanical inertia load, this loop can be indicated as the middle Bode plot of Fig. 30.12, in which $1/T_1$ represents the current-controlled system bandwidth. (Note that the damping factor D and the load torque T_L indicated in Fig. 30.11 have been neglected in this description for simplicity.) The current loop is normally designed by analyzing the block diagram of Fig. 30.11, the converter and the PI controller for the current loop using Bode analysis or other control system design tools.

The next step is usually the design of the speed controller. The 0 db intercept of $1/Js(1+T_is)$ is normally too low. Again, if a PI controller is selected for the speed loop, its Bode plot is superimposed on the current-controlled system as indicated in Fig. 30.12 to obtain the desired speed-control bandwidth.

30.2.5 Converter-DC Drive System Considerations

Several operational factors need to be considered in applying a dc drive. Some of the important ones are as follows:

1. The armature current may be rich in harmonics. This is particularly true for thyristor converters. The feedback of these current ripples into the FCC may cause overloading of individual switches and tripping. Adequate filtering is necessary to avoid such problems.
2. Since the converter is switched at regular intervals while the current controller operates continuously, current overshoot may occur because of the delay in the FCC. The current controller gains must be limited to limit this overshoot.
3. The switching frequency of the converter should be selected according to the desired motor-current ripple, supply input current harmonics, and the dynamic performance of the drive.
4. Ripple in the speed-sensor output limits the performance of the speed controller. Analog tachogenerator output is particularly noisy and defines the upper limit of the speed-control bandwidth. Digital speed sensors, such as encoders and resolvers, alleviate this limit significantly.

30.3 Induction Motor Drives

30.3.1 Introduction

The ac induction motor is by far the most widely used motor in the industry. Traditionally, it has been used in constant and variable-speed drive applications that do not cater for fast dynamic processes. Because of the recent development of several new control technologies, such as vector and direct torque controls, this situation is changing rapidly. The underlying reason for this is the fact that the cage induction motor is much cheaper and more rugged than its competitor, the dc motor, in such applications. This section starts with the induction motor drives that are based on the steady-state equivalent circuit of the motor, followed by vector-controlled drives that are based on its dynamic model.

30.3.2 Steady-State Representation

The traditional methods of variable-speed drives are based on the equivalent circuit representation of the motor referred to the stator, as shown in Fig. 30.13.

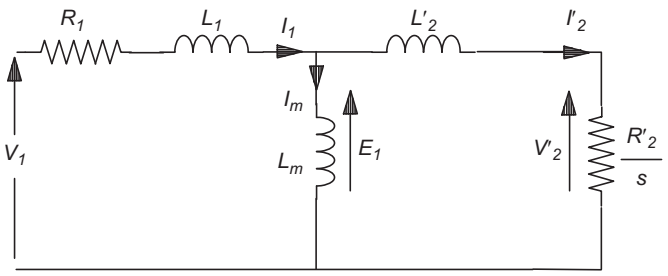

FIG. 30.13 Steady-state equivalent circuit of an induction motor.

From this representation, the following power relationships in terms of motor parameters and the rotor slip can be found:

$$\text{Power in the rotor circuit, } P_2 = 3I_2'^2\frac{R'_2}{s} = \frac{3sR'_2E_1^2}{R_2'^2+(s\omega_1L'_2)^2} \tag{30.13}$$

$$\text{Output power, } P_o = P_2 - 3I_2'^2R'_2 = (1-s)P_2 = \omega_0 T = \frac{(1-s)\omega_1}{p}T \tag{30.14}$$

where

$$\text{slip, } s = \frac{\omega_1-\omega_r}{\omega_1} = \frac{\omega_1 - p\omega_o}{\omega_1}$$
$$p = \text{number of polepairs}$$
$$\omega_o = \frac{2\pi N}{60}\text{ rad/s; } N \text{ is the rotor speed in rev/min,}$$
$$\omega_r = \text{rotor speed in electrical rad/s,} \tag{30.15}$$

and

$\omega_1 = 2\pi f_1$ rad/s (electrical), f_1 being the supply frequency.

$$\text{The developed torque, } T = \frac{P_2}{\omega_1/p}\text{Nm} \tag{30.16}$$

The slip frequency, sf_1, is the frequency of the rotor current and the air-gap voltage E_1 is given by

$$E_1 = \omega_1 L_m I_m = \omega_1 \lambda_m \tag{30.17}$$

where λ_m is the stator flux linkage due to the air-gap flux. If the stator impedance is negligible compared with E_1, which is true when f_1 is near the rated frequency f_o,

$$V_1 \approx E_1 = 2\pi f_1 \lambda_m \tag{30.18}$$

and

$$T = \frac{3p}{\omega_1}\frac{sR'_2V_1^2}{R_2'^2+(s\omega_1L'_2)^2} = \frac{3p}{\omega_1}\frac{sR'_2(2\pi f_1)^2\lambda_m^2}{R_2'^2+(s\omega_1L'_2)^2} \tag{30.19}$$

30.3.3 Characteristics and Methods of Control

The above analysis suggests several speed-control methods. The following are the widely used methods:

1. Stator voltage control
2. Slip power control
3. Variable-voltage, variable-frequency (*V-f*) control
4. Variable-current, variable-frequency (*I-f*) control

These methods are sometimes called *scalar controls* to distinguish them from *vector controls*, which are described in Section 30.3.4. The torque-speed characteristics of the motor differ significantly under different types of control, as will be evident in the following sections.

30.3.3.1 Stator Voltage Control

In this method of control, back-to-back thyristors are used to supply the motor with variable ac voltage, as indicated in the converter circuit diagram of Fig. 30.14A.

The analysis of Section 30.3.1 implies that the developed torque varies inversely as the square of the input root-mean-square (RMS) voltage to the motor, as indicated in Fig. 30.14B. This makes such a drive suitable for fan- and impeller-type loads for which the torque demand rises faster with speed. For other type of loads, the suitable speed range is very limited. Motors with high rotor resistance may offer an extended speed range. It should be noted that this type of drive with back-to-back thyristors with the firing-angle control suffers from poor power and harmonic distortion factors when operated at a low speed.

If unbalanced operation is acceptable, the thyristors in one or two supply lines to the motor may be bypassed. This offers the

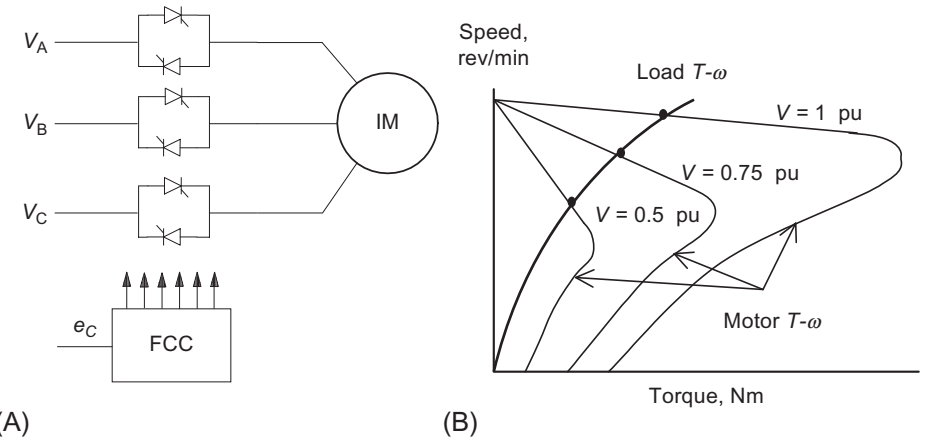

FIG. 30.14 (A) Stator voltage controller and (B) motor and load torque-speed characteristics under voltage control.

possibility of dynamic braking or plugging, desirable in some applications.

30.3.3.2 Slip Power Control

Variable-speed, three-phase, wound-rotor (or slip-ring) induction motor drives with slip power control may take several forms. In a passive scheme, the rotor power is rectified and dissipated in a liquid resistor or in a multitapped resistor that may be adjustable and forced cooled. In a more popular scheme, which is widely used in medium- to large-capacity pumping installations, the rectified rotor power is returned to the ac mains by a thyristor converter operating in a naturally commutated inversion mode. This static Scherbius scheme is indicated in Fig. 30.15. In this scheme, the rotor terminals are connected to a three-phase diode bridge that rectifies the rotor voltage. This rotor output is then inverted into mains frequency ac by a fully controlled thyristor converter operating from the same mains as the motor stator.

The converter in the rotor circuit handles only the rotor slip power, so that the cost of the power converter circuit can be much less than that of an equivalent inverter drive, albeit at the cost of the more expensive motor. The dc-link current, smoothed by a reactor, may be regulated by controlling the firing angle of the converter in order to maintain the developed torque at the level required by the load. The current controller (CC) and speed controller (SC) are also indicated in Fig. 30.15. The current controller output determines the converter firing angle α from the firing control circuit (FCC).

From the equivalent circuit of Fig. 30.13 and ignoring the stator impedance, the RMS voltage per phase in the rotor circuit is given by

$$V_R = \frac{V_s}{n}\frac{\omega_r}{\omega_s} = \frac{V_s}{n}\frac{s\omega_s}{\omega_s} = \frac{V_s s}{n} \tag{30.20}$$

where ω_s and ω_r are the angular frequencies of the voltages in the stator and rotor circuits, respectively, and n is the ratio of the equivalent stator to rotor turns. The dc-link voltage at the rectifier terminals of the rotor, v_d is given by

$$v_d = \frac{3\sqrt{6}V_R}{\pi}$$

Assuming that the transformer interposed between the inverter output and the ac supply has the same turns ratio n as the effective stator-to-rotor turns of the motor,

$$v_d = -\frac{3\sqrt{6}}{\pi}\frac{V_s}{n}\cos\alpha \tag{30.21}$$

The negative sign arises because the thyristor converter develops negative dc voltage in the inverter mode of operation. The dc-link inductor is mainly to ensure continuous current through the converter so that the expression (30.21) holds

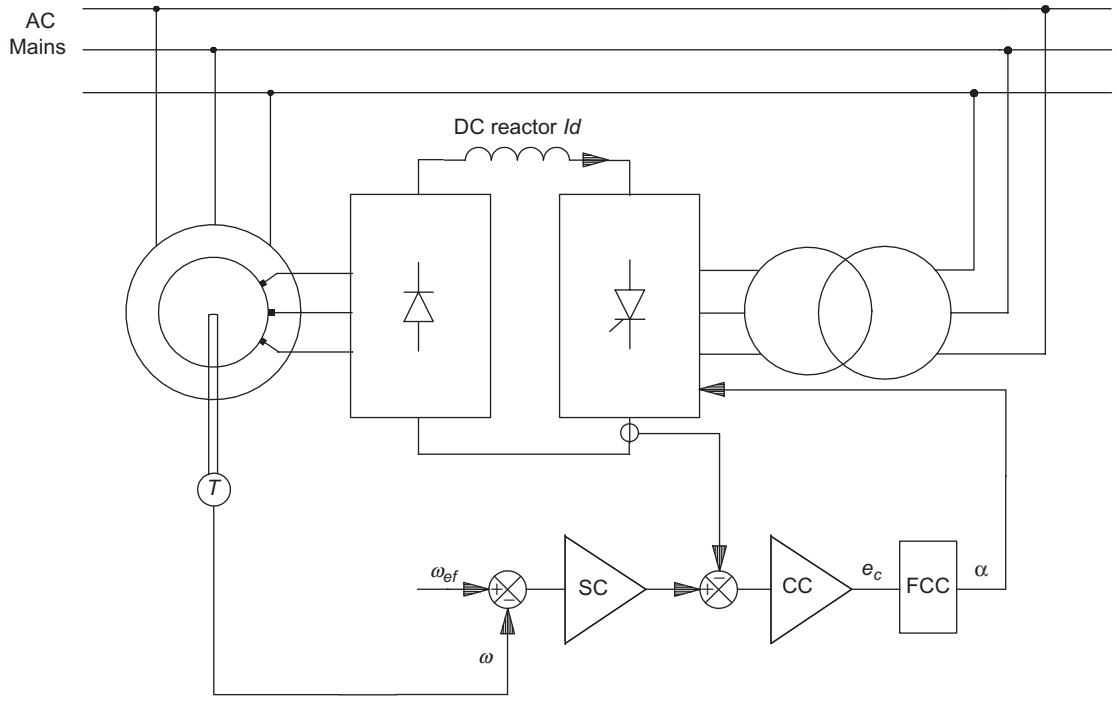

FIG. 30.15 The static Scherbius drive scheme of slip power control.

for all conditions of operation. Combining the preceding three equations gives

$$s\omega_s = -\omega_s \cos\alpha \text{ so that, } s = -n\cos\alpha$$

and the rotor speed

$$\omega_o = \frac{1}{p}(1-s)\omega_s = \frac{1}{p}\omega_s(1+n\cos\alpha) \text{ rad/s} \qquad (30.22)$$

Thus, the motor speed can be controlled by adjusting the firing angle α. By varying α between 180° and 90°, the speed of the motor can be varied from zero to full speed, respectively. For a motor with low rotor resistance and with the assumptions taken earlier, it can be shown that the developed torque of the motor is given by

$$T = 3p\frac{V_s}{\omega_s} i_d \approx 3p\lambda_m i_d \text{ Nm} \qquad (30.23)$$

where i_d is the dc-link current. Thus, the inner torque-control loop of a variable-speed drive using the Scherbius scheme normally employs a dc-link current loop as the innermost torque loop. Fig. 30.16 shows the transient responses of the dc-link, rotor, and stator currents of such a drive when the motor is accelerated between two speeds.

The drive is normally started with a short-time-rated liquid resistor, and the thyristor speed controller is started when the drive reaches a certain speed.

By replacing the diode rectifier of Fig. 30.16 with another thyristor bridge, power can be made to flow to and from the rotor circuit, allowing the motor to operate at higher than synchronous speed, as is used for grid-connected generator operation in wind power conversion. For very large drives, a cycloconverter may also be used in the rotor circuit with direct conversion of frequency between the ac supply and the rotor and driving the motor above and below synchronous speed.

30.3.3.3 Variable-Voltage, Variable-Frequency (V–f) Control

SPWM inverter drive

When an induction motor is driven from an ideal ac voltage source, its normal operating speed is less than 5% below the synchronous speed, which is determined by the ac source frequency and the number of motor poles. With a sinusoidally modulated (SPWM) inverter, indicated in Fig. 30.17, the supply frequency to the motor can be easily adjusted for variable speed. Eq. (30.18) implies that, if rated air-gap flux is to be maintained at its rated value at all speeds, the supply voltage V_1 to the motor should be varied in proportion to the frequency f_1, when the voltage drop across the stator resistance can considered to be negligible. The block diagram of Fig. 30.18A shows how the frequency f_1 and the output voltage V_1 of the SPWM inverter are proportionately adjusted with the speed reference. The speed reference signal is normally passed through a filter that only allows a gradual change in the frequency f_1. This type of control is widely referred to as the *V-f* inverter drive. Control of the stator input voltage V_1 as a function of the frequency f_1 is readily arranged within the inverter by modulating the switches $T_1 - T_6$. At a low speed, however, where the input voltage V_1 is low, most of the input voltage may drop across the stator impedance, leading to a reduction in air-gap flux and loss of torque.

Compensation for the stator resistance drop, as indicated in Fig. 30.18B, is often employed. However, if the motor becomes lightly loaded at a low speed, the air-gap flux may exceed the rated value, causing the motor to overheat.

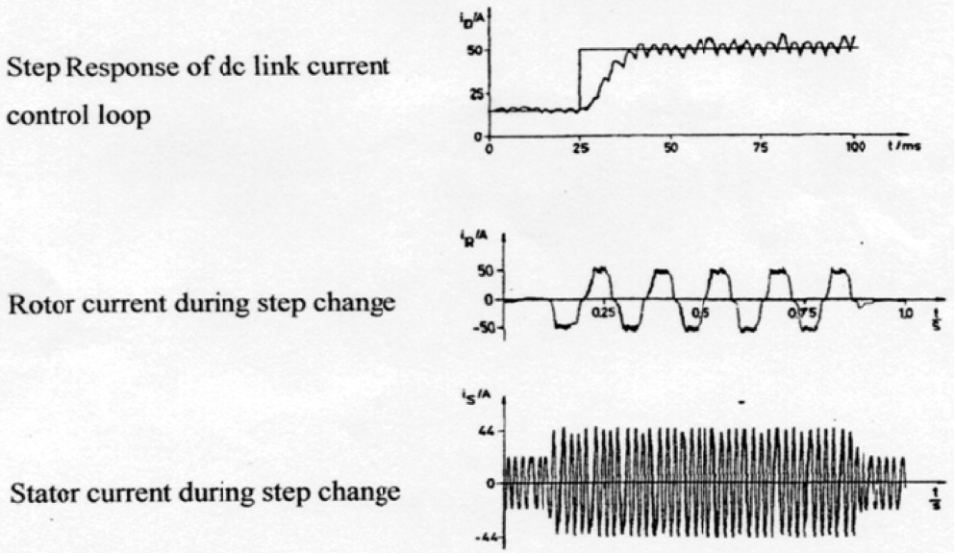

FIG. 30.16 Transient responses of a slip power-controlled drive under acceleration.

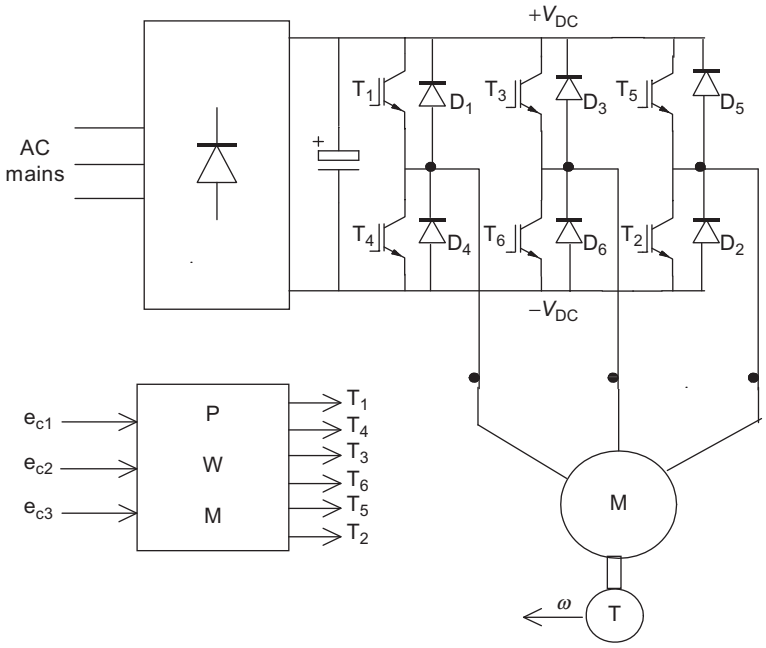

FIG. 30.17 *V-f* drive with SPWM inverter.

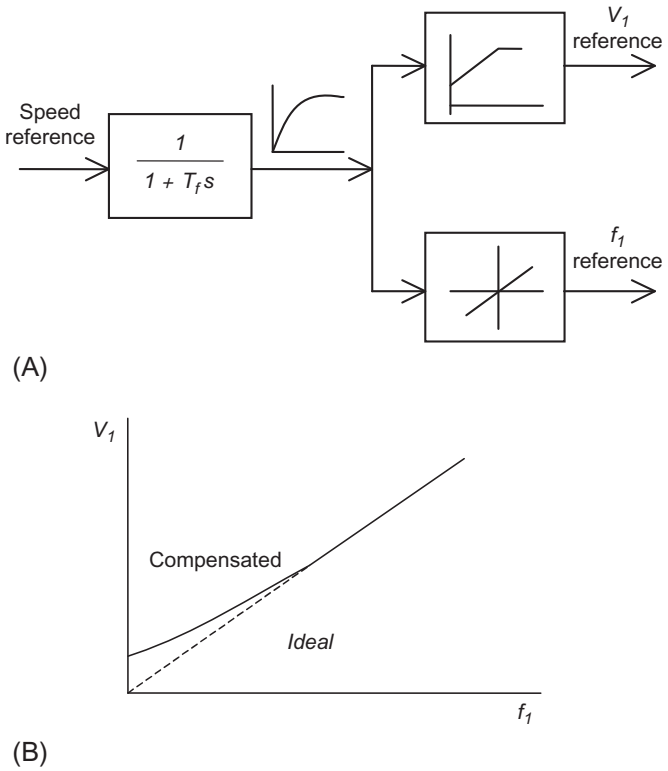

FIG. 30.18 (A) Input reference filter and voltage and frequency reference generation for the *V-f* inverter drive and (B) voltage compensation at a low speed.

From the equivalent circuit of Fig. 30.13 and neglecting the rotor leakage inductance, the developed torque T and the rotor current I'_2 are given by

$$I_2 = \frac{E_1 s\omega_1}{R'_2\omega_1} = \frac{\lambda_m}{R'_2} s\omega_1 A \tag{30.24}$$

and

$$T = 3p\frac{R'_2}{\omega_r} I'^2_2 Nm \tag{30.25}$$

where s ω_1 is the slip frequency, which is also the frequency of the voltages and currents in the rotor. Eq. (30.24) implies that by limiting the slip s, the rotor current can be limited, which in turn limits the developed torque Eq. (30.25). Consequently, a slip-limited drive is also a torque-limited drive. Note that this is true only in the steady state. A speed-control system with such a slip limiter is shown in Fig. 30.19. In this scheme, the motor speed is sensed and added to a limited speed error (or limited slip speed) to obtain the frequency (or speed reference for the V-f drive).

Many applications of the V-f controller, however, are open-loop schemes, in which any demanded variation in V_1 is passed through a ramp limiter (or filter) so that sudden changes in the slip speed ω_r are precluded, thereby allowing the motor to follow the change in the supply frequency without exceeding the rotor current and torque limits.

From the foregoing analyses, it is obvious that the V-f inverter drive essentially operates in all four quadrants, with rotor speed dropping slightly with the load and developing full torque at the same slip speed at all speeds. This assumes that the stator input voltage is properly compensated, so that the motor is operated with constant (or rated) air-gap flux at all speed. The motor can be operated above the base speed by keeping the input voltage V_1 constant, while increasing the stator frequency above base frequency in order to run the motor at speeds higher than the base speed. The air-gap flux and hence the maximum developed torque now fall with speed, leading to constant-power-type characteristic. Fig. 30.20 depicts the $T-\omega$ characteristics of such a voltage- and frequency-controlled drive for various operating frequencies. In this figure, the $T-\omega$ characteristic for base speed has been drawn in full, indicating the maximum developed torque T_{max} and the rated torque. Below base speed, the V_1-f_1 ratio is maintained to keep the air-gap flux constant. Above base speed, V_1 is kept constant, while f_1 increases with speed, thus weakening the air-gap flux. Forward driving in quadrant 1 takes place with the inverter output voltage sequence of $a-b-c$, whereas reverse driving in quadrant 3 takes place with the sequence $a-b-c$. Regenerative braking while forward driving takes place by adjusting the input frequency f_1 in such a way that

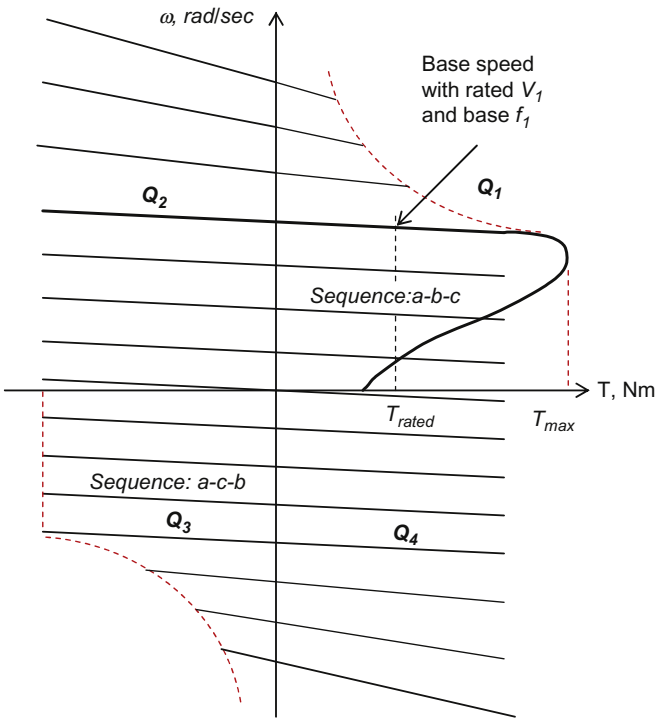

FIG. 30.20 Typical $T-\omega$ characteristics of V-f drive with the input frequency f_1 and voltage V_1 below and above base speed.

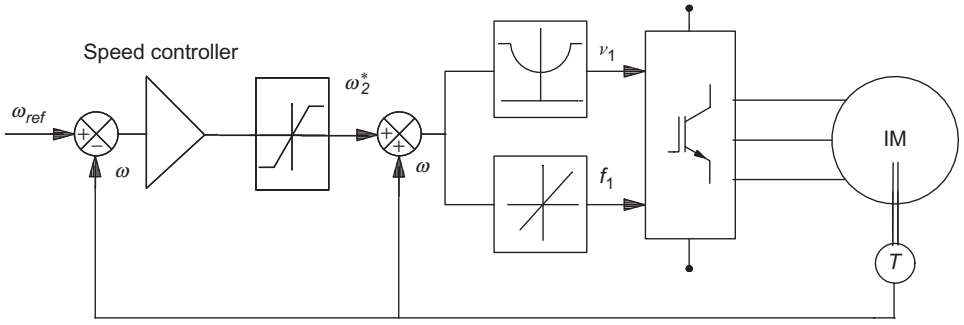

FIG. 30.19 Closed-loop speed controller with an inner slip loop.

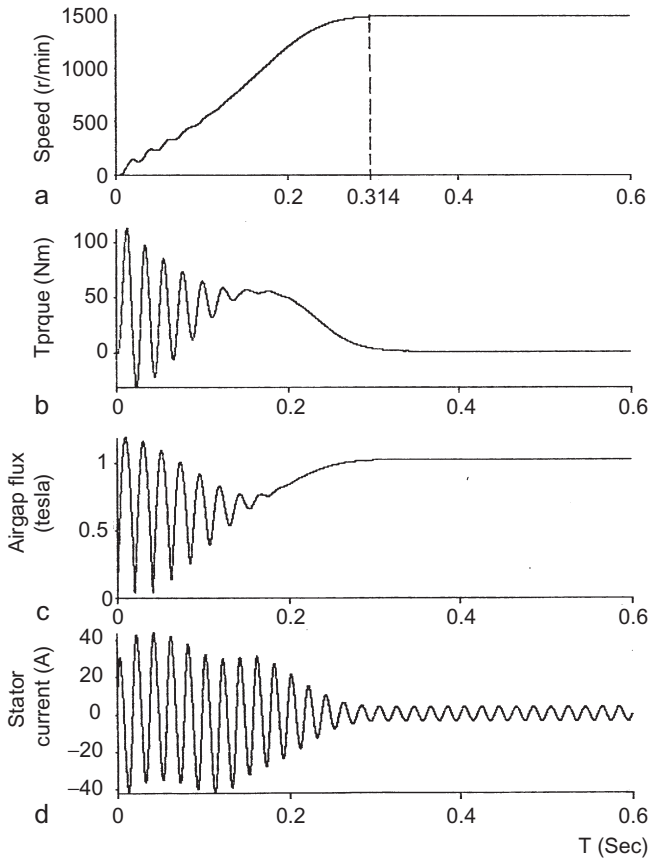

FIG. 30.21 Transient response of torque, speed, current, and air-gap flux during acceleration from standstill using a *V-f* inverter drive.

the motor operates in quadrant 2 (quadrant 4 for reverse braking) with the desired braking characteristic.

Note that the characteristics in Fig. 30.20 are based on the steady-state equivalent circuit model of the motor. Such a drive suffers from the poor torque response during transient operation because of time-dependent interactions between the stator and rotor fluxes. Fig. 30.21 indicates the machine air-gap flux during acceleration with *V-f* control obtained from a dynamic model. Clearly, the air-gap flux does not remain constant during the dynamic operation.

Cycloconverter drive

For large-capacity induction motor drives, the variable-frequency supply at variable voltage is effectively obtained from a cycloconverter in which a back-to-back thyristor converter pairs are used, one for each phase of the motor, as indicated in Fig. 30.22. Each thyristor block in this figure represents a fully controlled thyristor ac-dc converter. The maximum output frequency of such a converter can be as high as about 40% of the supply frequency. In view of the large number of thyristor switches required, cycloconverter drives are suitable for large-capacity but low-speed applications.

30.3.3.4 Variable Current–Variable Frequency (*I–f*) Control

In this scheme, medium- to large-capacity induction motors are driven from a variable but stiff current supply that may be obtained from a thyristor converter and a dc-link inductor as indicated in Fig. 30.23. The frequency of the current supply to the motor is adjusted by a thyristor converter with auxiliary diodes and capacitors. The diodes in each inverter leg and the capacitors across them are needed for turning off the thyristors when current is to be commutated from one to the next in sequence. The motor-current waveforms are normally six-step, or quasi-square, as indicated in Fig. 30.24. The switching states of the inverter thyristors are also indicated in this figure. The motor voltage waveforms are determined by the load. These waveforms are more nearly sinusoidal than the current waveforms.

The thyristor converter supplying the quasi-square current waveforms to the motor has firing-angle control, in order to regulate the dc-link current to the inverter. The dynamics of the dc-link current control is such that this current may be considered to be constant during the time the inverter switches commutate the dc-link current from one switch to the next.

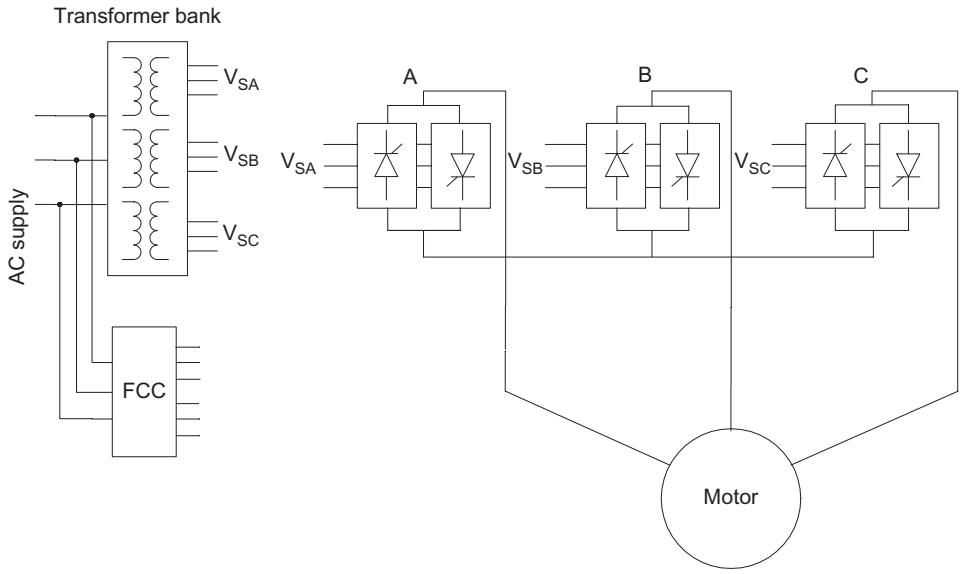

FIG. 30.22 *V-f* drive with cycloconverter drive.

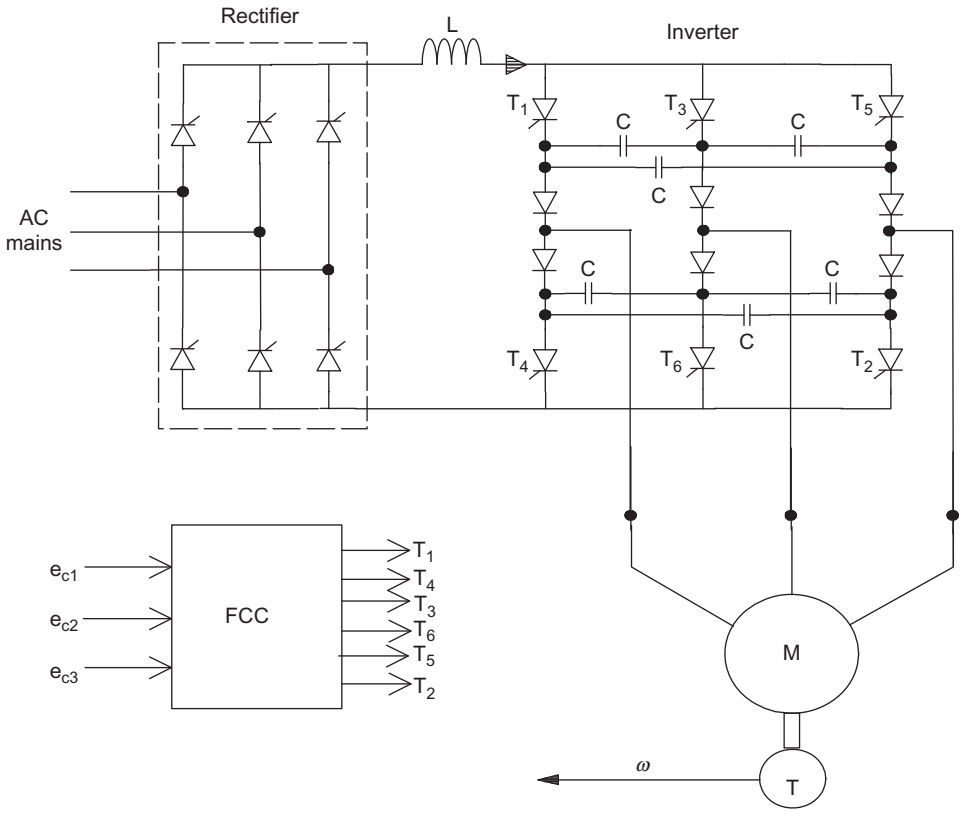

FIG. 30.23 DC-link current-source thyristor inverter drive.

Such a current-source drive offers four-quadrant operation, with independent control of the dc-link current and output frequency. One drawback is that the motor voltage waveforms have voltage spikes due to commutation.

From the analysis of Section 30.3.2, if the higher order harmonics of the current waveforms in Fig. 30.24 are neglected and it is assumed that the motor voltage and current waveforms are sinusoidal, the magnetizing current I_m in Fig. 30.13 can be kept constant (for constant air-gap flux operation) if the RMS value of the stator supply current I_1 is defined according to Eq. (30.26). This relationship is also shown in graphic form in Fig. 30.25.

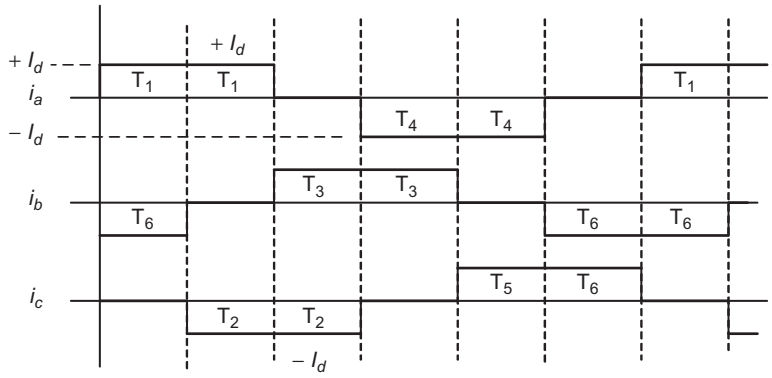

FIG. 30.24 Motor-current waveforms and the thyristor switching states for a current-source drive.

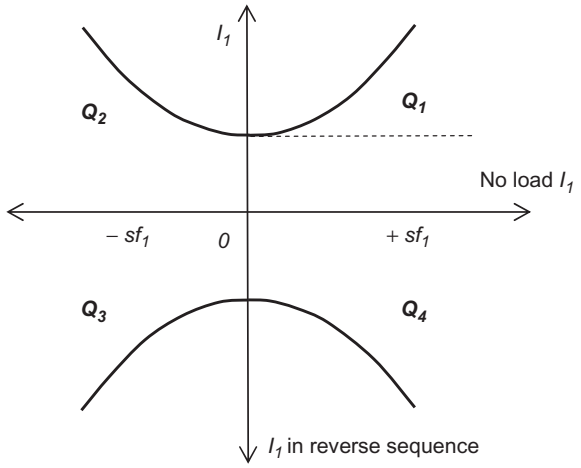

FIG. 30.25 Stator current versus rotor (slip) frequency for constant air-gap flux operation.

$$I_m = I_1 \left[\frac{R_2'^2 + \left(2\pi f_1 s L_2'\right)^2}{R_2'^2 + 2\pi f_1 \left(L_2' + L_m\right)^2} \right]^{1/2} = \text{constant} \qquad (30.26)$$

The control scheme for variable-speed operation with a current-source drive is indicated in the block diagram of Fig. 30.26. The speed reference defines the stator current reference according to Eq. (30.26), and the frequency reference is obtained by adding the rotor frequency to the actual speed of the motor. The inverter drive may consist of the thyristor current source and the inverter of Fig. 30.23 or a diode rectifier supplied SPWM transistor inverter of Fig. 30.17 with independent current regulators, one for each phase.

The dynamic performance of such current-controlled induction motor drives is not very satisfactory, just as for the voltage-source inverters. Furthermore, the current-source inverter drive cannot normally be operated open loop, like the *V-f* inverter drive. For high dynamic performance, vector-controlled drives are becoming popular.

30.3.4 Vector Controls

The foregoing scalar control methods are only suitable for adjustable-speed applications in which the load speed or position is not controlled like in a servo system. Instantaneous frequency control with a view to control motor speed or position cannot be defined, and therefore, instantaneous torque control cannot be addressed by scalar control methods. Vector control technique allows a squirrel-cage induction motor to be driven with high dynamic performance, comparable with that of a dc motor. In vector control, machine dynamic model rather than steady-state model (on which scalar controllers are based on) is used to design the controller. For this, the controller needs to know the rotor speed (in the indirect method) or the air-gap flux vector (in the direct method) accurately, using sensors.

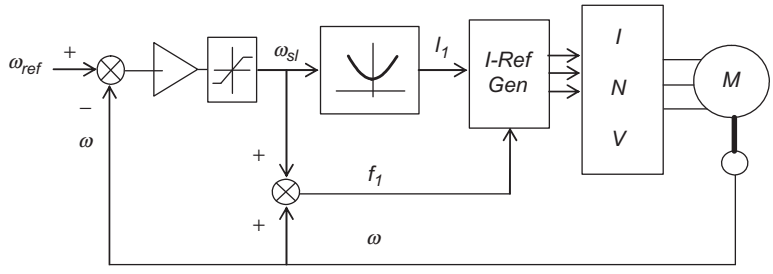

FIG. 30.26 Variable-current/variable-frequency inverter drive scheme.

The latter method is not practical because of the requirement of attaching air-gap flux sensors. The indirect method, which is being widely accepted in recent years, requires the controller to be matched with the motor being driven. This is because the controller also needs to know some rotor parameter(s), which may vary according to the conditions of operation, continuously.

30.3.4.1 Basic Principles

The methods of vector control are based on the dynamic equivalent circuit of the induction motor. There are at least three fluxes (rotor, air gap, and stator) and three currents or mmfs (stator, rotor, and magnetizing) in an induction motor. For high dynamic response, interactions among current, fluxes, and speed, must be taken into account in determining appropriate control strategies. These interactions are understood only via the dynamic model of the motor.

All fluxes rotate at synchronous speed. The three-phase currents create mmfs (stator and rotor) that also rotate at synchronous speed. Vector control aligns axes of an mmf and a flux orthogonally at all times. It is easier to align the stator current mmf orthogonally to the rotor flux.

Any three-phase sinusoidal set of quantities in the stator can be transformed to an orthogonal reference frame by

$$\begin{bmatrix} f_{\alpha s} \\ f_{\beta s} \\ f_o \end{bmatrix} = \frac{2}{3} \begin{bmatrix} \cos\theta & \cos\left(\theta - \frac{2\pi}{3}\right) & \cos\left(\theta - \frac{4\pi}{3}\right) \\ \sin\theta & \sin\left(\theta - \frac{2\pi}{3}\right) & \sin\left(\theta - \frac{4\pi}{3}\right) \\ \frac{1}{2} & \frac{1}{2} & \frac{1}{2} \end{bmatrix} \begin{bmatrix} f_{as} \\ f_{bs} \\ f_{cs} \end{bmatrix} \tag{30.27}$$

where θ is the angle of the orthogonal set $\alpha-\beta-0$ with respect to any arbitrary reference. If the $\alpha-\beta-0$ axes are stationary and the α-axis is aligned with the stator α-axis, then $\theta = 0$ at all times. Thus,

$$\begin{bmatrix} f_{\alpha s} \\ f_{\beta s} \\ f_{os} \end{bmatrix} = \frac{2}{3} \begin{bmatrix} 1 & -\frac{1}{2} & -\frac{1}{2} \\ 0 & \frac{\sqrt{3}}{2} & \frac{\sqrt{3}}{2} \\ \frac{1}{2} & \frac{1}{2} & \frac{1}{2} \end{bmatrix} \begin{bmatrix} f_{as} \\ f_{bs} \\ f_{cs} \end{bmatrix} \tag{30.28}$$

If the orthogonal set of reference rotates at the synchronous speed ω_1, its angular position at any instant is given by

$$\theta = \int_0^t \omega_1 t + \theta_o \tag{30.29}$$

The orthogonal set is then referred to as $d-q-0$ axes. The three-phase rotor variables, transformed to the synchronously rotating frame, are

$$\begin{bmatrix} f_{dr} \\ f_{qr} \\ f_o \end{bmatrix} = \frac{2}{3} \begin{bmatrix} \cos(\omega_e-\omega_r)t & \cos\left((\omega_e-\omega_r)t - \frac{2\pi}{3}\right) & \cos\left((\omega_e-\omega_r)t - \frac{4\pi}{3}\right) \\ \sin(\omega_e-\omega_r)t & \sin\left((\omega_e-\omega_r)t - \frac{2\pi}{3}\right) & \sin\left((\omega_e-\omega_r)t - \frac{4\pi}{3}\right) \\ \frac{1}{2} & \frac{1}{2} & \frac{1}{2} \end{bmatrix} \times \begin{bmatrix} f_{ar} \\ f_{br} \\ f_{cr} \end{bmatrix} \tag{30.30}$$

It should be noted that the difference $\omega_e - \omega_r$ is the relative speed between the synchronously rotating reference frame and the frame attached to the rotor. This difference is also the slip frequency, ω_{sl}, which is the frequency of the rotor variables. By applying these transformations, voltage equations of the motor in the synchronously rotating frame reduce to

$$\begin{bmatrix} v_{qs} \\ v_{ds} \\ v_{qr} \\ v_{dr} \end{bmatrix} = \begin{bmatrix} R_s + pL_s & \omega_e L_s & pL_m & \omega_e L_m \\ -\omega_e L_s & R_s + pL_s & -\omega_e L_m & pL_m \\ pL_m & (\omega_e-\omega_r)L_m & R_r + pL_r & (\omega_e-\omega_r)L_r \\ -(\omega_e-\omega_r) & pL_m & -(\omega_e-\omega_r)L_r & R_r + pL_r \end{bmatrix} \times \begin{bmatrix} i_{qs} \\ i_{ds} \\ i_{qr} \\ i_{dr} \end{bmatrix} \tag{30.31}$$

where the speed of the reference frame, ω_e, is equal to ω_1 and $L_s = L_{ls} + L_m$, $L_r = L_{lr} + L_m$.

Subscripts l and m stand for leakage and magnetizing, respectively, and p represents the differential operator d/dt, not the number of pole pairs. The equivalent circuits of the motor in this reference frame are indicated in Fig. 30.27A and B.

The stator flux linkage equations are

$$\lambda_{qs} = L_{ls} i_{qs} + L_m\left(i_{qs} + i_{qr}\right) = L_s i_{qs} + L_m i_{qr} \tag{30.32}$$

$$\lambda_{ds} = L_{ls} i_{ds} + L_m\left(i_{ds} + i_{dr}\right) = L_s i_{ds} + L_m i_{dr} \tag{30.33}$$

$$\hat{\lambda}_s = \sqrt{\left(\lambda_{qs}^2 + \lambda_{ds}^2\right)} \tag{30.34}$$

The rotor flux linkages are given by

$$\lambda_{qr} = L_{lr} i_{qr} + L_m\left(i_{qs} + i_{qr}\right) = L_r i_{qr} + L_m i_{qs} \tag{30.35}$$

$$\lambda_{dr} = L_{lr} i_{dr} + L_m\left(i_{ds} + i_{dr}\right) = L_r i_{dr} + L_m i_{ds} \tag{30.36}$$

$$\hat{\lambda}_r = \sqrt{\left(\lambda_{qr}^2 + \lambda_{dr}^2\right)} \tag{30.37}$$

The air-gap flux linkages are given by

$$\lambda_{mq} = L_m\left(i_{qs} + i_{qr}\right) \tag{30.38}$$

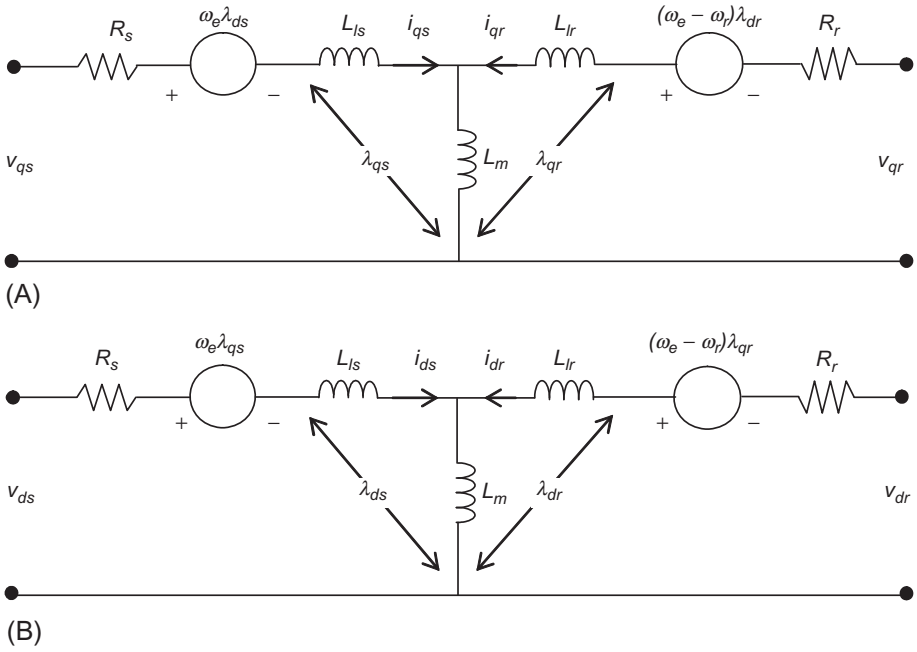

FIG. 30.27 Motor dynamic equivalent circuits in the synchronously rotating: (A) q- and (B) d-axes.

$$\lambda_{md} = L_m(i_{ds} + i_{dr}) \tag{30.39}$$

$$\hat{\lambda}_m = \sqrt{\left(\lambda_{mqs}^2 + \lambda_{mds}^2\right)} \tag{30.40}$$

The torque developed by the motor is given by

$$T = \frac{3p}{2}\left[\lambda_{ds} i_{qs} - \lambda_{qs} i_{ds}\right] \tag{30.41}$$

where p is the number of pole pairs.

From Eq. (30.31), the rotor voltage equations are

$$v_{qr} = 0 = L_m \frac{di_{qs}}{dt} + (\omega_e - \omega_r) L_m i_{ds} + \left(R_r i_r + L_r \frac{di_{qr}}{dt}\right) + (\omega_e - \omega_r) L_r i_d r \tag{30.42}$$

$$v_{dr} = 0 = L_m \frac{di_{ds}}{dt} + (\omega_e - \omega_r) L_m i_{qs} + \left(R_r i_r + L_r \frac{di_{dr}}{dt}\right) + (\omega_e - \omega_r) L_r i_{qr} \tag{30.43}$$

Using Eqs. (30.35) and (30.36),

$$\frac{d\lambda_{qr}}{dt} + R_r i_{qr} + (\omega_e - \omega_r)\lambda_{dr} = 0 \tag{30.44}$$

$$\text{and} \quad \frac{d\lambda_{dr}}{dt} + R_r i_{dr} + (\omega_e - \omega_r)\lambda_{qr} = 0 \tag{30.45}$$

Also from Eqs. (30.35) and (30.36),

$$i_{qr} = \frac{1}{L_r}\lambda_{qr} - \frac{L_m}{L_r} i_{qs} \tag{30.46}$$

$$i_{dr} = \frac{1}{L_r}\lambda_{dr} - \frac{L_m}{L_r} i_{ds} \tag{30.47}$$

The rotor currents i_{qr} and i_{dr} can be eliminated from Eqs. (30.44) and (30.45) by using Eqs. (30.46) and (30.47). Thus,

$$\frac{d\lambda_{qr}}{dt} + \frac{L_r}{R_r}\lambda_{qr} - \frac{L_m}{L_r} R_r i_{qs} + (\omega_e - \omega_r)\lambda_{dr} = 0 \tag{30.48}$$

$$\frac{d\lambda_{dr}}{dt} + \frac{R_r}{L_r}\lambda_{dr} - \frac{L_m}{L_r} R_r i_{ds} + (\omega_e - \omega_r)\lambda_{qr} = 0 \tag{30.49}$$

The elimination of transients in rotor flux and the coupling between the two axes occurs when

$$\lambda_{qr} = 0 \quad \text{and} \quad \hat{\lambda}_r = \lambda_{dr} \tag{30.50}$$

The rotor flux should also remain constant so that

$$\frac{d\lambda_{dr}}{dt} = 0 = \frac{d\lambda_{qr}}{dt} \tag{30.51}$$

From Eq. (30.48) to Eq. (30.51),

$$\omega_e - \omega_r = \omega_{sl} = \frac{L_m R_r}{\hat{\lambda}_r L_r} i_{qs} \tag{30.52}$$

$$\text{and} \quad \frac{L_r}{R_r}\frac{d\hat{\lambda}_r}{dt} + \hat{\lambda}_r = L_m i_{ds} \tag{30.53}$$

Substituting the expressions for i_{qr} and i_{dr} into Eqs. (30.35) and (30.36),

$$\lambda_{qs} = \left(L_s - \frac{L_m^2}{L_r}\right) i_{qs} + \frac{L_m}{L_r}\lambda_{qr} \tag{30.54}$$

$$\lambda_{ds} = \left(L_s - \frac{L_m^2}{L_r}\right) i_{ds} + \frac{L_m}{L_r}\lambda_{dr} \tag{30.55}$$

Substituting λ_{qs} and λ_{ds} from Eqs. (30.54) and (30.55) into the torque equation of Eq. (30.41),

$$T = \frac{3P}{2}\frac{L_m}{L_r}\left(\lambda_{dr} i_{qs} - \lambda_{qr} i_{ds}\right) = \frac{3P}{2}\frac{L_m}{L_r}\hat{\lambda}_r i_{qs} \tag{30.56}$$

It is clear from Eq. (30.53) that the rotor flux $\hat{\lambda}_{dr}$ is determined by i_{ds}, subject to a time delay T_r, which is the rotor time constant (L_r/R_r). The current i_{qs}, according to Eq. (30.56), controls the developed torque T without delay. Currents i_{ds} and i_{qs} are orthogonal to each other and are called the flux- and torque-producing currents, respectively. This correspondence between the flux- and torque-producing currents is subject to maintaining the conditions in Eqs. (30.50) and (30.51). Normally, i_{ds} would remain fixed for operation up to the base speed. Thereafter, it is reduced in order to weaken the rotor flux so that the motor may be driven with a constant-power-like characteristic.

Based on how the rotor flux is detected and regulated, two methods of control are available. One is the more popular indirect rotor-flux-oriented control (IFOC) method, and the other is the direct vector control method; both are described hereafter.

30.3.4.2 Indirect Rotor Flux Oriented (IFOC) Vector Control

In the indirect scheme, the relationship between the slip frequency and current i_{qs} given by Eq. (30.52) is used to relate the compensated speed error $\omega_1 - \omega_r$ to i_{qs}. The i_{qs}, in turn, is used to develop to the demanded torque T^* according to the Eq. (30.56). The rotor flux is maintained at the base value for operation below speed, and it may be reduced to a lower value for field weakening above base speed. The orthogonal relationship between the torque-producing stator current i_{qs} and the flux-producing stator current i_{ds} is maintained at all times by generating the stator current references in the synchronously rotating dq reference frame, using sine and cosine functions of angle θ_1. This angle is obtained as indicated in Fig. 30.28.

The compensated speed error produces the current reference i_{qs}^* according to Eq. (30.56). The current reference i_{qs}^* also gives the slip speed ω_{sl} according to Eq. (30.53). The slip speed ω_{sl} is added to the rotor speed ω, to obtain the stator frequency ω_1. This frequency is integrated with respect to time to produce the required angle θ_1 of the stator mmf relative to the rotor flux vector. This angle is used to transform the stator currents to the dq reference frame. Two independent current controllers are used to regulate the i_q and i_d currents to their reference values. The compensated i_q and i_d errors are then inverse transformed into the stator $a-b-c$ reference frame for obtaining switching signals for the inverter via PWM or hysteresis comparators.

It is clear that this scheme uses a feedforward scheme, or a machine model, in which the current reference for i_{qs} is also

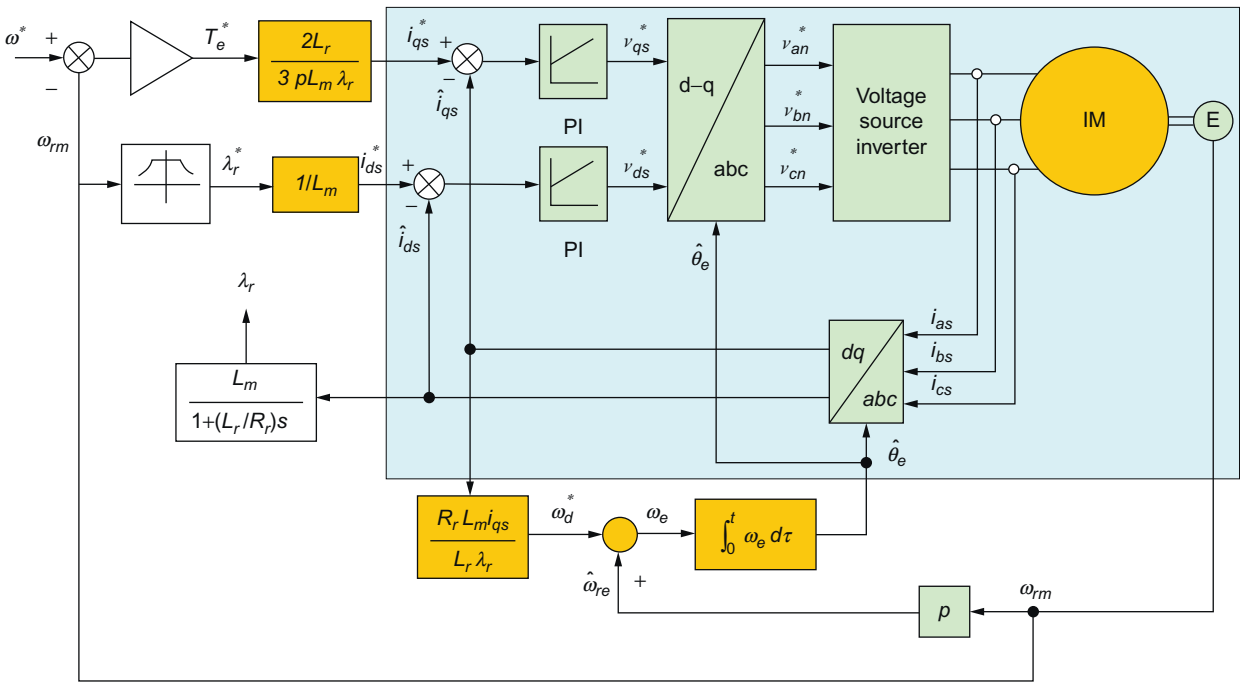

FIG. 30.28 Indirect rotor flux oriented vector control scheme.

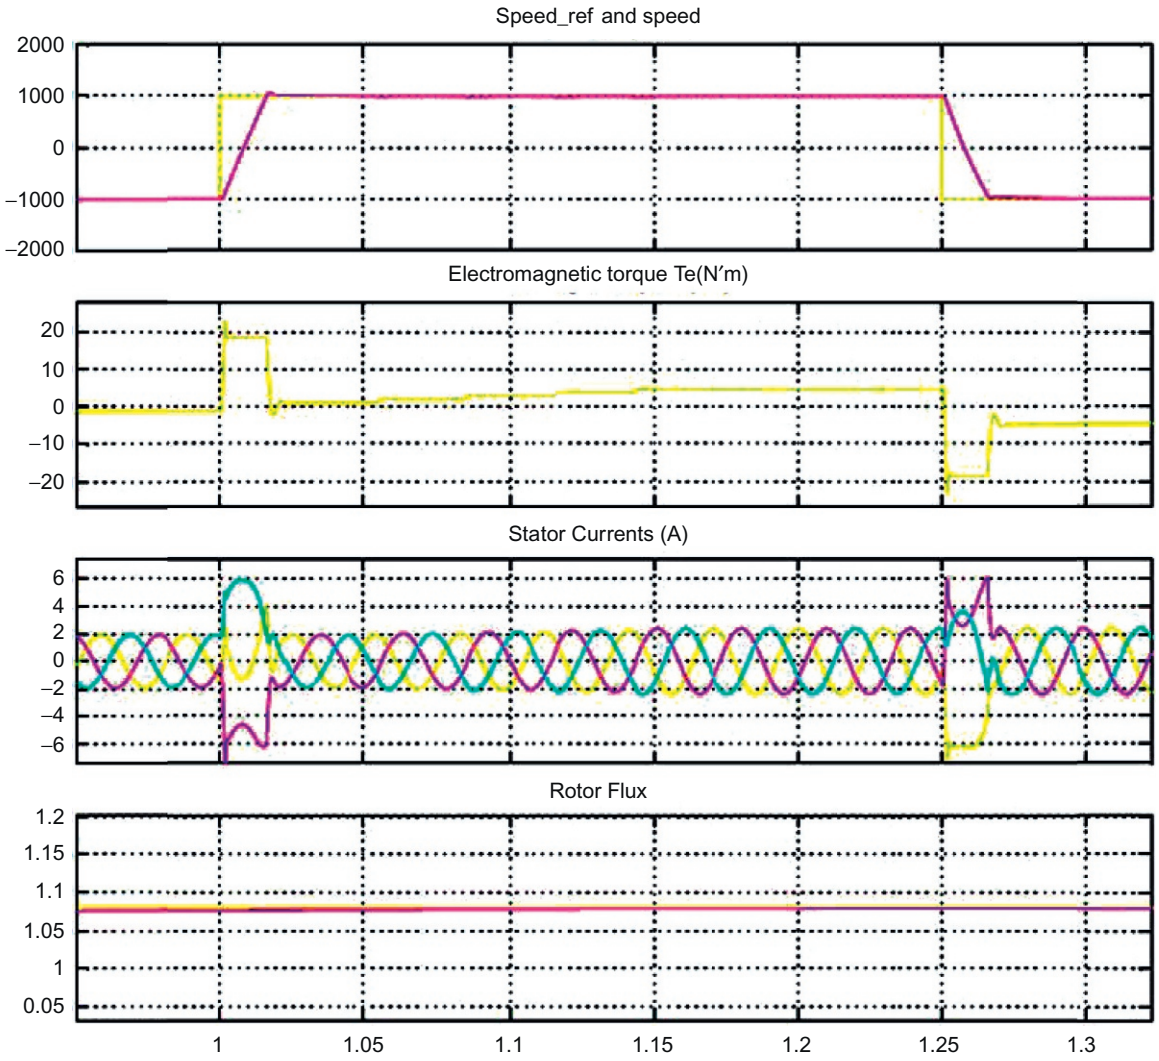

FIG. 30.29 Speed and current responses of an induction motor drive under the IFOC scheme of Fig. 30.28.

determined by the rotor time constant T_r. This is also indicated in Fig. 30.28. The rotor time constant T_r cannot be expected to remain constant for all conditions of operation. Its considerable variation with operating conditions means that the slip speed ω_{sl}, which directly affects the developed torque and the rotor flux vector position, may vary widely. Many rotor time-constant identification schemes have been developed in recent years to overcome the problem.

The mandatory requirement for a rotor-speed sensor is also a significant drawback, because its presence reduces the reliability of the IFOC drive. Consequently, sensorless schemes of identifying the rotor flux position have also drawn considerable interest in recent years.

Fig. 30.29 shows the transient response of an induction motor under the IFOC drive scheme of Fig. 30.28. In this case, the drive accelerates a large inertia load from standstill to the base speed of 1500 rev/min. It is clear that the overcurrent transients of Fig. 30.21 are eliminated, while the motor accelerates under a constant torque (implied by the constant rate at which the speed increases) and settles at the final speed with little over- or undershoot in speed. Clearly, rotor and air-gap fluxes remain constant at all times.

30.3.4.3 Direct Vector Control with Airgap Flux Sensing

In the direct scheme, use is made of the air-gap flux linkages in the stator d- and q-axes, which are then compensated for the respective leakage fluxes in order to determine the rotor flux linkages in the stator reference frame. The air-gap flux linkages are measured by installing quadrature flux sensors in the air gap, as indicated in Fig. 30.30.

By returning to Eqs. (30.32)–(30.40) in the stator reference frame and using some simplifications, it can be shown that

$$\lambda_{qr}^{s} = \frac{L_r}{L_m}\lambda_{qm}^{s} - L_{lr} i_{qs}^{s} \tag{30.57}$$

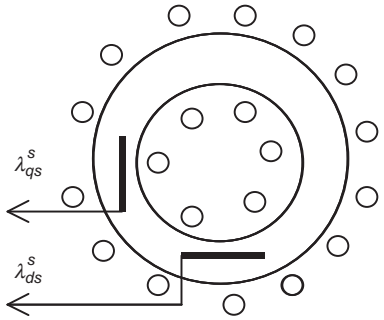

FIG. 30.30 Quadrature sensors for air-gap flux for direct vector control.

$$\lambda_{dr}^{s} = \frac{L_r}{L_m}\lambda_{dm}^{s} - L_{lr} i_{ds}^{s} \tag{30.58}$$

where the superscript s stands for the stator reference frame. Since the rotor flux rotates at a synchronous speed with respect to the stator reference frame, the angle θ_1 used for the coordinate transformations in Fig. 30.27 can be obtained from

$$\cos\theta_1 = \frac{\lambda_{dr}^{s}}{\hat{\lambda}_r} \tag{30.59}$$

$$\text{and} \quad \sin\theta_1 = \frac{\lambda_{qr}^{s}}{\hat{\lambda}_r} \tag{30.60}$$

where $|\hat{\lambda}_r| = \sqrt{\left(\lambda_{dr}^{2}\right)^2 + \left(\lambda_{qr}^{s}\right)^2}$.

The control of torque via i_{qs} and the rotor flux via i_{ds}, subject to satisfying conditions (30.50) and (30.51), remain as indicated in Fig. 30.28, according to the basic principle of vector control.

The requirement of air-gap flux sensors is rather restrictive. Such fittings also reduce reliability. Even though this method of control offers better low-speed performance than the IFOC, this restriction has practically precluded the adoption of this scheme. In an alternative method, the d- and q-axes stator flux linkages of the motor may be computed from integrating the stator input voltages.

30.4 Synchronous Motor Drives

30.4.1 Introduction

Variable-speed synchronous motors have been widely used in very large-capacity (> MW) pumping and centrifuge-type applications using naturally commutated current-source thyristor converters. At the low-power end, the current-source SPWM inverter-driven synchronous motors have become very popular in recent years in the form of permanent-magnet brushless dc and ac synchronous motor drives in servo-type applications. There are certain features of three-phase synchronous motors that have allowed them, especially the lower capacity motors, to be controlled with high dynamic performance using cheaper control hardware than is required for the induction motor of similar capacity. Since the average speed of the synchronous motor is precisely related to the supply frequency, which can be precisely controlled, multimotor drives with a fixed speed ratio among them are also good candidates for synchronous motor drives. This section begins with the performance of the variable-speed nonsalient-pole and salient-pole synchronous motor drive using the steady-state equivalent circuit followed by the dynamics of the vector-controlled synchronous motor drive.

30.4.2 Steady-State Equivalent-Circuit Representation of the Motor

Some of the operating characteristics of variable-frequency voltage- and current-source-driven synchronous motors can be readily obtained from their steady-state equivalent representation, as was the case with the scalar controls of induction motor drives. Assuming balanced, sinusoidal distribution of stator and rotor mmfs and a uniform air-gap (nonsalient-pole motor), the per-phase equivalent circuit of Fig. 30.31 represents the motor at a constant speed.

The representation in Fig. 30.31 is in terms of the RMS voltage V applied to the motor phase winding that consists of the phase resistance R, the synchronous reactance X_s (in Ω/phase), and the per-phase induced voltage E_f. The back emf E_f develops

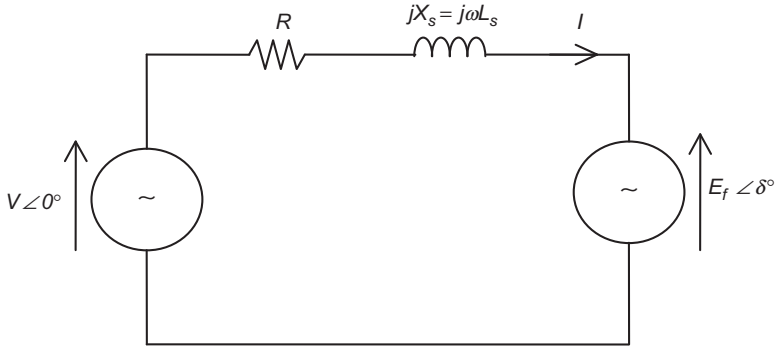

FIG. 30.31 Equivalent circuit of a nonsalient-pole motor.

in the stator phase winding as a result of rotor excitation supplied from an external dc source via slip rings or by permanent magnets in the rotor. The phasor E_f has an arbitrary phase angle δ with respect to the input voltage V. This is the load angle of the motor.

Unlike the induction motor, a synchronous motor may derive part or all of its excitation from the rotor via rotor excitation. For small synchronous motors that are used in the brushless dc and ac servo applications, this excitation is derived from permanent magnets in the rotor. This is readily and economically obtained with the modern permanent magnets, thus dispensing with the slip-ring-brush assembly. The i^2R losses in the rotor windings with the external excitation are also eliminated. These magnets also allow considerable reduction in space requirement for the rotor excitation. For large synchronous motors, this excitation is supplied more economically from an external dc source via slip rings or via an exciter.

The phasor diagrams of Fig. 30.32 may be used to analyze characteristics of the nonsalient-pole synchronous motor drive. Since the rotor magnetic field may be such that the motor may develop a back emf that is smaller or larger than the ac supply voltage to the stator windings, the motor may accordingly be underexcited or overexcited, respectively. The overexcited motor will normally operate at a leading power factor, as is the case in Fig. 30.32B. This is desirable in high-power applications.

In the phasor diagrams of Fig. 30.32C, the stator current I has been resolved into two components I_d and I_q, which are current phasors responsible for developing mmfs in the rotor d- and q-axes. These representations are in the stator reference frame, and hence are sinusoidal quantities at the frequency of the stator supply.

If the voltage drop across the stator resistance is neglected, which may be acceptable when the stator frequency is near the base frequency or higher, the developed torque T of the motor can be found from the phasor relationships of Fig. 30.32. Thus

$$T = \frac{3}{\omega_r}\frac{EV}{X_s}\sin\delta = \frac{3P}{\omega}\frac{EV}{\omega L_s}\sin\delta = \frac{3PK_\phi}{L_s}\frac{V}{\omega}\sin\delta \text{ Nm} \qquad (30.61)$$

for the nonsalient-pole motor (also for the sine wave PM ac motor with rotor magnets at the surface of the rotor) and

$$T = \frac{3P}{\omega_r}\left[\frac{EV}{\omega L_d}\sin\delta + \frac{V^2}{2}\left(\frac{L_d - L_q}{\omega L_d L_q}\right)\sin 2\delta\right] = 3P\left[\frac{K_\phi}{L_d}\frac{V}{\omega}\sin\delta + \frac{V^2}{2\omega^2}\left(\frac{L_d - L_q}{L_d L_q}\right)\sin 2\delta\right] \text{ Nm} \qquad (30.62)$$

for the salient-pole motor (also for the interior-magnet motor in which the rotor magnets are buried inside the rotor). Here, the flux constant of the motor, K_ϕ, is the ratio of the RMS value of the phase voltage E_f induced in the stator only due to the rotor excitation and speed. Note that for a given rotor excitation, the ratio $K_\phi = E_f/\omega$ remains constant at all speed.

30.4.3 Performance with Voltage-Source Inverter Drive

Eqs. (30.61) and (30.62) imply that if the motor is driven from a voltage-source supply and if the input voltage to frequency ratio, V-f, is kept constant, the motor will develop the same maximum torque at all speeds. For the nonsalient-pole motor, this maximum torque will occur for a load angle $\delta = 90°$. For the salient-pole motor, this will occur for a load angle, which is also influenced by the relative values of L_d and L_q.

At a low speed, where the supply voltage V is small, the voltage drop in the stator resistance may become significant compared with E_f. This may lead to a significant drop in the maximum available torque, as given by the torque Eqs. (30.63) and (30.64), which are derived from the phasor diagrams of Fig. 30.32. The stator per-phase resistance R is now included in the analysis. The developed torque is then given by

$$T = \frac{3PE_{fo}V_1}{\omega_o}\frac{\lambda X_{so}\sin\delta + R\left(\cos\delta - \dfrac{\lambda E_{fo}}{V_1}\right)}{R^2 + (\lambda X_{so})^2} \text{ Nm} \qquad (30.63)$$

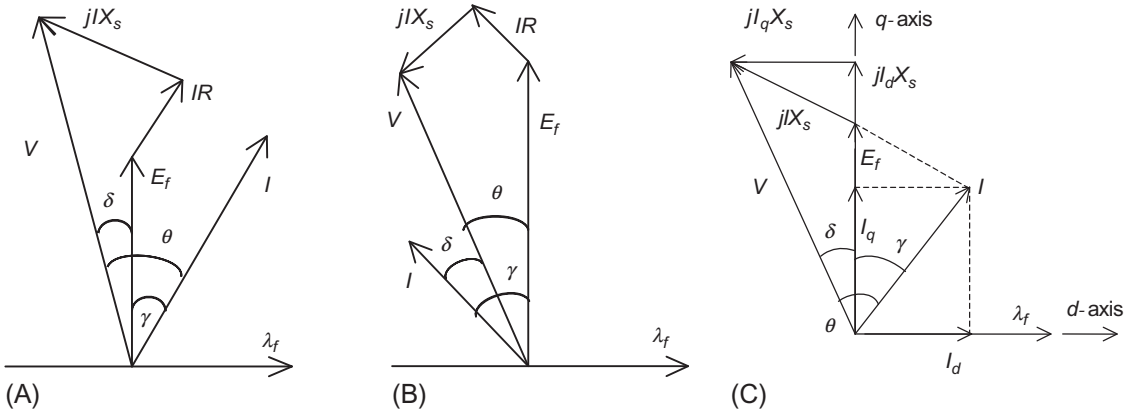

FIG. 30.32 Phasor diagrams of synchronous motors: (A) underexcited nonsalient-pole motor, (B) overexcited nonsalient-pole motor, and (C) underexcited salient-pole motor.

for the nonsalient-pole motor and

$$T = \frac{3P}{\omega_o}\left[\frac{\frac{V_1^2}{\lambda}R + VE_{fo}\lambda X_{qo}\sin\delta + \frac{V^2}{2}\left(X_{do} - X_{qo}\right)\sin 2\delta - VRE_{fo}\cos\delta}{R^2 + \lambda^2 X_d X_q}\right] \text{Nm} \tag{30.64}$$

for the salient-pole motor where the subscript o refers to the base quantities and λ refers to the per unit input frequency f_1/f_0.

Eqs. (30.63) and (30.64) indicate that the maximum torque that the motor can develop diminishes at a low speed because of the voltage drop across the stator resistance R. This drop in maximum available torque at a low speed can be avoided by boosting the input voltage at a low speed, as indicated in Fig. 30.33A. This voltage boosting is similar to the IR compensation applied to a variable-frequency induction motor drive.

Fig. 30.33 indicates an open-loop V-f inverter drive scheme, similar to the scheme for an induction motor drive in which the RMS stator input voltage is made proportional to frequency. The speed reference is passed through a first-order filter, as shown in Fig. 30.33A, so that a large and abrupt change in the input frequency command to the inverter is avoided. The filtered speed reference is translated into a proportional frequency reference f_1. The voltage reference V_1 is also proportional to frequency reference but with a zero frequency bias. The variable RMS input voltage V_1 to the motor may be obtained from an inverter by SPWM methods or from a cycloconverter with phase-angle control.

The available input voltage V_1 is normally limited by the available dc-link voltage to the inverter or the ac supply voltage to a cycloconverter. This limit is normally arranged to occur at base speed. Above this speed, the stator flux drops leading to field weakening and constant-power-like operation, as indicated in Fig. 30.33B. In some control scheme, the maximum load angle δ is not allowed to exceed a certain limiting value δ_{max}. By selecting δ_{max}, constant-power operation at various power levels is possible.

30.4.4 Characteristics Under Current-Source Inverter (CSI) Drive

A CSI-driven synchronous motor drive generally gives higher dynamic response. It also gives better reliability because of the automatic current-limiting feature. In a variable-speed application, the synchronous motor is normally driven from a stiff current source. A rotor-position sensor is used to place the phase current phasor I of each phase at a suitable angle with respect to the back-emf phasor (E_f) of the same phase. The rotor-position sensor is thus mandatory.

Two converter schemes have generally been used. In one scheme, as indicated in Fig. 30.34, a large dc-link reactor

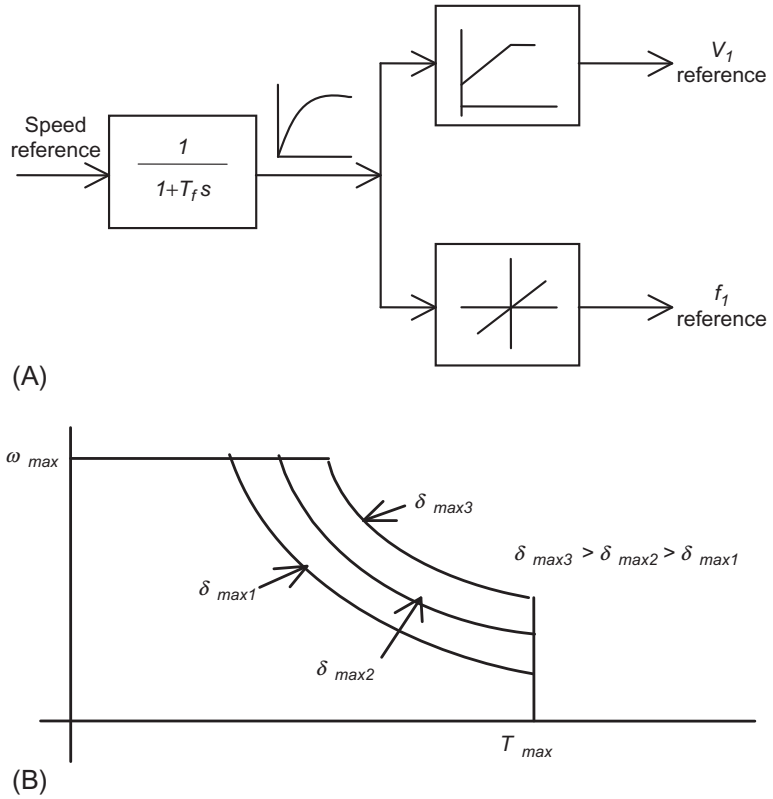

FIG. 30.33 (A) V-f controller for an open-loop inverter drive and (B) $T-\omega$ characteristics with a limited maximum δ for constant-power operation.

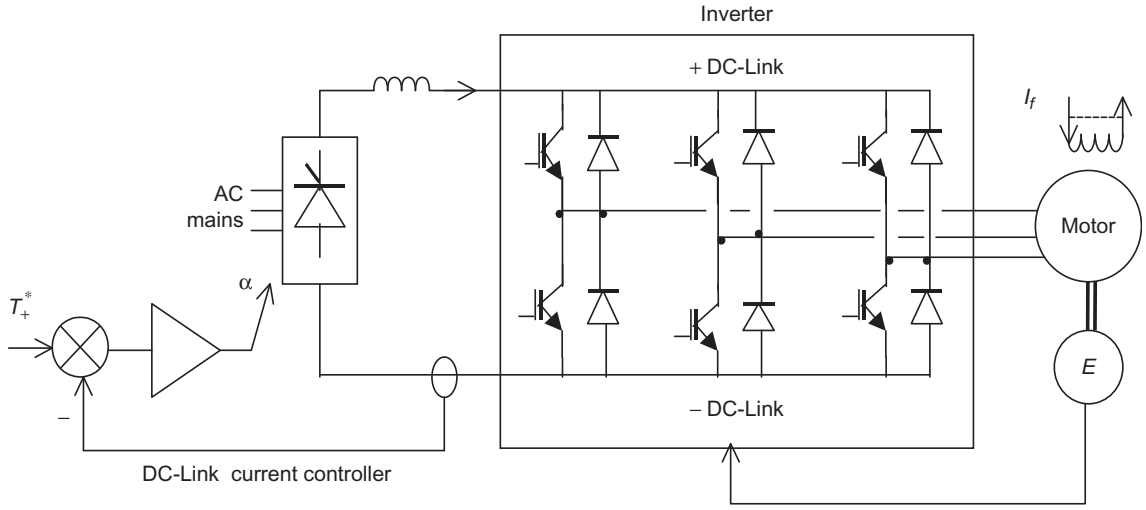

FIG. 30.34 Schematic of a current-source inverter (CSI)-driven synchronous motor.

(inductor) makes the current source to the inverter stiff. The scheme is suitable for large synchronous motors for which thyristor switches are used in the inverter. A current loop may also be established by sensing the dc-link current and by using a closed-loop current controller that continuously regulates the firing angle of the controllable rectifier in order to supply the inverter with the desired dc-link current. It can be shown that the motor-developed torque is proportional to the level of the dc-link current.

The inverter drives the motor with quasi-square-wave current waveforms as indicated in Fig. 30.35. The current waveforms are switched according to the measured rotor-position information, such that the current waveform in each phase has a fixed angular displacement, γ, with respect to the induced emf of the corresponding phase. Because of this, the drive is sometimes referred to as self-controlled. The angular displacement of these current waveforms (or their fundamental components) with the respective back-emf waveforms is

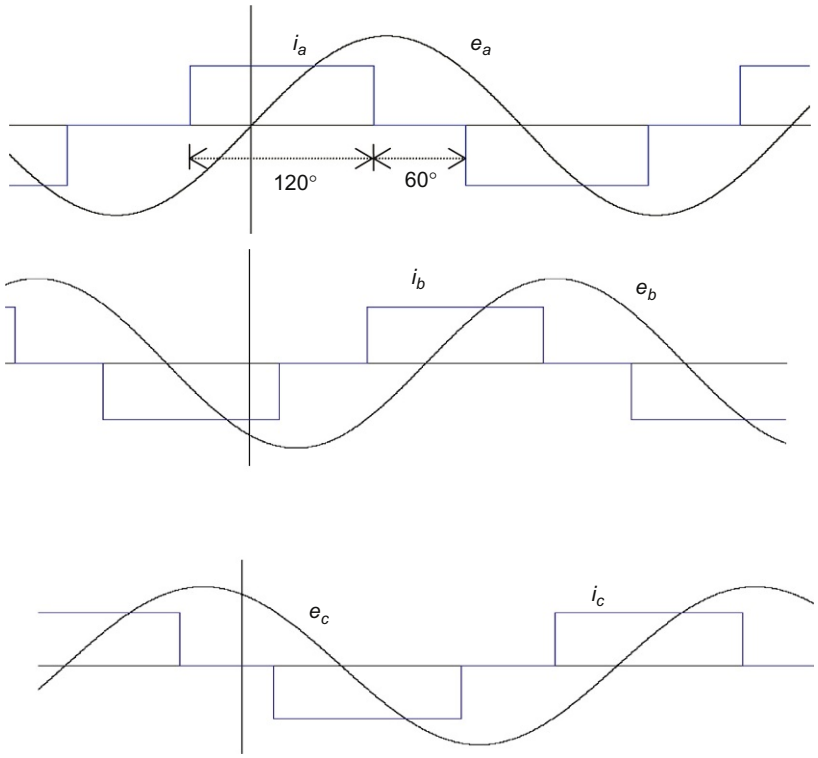

FIG. 30.35 Current waveforms in the dc-link current-source-driven motor.

indicated in Fig. 30.35. Because of the large dc-link inductor, the phase currents may be considered to remain essentially constant between the switching intervals. The quasi-square current waveforms contain many harmonics, and are responsible for large torque pulsations that may become troublesome at a low speed.

In the foregoing scheme, the motor can be reversed easily by reversing the sequence of switching of the inverter. It can also be braked regeneratively by increasing the firing angle of the input rectifier beyond 90° while maintaining the dc-link current at the desired braking level until braking is no longer required. The rectifier now returns the energy of the overhauling load to the ac mains regeneratively.

In another scheme, which is preferred for lower capacity drives for which higher dynamic response is frequently sought, phase currents are regulated within the inverter. The inverter typically employs gate turnoff switches, such as the IGBT, and pulse-width modulation techniques, as indicated in Fig. 30.36. Motor currents are sensed and used to close independent current controllers for each phase. Normally, two current controllers suffice for a balanced star-connected motor. Three-phase sinusoidal ac currents are supplied to the motor, the amplitude and phase angle of which can be independently controlled as required. The references for the current controllers are obtained from a three-phase current reference generator that is addressed by the feedback of the rotor position. The rotor position is continuously measured by a high-resolution encoder. In this way, the current references and hence the actual stator currents are synchronized to the rotor.

30.4.5 Brushless DC Operation of the CSI-Driven Motor

The torque characteristic of the CSI drive scheme of the foregoing section can be easily analyzed using the phasor diagrams shown earlier, if the harmonics in the motor-current waveform are neglected or if the motor-current waveforms are indeed sinusoidal as in the second scheme described earlier. In the following analysis, it is assumed that the supply current waveforms are sinusoidal. It is also assumed that the phase angle of these current sources with respect to the induced voltage in each phase can be arbitrarily chosen.

The phase back-emf and the current waveforms and the phasor diagram of the nonsalient-pole motor are shown in Fig. 30.37. The phase angle γ between the E_f and I phasors and the RMS value (or amplitude) of I are determined according to the desired torque and power factor considerations. The developed torque is found from the phasor diagram to be

$$T = \frac{3E_f I\cos\gamma}{\omega_r} = K\phi I\cos\gamma \text{ Nm} \tag{30.65}$$

If the angle $\gamma = 0°$ is chosen, the familiar dc-motor-like torque characteristic is obtained. It should be noted from the

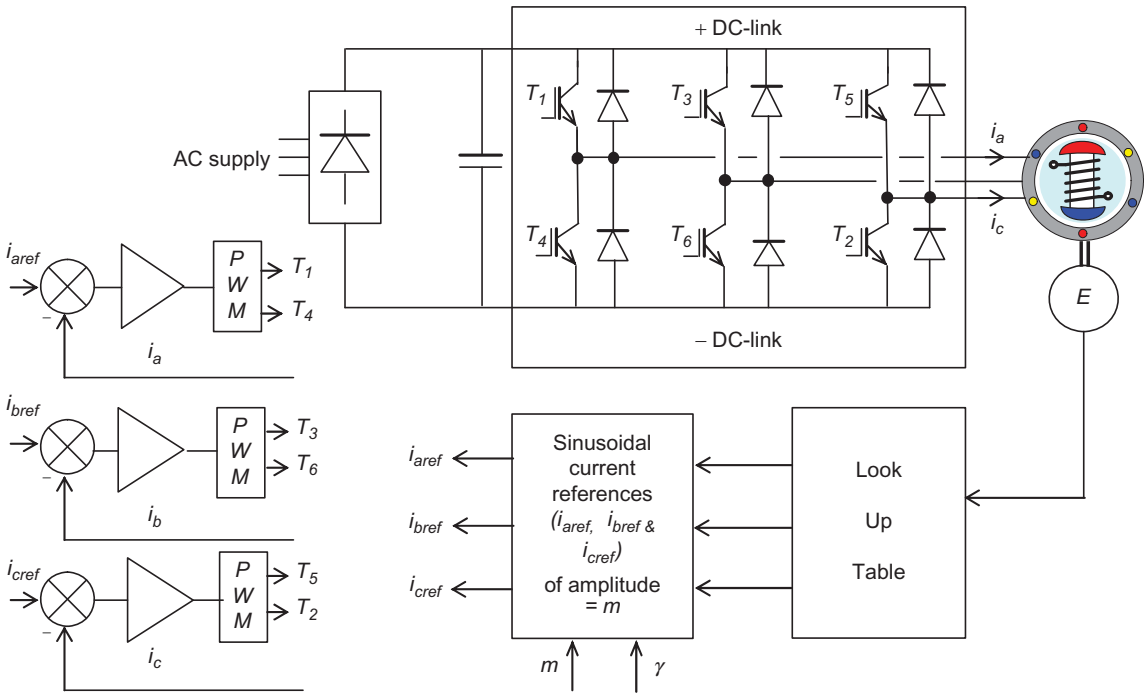

FIG. 30.36 Control scheme of the PWM current-source drive.

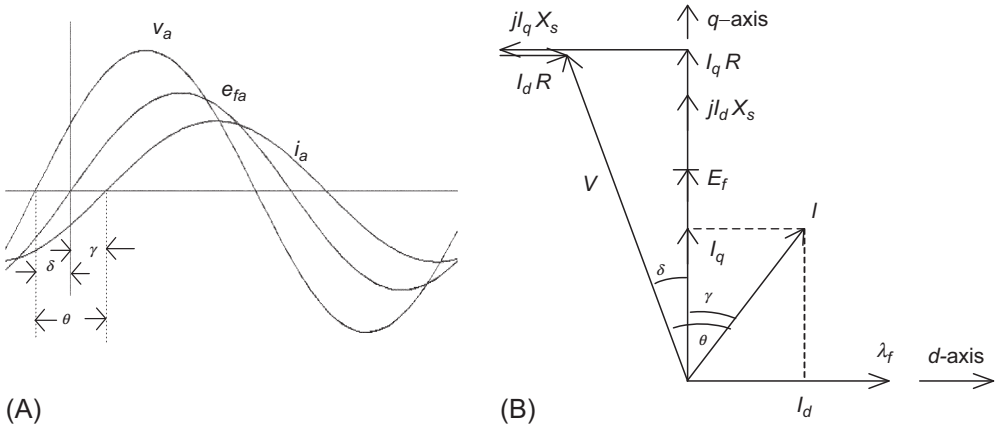

FIG. 30.37 Phasor relationships of CSI-driven motor: (A) back-emf and current waveforms and (B) the phasor diagram.

foregoing that the developed torque at any speed is independent of R since a high-gain (stiff) current-source drive is used. Note also that the ratio E_f/ω at any operating speed is proportional to the amplitude of the stator flux linkage, λ_f, due to rotor excitation. For fixed rotor excitation, this ratio is a constant.

Eq. (30.65) indicates that the developed torque of a nonsalient-pole synchronous motor can be controlled by controlling the amplitude of the rotor field (field control), or more conveniently, by controlling the amplitude of the stator phase current. The highest torque per ampere characteristic is achieved when $\gamma = 0°$. Note that the operation with a fixed γ angle is key to this dc-motor-like torque characteristic.

30.4.5.1 Operation with Field Weakening

If the stator impedance drop is neglected, the maximum E_f is largely determined by the dc-link voltage and $E_f = K\lambda_f\omega$ implies that speed ω can be increased by decreasing λ_f. Consequently, the operation above base speed is normally achieved with field weakening. In this speed range, because of the limited dc-link voltage, the rotor field must be weakened; otherwise, the amplitude of the phase-induced emf will exceed the dc-link voltage, and current control will not be effective. Field weakening is a means of keeping this voltage at the rated level for speeds higher than the base speed.

The flux linkage due to the rotor excitation, λ_f, can be adjusted when a variable rotor supply is available. This may also be achieved by demagnetizing the rotor mmf by using the mmf produced by the stator currents. For motors with permanent-magnet excitation, the latter is the only means of weakening the λ_f. Referring to the phasor diagram of Fig. 30.38, if I is made to lead E_f, the d-axis component of I, that is, I_d, will lead E_f by 90°. The mmf due to I_d then opposes the rotor d-axis mmf. The net rotor flux linkage along the q-axis is then given by

$$\lambda_f' = \lambda_f + L_d I_d \tag{30.66}$$

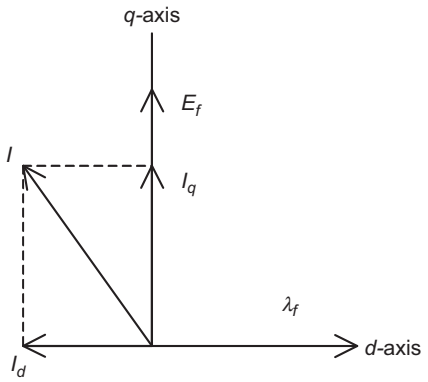

FIG. 30.38 Field weakening using stator mmf.

where I_d is negative when I leads E_f. If the air gap is small, the d-axis component of the armature current may reduce the rotor flux to the required extent.

30.4.6 Operating Modes

A synchronous motor may be driven with a view to achieving various operating characteristics, such as power factor compensation, maximum torque per ampere characteristic, and field weakening. The power factor at which a synchronous motor operates is an important issue, especially for a large drive. A large angle θ between the input voltage and current phasors of the motor results in a poor overall power factor. The operation of the synchronous motor with stator current waveforms with a certain phase angle with respect to the respective phase back-emf waveforms allows interesting power-factor compensation possibilities. Consider the following three cases.

30.4.6.1 Case 1: Operation with *I* Lagging E_f

In this case, the motor is underexcited and I lags E_f, by an angle γ, as indicated in Fig. 30.39. The overall power factor in this case

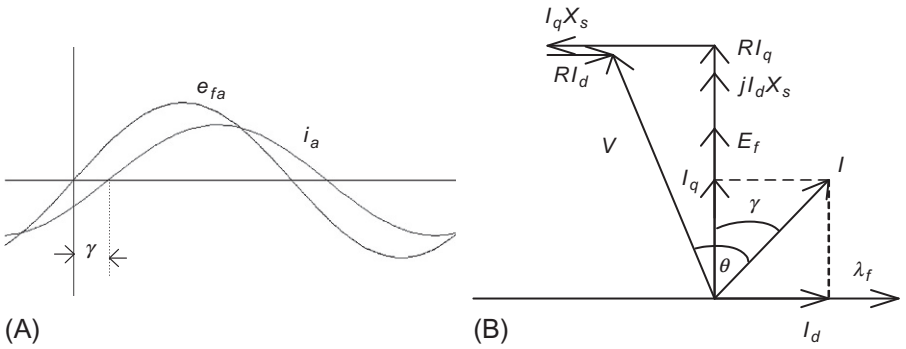

FIG. 30.39 (A) Phase back-emf and current waveforms and (B) the phasor diagram with I lagging E_f.

is lagging, since I lags V by an angle θ. The power-factor angle θ is larger than γ. Note that I_d now magnetizes the rotor field.

30.4.6.2 Case 2: I is in phase with E_f; Maximum Torque per Ampere Operation ($\gamma = 0°$)

If $\gamma = 0°$ is used, the motor input current i_a is in phase with the back emf e_a, as indicated in the waveforms of Fig. 30.40A. From Eq. (30.65), the developed torque is given by

$$T = K\phi I \tag{30.67}$$

Thus, for a fixed rotor excitation, the developed torque is the highest that can be achieved per ampere of stator current I. In other words, if $\gamma = 0°$ is chosen, the drive operates with its maximum torque per ampere characteristic. From the phasor diagram of Fig. 30.40B, it is clear that the input current I phasor now lags the voltage V phasor at the motor terminals (see the phasor diagram in the figure). Note that the level of E_f that is determined by the level of excitation also determines the angle θ to some extent. Clearly, when maximum-torque-per-ampere characteristic is required, a power factor less than unity has to be accepted.

30.4.6.3 Case 3: Operation with I Leading E_f

If I is chosen to lead E_f, the overall power factor can be higher, including unity, as is indicated in Fig. 30.41. Note that the

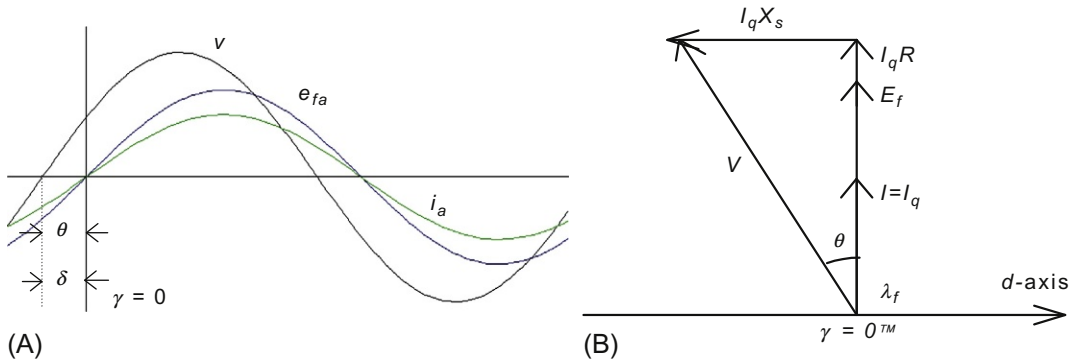

FIG. 30.40 (A) Phase back-emf and current waveforms and (B) phasor diagram for I in phase with E_f.

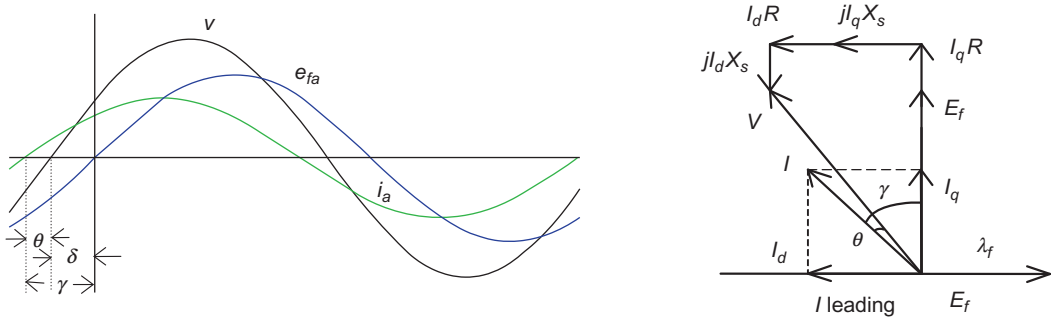

FIG. 30.41 Back-emf and current waveforms and phasor diagram for I leading E_f.

motor now operates with less than maximum torque per ampere characteristic. Note also that the d-axis component of I now tends to demagnetize the rotor and that the operation with field weakening is implied.

With a CSI-driven motor, the amplitude and the angle of the phase current relative to the back emf can be selected according to one of the desirable operating characteristics mentioned above. Additionally, other operational limits such as the inverter/motor-current limit, the maximum stator voltage limit, and the maximum power limit can also be addressed. The amplitude of the stator current I clearly determines the developed torque of the motor. Consequently, the error of the speed controller is used to determine the amplitude of I. The overall control system with an inner torque loop can be described by Fig. 30.42.

30.4.7 Vector Control

Controls described in foregoing sections were based on the steady-state equivalent circuit of the motor. Even though the torque Eq. (30.65) for a current-source drive evokes vector-control-like relationships, they do not address the dynamics of the current controls as is possible in an orthogonal reference frame. Using an orthogonal set of reference attached to the rotor, a simple set of decoupled, dc-motor-like torque-control relationships is readily obtained. Following the transformation technique used in Section 30.3.4, the stator voltage equations of a synchronous motor with fixed rotor excitation in the rotor reference frame are

$$\begin{bmatrix} v_q \\ v_d \end{bmatrix} = \begin{bmatrix} R+pL_q & \omega L_d \\ -\omega L_q & R+pL_d \end{bmatrix} \begin{bmatrix} i_q \\ i_d \end{bmatrix} + \begin{bmatrix} \omega\lambda_f \\ 0 \end{bmatrix} \tag{30.68}$$

$$T = \frac{3}{2}P\left(\lambda_f i_q + \left(L_d - L_q\right) i_d i_q\right) \tag{30.69}$$

where all the quantities in lower case represent instantaneous quantities in the rotor dq-frame. The λ_f is the flux linkage per phase due to the rotor excitation, ω is the electric angular velocity in radians per second, and P is the number of pole pairs. Here, p is the time derivative operator d/dt. Assuming the magnetic linearity, the stator flux linkages are

$$\begin{aligned} \lambda_d &= L_d i_d + \lambda_f \\ \lambda_q &= L_q i_q \end{aligned} \tag{30.70}$$

Note that the Eq. (30.68) can be written down directly from Eq. (30.31), taking into account the fixed rotor excitation so that the third and fourth rows and columns of Eq. (30.31) may be dropped. Since the reference frame now rotates at the speed of the rotor, $\omega_e = \omega$. The induced back emf due to the fixed rotor excitation occurs in the rotor q-axis and is included in Eq. (30.68), as a separate term. Similarly, the torque expression of Eq. (30.69) may also be written down from Eq. (30.41), using the flux linkages of Eq. (30.70).

Eqs. (30.67)–(30.69) are for a salient-pole motor for which $L_d \neq L_q$. For a nonsalient-pole motor, L_d is equal to L_q, and the developed torque is proportional to i_q only. In either case, the inner torque loop consist of two separate current loops: one for i_d and the other for i_q, as indicated in Fig. 30.43. The i_q current loop generally derives its reference signal from the output of the speed controller and constitutes the inner torque loop. The reference for the i_d current loop is normally specified by the extent of field weakening for which a negative i_d reference is used. Otherwise, the d-axis current is maintained at zero. Note that for large synchronous motors with variable external excitation, field weakening is normally applied through adjustment of the rotor excitation, using a spillover signal from the output of the speed controller.

From Eq. (30.68), it is clear that the couplings of q- and d-axis voltages exist through the d- and q-axis currents, respectively, and the back emf. During dynamic operation, such coupling effects become undesirable. The coupling effects of d- and q-axis currents and the back emf into q- and d-axis voltages, respectively, can be removed by the feedforward terms shown

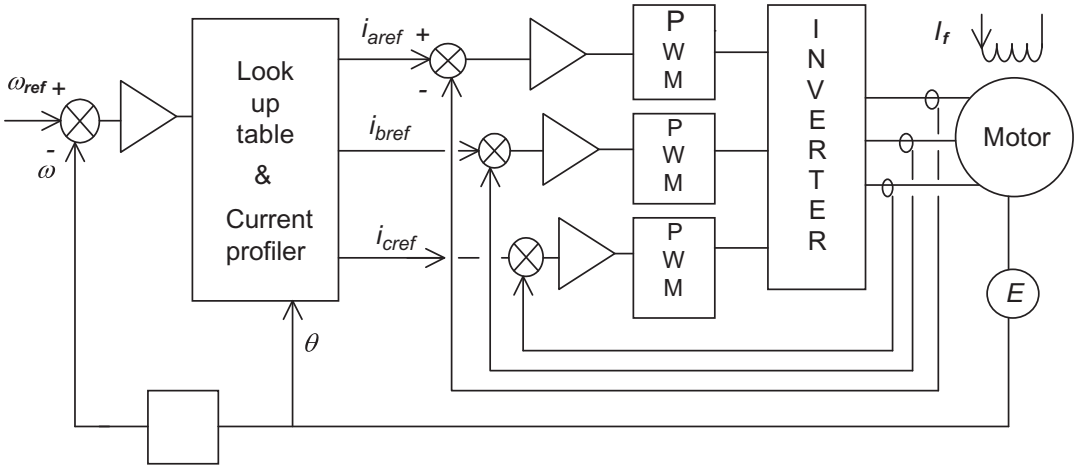

FIG. 30.42 Structure of a speed-control system with a CSI-driven synchronous motor.

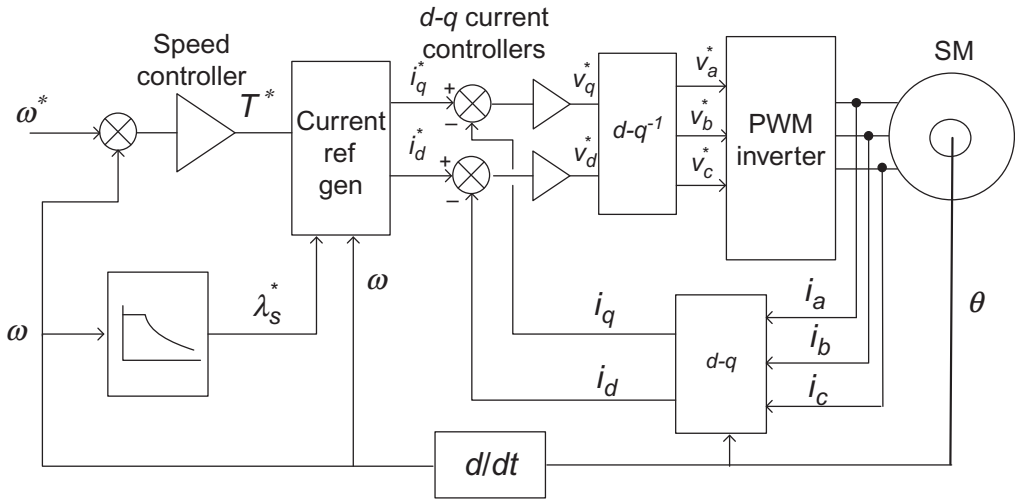

FIG. 30.43 Inner torque loop of a vector-controlled synchronous motor drive.

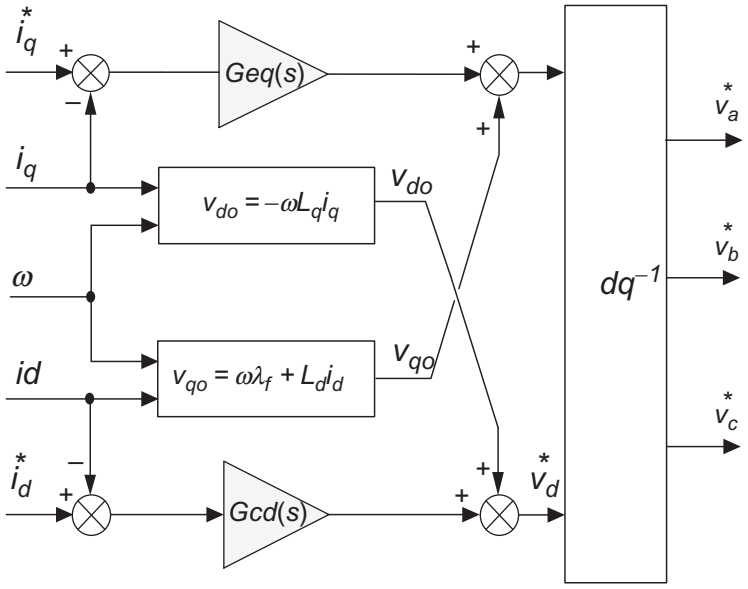

FIG. 30.44 The *d*- and *q*-axis decoupling compensation.

in the shaded part of the block the diagram of Fig. 30.44, which also shows the two current-control loops. The two outputs v_d^* and v_q^* from the decoupled current controllers are transformed to the stator reference frame before being subjected to pulse-width modulators or hysteresis comparators. Note that the current references i_d^* and i_q^* are obtained with due regard for the desired operating and limiting conditions as described in Section 30.4.5.

Under this type of control, which is exercised in the rotor reference frame, the *d*- and *q*-axis currents are separately regulated. The purpose of the *q*-axis current controller is primarily to control the developed torque, especially for the nonsalient-pole motor. For this motor, the *d*-axis current is normally maintained at zero, when the motor is operated below the base speed. The *d*-axis current may be used to weaken the air-gap flux so that the motor operates with a constant-power-like characteristic. It should be noted that the field weakening may also be carried out more directly by adjusting the rotor excitation current by using a spillover signal from the speed controller, when the base speed is exceeded.

The dynamic response of the drive under the vector control scheme indicated in Fig. 30.44 is the highest possible with a CSI drive. It should also be noted that the *dq* currents in the rotor reference frame vary only the mechanical dynamics of the rotor. In fact, they are dc quantities when the motor runs at a constant speed. Consequently, the following error (or lag)

associated with tracking a sinusoidally time-varying current reference, which is the case when current control is exercised in the stator $a-b-c$ reference frame, can be reduced easily by using an integral-type current controllers.

30.5 Permanent-Magnet Synchronous Motor Drives

30.5.1 Introduction

Since the introduction of samarium cobalt and neodymium-iron-boron magnetic materials in the 1970s and 1980s, respectively, synchronous motors with permanent-magnet excitation in the rotor have been displacing the dc motor in many high-performance applications. The trend is more noticeable in applications requiring high-performance motors of up to a few kilowatts. In low- to medium-power applications, the superior dynamics, smaller size, and higher efficiency of motors with PM excitation in the rotor, compared with all other motors, are well-known.

The arrangement just mentioned is very similar to a conventional synchronous motor. This is particularly so when the stator windings and the rotor mmf are sinusoidally distributed. Several rotor configurations of the PM synchronous motor have been developed, of which the important ones are indicated in Figs. 30.45–30.47.

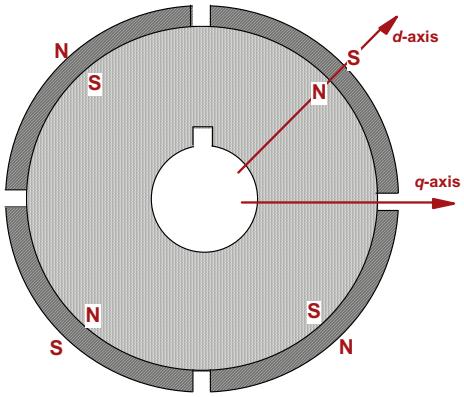

FIG. 30.45 Schematic of the cross section of a surface-magnet synchronous motor.

30.5.2 The Surface-Magnet Synchronous Motor with Trapezoidal Back Emf Waveform

The surface-magnet motor comes with the rotor magnets glued onto the surface of the rotor. An additional stainless steel (i.e., nonmagnetic) cylindrical shell may be used to cover the rotor in order to keep the magnets in place against centrifugal force in high-speed applications. Since the relative permeability of the magnetic material is very close to unity, the effective air gap is uniform and large. Because the air gap includes the magnet thickness, it is long. Consequently, the synchronous

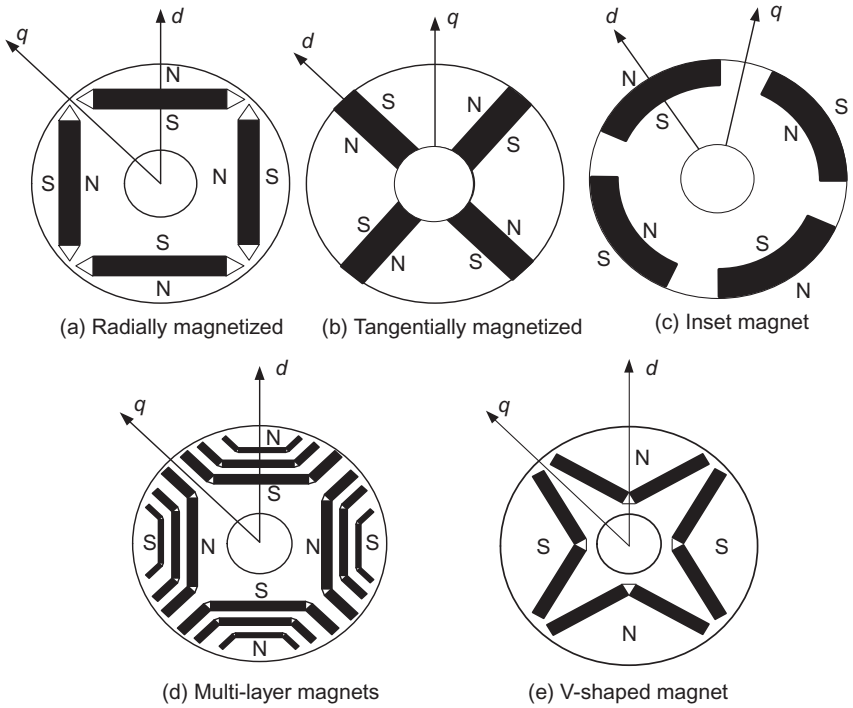

FIG. 30.46 Schematic of the rotor cross section of an interior-magnet motor.

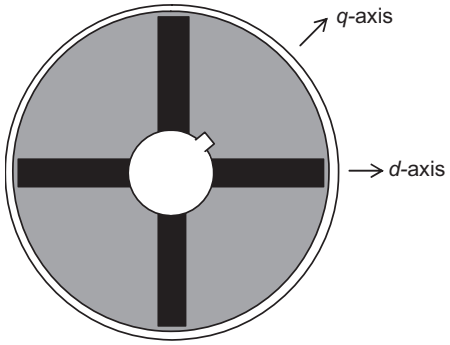

FIG. 30.47 Schematic of the rotor cross section of a circumferential-magnet motor.

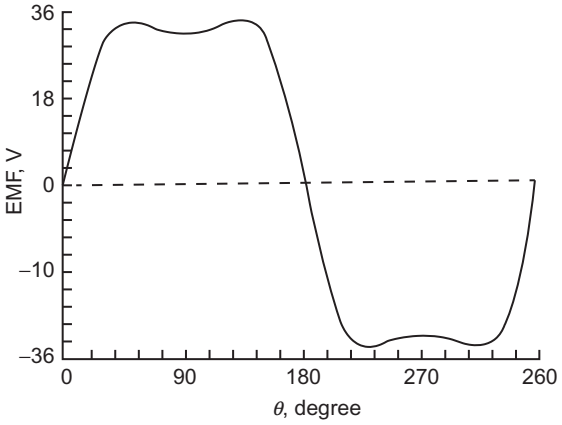

FIG. 30.48 Back emf of a trapezoidal waveform motor.

inductances along the rotor d- and q-axes, as indicated in Fig. 30.45, are equal and small (i.e., $L_d = L_q = L_s$). The armature reaction in this type of motor is small.

The three-phase winding in the stator has uniformly distributed windings. The span of the magnets are selected in such a way that the back emf induced in the stator windings are trapezoidal with nearly 120° of constant amplitude in each half cycle. Such a motor, often called a brushless dc (BLDC) motor because of its similarity to the inside-out conventional brushed PM DC motor, develops a trapezoidal back-emf waveform as indicated in Fig. 30.48, when it is driven at a constant speed. The back-emf waveforms have flattops for nearly 120° in each half cycle followed by 60° of transition from positive to negative polarity of voltage and vice versa. These motors are very suitable for variable-speed applications such as spindle drives in machine-tool and disk drives.

30.5.2.1 Control of the Trapezoidal-wave Motor

Neglecting higher-order harmonic terms, the back emf in the motor phases may be as indicated in Fig. 30.49. Each back emf has a constant amplitude (or flattop) for 120° (electric) followed by 60° of transition in each half cycle. The developed torque at any instant is given by

$$T = \frac{e_{an} i_a + e_{bn} i_b + e_{cn} i_c}{\omega} \text{ Nm} \tag{30.71}$$

It is readily seen that the ideal current waveform in each phase needs to be a quasi-square waveform of 120° of conduction angle in each half cycle. The conduction of current in each

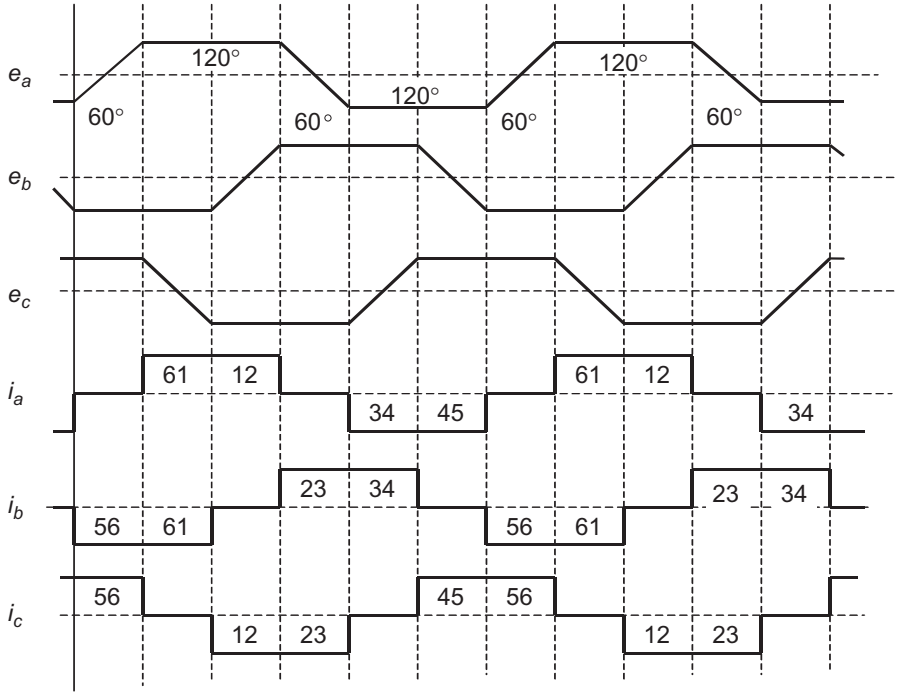

FIG. 30.49 Back-emf and current waveforms and on-states of transistor switches in the trapezoidal waveform motor.

phase winding coincides with the flat part of the back-emf waveforms, which guarantees that the developed torque, that is, $\left(\sum_{x=a}^{c}\frac{e_{xn}\cdot i_{xn}}{\omega_r}\right)$, is constant or ripple-free at all times. With such quasi-square current waveforms, a simple set of six opto-couplers or Hall-effect sensors would be required to drive the six inverter switches indicated in Fig. 30.36. The output current waveforms for the three-phase inverter and the switching devices that conduct during the six switching intervals per cycle are also indicated in Fig. 30.49. Since only six discrete outputs per electric cycle are required from the rotor-position sensors, the requirement of a high-resolution position sensor is dispensed with. Continuous current control for each phase of the motor, by hysteresis or PWM control, to regulate the amplitude of the motor current in each phase is normally employed. The operation of the BLDC motor drive is further described in detail in Section 30.6.

Even though careful electromagnetic design is employed in order to have perfect trapezoidal back-emf waveforms as indicated in Fig. 30.49, the back-emf waveforms in a practical brushless dc motor exhibit some harmonics, as indicated in Fig. 30.48. If ripples in the back-emf waveforms are significant, then torque ripples will also exist when the motor is driven with quasi-square phase current waveforms. These ripples may become troublesome when the motor is operated at a low speed, when the motor load inertia may not filter out the torque ripples adequately.

A second source of torque ripple in the permanent-magnet brushless dc (PM BLDC) motor is from the commutation of current in the inverter. Since the actual phase currents cannot have the abrupt rise and fall times as indicated in Fig. 30.49, torque spikes, one for each switching, may exist.

Even though the PM BLDC motor does not have sinusoidal back emf and inductance variations with rotor angle, the analysis of Section 30.4 in terms of the fundamental quantities will often suffice. The switching of the inverter using the six rotor-position sensors guarantees that the current waveform in each phase always remains in synchronism with the back emf of the respective phase. Since the quasi-square phase current waveform in each phase coincides with the flat part of the back-emf waveform of the same phase, the angle γ is clearly zero for such operation. Thus, considering fundamental quantities, the motor back emf and the torque characteristics can be expressed by

$$E = K_E\omega \text{ V} \tag{30.72}$$

$$T = K_T I\cos\gamma = K_T I \text{ Nm} \tag{30.73}$$

where K_E and K_T are equal in consistent units. Note that E and I are now RMS values of the fundamental components of these quantities.

30.5.2.2 Sensorless Operation of the PM BLDC Motor

In spindle and other variable-speed drive applications, where the lowest speed of operation is not less than a few hundred revolutions per minute, it is possible to obtain the switching signals for the inverter from the motor back emf, thus dispensing with rotor-position sensors. The method consists of integrating the back-emf waveforms, which are the same as the applied phase voltage if the other voltage drops are neglected, and comparing the integrated outputs with a fixed reference. These comparator outputs determine the switching signals for inverter. It may be noted that the amplitude of the back-emf waveforms is proportional to the operating speed, so that the frequency of the comparator outputs increases automatically with speed. In other words, the angle γ and the current waveform relative to the back-emf waveform in each phase remains the same regardless of the operating speed. Integrated circuits are available from several suppliers that perform this task of sensorless BLDC operation satisfactorily, covering a reasonable speed range.

30.5.3 The PM Synchronous Motor with Sinewave Back Emf Waveforms

The PM sine-wave motor, which may also have magnets on the rotor surface or buried inside the rotor (as in the interior-magnet motor of Fig. 30.46), typically has sinusoidally distributed windings. The air-gap flux distribution produced by the rotor magnets is also sinusoidal, arranged through magnet and rotor flux barrier shaping. Consequently, the back-emf waveform of each phase when running at a constant speed is also a sinusoidal waveform, as indicated in Fig. 30.50, when the motor is driven at a constant speed.

It should be noted, however, that with magnets mounted on the rotor surface, the effective air gap is large and uniform so that $L_d = L_q = L_s$. Because of the large equivalent air gap, these inductances are also small, and consequently, the armature reaction is small. As a result, this motor essentially operates with fixed excitation, and there is hardly any scope for altering the operating power factor or the rotor mmf, once the motor and its drive voltage and current ratings have been selected.

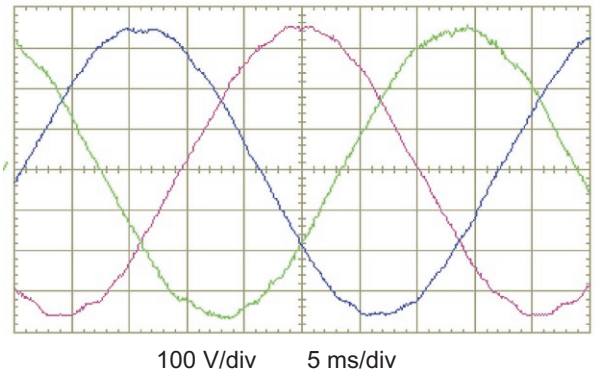

FIG. 30.50 Back-emf waveforms of a sine-wave PM motor. Speed = 1815 rev/min.

The interior permanent-magnet synchronous motor (IPMSM), which comes with magnets buried inside the rotor as indicated in Figs. 30.46, has an easier magnetization path along the rotor q-axis, so that $L_q > L_d$. The small air gap implies that the inductances L_d and L_q may not be small and hence may allow considerable scope for field weakening.

If the sine-wave motor is supplied from an PWM inverter, the analyses and vector diagrams of PM sine-wave motor are similar to those in Section 30.4 for the nonsalient-pole and salient-pole synchronous motor drives. The surface-magnet motor is more akin to the nonsalient-pole motor, since $L_d = L_q = L_s$, whereas the interior-magnet motor is more akin to the salient-pole motor because of the d- and q-axis inductances being unequal. Thus, the equations in Section 30.4 will apply equally well for this motor, both in the steady state and dynamically and for both voltage- and current-source supply.

30.5.3.1 Control of the PM Sinewave Motor

The sinusoidal back-emf waveforms imply that the three-phase motor must be supplied with a sinusoidal three-phase current if a dc-motor-like (or vector-control-like) torque characteristic is desired, as was found in Section 30.4. For such operation, the phase currents must also be synchronized with the respective phase back-emf waveforms, in other words, with the rotor dq- reference frame. This implies the operation with a specified γ angle. Two implementations are possible.

In one scheme, the stator currents are regulated in the stator reference frame, and the stator current references are produced with reference to the rotor position, as indicated in Fig. 30.51. The rotor position θ is continuously sensed and used to produce three sinusoidal current references of unit amplitude. The phase angle γ of the references relative to the respective back-emf waveforms is usually derived from the speed controller, which defines the field-weakening regime of the drive. The operating power factor of the drive may also be addressed using the γ angle control, as explained in Section 30.4.5. The amplitudes of these references are then multiplied by the error of the speed controller in order to produce the desired torque reference. In this way, both the RMS value I of the phase current and its angle γ with respect to E_f can be adjusted independently (which is equivalent to independent dq-axis current control). Three PWM current controllers are indicated, but two suffice for a balanced motor. Other types of current controllers, such as hysteresis controllers, may also be used.

In the second scheme, the motor currents are first transformed into the rotor dq-reference frame using continuous rotor-position feedback, and the measured rotor d- and q-axis currents are then regulated in the rotor reference frame, as indicated in Fig. 30.52. The main advantage of regulating the stator currents in the rotor reference frame, compared with the stator reference frame as in the first scheme, is that current references now vary more slowly and hence suffer from lower tracking error. At constant speed, the stator current references are in fact dc quantities as opposed to ac quantities, and hence, the inevitable tracking errors of the former scheme are easily removed by an integral-type controller. The other advantage is that the current references may now include feedforward decoupling so as to remove the cross coupling of the d- and q-axis variables as shown in the motor representation of Fig. 30.52. The latter scheme is currently preferred, since it allows more direct control of the currents in the rotor reference frame.

It should be noted that continuous transformations to and from rotor dq-axes are required; hence, the rotor-position sensor is a mandatory requirement. Rotor-position sensors of 10- to 12-bit accuracy are normally required. This is generally viewed as a weakness for this type of drive.

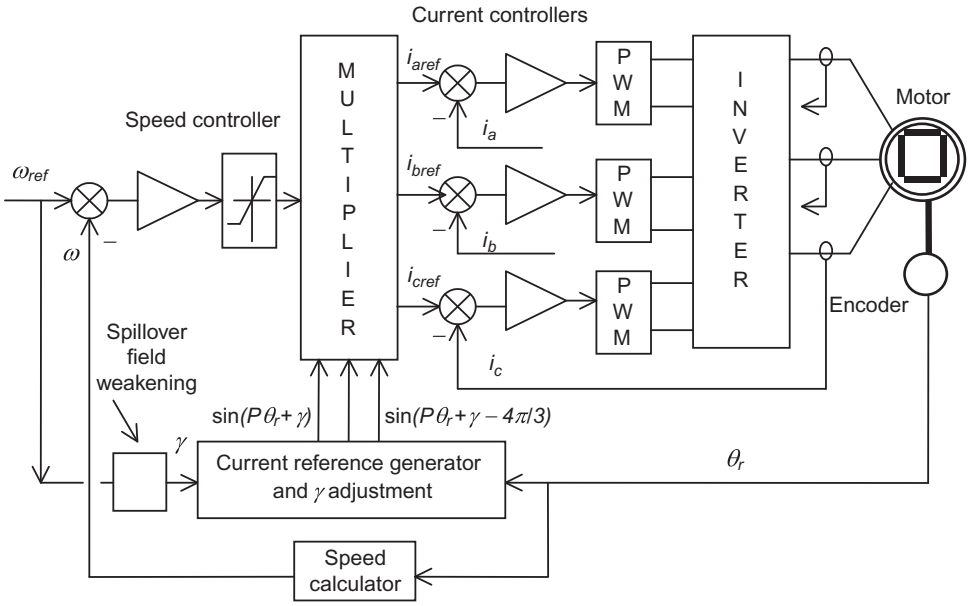

FIG. 30.51 Speed-controlled drive with the inner torque loop via current control in the stator reference frame.

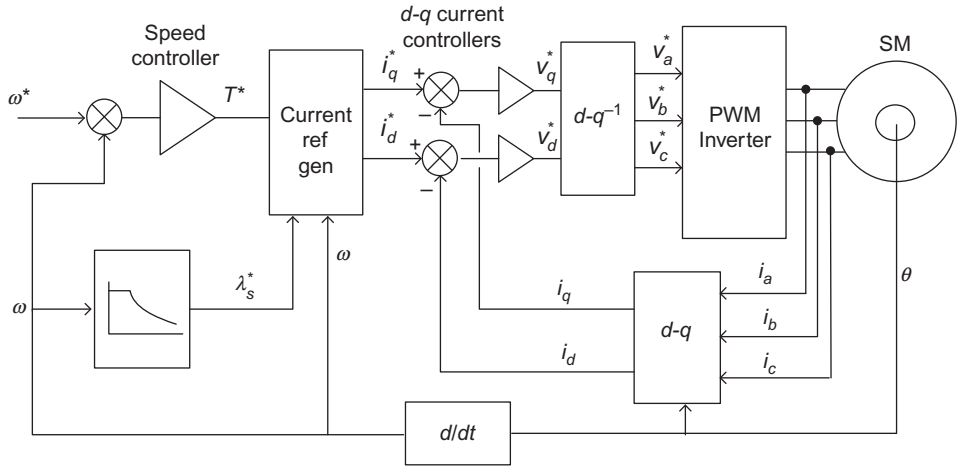

FIG. 30.52 Block diagram of a current-controlled drive.

The general torque relationship of a sine-wave motor supplied from a current-source SPWM inverter is given by Eq. (30.69) that is rewritten here:

$$T = \frac{3}{2}P\left(\lambda_f i_q + \left(L_d - L_q\right) i_d i_q\right) \tag{30.74}$$

Precise control of the developed torque control requires that both i_d and i_q be actively controlled in order to regulate it to the level determined by the error of the speed controller. For the surface-magnet synchronous motor, the large effective air gap means that $L_d \approx L_q$, so that i_d should be maintained at zero level. This implies that the i_d current reference in Fig. 30.52 should be kept zero. For the interior-magnet motor, $L_q > L_d$, so that i_d and i_q have to be controlled simultaneously to develop the desired torque. A few modes of operation are possible.

30.5.3.2 Operating Modes

Operation with maximum torque per ampere (MTPA) characteristic

In this mode of control, the developed torque T per ampere of stator current is the highest for a given rotor excitation. The combination of i_d and i_q that develops the maximum torque per ampere of stator current is indicated in Fig. 30.53. The reference signal for the inner torque loop normally determines the i_q reference, while the i_d reference is given by

$$i_d = \frac{\lambda_f}{2\left(L_q - L_d\right)} - \sqrt{\frac{\lambda_f^2}{4\left(L_q - L_d\right)^2} + i_q^2} \tag{30.75}$$

It should be noted that with $i_d = 0$, this mode of operation is achieved for the surface-magnet motor.

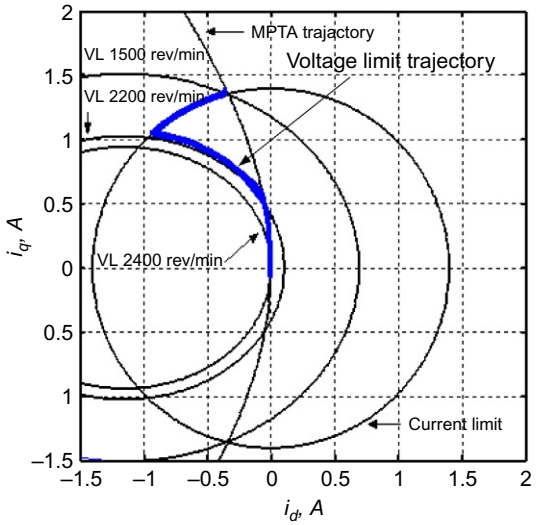

FIG. 30.53 $i_d - i_q$ Trajectories for the maximum torque per ampere characteristic and for maximum voltage and current limits of an interior PM motor.

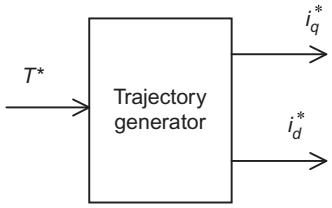

FIG. 30.54 i_d and i_q Trajectory generation satisfying the desired operating modes.

Operation with voltage and current limits

The maximum current limit of the motor/inverter, I_{smax}, is normally imposed by setting appropriate limits on i_d and i_q such that

$$i_d^2 + i_q^2 \leq I_{\text{smax}}^2 \tag{30.76}$$

Eq. (30.75) defines a circle around the origin of the $i_d - i_q$ plane.

The available dc-link voltage to the inverter places an upper limit of the motor phase voltage, V_{smax}, given by

$$V^2 = V_d^2 + V_q^2 \leq V_{\text{max}}^2 \tag{30.77}$$

$$\left(L_q i_q\right)^2 + \left(L_d i_d + \lambda_f\right)^2 \leq \left(\frac{V_{am}}{\omega}\right)^2 \tag{30.78}$$

where the stator voltages v_d and v_q are expressed in the rotor reference frame, as in Eq. (30.68). Eq. (30.78) is obtained from the voltage equation of Eq. (30.68) when the phase resistance R is neglected. Eq. (30.78) defines elliptical trajectories that contract as speed increases. All the three modes of operation are included in Fig. 30.53.

Operation with field weakening

This mode of operation is normally required for operating the motor above the base speed. A constant-power characteristic is normally desired over the full field-weakening range. For a given rotor excitation of λ_f and developed power of P_0, the developed torque T and the net rotor flux linkage required for constant-power operation can be determined. From this, the limiting values for i_d and i_q, which further constrain the allowable $i_d - i_q$ trajectory is also indicated in Fig. 30.53, can be determined.

The operating modes described in the preceding section are normally included in a trajectory controller that generates the references for i_d and i_q continuously, as indicated in Fig. 30.54.

30.6 Permanent-Magnet Brushless DC Motor Drives

30.6.1 Machine Background

Anyone studying electric machines would be aware that the classical synchronous machine offers the possibility of the very highest efficiencies. These machines have the current-carrying conductors in the stationary part; therefore, there is no need to transfer high power through a brush system. The field is provided on the rotating part either by an electromagnet, which does require some very low-power brushes, or, at best, by a permanent magnet with no power requirements at all.

This is clearly better than the traditional dc machine with high-power brushes and rotating conductors, with those conductors having a very poor path for heat to get away under overload conditions. You might ask, "why did we use so many of them?" It was of course because the dc machine offered the ability to control the speed fully and easily, which the synchronous machine, when running from the mains at a fixed frequency, was definitely not capable of. Thus, for example, all electric trains and trams built up to the 1980s, many of them still in service, use brushed dc motors. Low-cost, high-energy-density, and rare-earth PM materials available since 1984 changed this scene fundamentally.

The induction machine, the work horse of industry, is quite efficient, but because of the need to carry magnetizing current in the stator and load current and the existence of slip, it cannot be as good as the synchronous machine. It also innately has a very limited speed range.

All this changed with the advent of inexpensive, reliable power electronics. Quite suddenly, power electronics engineers had the ability to vary both the frequency and the amplitude of an ac supply and thus to provide the holy grail of variable-speed ac motors. This was first applied to induction machines, with the simplest form of open-loop control. The complexity of control for synchronous machines added substantially to the cost and was not so appealing. Today, the thought of putting a digital signal processor (DSP) or a microcontroller in a small motor controller is no longer as daunting as it was 10 years ago, so the distinction between the complexity of a controller for induction machines and synchronous machines has almost disappeared.

While power electronics radically changed our attitudes to electric machine design and operation, there was a second very important development that arrived on the scene at almost the same time: the appearance of very powerful rare-earth permanent-magnet materials.

The first rare-earth magnet material was samarium cobalt, used in very special applications such as space and defense, but it was then and still is very expensive. Neodymium-iron-boron (Nd-Fe-B) came next with even higher energy product. Energy product is a measure used to quantify the effectiveness of magnets. Nd-Fe-B began expensively but has continued to drop in price at a spectacular rate and recently became cheaper than ferrites in term of dollars per unit of energy product.

Thus, all the machines discussed here are permanent-magnet (PM) machines, in general using Nd-Fe-B magnets.

30.6.1.1 Clarifying Torque Versus Speed Control

As is well understood, given a fixed magnetic flux level, the magnitude of the current in a motor determines the magnitude of the torque out of the machine. In a general application if a torque is set, the speed is determined by the load. This is what happens when driving an automobile. The throttle or accelerator varies the torque. The speed can be very slow or very high for the same foot position, depending on the road conditions and vehicle motion history, even if the vehicle is in the same gear. This principle of torque control rather than speed control is fundamental to the operation of electric machines. When speed control is required in PMBDCMs, it is usual to implement torque control, with an extra outside control loop, like a cruise control in an automobile, to use the torque control to deliver speed control. So from here on, the discussion will describe torque control for the variable-speed motor.

30.6.1.2 Permanent-Magnet AC Machines

There are two quite different types of permanent-magnet ac machines, actually looking very similar in their physical realization but dramatically different in their electric characteristics and in the way in which they are controlled.

Permanent-magnet synchronous machines

These are simple extensions of the classical synchronous machine, where all of the voltages and currents are designed to be sinusoidal functions of time, as they are in the synchronous machine when used as a supply generator. These machines are known as permanent-magnet synchronous machines (PMSMs) or brushless ac machines and are discussed elsewhere in this book. While the application of sinusoidal waveforms everywhere is comforting to many and does result in less acoustic noise, less "stray losses," etc., there is in general a requirement to know the exact rotor angular position at every instant of time, with an accuracy in the order of one degree. This knowledge is then used to shape the current waveforms to be sure that they are in phase with the back emf of the windings. While much research is going on to run these machines without position sensors, the reality in the workplace today is that you need to include a relatively expensive shaft position encoder with your PMSM, if you wish to control it electronically.

Permanent-magnet brushless DC machines

A very much simpler possibility has emerged, which also gives the benefits of smooth torque and rapid controllability. This results in smaller minimum machine size, yielding maximum machine power density.

For this variant, the current waveforms and the back-emf waveforms are trapezoidal rather than sinusoidal. In this case, the machine is known as a permanent-magnet brushless dc machine (PMBDCM), with waveforms as shown in Fig. 30.55.

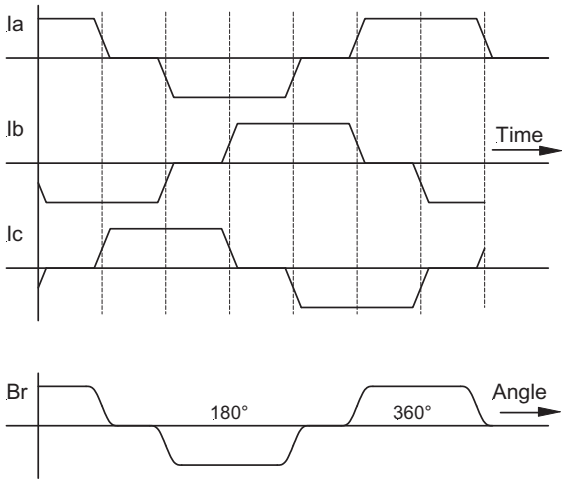

FIG. 30.55 Phase currents as functions of time and the flux density on the surface of the rotor as a function of angular position for a typical PMBDCM.

30.6.1.3 Brief Tutorial on Electric Machine Operation

The operation of electric machines can be explained in a variety of ways. Two possible and different methods are by the following:

1. Using an understanding of the interaction of magnetic fields and the tendency of magnetic fields to align. This tendency to align is what provides the force that makes a compass needle swing around, until it aligns with the earth's magnetic field.
2. Using the physical principle that "a current-carrying conductor in a magnetic field has a force exerted on it." This force is commonly known as the Lorentz force.

The difference between the two explanations is that the first method gives better "physical pictures." However, when one gets a little more serious, wanting to put in numbers, the force equations, while not greatly more difficult, are a little more challenging as they involve vector cross products.

With the second method, once the principle is accepted, there is a particularly simple scalar version of the force equation that very rapidly and simply gives numeric answers. The directions of the force, current, and motion are all orthogonal, that is, at right angles and a formal exposition would again use a vector cross product. However, provided the rules learned in high school science are applied, the scalar version, $F = BLI$ can be used, where F is the force in newtons, B is the flux density in tesla, L is the length of the conductor in meters, and I is the current in amperes.

Let us try both the methods, on the simple machine of Fig. 30.56.

The rotor is a magnet with a north and a south pole, and there is a coil of wire in the slots in the stator. Current is shown

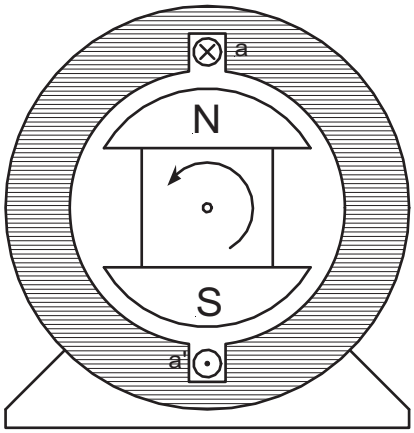

FIG. 30.56 A simple motor with a single coil in the stator and a permanent-magnet rotor.

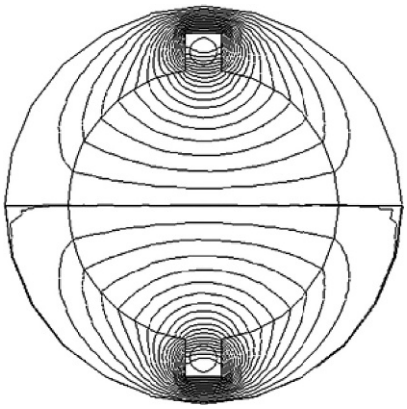

FIG. 30.57 A computer generated magnetic field for current in the windings and a stator made of electric steel.

going into the conductor called a at the top of the stator and coming out of the conductor called **a**′ at the bottom. To simulate a real machine more closely, one should imagine putting a one-turn "coil" of wire into the slot, with a connection made at the back of the machine to connect the top wire to the bottom, so that by applying a positive voltage to the top wire and a negative voltage to the end of the coil (the bottom wire), current will flow in at the top and out at the bottom as discussed previously.

Method 1. If the current is put into the top and comes out of the bottom as marked, then according to the right-hand rule (if you forget, then look at the Institution of Electrical and Electronic Engineers (IEEE) logo), magnetic flux will be forced to go through the center of the coil from right to the left, creating a north pole on the left. The flux will then double back through the iron frame of the motor to arrive back at the south pole on the right.

Fig. 30.57 shows a computer-generated magnetic field plot. This was produced using finite element analysis and modeling the stator as electric steel, the volume in the center as air and injecting current into the coil.

If the permanent-magnet rotor is then put inside the stator of Fig. 30.57, the rotor will align by rotating 90° counterclockwise.

Method 2. In this case, looking at Fig. 30.58, the conductor **a** will be immersed in a quite dense field produced by the magnets, with the flux lines going up the page in the rotor, across the air gap into the steel of the stator, heading down the stator to jump back across the lower air gap to return to the south pole. If a current is directed into the upper conductor and out of the bottom as before, it will produce force. Applying the direction rules associated with the Lorentz force, the force on the conductor will be to the right at the top and to the left at the bottom. Invoking Newton's third law, that action and reaction are equal and opposite, it is clear that if the wire is fixed, as it is, then there will be a force on the rotor to the left at the top and to the right at the bottom; thus, the rotor will move counterclockwise as before.

30.6.2 Electronic Commutation

If the rotor of Fig. 30.58 moves, then to keep it rotating in the same direction, sooner or later, the current in the conductors

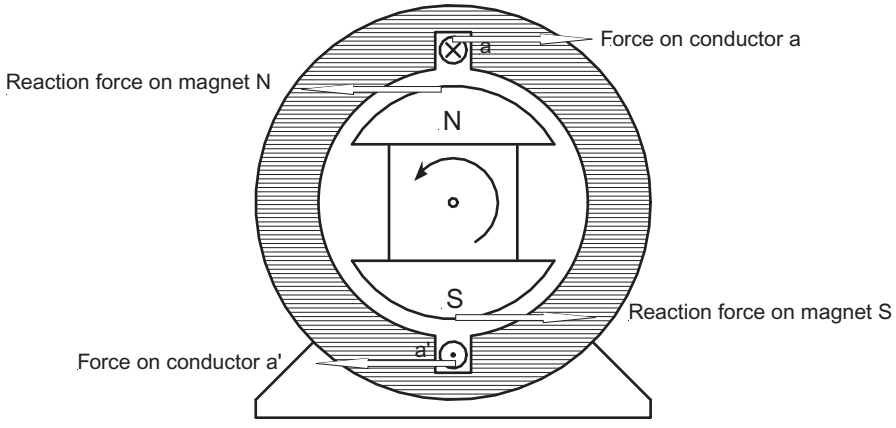

FIG. 30.58 Lorentz forces on conductor and rotor of a simple machine.

must be reversed. The time at which that needs to be done is when the rotor has moved to an almost aligned position, so it is not really a matter of time but a matter of rotor position. Since the rotor is a permanent magnet, it is a very simple matter to determine at least where the physical pole edges are using simple, reliable, and inexpensive Hall-effect (HE) sensors. These are small semiconductor devices that respond to magnetic flux density. (There are many ways to sense the position of the rotor; however, the remainder of this exposition will stay with the HE sensor for simplicity.)

A very simple motor, relying on the inertia of the rotor for continuous rotation, could have a control circuit that sensed when the rotor magnet was horizontal and then reversed the current in **aa**′ of Fig. 30.58.

The traditional "H-" bridge switching circuit shown in Fig. 30.59 does that very effectively. Switch drive logic must ensure that either S1 and S4 are on, or S2 and S3 are on and never S1 and S2 simultaneously or S3 and S4 simultaneously. This simultaneous operation would provide a short circuit. When this happens due to errors in the switch drive signal it is called "shoot through." There are generally important parts of the switch drive signal logic, discussed later, which try to make this impossible in normal operation.

In real motors, the permanent-magnet rotor field does not change instantaneously from north to south as the rotor rotates, so there would be reasonably large angles over which the torque could not be effectively produced. Also, more coils are put in so that the space of the machine frame is used more efficiently.

The use of three "phases," as in Fig. 30.60, is very common. There are many things that balance naturally in a three-phase system, and it is the simplest system with which it is possible to develop constant and unidirectional torque at all times and positions.

A very common method has developed, known as "six-step switching." In this system, three phases are used. They are connected in star, and there is a space between each of the magnet poles on the rotor, and the two phases are activated at any one time, the third "resting" as the space between the magnet poles passes over it.

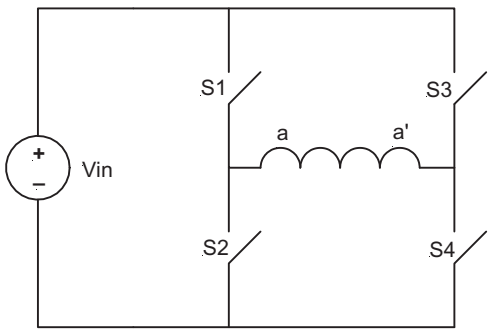

FIG. 30.59 An "H-" bridge circuit that can reverse the current through aa′, as drawn with mechanical switches.

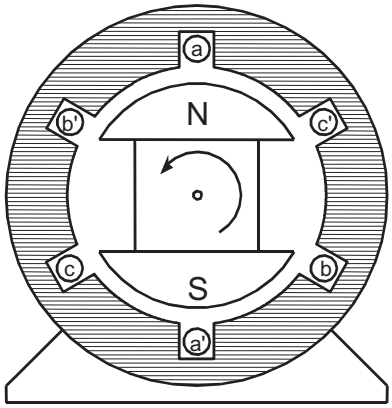

FIG. 30.60 The physical layout of a three-phase PMBDCM.

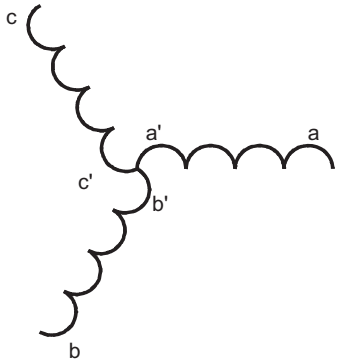

FIG. 30.61 The schematic connection of the windings shown in Fig. 30.60.

While the motor in Fig. 30.60 looks just like a three-phase synchronous machine, its operation is rather different.

As stated above, the windings are invariably star connected, as shown in Fig. 30.61.

30.6.2.1 Six Step Switching Explained

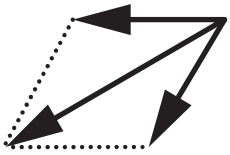
Consider the coil **aa**′, as shown in Fig. 30.60 and also diagrammatically in Fig. 30.61. Current driven into the **a** terminal, coming out of the **a**′ terminal, will produce, as discussed before, flux from left to right, as shown here.

Obviously if the current direction in **aa**′ is reversed, the flux will be

Similarly if current is driven into **b** and out of **b**′, flux will result

And if it is reversed,

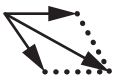
Finally, if current is driven into **c** and out of **c′**, flux will result

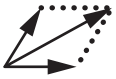


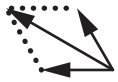
And if it is reversed,

The permanent-magnet rotor would tend to align with the flux arrow shown in each of the states above, as discussed under machine operation, Method 1.

Now, if the motor is wired in star as shown in Fig. 30.61 and a steady current is driven into **a** and out of **b**, the first and the fourth cases above occur at the same time. They add to produce a resultant,







and the rotor will tend to align with this resultant.

The Hall-effect sensors are positioned so that just as the rotor gets to within 60° of being aligned, another arrangement of the windings is energized, and the field jumps forward another 60°, so the rotor is 120° away from being aligned. The rotor is always an average of 90° away from its desired position!

If a controller has input power from positive and negative of a dc supply and outputs to the terminals **a**, **b**, and **c** only, then the sequence of connections shown in Table 30.2 will produce the resultant flux directions as shown, providing continuous rotation.

The switching of Table 30.2 is simply achieved by a variant of the "H" bridge, as shown in Fig. 30.62. This process of switching current into different windings is called commutation and is the equivalent of the sliding brush contacts in a traditional brushed dc machine.

TABLE 30.2 The sequence of connections that results in counterclockwise continuous rotation of the rotor of the PMBDCM of Fig. 30.60

When rotor gets to this position, connections are made as at right	Terminal a	Terminal b	Terminal c	Flux directions
	Current in	Current out	Zero	
	Zero	Current out	Current in	
	Current out	Zero	Current in	
	Current out	Current in	Zero	
	Zero	Current in	Current out	
	Current in	Zero	Current out	

30.6.3 Current/Torque Control

You may have noted that the discussion has been about current in the windings rather than the voltage across them. In very simple small brushless DC machines, like the one in the muffin fan in your computer power supply, voltages are connected directly to the windings. For these small motors, the resistance of the windings is relatively high, and this helps limit the actual current that flows and swamps inductive effects.

There is an extra difficulty that must be addressed with high-performance, high-efficiency, well-made machines, and it adds another layer to the control of the motor. Such machines can easily be designed with very low resistance windings. It is not uncommon to have windings for a 200 V machine at the 20 kw level with the winding resistances less than 0.1Ω.

When starting or at a low speed, the current in a winding is limited only by the very low resistance, and for the machine above by Ohm's law, $I = E/R$ would result in more than 2000 A.

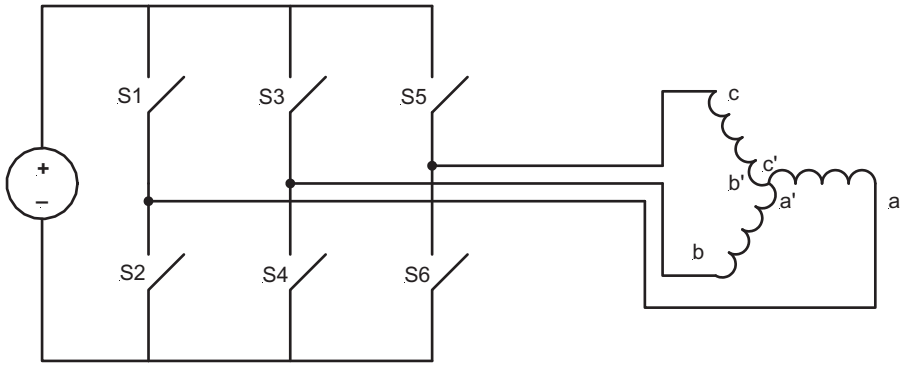


FIG. 30.62 The switching circuit used for commutation of a PMBDCM.

The most common requirement for a steady current in the windings is to provide a steady torque. There is always a back emf generated in the windings whenever the motor is rotating, which is proportional to speed and subtracts from the applied voltage. Thus, currents cannot be determined just by terminal voltage. The winding does however have inductance. Whenever the copper conductors are put in coils in an iron structure, particularly if there are low reluctance magnetic paths with only small air gaps, the creation of quite large inductances cannot be avoided. These are used to very good effect.

The nature of inductance is that when a voltage is applied to an inductor, instantaneous current does not result; rather, the current begins to increase and ramps up in a quite controlled fashion. If the voltage across the inductor is reversed, the current does not immediately reverse; rather, it ramps down, will go through zero, and reverses if the reversed voltage is left there long enough. However, if the voltage is alternated by switching rapidly, as can be done with power electronics, the current can be controlled to ramp-up and ramp-down either side of a desired current, staying within any determined tolerance of that desired current.

Figure 30.63 looks very much like the simple "H-" bridge commutation circuit but is performing a very different function. It is controlling the current amplitude to stay within a desired band. If S1 and S4 are turned on then the current will begin to increase from left to right in the winding. The current sensor in the circuit detects when the current reaches a value of half the hysteresis band of the comparator above the desired current level and initiates turnoff of S1 and S4 and turn-on of S2 and S3. (If they were all turned off at once, the inductive nature of the circuit would produce very high voltages that would cause arcing in mechanical switches or breakdown and failure of semiconductor switches; see later.) The current then begins to reduce. It reduces a small amount, down to half the hysteresis band of the comparator below the desired current level and then the switches reverse again. Thus, a desired current level is achieved, with an arbitrarily small triangular ripple superimposed, as shown in Fig. 30.64.

The general process of controlling by switching a voltage fully on or fully off at a high speed is called pulse-width modulation (PWM), and the specific method of current control

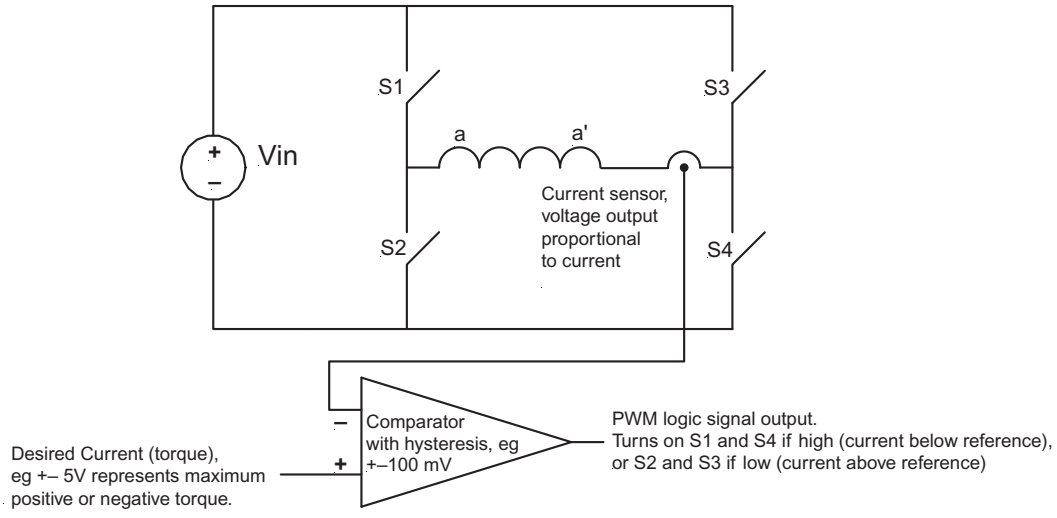

FIG. 30.63 Hysteresis band current control using pulse-width modulation (PWM).

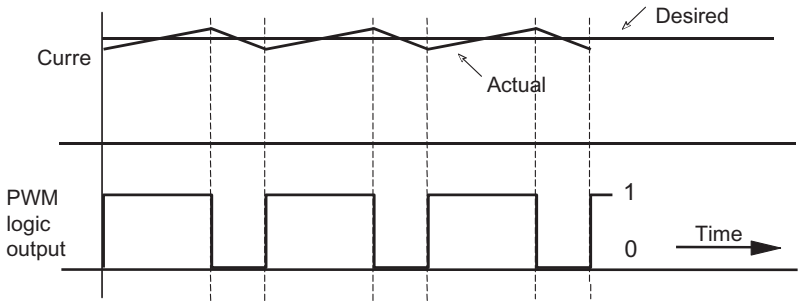

FIG. 30.64 Hysteresis band current control and PWM waveforms.

achieved above with PWM is called hysteresis band current control (HBCC).

Of course, to keep this current ripple small, the switching may need to be very fast, but with the modern semiconductor switches, there is no great problem up to 100 kHz for small machines and typically above 15 kHz for acoustic noise reasons, for machines rated up to several hundred kilowatts.

A perceived "drawback" of HBCC is that the switching frequency is determined by the circuit inductance, the width of hysteresis band, the back emf, and the applied voltage, ranging very widely in normal operation. It is not difficult, but it is a little more complicated, to use a fixed frequency, and a linear analog of the current error to modify the pulse width of the PWM signal.

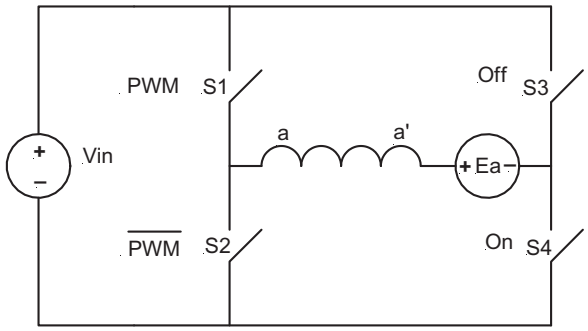

FIG. 30.65 H-bridge switching with one switch steadily on and a back emf.

30.6.3.1 Switching Losses

There is a practical limit to how often semiconductor switches can be operated. At every change of state, if the switch is carrying current as it is opened, then as the voltage rises across the switch and the current through it falls, there is a short pulse of power dissipated in the switch. Similarly, as the switch is closed, the voltage will take some time to fall and the current will take some time to rise, again producing a pulse of power dissipation. This loss is called switching loss. Fairly obviously, it will represent a power loss proportional to the switching frequency, and so the switching frequency is generally set as low as it can be without impinging on the effective operation of the circuit. "Effective operation" might well include criteria for acoustic noise and levels of vibration.

30.6.3.2 High Efficiency Method of Managing the Switching in the H Bridge

A very common way to control the current with the smallest number of switching transitions is to combine HBCC with, for example, alternating only S1 and S2 in Fig. 30.65 leaving S4 on all the time, on the understanding that there will be a back emf in the winding and the current can still be increased or decreased as desired.

Thus, when the motor is rotating and the back emf is somewhere between zero and the rail voltage, alternating two switches rather than four will still allow current control in the coil, using, for example, HBCC, exactly as before.

This is a very common control scheme and will need some extra logic to reverse the direction of rotation of the motor, either by turning S4 off and S3 on continuously or by swapping the control signals to the left and right "legs." For full-servo operation, normal H-bridge switching can be used, and the logic is slightly different, but not significantly more complicated. However, following the discussion above, the switching losses will be higher.

30.6.3.3 Combining Commutation and PWM Current Control

The real breakthrough is that one set of six switches can be used for both PWM and commutation. That is the clever part and also the confusing part when one first tries to understand what is going on.

Thus, in a controller, there are two control loops. The first is an inner current loop switching at, for example, 15 kHz to control carefully and exactly the current in two of the coils. Then, at a much lower rate, for example, at 50 times/s at 3000 rpm, the two coils doing the work are changed according to Table 30.2, controlled by an outer commutation loop, using information from the Hall-effect shaft position sensors.

A complete controller is shown in the block diagram form in Fig. 30.66. Various aspects of this block diagram will now be examined and explained in detail.

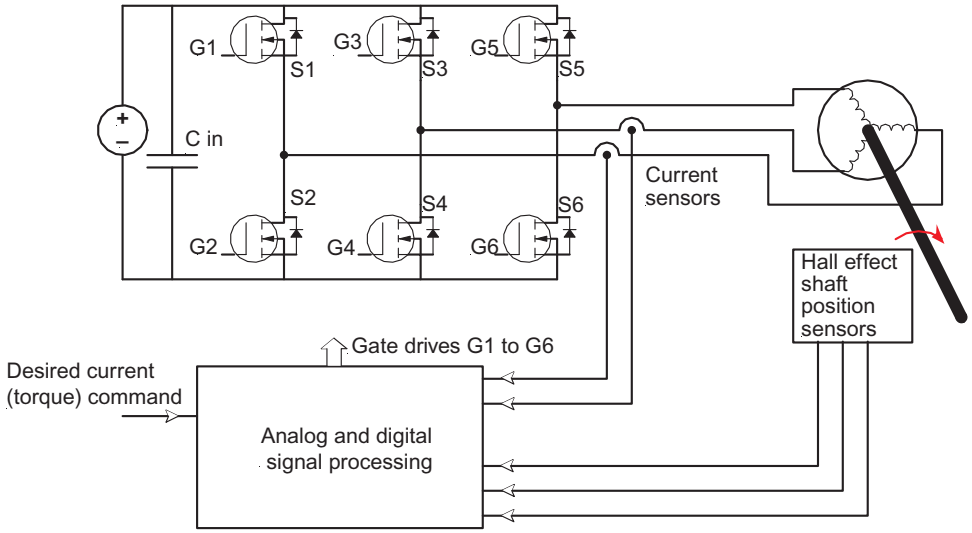

FIG. 30.66 A complete controller showing the two feedback paths, one for the position sensors and one for the current sensors.

Hardware details—semiconductor switches

The three most likely semiconductor switches for a six-step controller are the bipolar junction transistor (BJT), the metal oxide silicon field-effect transistor (MOSFET), and the insulated gate bipolar transistor (IGBT). Older controllers used BJTs; however, contemporary controllers tend to use MOSFETs for lower voltages and powers and IGBTs for higher voltages and powers. Both of these devices are controlled by a gate signal and will turn-on when the voltage of the gate above the source or emitter is greater than a threshold, which is typically about 5 V. Use of about 10 V is common. The devices are thus off when the gate voltage below the threshold. Systems typically use zero volts for the off state. The controller of Fig. 30.66 shows MOSFETs used for the six switches.

The trick is that the voltage at terminal **a**, also S1's source, is either ground or the positive potential of the battery, depending on which switches are on. Driving S2, S4, and S6 is easy since the MOSFET sources are all at the potential of the negative rail, and the lower gate drive signals are referred to this rail.

There is a range of dedicated integrated circuits that can drive the switches S1, S3, and S5 and that use a "charge pump" principle to generate the drive signal and the drive power internally, all related to the MOSFET source potential. Various approaches to this technical challenge of providing a floating gate drive are commonly discussed under the generic heading of "high-side drives."

For the most sophisticated drives, transformer coupling is used to provide a tiny power supply especially for the isolated gate drive and send the control signals either through an optocoupler or a separate transformer coupling. The high-side drive problems here are exactly the same as those encountered in the traditional buck converter or in drives for induction motors and PMSMs.

Dead time and flyback diodes

Two issues have been mentioned above that must be addressed when using high-speed electronic switches in inductive circuits.

The first, in Section 30.6.2 "Electronic Commutation," was that care should be taken to ensure that the upper and lower switches in the same "leg," (e.g., S1 and S2) are never turned on at the same time. If the controller attempts to turn one off and the other on at the same instant and switch turnoff is slower than turn-on (as it is with BJTs and IGBTs), then a short circuit will result for a brief time. The bus capacitor is usually very large to provide ripple current (see later) and usually of very high quality being fabricated especially for power electronic applications and can easily provide thousands of amperes for a few microseconds, which is enough to destroy the semiconductor switches.

The second issue, discussed in Section 30.6.3 "Current/Torque control," is that one cannot turn off both switches in a leg at the same time, even for a few nanoseconds, since the voltages resulting from attempting to interrupt current in an inductor will cause avalanche breakdown and failure of the semiconductors. This sounds like quite a dilemma.

There is actually a very simple and effective solution. At any transition, the control circuitry ensures that the active switches are all turned off before any switch is turned on, usually for a few microseconds. This is known as "dead time," and its provision is an essential part of most of the dedicated integrated circuits in use. Then, a "flyback"/"freewheel" diode is put in antiparallel with each semiconductor switch, and this provides the current path during dead time. These diodes are shown in Fig. 30.66.

The diode has a little more loss than the switch, since the diode forward drop is more than the switch drop. This is significant in a low-voltage controller. However, as stated above,

for a low-voltage controller, MOSFETs are the device of choice. They have a lesser known property, that when gated on, they can carry current in both directions. Intriguingly, the "on" state resistance is lower in reverse than in the forward direction! Thus, for low-voltage controllers, when the switch forward drop represents a significant contribution to losses, the MOSFET is turned on after dead time for both the current directions. Thus, the higher loss in the diode is only for a few microseconds.

It is not difficult to produce from the PWM signal an "I up" logic signal that is used to cause the current to increase and an "I down" logic signal used to decrease it, with the timing as shown in Fig. 30.67. The function can be executed in sequential logic, or with the simple analog timing circuits.

A. Semiconductor Detail

In MOSFETs and most IGBTs, there is a diode already within the device; it is unavoidable and results from the fabrication processes. In modern power semiconductors, this intrinsic diode is optimized to be a good switching diode. The serious designer, however, will check the specifications for reverse recovery of this diode, since in highly optimized controller designs, reverse recovery losses in the intrinsic diode can be significant and are very difficult to control. In low-voltage controllers, you can put a Schottky diode in parallel with the intrinsic body diode. The Schottky diode, with its lower forward voltage drop, will tend to take the current and has no reverse recovery problems, but the current must commutate to it from the semiconductor die, and the inductance of the connections is critical.

B. The Smoothing Capacitor on the Input to the Controller

This is a substantial capacitor, often very expensive, (it is shown in Fig. 30.66 as C in), and its design is quite challenging. The issue of smoothing is quite serious. If there are high frequencies or sudden current changes in the leads from the dc supply to the controller, they will radiate electromagnetic energy. Good design will limit the length of conductors in which the current is changing rapidly. Thus, a very large capacitor is placed physically as close to the positive bus of the switches as possible, aiming to have a steady current in the longer conductors from the dc supply, up to the capacitor. When the motor is running at, say, half speed and providing large torques, a very high level of ripple current is carried by this capacitor. Kirchhoff's current law (KCL) must be applied at node A, as shown in Fig. 30.68. Good capacitors have a ripple current maximum buried away in their specification sheet. It turns out that in general, the size of the capacitor in a given design has very little to do with how much voltage ripple you can tolerate at the bus but rather is determined by the ability to carry the ripple current without the capacitor heating up and failing. It has been known that the small electrolytics in prototype controllers mysteriously explode. On searching, it is found that they are in parallel with the main capacitor and quite close to it, so they carry a lot of ripple current, then heat up and explode!

30.6.4 The Signal Processing for Producing Switch Drive Signals from Hall Effect Sensors and Current Sensors

30.6.4.1 Operation of the Hall Sensors

The flux density directly under a magnet pole can be anywhere from 500 to 800 mT with Nd-Fe-B magnets. Hall-effect (HE) sensors with a digital output, called Hall-effect switches, change state at very close to zero flux density. Thus, they will change state when the north and south poles are equidistant from

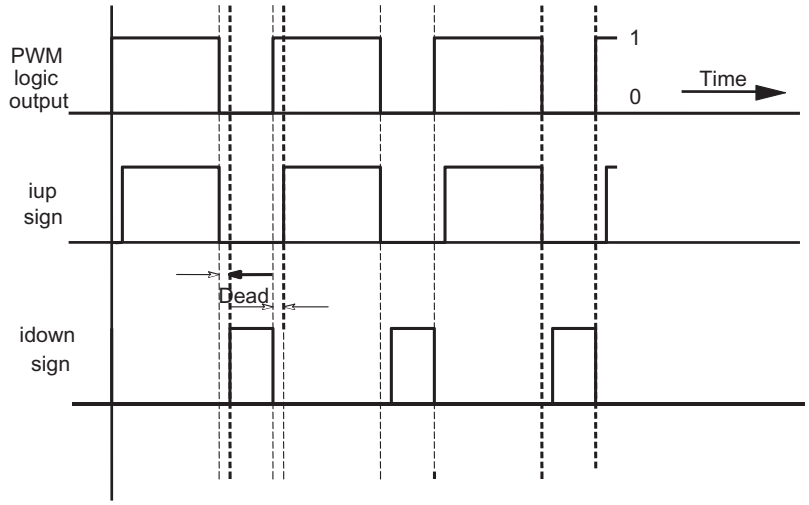

FIG. 30.67 Dead time introduced into the PWM logic signal, for switch drive.

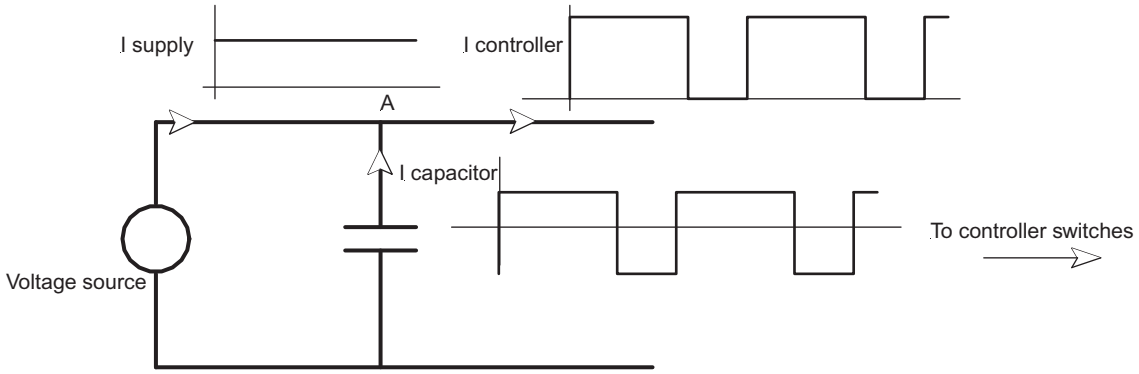

FIG. 30.68 Kirchhoff's current law at node A.

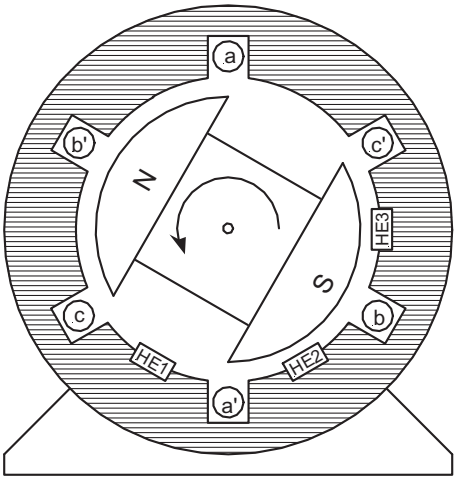

FIG. 30.69 Possible Hall-effect switch positions in a three-phase machine.

TABLE 30.3 Hall-effect switch outputs for rotor positions as shown, HE switches placed as in Fig. 30.69

When the center of the rotor north pole is in this sector	HE1 outputs	HE2 outputs	HE3 outputs
	1	0	0
	1	1	0
	1	1	1
	0	1	1
	0	0	1
	0	0	0

them, so that, for example, in Fig. 30.69, the switch HE1 is just changing state with the rotor as shown.

In practice, a motor designer needs to consider what magnetomotive force comes from the current in the windings that might result in flux that would trip the HE sensor at a slightly different time. If you follow all the above logic about six-step switching, you will see that you only need the magnet poles to have a span of a bit more than 120°. Using 180° magnet poles can add considerably to the cost and have an impact on such things as cogging torque. Actual designs often add extra "sense" magnets to cover 180° just at the circumferential strip where the HE switches are located, adding minimally to the magnet mass and ensuring good and accurate triggering.

However, if the switches operate as above, then Table 30.3 will result for the HE switches located as shown in Fig. 30.69.

30.6.4.2 Sensing the Current in the Motor Windings

Fig. 30.66 shows two current sensors. In the most sophisticated systems, there are two current sensors, one in each of the two motor phases. The current sensing is done at the winding and isolated either with a HE sensor in a soft ferromagnetic magnetic core surrounding the conductor (commercial items are available) or by using a resistive shunt sensor and some accurate analog signal isolation/coupling through transformers or optocouplers. The isolation is necessary since the potential at points **a**, **b**, and **c** is either the dc bus voltage or zero, depending on which switches are on, so that any current measure such as the small voltage across a shunt is superimposed on these very

large voltage changes. This is a very similar problem to that for the high-side gate drives discussed earlier. The current in the third winding is determined by the algebraic application of KCL, given the other two readings.

Simple controllers sometimes avoid the complexities of isolated current measurement and instead measure the current in the return negative supply, for example, from the bottom of the three lower switches to the bottom of the supply smoothing capacitor. This arrangement senses current when an upper and a lower switch is on, but not when the current is being carried in flyback diodes or by two lower switches. While it is inexpensive, it does not provide fully accurate control. The system works because the current should be decreasing when a measure is not available, heading toward zero, so switch or system failure due to overcurrent should not occur.

30.6.4.3 Management of Current Sensing

The controller must select the right current to increase or decrease, dependent on rotor position. The following convention is adopted. Positive current provides torque in the counterclockwise direction and therefore goes into winding **a**, **b**, or **c**.

All systems are capable of regeneration, which implies that negative torque can be commanded (without reversing the direction of rotation) to make the machine operate as a generator, developing retarding torque.

Thus, for the above sequence of sector determinations, referring back to Table 30.2, the output of current sensors should be directed to the current controller as shown in Table 30.4.

The addition and negation required can be carried out with the standard operational amplifier circuitry. The three required analog measures are then fed to a three to one analog multiplexer, gated from the HE switch signals suitably processed in combinational logic. The resulting single analog output is fed to the current comparator.

30.6.4.4 Distribution of Control Signals to the Switches

Given that the dead time is introduced elsewhere in sequential logic, or with timing circuits, it is a simple matter to develop the combinational logic for directing, or steering, the switching signals to the right switches. A typical scheme for a specific controller is shown in Table 30.5.

It is usual also to include some shutdown logic from dedicated protection circuits, for example, sensing overcurrent, overbus voltage, undervoltage for gate drive, and overtemperature both in the motor and in the controller power stage. For simplicity, this is not shown in the table.

TABLE 30.4 Current sensors to use as input to the current controller, for each of the six rotor-position sectors

30.6.5 Summary

30.6.5.1 What is Discussed in the Above

The physical principles of the operation of a PMBDCM have been discussed that lead to the development of the necessary parts of a power electronic controller. One specific type of current control, hysteresis band current control was explained in detail, and one specific type of switch logic pattern was developed. The exposition has included many of the issues that can cause difficulties for controller designers if they are not careful.

30.6.5.2 What is Not Discussed in the Above

Many PMBDCMs have more than one pair of poles. The arguments above can all be extended to higher pole count machines, by taking any mention of degrees to be electrical degrees rather than mechanical degrees. The controller discussed in detail only manages one direction of rotation. It is an excellent exercise and straightforward, but not trivial, to repeat the above steps, preparing the tables for clockwise rotation of the simple machine discussed above. Then, following the discussion in the first part of Section 30.6.3 "Current/Torque Control", about H-bridge switching, prepare the logic tables again for full bidirectional control, using the I up and I down logic signals exactly as above but applying them to both "legs" determined by the rotor position. Only one form of current sensing was discussed in detail. There are many simpler schemes in use that do not have quite the flexibility and accuracy of the above but that can suit certain applications. Similarly, there are other forms of current control such as the constant-frequency linear method briefly discussed. Shaft position sensors take many forms. Adherence to the HE sensor was for simplicity and to reinforce the magnetic field aspects of the machine operation.

30.7 Servo Drives

30.7.1 Introduction

Servo drives are motor drives that operate with high dynamic response. Historically, servo drives have implied motion-control systems in which sophisticated motor design, drive, and control techniques have been employed to obtain very much shorter positioning times than is possible with conventional drive systems. Examples are in machine-tool drives, robotic actuators, and computer disk drives. The power range for these drives has typically been in the range of a few kilowatts or less. This range has steadily increased in recent years as a result of advances in magnetic materials, machine design, power and signal electronic devices, and sensors.

Apart from the fast positioning times, "high dynamic response" also means that the drive operates with the following:

1. Very smooth torque up to a very low speed
2. Very high reliability and little maintenance
3. Immunity from load disturbances

The last of the foregoing items is brought about by robust and intelligent control algorithms; the first two items are brought about by innovative and often costly motor and controller designs. As a result of these, the cost of a servo-motor drive is usually much higher than the equivalent power-rated industrial drives.

The distinctions just mentioned may be easily recognized by noting, for example, that the drives that bring material to a mill may not require high performance, but the drives that take part in shaping, milling, or reducing the material should have high dynamic response in order to increase throughput and meet the accuracy requirements of the final product.

30.7.2 Servo Drive Performance Criteria

The performance of a servo drive can be expressed in terms of a number or factors such as servo bandwidth, accuracy, percentage regulation, and stiffness. While servo bandwidth indicates the ability of the drive to track a moving or cyclic reference, the percentage regulation and stiffness stipulate the drive's static holding performance for speed or position, in the face of disturbances from the load and in the supply conditions. The servo bandwidth, specified as a frequency in hertz or radian per second, is often found from the system frequency response plot, such as the Bode diagram.

The percentage regulation of a speed-controlled system often refers to the percentage change in speed from no load to full load. In a type-zero system, this figure will have a finite value. Many systems are type zero, albeit with a high gain so that the regulation is acceptably low. For such systems, the regulation is often necessary for operational reasons. In some applications, zero percentage error is required, which calls for type 1 or integral-type control system.

The servo stiffness is similar to the percentage error mentioned earlier, but it applies mainly for the position servo. It specifies the deflection of the load from its reference position, when full load torque is applied. It is usually the slope of the deflection versus the applied load torque in rad/Nm around the reference position.

30.7.3 Servo Motors, Shaft Sensors, and Coupling

Servo drives use motors that allow the desired goals of high dynamic response to be achieved. The important parameters/attributes of a servo motor are as follows:

1. High torque-to-inertia ratio
2. High torque-to-volume ratio
3. Low inductance of the motor windings
4. Low cogging torque at a low speed
5. Efficient heat dissipation
6. Low coefficient of shaft compliance
7. Direct-coupled, high-resolution, shaft-mounted sensors for position and speed

High torque-to-inertia ratio allows fast acceleration or deceleration of the drive when motion references are changed. This is often achieved through innovative low-inertia rotor design and low inductance in the stator winding. One example of a dc servo motor is the pancake-printed armature dc motor with no iron in the rotor, as indicated in Fig. 30.70. The rotor is sandwiched between axially mounted stator poles. The commutator is also on the printed armature. Another example is the disk rotor stepping motor, also without iron in the rotor, as indicated in Fig. 30.71.

The PM ac synchronous motors with modern high-energy-density magnets in the rotor, as described in Section 30.6, are also examples where the motor designer strives to minimize the rotor inertia. Modern permanent magnets allow the required air-gap flux to be developed with a much reduced volume of the magnets, consequently reducing the diameter of the rotor.

FIG. 30.70 Pancake armature of a dc servo motor. Courtesy—printed Motors Ltd., the United Kingdom.

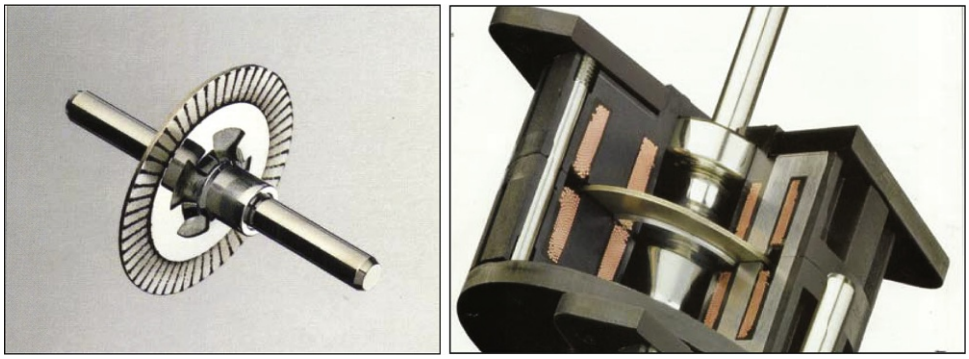

FIG. 30.71 A disk rotor stepping motor with ironless rotor for low inertia and inductance. Courtesy—Escap Motors.

It is well-known that the moment of inertia of a motor increases as the fourth power of its outer radius!

Another benefit of the modern permanent-magnet material is that the motor volume is also reduced. Servo motors often have to be located in a very confined space, and this reduction in volume is an important attribute.

The ironless designs mentioned earlier bring other benefits in the form of reduced inductance and cogging torque. Brushed pancake ironless motors are available with armature inductance as low as 100 μH.

From Section 30.2.2, the mechanical and electric time constants of a brushed dc motor are given by

$$\tau_m = \text{mechanical time constant} = \frac{R_a J}{K_E K_T} s$$

$$\text{and} \quad \tau_a = \text{electrical time constant} = \frac{L_a}{R_a} s.$$

It is well-known that for the highest load acceleration, the load inertia referred to the motor should be equal to the rotor inertia. Thus, in a matched system, the total inertia the motor accelerates is twice its own inertia. In other words, the motor inertia should also be minimized.

For a good servo motor, the ratio between the mechanical and the electric time constants is often of the order of five or more. This allows the speed and the current-control loops to be decoupled and noninteracting. The electric time constant of a motor determines how quickly the motor current may be changed and hence how quickly the torque can be changed. As also mentioned in Section 30.2, drives with a reasonable dynamic performance should have an inner torque loop. This torque loop is built around current loops, for the armature, for the brushed dc motor, or for the *d*- and *q*-axis currents for the induction and synchronous motor drives. Having a low inductance in the winding allows these currents to be followed dynamically changing current or the torque references with higher accuracy and bandwidth.

The cogging torque, if appreciable, causes the rotor to have preferential positions. As a result, the position accuracy of the motor may suffer. Another problem is the ripple in speed as the motor is operated at a low speed. At a high speed, these ripples due to cogging torque may be filtered out by the motor inertia; however, the extra loss due to cogging remains. The ironless or toothless rotor obviously produce very small cogging torque because of the absence of preferential paths for the air-gap flux to establish through the rotor iron of the brushed dc motor. The surface-magnet synchronous motor also has this feature. The interior-magnet motor normally has skewed stator slots to avoid the production of cogging torque.

Servo motors often operate with frequent start-and-stop duty, with the fastest allowable acceleration and deceleration during which the motor current is allowed to reach about 2–3 times the continuously rated current. The increased I^2R loss in such duty must be dissipated. This calls for adequate cooling measures to be incorporated in the motor housing. With such operation, it is sometimes possible to excite the mechanical resonance due to shaft compliance. This is avoided through proper arrangement of the shaft position/speed sensor and the coupling between the motor and the sensor. A belt-driven speed sensor may be acceptable for an industrial drive; however, for servo applications, a rigid, direct-coupled sensor mounted as close as possible to the motor armature is preferable. Additionally, the speed sensor is also required to have negligible noise. Speed signal from analog tachogenerators, which were used for speed sensing until recently, invariably needed to be filtered to remove the cyclic ripple/noise that existed. Such filtering often limits the maximum speed-control bandwidth of a drive.

30.7.4 The Inner Current/Torque Loop

The inner current loops in a servo-motor drive play a more important role than just limiting the current in case of overload. These loops operate continuously to regulate the motor-developed torque so as to meet the load demand, and for meeting the speed trajectory specified by the motion controller. Motor drives of high dynamic response currently employ PWM current sources. These sources use MOSFET or IGBT switching devices that allow the modulator to be operated with a switching frequency between 10 and 25 kHz. At these

frequencies, the inherent switching delay, which is equivalent to half of the PWM switching period, is made rather small for the bandwidth of the torque-control loop. The bandwidth of the current-control loops closely represents the bandwidth of the torque control. This is because the motor-developed torque generally is proportional to these currents. Servo drives up to a few kilowatts presently have torque-/current-control-loop bandwidths in excess of 1 kHz.

For higher power, fast-response drives, such as those used in the metal-processing industries, thyristor converters have been used for many years. The switching frequencies of these converters are rather low, being some multiple of the mains frequency, according to the converter chosen. Fortunately, the larger mechanical time constant of the larger power motor and the nature of the applications have allowed the 300 Hz (360 Hz in the United States) switch frequency of the three-phase thyristor bridge converter to be used satisfactorily in many applications requiring high dynamic response. The growing availability of faster and higher power IGBT devices is continually enhancing the dynamic performance of larger drives.

Fast-response, inner torque-control loops have in recent years been extended to ac induction and synchronous motors. These motors were hitherto considered only for industrial drives. The vector methods described in Sections 30.3 and 30.4, which employ inner quadrature axis current controllers in the synchronous (for the induction motor) or the rotor (for the synchronous motor) reference frame, have transformed the prospects of ac motor drives in servo applications.

Because of the fast dynamic response requirement of servo drives, the servo motor is nearly always driven with the maximum torque per ampere (MTPA) characteristic. Field weakening is normally not used. In other words, field control either directly for a brushed dc motor or a synchronous motor or indirectly through armature reaction (i.e., through i_d current control) for induction, or PM ac synchronous motors is not used for field weakening. It is nevertheless used for regulating the field at the desired level. Field weakening are mainly used for drives where the operation at higher than base speed with constant-power characteristic is desirable.

30.7.5 Sensors for Servo Drives

Servo drives require high-bandwidth current sensors for the inner torque loop and high-accuracy, noise-free speed and position sensors for the outer loops. The current sensor is often a Hall device with an amplifier, which can have bandwidths as high as 100 kHz. The inner current loop both limits and continuously regulates the motor current in all operating modes of the drive, including acceleration and deceleration. About 2–3 times, the continuous rated current of the motor is tolerated during acceleration and deceleration. This entails limiting the speed controller output to the level corresponding to the current sensor output for the limiting values of motor currents.

The current-sensor output has to be filtered to adequately remove the switching frequency noise. Otherwise, certain switching devices in converter may be overloaded. This task is more important for the thyristor converters for dc drives for which the switching frequency is rather low. This filtering of the current-sensor output limits the bandwidth of the current-control system, that is, the inner torque-control loop.

Performance of servo-motor drives depends critically on the noise and accuracy of the speed and position sensors. Synchro resolvers with 12-bit or higher digital accuracy were used in many servo-drive systems until recently. The advent of cheaper incremental and absolute optical encoders has altered this situation completely. These digital sensors are actually position sensors. The speed information is derived from positions measured by discrete differentiation. Such differentiation is not feasible with analog position sensors, because of the noise.

Analog tachogenerators are also avoided for speed servo systems. This is because of the tachogenerator ripples inherent in the sensor.

Modern discrete position sensors provide for virtually noise-free speed and position sensing. This allows very fast dynamic response to be achieved if the switching frequency of the converter allows it.

30.7.6 Servo Control-Loop Design Issues

30.7.6.1 Typical Controllers

Proportional controller

A proportional controller provides for a straight gain to amplify the error signal. It has no discriminatory properties. With the input and feed-resistance values indicated in Fig. 30.72, the total gain of the controller is $(K+1)$.

$$\text{For this controller,} \quad v_c = (K+1)(\theta_i - \theta) \tag{30.79}$$

Transient velocity feedback controller

It is well-known that a following error will exist in the preceding system when a moving or ramp reference is tracked. If a rate feedback, such as the speed feedback in a position-control system, is used to damp the system, this error is further increased.

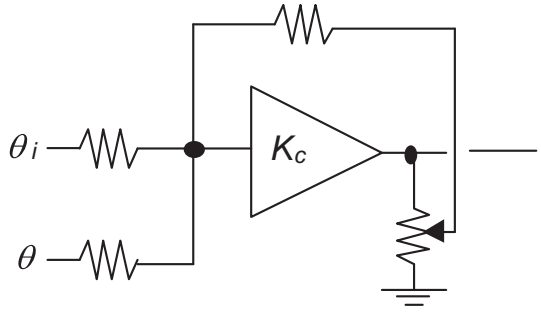

FIG. 30.72 Proportional controller.

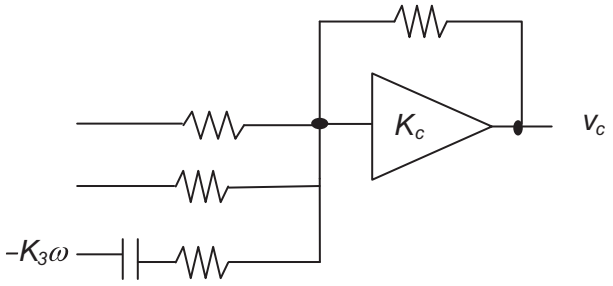

FIG. 30.73 Transient velocity feedback controller.

To overcome this following error due to velocity feedback, transient velocity feedback can be used as indicated in Fig. 30.73.

The speed (velocity) signal is passed through an RC circuit at the input of the amplifier circuit. An input current occurs only when the speed signal changes. In the steady state, the capacitor is fully charged, so that no following error in the steady state due to the velocity feedback can exist.

In the steady state when the velocities are equal, the output may lag or lead depending on the relative values of R_1 and R_2. It can be shown that in the absence of frictional load torque, as is often the case in servo applications, no following error is introduced if $R_1 = R_2$.

Integral controller

In the transient-velocity and error-rate feedback schemes, the following error will exist if viscous friction and load torque are present. If such loads are present, the system gain has to be infinity to have a zero error. Very large gains will make any physical systems unstable, unless bandwidth limitations exist. One way to employ infinite gain in the steady state is to use an integrator. This amplifies the steady-state error until it is eliminated.

Normally, a proportional plus integral (PI) action is used. A derivative term is normally not used in the control system of a drive system, since the drive feedback signals are very noisy. Instead, derivative signals are obtained through sensors such as tachogenerators. The structure of a PI controller is indicated in Fig. 30.74.

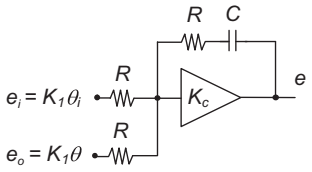

FIG. 30.74 Integral controller.

It can be shown that there will be no steady-state error even in the presence of frictional or other load torque.

Many types of more complex controllers are available, such as the variable structure controller. Drives with fuzzy controllers have also been in the marketplace for some years.

The controller circuits just described are usually implemented in analog circuits using operational amplifiers. Digital implementations are also being gradually introduced using the embedded microcontrollers and digital signal processors.

30.7.6.2 Simplified Drive Representations and Control

Consider the block diagram of Fig. 30.75 in which the individual elements (blocks) are represented in terms of their transfer functions in terms of the Laplace operators.

Here, $G_A(s)$, $G_C(s)$, $G_L(s)$, $H_T(s)$, and $H_F(s)$ represent the transfer functions of the power converter plus the motor, the controller, the load, the sensor (of speed in this example), and the filter following the sensor, respectively. The reference input for speed and the feedback signal are connected to a summing junction of an operational amplifier through resistors R_i and R_f, respectively.

The preceding system can be simplified to that shown in Fig. 30.76 and further to that in Fig. 30.77.

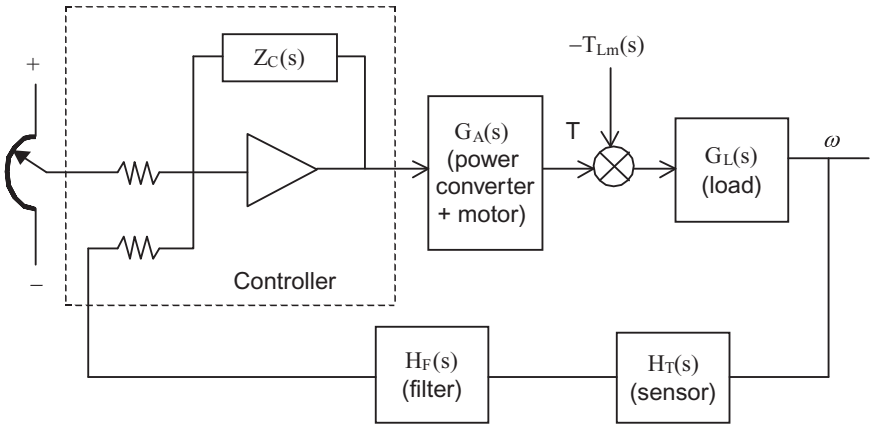

FIG. 30.75 Block diagram of a speed-control system.

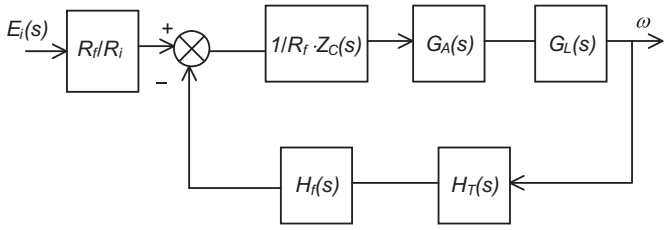

FIG. 30.76 Simplified representation of Fig. 30.75.

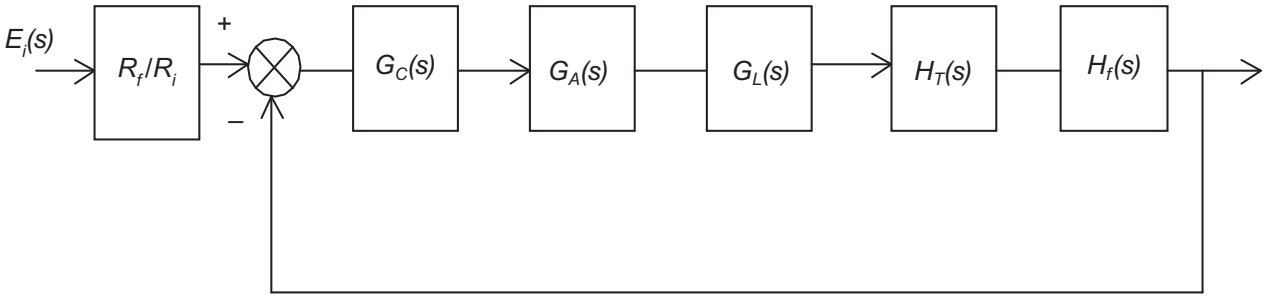

FIG. 30.77 Further simplified representation of Fig. 30.75.

In general, if the individual control blocks are approximated as first-order systems and are mutually decoupled, meaning that each block operates in a frequency band that is far outside the frequency bands of all other blocks, then the foregoing systems can be represented by a transfer function of the form

$$G_1(s) = \frac{K}{(1+sT_1)(1+sT_2)(1+sT_3)(1+sT_4)\cdots} \tag{30.80}$$

When T_3 and T_4 are much smaller time constants than T_1 and T_2, the preceding may be approximated by

$$G_1(s) \approx \frac{K}{(1+sT_1)(1+sT_2)(1+sT_s)} \tag{30.81}$$

where $T_s = T_3 + T_4 + \cdots$. A dc-motor speed-control system with current and speed sensors falls in this category. For such a system, there exist two dominant time constants (poles).

For such a system, a proportional plus integral controller is of the form

$$G_c(s) = \frac{(1+s\tau_1)(1+s\tau_2)}{s\tau_0(1+s\tau_{F1})(1+s\tau_{F2})} \tag{30.82}$$

One optimization criterion (Kessler's) stipulates that $\tau_1 \approx T_1$, $\tau_2 \approx T_2$, and $\tau_o \approx 2KT_s$. With this stipulation, the transfer function of the complete system is given by

$$G(s) = G_1(s)G_c(s) = \frac{1}{2sT_s(1+T_s)} \tag{30.83}$$

and

$$\frac{V(s)}{V_i(s)} = \frac{G}{1+G} = \frac{1}{1+2sT_s+2s^2T_s} \tag{30.84}$$

Note that the two filter time constants τ_{F1} and τ_{F2} are included in $G_c(s)$ for the sake of its realizability. These can be relegated to frequencies far higher than the range of interest and can be ignored for further analysis of the system. For an unit step input of V_i, the output V is given by

$$v(t) = 1 - \sqrt{2}e^{-1/2T_s}\sin\left(\frac{t}{2T_s} + \frac{\pi}{4}\right) \quad \text{for} \quad t \geq 0. \tag{30.85}$$

A typical output is indicated in Fig. 30.78.

If the transfer function $G_1(s)$ has one dominant time constant $T_1(s)$, as for the field current control of a dc motor, a suitable controller is the form

$$G_c(s) = \frac{(1+sT_1)}{s\tau_0(1+sT_F)} \tag{30.86}$$

In some cases, the transfer function $G_1(s)$ is of the form

$$G_1(s) = \frac{K}{sT_1(1+sT_2)(1+sT_s)} \tag{30.87}$$

where T_s is the sum of a number of short-time constants, associated with sensors, switching frequency, and so on. The

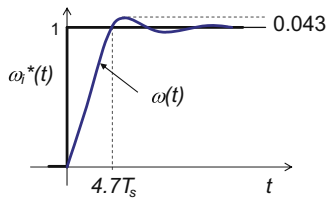

FIG. 30.78 Response of the optimized system of Fig. 30.75.

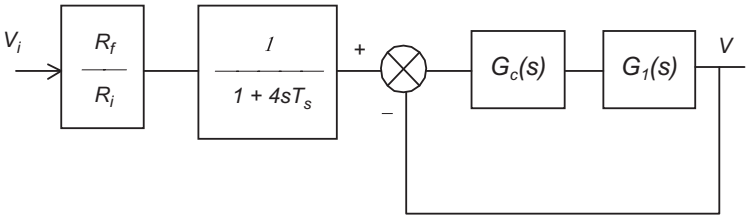

FIG. 30.79 Block diagram representation of a drive with one dominant time constant.

current controller of the dc motor with back emf has such a characteristic. A suitable PI controller for this system is

$$G_c(s) = \frac{(1+s\tau_1)(1+s\tau_2)}{s\tau_0(1+s\tau_{F1})(1+s\tau_{F2})} \tag{30.88}$$

For this system, Kessler's optimization criterion stipulates that

$$\tau_1 = 4T_s, \tau_2 = T_2, \text{ and } \tau_0 = \frac{8KT_s}{T_1}$$

The transfer function of the complete system is then

$$\frac{V(s)}{V_i(s)} = \frac{1+4sT_s}{1+4sT_s+8s^2T_s^2+8s^3T_s^3} \tag{30.89}$$

The peak overshoot of this system to a unit step unit is usually unacceptable, as indicated by the response of Fig. 30.79. This overshoot is usually reduced by inserting a first-order filter in the reference circuit. The filter network and the responses are given in Fig. 30.80.

30.8 Stepper Motor Drives

30.8.1 Introduction

A stepper motor is a positioning device that increments its shaft position in direct proportion to the number of current pulses supplied to its windings. A digital positioning system without any position or speed feedback is thus easily implemented at a much lower cost than with the other types of motors, simply by delivering a counted number of switching signals to the motor. Typically, a 200 steps-per-revolution stepper motor with 5% stepping accuracy will be equivalent to a dc motor with a 12-bit (or 4000 counts/rev) encoder plus the closed-loop speed and position controllers for obtaining similar positioning resolution. This advantage, however, is obtained at a cost of increased complexity of the drive circuits. A disadvantage of the motor is perhaps its inability to reach an absolute position, since the final position reached is only relative to its arbitrary initial position. Nevertheless, the true digital nature of this motor makes it a very suitable candidate for digital positioning systems in many manufacturing, automation, and indexing systems.

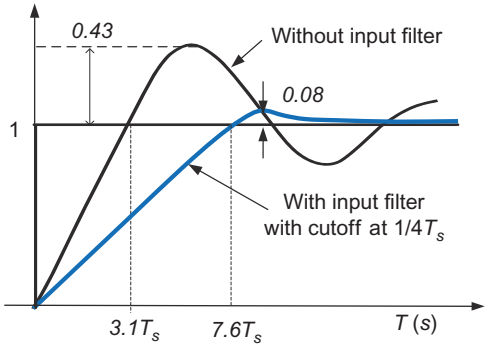

FIG. 30.80 Optimized response of the system of Fig. 30.79.

The working principle of stepper motors is based on the tendency of the rotor to align with the position where the stator flux becomes maximum (i.e., seeking of the minimum-reluctance position, also called the detent position). The rotor and the stator are both toothed structures, and the stator normally has more than two windings to step the rotor in the desired direction when they are energized in certain combinations with current. Some motors additionally have permanent magnets embedded in the rotor that accentuate an already existing, zero-excitation detent torque. These motors hold their positions even when the stator excitations are removed completely, a feature desirable for some applications.

In addition to the point-to-point stepping action, these motors can also be operated at high slewing speed, simply by increasing the pulsing rate of phase currents. Since the motor is inherently a synchronous actuator, the pulsing rate has to be increased and decreased properly, so that the rotor may follow it. At the end of a complete run, the motor always stops at the desired incremental position or angle without any accumulated error. The only error that may be encountered is mainly due to the machining accuracy of the teeth in the stator and rotor. This error is of the order of about 5% of one step position/angle, and it is nonaccumulative.

30.8.2 Motor Types and Characteristics

30.8.2.1 Single-Stack Variable-reluctance Stepper Motor

Single-stack motors are normally of the variable-reluctance type with no excitation in the rotor. The cross section of a three-phase motor with two stator poles/phase and four rotor poles is indicated in Fig. 30.81. The motor can be stepped clock or anticlockwise by energizing the phase winding in the ABCA

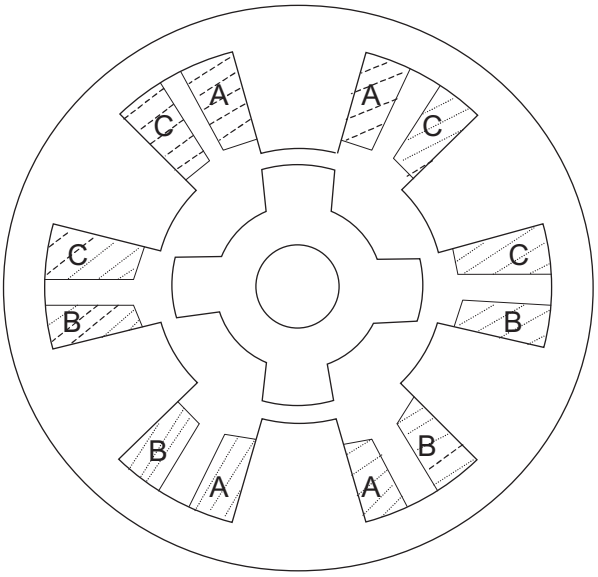

FIG. 30.81 Cross section of a single-stack variable-reluctance stepper motor.

or ACBA sequence, respectively. The step angle, that is, the angle moved by the rotor for each change in excitation sequence, of the motor is given by

$$\theta_s = \frac{360}{NP} \text{ degrees} \tag{30.90}$$

where N is the number of phases in the stator and P is the number of poles in the stator. Single-stack motors typically have larger step angles than other types because of limitations of space for the windings. The step angle of these motor tend to be larger than the multistack and hybrid stepper motors.

For each excited winding, the motor develops a torque angle ($T-\theta$) characteristic as indicated in Fig. 30.82. Note that there are two equilibrium positions of the rotor, namely, X and Y, where the motor develops zero torque.

The position X is referred to as the stable detent position, around which the rotor develops a restoring torque when displaced. The restoring torque increases as the rotor is moved from its detent position, becoming a maximum T_{max} on either side of this position. The slope of the $T-\theta$ characteristic around this detent position and the maximum torque, both of which depend on the level of excitation, indicate how far the rotor will be displaced under load torque. This means that the level of excitation also affects the position holding accuracy of the motor.

The motor may also be excited in the sequence: AB-BC-CA or AB-CA-BC for forward and reverse stepping, respectively. The two-phases-on scheme develops more torque around the detent positions at the expense of twice the resistive losses.

Yet, another excitation scheme is AB-B-BC-C-CA-A-AB for forward stepping and AB-A-AC-C-BC-B-AB for reverse stepping. In this scheme, the step size is halved as opposed to the full-step size of the previous sequences. Two different levels of torque are produced for alternate detent positions. However, the reduced step size and the more damped nature of each step may outweigh this disadvantage.

30.8.2.2 Multi Stack Variable-Reluctance Stepping Motor

In a multistack variable-reluctance motor, the stator windings are stacked along the shaft. Each stack section now has the same

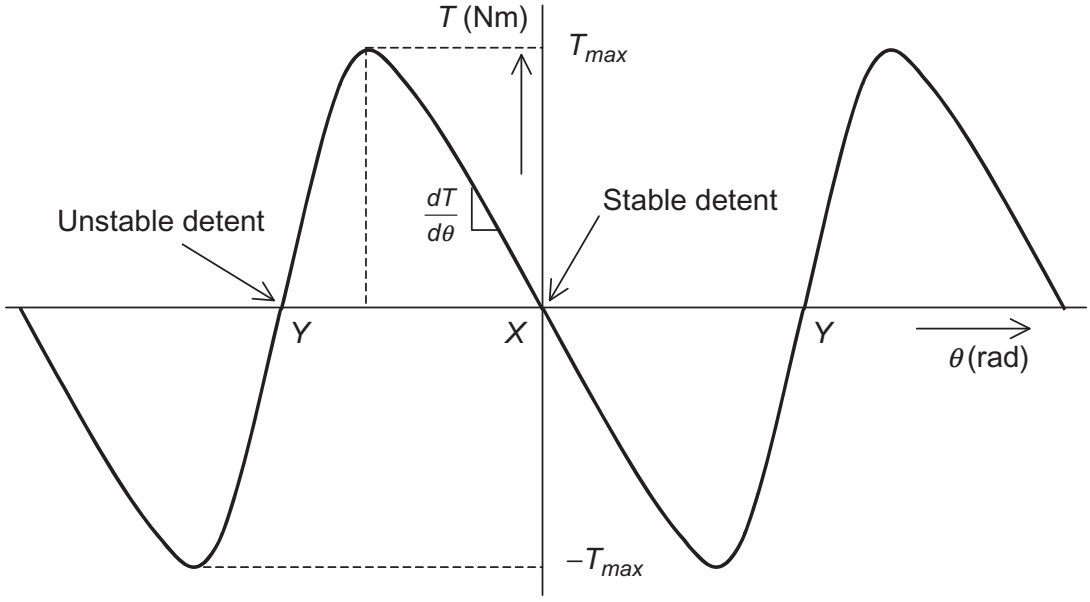

FIG. 30.82 Static torque characteristic of a stepper motor.

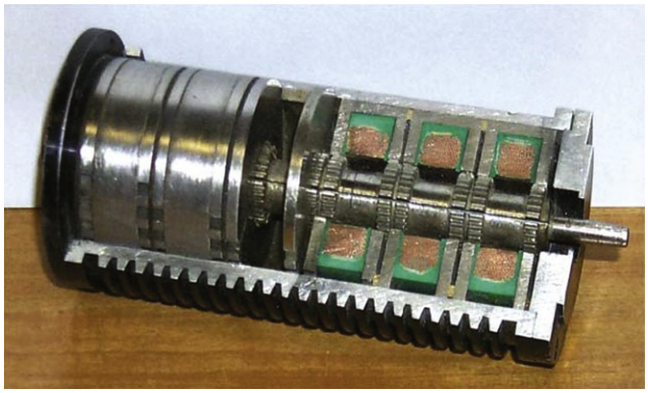

FIG. 30.83 Cutout view of a six-phase, multistack, and variable-reluctance stepper motor. Courtesy: Pratt Hydraulics, the United Kingdom.

number of poles in the stator and the rotor. Normally, each stator stack is staggered with respect to its neighbor by *one/Nth* of a pole pitch, where N is the number of stator/rotor phases or sections. The cutout view of Fig. 30.83 shows some internal details of a six-phase multistack motor, in which each stack has a phase winding between two rings, each with 32 stator and rotor poles. The step size of this motor is

$$\theta_s = \frac{360^\circ}{Np} = \frac{360^\circ}{6 \times 32} = 1.875^\circ \tag{30.91}$$

The excitation sequence of this motor is similar to the ones mentioned in Section 30.8.2.1, except that more excitation sequences are available. When a stator winding is energized, the rotor poles of that section tend to align with those defined by the stator excitation. The stator and rotor teeth in the other sections are not aligned. By changing the combination of excited phases to the next in sequence, the rotor is made to move by one step angle.

30.8.2.3 Hybrid Stepping Motor

A hybrid stepper motor has an axially oriented permanent magnet sandwiched between two sections of the stator and rotor, as indicated in Fig. 30.84. The magnetic flux distributes radially through the two stator and rotor sections, both of which are toothed, and axially through the back iron of the stator and the shaft. The stator has two-phase windings, each of which creates alternate polarities of magnetic poles in both sections of the stator. Stator windings are excited with bipolar currents, as opposed to the unipolar currents in the variable-reluctance motors of the two preceding sections. The magnetic flux produced by the stator windings not only is circumferential in each stator and rotor section but also crosses the air gap radially. It does not, however, pass through the rotor magnet. The two rotor sections are offset by half its tooth pitch.

The rotor magnet causes to the stator and rotor teeth to settle at the minimum reluctance position with a modest amount of

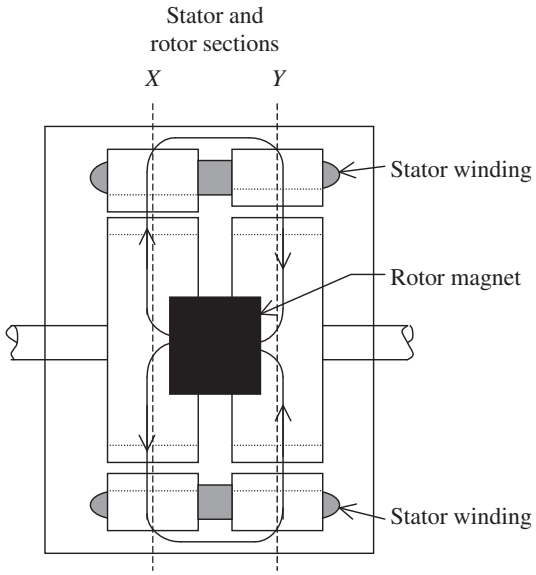

FIG. 30.84 Axial cross section of the hybrid motor.

detent torque to keep the rotor in position, when the stator windings are not energized. The rotor magnetic flux distributes outward through stator poles 3 and 7 in section X and inward through poles 1 and 5 in section Y, as shown in Fig. 30.85A and B. When the stator windings A and B (indicated as dark and faint shaded, respectively) are energized with positive and negative currents, respectively, the resulting stator flux also distributes through these same poles, so that the rotor then develops a much higher detent torque $(T-\theta)$ characteristic. The motor can be stepped forward or backward by energizing windings in sequence $A\overline{B} - AB - \overline{A}B - \overline{AB}$ or $A\overline{B} - \overline{AB} - \overline{A}B - A\overline{B}$ respectively, where the over bar indicates the polarity of currents in phases A and B.

The stepping angle of a hybrid stepper motor is given by

$$\theta_s = \frac{90^\circ}{P} \tag{30.92}$$

where P is the number of rotor poles.

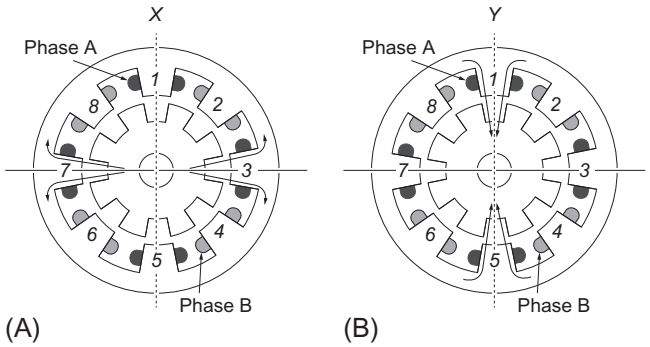

FIG. 30.85 Cross section of the hybrid motor: (A) section X and (B) section Y.

30.8.2.4 Permanent-Magnet Stepping Motor

Permanent-magnet stepper motors have alternate polarities of permanent magnets on the rotor surface, while the rotor iron, if it is used, has no teeth. In one type of construction, the rotor has no iron, and the stator consists of two windings that set up alternate poles when energized, just as in the case of the hybrid motor. The rotor consists of permanent magnets, alternately polarized, attached to the surface of a nonmagnetic disk, as shown in Fig. 30.86. The stator and rotor fluxes cross the air gap, one on either side of the disk, axially.

30.8.3 Mechanism of Torque Production

30.8.3.1 Variable-Reluctance Motor

If it is assumed that the current in the excited winding remains constant, the production of static torque of a variable-reluctance motor around a detent position is given by

$$T = \frac{dW_m}{d\theta} \tag{30.93}$$

This torque expression may also be expressed as in Eq. (30.94), when it is further assumed that the inductance of the excited winding at any given position remains constant for all currents:

$$T = \frac{1}{2} i^2 \frac{dL}{d\theta} \tag{30.94}$$

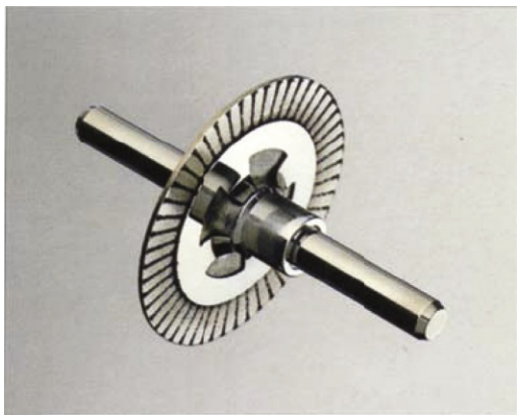

FIG. 30.86 Rotor of a PM stepper motor. Courtesy: Escap Motors.

The developed torque is due to the variation of inductance (or reluctance) with position. Note that the direction of current has no bearing on the developed torque. When the stator and rotor poles are perfectly aligned, as indicated in Fig. 30.87A, the inductance L changes little with a small change in θ. The developed torque is thus very small around this position, corresponding to the position X in Fig. 30.82. When the stator and rotor teeth are unaligned, as in Fig. 30.87B, L changes more significantly with θ, and the restoring torque becomes much larger. As θ increases, $dL/d\theta$ goes through a maximum, producing T_{max}. It should be noted that around a stable detent, L reduces as θ increases, so that the slope of the $T-\theta$ characteristic is negative at the origin. Beyond the position where T_{max} is developed, L increases as a result of the next set of rotor teeth coming under the stator teeth. This explains the drop in T_{max} and the positive slope of the $T-\theta$ characteristic in the region between where T_{max} is developed and Y in Fig. 30.82.

If stepper motors are operated in magnetically linear region where L remains constant with the current for a given angular position, the developed torque per unit volume is small. Because of this, steppers motors are normally driven far into saturation. Eq. (30.94) then does not represent the torque characteristic adequately.

For a saturated stepper motor, the calculation of the $T-\theta$ characteristic for any given current involves complex computation of stored energy, or coenergy, for each position of the rotor. This requires the magnetization characteristics of the motor for different levels of stator currents and rotor positions to be known. Reference [33] may be consulted for further reading on this.

30.8.3.2 Hybrid and PM Motors

In hybrid stepper motors, most of the developed torque is contributed by the variable-reluctance principle explained earlier. The rest is developed by the rotor magnet in striving to find the minimum-reluctance position. It should be noted that the alternate polarities of the magnetic poles created by each winding may be reversed by the direction of its current. Consequently, the polarity of the winding currents also determines the direction in which the developed torque increases positively around a detent position.

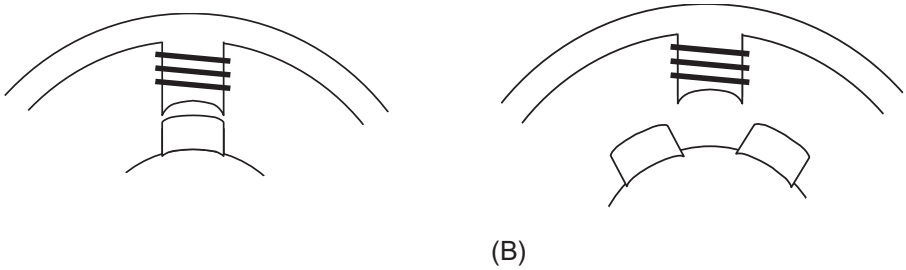

FIG. 30.87 Stator and rotor teeth alignment: (A) aligned position, $\theta = X$, and (B) unaligned position, $\theta = Y$.

30.8.4 Single- and Multi-Step Responses

When the rotor is at a detent position and phase currents are changed to a new value, the detent position is moved, and the rotor proceeds toward it and settles down at the new detent position. The movement of the rotor is influenced by the shape of the $T-\theta$ characteristic and the load friction. The rotor stepping is normally quite underdamped. The final positioning error is also determined largely by the load torque. For instance, if the $T-\theta$ characteristic is assumed to be a sinusoidal function of θ, the error in stepping is given by Eq. (30.95), where T_{max} is the peak of the $T-\theta$ characteristic and T_L is the load friction torque.

$$\theta_e = \left|\sin^{-1}(T_L/T_{\max})\right| \tag{30.95}$$

However, this error does not accumulate as further stepping is performed. If the phase currents are switched in succession, the rotor makes multiple steps. Typical single- and multistep responses are as indicated in Fig. 30.88

The maximum rate at which the rotor can be moved depends on several factors. The rise and fall times of the winding currents, which are largely determined by the electric parameters of the windings and the type of drive circuits used, and the combined inertia and friction parameters of the motor and load are important factors.

The discrete signals to step the motor in the forward or reverse direction are translated into current-switching signals for the drive circuits. This translator is a simple logical operation that is embedded in most of the integrated circuits available for driving stepper motors.

In many applications, the stepper motor is operated at far higher speeds than that it can start/stop from. The performance of a stepper motor at a high speed is normally given in terms of its pullout torque-speed ($T-\omega$) characteristic. This characteristic indicates the maximum average torque; the motor may develop while stepping continuously at a given rate. This torque is also largely determined by the parameters of the motor and its drive circuits. Fig. 30.89 indicates the typical shape of the pullout $T-\omega$ characteristic of a stepper motor drive.

At a low speed, the pullout torque is roughly equal to the average value of the positive half cycle of the $T-\theta$ waveforms of Fig. 30.82. At a high speed, the finite but fixed rise and fall

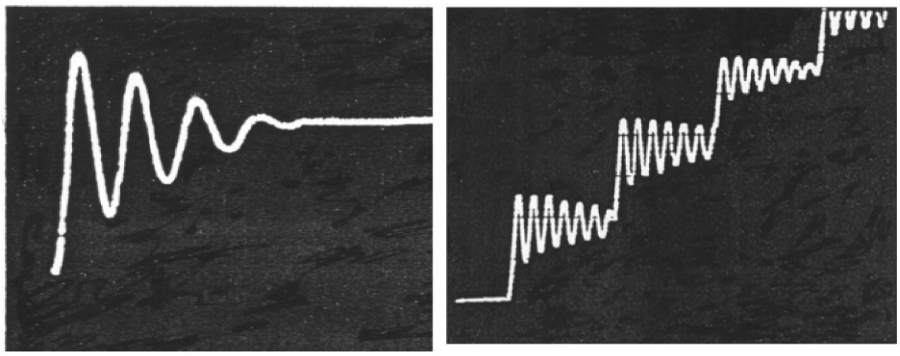

FIG. 30.88 Typical step responses of a stepper motor: (A) single-step response and (B) multistep response.

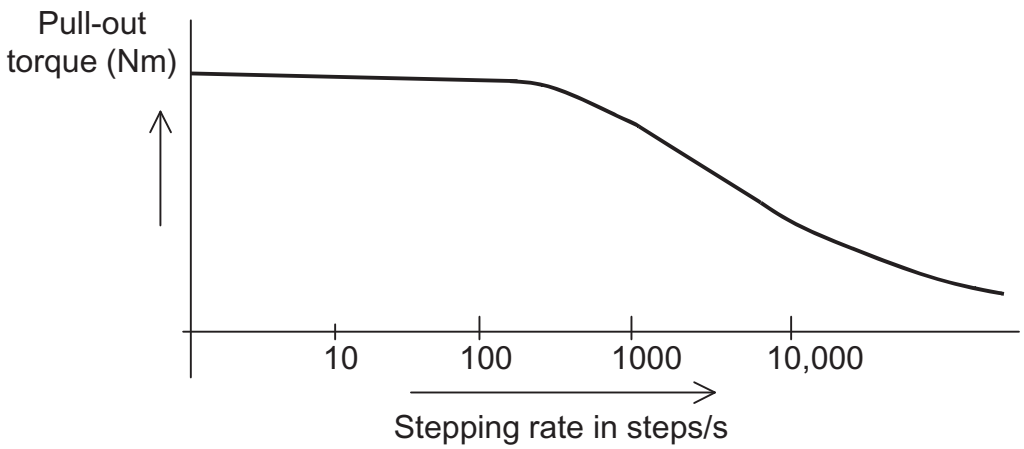

FIG. 30.89 Typical pullout torque characteristic of a stepper motor.

times of the currents and the back emf of the winding reduces the extent to which the windings are energized during each switching period. Consequently, the pullout torque of the motors falls as the stepping rate (speed) increases.

For operation at a high speed, the stepping rate is gradually increased and decreased from one speed to another. Without careful acceleration and deceleration to and from a high speed, the motor will not be able to follow the stepping commands and will lose its synchronism with the stepping pulses or winding excitations. The acceleration and deceleration rates of a stepper motor are also determined largely by the pullout torque characteristic.

Stepper motors are known to suffer from mechanically induced resonance and consequent misstepping when its switching rate falls within certain bands, which are largely determined by the way the developed torque varies with time, as the motor steps. Careful selection of stepping rate is normally employed to overcome the problem. Some shaft-mounted external damping measures may also be used when the stepping rate needs to be continuously varied, such as in the case of machine-tool profile following.

30.8.5 Drive Circuits

Two types of drive circuits are in general use for stepper motors. The unipolar drive is suitable for variable-reluctance stepper motors, for which the developed torque is determined by the level of current, not its polarity. For hybrid and permanent-magnet motors, the direction of current is also important, so that the bipolar drive circuits are more suitable.

30.8.5.1 Unipolar Drive Circuits

In its simplest form, the unipolar drive circuits, one for each winding, are as indicated in Fig. 30.90. The transistor (MOSFET) is turned on to energize the winding, with a current that is limited either by the winding resistance or by hysteresis or PWM current controllers. The freewheeling diode allows the

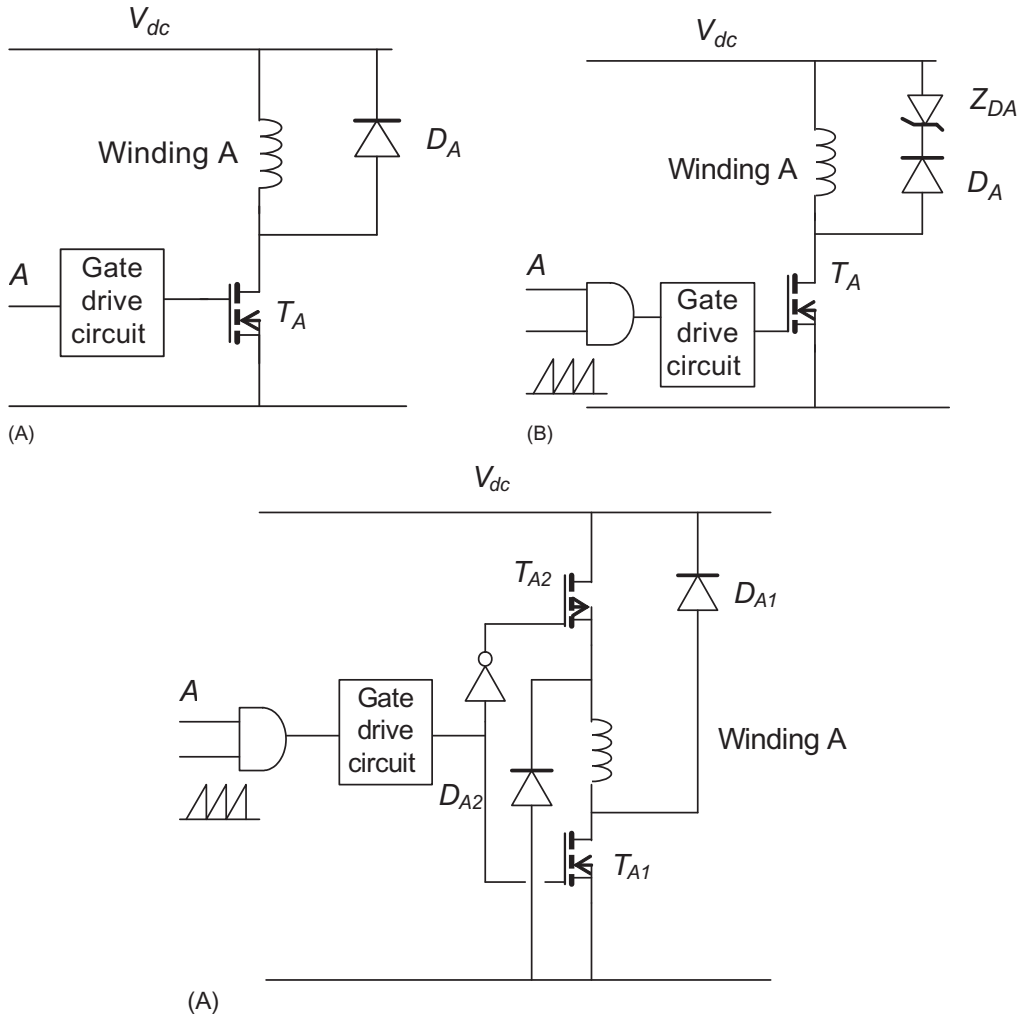

FIG. 30.90 Three commonly used unipolar drive circuits: (A) the basic unipolar drive, (B) unipolar drive with PWM current limiting and zener diode turnoff, and (C) unipolar drive with regenerative turnoff.

winding current a circulating path when the transistor is turned off.

The drive circuit of Fig. 30.90A is a basic one. A better drive circuit is shown in Fig. 30.90B, which includes a zener diode in the freewheeling path. A pulse-width modulator is also included in the gate driving circuit. The pulse-width modulator allows a higher dc supply voltage (typically 5–10 times the voltage for the resistance-limited drive) to be used, thereby reducing the rise time of current at switch on by 5–10 times. The zener diode allows a fast fall time for the current when the transistor is turned off by dissipating the trapped energy of the winding at switch-off faster. Yet another scheme is shown in Fig. 30.90C that allows the trapped energy of the winding at switch-off to be returned to the dc source when the transistor is turned off, rather than being dissipated in the winding or the freewheeling circuits. This circuit is by far the most efficient and at the same time gives the fastest possible rise and fall times for the winding currents.

30.8.5.2 Bipolar Drive Circuits

The bipolar drive allows the motor windings to be driven with bidirectional currents. The four-transistor bridge drive circuit of Fig. 30.91, one for each winding, is the most popular. The circuit can cater to the required rise and fall times of the winding by properly selecting the dc supply voltage V_{dc}, the pulse-width modulator, and the current controller gains.

Some hybrid and PM motors come with four windings, two for each phase. These may be connected in series or parallel, depending on the torque characteristics desired. In any case, only two drive circuits of the type indicated in Fig. 30.91 are required.

30.8.5.3 Drive Circuits for Bifilar Wound Motors

Hybrid stepping motors may also come with bifilar windings, which allow the simpler unipolar drive circuits to be used. These motors have two tightly coupled windings for each phase. Fig. 30.92 illustrates two bifilar windings on stator pole and their unipolar drives. The two windings on each pole have opposite sense, so that the magnetic polarity is reversed by simply switching the other winding. Since only unidirectional current is involved, the unipolar drive circuits of Fig. 30.90A or B may be used at a considerable savings in terms of the drive circuits. This benefit is, however, derived at the cost of extra winding space, and hence larger volume, for the same torque.

30.8.6 Micro Stepping

The drive sequences mentioned in Section 30.8.2 normally switch-rated current through the motor windings. These

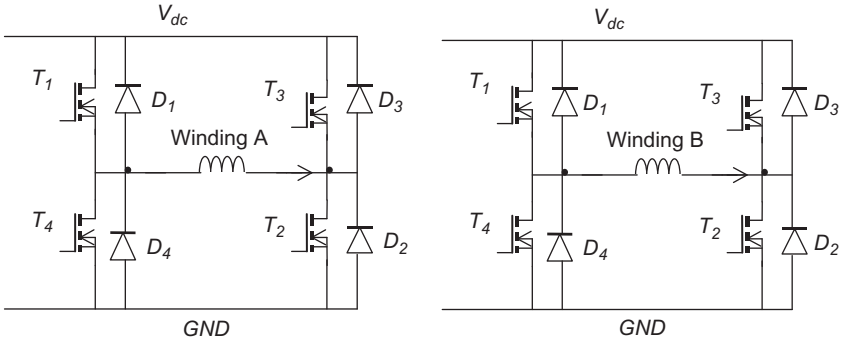

FIG. 30.91 Bipolar drive circuit (gate-drive circuits omitted).

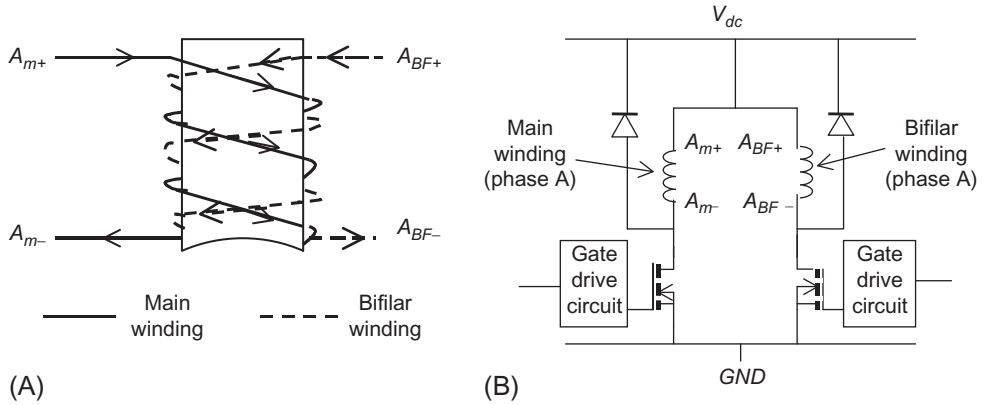

FIG. 30.92 Drive circuits for one phase of a bifilar-wound motor: (A) bifilar pole windings and (B) drive circuits.

produce regular step angles. The half-stepping operation also uses rated motor currents. Halving of the step angle is arranged mainly through the selection of the windings switched.

In microstepping, the regular step angle of the motor is subdivided further by a factor, typically from 10 to 100, by energizing the windings partially, with combinations of currents ranging from zero to full rated value in more than one windings simultaneously. This does not lead to any sacrifice of the developed torque, since the phase currents are so selected that the peak of total torque contributed by two partially energized windings is not lower than the peak detent torque T_{max} obtained in regular stepping.

The idea behind microstepping is readily understood when it is considered that by increasing the current in phase A of a two-phase hybrid in 10 equal steps to full value and decreasing the current in phase B in a similar manner, the motor step size may be divided by a factor of 10. If the closed-loop current controllers are added to the two drive circuits of Fig. 30.91 and distinct current references are obtained from a reference generator, a complete microstepping drive is realized.

In microstepping, the two current references must have values such that the motor does the following:

1. Develops the same T_{max} for every combination of winding currents
2. Develops the same torque slope, that is, $dt/d\theta$ at every microstepping detent position
3. Dissipates no more than the rated power loss (I^2R) for every combination of winding currents

The preceding conditions are necessary if the motor is to retain its static accuracy, maximum torque, and power dissipation characteristics.

The static torque characteristics (Fig. 30.92) of stepper motors are close to, but not exactly, sinusoidal functions of angle θ. The required current references for all windings of a stepper motor, including the variable-reluctance motor of three or more phases, can easily be calculated from the data of the $T-\theta$ characteristics of the motor for each phase for various currents and rotor positions. A typical set of $T-\theta$ data for a three-phase variable-reluctance motor is shown in Fig. 30.93.

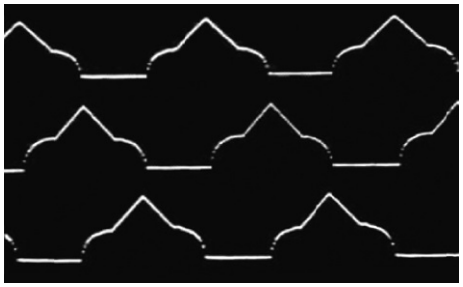

FIG. 30.94 Microstepping current references for the VR motor of Fig. 30.93. Stepping rate: 28,800 steps/s, $I = 6$ A (maximum).

The application of the three conditions mentioned earlier leads to a unique set of current references for each phase of the motor for each microstep. Fig. 30.94 shows the current references for this motor for microstepping.

In multi stepping operation, these microstepping current references have to be issued to the current controllers for each phase, at a rate determined by the commanded stepping rate.

Care has to be taken in designing the phase-current controllers so that the actual winding currents match the current references in both single- and multistepping operation up to the maximum stepping rate desired. Since the current references are time-varying, high-bandwidth current controllers are normally required to cover the desired speed range.

30.8.7 Open-Loop Acceleration–Deceleration Profiles

As mentioned in Section 30.8.4, many applications require the stepper motors to be driven far above the stepping rates to and from which the motor can start and stop abruptly without losing or gaining any step. This calls for carefully designed acceleration-deceleration profiles that the stepping pulse rate must not exceed.

The number of steps the motor is to be stepped and its direction are normally under the control of the motion controller. Once this reference is known, a digital timer/counter circuit

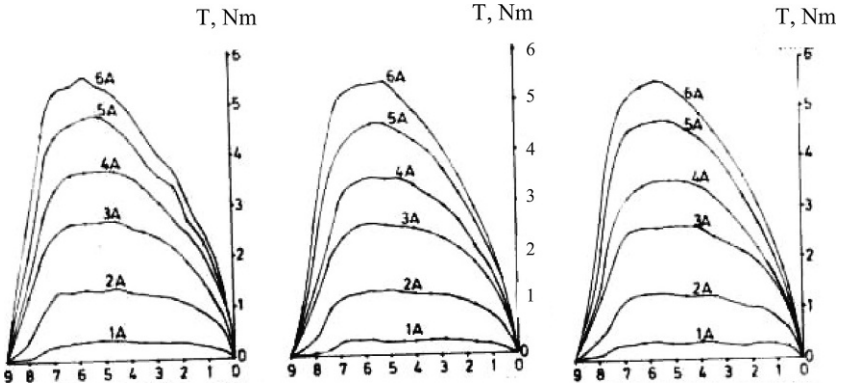

FIG. 30.93 $T-\theta$ characteristics of a three-phase variable-reluctance motor.

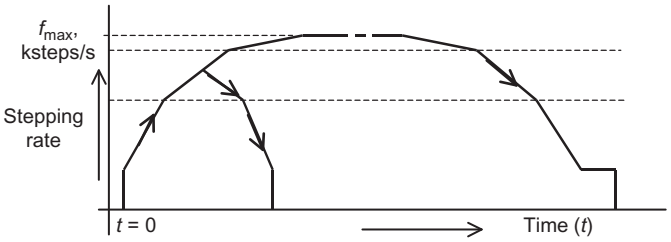

FIG. 30.95 Typical acceleration-deceleration profiles.

can be used in the controller to progressively adjust the time between the stepping pulses such that a prescribed acceleration-deceleration profile, as indicated in Fig. 30.95, is followed. The timer/counter and the pulsing sequence controller (the translator) need to be managed in real time to execute the motion-control task at hand.

The fastest acceleration-deceleration profile, a stepper motor is capable of is largely determined by its pullout $(T-\omega)$ characteristic, which in turn is determined by the motor winding parameters and the drive circuit. An optimized stepping profile to and from the top speed may have a number of segments as indicated in Fig. 30.95. These profiles are easily computed from the pullout $(T-\omega)$ characteristic by integrating the dynamic torque balance equation of the drive. For a large positioning angle, the entire profile, including some constant speed running at the top speed, may be used. For short-positioning angles, only part of the profile may be traversed. In general, a single-segment acceleration-deceleration profile is used in commercial stepper motor controllers, so as to avoid a great deal of real-time number crunching by the profile controller.

The overall stepper motor controller thus consists of the blocks depicted in Fig. 30.96.

30.9 Switched-Reluctance Motor Drives

30.9.1 Introduction

The switched-reluctance (SR) motor is a doubly salient electric machine with salient-poles on both the stator and rotor. The machine is operated by switching current pulses to each stator winding on and off in a continuous switching sequence. The rotor poles have no excitation. Fig. 30.97 shows the physical topology of a typical SR motor. The diagram illustrates a motor with eight salient stator poles (numbered A1–D2) and six

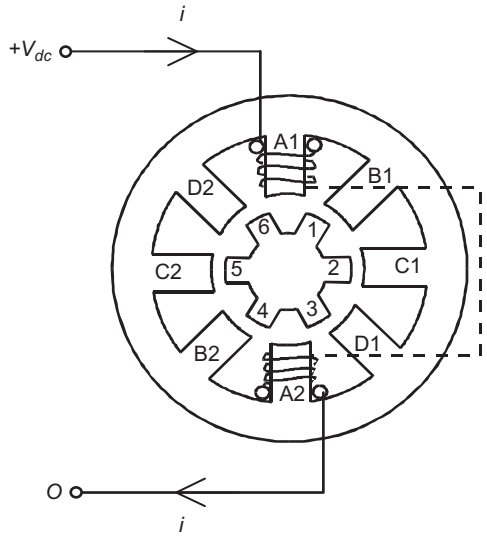

FIG. 30.97 Four-phase SR motor topology.

salient rotor poles (numbered 1–6). Although many combinations of the number of stator and rotor poles are possible, this particular type has found widespread use.

The phase windings on the stator of the SR motor consist of concentrated windings wrapped around the stator poles. In the conventional arrangement, each stator pole winding is connected with that of the diametrically opposite pole to form a stator phase. In Fig. 30.97, the connected stator pole pairs are indicated by the same prefix letter.

The general principle of operation of the SR motor is the same as all types of reluctance machines, that is, the stator and the rotor poles seek the minimum-reluctance position, so that the stator excited flux becomes maximum. Hence, when current flows in an SR motor stator phase and produces a magnetic field, the nearest rotor pole will tend to position itself with the direction of the developed magnetic field. This position, which is termed the *aligned position*, is reached when the rotor pole center axis is aligned with the stator pole center axis (assuming symmetrical poles). The aligned position also corresponds to the position of minimum reluctance and hence the position of maximum inductance.

It should be noted that the *unaligned* position is defined as the position when the *interpole axis*, or the axis of the center of the interpolar space in the rotor, is aligned with a stator pole axis.

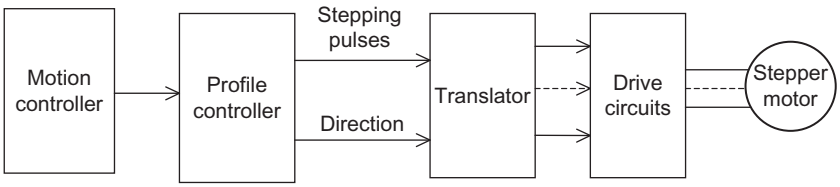

FIG. 30.96 Structure of an open-loop motion controller for a stepper motor.

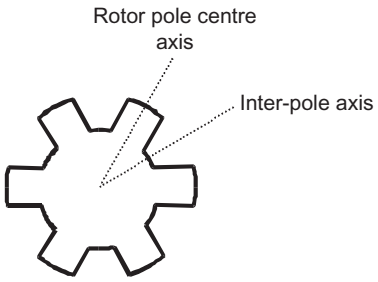

FIG. 30.98 Rotor pole axis positions.

This position corresponds to the position of minimum inductance. These rotor axis positions are illustrated in Fig. 30.98.

To achieve continuous rotation, the stator phase currents are switched on and off in each phase in a sequence according to the position of the rotor. Consider the motor schematic illustrated in Fig. 30.97. If coils A1 and A2 of phase A are excited and produce a magnetic field in a vertical direction, then poles 1 and 4 on the rotor will align themselves with the stator poles of phase A. If the coils of phase A now have their current switched off and coils B1 and B2 of phase B are now excited, then in a similar fashion, the rotor will move so that the poles 2 and 5 are aligned with stator poles B1 and B2. Exciting phases A, B, C, and D in sequence will produce rotor rotation in the counterclockwise direction.

From the preceding discussion, one may see that the switching on and off of excitation current to the motor phases is related to the rotor pole positions. This means that some form of position sensor is essential for the effective operation of the SR motor.

30.9.2 Advantages and Disadvantages of Switched-Reluctance Motors

The SR motor has a number of inherent advantages that makes it suitable for use in certain variable-speed drive applications. Nevertheless, the motor also has some inherent disadvantages that must be considered before choosing the motor for a particular application. In Table 30.6, the main advantages and disadvantages of the SR motor drive are summarized.

TABLE 30.6 Advantages and disadvantages of SR drives

Advantages	Disadvantages
Low-cost motor	Need for position measurement
Robust motor construction	Higher torque ripple than other machine types
Absence of brushes	Higher noise than other machine types
No motor short-circuit fault	Nonlinear and complex characteristics
No shoot-through faults	
Ability to operate with faulted phase	
High torque-to-inertia ratio	
Unidirectional currents	
High efficiency	

30.9.3 Switched-Reluctance Motor Variable-Speed Drive Applications

The main application for SR motors is in variable-speed drive systems. One application area has been general-purpose industrial drives where speed, acceleration, and torque control are desired. SR-motor-based industrial drives provide the advantages of a very wide range of operating speeds and high efficiency and robustness. Other applications of the SR drive include automotive applications, where the SR motor has advantages of robustness and fault tolerance. The SR motor in this application can also be easily controlled for acceleration, steady speed, and regenerative braking.

The SR motor is also well suited to aerospace applications where the ability to operate under faulted conditions and its suitability for operation under harsh environments are critical. Additionally, the very high-speed capability and high power density also make these motors well suited in the aerospace field. There are also many domestic appliances where cost is of primary concern. In these products, the SR motor can provide a low-cost solution for a brushless fully controllable motor drive. In addition, the motor can be used in battery-powered applications, where the motor-high efficiency and ability to use a dc supply are important.

30.9.4 SR Motor and Drive Design Options

The main components of the drive system are shown in Fig. 30.99. It is important to design the motor and drive together in an integrated manner. The main criteria that need to be considered in designing the components of the SR drive system will be discussed later. It will be seen that certain design choices, which may be advantageous for one component of the drive system, may bring about disadvantages in another component. This highlights the need for a careful, integrated system approach to be taken when designing the drive system.

30.9.4.1 Number of Motor Phases

There are many possibilities in choosing the number of stator phases and rotor poles in SR motors. The simplest SR motor may consist of only one phase; however, to operate the motor in four quadrants (motoring or generating in both forward and reverse directions), at least three phases are required. The most common configuration to date has been the four-phase SR motor, which has eight rotor poles and six stator poles, as was shown in Fig. 30.97.

30.9.4.2 Maximum Speed

The SR motor is capable of operating at very high speeds because of its robust rotor construction, and in most applications, the maximum speed is limited by the inverter switching speed and not limited by the motor itself. The maximum speed of the SR motor is itself normally greater than 15,000 rpm for a standard SR motor.

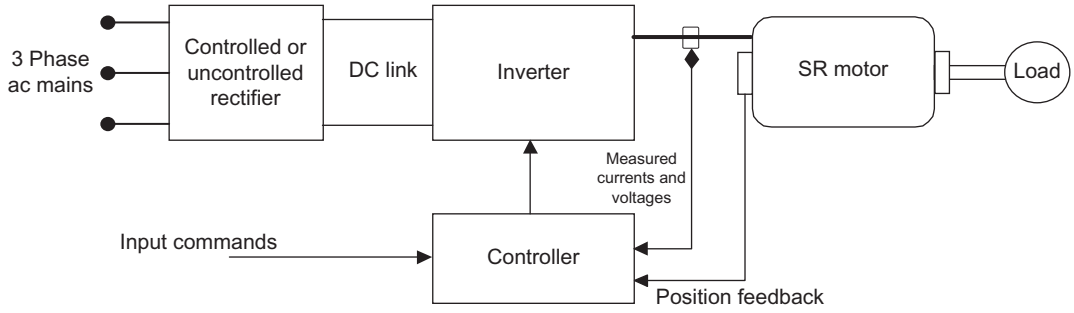

FIG. 30.99 Main components of an SR drive.

However, to determine the maximum drive speed, the controller and motor must be considered together. This is because the power-electronic device switching speed is directly proportional to the commutation frequency, which is in turn proportional to the motor speed. The maximum switching frequency of the power devices must therefore be taken into account in the SR drive design.

30.9.4.3 Number of Power Devices

In general, the number of switches per phase in SR motor drives will vary according to the inverter topology. A wide range of different SR drive circuits are available for SR drives, and these are detailed below. Circuits with only one switch per phase are possible; however, these have various disadvantages such as control restrictions, a need for extra windings, or higher switch voltages. However, with two switches per phase, the motor is fully controllable in four quadrants and has completely independent motor phase control. Therefore, the maximum number of power switches required for the motor operation is normally $2q$, where q is the number of phases.

30.9.4.4 Inverter Topology Types for SR Motors

As was mentioned, the torque produced in the SR motor is independent of the direction of current flow in each motor phase. This means the inverter is only required to supply unidirectional currents into the stator windings. The three major circuit topology types that have been used for each winding of SR motor drives are shown in Fig. 30.100. As indicated in this figure, these are commonly termed the *bifilar-*, *split-dc-supply-*, and *two-switch*-type inverter circuits.

In the circuits shown in Fig. 30.100, only one or two switching components per phase are required. Other circuit topology types that use shared components between the motor phases have limitations in control flexibility.

Bifilar type inverter circuit

In Fig. 30.100A, a drive circuit for a bifilar-wound SR motor is shown. The bifilar windings are closely coupled, with one winding being connected to a switching device, while the other is connected to a freewheeling diode. Current is increased in the winding when the switching device closes. At turnoff, the current transfers to the secondary winding through transformer action, and the inductive energy flows back into the supply via the freewheeling diode. If perfect coupling is assumed, then the voltage across the switching device will rise to twice the dc supply voltage during turnoff. However, in practice, this would be higher. This is because there will be some uncoupled inductance in the primary that will cause high induced voltages when the current in the winding collapses to zero. Thus, snubbing circuits would almost certainly be required to protect the switching components from overvoltage.

The advantage of the bifilar circuit is that it requires only one switching device per phase. However, with the advent of modern power electronic devices, which have both low cost and low losses, this advantage quickly disappears.

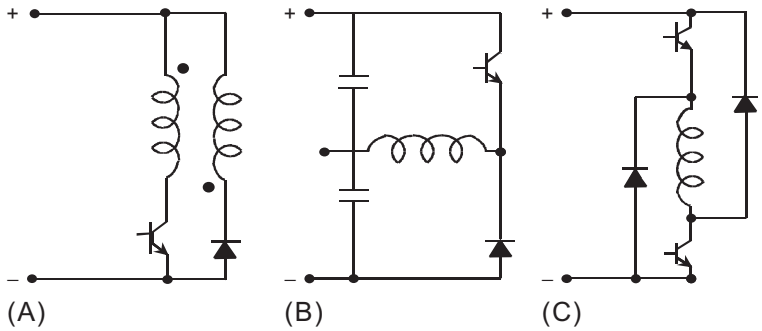

FIG. 30.100 Major SR inverter topology types: (A) bifilar type, (B) split-dc-supply type, and (C) two-switch type.

Split DC supply inverter circuit

The split-dc-supply-type inverter circuit is in Fig. 30.100B. As in the bifilar circuit, this configuration also uses only one switching device and one diode per phase. However, a center-tapped dc source is required. When the switching device is turned on, current increases in the phase winding because of the positive capacitor voltage being applied. At turnoff, the current is forced to flow through the diode and thus decays to zero more quickly because of the connection to the negative voltage. It is usual for the dc center tap to be implemented using a split capacitor in the dc-link. The voltages across each capacitor must remain balanced, which means that there can be no significant power-flow difference between the two capacitors.

Upon examination of the circuit, it can be seen that because of the split capacitor bank, only half the available dc voltage can be switched across the phase winding. Thus, for the same voltage across the motor phases that is supplied by the bifilar circuit described earlier, the dc supply voltage must be doubled with respect to the bifilar circuit supply. This means that the voltage rating of the devices would effectively be the same as in the bifilar circuit.

This is inherently inefficient. The configuration also has the need for balanced split capacitive components. In addition, it will be seen that the *soft-chopping* form of control described in Section 30.9.7 is not available in this drive.

Two-switch inverter circuit

The two-switch-inverter-type circuit, which is shown in Fig. 30.100C, uses two switching devices and two diodes per phase. Unlike the previous two circuits, three modes of operation are possible:

Mode 1—positive-phase voltage

A positive-phase voltage can be applied by turning both switching devices on. This will cause the current to increase in the phase winding.

Mode 2—zero-phase voltage

A zero-voltage loop can be imposed on the motor phases when one of the two switches is turned off while current is flowing through the phase winding. This results in current flow through a freewheeling loop consisting of one switching device and one diode, with no energy being supplied by or returned to the dc supply. The current will decay slowly because of the small resistance of the semiconductors and connections, which leads to small conduction losses. This mode of operation is used in soft-chopping control, as described in Section 30.9.7.

Mode 3—negative-phase voltage

When both switches in a motor phase leg are turned off, the third mode of operation occurs. In this mode, the motor phase current will transfer to both of the freewheeling diodes and return energy to the supply. When both of the diodes in the phase circuit are conducting, a negative voltage with amplitude equal to the dc supply voltage level is imposed on the phase windings.

In this circuit, the switching devices and diodes must be able to block the dc supply voltage amplitude when they are turned off, in addition to any switching transient voltages. However, because the circuit contains two devices in series, the blocking voltage is essentially half the value seen in the previous two circuit types for the same applied motor phase voltage amplitude. Another advantage of the two-switch inverter circuit is that it offers greater control flexibility with its three modes of voltage control.

A disadvantage of this inverter type, as compared with the bifilar and split dc supply types, is that it contains twice as many switching components per phase. However, with the current wide availability and economy of power semiconductors, in most applications, the advantages of the two-switch circuit outweigh the cost of an extra switching device per phase.

30.9.5 Operating Theory of the Switched-Reluctance Motor: Linear Model

If a linear magnetic circuit is assumed, the flux linkage is proportional to phase current for any rotor position θ. This is demonstrated in Fig. 30.101, where the magnetization curves for the linear SR motor for various rotor positions and currents are shown. In this linear case, the inductance L at any position θ, which is the slope of these curves, is *constant* and independent of current.

As the motor rotates, each stator phase undergoes a cyclic variation of inductance. As can be seen in Fig. 30.101, in the fully aligned position (when a rotor pole axis is directly aligned with the stator pole axis) the reluctance of the magnetic circuit through the stator and rotor poles will be at a minimum, and thus the inductance of the stator winding will be at a maximum. The opposite will occur in the fully unaligned position (when the rotor interpole axis is aligned with the stator pole). Thus, the inductance becomes a function of position only and is not related to the current level. If it is also assumed that mutual inductance between the phases is zero, then a typical inductance variation $L(\theta)$ with respect to the rotor position similar to that shown in Fig. 30.102 arises. Although this is an idealized inductance variation, it

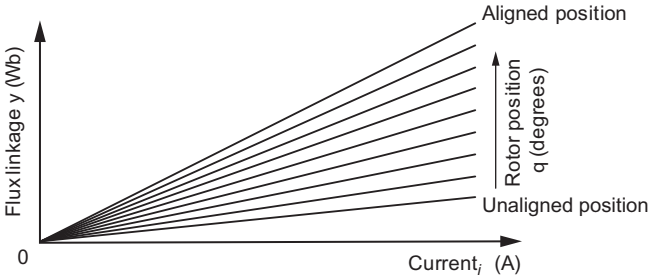

FIG. 30.101 Magnetization characteristics of linear SR motor.

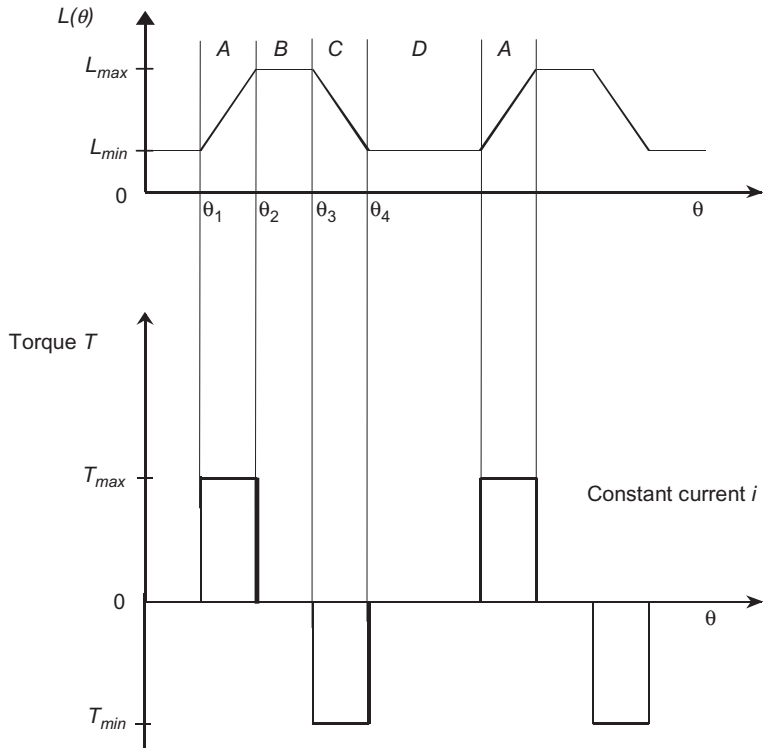

FIG. 30.102 Typical linear inductance variations and corresponding torque variations for constant phase current.

is helpful in the understanding of key operating principles of the machine. One should note that in the idealized inductance variation, there are sharp corners, which can only arise if flux fringing is completely ignored.

Four distinct regions can be identified in the plot of the linear inductance variation shown in Fig. 30.102. These distinct regions correspond to a range of rotor pole positions relative to the stator pole positions as described below:

Region A

This region begins at rotor angle θ_1, where the first edge of the rotor, with respect to the direction of rotation, just meets the first edge of the stator pole. The inductance will then rise in a linear fashion until the poles of the stator and rotor are completely overlapped at angle θ_2. At this point, the magnetic reluctance is at a minimum, and the phase inductance is at a maximum. These rotor positions are illustrated in Fig. 30.103A and B, for example, four-phase motor with rotor pole 1 approaching the stator pole of phase A.

Region B

This region spans from rotor positions θ_2 to θ_3. In this region, the inductance remains constant because the rotor pole is completely overlapped by the stator pole (i.e., the overlap area of the poles remains constant). At rotor angle θ_3, the edge of the rotor pole leaves the stator pole overlap region, and thus, the area of overlap will again begin to decrease. The position at which this occurs is illustrated in Fig. 30.103C.

Region C

When the rotor moves past θ_3, the rotor pole leading edge begins to leave the pole overlap region, and region C begins. At this point, the inductance begins to linearly decrease, until at θ_4, the rotor pole has completely left the stator pole face overlap region. At this point, the inductance is at its minimum once more. The rotor position at which the rotor pole has completely left the overlap is indicated in Fig. 30.103D.

Region D

In this region, the rotor and stator have no overlap, and thus, the inductance remains constant at the minimum level, until region A is reached once again.

It was mentioned earlier that when a stator phase is excited, the rotor poles will tend to move toward the maximum-inductance region. Thus, a motoring torque is produced when a stator phase is provided with a current pulse during the angles when the inductance is rising (assuming motoring rotation is in the direction of increasing θ in Fig. 30.102). This means that if positive torque is desired, excitation should be arranged such that the current flows between the appropriate rotor angles when the inductance is rising.

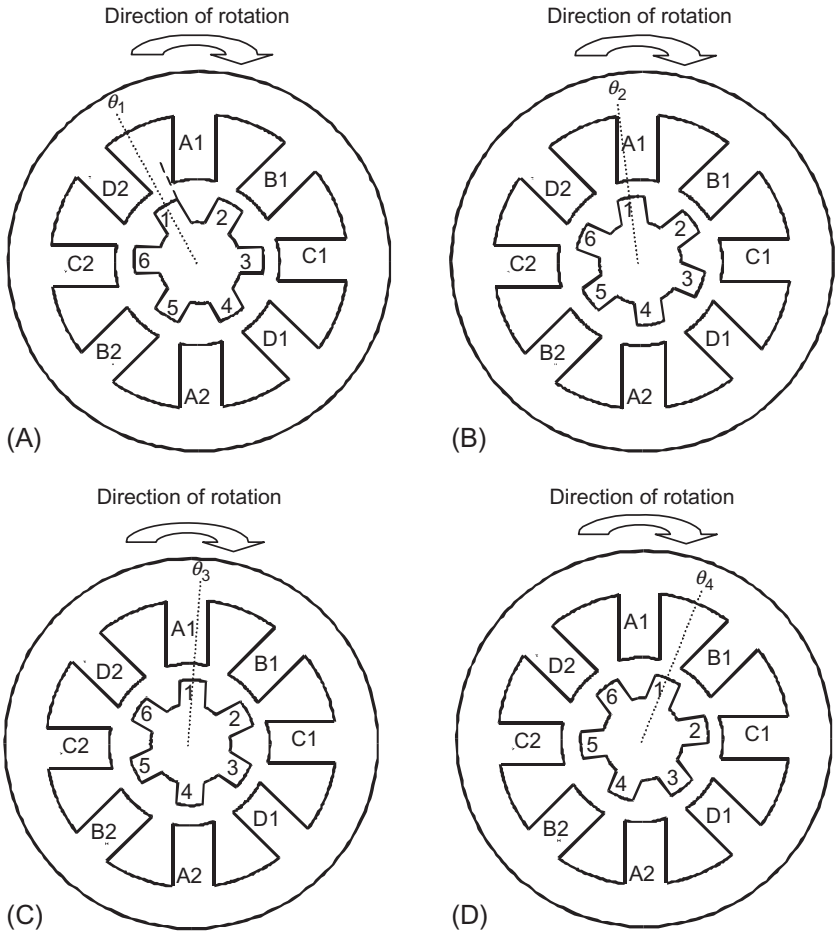

FIG. 30.103 Rotor pole 1 positions: (A) meeting edge of stator pole A, (B) overlapped by stator pole A, (C) edge of rotor pole leaving overlap region, and (D) rotor pole completely leaving overlap region. (Note that air-gap space is exaggerated for clarity.)

Conversely, if current flows during the decreasing inductance region, a negative torque would result. This is because the rotor will be attracted to the stator pole in such a way that it rotates in the opposite direction to the motoring rotation, or in other words, the rotor experiences a torque opposite to the direction of rotation.

It should be noted that this reluctance-machine torque always acts to decrease the reluctance. The direction of current flowing into the stator winding is irrelevant. This signifies that unidirectional current excitation is possible in the SR motor drive.

The variation of torque with rotor angle for a constant phase winding current is as shown in Fig. 30.102. It can be seen that the torque is constant in the increasing and decreasing inductance regions and is zero when the inductance remains constant.

The preceding physical explanation of the developed torque is also given by the familiar torque Eq. (30.96) for a variable-reluctance machine.

$$T = \frac{1}{2} i^2 \frac{dL(\theta)}{d\theta} \tag{30.96}$$

From Eq. (30.96), it is evident that the magnitude of the instantaneous torque developed in the SR motor is proportional to both i^2 and $dL/d\theta$. If the inductance is increasing with respect to the angle, and current flows in the phase winding, then the torque will be positive and the machine will operate in motoring mode. Hence, from Eq. (30.96), it can be seen that when the motor phase is excited during a rising inductance region, part of the energy from the supply is converted to mechanical energy to produce the torque, and another part is stored in the magnetic field. If the supply is turned off during this region, then any stored magnetic energy is partly converted to mechanical energy and partly returned to the supply.

However, a negative or braking torque will be developed by the motor if the inductance is decreasing with respect to the rotor angle and current flows in the phase winding. In this case, energy flows back to the supply from both the stored magnetic energy and the mechanical load, which acts as a generator.

It can also be seen from Eq. (30.96) that the sign (or direction) of the torque is independent of the direction of the current

and is only dependent on the sign of $dL/d\theta$. This explains the torque waveforms that were seen in Fig. 30.102, where for constant current (and constant $dL/d\theta$ magnitude), the magnitude of the torque was constant in the rising or decreasing inductance regions. However, it was seen that the torque changes from positive to negative according to the sign of $dL/d\theta$.

Hence, the ideal waveform for the production of motoring torque would be a square-wave pulse of current (with magnitude equal to the maximum possible supply current) flowing only during the increasing inductance period (Fig. 30.104). This current waveform is illustrated in Fig. 30.104B. However, in practice, this type of current waveform is difficult to produce in a motor phase. This is because the motor phase current is supplied from a finite dc voltage source, and thus, inductance of the stator phase winding would delay the rise and fall of current at the pulse edges. Instead, a more practical current waveform is normally used as is illustrated in Fig. 30.104C. It can be seen that in this waveform, the ideal square waveform is closely approximated by the use of hysteresis current control. At higher speeds, hysteresis current control can no longer be used and a current waveform similar to that shown in Fig. 30.104B is seen in the phase winding. These two types of practical current waveforms, which approximate the ideal square pulse waveform *(a) at low to medium speeds* and *(b) at high speeds*, will be discussed next.

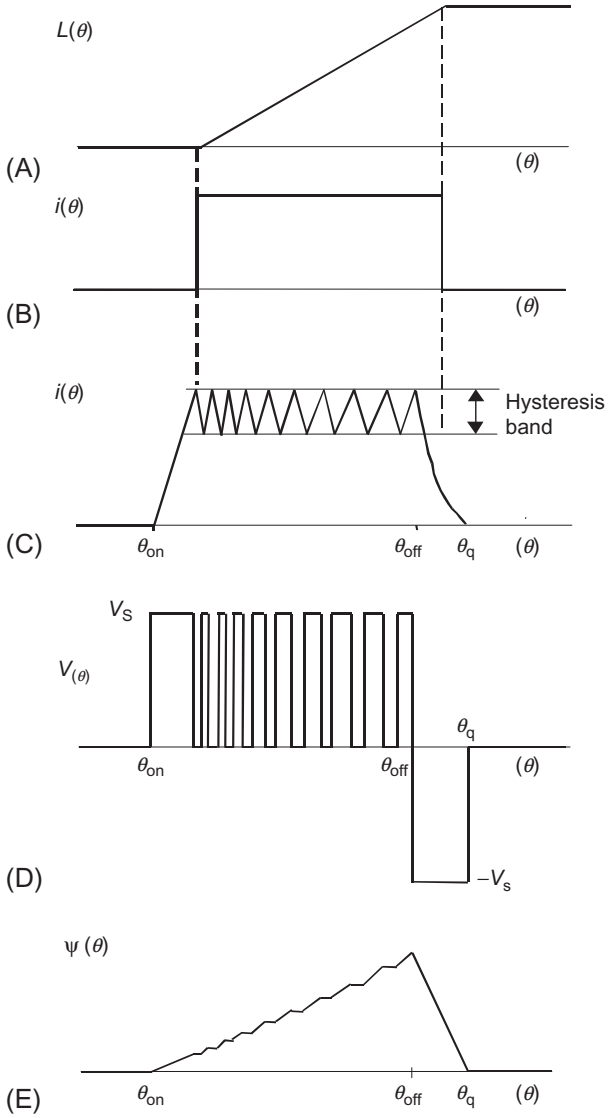

FIG. 30.104 (A) Linear phase inductance variation, (B) ideal square-wave phase current, (C) chopping-mode phase current, (D) chopping-mode phase voltage, and (E) flux linkage waveform corresponding to chopping-mode current.

30.9.5.1 Low to Medium-Speed Approximation to Square-pulse Current Waveform

At low to medium motor speeds, the ideal square-pulse current waveform is approximated in the practical motor drive using hysteresis current control, as is shown in Fig. 30.104C. The hysteresis method of controlling the current is termed the *chopping-mode control* method in SR motor drives. During the time of conduction (between the turn-on and turnoff angles), the current is maintained within the hysteresis band by the switching off and on of the phase voltage by the inverter when the phase current reaches the maximum and minimum hysteresis band. An example of the voltage waveform used for the hysteresis current control is shown Fig. 30.104D, where a constant inverter dc supply voltage of magnitude V_s is used. It can be seen that the switching frequency of the voltage waveform decreases as the angle increases. This is due to the fact that the phase inductance is linearly increasing with angle, which has the effect of increasing the current rise and fall time within the hysteresis band.

In the chopping-mode control method, the *turn-on region* is defined as the angle between the *turn-on angle* θ_{on} and the *turn-off angle* θ_{off} and is chosen to occur during the rising inductance region for motoring torque. In the practical chopping current waveform, the current turn-on angle θ_{on} is placed somewhat before the rising-inductance region. This is to ensure that the current can quickly rise to the maximum level in the minimum-inductance region before the rising-inductance, or torque-producing, region. Similarly, the turnoff angle θ_{off} is placed a little before the maximum-inductance region so that the current has time to decay before the negative-torque, or decreasing-inductance, region. The angle at which the current decays to zero after turnoff is labeled as θ_q in Fig. 30.104C.

30.9.5.2 High-Speed Approximation to Square-Pulse Current Waveform

The chopping-mode of operation cannot be used at higher speeds, as at these speeds, the hysteresis band current level will not be reached. This is because at high speeds, the back emf of the motor becomes equal to or larger than the voltage supply in the rising-inductance region (Fig. 30.105), which limits the increase of the motor phase current. In addition, the rise time of the current will correspond to an ever-increasing angle as the speed is increased. Eventually, at high speeds, the rise-time

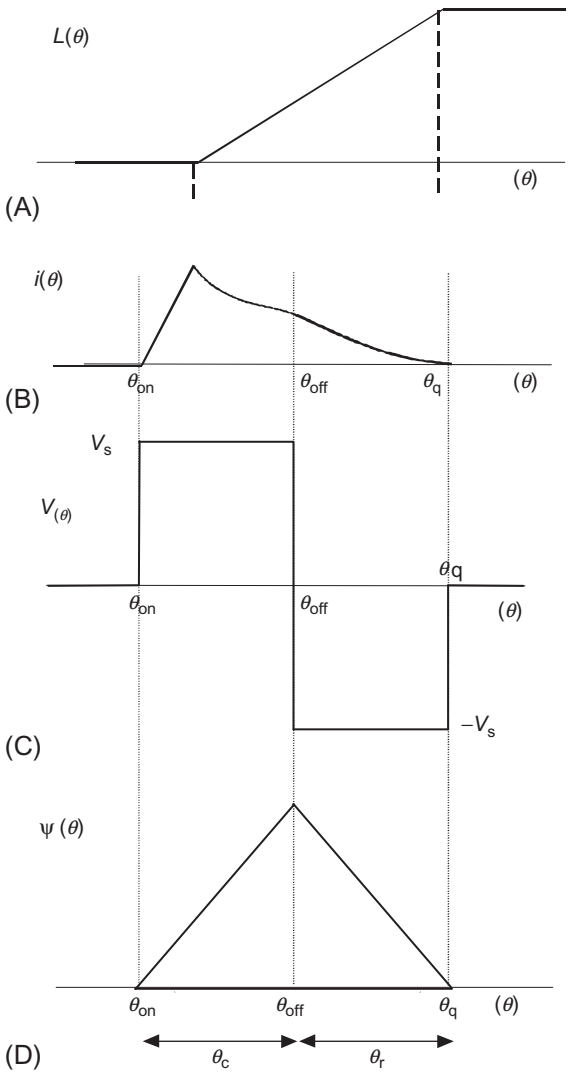

FIG. 30.105 (A) Linear phase inductance variation, (B) single-pulse mode phase current, (C) single-pulse mode phase voltage, and (D) flux linkage waveform corresponding to single-pulse mode current.

angle will be so large that the turnoff angle θ_{off} will be reached before the hysteresis current level has been exceeded. Thus, at high speeds, the current is switched on and off only once per cycle. In SR motor-drive control, this is called the *single-pulse mode* of operation. An example of the single-pulse mode current is illustrated in Fig. 30.105B.

In the single-pulse mode of operation, the inverter power switches turn-on at rotor angle θ_{on}, which places the dc voltage supply V_s across the phase winding, as is shown for the example single-pulse voltage waveform in Fig. 30.105C.

As for the chopping-mode case, in order to maximize torque, θ_{on} must usually be located prior to the rising-inductance region. This is so that, while the inductance is low, the current has a chance to rise rapidly to a substantial value before the torque-producing region begins and the motor back emf increases. At rotor angle θ_{off}, the power switches are turned off, and the phase will have a negative voltage (typically $-V_s$) thrown across it. The current will then decay until it becomes zero at rotor angle θ_q.

30.9.6 Operating Theory of the SR Motor (II): Magnetic Saturation and Nonlinear Model

In the linear model described earlier, it was assumed that the inductance of a phase winding is independent of current. However, in a real SR motor, significant saturation of the magnetic circuit normally occurs as the phase current increases, and thus, the phase inductance is related to both the phase current level and position. Because of the magnetic saturation effect, the actual phase inductances at a given rotor position can be reduced significantly compared with the inductance given by linear magnetization characteristics. In addition, the effect of magnetic saturation becomes larger as the motor current level increases.

The effects of saturation in an SR motor can be observed in a plot of its magnetization curves. This shows the relationship of flux linkage versus current, at rotor positions varying between the fully aligned and unaligned angles. A typical set of SR motor magnetization curves is shown in Fig. 30.106, where it can be seen that there is a nonlinear relationship between the flux linkage and current for each curve.

Due to the magnetic saturation effect discussed earlier, the instantaneous torque Eq. (30.96), which was derived assuming linear conditions, will not be generally valid for calculating the torque in SR motors. Therefore, for accurate calculations, the torque must take into account the dependence of phase inductance with current and position.

If one considers the phase-inductance saturation, the expression for instantaneous torque production of an SR motor phase can be written as

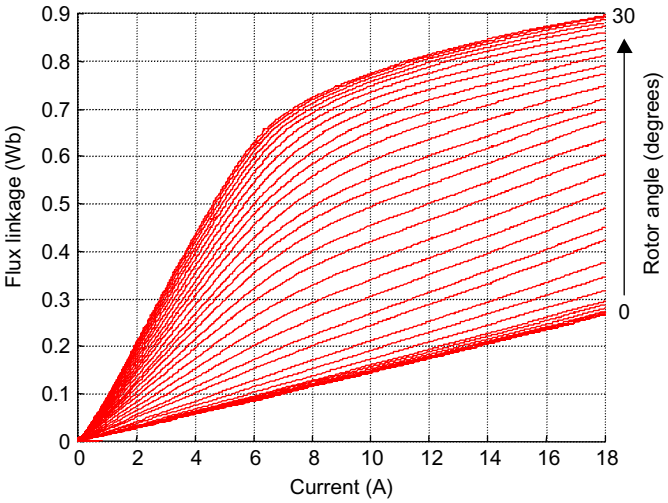

FIG. 30.106 Measured four-phase SR motor magnetization characteristics (each curve represents a constant rotor position).

$$T = \left[\frac{\partial W'}{\partial \theta}\right]_{i=constant} \tag{30.97}$$

where the coenergy W' is defined as

$$W' = \int_0^i \Psi di \tag{30.98}$$

30.9.7 Control Parameters of the SR Motor

A variety of performance characteristics can be obtained in the SR motor by controlling various parameters. These parameters include the chopping-mode control hysteresis level at low to medium speeds and the turn-on and turnoff angles θ_{on} and θ_{off} at all motor speeds. By controlling these parameters, it is possible to produce any desired characteristic such as constant torque, constant power, or some other particular characteristic in between.

As discussed in Section 30.9.5, two distinct modes of operation apply in the SR motor depending on the nature of the current waveform. These modes are the chopping-mode control, which can be used at low to medium motor speeds, and single-pulse mode of control, which is used at high speeds. Both of these modes of operation will be further detailed hereafter, with an explanation of the corresponding inverter switching operation.

30.9.7.1 Chopping-Mode Control

In the chopping-mode control region, the turn-on and turnoff angles are controlled together with the current level. As described in Section 30.9.5, the turn-on angle and turnoff angle are controlled, so that the current flows during the rising-inductance, or positive torque-producing, region. This normally means that the turn-on angle is placed shortly before the place where the rising-inductance angle begins and the turnoff angle is placed shortly before this region ends.

In the chopping mode, the current level is controlled to remain below the maximum allowable level. This involves switching the voltage across the phase on and off in such a manner that the current is maintained between some chosen upper and lower hysteresis current levels. An example of this form of current chopping control was shown in Fig. 30.104C.

The actual torque production of the motor in the chopping mode is set by the control turn-on and turnoff angles and the current hysteresis level. Within the chopping-mode of operation, two current hysteresis control schemes can be used. These are termed *soft* and *hard* chopping. Soft chopping can only be used in some circuit configurations, such as that shown in Fig. 30.107. For soft-chopping control, one switching device remains on during the entire conduction period, while the other is switched on and off to maintain the desired current level. This can be seen in Fig. 30.107A and B, where the two conduction modes during chopping are shown. When both switches are on, the phase winding receives the full positive supply, whereas when only one switching device is on, the phase experiences a zero-voltage freewheeling loop that will decrease the current.

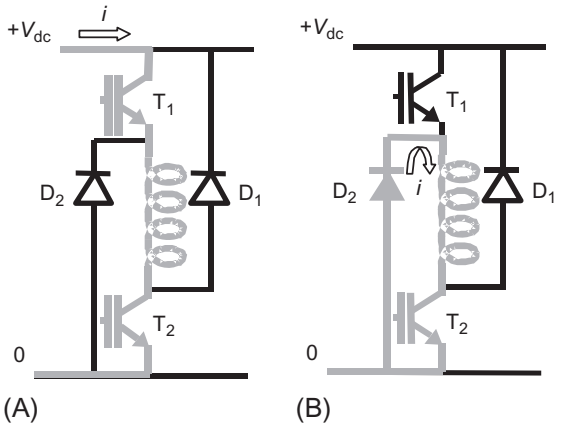

FIG. 30.107 Soft-chopping mode conduction paths: (A) both devices on: positive voltage applied to motor phase and (B) T1 turned off: zero voltage freewheeling loop applied to motor phase.

In the hard-chopping scheme, both devices are switched simultaneously and have the same switching state at all times. If both switching devices are turned on, the phase winding sees the full positive supply. To decrease the current, the full negative supply is applied by turning both devices off as shown in Fig. 30.108. In circuit configurations with fewer than two switches per phase, only hard chopping can be used.

Soft chopping is more advantageous than hard chopping. This is because of a smaller dc ripple current in the supply, which can substantially minimize the ripple-current rating of the dc-link capacitor and lower the hysteresis loss in the motor. It has also been found that the soft chopping lowers acoustic noise and electromagnetic radiation.

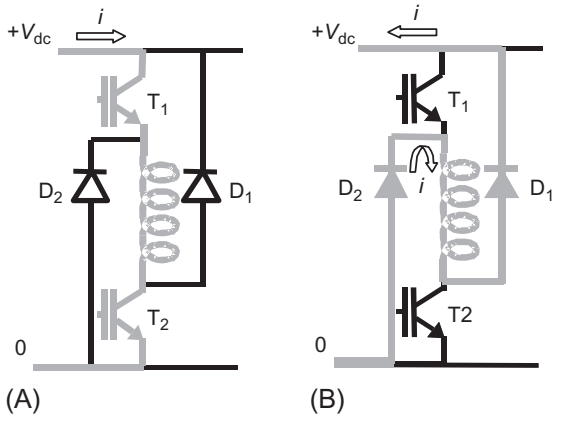

FIG. 30.108 Hard-chopping mode conduction paths: (A) both devices on: positive voltage applied to motor phase and (B) T1 and T2 turned off: negative voltage applied to motor phase.

30.9.7.2 Single-Pulse Mode Control

At higher speeds, the back emf of the SR motor eventually becomes greater than or equal to the supply voltage during the rising-inductance region. This means that even if a phase is excited, the current in the motor phase will not increase in the rising-inductance region. Therefore, at higher speeds, the turn-on angle must be placed before the beginning of the increasing inductance region, so that the phase current will have an adequate time to increase before the back emf becomes high.

In addition, the time available for the current to rise after turn-on becomes less and less as the speed of the motor increases. This is due to the fact that the available conduction time is lower for constant switching angles as the speed of rotation increases. This can be seen by considering that speed is the time rate of change of angle. Thus, as the speed increases, there will be a point when the current level never rises to the chopping level. At this point, the single-pulse mode of operation will come into effect and the current will decrease or remain constant throughout the increasing-inductance zone. An example of a single-pulse mode current waveform was seen in Fig. 30.105B.

As the current is not commutated in the single-pulse mode, the control in this mode consists only of controlling the on and off angles. The turn-on angle θ_{on} can be placed at some point in advance of the rising-inductance region where the phase inductance is low, so that the current can increase at a faster rate before the increasing-inductance region. The angle can be advanced up until maximum allowable current occurs at the peak of the waveform (this may even mean switching on in the previous decreasing-inductance zone). The actual control turn-on and turnoff angles for the single-pulse mode, for a given load torque and speed, can be determined by simulating the motor equations.

The speed at which a changeover between single-pulse and chopping-mode occurs is called the *base speed*. Base speed is defined as the highest speed at which the chopping mode can be maintained at the rated voltage and with fixed on and off angles. Below the base speed, the current increases during the rising-inductance region, unless it is maintained at the maximum or a lower level by chopping.

Therefore, it can be seen that at lower speeds that are below the base speed, the motor is controlled using chopping-mode control, whereas at speeds above the base speed, the single-pulse mode of control is used. In both the control modes, the control turn-on and turnoff angles are chosen so that the motor provides the required load torque.

30.9.8 Position Sensing

It can be seen from the preceding discussion that to control the SR motor satisfactorily, the motor phases are excited at the rotor angles determined by the control method. It is therefore essential to have knowledge of the rotor position. Furthermore, the rotor-angle information must be accurate and have high resolution to allow implementation of the more sophisticated nonlinear control schemes that can minimize torque ripple and optimize the motor performance.

This means that the performance of an SR drive depends on the accurate position sensing. The efficiency of the drive and its torque output can be greatly decreased by the inaccurate position sensing, and the corresponding inaccurate excitation angles. It has been demonstrated that at high motor speeds, an error of only 1° may decrease the torque production by almost 8% of the maximum torque output.

Traditionally, the rotor-position information has been measured using some form of mechanical angle transducer or encoder. The position-sensing requirements are in fact similar to those for brushless PM motors. However, although position sensing is required for the motor operation, the position-measurement sensors are often undesirable. The disadvantages of the electromechanical sensors include the following:

(a) The position sensors have a tendency to be unreliable because of environmental factors such as dust, high temperature, humidity, and vibration.
(b) The cost of the sensors rises with the position resolution. Hence, if high-performance control is required, an expensive high-resolution encoder needs to be employed.
(c) There is an additional manufacturing expense and inconvenience due to the sensor installation on the motor shaft. In addition, consideration must be given to maintenance of the motor because of the mechanical mounting of the sensors, which also adds to the design time and cost.
(d) Mechanical position sensors entail extra electric connections to the motor. This increases the quantity of electric wiring between the motor and the motor drive. This wire normally needs to be shielded from electromagnetic noise and thus further adds to the expense of the drive system.
(e) The allocation of space for the mounting of the position sensor may be a problem for small applications (such as for motors used in consumer products).

Hence, to overcome the problems induced by rotor-position transducers, researchers have developed a number of methods to eliminate the electromechanical sensor for deriving position information. This is achieved by indirectly determining the rotor position. Such methods are commonly termed *sensorless* rotor-position estimation methods. The term sensorless seems to imply that there are no sensors at all. However, there must be some form of sensor used to measure the rotor position. In fact, the term sensorless position estimation in reality implies that there are no additional sensors required to determine position apart from those that measure the motor electric parameters to control the motor. These are normally current- or voltage-measuring circuits.

Hence, all sensorless position estimation methods for the SR motor use some form of processing on electric waveforms of the motor windings. In essence, the major difference between sensorless position detection, and the electromechanical sensors mentioned above, is that there is no mechanical connection of the sensor to the motor shaft. Therefore, sensorless position detection involves electric measurements only.

30.10 Synchronous Reluctance Motor Drives

30.10.1 Introduction

In recent years, there has been a revival of interest in reluctance machines. Two main machines have been the focus of this interest: the switched-reluctance machine (SRM) and the synchronous reluctance machine (Syncrel). The SRM is a machine that does not have sine-wave spatial distributed windings, but instead has concentrated coils and a doubly salient rotor and stator structure. The operation of this machine is highly nonlinear in character, and normal ac machine modeling techniques cannot be applied in a straightforward manner to describe its operation. The SRM drive has been considered in detail in an earlier section.

The Syncrel, on the other hand, has conventional three-phase sinusoidally distributed windings on the stator. The word "synchronous" in the machine's name emphasizes the fact that the stator windings generate a spatial sinusoidally distributed magnetomotive force (mmf) in the air gap between the stator and the rotor and under steady-state conditions the rotor rotates in synchronism with this field. Therefore, the stator winding configuration of this machine is virtually exactly the same as that of the induction machine or the conventional synchronous machine. The major difference between the Syncrel and conventional synchronous and induction machines is in the rotor structure. In both the induction machine and the synchronous machine, there is a source of flux in the rotor itself. In the case of the induction machine, this flux is produced by currents resulting from an induction mechanism, and for the synchronous machine, there is a field winding wound on the rotor that is fed with the dc current to produce flux. The permanent-magnet synchronous machine replaces the wound field on the rotor with a permanent magnet. The Syncrel, on the other hand, does not have any source of flux on the rotor, but instead, the rotor is designed to distort the flux density distribution produced by the sinusoidally distributed mmf.

Sinusoidally wound reluctance machines were traditionally used in the fiber-spinning industry because of their synchronous nature. This made it simple to keep a large number of machines running at the same speed using just the frequency of the supply to the machines. These machines were direct-on-line-start machines. This was facilitated by the presence of an induction machine starting cage on the rotor. This cage was also essential to damp out oscillations in the rotor speed when running at synchronous speed. It should be pointed out that these machines are not considered to be Syncrels—*a Syncrel does not have an induction machine cage on the rotor*. A Syncrel is absolutely dependent on an intelligent inverter drive in order to start the machine and to stabilize it when running. The lack of a requirement for a starting cage means that the rotor design can be optimized for best torque and power performance.

The revival of interest in the Syncrel in the early 1980s was motivated by the development of low-cost microprocessors and reliable power electronics, coupled with the perception that the Syncrel may be more efficient and simpler to control in variable-speed applications compared with the induction machine. The control simplicity is achieved in practice, mainly because one does not have to locate the flux vector in order to implement vector control. The potential for improved efficiency and torque density compared with the induction machine is very much dependent on the rotor design. The Syncrel has the advantage over the switched-reluctance machine; in that it produces relatively smooth torque naturally, and it uses a conventional three-phase inverter. Therefore, inverter technology developed for the induction machine can be applied directly.

30.10.2 Basic Principles

Reluctance machines are one of the oldest electric machine structures, since they are based on the basic physical fact that a magnet attracts a piece of iron. In fact, Syncrel structures were being published in the early 1920s [1]. The essential idea behind the operation of all reluctance machines is that the windings of the machine produce magnetic poles that are used to attract the reluctance rotor. If the magnetic poles are moved around the periphery of the machine at the rate at which the rotor is moving, then sustained torque and rotation can be achieved.

A conceptual diagram of a Syncrel is shown in Fig. 30.109. In this figure, the rotor is represented as a simple "dumbbell"-type rotor. The axes of the three-phase sinusoidally distributed windings are indicated by the dashed lines. If these windings are being fed with currents, then a spatial sinusoidally distributed, mmf results. Because this mmf is sinusoidally distributed, it can be represented by a "space vector" (similar to sinusoidal time-varying quantities being represented by a time phasor). In Fig. 30.109, this resultant space vector is indicated by F, F_d, and F_q are the components of this vector that lie along the high-permeance and low-permeance axes of the machine, respectively.

If one considers the situation shown in Fig. 30.109, then the rotor would tend to rotate in the direction indicated. This rotation would continue until the high-permeance d_r axis (i.e., the least-reluctance axis) of the machine aligns with the mmf vector. When this alignment occurs, the flux produced by

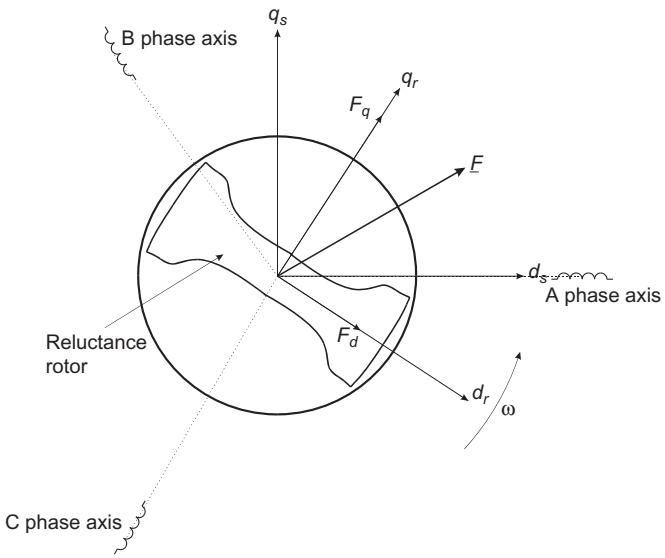

FIG. 30.109 Conceptual diagram of a synchronous reluctance machine.

the stator mmf vector would be maximized. If the vector F also rotates as the rotor rotates, then as mentioned previously, the angle between F and d_r will remain constant and the rotor will continue to chase the F vector, continuous rotation being the result.

One can ask even more fundamental questions such as "why does the rotor rotate to the position that maximizes the flux density?" This is essentially asking why a magnet attracts a piece of iron. To completely answer this question, one has to delve into the field of quantum physics, which is beyond the scope of this presentation. A less complicated explanation is based on the fact that the stator flux density tends to align the domains in the ferromagnetic rotor material, which produces an effect similar to having a current-carrying winding wrapped around the rotor. This effective current then interacts with the stator flux density to produce a force that has a component that is oriented radially around the periphery of the machine. It is this component that produces the torque on the rotor that causes the alignment with the stator mmf vector.

It was mentioned previously that in order to have a continuous motion, the mmf vector F must rotate at the same angular velocity as the rotor, so that the angle between the mmf vector and the d_r axis of the rotor is kept at a constant value. The rotation of the mmf vector is achieved by feeding the three-phase windings of the machine with time-varying currents. It can be shown that if these form a balanced 120° temporally phase-shifted set of sinusoidal currents, then the resultant mmf vector will rotate at a constant velocity related to the frequency of the input current waveforms and the number of pole pairs in the machine.

In order to get a more precise figure for the torque produced by a Syncrel, one has to develop techniques of modeling the machine. Because the Syncrel is a reluctance machine, the coenergy technique for developing the torque expressions can be used [2,3]. The coenergy technique is a very accurate way of determining the torque as it explicitly takes into account, the saturation nonlinearities in the iron of the machine. However, the technique does not lend itself to mathematical analysis and is not a good way of understanding the basic dynamic properties of the machine. The coenergy approach will not be pursued any further in this presentation.

30.10.3 Machine Structure

The essential difference between the Syncrel and, say, the induction machine is the design of the rotor. Most experimental Syncrel systems that have been built use the stator of an induction machine, including the same windings. The rotor designs can take on a number of different forms, from the very simple and basic dumbbell-shaped rotor (such as that sketched in Fig. 30.109) to more complex designs. Unfortunately, the designs that are simple to manufacture (such as the dumbbell design) do not give good performance; therefore, one is forced into more complex designs. The design of the rotor in a Syncrel is the key to whether it is economic to manufacture and has competitive performance with similar machines.

The design of Syncrel rotors fall into four main categories of increasing manufacturing complexity and performance: dumbbell or higher pole-number equivalent designs, flux-barrier designs, radially laminated flux-barrier designs, and axially laminated designs. The first two of these design methodologies are old and lead to designs with poor to modest performance. Therefore, they will not be considered any further. The latter two, however, lead to machine designs with performance comparable with that of the induction machine.

Figs. 30.110 and 30.111 show the cross section of a four-pole machine with a radial lamination flux barrier designed rotor and an axially laminated rotor. The radial lamination design allows the rotor to be built using similar techniques to standard radial laminations for other machines. The flux barriers can be punched for mass production, or wire-eroded for low production numbers. These laminations are simply stacked onto the shaft to form the rotor. The punched areas can be filled with plastic or epoxy materials for extra strength, if required. The iron bridges at the outside of the rotor are designed to saturate under normal flux levels and therefore do not adversely affect the performance of the machine. They are there to provide mechanical strength.

The axially laminated rotor is constructed with laminations running the length of the rotor (i.e., into the page on Fig. 30.111). In between the laminations, a nonmagnetic packing material is used. This can be aluminum or bronze, for example, but a nonconductive material such as slot insulation is better since eddy currents can be induced in conductive materials. The ratio of the steel laminations to nonmagnetic material is usually about 1:1. The axial laminations are all stacked on top of each other, and a nonmagnetic pole piece is bolted on top

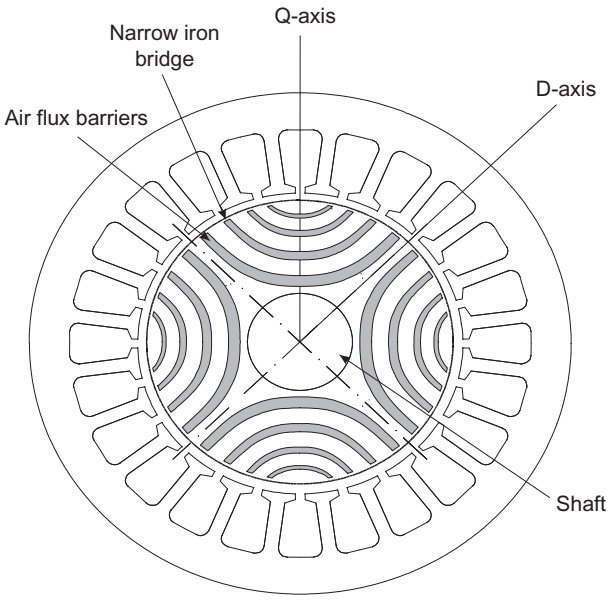

FIG. 30.110 Cross section of a radially laminated Syncrel.

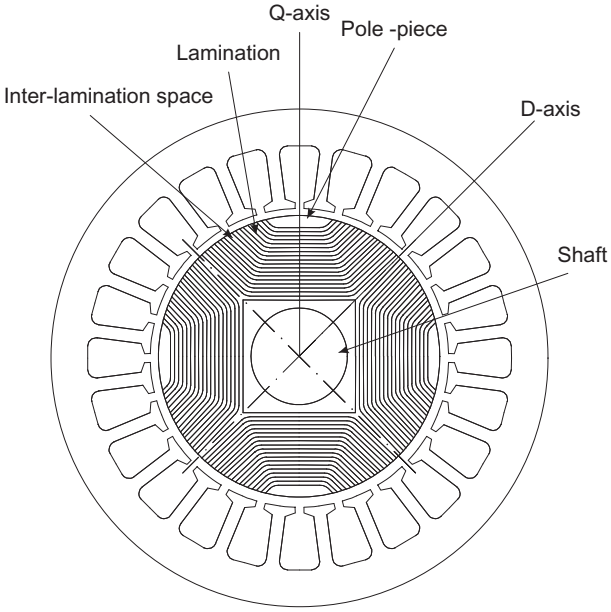

FIG. 30.111 Cross section of an axially laminated Syncrel.

of the stack to hold the laminations to the shaft. The strength of these bolts is usually the main limitation on the mechanical strength and hence the speed of rotation of this rotor. If more or thicker bolts are used to increase strength, the magnetic properties of the rotor are compromised because of the amount of lamination that has to be cut out to make room for them.

Radial- and axial-laminated rotors are usually limited to four-pole or higher machines because of the difficulty of accommodating the shaft in two-pole designs. An axially laminated two-pole rotor has been built with the shafts effectively bonded onto the end of the rotor. Another design was constructed of a block of alternating steel and bronze laminations, the whole structure being brazed together and the resultant stack then being machined into a round rotor and shafts (this rotor was used for high-speed generator applications).

Of the two rotor designs, the radially laminated one has the best potential for economic production. The axially laminated rotor in general gives the best performance, but the mass production difficulties with folding and assembling the laminations make its adoption by industry unlikely. On the other hand, improved designs for radially laminated rotors mean that they can now produce performance very close to that of the axial-laminated designs, and the ease of manufacture would indicate that these rotors are the future of Syncrel rotors.

30.10.4 Basic Mathematical Modeling

In order to give a more quantitative understanding of the machine, a basic mathematical dynamic model of the machine will be introduced.[1] This model will assume that the iron material in the machine does not saturate. This means that the flux density and flux linkage of the windings in the machine are linear functions of the currents in the machine.

To derive the electric dynamic model of a machine, one usually uses Faraday's flux linkage expressions. In the case of the Syncrel, the self and mutual flux linkage between the phases is obviously a function of the angular position of the rotor; therefore, one needs to have expressions for these inductances in terms of rotor position. The fundamental assumption used to make this mathematically tractable is that the inductances vary as a sinusoidal function of the rotor position.[2] The other major part of the modeling process is the conversion from a three-phase model to a two-phase model. This is a process that is carried out for most sinusoidally wound machines, since it allows a variety of machines to be represented by very similar models.

A further complication in this process is that the two-phase model is derived in a "rotating reference frame," as opposed to a stationary reference frame. Developing the equations in a rotating reference frame has the advantage that the normal sinusoidal currents feeding the machine are transformed into dc currents in the steady state, and the angular dependence of the machine's inductances disappear.

One way of heuristically understanding the effect of the rotating frame transformation is to imagine that we are observing the machine's behavior from the vantage point of the rotor. Because the sinusoidal flux density waveform is rotating around the machine in synchronism with the rotor, it appears

[1]Note that the model is not derived but instead just stated. The structure of the model will be heuristically explained.

[2]The sinusoidal variation of inductance with rotor position turns out to be very accurate because of the fact that the stator windings are sinusoidally wound. This forces the flux linkage to behave in a sinusoidal fashion.

from the rotor that the flux density is not changing with time—that is, it is a flux density created by dc currents flowing in a single sinusoidally distributed winding. This single sinusoidal winding is effectively rotating with the rotor. It should be noted that the transformation process of the fluxes, currents, voltages, and machine parameters to the two-phase rotating frame is an invertible process; therefore, one can apply the inverse transformation to ascertain what is happening in the original three-phase machine.

The models derived using the three-phase to two-phase transformations are known as *dq* models, the *d* and *q* referring to the two axes of the machine in the two-phase model (both stationary and rotating frame *dq* axes are shown in Fig. 30.109). The linear[3] *dq* equations for the Syncrel can be derived as [4]

$$v_d = Ri_d + L_d\frac{di_d}{dt} - \omega L_q i_q \tag{30.99}$$

$$v_q = Ri_q + L_q\frac{di_q}{dt} - \omega L_d i_d \tag{30.100}$$

where

$v_d i_d$ = the *d*-axis voltage and current,
$v_q i_q$ = the *q*-axis voltage and current,
L_d, L_q = the *d*- and *q*-axis inductances, respectively,
ω = the electric angular velocity of the rotor.

Thus far, we have concentrated on the electric dynamics of the machine. The other very important aspect is the torque produced by the machine. It is possible to derive the torque of the Syncrel using the principle of virtual work based on coenergy as

$$T_e = \frac{3}{2}p_p\left(L_d - L_q\right)i_d i_q \tag{30.101}$$

The 3/2 factor is to account for the fact that the two-phase machine produces two-thirds the torque of the three-phase machine.[4]

The only other remaining equation is the mechanical equation for the system

$$J\dot{\omega}_r + D\omega_r + T_F = T_e \tag{30.102}$$

where

$J \equiv$ the rotational inertia of the rotor/load,
$D \equiv$ the friction coefficient for the load,
$T_F \equiv$ the fixed load torque of the load,
$\omega_r \equiv$ the rotor mechanical angular velocity ($= \omega/p_p$).

[3]Linear refers to the fact that the equations are derived assuming that the iron circuit behaves linearly in relation to applied mmf and the flux produced.

[4]The 3/2 conversion factor is required if the transformations are power-variant transformations, as opposed to the power-invariant transformations. The power-variant transformations are the most common ones used because the single-phase machine parameters can be used directly in the resultant models, and the two-phase voltages and currents are identical in magnitude to their three-phase counterparts.

Remark Eq. (30.101) shows that the machine must be designed so that $L_d - L_q$ is as large as possible. This will maximize the torque that is produced by the machine for given d- and q-axis currents. To lower L_q, one must design the q-axis so that it has as much air obstructing the flow of flux as possible, and the d-axis must be designed so that it has as much iron as possible. In practice, these quantities cannot be varied independently.

Fig. 30.112 shows the equivalent circuit for the Syncrel corresponding to Eqs. (30.99) and (30.100). One can see that the dynamic equations for the Syncrel are intrinsically simple. In contrast, the induction machine electric equations consist of a set of four complex coupled differential equations.

30.10.5 Control Strategies and Important Parameters

The *dq* model captured in Eqs. (30.99)–(30.101) can be used to explain a number of control strategies for the Syncrel. It is beyond the scope of this section to present the derivation of these. The interested reader should consult references [4–6] cited at the end of this chapter.

One of the most common control strategies for any electric machine is to maximize the torque per ampere of input current. The following discussion should be considered in conjunction with Fig. 30.113, which shows the relationship of the various vectors in the machine to the $d_r q_r$- and $d_s q_s$-axes.

It turns out that one of the critical parameters for the control of the Syncrel is the angle of the resultant current vector in the machine in relation to the *d*-axis of the machine. It is possible to write the torque expression for the Syncrel in terms of this as

$$T_e = \frac{3}{2}p\left(L_d - L_q\right)|i|^2 \sin 2\delta \tag{30.103}$$

It is obvious that this expression is maximized for a given value of i if $\delta = \frac{\pi}{4}$. Therefore, one should control the currents so that δ stays at this angle, if maximum torque per ampere is desired.

Another control objective for the Syncrel is to maximize the power factor for the machine. This is important to minimize the kVA for the inverter. It can be shown that the current angle to maximize the power factor is [4]

$$\delta = \tan^{-1}\sqrt{\xi} \tag{30.104}$$

where $\xi = L_d/L_q$ (the inductance ratio).

Remark Eq. (30.104) indicates that ξ is the important parameter in relation to power factor. In order to obtain a power factor of 0.8, one requires an inductance ratio of approximately 10.

Finally, we shall consider another control objective—to maximize the rate of change of torque with a

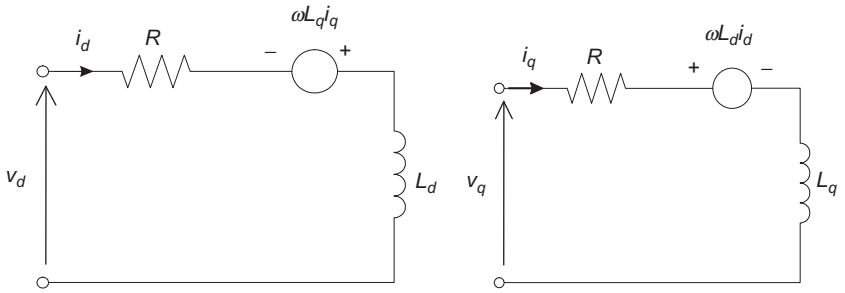

FIG. 30.112 Two-phase equivalent circuit of the Syncrel in a rotating frame.

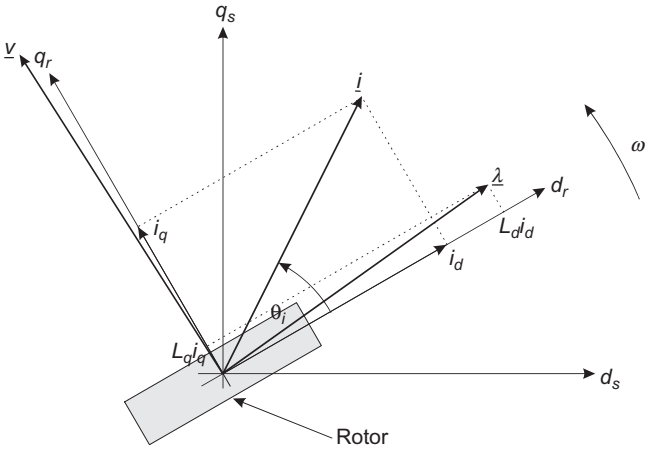

FIG. 30.113 Space phasor diagram of a Syncrel.

fixed-current-angle control strategy. In effect, this means that one is maximizing the rate of change of the currents in the machine for a given voltage applied to it. The analysis of this requirement results in [4]

$$\delta = \tan^{-1}\xi \tag{30.105}$$

Remark As with the maximum-power-factor case, ξ is the most important parameter in relation to the rate of change of torque. Because this control effectively optimizes the current into the machine for a given voltage and angular velocity, this angle also corresponds to that required to maximize the field-weakening range of the machine.

Other control strategies for the machine can be devised, as well as the current angles required to obtain the maximum power from the machine during field-weakening operation.

Remark If one carries out a thorough analysis of all the control properties of the Syncrel, then it emerges that all performance measures for the machine are enhanced by a large value of the ξ ratio.

30.10.6 Practical Considerations

The control strategies discussed in the previous section were all derived assuming that the machine does not exhibit saturation and there are no iron losses. The q-axis of the machine does not have any saturation, as the flux path on this axis is dominated by air. However, the d-axis of the machine does exhibit substantial saturation under operational flux levels, and this effect must be accounted for to optimize the drive performance.

The effect that saturation has on the ideal current angles is to increase them. This increase is most pronounced for the maximum torque per ampere control strategy, since this strategy results in a larger component of current in the d-axis, and consequently more saturation. Maximum power factor and maximum rate of change of torque are not affected as much. In order to get the correct current angle for maximum torque per ampere, a lookup table of the saturation characteristic of the machine must be stored in the controller, which is consulted in order to calculate the desired current angle [7].

It has been found that iron losses in the stator and the rotor also affect the optimal current angles. However, usually saturation effects dominate, and the effects of iron losses can be ignored.

30.10.7 A Syncrel Drive System

The basic structure of a variable-speed drive system based on using the Syncrel is shown in Fig. 30.114. Many components of this drive are very similar to those found in an induction machine drive system. One notable exception is the L_d lookup table block and the current reference generator. The L_d lookup stores the current versus d-axis inductance table for the machine, thereby allowing the inductance to be determined for various current levels. This table is also used to generate the incremental d-axis inductance. The inductance values generated from this table are used in the state feedback block and the torque estimator.

The state feedback block effectively generates an offset voltage to the PWM generator so that the voltage it produces is at least enough to counter the back emf. This technique effectively eliminates the back-emf disturbance from the current-control loops.

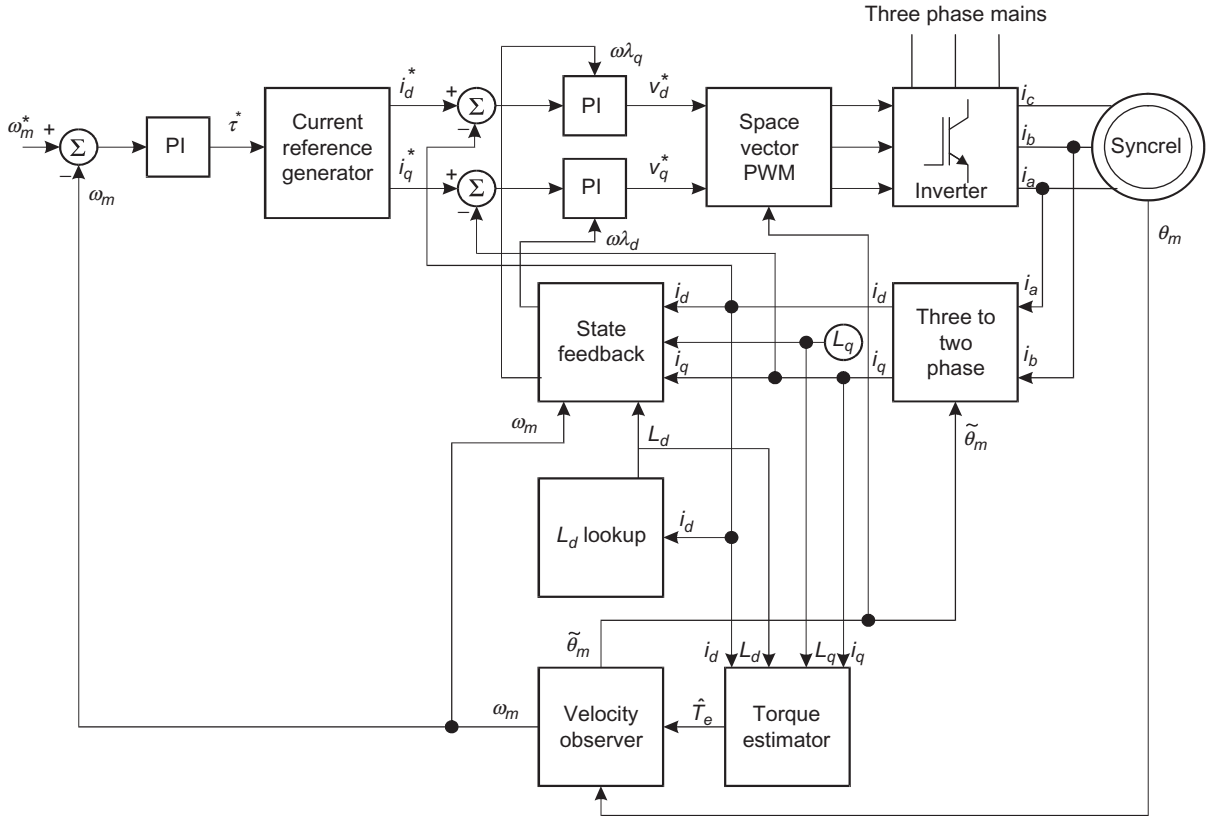

FIG. 30.114 Block diagram of a Syncrel drive system.

The current reference generator takes the desired torque as an input and generates the required *d*- and *q*-axis currents at the output. This block uses a lookup-table technique together with an inverse of the torque equation to generate these currents and takes into account the saturation characteristics of the machine.

The three-to-two-phase block converts the currents from a three-phase stationary frame to a two-phase rotating frame. This is a standard block in induction machine drives, and as with induction machine drives, this means that the Syncrel control algorithm is implemented in a rotating reference frame. The conversion from this frame back to the stationary frame occurs implicitly in the space vector PWM generator.

The Syncrel control algorithm is essentially a simplified vector controller, and consequently, the computational requirements are not high. This means that a Syncrel controller can be implemented on a modest microprocessor. As far as input and output hardware is concerned, the requirements are basically the same as those for an induction machine system—that is, sample two of the phase currents, the link voltage, and the rotor position.

30.10.8 Conclusion

The Syncrel-based drive system offers simplicity in control, excellent performance for variable-speed and position-control applications, good torque and power density, and efficiency that is more than competitive with that of the induction machine drive systems. To date, very few commercial drive systems are available using Syncrels, this being mainly due to the slow emergence of easy-to-manufacture rotors that give good performance and the conservatism of the motor-drive industry. One commercial application that has emerged is ac-servo applications, where the Syncrel offers low torque ripple (with appropriate rotor design) together with a small moment of inertia. Other applications under consideration are in the area of drives for electric vehicles and generators for flywheel energy storage systems. It remains to be seen whether the Syncrel can ever challenge the supremacy of the vector-controlled induction machine in mainstream industrial applications.

The interested reader who wishes to pursue Syncrel drives in more detail can find a good coverage of the control and motor design issues in [8].

31.1 Introduction

After the energy-generating industries, transportation system is utilizing a big part of world's energy resources. Thus, it is responsible for a comparable share of environment pollutants caused by the combustion of fossil fuel (viz. petrol, diesel, and ethanol) [1]. A global transformation of transportation system for environment protection, energy conservation, energy-efficient system, and low-carbon emission will require significant improvement in the process of onboard energy production and its efficient consumption [2–4]. This technological transformation requires systematic development of fuel- and energy-efficient technologies in transportation sector.

31.1.1 Motivations for Vehicular Electrification

Conventional transportation system employs internal combustion engine (ICE)-based propulsion system, which uses petroleum products for propulsion. It is estimated that, at the present consumption rate, the current global petroleum resources will be used up within the next 50 years [4]. It has also raised growing concerns about environmental pollution and subsequent climate changes. For example, in the United States of America (USA), conventional transportation system accounts for 30% of total greenhouse gases (GHG) emission, causing significant global warming [3]. Moreover, it is projected that world population will increase from the existing 6 billion to around 10 billion in the next 50 years while the number of vehicles in operation is set to increase from 700 million to 2.5 billion [4].

With the projected growth of small cars and its CO_2 emissions, the importance of addressing fuel efficiency in road transport is significantly important on global environment, energy, and climate change agendas. Road transportation system is responsible for approximate 20% of global CO_2 emissions from fossil-fuel combustion, and in most countries, CO_2 emissions from transportation are growing at a faster rate than total CO_2 emissions [2,3]. Projections for road transport growth and car ownership for the next few decades as shown in Fig. 31.1 show that road transport will continue to dominate, despite the rapid growth in shipping and aviation sectors.

Significant fuel economy improvements and reduction in tailpipe emission in road transportation sector are required to stabilize and reduce greenhouse gas and CO_2 emissions. The United Nations Intergovernmental Panel on Climate

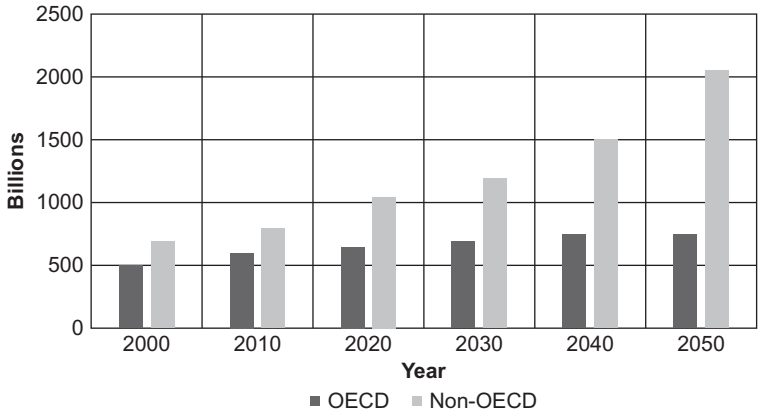

FIG. 31.1 Global growth in light-duty vehicles. Data from Mobility 2030: "Meeting the Challenges of Sustainability," World Business Council forSustainable Development (WBCSD) July 2004a and 2004b.

Change (IPCC) states that an ambitious 50%–80% reduction in global CO_2 emissions is required by 2050 (as compared with 2000 levels) in order to limit temperature rise to 2–2.4°C and stabilize atmospheric CO_2 concentration at 450 ppm, thus avoiding severe climate change [2,3]. Doubling the fuel efficiency of road vehicles is one of the most cost-effective and accessible measures toward achieving global stabilization of CO_2 emissions. However, the targets for both reduction of global CO_2 emission and improvement in fuel efficiency require that all countries should adopt cleaner technology on a large scale. Given this scenario, meeting the worldwide energy demand for the present and future transportation systems with the least impact on the environment is an important challenge in terms of technological and societal development.

In order to meet this challenge, novel concepts and innovations are being infused to make transportation systems more and more energy-efficient, reliable, and safe with zero or reduced emissions at an affordable cost. These novel concepts and innovations can be seen in terms of use of low-carbon fuel such as bioethanol or biodiesel, substitution of the petroleum energy by electric energy to drive vehicles, and hydrogen-based power generation. [4]. Majority of these innovations are solely relying on electrification of conventional vehicular technology and are grouped under the genre of electric vehicular technology (EVT). In EVT, ICE-based propulsion systems are being replaced by electric propulsion system (EPS), either partially or fully, to minimize fuel consumption and tailpipe emission. Vehicles that employ EVT can be broadly classified as follows [5–15]:

- Battery electric vehicles (BEVs)
- Hybrid electric vehicles (HEVs)
- Plug-in hybrid electric vehicles (PHEVs)
- Fuel-cell vehicles (FCVs)

BEVs are mainly the combination of energy storage system (ESS) and electric propulsion unit that together constitute the power to propel the wheels. Limited operating range and comparatively poor performance and limitation of storage system are the major concerns with BEVs. HEVs are the combination of BEVs and ICE vehicles to bring the advantages of both the vehicles together. Hybrid technologies can be used for almost all kinds of energy sources and engines. The additional electric and mechanical components make the HEVs more complex, bulkier, and costlier. PHEVs are the integration of EVs and HEVs to extend the degree of electrification and electric driving range of the vehicles to achieve the higher efficiency and reduced emission. However, infrastructures for charging stations are major concern. FCVs use hydrogen as fuel to produce electricity; therefore, they are basically emission-free.

31.1.2 Advancement of Electric Vehicular Technology

In the last decade, EVT is accelerated globally as competitor and sustainable alternatives of conventional ICE-based vehicles. Efforts and substantial resources are directed to meet market expectations for high-performance, energy-efficient, durable, safe, and affordable electrified vehicles [5]. The technological development and growth of EVT has taken on an accelerated pace on their road map to overcome the abovementioned issues associated with each of the electrified vehicles. Therefore, the dream of having commercially viable EVs/HEVs/FCVs/PHEVs is becoming a reality. EVs/HEVs are gradually commercializing and capturing the significant market space; PHEVs are ready to be commercialized, whereas FCVs are under development and yet to be commercialized [5–13]. The vision of vehicular electrification also includes generating electricity more and more from carbon-free and renewable energy sources such as wind, solar, hydro, fuel cell, and using them in transportation [12]. The next generation of electrified vehicles will therefore be integrated with electric power systems through EVs and PHEVs that will enable to implement grid-to-vehicle (G2V) and vehicle-to-grid (V2G) concept and will reduce environmental footprint significantly

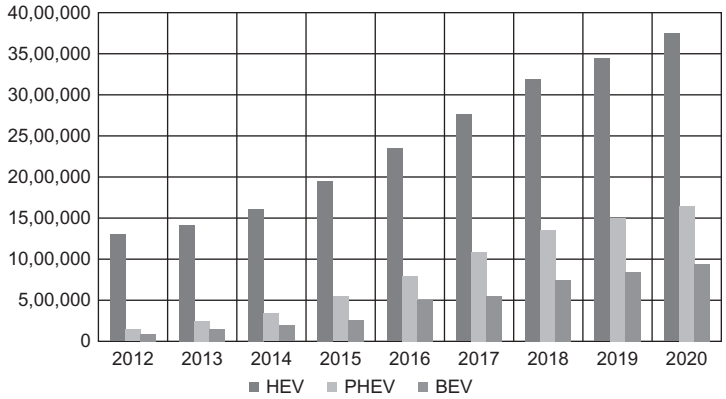

FIG. 31.2 Electrified vehicles sales worldwide. Data from https://www.navigantresearch.com/research/transportation-forecast-light-duty-vehicle/ (accessed 09.08.15).

[12–14]. The world-wise sales of BEVs, HEVs, and PHEVS are presented in Fig. 31.2.

In the last decade, successive development in vehicular electrification brought back the electrified vehicles specially HEVs in competition with ICE vehicles in terms of dynamic behavior, driving range, and practicability with added advantage of higher efficiency, reduced emission, and globally emerged as sustainable alternative of conventional ICE-based vehicles [5–10]. Therefore, at present, major attention has been focused on technological advancement and modernization of HEVs. Moreover, automobile industries are shifting toward more fuel-efficient, improved performance, higher degree of reliability, durability, safety, and added comforts. Thus, significant efforts and resources are being spent by leading car manufacturers and government to meet these market expectations at an affordable cost [16].

31.1.3 Hybridization of Energy System for EVT

In an EVT, the onboard energy sources are limited and acting as bottleneck of the technology [17]. However, it is essential that the power requirement of vehicle load should be met on board. It is impractical and very expensive to size a single-source energy system to offer continuous power with a capacity many times higher than the average power demand, just to meet momentary peaks in power needs. Therefore, adopting multiple energy sources on board that are specialized for the various segments within a vehicular power demand bandwidth becomes a viable solution [17]. The combination of storage system with high-energy-density specifications and storage system with high-power-density specifications provides sustainable solutions [18]. The task of a power and energy management system then is to properly coordinate the dynamics of the energy systems without compromising the vehicle's targeted performance [19].

In EPS, none of the available energy sources are capable enough to meet power and energy requirement of the vehicle for all driving profile [18]. In recent years, it has been observed that to fix the onboard energy demand of electrified vehicles, there is need to mix the energy sources. This encapsulates the idea that the solution to problem of meeting onboard energy demand is hybridization of diverse energy sources such as fossil fuel, solar, hydrogen, and portable source of electric energy like battery, ultracapacitor, and fuel cell.

As an alternative to onboard single-source energy system, hybridization of energy sources is considered as durable and sustainable energy system. HES is gaining more and more popularity in vehicular electrification due to their ability to provide high-power and high-energy-density systems. A well-designed HES offers features like reliability, durability, cleanliness, and efficient power processing operation compared with single-source energy system [17–20]. It provides optimum solution between availability and utilization of energy sources and offers good power-handling capability in steady-state operation and superior dynamic response during transient conditions.

31.1.4 Power Electronics for EVT

The integration of different components from different branches is a major challenge and is a growing concern in the road map of vehicular electrification. PECs and switches are playing a very significant role in incorporating different components and provide compatibility for proper coordination among them to meet vehicle's requirement in all driving profiles [21–25]. Advancement in power electronic devices is an enabling technology for the next generation of vehicles that offers smarter, efficient, cleaner, precise, environmentally friendly, and more flexible drive. The reasons for rapid acceleration in growth of vehicular power electronics as discussed in [23] are as follows:

- The new vehicle architecture integrated with power electronics makes the switching and fusing functions through single component with higher degree of reliability.

- Integrated of sensing technique with power electronic devices enables easy fault detections and diagnosis and makes system capable for fault-tolerant operation.
- PECs make on demand power conversion as per auxiliary load profile and for propulsion motor resembling the functions of adjustable speed drives.
- Voltage conversion for different voltage level especially in dual-voltage architecture and dc/ac and ac/dc conversion can be done using power electronics.
- Power electronics devices are used in the development of electronically controlled actuators and variable valves with high degree of precision and accuracy.
- Power electronics with modern digital signal controller provides very fast and high-power motion control of propulsion system by enabling high-power actuation and dynamics.

Power semiconductor devices constitute the heart of modern power electronic apparatus, and today's power electronic evolution has been possible primarily due to evolution in power electronic devices [21]. In the past few years, power device technology has made remarkable progress and grown in power rating and performance by an evolutionary process.

For EVT, there is a need of highly reliable, flexible, and fault-tolerant EPS. Suitable integration of ESS, power electronic converters (PECs), electric motors (EM), and electronic control unit (ECU) makes the EPS to compete against the conventional ICE-based vehicle [25]. The responsibility of integration of these components is well taken care by power electronic devices. A PEC, consisting of a matrix of power semiconductor switches and one or several passive components, helps to convert and control electric power from one form to another form at different voltage and current profile between ESSs and EMs according to the driving profile of the vehicle. PECs act as an interfacing medium for the hybridization of different energy sources like battery, ultracapacitor and fuel cell to match the onboard power and energy requirement. For vehicle acceleration, PECs take power from onboard energy system and supply power to the electric motor as per the demanded vehicle operation. On the other hand, PECs can also be used to utilize recovered energy during deceleration and regenerative braking to charge ESS. The electronic controllers composed of sensors, digital signal processors, and interfacing circuitry are used to generate the control signals for PECs [26].

Power electronics is an enabling technology for efficient electric power processing, which plays crucial role in shifting paradigm from conventional ICE vehicles to electrified vehicles [22,25]. The demand of electric power in vehicular application is growing rapidly as the mechanical components are being replaced by the electric and electronic components. It is expected that the power demand in electrified vehicle could reach 2–3 times of the current demand [23]. In order to accomplish the growing power demands of electrified vehicles in desired manner, integration of power electronic components with electric and mechanical loads of the vehicle becomes crucial [24]. The integration of PEC not only improves the overall performance and fuel economy but also reduces the emission as well as weight and size of the EPS.

31.2 Electric Vehicular Technology

The development process of the electrified vehicles is interesting, as the first battery-operated electric vehicle is invented in 1834 [8]. Due to the lack of technology, primarily for electrochemical storage units, the interest in EVs gradually diminished and ceased to receive any attention after 1920. In the early 1970s, circumstances changed in favor of the electrified vehicle concept due to the dramatic increase in petroleum prices, global awareness about environmental pollution, and stringent emission regulation [8]. The research on EVT is motivated by the argument that electric vehicles represent an economical and technically sustainable option for future transportation systems. Environmental impacts, escalating prices of petroleum fuels, emission restrictions, and the depletion of natural resources provide compelling impetus toward the development of more eco-friendly solutions. It represents one of the greatest challenges of today, a challenge that calls for sustainable advancements and development of EVT.

EVT, essentially, has two major components:

(1) Vehicle architecture and configuration
(2) Electric propulsion system that includes
   - energy storage system (ESS),
   - power electronic converter (PEC),
   - electric motor (EM),
   - electronic control unit (ECU).

There are plenty of review papers and literature that deal individually with topological architecture and configuration [4–15,27–29], energy source and storage systems [17–20,30–47], electric machines [21,48–62], power electronic converters [21–25,63–75], and power-flow management and control strategy [76,77]. This section discusses the architecture of HEVs that includes series, parallel, series-parallel, and complex HEV.

31.3 Classification of Electric Vehicular Technology [6]

The vehicular technology can be classified as ICE-based vehicles and EPS-based vehicles or electrified vehicles. Electrified vehicles that are driven by EPS either fully or partially further are classified as EVs, HEVs, PHEVs, and FCVs. In EVT, each vehicle has its own capability and limitation in terms of energy density, power density, emission rate, performance, fuel efficiency, size, weight, cost, and safety [4–10]. These factors are heavily governed by the particular vehicle architecture and

propulsion system configuration. Out of the several class of electrified vehicle mentioned above, HEV is the only option that has potential to compete the ICE vehicles in terms of performance. The major advantages of HEV are extended electric range of operation, good fuel economy, higher efficiency, and sufficient onboard power and better dynamic response. Different characteristic such as size versus distance characteristic is depicted in Fig. 31.3, whereas driving distance of some popular BEVs, HEVs, and PHEVs commercialized so far is given in Table 31.1 along with their associated benefits.

31.3.1 ICE Vehicles

A conventional ICE burns a high-energy-density petroleum fuel (gasoline/diesel) in its combustion chamber and produces power that can be utilized to propel the vehicle by means of

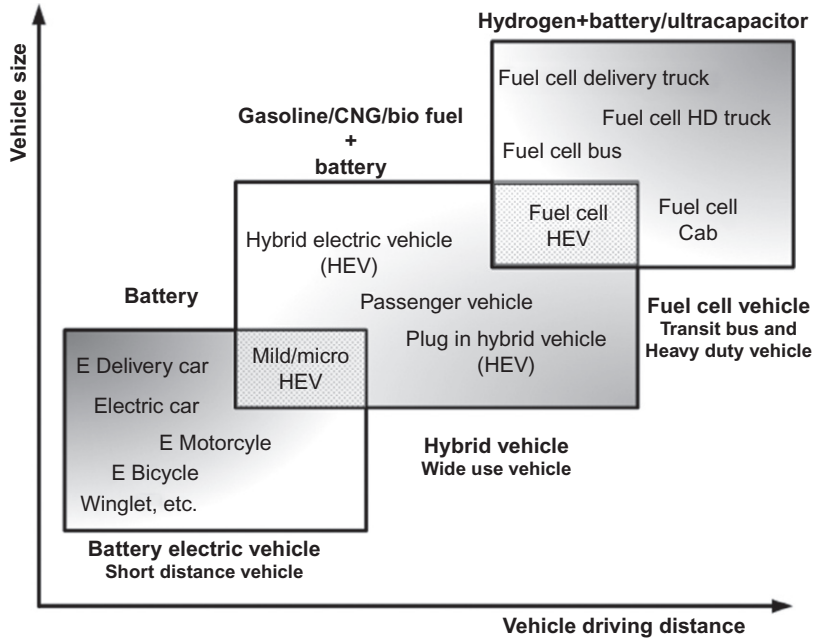

FIG. 31.3 Classification of EVs/HEVs/PHEVs/FCVs based on size versus distance. Based on www.toyota-global.com.

TABLE 31.1 Characteristic of different electrified vehicles

S.No	Car Model	Range (miles)	Top Speed (mph)	Charge Time (hrs)	Battery (kWh)	Rated output (HP)	Acceleration (0-60 mph)

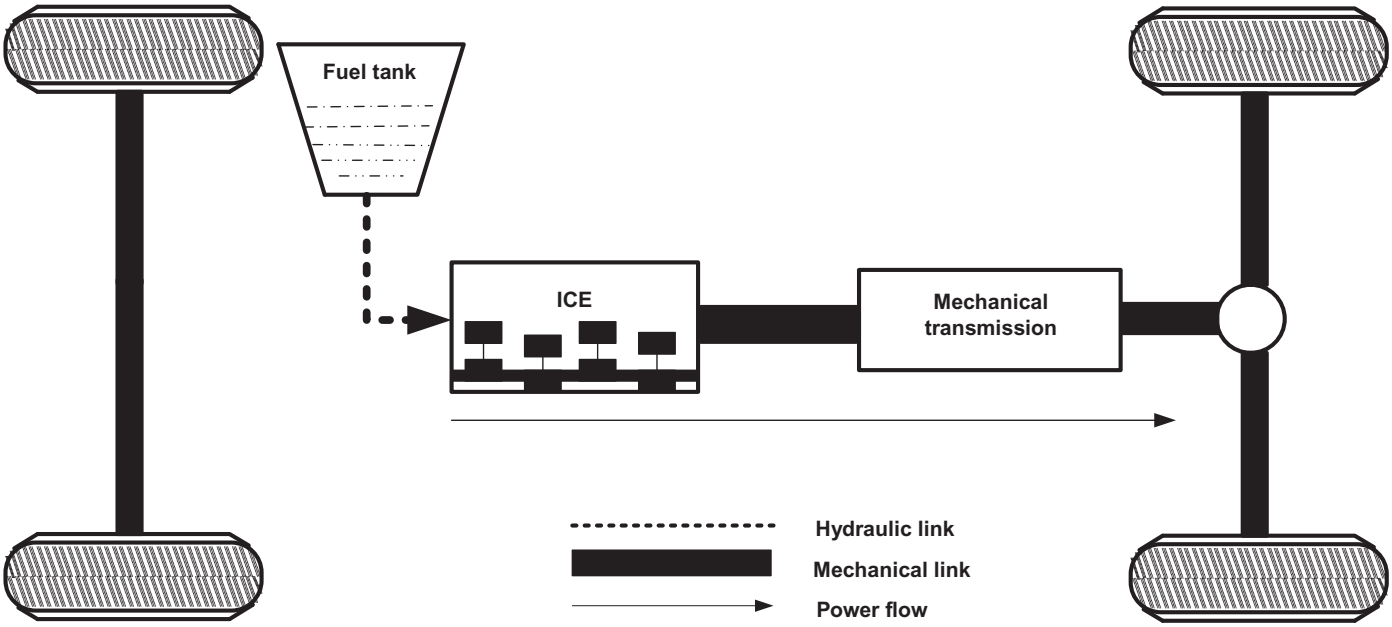

FIG. 31.4 Configuration of ICE-based vehicles [6].

mechanical transmission. An ICE-based power train is shown in Fig. 31.4. It consists of a fuel tank that provides onboard high-density-energy source, the internal combustion engine, and a mechanical transmission to transport the power from engine to wheel. The ICE vehicles score in driving distance because of the high energy density of liquid hydrocarbon fuels and dominate in recharging times as a refilling station takes minutes, compared with hours of battery charging time in electrified vehicles [6,29]. The main drawbacks of the conventional ICE vehicles are poor efficiency to convert the fuels into useful power and excessive tailpipe emission, which produces harmful impact on the environment. It has been proved that the maximum fuel conversion efficiency of conventional ICE-based vehicles is 25%–30% at best [6,7]. The main reason of inefficiency of ICE vehicles is the mismatch of engine power characteristic with the real load characteristic of the vehicles as shown in Fig. 31.5, poor efficiency of mechanical transmission and waste of kinetic energy during braking [29]. Although

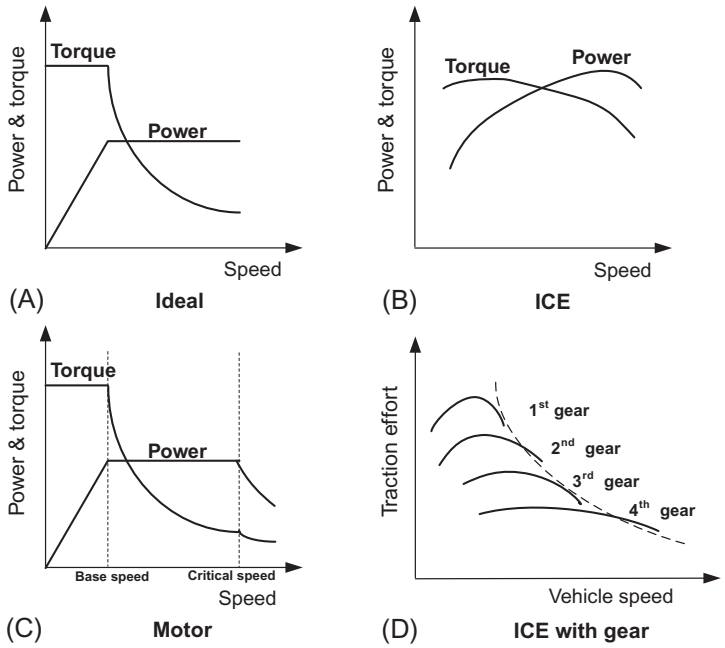

FIG. 31.5 (A) Ideal torque-speed characteristic for vehicles, (B) torque-speed characteristic of ICE, (C) torque-speed characteristic of electric motor, and (D) torque-speed characteristic of ICE with gear arrangement [29].

internal combustion engines have been used for more than a century, significant improvements in fuel economy, energy efficiency, and emission reduction have been achieved, and still, great research for optimization is going on.

31.3.2 Battery Electric Vehicles

New environmental concerns over the amount of pollutants released into the atmosphere by internal combustion engines (ICE), unstable petroleum prices in international market, and various emission regulations such as the California Air Resources Board (CARB) have mandated the concept of zero-emission vehicle (ZEV). This becomes a powerful motivation for the use of battery electric vehicles.

The concept of electric vehicles is based on electric drives that consist of the electric motor, power modulator, and onboard energy source and a controller. A simplified architecture of a BEV is shown in Fig. 31.6. A BEV has various advantages such as zero emission, high efficiency, independence of petroleum fuels, less noise, safe, and smooth operation. Moreover, while the maximum efficiency of the ICE vehicle can be 30%–35%, electric propulsion system drawing the power from battery can operate with a peak efficiency of 90% [4–8]. Also, electric vehicles have the capability to recover the waste energy through regenerative braking.

Apart from significantly large battery charging time, lower flexibility, and dynamic performance, an important limitation of BEV is its limited operating range per cycle of battery charge. For BEVs to compete against ICE vehicles, advanced energy sources and intelligent energy management system would play key roles.

31.3.3 Hybrid Electric Vehicles

A hybrid electric vehicle (HEV) is powered by the existing ICE technology and a suitable electric drive system. According to technical committee 69 (electric road vehicles) of the International Electrotechnical Commission, "a hybrid electric vehicle (HEV) is a vehicle in which at least one of the ESSs or converter can deliver electric energy." Conceptually, HEV uses two energy sources, namely, a fuel (like gasoline, diesel, and hydrogen) and stored energy (as in battery, ultracapacitor, and flywheel), to propel the wheel. The concept of HEV is to combine the EV and ICE vehicle so that better fuel utilization, good dynamic performance, and reduced tailpipe emission can be achieved, and their respective limitations can be overcome [6–9].

The major advantages of HEV are extended electric range of operation, good fuel economy, higher efficiency, and sufficient onboard power to meet the vehicles' demand in all driving profile. Combining automobile technology with electric technology adds complexity in controls and makes the system heavier and costly. Management and control of power flow from more than one energy sources to the load is a major concern and has to be treated in an optimized way so that better utilization of energy at predicted cost is achieved [6,10]. Fig. 31.7 shows the conceptual power-flow diagram of HEV.

To meet the desired load demand and to optimize the utilization of energy source(s), there are following possible operating modes to combine the two energy sources as illustrated in Fig. 31.7:

Mode I—Energy source A alone supplies power to the load.
Mode II—Energy source B alone supplies power to the load.

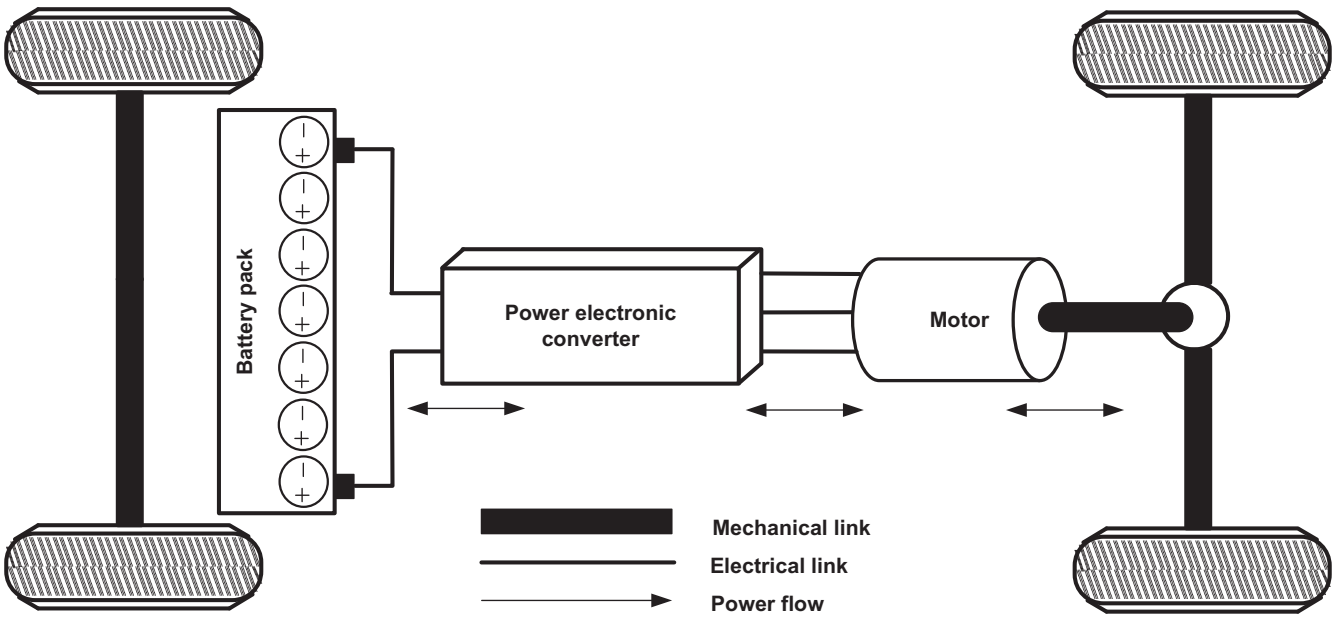

FIG. 31.6 Topological structure of BEVs [6].

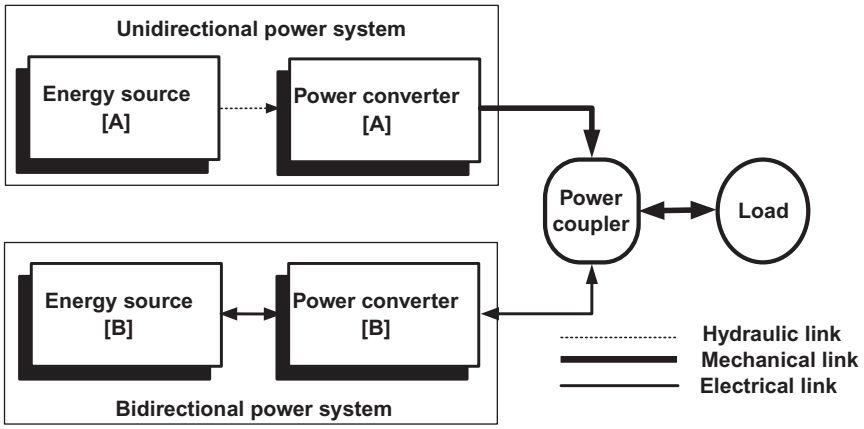

FIG. 31.7 Power flow in HEVs [78].

Mode III—Both energy sources A and B supply power to the load simultaneously.
Mode IV—Energy source B draws power from energy source A.
Mode V—Energy source B draws power from load at the time of braking (regenerative braking).
Mode VI—Energy source A supplies power to energy source B and the load simultaneously.
Mode VII—Energy source B draws power from energy source A and load simultaneously.
Mode VIII—Energy source A supplies power to energy source B, and energy source B supplies to the load.
Mode IX—Energy source A supplies power to load, and load supplies power to energy source B.

Energy source A could be gasoline/diesel/fuel cell, and power converter A is unidirectional in nature and converts chemical energy into mechanical energy. Energy source B could be a battery and/or ultracapacitor, and power converter B is bidirectional in nature and delivers electric output. Topological configuration of HEVs is based on energy utilization scheme of energy sources. In the automobile industry, development trends are toward mounting sophisticated electric systems and replacing various mechanical and hydraulic systems to provide more comfort and to increase safety [8].

HEVs are traditionally classified into four categories: series hybrids, parallel hybrids, series-parallel hybrids, and complex hybrids, where the entire configuration brings together the electric and mechanical power through various components.

31.3.3.1 Series Hybrid Electric Vehicles

A series hybrid is an HEV that has two energy sources empowering an electric motor that propels the vehicle. SHEVs are the simplest form of HEVs in which an ICE is mechanically coupled with an electric generator that, in turn, is connected to the electric motor and electrochemical battery pack through a power electronic converter as shown in Fig. 31.8. With the help of generator, mechanical power of ICE is transformed into electric power. The transformed electric power can be used to

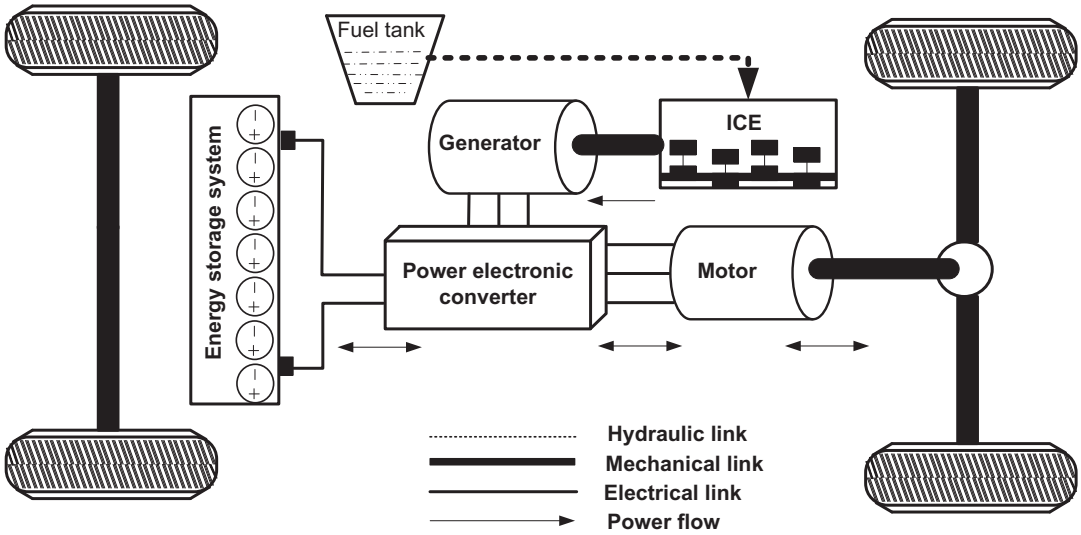

FIG. 31.8 Architecture of an SHEV [6].

charge the battery or can evade the battery to supply the electric motor to propel the vehicle, or both can happen simultaneously by means of power electronic converter [5,10]. The power flow from fuel tank to power electronic converter is unidirectional and from battery to electric motor is bidirectional.

Basically, it is ICE-based EVs where there is no mechanical link between ICE and wheel. The start/stop of ICE is controlled by the battery state of charge (SOC). When the battery reaches at a preset minimum SOC, the ICE starts in order to charge the battery. The ICE stops when the battery has reached a desirable maximum SOC. The control algorithm for the optimal operation of engine, having high efficiency and low fuel consumption, is selected such that the battery SOC should be maintained at around 65%–75% of full charge [9]. However, power transportation from energy sources to the wheel takes two stages of power conversion (mechanical to electric and electric to mechanical) and leads to increased energy losses and reduction in overall efficiency of the vehicle. All possible combinations (modes I–IX) of two energy sources are applicable for the SHEVs, but practically, only modes I–VI have been used so as to extend the life of battery [6]. The mechanical decoupling between the engine and wheels increases the degree of flexibility and reduces the complexity. Since the electric motor has the desired torque-speed characteristic, multigear mechanical transmission system can be eliminated. Simplified construction, control strategy, and reduced costs are the salient features for such a system. However, addition of generator and size of propulsion unit are two major concerns. The SHEVs are best suited for city driving where frequent "starts" and "stops" occur over a part of distance being traveled [5].

31.3.3.2 Parallel Architecture

In a parallel hybrid configuration, ICE and electric motor are connected in parallel to deliver power to the wheel as shown in Fig. 31.9. The powers from electric motor and ICE are pooled together with the help of mechanical coupling. However, the mechanical coupling adds to the complexity in control algorithm for the vehicle. The vehicle can be driven with the ICE, the electric motor, or both simultaneously, and therefore, it is possible to feed the desired amount of power at any given period of time [5–10]. In parallel HEV, except modes VII, VIII, and IX, all other modes (I–VI) can be used for better utilization of energy sources and reliable operation [6]. In this configuration, efforts are made to operate the electric motor alone at lower speed and ICE alone at higher speeds. Thus, at higher speed, ICE is operated at most efficient point, and hence, higher efficiency and better fuel consumption along with reduced tailpipe emission can be achieved. In case of acceleration or hill climbing, both the power sources are activated to fulfill the desired power demand. When ICE is working alone or in case of regenerative braking, the electric motor can operate as a generator to charge the battery.

As compared with series HEV, elimination of generator leads to single-stage power conversion that increases the efficiency and reduces the weight and cost of the vehicle. The parallel coupling of the power sources leaves space for further research and improvement of vehicle's performance. The major research efforts on parallel HEVs are focused on the implementation of continuously variable transmission (CVT) instead of a fixed-step transmission that gives the freedom to operate the ICE at its most efficient point at demanded torque [9].

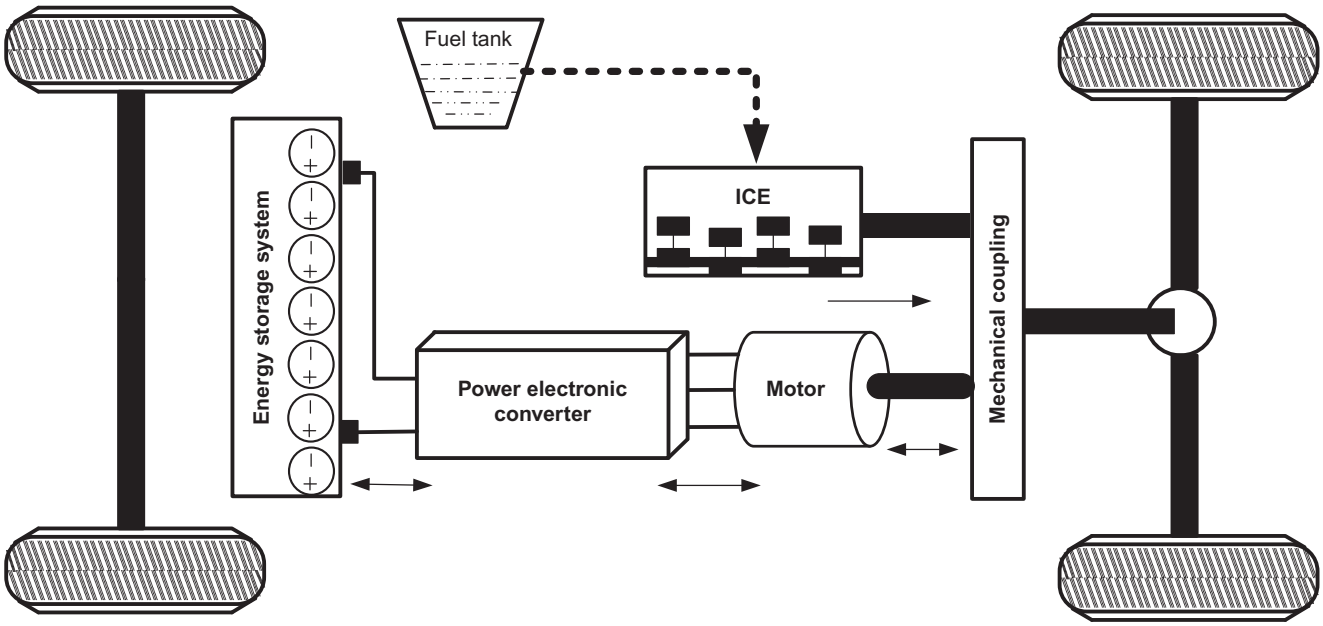

FIG. 31.9 Architecture of parallel HEV [6].

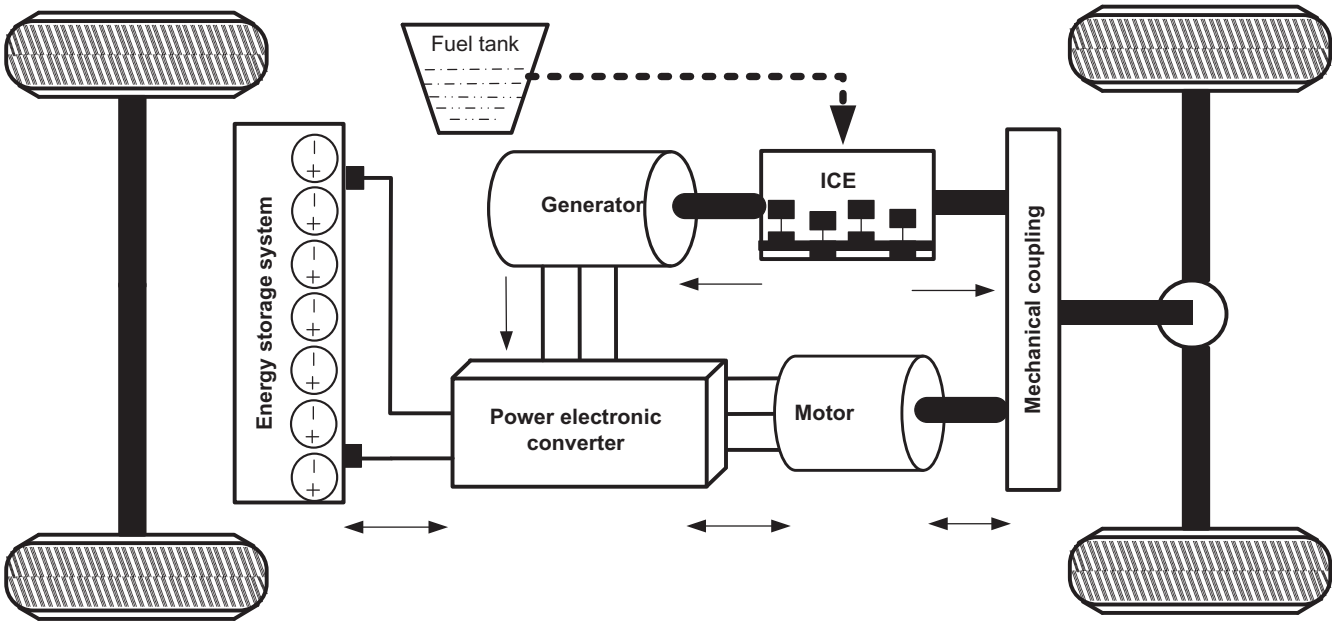

FIG. 31.10 Architecture of series-parallel HEVs [6].

31.3.3.3 Series Parallel Architecture

Series-parallel HEV is an integration of the series and parallel hybrids as shown in Fig. 31.10. The configuration introduces an additional mechanical link (unlike the series hybrid) and an additional generator (unlike the parallel hybrid) to facilitate the advantages of both configurations [4–10]. Among various possibilities in series-parallel hybrids, the general classification includes electric-intensive and engine-intensive. In electric-intensive configuration, electric motor is more dominating than the ICE. In engine-intensive configuration, ICE is more dominating than electric motor [10]. Accordingly, the dominating components are designed. The operating modes (start, normal driving, acceleration, deceleration, braking, and battery charging) of electric-intensive and ICE-intensive are almost the same except for the normal driving mode. In normal driving mode, efforts are made to operate the engine at its most efficient point. Therefore, in ICE-intensive configuration, the engine propels the wheels solely, and in electric-intensive configuration, the ICE can assist the electric motor to propel the wheels. Although the series-parallel hybrid vehicle incorporates the advantages of both the series and parallel hybrid, the use of additional electric and mechanical components (generator and planetary gear arrangement) adds to the complexity, weight, and costs.

31.3.3.4 Complex Hybrid System

All the configurations discussed previously are implemented for single-axle propulsion, for either the front or the rear wheel. A new hybrid scheme known as complex hybrid configuration is designed for dual-axle propulsion. In such an architecture, illustrated in Fig. 31.11, both the front and rear wheels propel the vehicle. In this configuration, the front-wheel and rear-wheel axles are decoupled from each other, and there is no mechanical link between them; hence, both the axles are driven independently [10]. In complex hybrid vehicle, the electric generator offers bidirectional power flow, whereas in case of series-parallel, it offers unidirectional power flow. However, both the configurations involve ICE, electric generator, and motor to propel the vehicle. The capability of complex hybrid system, to drive the wheels by either electric propulsion or hybrid propulsion or combination of both, offers additional flexibility and reliability. The front wheels are propelled by hybrid propulsion system, and rear wheels are propelled by electric propulsion system or vice versa. The operating modes for both the scheme are almost common, except when front wheels are propelled by hybrid system, all the wheels are driven; however, when front wheels are propelled by electric system, only front wheels are driven at starting [8–10]. A planetary gear arrangement is used to coupled ICE, front electric motor, and front axle altogether. Independent control of front and rear wheels provides smooth vehicle operation and flexibility in casing. This, however, increases complexity and costs. Also, regenerative braking in all four wheels can significantly improve efficiency of the system and hence fuel economy.

31.3.4 Plug-in Hybrid Electrical Vehicles

Plug-in hybrid electric vehicle is a transitional technology between BEVs and HEVs. The IEEE (board of directors, 2007) defines a PHEV as "any hybrid electric vehicle that contains at least (i) a battery storage system of 4 kWh or more, used to power the motion of the vehicle; (ii) a means of

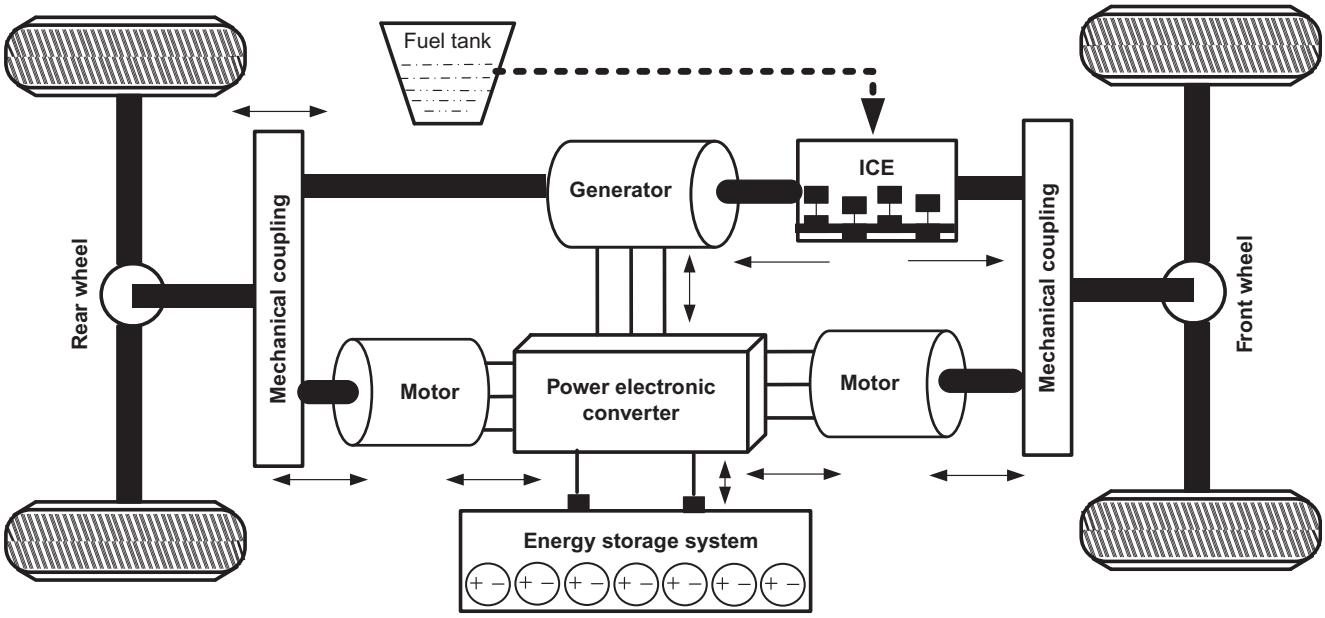

FIG. 31.11 Operating modes of complex HEVs [6].

recharging that battery system from an external source of electricity; and (iii) an ability to drive at least 10 mi in all-electric mode, and consume no gasoline" [15]. Conceptually, a PHEV is a HEV with large battery pack that can be recharged from the external source (utility grid or renewable source of energy) to extend the all-electric range (AER) of the vehicles as shown in Fig. 31.12.

In this vehicle, fuel tank and battery pack both can be recharged by external sources and are entirely different from hybrid vehicles that do not utilize any electric energy from the external sources or grid. When the battery pack is fully charged by external source, PHEV operates as EV with extended AER (30–60 km) and then switches to hybrid mode when battery reaches its predefined SOC or vehicle demands extra power for acceleration [13,14]. Moreover, not only PHEV has the capability to charge the battery pack from the grid, but also it will be able to supply the power to the grid, and hence, the vehicle-to-grid (V2G) concept is evolved [15]. The emerging technology of V2G must be bidirectional in nature so that grid can transfer power to the vehicle in charging mode, and vehicle delivers power to the grid in discharging mode at peak hours. All vehicles with V2G capability must meet the IEEE Standard 1547 for connecting to the utility.

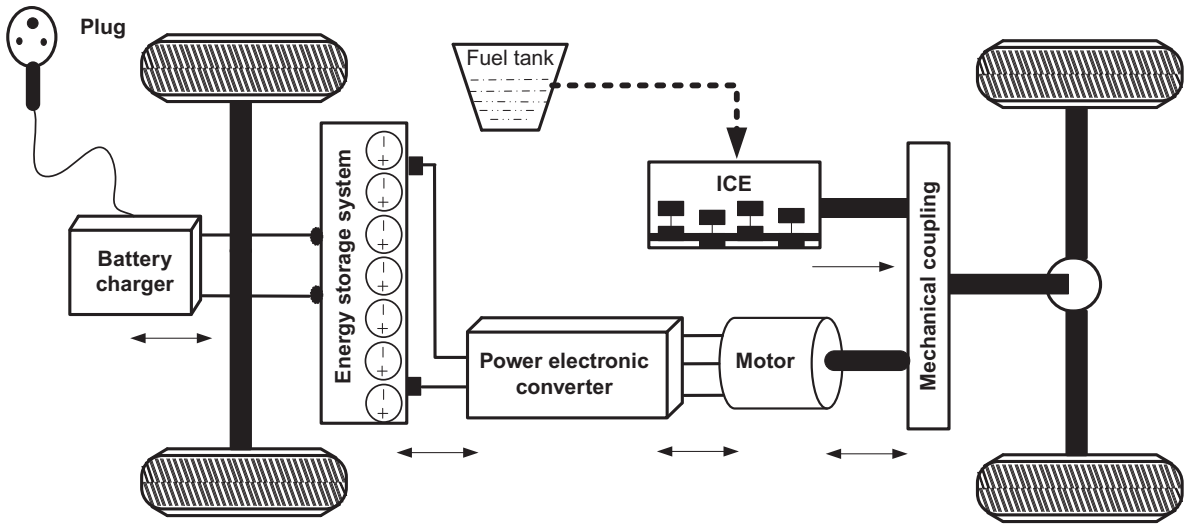

FIG. 31.12 Schematic diagram of PHEVs [6].

31.3.5 Fuel Cell Vehicles

In recent times, fuel-cell vehicle (FCV) is an upcoming technology, which involves automobile, electric, and chemical engineering. A fuel cell is a chemical engine that produces electricity from hydrogen, emitting only water as a by-product. The electricity produced is used for driving electric motor coupled with wheel of the vehicles. Fuel-cell technology offers the advantages of portable power supply. Unlike ICE, a fuel cell directly converts chemical energy into electric energy without internal combustion and pollution. In contrast to a battery, the fuel cell generates electric energy rather than storing it and continues to supply energy as long as fuel is fed [9].

Fuel-cell vehicles (FCVs) can be fueled with pure hydrogen gas stored on board in high-pressure tanks. They can also be fueled with hydrogen-rich fuels including methanol, natural gas, or even gasoline; these fuels must first be converted into hydrogen gas by an onboard device called a "reformer." This will add cost, complexity, and weight to the vehicle but will make the fuel distribution easier [28]. FCVs fueled with pure hydrogen emit no pollutants, only water and heat, while those using hydrogen-rich fuels and a reformer produce only small amounts of air pollutants. In addition, FCVs can be twice as efficient as similarly sized conventional vehicles and may also incorporate other advanced technologies to increase efficiency [9]. A conventional FCV system is shown in Fig. 31.13, where hydrogen-enriched fuel is first refined by the reformer to acquire pure hydrogen gas. This hydrogen gas is fed to fuel-cell stack where it directly meets oxygen of the atmosphere and undergoes a chemical reaction; consequently, electricity is produced. The output power of fuel-cell stack is processed by *PEC* to meet the power requirement of the EPS.

Since the power flow from the fuel cell to propulsion unit is unidirectional, to recover the braking energy by means of regenerative braking, storage medium such as battery and ultracapacitor can be included in the system. The storage unit stores energy and supplies to propulsion system at the time of acceleration to assist the fuel cell [27]. The integration of ICE and battery pack with fuel-cell system gives the concept of hybrid FCVs where all the configuration and advantages of HEVs can be utilized. With suitable power electronics arrangement, FCVs can also be operated as plug-in fuel-cell vehicles (PFCVs) where battery pack can be charged from grid or discharged to supply the grid [34]. Higher efficiency, reliability, and quieter operation with negligible emissions are some of the important features, which continue to attract the attention of researchers. As efforts are being directed to further improve the fuel-cell technology along with significant cost reduction, it has high potential to energize future automobile [8,9]. A fuel-cell system integrated with vehicular propulsion system must have the ability to compete against the ICE vehicles on cost, weight, onboard energy density, start-up, and transient response with the attainment of benefits such as zero emission and higher efficiency of the battery-operated vehicles.

Different types of electrified vehicles have their own capabilities and limitations in terms of emission rate, performance, fuel efficiency, durability, size, weight, cost, safety, and comfort. Among different types of electrified vehicles, HEV is the only one that currently has the potential to compete the ICE vehicle in terms of performance and all driving profiles and offers advantages like extended electric range of operation, good fuel economy, higher efficiency, sufficient onboard power, and better dynamic response [5–10]. However, integration of automobile technology with electric technology adds complexity in controls and makes the HEV system comparatively bulky and costly. At present, HEV technology is rated as a promising technology that is growing rapidly and capturing significant market space at a fast growth rate [7–9]. Plug-in HEVs are currently at the commercialization stage. To be commercially viable, they require good energy policies and infrastructure for charging stations in the near future [13–15]. The efficiency

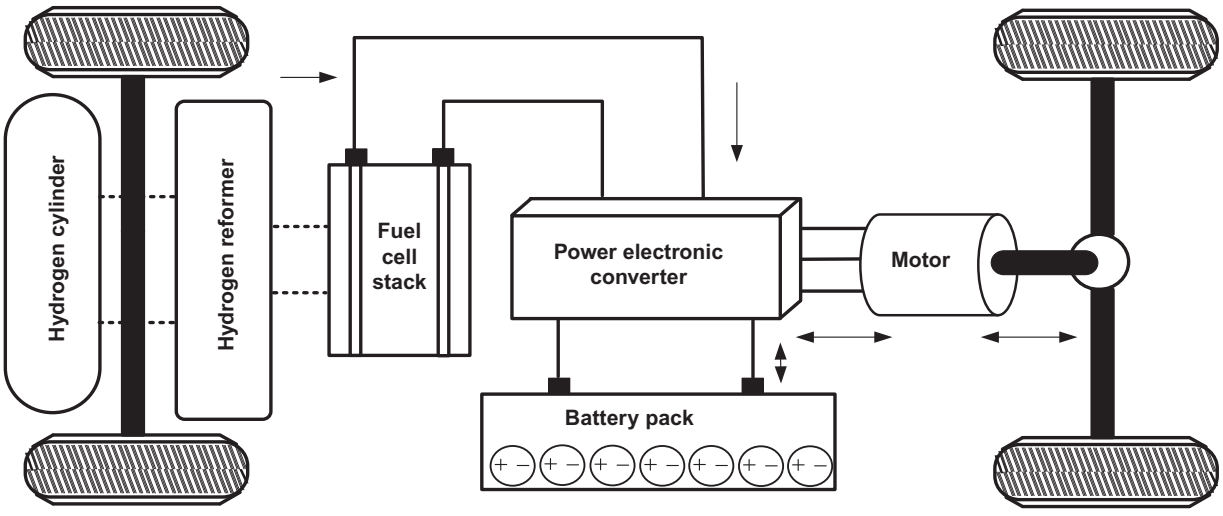

FIG. 31.13 Schematic diagram of FCVs [6].

analysis from well to wheels, the concept of V2G and G2V, and the impact of charging station on the grid are the major issues that are being researched for successful commercialization. On the other hand, fuel-cell vehicles, powered by hydrogen, are considered as the future of EVT [27,28]. The different characteristics and issues of ICEV and EVT presented in [8] are revised and summarized in Table 31.2.

31.4 Electrical Propulsion System

The sustainability of EVT is relying on maturity, which depends on technological advancement and development of its components such as ESS, PEC, electric motor, and ECU [29,78]. The ESS replaces the fuel tank and fulfills the energy requirement of the electric vehicular system.

TABLE 31.2 Different characteristics of ICEV/EV/HEV/PHEV/FCV [4]

Characteristic	Propulsion system	Energy storage	Energy source infrastructure	Advantages	Drawbacks	Important issues
ICE vehicles	■ ICE based drives	■ Fuel tank	■ Petroleum products with refueling station	■ Matured technology ■ Fully commercialized ■ Better performance ■ Simple operation ■ Reliable and durable	■ Less efficient ■ Poor fuel economy ■ Harmful emission ■ Comparatively ■ Bulky	■ Fuel economy ■ Harmful Emission ■ Highly dependency on petroleum products
EVs	■ EPS based drive	■ Battery ■ Ultra capacitor ■ Flywheel	■ Electrical energy with charging facilities	■ Energy efficient ■ Quite and Zero emission ■ Independency from petroleum products ■ Smooth operation ■ Commercialized	■ Limited driving range ■ Higher recharging time ■ Poor dynamic response	■ Size and weight of battery Pack ■ Vehicle performance ■ Infrastructure for charging station
Hybrid EVs	■ EPS and ICE based drive	■ Fuel tank ■ Battery ■ Ultra capacitor ■ Flywheel	■ Electrical power ■ Petroleum products with refueling station	■ Higher fuel economy ■ Very low emission ■ Long electric driving range ■ Reliable and durable ■ Commercialized	■ Costly and Bulky ■ Complex system ■ Complexity in control algorithm ■ Large component count	■ Power management of multi input source ■ Size and weight of battery Pack and ICE ■ Integration of components
Plug In HEVs	■ EPS and ICE based drive	■ Fuel tank ■ Battery ■ Ultra capacitor ■ Flywheel	■ Electrical power with charging station ■ Petroleum products with refueling station	■ Lower emission ■ Higher fuel efficient ■ Extended electric driving range ■ V2G or G2V capability ■ Partially commercialized	■ Higher complexity ■ Impact on grid ■ Higher initial cost ■ Sophisticated electronic circuitry ■ Battery technology	■ Size and weight of battery pack and ICE ■ Charging station infrastructure ■ Power flow control ■ Impact on grid
FCVs	■ EPS based drive	■ Fuel cell stack ■ Battery ■ Ultra capacitor	■ Hydrogen cylinder or Hydrogen enriched fuel ■ Hydrogen refueling station	■ Ultra low emission ■ Highly efficient ■ Independency from petroleum products ■ Competent driving range ■ Reliable and durable	■ High cost ■ Slow transient response ■ Not commercialized yet ■ Sophisticated ECU	■ Cost of fuel cell ■ Cycle life and reliability ■ Infrastructure for Hydrogen conditioning, storage and refilling system

Basically, ESS provides electric energy that has been processed and utilized by the other components of EPS. The electric motors transform the electric energy into mechanical energy or vice versa, as and when required. It converts electric energy of the ESS into mechanical energy to meet the power demands of the vehicle. The reversible process can also be achieved by regenerative braking, or electric energy can also be generated by electric motor to charge the ESS. The power electronic converters (PECs) are used to modulate power with suitable voltage and current between ESSs and electric motors. For vehicle acceleration, PECs supply required power to the electric motor to achieve the demanded operation. On the other hand, PECs can also be used to utilize the recovered energy of regenerative braking for the charging of ESS. The electronic controllers are composed of sensors, digital processors, and interfacing circuitry to generate the control signals for PECs and other electric and mechanical components.

In order to achieve the vision of sustainable EVT, electric propulsion system should address some important issues such as driving profile, weight and volume of vehicle, reliability and flexibility, packaging and installation, cooling system and maintenance, and all at affordable costs [16,79]. At present, the major challenges of EPS manufactures are to design and implement electric machines and power electronic converters that give better performance and can be more easily integrated for next-generation vehicles.

A functional block diagram of electric propulsion system, including the possible types of motors, computer-aided design methodologies, power converter devices/topologies, control hardware, software, and strategies, is shown in Fig. 31.14.

31.4.1 Energy Storage System

The strength of ESS is an important factor and plays vital role in vehicular electrification [17–20]. Basically, ESS constitutes the

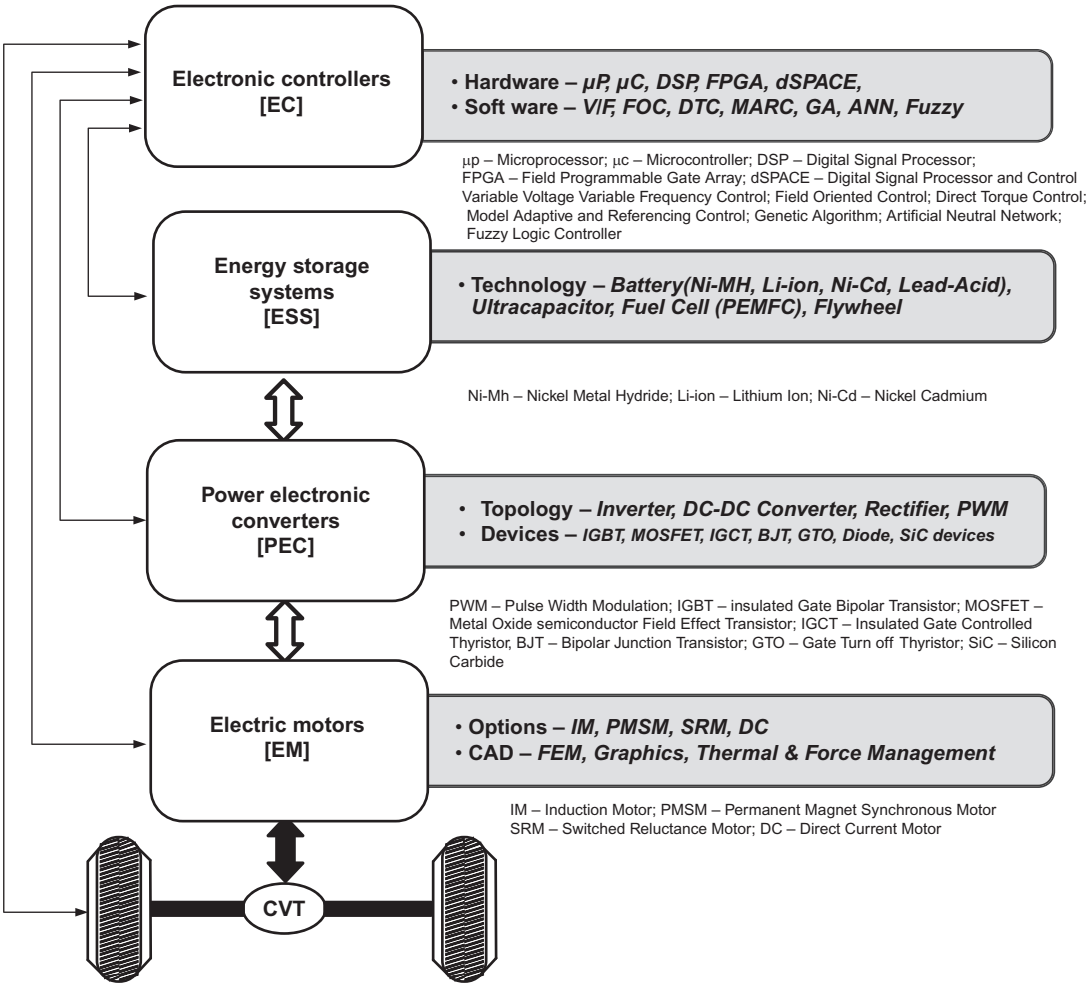

FIG. 31.14 Functional block diagram of electric propulsion system [4]. Modified from C.C. Chan, Y.S. Wong, Electric vehicles charge forward, IEEE Power Energy Mag. 2(6) (2004) 24–33.

source (fuel cell) and onboard energy storage devices that include battery, ultracapacitor, and flywheel. Battery and fuel cell both produce onboard electric energy by means of electrochemical energy conversion; however, a battery stores energy, whereas a fuel cell generates energy. Ultracapacitor relies on electrostatic principle to store energy, and therefore, it has capability to store high specific power rather than energy [18]. Use of flywheel is considered an optional technology for vehicle electrification due to weight and size considerations. The efficiency, fuel economy, and all-electric range (AER) of EVs/HEVs/PHEVs/FCVs are highly dependent on the onboard ESS of the vehicles. The ESS units must be sized so that they store sufficient energy (in kilowatt hours) and provide adequate peak power (in kilowatts) for the vehicle to have a specified acceleration performance and capability to meet appropriate driving cycles [8]. The major factors that affect the design of ESSs for vehicular application include energy density, power densities, life cycle, size, safety, maintenance, and recyclability at projected cost. The basic characteristics of specific power (W/Kg) versus specific energy (Wh/kg) of fuel cell, battery, ultracapacitor, and flywheel in comparison with petroleum-fuel-based ICE are shown in Fig. 31.15.

31.4.1.1 Battery

Battery converts chemical energy into electric energy and vice versa at the time of charging and discharging, respectively. The electrochemical battery is a combination of independent cells that possess all the electrochemical properties. Each cell is capable to store or deliver a significant amount of energy individually or in combination based on their connections [30]. High energy density, modularity, flexibility, and affordability are the factors that guide the battery technology on the road map of vehicle electrification [17]. In EVT, battery stores major onboard energy and contains high energy and power density to meet complete driving cycles of vehicle operation. The basic characteristics of battery for different vehicles are different. High-energy-density batteries are required for EVs, whereas high-power-density battery is required for HEVs and FCVs. For PHEVs, intermediate battery technology is required so that it can match the energy density of an EV battery and the power density of an HEV battery. However, batteries that fulfill the demand of PHEVs are yet to be designed specifically. A suitable battery type for EVT is the lithium-based battery such as lithium ion and lithium polymer and lead-acid and nickel-based battery such as Ni-Cd and Ni-MH [18,30–33].

Among these, lead-acid batteries are used for short-term use because of their low energy density. On the other hand, lithium- and nickel-based batteries are preferred for medium- and long-term use, respectively. However, Ni-Cd and Ni-MH battery technologies are matured, and their potential is fully explored. Therefore, significant improvement and cost reduction in these batteries in the coming years are least expected. The inherent advantages like high energy density, low weight, and low cost of lithium-based batteries invite attraction from automakers. In addition, the potential of lithium-based batteries is still not fully explored, and maturity level is yet to be achieved. Therefore, lithium-based batteries are considered as future's battery technology to power the electrified vehicles. The dominating characteristics and

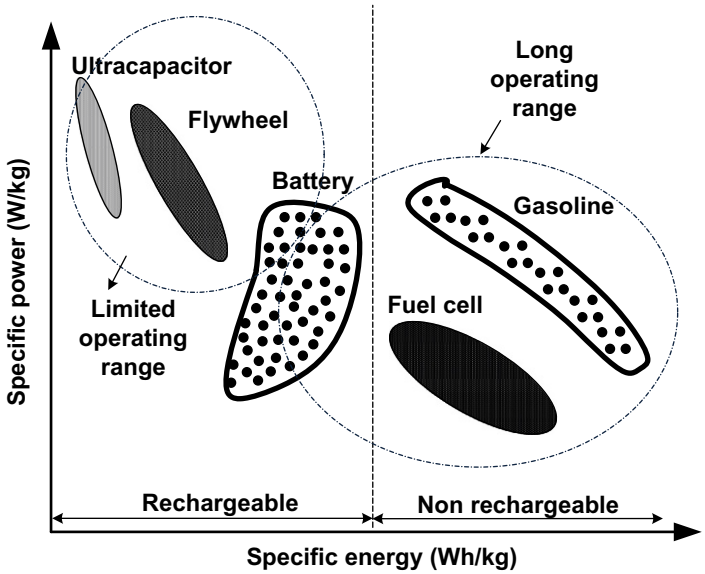

FIG. 31.15 Specific power versus specific energy characteristic for different ESS [8]. Reproduced with permission from C.C. Chan, The state of the art of electric, hybrid, and fuel cell vehicles, Proc. IEEE 95(4) (2007) 704–718.

comparison of different battery technologies available in [4] are given in Tables 31.3 and 31.4, respectively.

31.4.1.2 Ultracapacitor

Ultracapacitor is an electrochemical device that works on electrostatic principle to store energy; therefore, it can be charged/discharged hundreds or thousands of time without degrading the performance [34–36]. Basically, in ultracapacitor, porous carbon electrodes, which offer high surface area (1000 m^2gm^{-1}), are impregnated with electrolyte and small charge separation (10 Å) created by the dielectric separator between the electrodes as shown in Fig. 31.16. Appropriate modification in material selection and fabrication brought the ultracapacitor far away from conventional capacitor with very high capacitive (1000–5000 F) density [34]. Ultracapacitor stores energy higher than traditional capacitor but lower than battery, and hence, it can be used for applications, reserved for battery and capacitor.

The detailed comparison is given in Table 31.5. It offers high power density, long cycle life, and efficient operation. Since the rates of charge and discharge are determined by its physical properties, an ultracapacitor can release energy much faster (with more power) than a battery that relies on slow chemical reactions [34–36]. Ultracapacitors have been used for ICE-based vehicle tanks and submarines starting due to its ability of burst power delivery. In EVT, ultracapacitors can be used as primary energy devices for power delivery during starting, acceleration, and hill climbing and for recovery of braking energy during regenerative braking. The combination of ultracapacitor with a battery improves the energy performance of the former with greater energy storage capability of the latter [18]. It can downsize and extend the life of a battery, reducing maintenance and replacement costs. In future, it is expected that ultracapacitor can become a major dominating technology in vehicle electrification; however, desired energy density at reasonable weight and cost is a major concern.

The application of ultracapacitor in vehicle electrification is under development, and significant improvement has to be done for achieving maturity and commercialization in mass scale.

31.4.1.3 Fuel Cell

Recent technical advancements in fuel-cell technology have constructed the road map for its application in EVT as onboard energy source [40]. Significant advantages of a fuel cell are eco-friendly, simplicity, continuous power supply, durability, and silent operation along with strict confirmation to emission norms of vehicular systems. In fact, a fuel cell combines the best features of ICE (they can operate as long as fuel is supplied) and batteries (they can produce electricity directly from fuel, without combustion), thereby reducing emissions and noise and increasing the efficiency [41]. A fuel cell is an electrochemical device that uses hydrogen (H_2) as fuel and oxygen (O_2) from air to produce electricity with water and heat as by-products as shown in Fig. 31.17. To speed up the rate of these reactions, a catalyst such as platinum is used.

In a fuel cell, chemical energy of hydrogen is directly converted into electric power, thus eliminating the intermediate steps of converting fossil fuel to heat and then electric power that enhances efficiency comparatively. The specific energy of a fuel cell is as good as gasoline; however, its specific power is much lesser; therefore, the starting performances of fuel-cell vehicles are very poor. Consequently, to improve the power density and starting performance, battery or ultracapacitor can be used in conjunction with the fuel cell for vehicular application [41,42]. Therefore, it can be said that fuel cells and ultracapacitors are made for each other to lead perfect ESS for automotive. The types of fuel cell and their detailed comparison are presented in [43–45]. Among different fuel-cell technologies presented in [43–45], a PEM fuel cell is promising and is being used as energy source in fuel-cell vehicles. It offers easy start at low temperature, comparatively high power density, simple structure, small size, maintenance-free operation, and ability to operate in hostile environment [44].

31.4.1.4 Flywheel

A flywheel that stores and delivers mechanical energy in the form of rotational kinetic energy has been researched for many decades, but due to heavy weight and high cost, its implementation in vehicular system has been limited. Recent advancement in frictionless magnetic bearing, carbon-fiber composite materials, manufacturing technique, and sophisticated power electronic controllers has accelerated the development of flywheel energy storage system (FESS) [37]. The numerous features of advanced FESS such as higher power density, reliability, efficiency, and higher speed at reduced size made it a potential candidate for ESS in EVT [37–39]. The flywheel rim rotates in an evacuated containment that reduces frictional losses and ensures safety in case of failure.

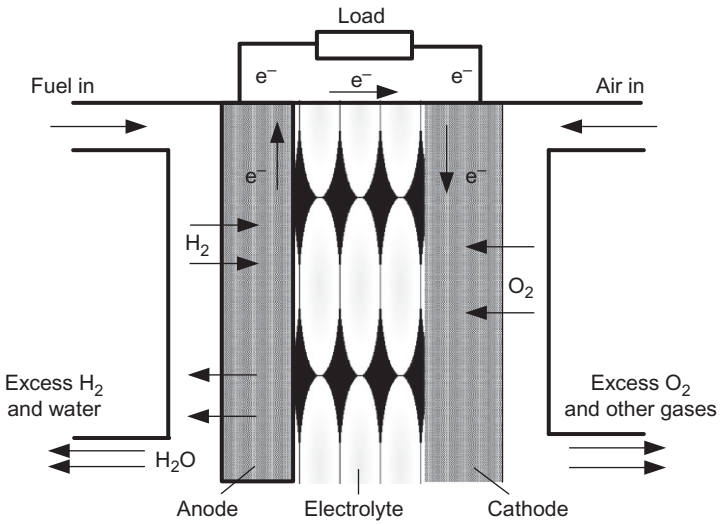

FIG. 31.17 Fuel-cell construction and operation [78].

A flywheel stores energy linear to its mass but square proportional to velocity from supply and delivers it to the load as per the requirements. The stored mechanical energy can be converted to electric energy or vice versa by means of integrated motor/generator set and PEC. Flywheel gets charged by speeding up as it accumulates mechanical energy and discharges by slowing down as it supplies mechanical energy to the EPS. The energy of regenerative braking can be recovered by charging the flywheel, which is further used for battery charging. Modern flywheels can store more energy and power than existing metal hydride or lead-acid batteries of similar weight and volume [38,39]. Unlike battery and ultracapacitor, flywheels are independent of in-depth discharge that improves its life cycle. It spins at a very high speed; therefore, safety, tensile strength of the material, and location of the placement of flywheel in EVT are prime concerns and need to be dealt with properly.

31.4.1.5 Hybrid Energy System

It can be concluded that not only the power and energy densities but also the voltage and current characteristics of different energy systems are different. Therefore, exclusive employment of one of the aforementioned energy sources cannot meet the energy and power demands of vehicle operation for all driving profiles. Compared to ultracapacitors and flywheel, a battery and a fuel cell have much higher specific energy but much lesser specific power as depicted in Table 31.6. Employment of such energy systems alone results higher cost, weight, and volume [46]. However, when these different energy systems are combined, an energy system with high power and high energy density can be obtained. Such kind of energy system is termed as hybrid energy system (HES), where batteries and a fuel cell supply the energy demand and the ultracapacitors and flywheel supply the power demand [46,47]. The combination of energy system can be chosen on the basis of vehicle design, operating profiles, and application. The prime concerns of hybrid energy system formation are their suitable integration, life expectancy, maintenance, cost, durability, and reliability.

TABLE 31.6 Comparison of different energy source and storage systems [78]

31.4.2 Electric Motor

In EVT, the electric motor needs to go through frequent starts and stops, high rate of acceleration, and deceleration, such as low-speed hill climbing and high-speed cruising along with different environmental and hostile conditions. Industrial motors, on the other hand, are usually operated at rated speed under common circumstances [16]. Thus, the electric motors used in EVT cannot be compared with motors being used for industrial processes. The electric motors used for EPS should be able to satisfy some basic characteristic for efficient operation. These characteristics are high torque for starting and low-speed hill climbing operation; high power density for acceleration and high-speed cruising for highway; high efficiency over wide torque and speed range; suitability for regenerative braking; overload capability during certain period of time; and controllability, high reliability, and robustness at affordable costs [48–50]. In addition, fault-tolerant capability, minimum torque ripple, temperature management, and low acoustic noise are other important issues for design consideration [21–24,63,64]. Suitability of electric motor in propulsion application should be strongly approved by torque-speed characteristic as discussed in [56] and illustrated in Fig. 31.18A. Moreover, the standard torque-speed characteristic of EPS is shown in Fig. 31.18B.

The choice of electric motor is the key factor in overall EPS design. A brief classification of the family of electric motor for EPS is summarized in Fig. 31.19. The commonly used electric motors for EPS include dc motor, induction motor, permanent-magnet (PM) motor, and switched reluctance (SR) motor [50–53]. Existing literature indicates that squirrel-cage rotor induction motors and PM motors are best suitable options. Also, SR motors are gaining more popularity and becoming reliable alternative for the future, while use of dc motors is declining gradually.

31.4.2.1 DC Motors

Traditionally, a dc motor has been used prominently for EPS due to its high starting torque and simple speed control. The torque-speed characteristics of dc motor exhibit good compliance for propulsion application; however, the inherent disadvantage of bulky construction, low efficiency, and the presence of mechanical commutators and brushes that aggravate maintenance requirements limit its use in light, high-speed, and maintenance-free vehicle application in hostile conditions [48–51]. Nevertheless, due to simple speed control and technical maturity, dc motors are prominent for low-power EPS. Technological advancements in power electronic converters and switches have helped to replace dc machines with commutatorless motors such as induction motors, PM motors, and SR motors. The commutatorless motors offer some tremendous advantages such as high power density, higher efficiency, and more reliable and maintenance-free operation with wide speed range over the dc motors.

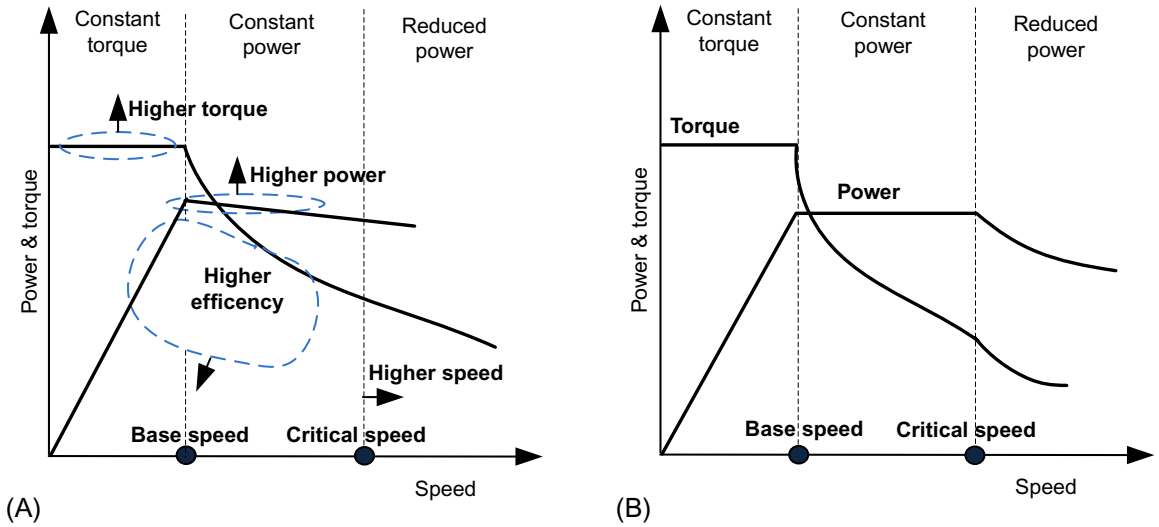

FIG. 31.18 Desired torque-speed characteristic of (A) vehicle propulsion system and (B) electric motors [56].

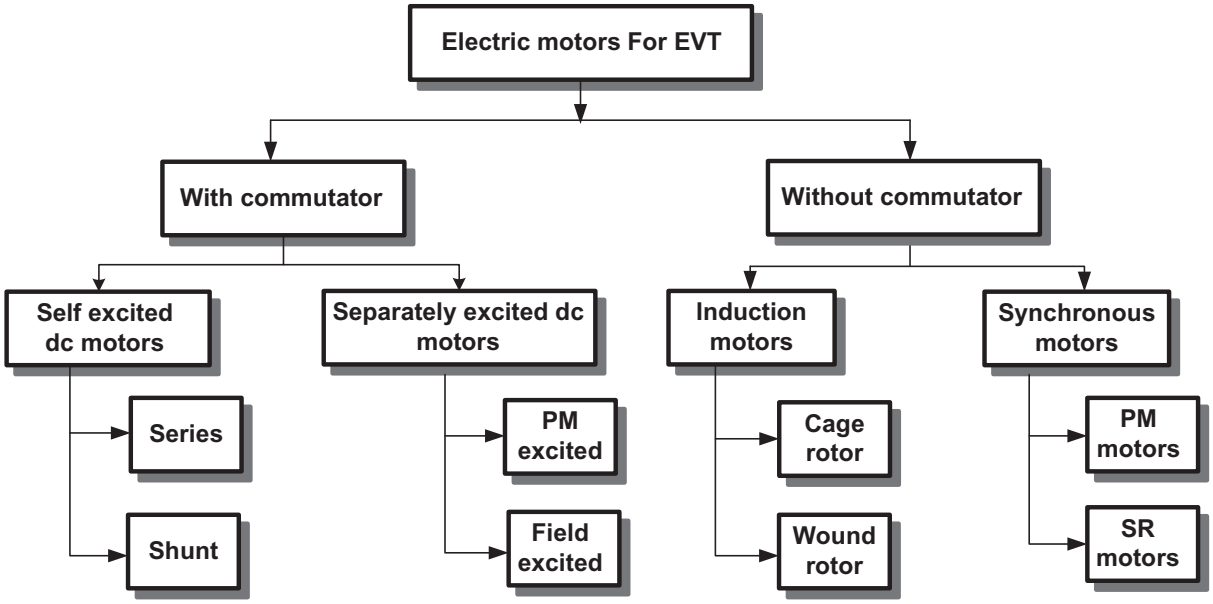

FIG. 31.19 Classification of electric motor for EPS.

31.4.2.2 Induction Motor

Induction motor (IM)-based propulsion systems are mature and are being extensively accepted as dominating candidate for EPS among various commutatorless motors. The numerous attractive features of IM are simplicity, high reliability, robustness, wide speed range, low maintenance, low torque ripple/noise, low cost, established power electronic converters, and ability to operate in hostile environment [48–53]. The behavior and performance characteristics of dc series motors can also be achieved with induction motor by employing well-matured field-oriented control (FOC) that provides decoupling of torque control from flux control [56]. The dynamic performance of IM can be further improved by applying either vector control or direct torque control (DTC) technique [57]. High-speed operation with extended constant power range of up to 4–5 times the base speed can be achieved by flux weakening, which is one of the desirable requirements for vehicle operation [56], although the high-speed operation and constant power range are limited by its pullout torque.

Apart from the various advantages, there are several disadvantages such as high losses, poor power factor, low efficiency, and low inverter usage. Moreover, its weight and volume are greater for the same power rating as compared with PM motors. These drawbacks of induction motor have been acting as speed bump in the race track. These limitations have been taken into account by the researchers. Efforts are being made to resolve these issues either at design level or by proposing new control schemes and/or converter topologies.

31.4.2.3 Permanent Magnet Motor

Among the available commutatorless motors, only permanent-magnet brushless motors have the capability to compete against the induction motors in EPS [48]. In recent times, PM motors are widely accepted by the leading vehicle manufacturers for designing the existing and upcoming EPS. Generally, PM motors are classified based on supply voltage and current as brushless dc and brushless ac. To maximize the torque density while keeping torque pulsation low, it is preferred to operate a PM machine in BLDC mode for trapezoidal back EMF waveform and in BLAC mode for sinusoidal back EMF waveform [58]. PM motors possess some inherent advantages: PMs excite the field that offers high power density and reduced weight and volume of the motor for a given power rating; due to reduced rotor losses, it offers highly efficient operation; compact packaging provides higher degree of reliability and maintenance-free operation; effective dissipation of heat into atmosphere enables efficient cooling [48–53]. Despite their numerous advantages, PM motors have some limitations such as short constant power region due to limited field weakening capability. In addition, control and management of back EMF at high speed increase size and ratings of PECs, and fault-tolerant capability is an issue. The extended speed range up to 3–4 times the base speed and enhanced efficiency of PM motors can be achieved by applying suitable control algorithms of power converters above the base speed [59]. Important design considerations for PM motors associated with fixed excitation for EPS include torque density, flux weakening capability, overload capability, stator iron losses, rotor eddy-current losses, and demagnetization withstanding capability.

The basic configurations of PM motors are classified based on the location of PMs. In conventional PM motors, PMs either are mounted on rotor surface or buried within the rotor. Surface-mounted PM (SPM) motors are widely used design and uses less magnet, whereas interior PM (IPM) motors use more magnets and offer higher air-gap flux density with higher degree of ruggedness [60]. Therefore, the interior PM motors are exceedingly being preferred for extended speed range and constant power operation over surface PM motors. In conventional PM motors, a compromise has to be made between low-speed torque capability and high-speed power capability. In order to overcome this problem, the concept of hybrid PM motor and field excitation technique has been adopted [49]. Conceptually, hybrid PM motor is either a combination of PM motor and reluctance motor or an inclusion of additional field winding that limits air-gap field. Thus, the hybrid PM motors enhance the overall operational efficiency and offer wide speed, constant power operation with more complex structures. Availability, cost, and supply issues with rare-earth PMs may affect their wide applications in EPS.

31.4.2.4 Switched Reluctance Motor

SR motor is gaining more and more attention for EPS in vehicular application. An SR motor offers tremendous potential for vehicular application especially for HEVs and FCVs [61,62]. The remarkable features of SR motors are the following: rotor without magnet and windings offers simple and robust construction that is desirable for very-high-speed and high-temperature operation; excellent torque-speed characteristics; fault-tolerant capability; and constant power region that can be extended up to 3–7 times, smooth and hazard-free operation [48–53]. Limitations of SR motors include high acoustic noise, vibrations, high torque ripple, complex control mechanism, and requirement of special converter topology. Although the cost of SR motors is relatively high, their mass production is expected to render them as cost-effective as induction motors. All the advantages are prominent for vehicular application, whereas the disadvantages are needed to be taken care properly to have feasible SR motor-based EPS.

Comparison of different motors based on desirable characteristic for EPS is shown in Table 31.7. The suitability of particular motor at particular characteristic is rated in the scale of 1–5 relatively. The point 5 indicates the higher attributes, whereas point 1 shows the poor attributes. This comparison is indicative and measured relatively on the basis of existing

literature; however, it may vary with several factors like the design consideration of motor's type, placement of motor (in wheel or out of wheel), material used for magnet, core and laminations, relevant power electronics converter, and their control algorithms [21]. The main purpose of Table 31.7 is to bring out the motor technology with higher attributes to vehicular application.

31.4.3 Power Electronics Converters for EVT

For sustainable EVT, there is a need of highly reliable, flexible, and fault-tolerant electric power processing system on board to deliver high quality of power, as per vehicle demands [24]. At present, this responsibility has been taken care by the available PEC that includes dc/dc converters, rectifiers (dc/ac), inverters (ac/dc), and battery charger that is composed of ac/dc and dc/dc converters.

Individually or combination of these converters can be taken to serve the purpose of onboard power processing; however, operation of each PEC is entirely different from the other. Conceptually, PECs perform some of the critical tasks like ON/OFF switching of various actuators, valves, and equipments; power conditioning and voltage/current modulation to create compatibility among the sources; traction motors; and auxiliary loads like air conditioner, head lamp, power steering, power window, etc. [63]. PECs not only serve the purpose of converting electric power from one form to another (dc/dc and dc/ac) but also help to step up or step down the system voltage level on board.

These PECs are composed of power electronic devices that play significant role and are evolving rapidly. The selection of PEC devices for EV propulsion is generally based on the requirements of the voltage rating, current rating, switching frequency, power loss, and dynamic characteristic of the system [63]. The voltage rating depends on the battery nominal voltage, maximum voltage during charging, and regenerative braking. The current rating depends on the motor peak power rating and number of devices connected in parallel. Furthermore, the switching frequency should be high enough to reduce the noise, filter size, and EMI problem with good dynamic characteristics. The device protection, packaging, reliability, and cost should also be considered while choosing particular device. Among the available power devices, the GTO, BJT, MOSFET, IGBT, and MCT are particularly suitable for EV propulsion [38]. Some of their operating characteristics as presented in [74] are given in Table 31.8. At present, the most attractive and suitable device for EVT is IGBT, which possesses high-speed characteristics of a MOSFET with the high-conductivity characteristic of a BJT. In the near future, the wideband gap (WBG) devices like SiC and GaN will be the most favorable candidate for EPS because they provide high-temperature operation, high-power-handling capability, superior dynamic characteristic, low switching losses, and high reliability [74].

In the last decade, significant advancement in converter topologies dealing with battery charger, voltage-source inverter for motor drives, and bidirectional dc/dc converter for ESS integration has been made. Regardless of this topological advancement, still conventional PEC topologies are being used in modern electrified vehicles. Therefore, PECs for EVT can be broadly classified as shown in Fig. 31.20. The classification of the PECs is done based on their basic operation rather than topological advancement.

The current trends and future status of EM, PEC, and EPS based on essential characteristics of vehicle application are summarized in Table 31.9.

31.4.3.1 PEC Configuration for EPS

PECs are controlling, managing, and optimizing the power flow among energy sources and vehicle loads, and hence, they are considered as the heart of EPS, whereas EPS is the heart of EVT. The architecture of modern EPS for EVT with interconnection among electric power system, ESS, propulsion system, and control and protection system is shown in Fig. 31.21. The main elements for the power processing and conversion comprise an ac/dc charger, a bidirectional dc/dc converter, a dc/ac inverter, and a digital controller.

Charging from utility grid inevitably needs a battery charger with power factor correction (PFC). The bidirectional dc/dc converter with a proper charging-discharging profile is required to transfer energy between the ESS and the propulsion system [73]. The plug-in charger is usually composed of ac/dc rectifier and dc/dc converter. The bidirectional dc/dc converter is placed between the add-on battery and the high-voltage bus of the HEV. The digital controller is in charge of the control and monitoring of the ac/dc charger, bidirectional dc/dc

converter, dc/ac inverter for propulsion, battery state of charge (SOC), and communication with external systems. Three voltage sources, that is, ac outlet voltage V_{ac}, battery voltage V_{batt}, and input to the propulsion inverter V_o, are shown in Fig. 31.21. These voltages are might be different from input/output voltage magnitude in each converter stage. This variation in voltage magnitude governs the operating modes and switching strategy of the converters under the supervision of digital controller.

The PECs contributing weight and volume of EPS are inverter, onboard charger, and bidirectional dc/dc converter. The main attention is being focused on bidirectional dc/dc converter for power-flow optimization [70]. Apart from dc/dc converter, innovative efforts are also directed toward inverters that drive the traction motors and supply the auxiliary loads of electrified vehicle in desired manner. The selection of inverter should be done based on the topology, power rating, type of motors, and the packaging methods [71]. Despite of significant topological advancement in multilevel inverters, as of now, the conventional two-level voltage-source PWM inverter is the most popular topology used in almost all the commercial electrified vehicles.

In EPS, two popular configurations are used to interface the ESS with propulsion inverter motor: (i) A high-voltage ESS is directly connected to propulsion inverter motor; (ii) a bidirectional dc/dc converter is placed between low-voltage ESS and propulsion inverter-motor drive [24]. In the first configuration, battery voltage level should match with propulsion inverter dc-link voltage level as shown in Fig. 31.22. This imposes certain constraints over the design and optimization of battery, inverter, and motor [24]. In the second configuration, a bidirectional dc/dc converter is placed between low-voltage ESS and high-voltage dc link of propulsion inverter motor as shown in Fig. 31.23. Inclusion of dc/dc converter increases overall component count but offers several advantages over the first configuration. It boosts voltage level of ESS to match the rated voltage of propulsion inverter dc link. It provides regulated bidirectional power flow between ESS and motor drive, which assists rapid acceleration and recovers energy to charge the battery during deceleration and regenerative braking. It not only offers significant reduction in weight, size, and cost of ESS but also gives space and flexibility in inverter control and motor design [24]. Another most important aspect of the inclusion of dc/dc converter is to recover the energy during regenerative braking that can be further utilized to recharge the battery or storage unit.

Addition of bidirectional dc/dc converter imposes certain disadvantages such as multistage power conversion, increased cost, power losses, integration, and control complexity. It also raises concern about size and cost of power switches and passive components. In addition, the reliability issues due to the integration of additional components must be taken into

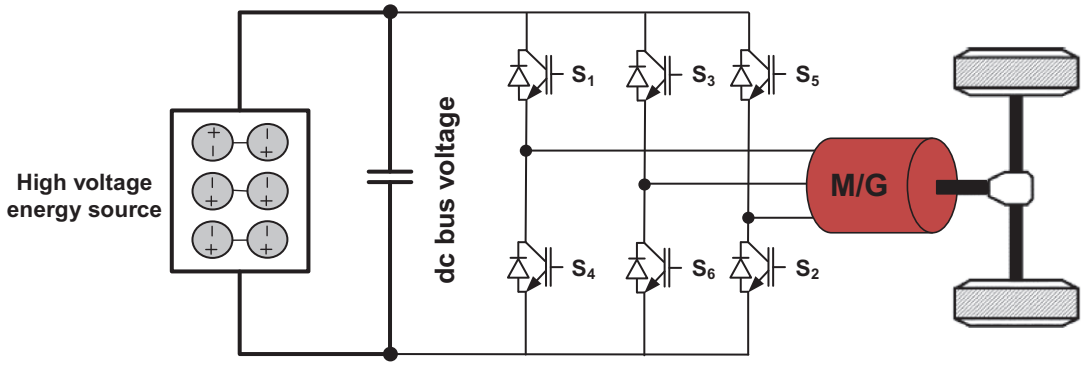

FIG. 31.22 Conventional battery-fed EPS.

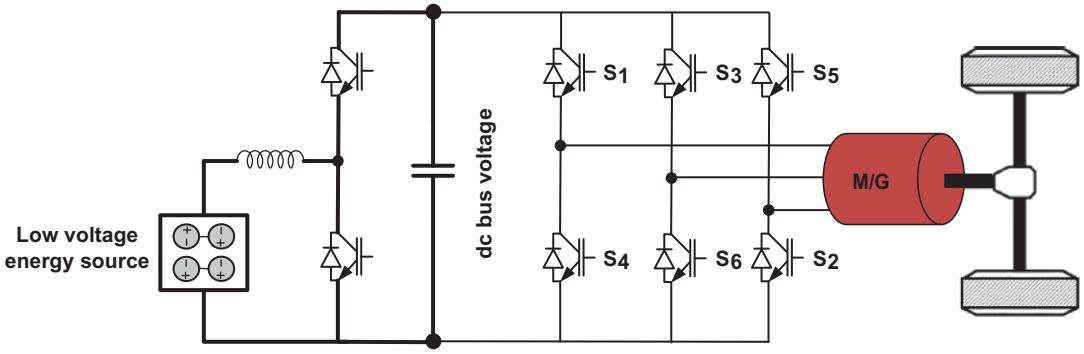

FIG. 31.23 Conventional bidirectional dc/dc converter-fed EPS.

account properly. However, the role of bidirectional dc/dc converter is very significant especially in terms of better utilization of onboard energy sources, power management, dynamic performance, flexibility, system optimization, and reduction of weight and cost [64].

31.4.3.2 PEC Configurations for Electrified Vehicle

PEC integration for EPS that completely replaces ICE-based propulsion system is shown in Fig. 31.24. In conventional configuration of EVs propulsion system, a battery bank is directly connected to propulsion inverter that converts dc voltage into three-phase variable ac voltage. This configuration is applicable to the system where battery bank is sufficiently large to match with the voltage of propulsion inverter-motor drives as discussed in previous section. In the second configuration of BEV propulsion system, a bidirectional dc/dc converter is connected in between battery bank and propulsion motor as shown in Fig. 31.24A. Inclusion of bidirectional dc/

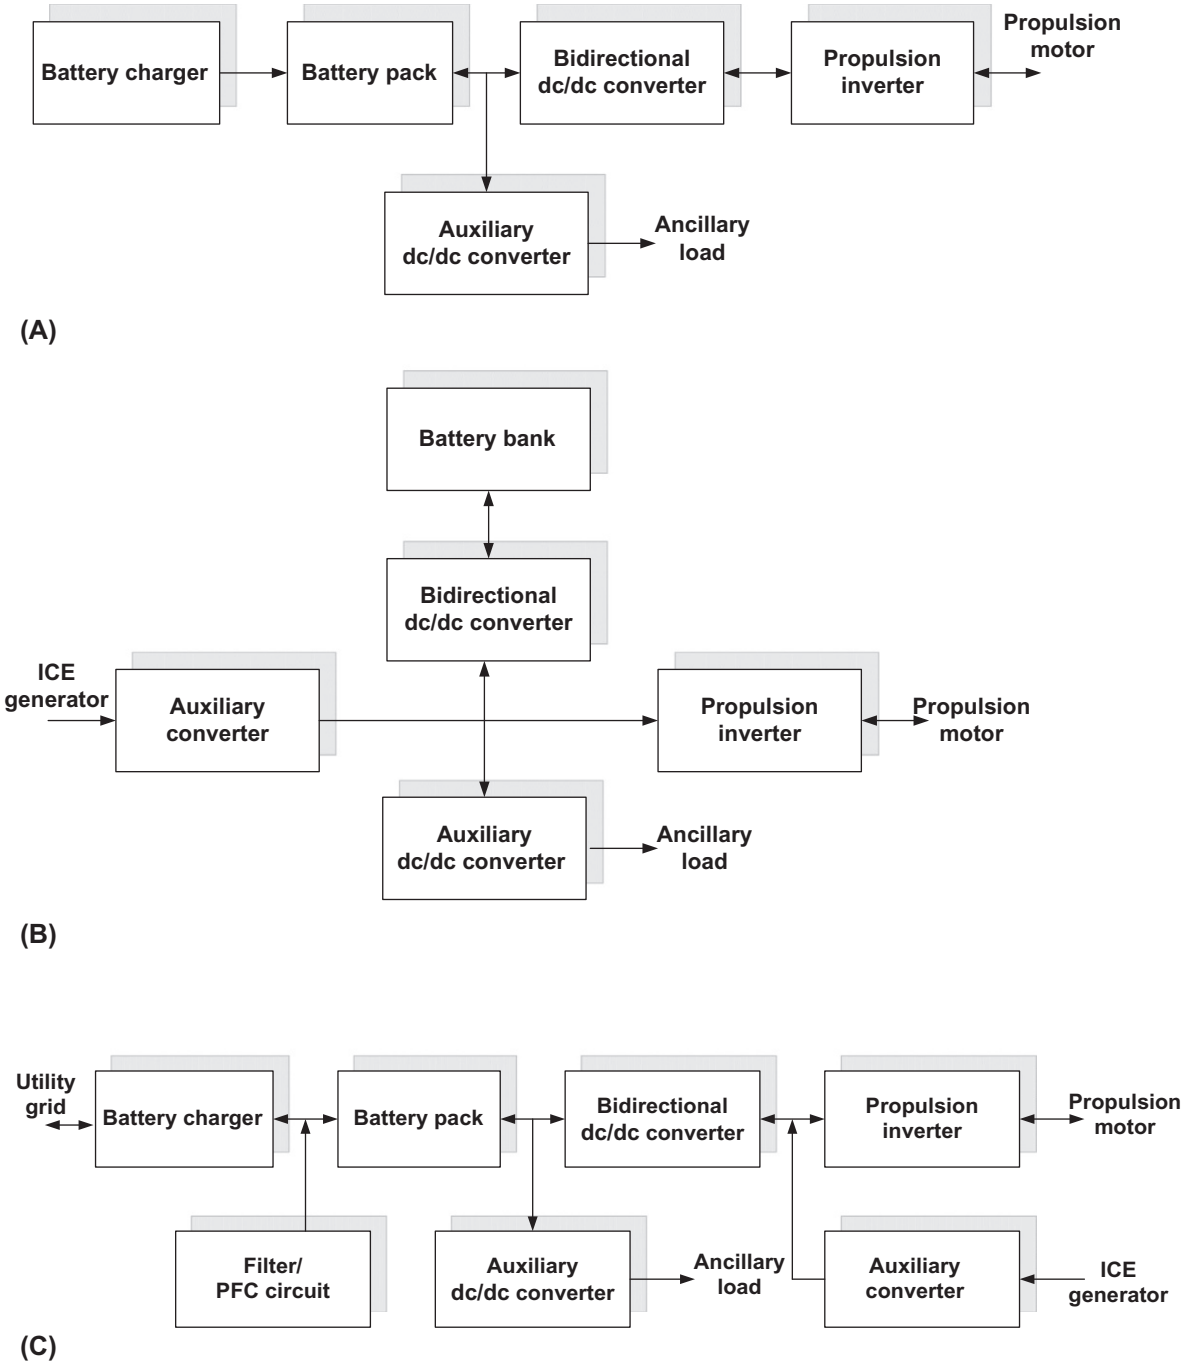

FIG. 31.24 Schematic diagrams of PECs for BEV, HEV, and plug-in HEV. (A) PEC configuration for BEVs, (B) PEC configuration for HEVs, and (C) PEC configuration for PHEVs.

dc converter increases flexibility and control in power flow and management from battery bank to propulsion inverter. It offers better utilization of battery bank and extends life of battery with controlled charging and discharging. It also helps to recover energy during regenerative braking. A battery charger is connected to battery bank to charge the battery from ac outlet. BEVs practically replace the ICE and the various mechanical systems with electric system.

It is well-established fact that the traditional rechargeable batteries are the main source of energy though they are heavy and expensive to replace and hence acting as a bottleneck of the BEV technology. In addition to traditional batteries like lead-acid, nickel-metal hydride (Ni-MH), and nickel-cadmium (Ni-Cd), there are advanced technologies like lithium-polymer (Li-polymer) and lithium-ion (Li-ion) batteries. Despite the popularity of these advanced batteries in portable electronic applications, they fail to keep same reputation for use in BEVs [22]. Consequently, the vehicle manufacturers are cutting down the production of BEV and shifting toward development on HEVs and FCVs.

The PEC for HEVs as shown in Fig. 31.24B consists of an ac/dc converter for converting the alternator ac output voltage into dc voltage for charging the batteries, an inverter for dc/ac conversion to power the propulsion motor, and a bidirectional dc/dc converter for charging the battery and maintaining bidirectional power flow. In addition to this, a low-voltage dc/dc converter is also connected to the battery bank to supply power to low-voltage ancillary loads of the vehicles. Furthermore, an electric air-conditioning unit, pump, and compressor units need an inverter and associated control systems [22].

The PEC configuration of plug-in HEV shown in Fig. 31.24C is similar to HEV with the charger facility to charge the battery bank from utility grid. The high-energy battery bank must be able to store enough electric energy from external charging and from regenerative braking and must be able to supply the stored electric energy to a propulsion inverter-motor system [23]. ac outlet charging should inevitably need a battery charger that is composed of a PFC-integrated ac-dc converter with a proper voltage-current profile for high-energy battery bank. A bidirectional dc-dc converter and charge-discharge profile is also necessary so as to transfer energy between the battery and the propulsion motor system as per requirement [23].

The main task of the fuel-cell propulsion system is converting the fuel-cell stack power output into a usable power for different electric and mechanical loads. Furthermore, the objective is to realize the full potential of the onboard fuel-cell stack by implementing efficient PEC in cost-effective manner. The primary power conversion would be used for three-phase ac output with variable voltage and variable frequency for the propulsion motor of the vehicle [80]. It is important to note that a high-peak-to-average power ratio is generally demanded from the PEC. If there is no ESS, the fuel-cell stack also needs to maintain the above critical power ratio to a maximum that increases size and volume of fuel-cell stack. Secondary power conversion is required for 12 or 42 V auxiliaries and for other loads such as air conditioning, pump, and power steering [80].

The different configuration of fuel-cell-based propulsion system for passenger car is shown in Fig. 31.25. The output voltage of the fuel-cell stack is first conditioned and processed to be compatible with the ESS voltage and propulsion motor using a dc/dc converter. The type of dc/dc converter depends on the voltage level of a fuel cell and ESS. A propulsion inverter is used to convert the dc voltage into modulating ac voltage at variable frequency to drive the propulsion motor under different torque

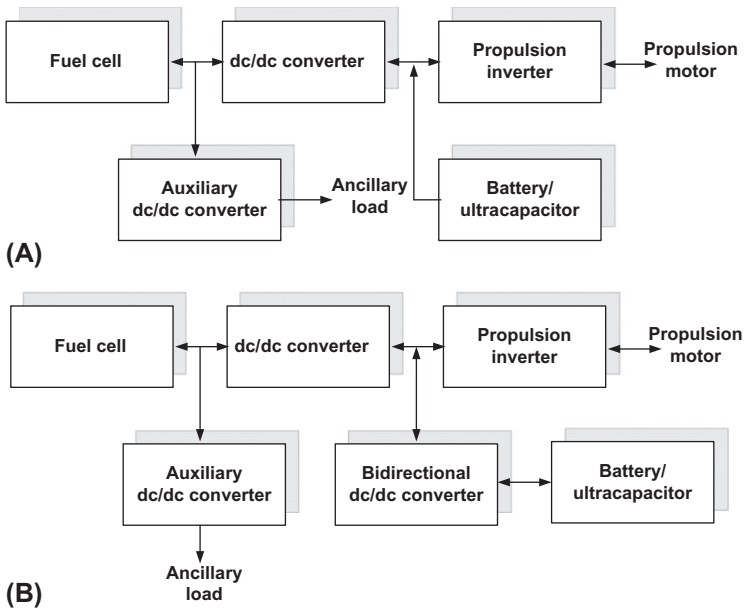

FIG. 31.25 PEC configuration for fuel-cell vehicles. (A) Parallel connected battery/ultracapacitor and (B) interfacing of battery and ultracapacitor through dc/dc converter.

and speed. The electronic controller unit (ECU) sends control signals to regulate the power output of the fuel cell, the dc/dc converter, and the dc/ac inverter based on the feedback signals of speed and torque and driver commands [80].

To begin with fuel-cell vehicle, a simplest configuration of a fuel cell is directly connected to propulsion motor through dc/ac converter. This configuration is applicable to the system only if the fuel-cell stack can produce a voltage level that is suitable for the propulsion inverter motor. However, this configuration is not preferred in general; hence, a unidirectional dc/dc boost converter is connected in between the fuel-cell stack and propulsion inverter as shown in Fig. 31.25A. The purpose of the dc/dc converter is to condition the fuel-cell power and raise the voltage level to match with the dc-link voltage. Typically, dc-link voltage in the range of 300–400 V is favorable for power levels up to about 100 kW [23]. A diode is connected in series with the output of the fuel-cell stack to prevent it from overload, getting short-circuited at output terminal, and to prevent current flowing back into fuel-cell stack [22]. Further, an additional low-voltage dc/dc buck converter is connected to supply the power to ancillary loads. Unlike the ICE-driven alternator, a fuel cell can produce power on board for different ancillary electric loads of vehicles that can eliminate the need of an alternator.

Fig. 31.25B shows the modification to system shown in Fig. 31.25A, with a low-voltage ESS connected through bidirectional dc-dc converter that performs the crucial task of power management and control. Generally, fuel cells are very efficient over particular load range but exhibit poor efficiency under light load condition and poor dynamic response during transient [24]. Therefore, integration of battery and ultracapacitor with a fuel cell makes it sustainable HES onboard for vehicular application. The ESS provides an input power to the propulsion inverter during warm-up time of the fuel cell. Once the fuel cell starts providing the required power, the ESS is disconnected, and the system can completely run on the fuel cell. The ESS system also provides power during transient conditions, to support the fuel cell, which improves the dynamic response and load leveling of overall system [80].

The fuel-cell propulsion system wins over ICE propulsion system on higher fuel conversion efficiency and fuel flexibility, emits practically no toxic pollutants, and reduces CO_2 emission drastically. However, a fuel-cell system designed for vehicular propulsion system should have weight, volume, power density, start-up, and a transient response similar to present-day ICE-based propulsion system [23].

31.4.3.3 PEC Configurations for ESS and HES

ESS whether battery and/or ultracapacitor is employed to reduce the cost and improve the performance of electrified vehicles [18]. The voltage level, *V-I* characteristics, and dynamic response of the ESS are normally different from the primary energy sources (ICE or fuel cell). Thus, a PEC needs to be incorporated to manage and control the power flow in overall vehicle system, which is a key component for achieving better fuel efficiency and dynamic performance [68,69]. For HES, storage element is an essential requirement to act as an energy buffer during transients in the system, to improve the dynamics of the overall system. Also, the storage element compensates the mismatch in power, between the source and load. Therefore, the choice of source combinations, such as battery/ultracapacitor or fuel cell/battery, fuel cell/ultracapacitor, and fuel cell/battery/ultracapacitor, is primarily governed by characteristics of the primary source and operating condition of the load [40,41].

In a fuel cell, the amount of power delivered depends on hydrogen pressure and slow chemical reaction results in poor dynamic response. Therefore, it should be combined with battery or ultracapacitor to achieve sustainable HES [40]. For example, a fuel cell and an ultracapacitor are combined together to constitute a portable HES that can meet different energy and power requirements as necessitated by different driving profiles of vehicle [41]. During acceleration, bulk amount of power has to be released to develop sufficient thrust. This responsibility can be well taken care by ultracapacitor as it can deliver power quickly. Similarly, a fuel cell can support to extend all-electric driving range of the vehicles, by supplying constant power, which in turn enhances durability and life span of the fuel-cell membrane [44].

In HEV, it is desired for the energy system to have high power density and high energy density to cater the sudden changes in the load demand [9]. Moreover, applications that require instantaneous power input and output delivery typically find batteries suffering from frequent charge and discharge cycle, which have an adverse effect on battery life. For such systems, it is crucial to have an additional storage system that is much better and robust in handling surge current. Here, the basic idea of HES is to combine battery and ultracapacitor to achieve a better performance than the latter system. Thus, an ideal source for EVT would be the combination of both the storage sources [18]. Also, the hybridization of battery and ultracapacitor offers much better utilization of energy recovered during regenerative braking.

HES demands suitable PEC to incorporate different energy sources and manages power flow among different sources and vehicle loads [18]. Therefore, investigation on PEC for HES is crucial task in EPS design for achieving optimal balance among efficiency, performance, durability, and reliability of system [63]. In HES, a dc/dc converter is the key constituent that provides compatible interfacing and integration of energy sources [64]. Beside output voltage regulation, a well-designed dc/dc converter can also control and manage power flow through different components. Therefore, selection and design considerations of dc/dc converters are important aspect in ESS. Apart from dc/dc converter, multiple-input dc/dc converter and multiphase interleaved converters are also employed for better energy diversification and utilization of the onboard HES [66,67]. Several topologies for HES configuration for EVT have been proposed in [68–70] to improve fuel efficiency

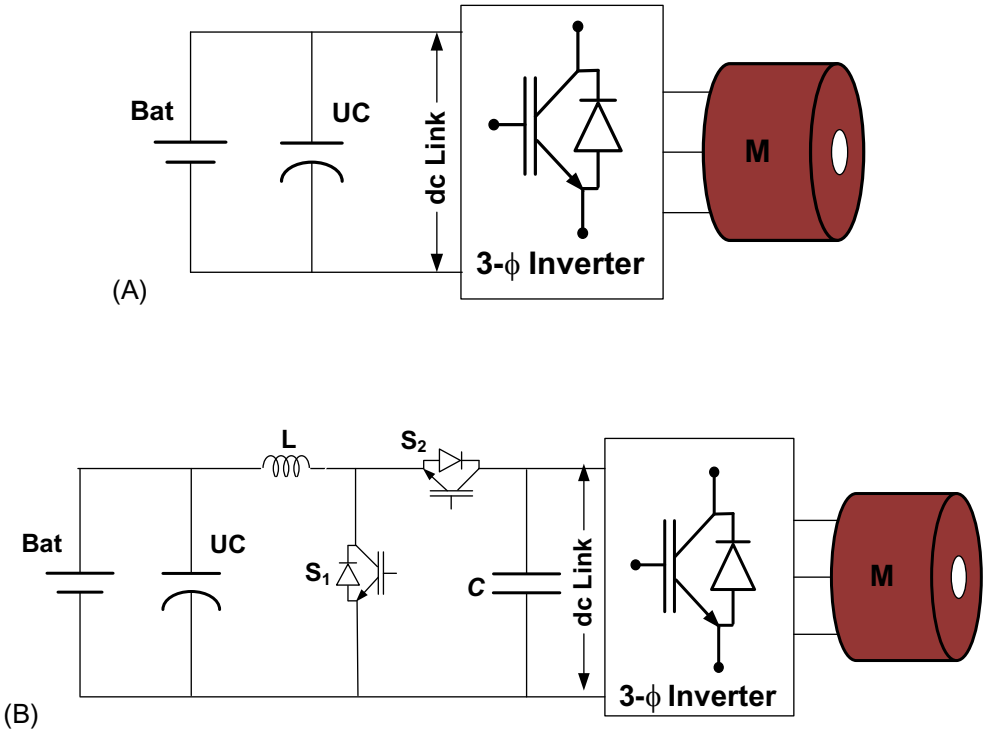

FIG. 31.26 Passive configurations of battery and ultracapacitor parallel with dc/dc converter. (A) Direct interfacing of battery and ultracapacitor and (B) interfacing of battery and ultracapacitor through dc/dc converter.

and dynamic performance that range from simple to complex circuits. On the basis of the use of dc/dc converter, HES can be classified into two categories: passive configuration and active configuration.

Passive configuration

Passive configuration [33] is the simplest method of combining battery and ultracapacitor (UC) bank together as shown in Fig. 31.26A, where battery and ultracapacitor are connected together in parallel without any dc/dc converters. In this method, since the two sources are connected in parallel, battery voltage, ultracapacitor voltage, and dc-link voltage should be maintained at the same level, and ultracapacitor essentially acts as filter. This configuration is easy to implement and eliminates need of expensive PEC and peripheral circuitry. However, major problem with this configuration is inefficient utilization of stored energy in ultracapacitor and battery.

To improve power flow and its proper utilization, a bidirectional dc/dc converter interfaces the parallel-connected ultracapacitor and battery with the dc link as shown in Fig. 31.26B. Despite wide voltage variation across ultracapacitor terminals, the dc-link voltage remains constant due to the regulation of the dc/dc converter. However, in this configuration, the battery voltage is always the same with the ultracapacitor voltage due to the lack of interfacing control between the battery and the ultracapacitor [18]. The battery current must charge the ultracapacitor and provide power to the load side as well.

Active configuration of battery/ultra capacitor

Conventional active methods use one or multiple full-size dc/dc converters to hybridize the battery and ultracapacitor to the dc link. In this case, full size refers to the fact that the dc/dc converter forms the sole path for the flow of energy in the device. The UC/battery configuration as shown in Fig. 31.27A proposed in [31] is the most studied and researched HES. By using a bidirectional dc/dc converter to interface the ultracapacitor, the voltage of ultracapacitor can be used in a wide range. However, the bidirectional converter needs to be of a larger size in order to handle the power of the ultracapacitor. The battery is connected directly to the dc link; as a result, the dc-link voltage cannot be varied. By swapping the positions of the battery and ultracapacitor in the ultracapacitor/battery configuration, we get the battery/ultracapacitor configuration as discussed in [68] and shown in Fig. 31.27B. In this configuration, the voltage of the battery can be maintained lower or higher than the ultracapacitor voltage. The ultracapacitor is connected in parallel with the dc link directly working as a low-pass filter. The control strategy applied to this configuration allows the dc-link voltage to vary within a range such that the ultracapacitor energy can be utilized more efficiently. However, in standard practice to achieve efficient HES, it is preferred that fast-response components are connected with high-power-density system whereas slow response devices are connected to high-energy-density system.

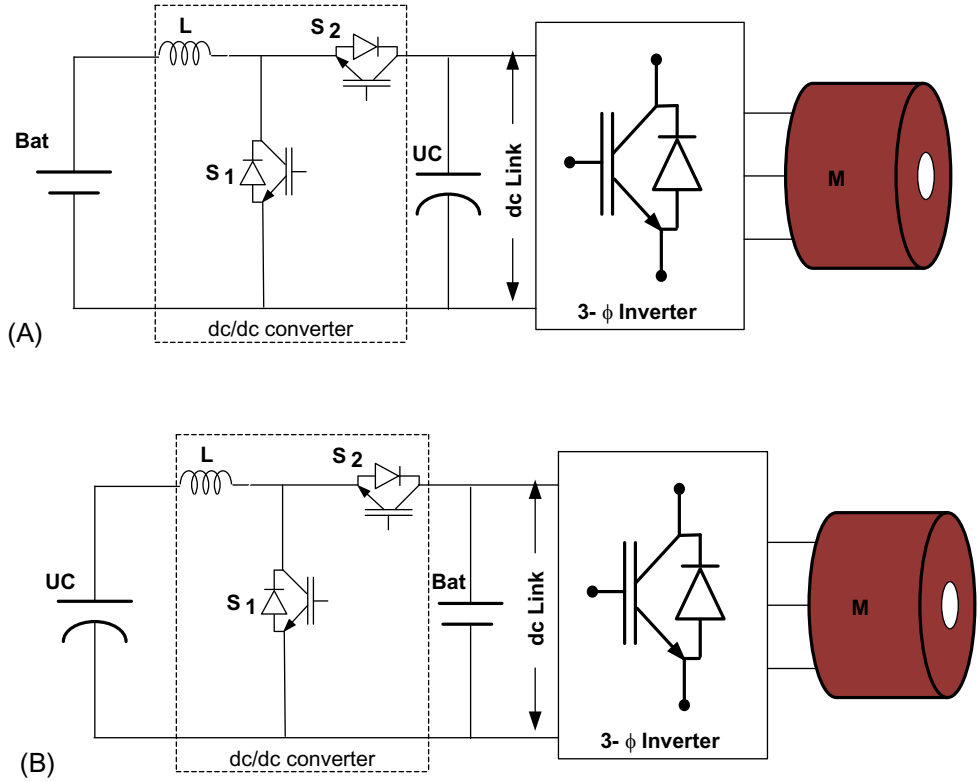

FIG. 31.27 Active configuration of battery and ultracapacitor. (A) Battery is connected through dc/dc converter. (B) Ultracapacitor is connected through dc/dc converter.

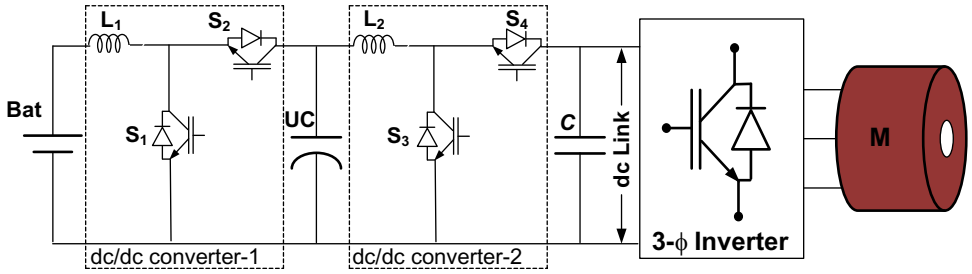

FIG. 31.28 Cascaded configuration of battery and ultracapacitor.

Cascaded configuration

To make a better working range of the ultracapacitor of the battery/ultracapacitor configuration, another bidirectional dc/dc converter is added between the ultracapacitor bank and the dc link, as shown in Fig. 31.28. This forms a cascaded configuration where two dc/dc converters are connected in series. In this configuration, a smaller size battery can be used with lower voltage level, which can be boosted up to a higher voltage level, to reduce the cost. In addition, the battery current can more efficiently be controlled compared with the passive configuration. Due to the existence of the boost converter, the battery current is smoothened, and the stress on the battery is reduced [18]. The battery supplies average power to the load, whereas the ultracapacitor delivers instantaneous power charge and gets charged quickly by recovering energy during regeneration. The drawback of this topology is that the battery can be charged neither by braking energy nor by the ultracapacitor due to the unidirectional boost converter [18]. However, the possibility of battery charging can be explored by replacing unidirectional dc/dc converter with a bidirectional dc/dc converter.

Parallel configuration

Instead of cascaded connection of the two converters, parallel configurations of battery/ultracapacitor are also used as shown in Fig. 31.29 proposed in [66]. The battery bank and the ultracapacitor are connected to the dc link in parallel through bidirectional dc/dc converter. In this configuration, both the battery and the ultracapacitor present a lower voltage level than the dc-link voltage. The voltage of the ultracapacitor can vary in a wide range so that capacitor is fully used. The voltages of the

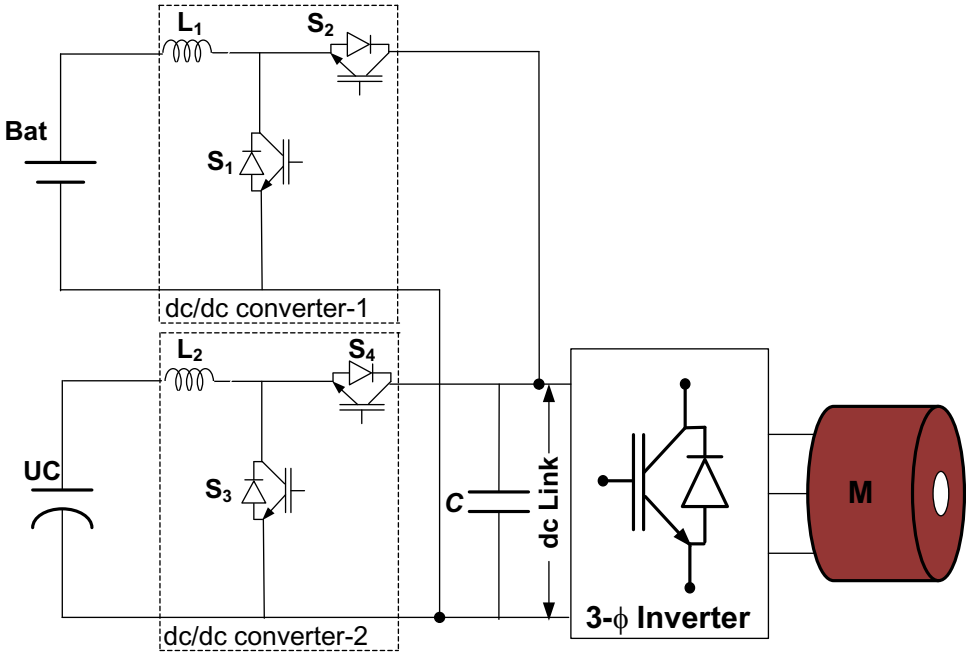

FIG. 31.29 Parallel configuration of battery and ultracapacitor.

battery and the ultracapacitor will be boosted up when the propulsion system demands power and bucked down under recharging conditions. Power-flow directions in/out of the battery and the ultracapacitor can separately be controlled, allowing flexibility for power management [18]. However, if two full-sized dc/dc converters are integrated in parallel, the cost, size, and complexity of control increase.

Multiple input configuration

As discussed in previous section, multiple-converter configuration is expensive because it requires two full-size bidirectional converters to interface both battery and ultracapacitor. Therefore, multiple-input converter (MIC) topologies [81–84] are proposed in order to reduce the cost of the overall system. The configurations of the MIC are shown in Figs. 31.30 and 31.31. MIC is a converter that can combine different energy sources with a single stage of power conversion. It offers simplicity, flexibility, and compact design and reduces the cost and control complexity of the system [82–84]. In the multiple-input bidirectional converter shown in Fig. 31.30, both the battery and the ultracapacitor are connected to one common inductor by parallel switches [81]. Each switch is paired with a diode, which is designed to avoid short circuit between the battery and the ultracapacitor. In parallel-connected switch, the higher-voltage-source cell will be dominating, which needs time multiplexing switching. The second approach is to form a pulsating voltage-source cell (PVSC) of the sources and connect these PVSC in series as shown in Fig. 31.31 and proposed in [82]. In series configuration of MIC, voltage magnitude of battery and ultracapacitor can be asymmetrical, and each of the sources can deliver power individually and simultaneously. Both input voltages are less than the dc-link voltage; thus, the

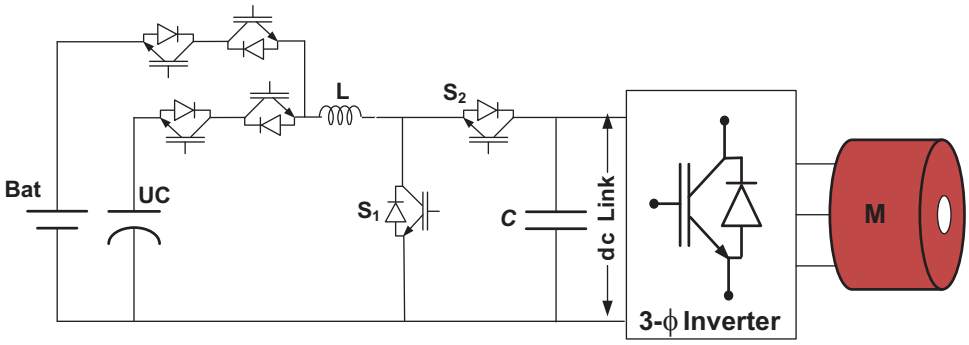

FIG. 31.30 Parallel configuration of multiple-input converters.

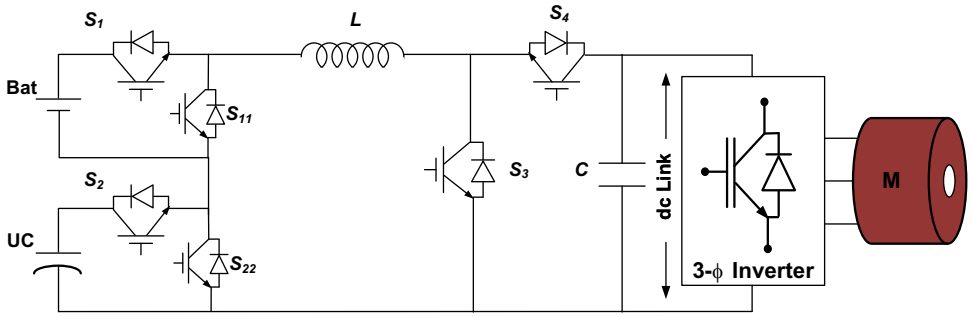

FIG. 31.31 Series configuration of multiple-input converter.

converter works in boost mode when input sources supply energy to drive load and in buck mode for recovering regenerative braking energy to recharge the battery and the ultracapacitor [81]. Only one inductor is needed, even if more inputs are added into the system. However, the controlling strategy and power-flow management of the system are relatively complex.

As discussed in parallel configuration, in HES, each energy source is connected together through separate single-input dc/dc converter (SIC), and their outputs are connected in parallel to a common dc bus as shown in Fig. 31.32. In conventional configuration paralleling, the whole system including energy sources offers good solution to obtain high degree of availability [76,83,84]. However, such configurations are costly, bulky, and relatively complex in design and reduce overall efficiency and flexibility and increase control complexity of the system. If costs and availability are being considered, then the single-input converters can be successfully replaced by a single multiple-input converter as shown in Fig. 31.33.

The conventional structure of interfacing multiple energy sources in multiple power stages can be successfully replaced by a single MIC that integrates multiple energy sources with a single stage of power conversion. In this structure, the system voltage is regulated, and the power flow among the energy sources, storage devices, and load can be controlled optimally and centrally. It eliminates the need for redundant power stages of the conventional structure and thus achieves reduced parts count [83]. MICs have advantages of easy power management, efficient thermal management, better utilization of available input sources, and centralized control compared with a conventional structure. The overall system efficiency is increased due to the reduction of the conversion stages, redundant passive elements, power switches, and hence their associated losses. The disadvantage of the MIC configuration is that the output stage of a MIC can act as a single point of failure. However, a MIC with modular component can compensate for this drawback by reducing the mean downtime (MDT) of the system [67].

In HEV, as shown in Fig. 31.34, where the combination of battery and ultracapacitor is preferred, battery supplies constant power, whereas additional power demand by the load during start-up and acceleration is delivered by the ultracapacitor while maintaining dc-link voltage constant. The amount of power drawn from the battery relies on the state of charge (SOC) of the battery; thus, for change in power drawn from the battery, power delivered by the ultracapacitors should also be changed.

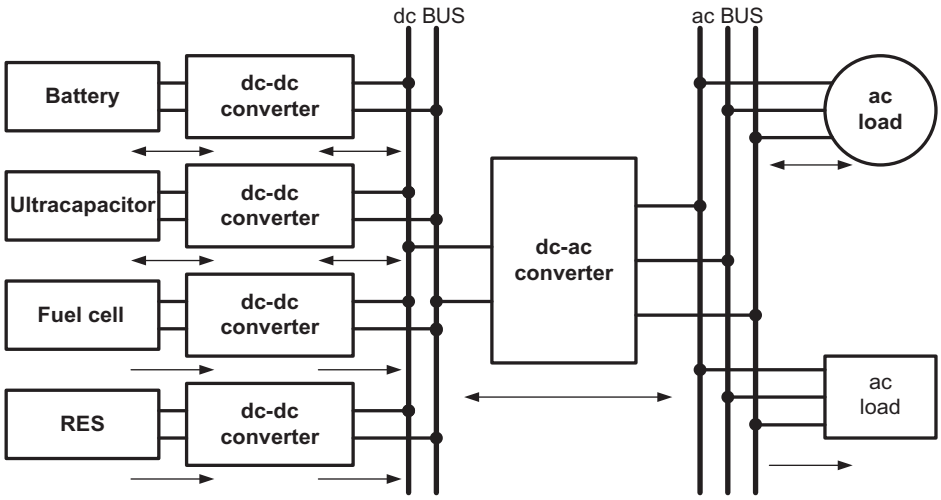

FIG. 31.32 Conventional hybrid energy system configuration with single-input dc/dc converter [83].

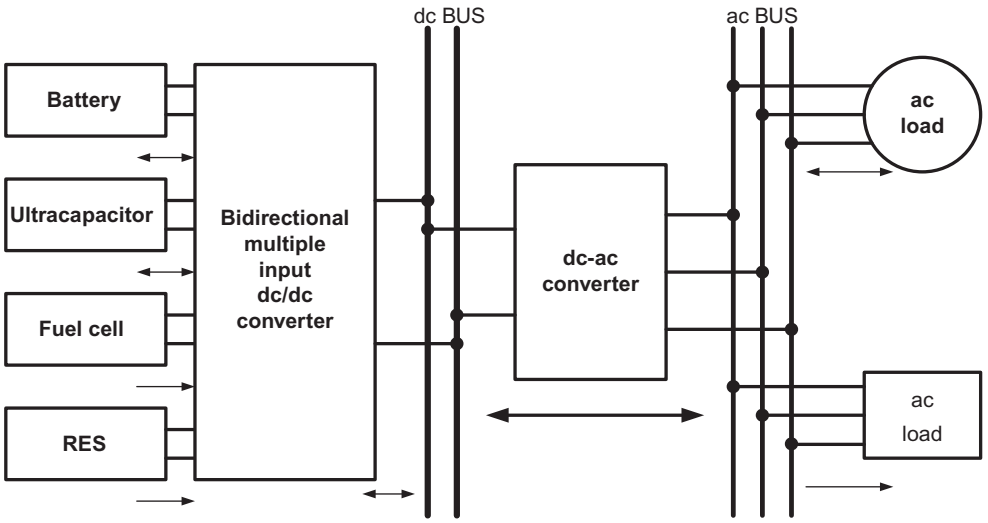

FIG. 31.33 Hybrid energy system configuration based on multiple-input dc/dc converter [83].

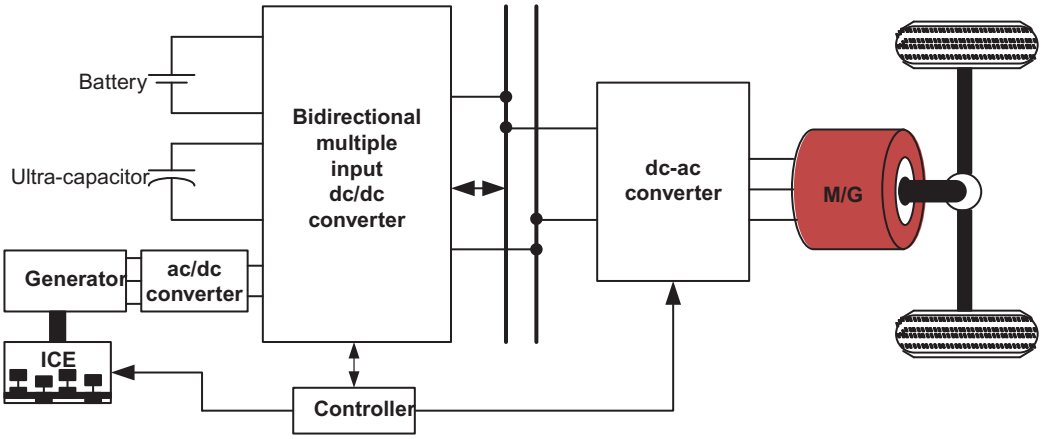

FIG. 31.34 Multiple-input converter-based hybrid electric vehicle.

Thus, effective power sharing can be achieved by MICs depending on the control strategies and operating mode. This modulation of power between battery and ultracapacitor is not possible in conventional structure because both the sources have to supply constant power to regulate the output dc-link voltage.

MIC structure has an explicit advantage over the conventional structure in terms of total component count and conversion stages used due to mutual sharing of system components. As a result, compact design and improved system efficiency can be achieved. Comparison of these two structures given in Table 31.10 shows that the MIC structure is promising alternatives in vehicular application to interface multiple sources on board.

TABLE 31.10 Comparison of SIC and MIC structure [83]

Characteristics	SIC structure	MIC structure
Common dc bus	Yes	No
Conversion step	Multiple	Single
Control scheme	Individual control	Centralized control
Power-flow management	Complicated and slow	Simple and fast
Transformer (isolated)	Multiple	Single multiwinding
Implementation effort	High	Low
Component count	High	Low
Flexibility	Low	High
Cost and volume	High	Low

31.4.3.4 PEC Configurations for Battery Charger

PEC configuration for battery chargers plays a critical role in the sustainable development of BEVs/PHEVs. The challenge of transforming BEVs/PHEVs from concept to reality is to make it safe, convenient, and affordable for consumers to charge batteries [63]. In order to improve convenience and increase charging efficiency, a number of charging schemes have been proposed as house charging, solar charging station, park and charge (PAC), move and charge (MAC), and regenerative

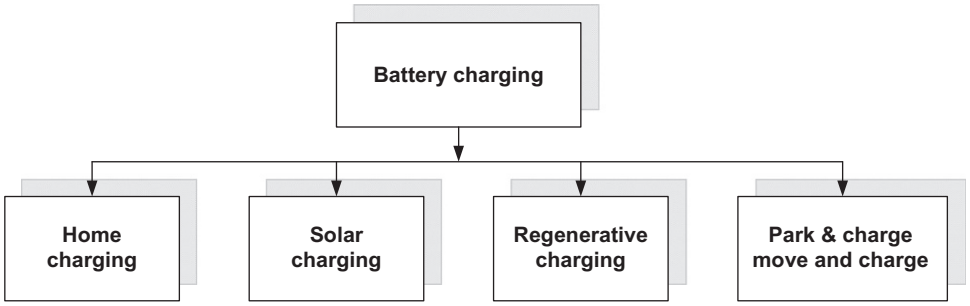

FIG. 31.35 Multiple options for charging of BEVs/PHEVs.

charging as shown in Fig. 31.35. A battery charger composed of several PECs should be reliable and efficient with high power delivery capacity at low cost and weight. Its operation depends on power electronics component, switching strategies, and control algorithms. A BEV/PHEV charger must ensure the operation at unity power factor or close to unity power factor to draw maximum amount of real power from utility grid with less distortion in current to minimize the power quality impact on grid. The battery charger should be designed according to IEEE-1547, SAE-J2894, and similar standards such that the amount of harmonic and dc current injected into the utility grid must be controlled within the preset limit.

A variety of PEC configurations and control methods have been developed as BEVs/PHEVs battery chargers, which includes single-stage and multistage power conversion. Single-stage conversion (ac/dc) configuration suffers with large low-frequency ripple in the output current, and hence, its application is limited to lead-acid batteries only. Conversely, multistage conversion configuration (ac-dc and dc-dc) inherently offers low-voltage ripple and relatively high power rating and hence is suitably adopted for lithium-ion and Ni-MH batteries, which are being used in PHEVs [43]. A simplified universal two-stage battery charger for BEVs/PHEVs is shown in Fig. 31.36. The input voltage is first filtered out and fed to the PFC integrated ac/dc converter. The rectified voltage is fed to a regulated intermediate dc-link bus. The dc/dc converter then converts dc-link voltage to a regulated output voltage for battery charging. The galvanic isolation is achieved at dc/dc conversion stage by using isolated dc/dc converter.

The availability of infrastructure for charging facility will help to reduce the size and capacity of onboard ESS, and consequently, cost and size will be reduced. Charging stations are classified as three types, on the basis of power-handling capacity, charging time, and location of charger installation. Type-I charging is the slowest method of charging, designed for home or business sites with readily available power outlet, and no additional infrastructure is required. It uses standard 120/230 V, 15 A single-phase charger outlet with standard J1772 connector [85]. In type-II charging, dedicated infrastructure and charging equipments are required, which be installed either on board or off-board to avoid redundancy in PEC. It charges battery with 240 V, 80 A single-phase or three-phase and offers fast charging compared with type-I charging. The BEVs/PHEVs owners are likely to prefer type-II charging technology due to its faster charging time and standardized vehicle-to-charger connection. Type-III charging is a commercialized fast charging method and offers the possibility of charging in less than 1.0 h. It can be installed in highway and city refueling points, analogous to conventional fuel stations. It typically operates with 480 V and requires an off-board charger to provide regulated power conversion. The SAE J1772 standard prescribes that type-I and type-II charging infrastructures should be installed on board, whereas type-III chargers should be mounted off-board. It is expected to use type-I and type-II charging stations to enable fast charging in public and private places with less impact on utility [86]. However, type-III charging can increase peak demand and has the potential to quickly overload local distribution system and equipment at peak

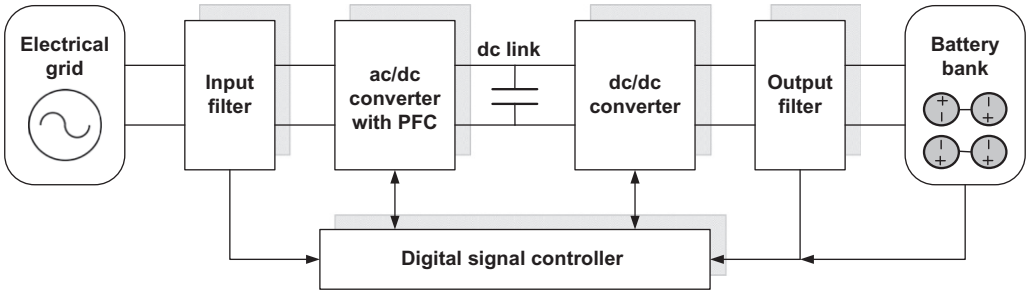

FIG. 31.36 Simplified diagram of universal battery charger.

TABLE 31.11 Charging types and power level [72]

Charging type	Charger location	Charger interface	Power rating (kW)	Charging time (h)	Vehicle technology
Type-I	Onboard	Home outlet	1.4 (12 A)	4–11	BEV (5–15 kWh)
	One-phase		1.9 (20 A)	11–36	PHEV (16–50 kWh)
Type-II	Onboard	Dedicated public or private outlet	8 (32 A)	1–4	BEV (5–15 kWh)
	One-phase		19.2 (80 A)	2–6	PHEV (16–30 kWh)
Type-III	Off-board	Dedicated commercial outlet	50	0.4–1	BEV (20–50 kWh)
	Three-phase		100	0.2–0.5	

times. The charging characteristics and infrastructure aspects for different type of charging methods are presented in [72] and are given in Table 31.11.

Battery chargers for BEVs/PHEVs can be classified as follows:

I. On-board and off-board charger
II. Unidirectional and bidirectional charger
III. Integrated charger
IV. Inductive charger

On-board and off-board charger

The onboard charger should be installed in the vehicle and designed for the slow charging rate, that is, it takes longer time to charge relatively. Due to limitation in available space in vehicle and payload, the onboard charger for BEVs/PHEVs should be light and compact in design. The advantage of onboard charger is that the battery can be charged at anyplace where there is electric outlet is available. An off-board battery charger is less constrained by size and weight and keeps redundancy in power electronic converters, which adds flexibility in the system. The onboard and off-board charger are usually implemented either with unidirectional or bidirectional power flow. Initially, the unidirectional charging should be the first step because it reduces power electronic component requirement, simplifies interconnection issues and control complexity, and reduces battery degradation [85]. These chargers typically use a diode bridge rectifier in conjunction with a power factor correction (PFC) and dc-dc converters [85].

Unidirectional and bidirectional charger

The classification of conventional unidirectional and bidirectional charger topology is shown in Fig. 31.37. The classification is made on the basis of operation of particular PEC topologies. A unidirectional PEC topology for a type-I battery charging system [87] is shown in Fig. 31.38. Simple control and operation of unidirectional chargers make it relatively unproblematic for a utility grid to manage heavily loaded distribution network to charge multiple BEVs at a time [88]. Battery charger with active front-end converter can control the supply current phase angle to deliver reactive power without discharging the battery. In unidirectional charging, it needs to optimize charging strategy to maximize the benefits and to minimize the impact on distribution system [87,88]. For high penetration of BEVs/PHEVs and active control of charging current, unidirectional chargers can meet practically all the objectives of the utility grid.

The conventional boost converter topology with PFC as battery charger is shown in Fig. 31.39 that is very popular configuration for unidirectional battery charging. A dedicated diode bridge rectifier is used to rectify the ac input voltage to dc that is further converted to dc followed by boost section. In this topology, the output ripple current, which is a difference between diode current and dc output current, is very high [89]. To

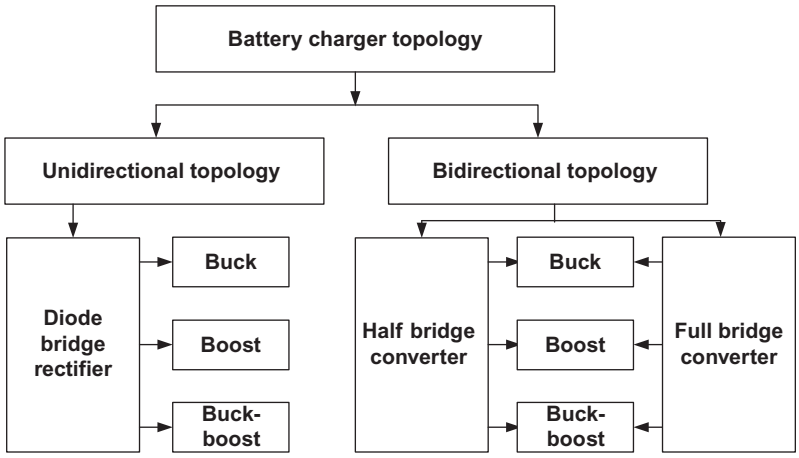

FIG. 31.37 Classification of conventional battery charger topology.

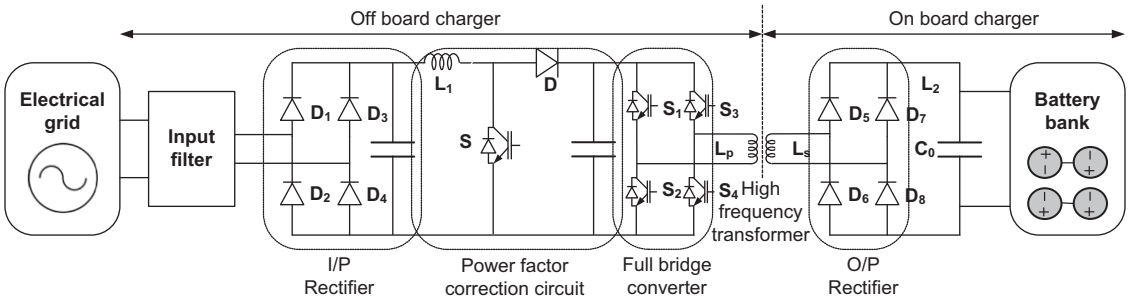

FIG. 31.38 Battery charger configuration for unidirectional power flow.

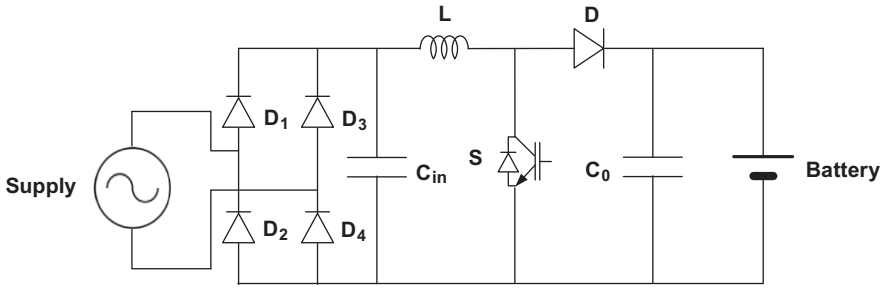

FIG. 31.39 Conventional single-switch PFC boost converter for battery charging.

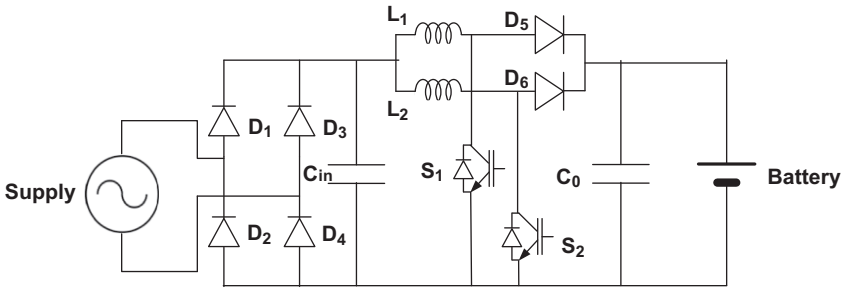

FIG. 31.40 Interleaved dc/dc boost converter for battery charging.

reduce the current ripple, the interleaved boost converter is presented as shown in Fig. 31.40. It consists of two boost converters in parallel operating 180 degrees out of phase [88,90]. The input current is the sum of the two input inductor currents that are out of phase and consequently cancel out each other, reducing the current ripple and stress across dc-link capacitor. The advantages of interleaved boost converter are parallel-connected switches that increase flexibility, switching out of 180 phase which increases the effective switch frequency and causes the reduction in filter size with lesser ripple content.

A bidirectional charging system supports grid-to-vehicle (G2V) and vehicle-to-grid (V2G) operation by injecting power to the grid and power stabilization with adequate power conversion [73,91,92]. A conventional bidirectional charger process supplies power in two stages. In the first stage, an active grid connected bidirectional ac/dc converter integrated with EMI filter and PFC is connected that enforces power factor to be close to unity. In the second stage a dc/dc converter is connected to regulate charging voltage and current [72]. In charging mode, charger should draw sinusoidal current with defined phase angle to control active and reactive power. In discharging mode, the charger should feed back power to the grid with sinusoidal current [91]. In ac/dc and dc/dc conversion, isolated and nonisolated converter topologies are used. An isolated bidirectional dual active bridge battery charger system is shown in Fig. 31.41 that offers high power density and fast control; however, the large number of component's count can add to cost [25].

The development of charger infrastructure with bidirectional power flow is growing rapidly; however, it imposes some serious challenges and issues such as reduction in battery life due to frequent charging and discharging, increased cost of charger, upgradation of existing distributed network, metering, and pricing [92]. Successful implementation of battery charger with bidirectional power flow needs to solve the abovementioned

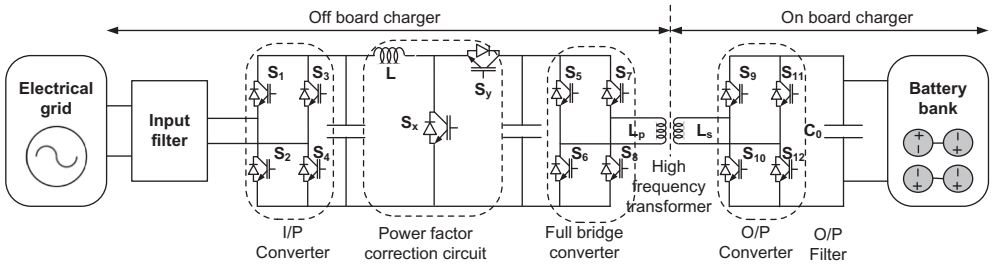

FIG. 31.41 Battery charger for EV/PHEV with bidirectional power flow.

issues. Also, it requires extensive safety measures and anti-islanding protection [92]. A unidirectional charger can be used for types I, II, and III charging; however, bidirectional chargers that are expected only for type-II charging system due to output power limit and cost target that are low and relatively high degree of freedom and flexibility in operation.

Integrated charger

At present, the onboard chargers face constraints on weight, volume cost, and space over specific power capacity of the battery. To overcome the abovementioned problems, charger configuration with integrated propulsion inverter-motor drive has been proposed [93,94]. The concept of integrated charger is feasible only if the vehicle is at rest. In an integrated charger, the propulsion inverter serves as a bidirectional ac/dc converter, and motor windings are used as filter inductors. Low cost, high-power-density bidirectional power flow, and fast charging with unity power factor are the advantages of the system. However, extra component requirement and control complexity are some of the challenges in its successful implementation. The schematic of a typical single-motor- and single-converter-based integrated charger system is shown in Fig. 31.42.

The classification of integrated charger topologies is done on the basis of the number of total converter and motor used such as one motor with a converter topology, one-motor and two-converter topology, and two-motor and two-converter topology [93–97]. A two-motor and two-converter integrated charger system is shown in Fig. 31.43 as discussed in [95]. In this system, main converter is used to drive the main motor, and auxiliary converter is used to drive the auxiliary motor during propulsion. During charging, two converters operated as ac/dc converter, and three-phase windings of the two motors act as filter inductor with neutral point connected to the grid [95,96]. The main converter recovers energy from main motor during regenerative braking for battery charging while maintaining the driving force for propulsion. The auxiliary converter coupled with auxiliary motor serves the purpose of starting of ICE and battery charging. This configuration of integrated charger is more popular for PHEVs. The inherent disadvantages of this integrated charger are the large number of extra components (twelve power switches, three contactors, and two motors) and control complexity.

A dual-inverter, single-motor integrated charger topology is shown in Fig. 31.44, where one motor with a double set of stator windings comprises two motor halves [97]. The working principle of this configuration is similar to two-motor and two-inverter configuration. However, in this configuration, elimination of one motor leads to reduction in cost and weight but still requires three contactors, 12 power switches, and a specially designed dual winding motor.

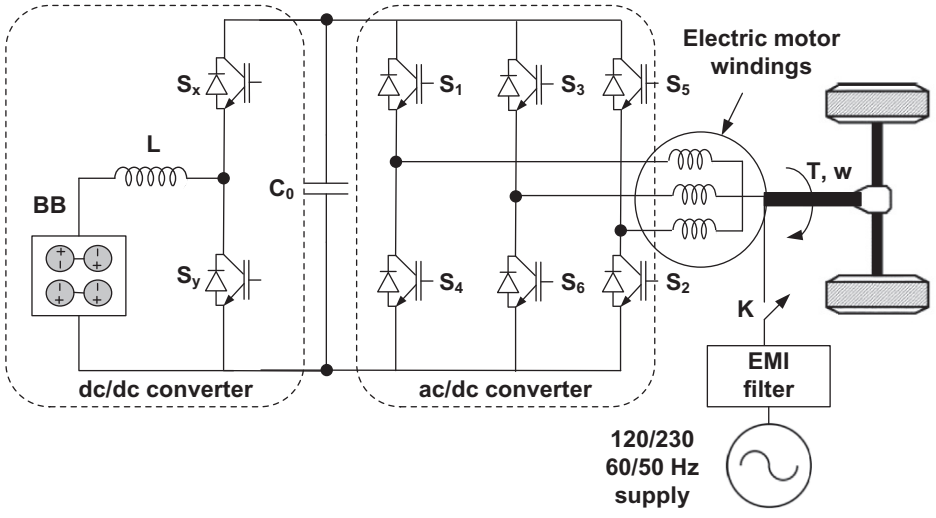

FIG. 31.42 Typical structure of integrated BEV charger.

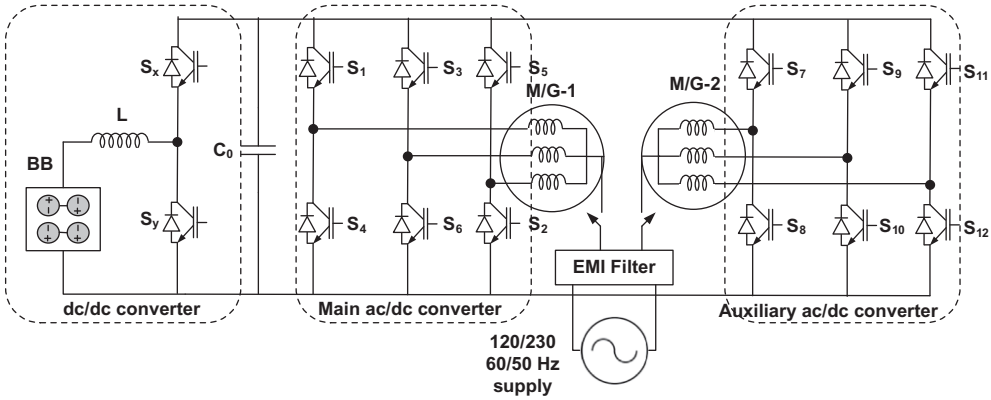

FIG. 31.43 Dual-motor dual-inverter integrated charger configuration.

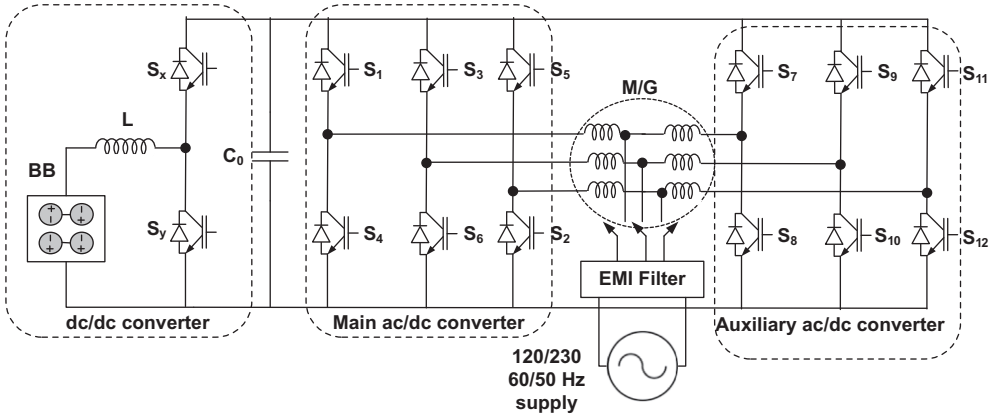

FIG. 31.44 Dual-inverter single-motor integrated charger configuration.

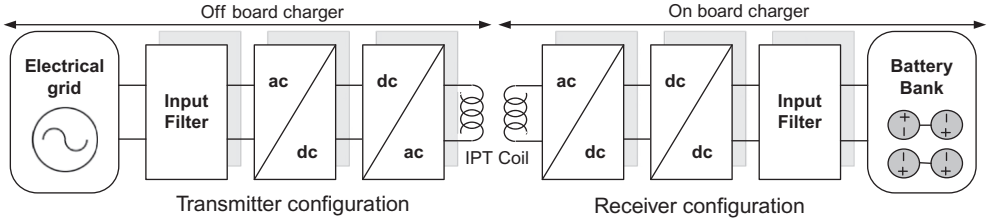

FIG. 31.45 Contactless, inductive, and wireless charging System.

Inductive charging

In conductive charging systems, battery bank is directly connected to the power outlet through charger connecting cable [98]. The standard charging port like domestic power outlets (type I and type II) or commercialized charging station (type II and type III) can be used for battery charging. However, in conductive charging, vehicles need to be parked and plugged into charging outlet.

As an alternative, inductive power charging concept has been introduced and mostly known as inductive power transfer (IPT). In IPT, the energy from power outlet is transferred to the onboard battery magnetically. The basic scheme of the IPT is illustrated in Fig. 31.45. The working principle of IPT is based on the magnetic coupling between two coils of a very-high-frequency transformer. The first coil of the transformer is mounted on the charger side, and the second coil is installed on the vehicle. Single-phase or three-phase ac supply of frequency 50–60 Hz is first rectified to dc, and then, this rectified dc is inverted to very-high-frequency ac within the charging station. This high-frequency power is transferred to the onboard battery through magnetically coupled primary and secondary coil. This high-frequency ac power received through vehicle side coil is converted to dc to charge the battery on board. The clear advantages of IPT are elimination of charger connectors, user convenience, and galvanic isolation. Also, it is possible to build charging strips on road, which enables

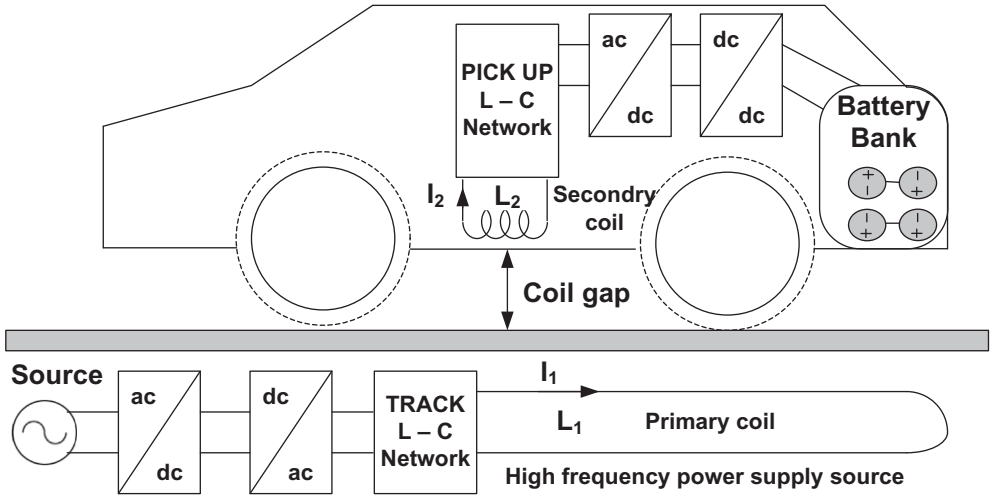

FIG. 31.46 Inductive coupling road bed BEV battery charger.

charging while driving as shown in Fig. 31.46. Relatively low power density and reduced efficiency, high control complexity, and manufacturing cost are some of the major disadvantages of this method [99–101].

31.5 Electronic Control Unit

The electronic control units (ECU) are designed to provide supervisory control of electric vehicular system [102]. It is a combination of dedicated system control software and electronic circuitry that includes interfacing hardware, sensing circuitry, driver and isolator circuitry, and communication buses. Basically, ECU is the integration of sophisticated electronic circuitry; dedicated digital controllers like microprocessors, microcontrollers, digital signal processors (DSP), and/or field programming gate array (FPGA); and modeling and simulation tools with autocode generation systems like MATLAB/Simulink, ADVISOR, PSAT, PSIM, SABER, SIMPLORER, and VTB, along with embedded software [26,102,103].

ECU provides the flexible multi-input/multi-output channels for communication among various components of the vehicular system. The controller synchronizes or coordinates with the components of EPS such as ESSS, PEC, electric motors along with ICE, transmission system, pilot commands, and operating modes of the vehicle. The ECU controls and maps the status of electric motor, ICE, and vehicle behavior based on a selection of system inputs. Standard pilot commands, such as braking and acceleration, are supplied as system input to the ECU from appropriate sensors and CAN buses. Based on system input and CAN bus information, certain mappings of different system components are performed to monitor their current status to select the vehicle's mode of operation [104,105]. The entire information is processed in digital controllers through programming, which performs the required calculation and converted into desired power and/or torque and/or speed commands for each wheel individually or simultaneously. The output of ECU that is driving signals for various components of the vehicle is communicated through CAN transmitter over different sections of vehicles. Not only the ECU is able to implement a variety of advanced vehicle control and dynamic algorithms, but also it monitors overall vehicle behaviors and observes the performance. The ECU is placed near to motor drives and engine; therefore, it should be designed such that it can bear temperature ranging from 80°C to 140°C and extreme vibrations that are a major challenge. A self-explanatory architecture of the ECU is shown in Fig. 31.47.

31.6 Power Management and Control Algorithm

In EVT, the control and management of power flow from multiple energy sources to power electronic converters and from converters to different vehicle loads is a major challenge. The technological advancement transforms the early ON/OFF control system to modern adaptive predictive control era that improves the overall performance of control system [106,107]. Dedicated efforts are being given for the development of appropriate control and energy management strategy that is very essential, specifically in HEV operation.

A control strategy is defined as an algorithm, which is a set of instructions or laws regulating the overall operation and power flow of the vehicular system. The algorithm can be considered as a black box that performs desired calculation on the basis of given information. Input information mainly contains measured data of vehicle's operating condition such as acceleration, braking, torque demand, traffic information, and driving profile. The output of the algorithms is a decision that commands

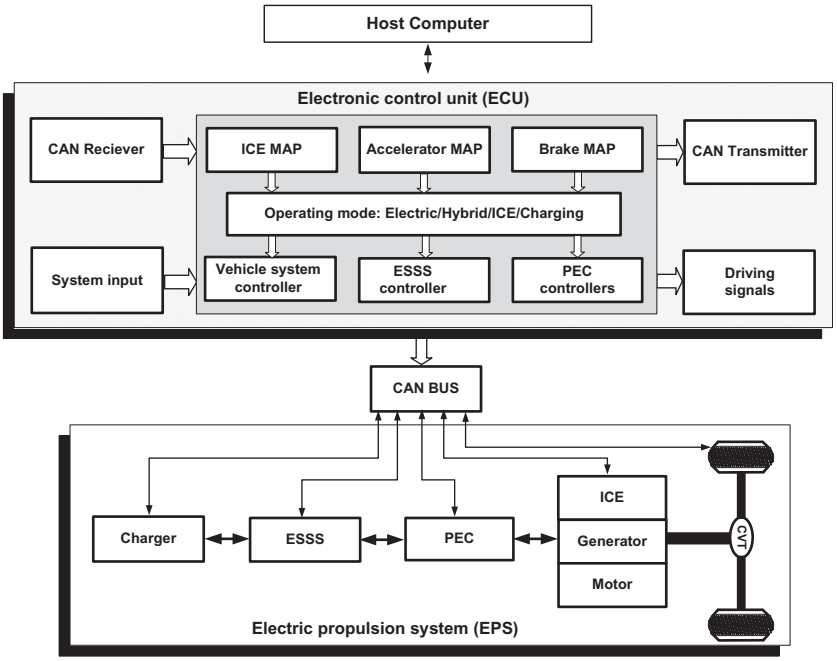

FIG. 31.47 Architecture of electronic controller in electrified vehicles [104].

the driver circuits to turn ON or OFF the vehicle's components or to modify their operating region toward optimization [106]. A properly developed control algorithm and management strategy should satisfy certain objectives such as vehicle power demand, monitoring of battery's state of charge, fuel economy, reduced emission, efficiency optimization, and smooth coordination between electric and mechanical components. Therefore, it becomes prime concern to adopt systematic process for power-flow control and optimization while designing the controllers and control algorithms.

Controllers are mainly classified into two groups based on their mathematical modeling strategy: (1) rule-based systems and (2) optimization-based systems [107]. The detailed classification of both the controllers is given in Fig. 31.48. Basically, rule-based controllers are designed to obtain maximum fuel economy and efficiency and reduced emission for predefined

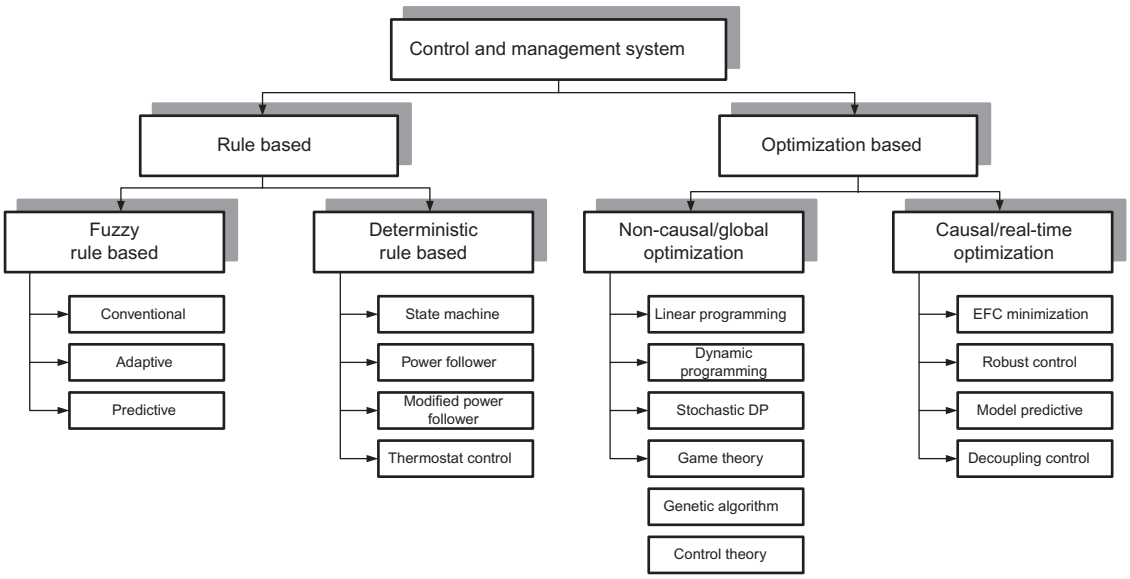

FIG. 31.48 Classification of control algorithms and power management techniques for EPS [107].

TABLE 31.12 Comparison between rule-based and optimization-based controllers

	Rule-based	Optimization-based
Implementation	Simple	Complex
Speed	Fast	Slow
Sensitivity	Low	High
Optimality	Approximate	Exact
Information needed	Less	More

driving profiles. Rule-based controllers are tuned based on sets of rules or criteria written on the basis of vehicle information. In this controller, state diagram and flow charts are commonly used for performance optimization of each component individually rather than cumulative. On the other hand, optimization-based controllers are designed to develop optimal control strategy for propulsion system by reducing the cost function. The cost function is derived based on the past and future information of driving profile, component parameters, and expected performance of the vehicles.

This controller is tuned for overall vehicular system optimization rather than component level. Both the controllers have their own pros and cons that are summarized in Table 31.12 and need to be addressed properly before implementing the algorithms. The global control strategy with real-time optimization has been the best proposed solution for HEV/PHEV so far [106].

31.7 Summary

Contemporary and futuristic global scenario of environmental, economical, and technological factors has accelerated the interest toward partial and/or complete electrification of vehicular technology. In this chapter, topological configuration of different vehicles has been presented with emphasis on EPS and its components to understand the fundamentals of EVT. The comprehensive review of the electrified vehicle architecture and EPS shows that EVT is a promising technology for sustainable future transportation system. At present, HEVs are dominating vehicle configurations, emerging rapidly and capturing the significant market space at very fast growth rate. Suitable energy policy and infrastructures for charging station will accelerate the commercialization of plug-in HEV very soon in the near future, and it will sustain for long time. FCVs are under development stage, and it will take time for their successful commercialization. FCV can be seen as the future of transportation system in long run.

The comprehensive review of EPS indicates that the recent modification in EPS due to technological advancement of its members, like ESS, PEC, EM, and ECU, makes EVT capable enough to compete against conventional ICE-based vehicular technology. Among all the components, PECs play crucial role as it bears the responsibility of compatible integration proper coordination among all the electric, mechanical, and electronic components on board. Also, the PEC controls and manages power flow from different energy sources and vehicle loads at appropriate voltage level and hence behaves as a heart of EPS in vehicle architecture. The integration and packaging of different components of EPS along with power electronic components are the challenging issues that need to be addressed properly so that weight, volume, and cost can be reduced significantly. For successive advancement of EPS, technical breakthroughs are necessary from device level to system level, so that improved performance, higher efficiency, longer driving distance, and higher degree of reliability can be achieved from electrified vehicles.

32.1 Introduction

The modern automobile has an extensive electric system consisting of a large number of electric, electromechanical, and electronic loads that are central to vehicle operation, passenger safety, and comfort. Power electronics is playing an increasingly important role in automotive electric systems—conditioning the power generated by the alternator, processing it appropriately for the vehicle electric loads, and controlling the operation of these loads. Furthermore, power electronics is an enabling technology for a wide range of future loads with new features and functions. Such loads include electromagnetic engine valves, active suspension, controlled lighting, and electric propulsion.

This chapter discusses the application and design of power electronics in automobiles. Section 32.2 provides an overview of the architecture of the present automotive electric power system. The next section, Section 32.3, describes the environmental factors, such as voltage ranges, EMI/EMC requirements, and temperature, which strongly influence the design of automotive power electronics. Section 32.4 discusses a number of electric functions that are enabled by power electronics, while Section 32.5 addresses load control via multiplexed remote switching architectures that can be implemented with power electronic switching. Section 32.6 considers the application of power electronics in automotive electromechanical energy conversion, including power generation. Section 32.7 describes the potential evolution of automotive electric systems toward high- and dual-voltage systems and provides an overview of the likely requirements of power electronics in such systems. Finally, the application of power electronics in electric and hybrid electric vehicles (HEVs) is addressed in Section 32.8.

32.2 The Present Automotive Electrical Power System

Present-day automobiles can have over 200 individual electric loads, with average power requirements in excess of 800 W.

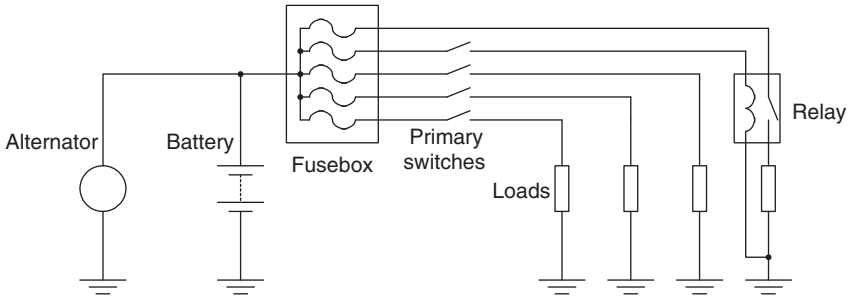

FIG. 32.1 The 12 V point-to-point automotive electric power system.

These include such functions as the headlamps, tail lamps, cabin lamps, starter, fuel pump, wiper, blower fan, fuel injector, transmission shift solenoids, horn, cigar lighter, seat heaters, engine control unit, cruise control, radio, and spark ignition. To power these loads, present-day internal-combustion-engine (ICE) automobiles use an electric power system similar to the one shown in Fig. 32.1. Power is generated by an engine-driven three-phase wound-field synchronous machine—a Lundell (claw-pole) alternator [1,2]. The ac voltage of this machine is rectified and the dc output regulated to about 14 V by an electronic regulator that controls the field current of the machine. The alternator provides power to the loads and charges a 12 V lead-acid battery. The battery provides the high power needed by such loads as the starter and supplies power when the engine is not running or when the demand for electric power exceeds the output power of the alternator. The battery also acts as a large capacitor and smoothes out the system voltage.

Power is distributed to the loads via fuses and point-to-point wiring. The fuses, located in one or more fuse boxes, protect the wires against overheating and fire in the case of a short circuit. Most of the loads are controlled directly by manually actuated mechanical switches. These primary switches are located in areas in easy reach of either the driver or the passengers, such as the dashboard, the door panels, and the ceiling. Some of the heavy loads, such as the starter, are switched indirectly via electromechanical relays.

32.3 System Environment

The challenging electric and environmental conditions found in the modern automobile have a strong impact on the design of automotive power electronic equipment. Important factors affecting the design of electronics for this application include static and transient voltage ranges, electromagnetic interference and compatibility requirements (EMI/EMC), mechanical vibration and shock, and temperature and other environmental conditions. This section briefly describes some of the factors that most strongly affect the design of power electronics for automotive applications. For more detailed guidelines on the design of electronics for automotive applications, the reader is referred to [1,3–16] and the documents cited therein, from which much of the information presented here is drawn.

32.3.1 Static Voltage Ranges

In most present-day automobiles, a Lundell-type alternator provides dc electric power with a lead-acid battery for energy storage and buffering. The nominal battery voltage is 12.6 V, which the alternator regulates to 14.2 V when the engine is on in order to maintain a high state of charge on the battery. In practice, the regulation voltage is adjusted for temperature to match the battery characteristics. For example, in Ref. [1], a 25°C regulation voltage of 14.5 V is specified with a −10 mV/°C adjustment. Under normal operating conditions, the bus voltage will be maintained in the range of 11–16 V [3]. Safety-critical equipment is typically expected to be operable even under battery discharge down to 9 V, and equipment operating during starting may see a bus voltage as low as 4.5–6 V under certain conditions.

In addition to the normal operating voltage range, a wider range of conditions is sometimes considered in the design of automotive electronics [3]. One possible condition is reverse-polarity battery installation, resulting in a bus voltage of approximately −12 V. Another static overvoltage condition can occur during jump starting from a 24 V system such as on a tow truck. Other static overvoltage conditions can occur due to failure of the alternator voltage regulator. This can result in a bus voltage as high as 18 V, followed by battery electrolyte boil-off, and a subsequent unregulated bus voltage as high as 130 V. Typically, it is not practical to design the electronics for operation under such an extreme fault condition, but it should be noted that such conditions can occur. Table 32.1 summarizes the range of static voltages that can be expected in the automotive electric system.

32.3.2 Transients and Electromagnetic Immunity

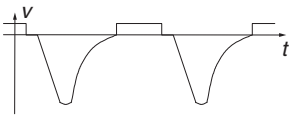
Power electronic circuits designed for automotive applications must exhibit electromagnetic compatibility, that is, the conducted and radiated emissions generated by the circuit must not interfere with other equipment on board the vehicle, and the circuit must exhibit immunity to radiated and conducted disturbances. The Society of Automotive Engineers (SAE) has laid out standards and recommended practices for the electromagnetic compatibility of automotive electronics in a set of technical reports [4]. These reports are listed in Table 32.2.

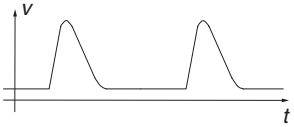
TABLE 32.1 Static voltage range for the automotive electric system [3]

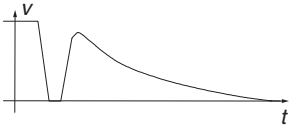
Static voltage condition	Voltage
Nominal voltage with engine on	14.2 V
Nominal voltage with engine off	12.6 V
Maximum normal operating voltage	16 V
Minimum normal operating voltage	9 V
Minimum voltage during starting	4.5 V
Jump-start voltage	24 V
Reverse-battery voltage	−12 V
Maximum voltage with alternator-regulator failure followed by battery failure	130 V

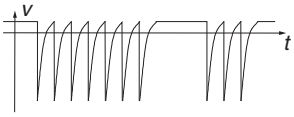
Here, we will focus on two of the basic requirements of automotive power electronics, immunity to power lead transients and limitation of conducted emissions.

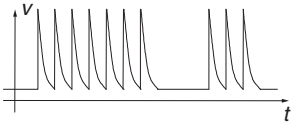
A major consideration in the design of an automotive power electronic system is its immunity to the transients that can appear on its power leads. A number of transient sources exist in the vehicle [5], and procedures for validating immunity to these transients have been established in documents such as SAE J1113/11 [4,6] and DIN 40389 [1]. Table 32.3 illustrates the transient test pulses specified in SAE J1113/11. Each test pulse corresponds to a different type of transient. The vehicle manufacturer determines which test pulses apply to a specific device.

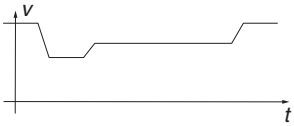


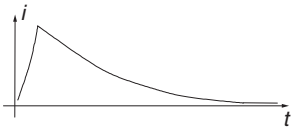












Transients occur when inductive loads such as solenoids, motors, and clutches are turned on and off. The transients can be especially severe when the bus is disconnected from the battery, as is the case for the accessory loads when the ignition is switched off. Test pulse 1 in Table 32.3 simulates the transient generated when an inductive load is disconnected from the battery and the device under test remains in parallel with it. When the inductive load is a dc motor, it may briefly act as a generator after disconnection. This transient is simulated by test pulse 2b. Test pulse 2a models the transient when current in an inductive element in series with the device under test is interrupted. Test pulses 3a and 3b model switching spikes that appear on the bus during normal operation. Test pulse 4 models the voltage transient that occurs on starting.

Perhaps, the best-known electric disturbance is the so-called load-dump transient that occurs when the alternator load current drops sharply and the battery is unable to properly buffer the change. This can occur when the battery becomes disconnected while drawing a large amount of current. To understand why a major transient can occur under this situation, consider that the Lundell alternator has a very large leakage reactance. The high commutating reactance interacting with the diode rectifier results in a high degree of load regulation, necessitating the use of a large back emf to source-rated current at high speed [7]. Back voltages as high as 120 V may be needed to generate rated current into a 14 V output at top speed. Analytic modeling of such systems is addressed in Ref. [8]. Two effects occur when the load on the alternator suddenly steps down. First, as the machine current drops, the energy in the alternator leakage reactances is immediately delivered to the alternator output, causing a voltage spike. The peak voltage reached depends on the electric system impedance and may be limited by suppression devices. Second, once the alternator current is reduced, the voltage drops across the leakage (commutating) reactances are reduced, and a much larger fraction of the machine back emf is impressed across the dc output. The proper output voltage is only reestablished as the voltage regulator reduces the field current appropriately. With conventional regulator circuits, this takes place on the time scale of the field-winding time constant (typically 100 ms) and results in a major transient event. In systems without centralized protection, a load dump can generate a transient with a peak voltage in excess of 100 V lasting hundreds of milliseconds. Test pulse 5 in Table 32.3 (expressed as a current waveform in parallel with an output resistance) is designed to simulate such a load-dump transient; other load-dump tests are even more severe [1,3].

TABLE 32.2 SAE J1113 electromagnetic compatibility technical reports

SAE specification	Type	Description
SAE J1113/1	Standard	Electromagnetic compatibility measurement procedures and limits, 60 Hz–18 GHz
SAE J1113/2	Standard	Conducted immunity, 30 Hz–250 kHz
SAE J1113/3	Standard	Conducted immunity, direct injection of RF power, 250 kHz–500 MHz
SAE J1113/4	Standard	Conducted immunity, bulk current injection method
SAE J1113/11	Standard	Conducted immunity to power lead transients
SAE J1113/12	Recommended practice	Electric interference by conduction and coupling—coupling clamp
SAE J1113/13	Recommended practice	Immunity to electrostatic discharge
SAE J1113/21	Information report	Electric disturbances by narrowband radiated electromagnetic energy—component test methods
SAE J1113/22	Standard	Immunity to radiated magnetic fields from power lines
SAE J1113/23	Recommended practice	Immunity to radiated electromagnetic fields, 10 kHz–200 MHz, strip-line method
SAE J1113/24		Immunity to radiated electromagnetic fields, 10 kHz–200 MHz, TEM cell method
SAE J1113/25	Standard	Immunity to radiated electromagnetic fields, 10 kHz–500 MHz, triplate-line method
SAE J1113/26	Recommended practice	Immunity to ac power line electric fields
SAE J1113/27	Recommended practice	Immunity to radiated electromagnetic fields, reverberation method
SAE J1113/41	Standard	Radiated and conducted emissions, 150 kHz–1000 MHz
SAE J1113/42	Standard	Conducted transient emissions

TABLE 32.3 Transient pulse waveforms specified in SAE J1113/11

Pulse	Shape	Maximum excursion	Source impedance	Duration and repetition rate
1		−100 V	10 Ω	$T_{pulse}=2$ ms 0.5 s < T_{rep} < 5 s
2a		100 V	10 Ω	$T_{pulse}=50$ μs 0.5 s < T_{rep} < 5 s
2b		10 V	0.5–3 Ω	$T_{pulse} \geq 200$ ms
3a		−150 V	50 Ω	$T_{pulse}=100$ ns $T_{rep}=100$ μs
3b		100 V	50 Ω	$T_{pulse}=100$ ns $T_{rep}=100$ μs
4		−7 V	0.01 Ω	$T_{pulse} \leq 20$ s
5		84 A	0.6 Ω	$\tau=115$ ms $T_{pulse} \sim 4\,\tau$

32.3.3 Electromagnetic Interference

Strict limits also exist for the amount of electromagnetic interference (EMI) that an automotive electronic component can generate. Limits for both conducted and radiated emissions are specified in SAE standards J1113/41 and J1113/42 [4,9,10]. Here, we will consider the conducted EMI specifications for power leads, since they directly impact the design of EMI filters for automotive power electronics. Meeting the conducted specifications is a major step toward achieving overall compliance.

The conducted EMI specifications in SAE J1113/41 limit the ripple that an electronic circuit can inject onto the voltage bus over the frequency range from 150 kHz to 108 MHz. The amount of ripple injected by a circuit usually depends on the bus impedance. To eliminate any variability due to this, EMI compliance testing is done using a line impedance stabilization network (LISN) between the bus and the device under test, as illustrated in Fig. 32.2. The LISN is also sometimes referred to as an artificial mains network (AN). Essentially, the LISN ensures that the equipment under test receives the proper dc voltage and current levels and also sees a controlled impedance for the ripple frequencies of interest. Fig. 32.3 shows the magnitude of the LISN output impedance for a low-impedance input source; the effective impedance is 50 Ω over most of the frequency range of interest. The 50 Ω termination impedance of the LISN is typically provided by the measurement equipment. The EMI specifications are stated in terms of the

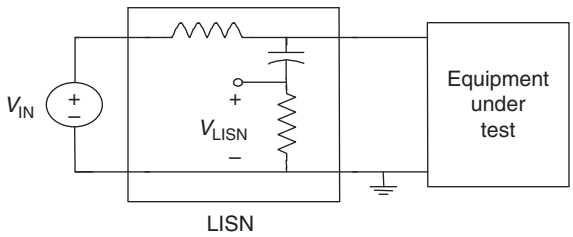


FIG. 32.2 Conducted EMI test setup with LISN. $L_{LISN}=5$ μH, $C_{LISN}=0.1$ μF, and $R_{LISN}=50$ Ω.

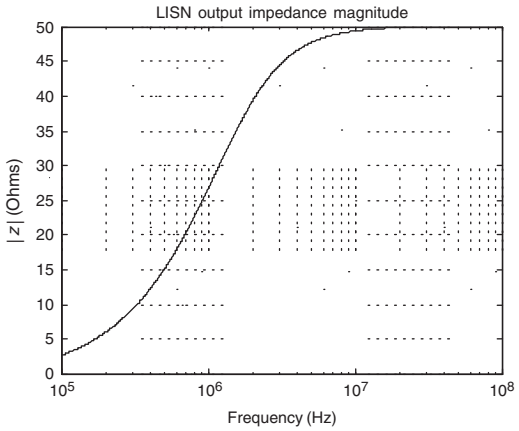

FIG. 32.3 The LISN output impedance magnitude for a low-impedance input source.

allowable voltage ripple (in dB μV) appearing across the 50-Ω LISN resistance as a function of frequency.

There are a wide range of other technical considerations for EMI testing, including the arrangement of the equipment over a ground plane and the types and settings of the measuring devices. One characteristic to consider is that the EMI measurements are done across frequency with a spectrum analyzer having a prespecified receiver bandwidth (RBW). For frequencies between 150 kHz and 30 MHz, the receiver bandwidth is 9 kHz, resulting in spectral components within 9 kHz of one another being lumped together for purposes of the test. A full test procedure is defined in the SAE specifications, beginning with narrowband measurements and moving to wideband measurements if necessary. Fig. 32.4 illustrates the narrowband conducted EMI limits for power leads in SAE J1113/41. It is interesting to note that for the commonly used class 5 limits, the allowable ripple current into the LISN at 150 kHz is less than 100 μA!

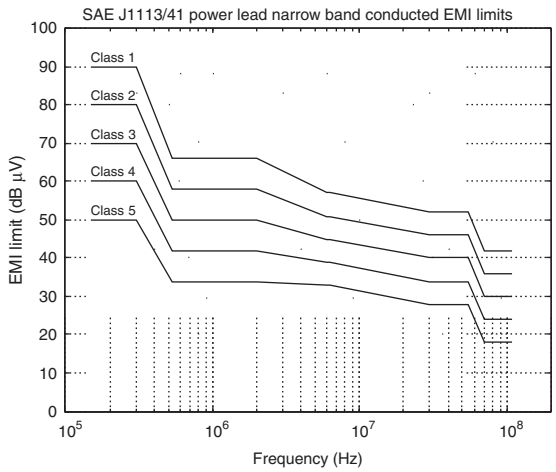

FIG. 32.4 SAE J1113/41 narrowband conducted EMI limits for power leads. The specification covers the frequency range from 150 kHz to 108 MHz.

As seen in the previous section, the transient disturbances generated by electric and electronic equipment are an important consideration in automotive applications. Because power electronic circuits typically contain switches and magnetic elements, they are potential sources for such transients, especially when powered from the switched ignition line. SAE J1113/42 specifies methods for testing and evaluating the transients generated by automotive electric components and proposes transient waveform limits for different severity levels. The equipment under test is set up in a configuration similar to that in Fig. 32.2 but with a switching device on one side or the other of the LISN, depending on the application. The equipment under test is then evaluated for transient behavior at turn-on, turnoff, and across its operating range. The voltage transients at the input of the equipment are measured and evaluated with respect to magnitude, duration, and rise and fall times. Specific limits for such transients are specified by the vehicle manufacturer, but SAE J1113/42 proposes a representative set of limits for four different transient severity levels.

Due to the tight conducted emission limits, input EMI filter design is an important consideration in automotive power electronics. Single- or multistage low-pass filters are typically used to attenuate converter ripple to acceptable levels [11–13]. When designing such filters, the parasitic behaviors of the filter components, such as capacitor equivalent series resistance and inductance and suitable filter damping, are important considerations [14]. One must also ensure that the filter design yields acceptable transients at switch on and off, and does not result in undesired dynamic interactions with the power circuit [13]. Attention to appropriate filter design, coupled with proper circuit layout, grounding, and shielding, goes a long way toward meeting electromagnetic interference specifications [14].

32.3.4 Environmental Considerations

The automobile is a very challenging environment for electronics. Environmental factors influencing the design of automotive electronics include temperature, humidity, mechanical shock, vibration, immersion, salt spray, and exposure to sand, gravel, oil, and other chemicals. In 1978, the SAE developed a recommended practice for electronic equipment design to address these environmental considerations [3,4]. This document, SAE J1211, provides quantitative information about the automotive environment to aid the designer in developing environmental design goals for electronic equipment. Here, we briefly summarize a few of the most important factors affecting the design of power electronics for automotive applications. For more detailed guidelines, the reader is referred to [3] and the documents cited therein.

Perhaps, the most challenging environmental characteristic is the extreme range of temperatures that can occur in the automobile. Table 32.4 summarizes some of the temperature

TABLE 32.4 Automotive temperature extremes by location [3]

Vehicle location	Min temp. (°C)	Max temp. (°C)
Exterior	−40	85
Chassis		
Isolated	−40	85
Near heat source	−40	121
Drivetrain high-temperature location	−40	177
Interior		
Floor	−40	85
Rear deck	−40	104
Instrument panel	−40	85
Instrument panel top	−40	177
Trunk	−40	85
Under hood		
Near radiator support structure	−40	100
Intake manifold	−40	121
Near alternator	−40	131
Exhaust manifold	−40	649
Dash panel (normal)	−40	121
Dash panel (extreme)	−40	141

extremes listed in SAE J1211 for different locations in the automobile. Ambient temperatures as low as −40°C may be found during operation, and storage temperatures as low as −50°C may be found for components shipped in unheated aircraft. Maximum ambient temperatures vary widely depending on vehicle location, even for small differences in position. Because ambient temperature has a strong impact on the design of a power electronic system, it is important to work closely with the vehicle manufacturer to establish temperature specifications for a particular application. For equipment that is air-cooled, one must also consider that the equipment may be operated at altitudes up to 12,000 ft above sea level. This results in low ambient pressure (down to 9 psia), which can reduce the heat transfer efficiency [3]. For equipment utilizing the radiator-cooling loop, maximum coolant temperatures in the range of 105–120°C at a pressure of 1.4 bar are possible [15].

In addition to the temperature extremes in the automobile, thermal cycling and shock are also important considerations due to their effect on component reliability. Thermal cycling refers to the cumulative effects of many transitions between temperature extremes, while thermal shock refers to rapid transitions between temperature extremes, as may happen when a component operating at high temperature is suddenly cooled by water splash. The damaging effects of thermal cycling and shock include failures caused by thermal expansion mismatches between materials. Test methods have been developed that are designed to expose such weaknesses [3,16]. The thermal environments in the automobile, including the temperature extremes, cycling, and shock, are challenging issues that must be addressed in the design of automotive power electronics.

A number of other important environmental factors exist in the automobile. Humidity levels as high as 98% at 38°C can exist in some areas of the automobile, and frost can occur in situations where the temperature drops rapidly. Salt atmosphere, spray, water splash, and immersion are also important factors for exterior, chassis, and underhood components. Failure mechanisms resulting from these factors include corrosion and circuit bridging. Dust, sand, and gravel bombardment can also be significant effects depending on equipment location. Mechanical vibration and shock are also important considerations in the design of automotive power electronic equipment. Details about the effects of these environmental factors, sample recorded data, and recommended test procedures can be found in Ref. [3].

32.4 Functions Enabled by Power Electronics

Over the past 20 years, power electronics has played a major role in the introduction of new functions such as the antilock braking system (ABS), traction control, and active suspension, as well as the electrification of existing functions such as the engine-cooling fan, in the automobile. This trend is expected to continue, as a large number of new features being considered for introduction into automobiles require power electronics. This section discusses some of the new functions that have been enabled by power electronics and some existing ones that benefit from it.

32.4.1 High Intensity Discharge Lamps

High-intensity discharge (HID) lamps have started to appear in automobiles as low-beam headlights and fog lights. The HID lamps offer higher luminous efficacy, higher reliability, longer life, and greater styling flexibility than the traditional halogen lamps [17,18]. The luminous efficacy of an HID lamp is over three times that of a halogen lamp, and its life is about 2000 h, compared with 300–700 h for a halogen lamp. Therefore, HID lamps provide substantially higher road illumination while consuming the same amount of electric power and, in most cases, should last the life of the automobile. The HID lamps also produce a whiter light than halogen lamps since their color spectrum is closer to that of the sun.

High-intensity discharge lamps do not have a filament. Instead, light is generated by discharging an arc through a pressurized mixture of mercury, xenon, and vaporized metal halides—mercury produces most of the light, the metal halides determine the color spectrum, and xenon helps reduce the start-up time of the lamp [17,19]. Unlike halogen lamps that can be powered directly from the 12 V electric system, HID lamps require power electronic ballasts for their operation. Initially, a high-voltage pulse of 10–30 kV is needed to ignite the arc between the electrodes, and a voltage of about 85 V is needed to sustain the arc [4.3]. Fig. 32.5 shows a simplified power electronic circuit that can be used to start and drive an HID lamp. A step-up dc-dc converter is used to boost the voltage from 12 V to the voltage needed for the steady-state

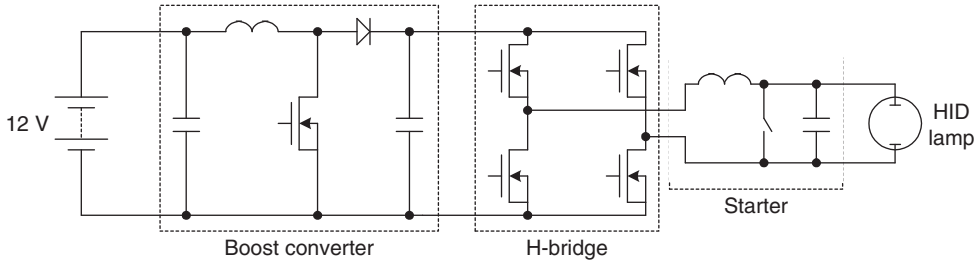

FIG. 32.5 Simplified power electronic circuit for an HID lamp ballast.

operation of the HID lamp. Any dc-dc converter that can step up the voltage, such as the boost or flyback converter, can be used for this application. An H-bridge is then used to create the ac voltage that drives the lamp in steady state. The circuit to initiate the arc can be as simple as a circuit that provides an inductive voltage kick, as shown in Fig. 32.5.

32.4.2 Pulse-Width Modulated Incandescent Lighting

Future automobiles may utilize a 42 V electric system in place of today's 14 V electric system (see Section 32.7). Because HID lamps are driven through a power electronic ballast, HID lighting systems operable from a 42 V bus can be easily developed. However, the high cost of HID lighting—as much as an order of magnitude more expensive than incandescent lighting—largely limits its usefulness to headlight applications. Incandescent lamps compatible with 42 V systems can also be implemented. However, because a much longer, thinner filament must be employed at the higher voltage, lamp lifetime suffers greatly. An alternative to this approach is to use pulse-width modulation to operate 12 V incandescent lamps from a 42 V bus [20].

In a pulse-width modulated (PWM) lighting system, a semiconductor switch is modulated to apply a periodic pulsed voltage to the lamp filament. Because of its resistive nature, the power delivered to the filament depends on the rms of the applied voltage waveform. The thermal mass of the system filters the power pulsations so that the filament temperature and light production are similar to that generated by a dc voltage with the same rms value. The PWM frequency is selected low enough to avoid lamp mechanical resonances and the need for EMI filtering while being high enough to limit visible flicker; PWM frequencies in the range of 90–250 Hz are typical [20].

Ideally, an 11.1% duty ratio is needed to generate 14 V rms across a lamp from a 42 V nominal voltage source. In practice, deviations from this duty ratio are needed to adjust for input voltage variations and device drops. In some proposed systems, multiple lamps are operated within a single lighting module with phase-staggered (interleaved) PWM waveforms to reduce the input rms current of the module.

Another issue with PWM lighting relates to start-up. Even with operation from a 12 V dc source, incandescent lamps have an inrush current that is 6–8 times higher than the steady-state value, because of how filament resistance changes with temperature; this inrush impacts lamp durability. The additional increase in peak inrush current due to operating from a 42 V source can be sufficient to cause destruction of the filament, even when using conventional PWM soft-start techniques (a ramping up of duty ratio). Means for limiting the peak inrush current—such as operating the controlling MOSFET in current-limiting mode during start-up—are needed to make practical use of PWM lighting control.

While PWM incandescent lighting technology is still in the early stages of development, it offers a number of promising advantages in future 42 V vehicles. These include low-cost adaptation of incandescent lighting to high-voltage systems; control of lighting intensity independent of bus voltage; ability to implement multiple intensities, flashing, dimming, etc. through PWM control; and the potential improvement of lamp durability through more precise inrush and operating control [20].

32.4.3 Piezoelectric Ultrasonic Actuators

Piezoelectric ultrasonic motors are being considered as actuators for window lifts, seat positioning, and head restraints in automobiles [21,22]. These motors work on the principle of converting piezoelectrically induced ultrasonic vibrations in an elastic body into unidirectional motion of a moving part. Unidirectional motion is achieved by allowing the vibrating body to make contact with the moving part only during a half cycle of its oscillation, and power is transferred from the vibrating body to the moving part through frictional contact. Ultrasonic motors have a number of attractive features, including high torque density, large holding torque even without input power, low speed without gears, quiet operation, no magnetic fields, and high dynamics [21,23]. These characteristics make ultrasonic motors an attractive alternative to electromagnetic motors for low-power high-torque applications.

Various types of ultrasonic motors have been developed. However, because of its compact design, the traveling-wave type is the most popular ultrasonic motor [24]. Fig. 32.6A shows the basic structure of such a motor. It consists of a metal stator and rotor, which are pushed against each other by a spring. The rotor is coated with a special lining material to increase friction and reduce wear at the contacting surfaces. A layer of piezoelectric material, such as lead zirconate titanate

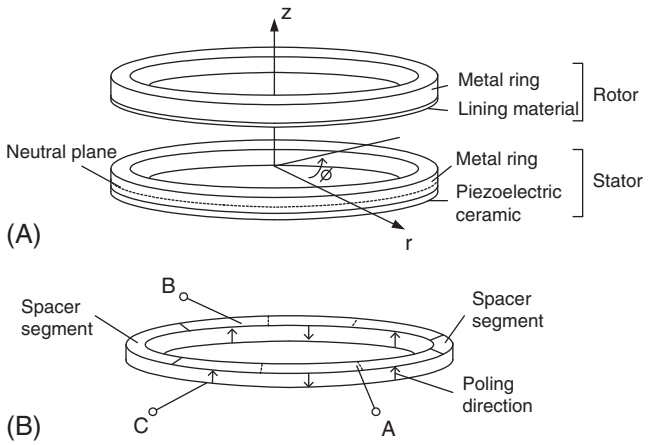

FIG. 32.6 (A) Basic structure of a traveling-wave piezoelectric ultrasonic motor and (B) structure of the piezoceramic ring and electrode for a four-wavelength motor. Arrows indicate direction of polarization. Dashed lines indicate segments etched in the electrode for poling but electrically connected during motor operation.

(PZT), is bonded to the underside of the stator. Silver electrodes are printed on both sides of the piezoceramic ring. The top electrode is segmented, and the piezoceramic is polarized as shown in Fig. 32.6B. The number of segments is twice the order of the excited vibration mode.

When a positive voltage is applied between terminals A and C, the downward-poled segment elongates, and the upward-poled segments contract. This causes the stator to undulate, waving down at the elongated section and up at the contracted one. When the polarity of the voltage is inverted, the undulations are also inverted. Hence, when an ac voltage is applied, a flexural standing wave is created in the stator. To get a large wave amplitude, the stator is driven at the resonance frequency of the flexural mode. An ac voltage between terminals B and C similarly produces another standing wave. However, because of the spacer segments in the piezoceramic ring, the second standing wave is 90 degrees spatially out of phase from the first one. If the two standing waves are excited by ac voltages that are out of phase in time by 90 degrees, a traveling wave is generated. As the traveling wave passes through a point along the neutral plane, that point simply exhibits axial (z-axis) motion. However, off-neutral plane points also have an azimuthal (ϕ-axis) component of motion. This azimuthal motion of the surface points propels the rotor. Ultrasonic motors require a power electronic drive. A power electronic circuit suitable for driving an ultrasonic motor is shown in Fig. 32.7. The two H-bridges are controlled to generate waveforms that are 90 degrees out of phase with each other.

32.4.4 Electromechanical Engine Valves

Electromagnetic actuators are finding increasing application in automotive systems. These actuators are more desirable than

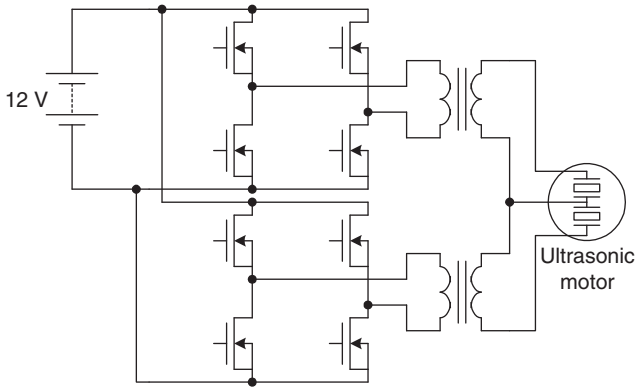

FIG. 32.7 Drive circuit for an ultrasonic motor.

the other types of actuators, such as the hydraulic and pneumatic actuators, because they can be more easily controlled by a microprocessor to provide more precise control. An application of electromagnetic actuators that is of particular interest is the replacement of the camshaft and tappet valve assembly by electromechanically driven engine valves [25]. The opening and closing of the intake and exhaust valves can be controlled to achieve optimum engine performance and improved fuel economy over a wide range of conditions determined by variables such as the speed, load, altitude, and temperature. The present cam system provides a valve profile that can give optimum engine performance and improved fuel economy only under certain conditions.

Two power electronic circuits suitable for driving the solenoids for valve actuation are shown in Fig. 32.8. The circuit of Fig. 32.8A is suitable for solenoids that require unidirectional currents through their coils, while the circuit of Fig. 32.8B is suitable for solenoids that require bidirectional currents through their coils.

32.4.5 Electric Air Conditioner

It is desirable to replace some of the engine-driven functions of a vehicle with electrically driven counterparts. The benefits of driving these functions electrically include the elimination of belts and pulleys, improved design and control due to independence from engine speed, and resulting increased efficiency and improved fuel economy. Furthermore, there is the opportunity for operation of the function in the engine-off condition.

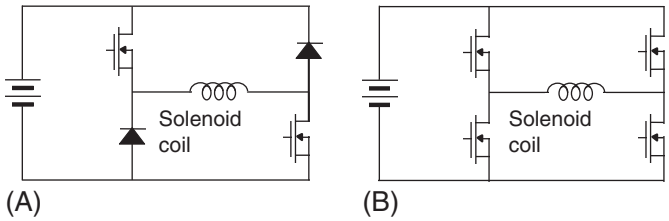

FIG. 32.8 Power electronic circuits for driving solenoids.

The air conditioner is an example of an engine-driven function that could benefit from electrification. The engine drives the compressor of the air conditioner. Consequently, the speed of the compressor varies over a wide range, and the compressor has to be oversized to provide the desired performance at engine idle. Also, since the compressor speed is dependent on the engine speed, excessive cooling occurs at highway speeds requiring the cool air to be blended with the hot air to keep the temperature at the desired level. Furthermore, shaft seals and rubber hoses can lead to the loss of refrigerant (CFC) and pose an environmental challenge.

In an electric air conditioner, an electric motor is used to drive the compressor [26]. The motor is usually a three-phase brushless dc motor driven by a three-phase MOSFET bridge. The speed of the compressor in an electric air conditioner is independent of the engine speed. As a result, the compressor does not have to be oversized, and excessive cooling does not occur. Also, shaft seals and hoses can be replaced with a hermetically sealed system. Another benefit of an electric air conditioner is the flexibility in its location, since it does not have to be driven by the engine.

32.4.6 Electric and Electrohydraulic Power Steering Systems

The hydraulic power steering system of a vehicle is another example of an engine-driven accessory. This system can be replaced with an electric power steering (EPS) system in which a brushless dc motor is used to provide the steering power assist [27]. The electric power steering system is more efficient than the hydraulic power steering system because, unlike the engine-driven hydraulic steering pump, which is driven by the engine all the time, the motor operates only on demand. Another system that can replace the hydraulic power steering system is the electrohydraulic power steering (EHPS) system. In this case, a brushless dc motor and inverter can be employed to drive the hydraulic steering pump. The ability of the EHPS system to drive the pump only on demand leads to energy savings of as much as 80% as compared with the conventional hydraulic system. Challenges in implementing EPS and EHPS systems include meeting the required levels of cost and reliability for this critical vehicle subsystem.

32.4.7 Motor Speed Control

Some of the motors used in a vehicle require variable speed control. Consider, as an example, the blower motor used to provide air flow to the passenger compartment. This motor is typically a permanent-magnet dc motor with a squirrel-cage fan. The speed of the motor is usually controlled by varying the resistance connected in series with the motor winding. This method of speed control leads to a significant power loss. A low-loss method of speed control employs semiconductor devices as shown in Fig. 32.9. In this case, the speed of the motor is controlled via PWM—that is, by switching the MOSFET on and off with different duty ratios for different speed settings. An input filter is needed to reduce the EMI generated by the switching of the MOSFET. This method of speed control is equivalent to supplying power to the motor through a variable-output dc-to-dc converter. The converter is located close to the motor, and no filter is required between the converter output and motor winding.

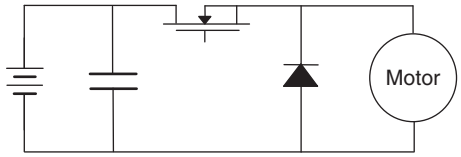

FIG. 32.9 Low-loss circuit to control the speed of a motor.

Another low-loss method that can be used to control the speed of a motor employs a three-phase brushless dc motor. The speed in this case is controlled by controlling the MOSFETs in the dc-to-three-phase-ac converter that drives the motor.

32.5 Multiplexed Load Control

Another emerging application of power electronics in automobiles is in the area of load control. In the conventional point-to-point wiring architecture, most of the loads are controlled directly by the primary mechanical switches, as shown in Fig. 32.1. In a point-to-point wiring architecture, each load has a dedicated wire connecting it to the fuse box via the primary switch. Consequently, fairly heavy wires have to be routed all over the vehicle, as illustrated in Fig. 32.10A. The situation is made worse when multiple switches control the same load, as is the case with power windows and power door locks. The complete harness of a 1994 C-class Mercedes-Benz that uses point-to-point wiring has about 1000 wires, with a total length of 2 km, over 300 connectors, and weighs 32 kg. The process of assembling the wiring harness is difficult and time-consuming, leading to high labor costs. Retrofitting, fault tracing, and repairing are time-consuming and expensive. The bulky harness also places constraints on the vehicle body design, and the large number of connectors compromises system reliability.

An alternative wiring technique is to control the loads remotely and multiplex the control signals over a communication bus, as shown in Fig. 32.10B and C. A control message is sent on the communication bus to switch a particular load on or off. This allows more flexibility in the layout of the power cables and could allow the preassembly of the harness to be more automated. Furthermore, with communication between the remote switches, it is practical to have a power management system than can turn off nonessential loads when there is a power shortage. One possibility is to group the remote switches

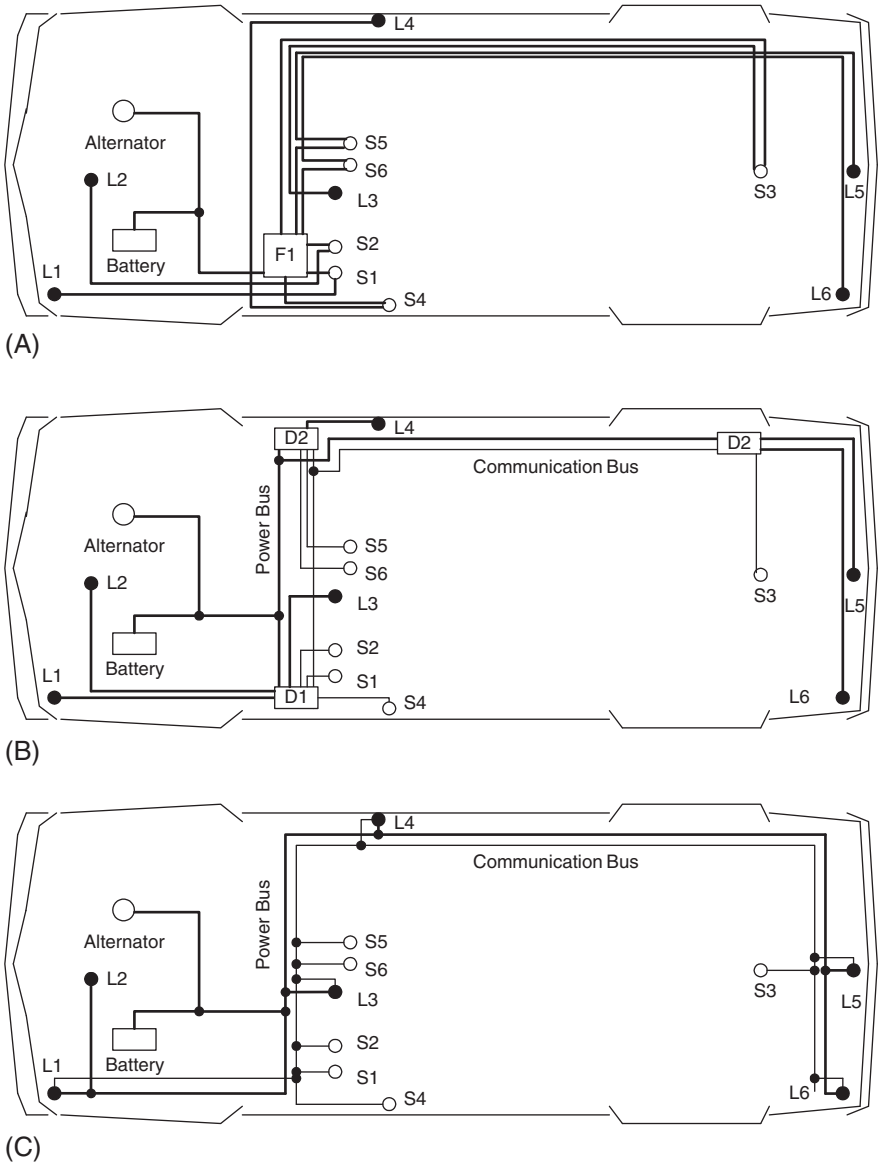

FIG. 32.10 Alternative control strategies illustrated for a simple automotive electric system with six loads (L1-6) and six primary switches (S1-6): (A) conventional direct switching architecture with a single fuse box (F1); (B) multiplexed remote switching architecture, with remote switches and transceivers in three distribution boxes (D1-3); and (C) multiplexed point-of-load switching with electronics integrated into the loads and the primary switches.

into strategically located distribution boxes, as shown in Fig. 32.10B. A power and a communication bus connect the distribution boxes. Another possibility is to integrate the remote switches with the load, that is, point-of-load switching, as shown in Fig. 32.10C. In Fig. 32.10B, the transceivers are also built into the distribution boxes, while in Fig. 32.10C, each load and primary switch has an integrated transceiver. The point-of-load switching topology is attractive because of its simplicity but raises cost and fusing challenges.

Multiplexed remote switching architectures have been under consideration since at least the early 1970s, when Ziomek investigated their application to various electric subsystems [28]. The initial interest was dampened by cost and reliability concerns and the nonavailability of appropriate remote switches. However, advances in semiconductor technology and rapid growth in the automotive electric system revived interest in multiplexed architectures. The SAE Multiplexing Standards Committee has partitioned automotive communications into three classes: class A for low-data-rate (1–10 kbit/s) communication for the control of body functions, such as headlamps, windshield wipers, and power windows; class B for medium-data-rate (10–100 kbit/s) parametric data exchange; and class C for high-data-rate (1 Mbit/s) real-time communication between safety-critical functions, such as between ABS sensors and brake actuators [29]. Although load control is categorized as class A, the lack of any widely accepted class A communication protocols has led to the application of class B and class C communication IC's to load control. Class B has

received the most attention due to the California Air Resources Board mandated requirement for onboard diagnostics (OBD II), and a large number of competing protocols, including the French vehicle area network (VAN), the ISO 9141, and the SAE J1850, have been developed [30]. Of these, the SAE J1850 is the most popular in the United States. Another popular protocol is the controller area network (CAN) developed by Bosch [31]. Although designed for class C with bit rates up to 1 Mbit/s, it is being applied for class A and class B applications due to the availability of inexpensive CAN ICs from a large number of semiconductor manufacturers.

Remote switching systems require remote power switches. An ideal remote switch must have a low on-state voltage, be easy to drive from a microcontroller, and incorporate current sensing. A low on-state voltage helps minimize the heat sinking requirements, while current sensing is needed for the circuit protection function to be incorporated into the switch. To withstand the harsh automotive environment, the switch must also be rugged. Furthermore, if PWM control is required for the load, the switch must have short turn-on and turnoff times and a high cycle life. The traditional means of remotely switching loads in an automobile is via electromechanical relays. Although relays offer the lowest voltage drop per unit cost, they require large drive current, are relatively large, are difficult to integrate with logic, and are not suitable for PWM applications [32–34]. Therefore, their use will be limited to very-high-current, non-PWM applications. The power levels of the individual loads in the automobile are too low for IGBTs and MCTs to be competitive. Bipolar transistors are also not very attractive because they are harder to drive than a MOS-gated device. Because of its fast switching speed, low voltage drop, relative immunity to thermal runaway, low drive requirements, and ease of integration with logic, the power MOSFET is the most attractive candidate for remote switching. Smart-power MOSFET devices with integrated logic interface and circuit protection have recently become available. Use of these devices for power electronic control of individual loads has become economically competitive in some subsystems and may be expected to become more so with the advent of higher-voltage electric systems.

The benefits of remote switching electric distribution systems have been demonstrated by Furuichi et al. [35]. The multiplexed architecture they implemented had 10 remote units (two power units with fuses, power drivers and signal inputs, five load control units with power drivers and signal inputs but no fuses, and three signal input units with only signal inputs). To increase system reliability, each power unit was connected to the battery via independently fused power cables. Although wiring cost decreased, the authors report an increase in overall system cost due to the additional cost of the remote units. Intel's CAN ICs with data rates of 20 kbit/s were used for the transmission and reception of control signals over an unshielded twisted-pair ring bus. Intelligent power MOSFETs were used as the remote switches, and fusing was done with minifuses. The results of their work are shown in Table 32.5.

TABLE 32.5 Comparison of a multiplexed and the conventional system, as reported by Furuichi et al. for a compact vehicle [35]

	Point-to-point	Multiplexed	Change (%)
Harness weight (kg)	14.0	9.8	−30
ECU weight (kg)	1.2	0.0	N/A
Remote unit weight (kg)	0.0	3.5	N/A
Total weight (kg)	15.2	13.3	−12.5
Number of wires	743	580	−21.9
Number of terminals	1195	915	−23.4
Number of splices	295	246	−16.6
Length of wire (m)	809	619	−23.5

In the multiplexed system, the function of nine electronic control units (ECUs) was integrated into the remote units.

Although weight of the wiring harness was reduced by 30%, the total system weight decreased by only 12.5% due to the added weight of the remote units.

32.6 Electromechanical Power Conversion

Power is generated in the automobile by an electric machine driven by the engine. In the early days of the automobile, the electric load was small, and a dc generator was used for this purpose. As the electric loads grew, the dc generator could not meet the growing demand of electric power and was displaced by a three-phase alternator and diode rectifier. Continuously increasing power and performance requirements are driving further evolution in automotive power generation and control and are motivating the introduction of power electronics and improved electric machines in automobiles. In addition to high-power alternators, future applications of electromechanical power conversion may include integrated starter/alternators and propulsion systems. This section describes some of the machine and power electronic technologies that are useful for meeting the increasing challenges in the automobile.

32.6.1 The Lundell Alternator

The Lundell or claw-pole alternator is a three-phase wound-field synchronous machine that is almost universally used for power generation in present-day vehicles [1]. As illustrated in Fig. 32.11, the rotor is made of a pair of stamped pole pieces (claw poles) fixed around a cylindrical field coil. The field winding is driven from the stator via a pair of slip rings and brushes and causes the two pole pieces to become opposing magnetic poles. A full-bridge diode rectifier is traditionally used at the machine output, and a fan mounted on the rotor is typically used to cool the whole assembly.

The dc output voltage of the alternator system is regulated by controlling the field current. A switching field regulator applies a pulse-width modulated voltage across the field. The

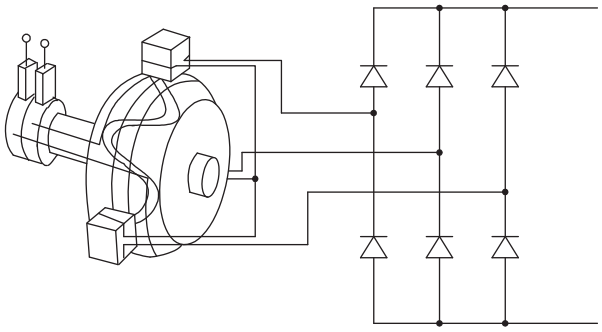

FIG. 32.11 Structure and circuitry of the conventional Lundell alternator.

steady-state field current is determined by the field-winding resistance and the average voltage applied by the regulator. Changes in the field current occur with an L/R field-winding time constant in the order of 100 ms or more. This long field-winding time constant and a large stator leakage reactance are the characteristic of this type of alternator and tend to dominate its performance.

The alternator is driven by means of a belt and is designed to operate over a wide speed ratio of about 10:1, though much of its operating lifetime is spent within a narrower 3:1 or 4:1 range. The gearing ratio provided by the belt is a design variable for the alternator; an alternator mechanical speed range from 1800 to 18,000 rpm for a 12-pole machine is typical.

A simple electric model for the Lundell alternator is shown in Fig. 32.12. The armature of the alternator is modeled as a Y-connected set of leakage inductances L_s and back voltages v_{sa}, v_{sb}, and v_{sc}. The fundamental electric frequency ω of the back emfs is one-half of the product of the number of machine poles p and the mechanical speed ω_m. The magnitude of the back emfs is proportional to the electric frequency and the field current. For the sinusoidal case, the line-to-neutral voltage back-emf magnitude can be calculated as

$$V_s = k\omega i_f \tag{32.1}$$

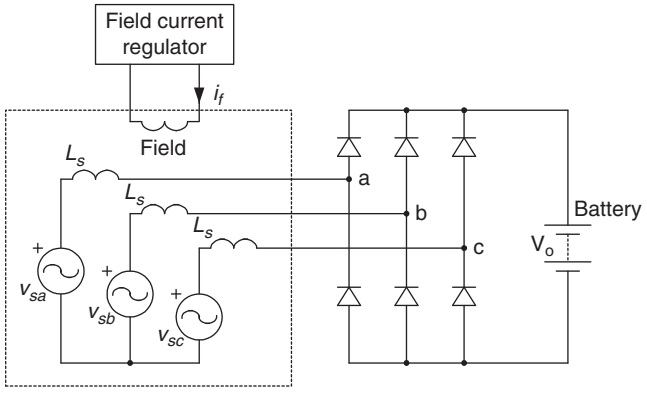

FIG. 32.12 A simple Lundell alternator model.

where k is the machine constant and i_f is the field current. The diode bridge feeds a constant voltage V_o representing the battery and other loads. This simple model captures many of the important characteristics of the Lundell alternator while remaining analytically tractable. Other effects, such as stator resistance, mutual coupling, magnetic saturation, and waveform harmonic content, can be incorporated into this model at the expense of simplicity. The constant-voltage battery load on the alternator makes the analysis of this system different from the classic case of a diode rectifier with a current-source load. Nevertheless, with reasonable approximations, the behavior of this system can be described analytically [8]. Using the results presented in Ref. [8], alternator output power versus operating point can be calculated as

$$P_o = \frac{3V_o\sqrt{V_s^2 - \left(4V_o^2/\pi^2\right)}}{\pi\omega L_s} \tag{32.2}$$

where V_o is the output voltage, V_s is the back-emf magnitude, ω is the electric frequency, and L_s is the armature leakage inductance. Extensions of Eq. (32.2) that also include the effect of the stator resistance are given in Ref. [8].

As can be inferred from Eq. (32.2), alternator output power varies with speed and is maximized when the back-emf magnitude of the machine is substantially larger than the output voltage. In a typical Lundell alternator, back voltages in excess of 80 V may be necessary to source-rated current into a 14 V output at high speed. Furthermore, as can be seen from Eq. (32.2), the armature leakage reactance limits the output power capability of the alternator. These characteristics are a result of the fact that significant voltage drops occur across the leakage reactances when current is drawn from the machine. These drops increase with speed and current and cause the alternator to exhibit significant drop in output voltage with increasing current. Thus, an appropriate dc-side model for a Lundell alternator is a large open-circuit voltage (related to the back-emf magnitude) in series with a large current- and speed-dependent output impedance. This characteristic, coupled with the long field time constant, is the source of the undesirable load-dump transient characteristic of the Lundell alternator. In this transient, the large open-circuit voltage is transiently impressed across the alternator output when the load is suddenly reduced.

The efficiency of the conventional Lundell alternator is relatively poor. Typical efficiency values are in the order of 40%–60%, depending on the operating point [1,36,37]. At low and medium speeds, losses tend to be dominated by stator copper losses. Iron losses become dominant only at very high speeds [1].

32.6.2 Advanced Lundell Alternator Design Techniques

The conventional diode-rectified Lundell alternator, though inefficient, has so far met vehicle electric power requirements

in a cost-effective manner. However, continuing increase in electric power demand and growing interest in improved fuel economy is pushing the limits of conventional Lundell alternator technology. This section describes some established and emerging technologies that can be used to improve the performance of the Lundell alternator.

32.6.2.1 Third-harmonic Booster Diodes

One widely used approach for improving the high-speed output power capability of Lundell alternators is the introduction of third-harmonic booster diodes [1]. In this technique, the neutral point of the Y-connected stator winding is coupled to the output via a fourth diode leg, as illustrated in Fig. 32.13. While the fundamental components of the line-to-neutral back voltages are displaced by 120 degrees in phase, any third-harmonic components will be exactly in phase. As a result, third-harmonic energy can be drawn from the alternator and transferred to the output by inducing and rectifying common-mode third-harmonic currents through the three windings. The booster diodes provide a means for achieving this. At high speed, the combination of the third-harmonic voltages at the main rectifier bridge (at nodes a, b, and c in Fig. 32.13), combined with the third harmonic of the back voltages, is large enough to forward bias the booster diodes and deliver third-harmonic energy to the output. In systems with significant (e.g., 10%) third-harmonic voltage content, up to 10% additional output power can be delivered at high speed. Additional power is not achieved at low speed or in cases where the third harmonic of the back voltage is small.

32.6.2.2 Lundell Alternator With Permanent Magnets

The structure of the rotor of the claw-pole alternator is such that the leakage flux is high. This reduces the output current capability of the alternator. The leakage flux can be reduced by placing permanent magnets on the pole faces or in the spaces between the adjacent poles of the rotor. This modification allows the alternator to deliver more output current. Placing the magnets in the spaces between adjacent poles is a better approach because it is simpler to implement and leads to a higher output current at engine idle [38].

32.6.2.3 Twin-rotor Lundell Alternator

The maximum power capability of the Lundell alternator is limited in part by the limit on its length-to-diameter ratio imposed by mechanical stresses on the stamped pole pieces. This prevents the Lundell alternator from being arbitrarily scaled up in size. The power capability of conventional designs is probably limited to 3 kW, which is likely to be unacceptable in the foreseeable future [39]. One way to retain the cost-effectiveness of the claw-pole alternator while achieving higher output power is to place two claw-pole rotors back-to-back on a common shaft inside a common stator [40]. This effectively increases the length of the claw-pole alternator without changing its diameter. This design allows higher power alternators to be built while retaining most of the cost benefits of the claw-pole design.

32.6.2.4 Power Electronic Control

Another approach for improving the output power and efficiency of the Lundell alternator is through the use of more sophisticated power electronics. Power electronics technology offers tremendous value in this application. For example, replacing the conventional diode rectifier with a switched-mode rectifier provides an additional degree of design and control freedom and allows substantially higher levels of power and efficiency to be attained from a given machine. One such design is shown in Fig. 32.14. It employs a simple switched-mode rectifier along with a special load-matching control technique to achieve dramatic improvement in alternator output power, efficiency, and transient performance [37]. The switched-mode rectifier provides improved control without the cost and complexity of a full active converter bridge. By controlling the duty ratio of the switched-mode rectifier based on available signals such as alternator speed, the alternator output power characteristic Eq. (32.2) can be altered and improved, particularly for speeds above idle [37]. Improvements in average power capability of a factor of two and average efficiency improvements

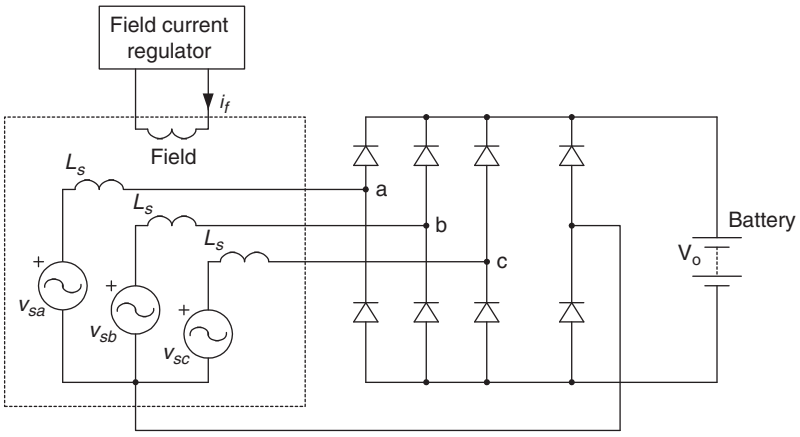

FIG. 32.13 Lundell alternator with booster diodes.

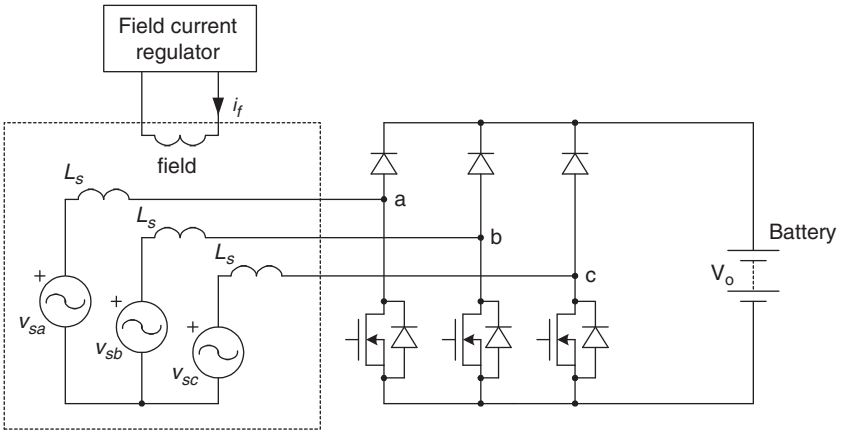

FIG. 32.14 Lundell alternator with a switched-mode rectifier.

on the order of 20% are possible with this technology. Furthermore, the switched-mode rectifier can be employed to achieve greatly improved load-dump transient control.

32.6.3 Alternative Machines and Power Electronics

The demand for increased alternator power levels, efficiency, and performance also motivates the consideration of alternative electric machines, power electronics, and design approaches. While no alternative machine has yet displaced the Lundell alternator in production vehicles, primarily due to cost considerations, some potential candidates are reviewed in this section. These include machines that are mounted directly on the engine rather than driven from a belt. These direct-driven machines become important as power levels rise. This section also addresses the more general case of the combined starter/alternators. While the use of a single machine to do both starting and generation functions is clearly possible, a separate (transient-rated) dc machine is presently used for starting. This is because the large mismatch in starting and generating requirements has made the combined starter/alternator approach unattractive. However, as alternator power ratings increase, the mismatch is reduced, and a single starter/alternator system becomes more practical. A combined system has the potential to eliminate the need for a separate flywheel, starter, solenoid switch, and pinion-engaging drive. It also has the potential to allow regenerative braking and "light hybrid" operation and to provide idle-stop capability (i.e., the ability to turn off the engine when the vehicle is stopped and seamlessly restart when the vehicle needs to move) for reduced fuel consumption. A move to this more sophisticated approach relies upon advanced electric machines and power electronics.

32.6.3.1 Synchronous Machine with a Cylindrical Wound Rotor

The claw-pole rotor can be replaced with a cylindrical rotor to achieve better coupling between the stator and rotor. The cylindrical rotor is made from steel laminations, and the field winding is placed in the rotor slots. The cylindrical rotor is similar to the armature of a dc machine except that the connection of the field winding to the external circuit is made through slip rings instead of a commutator. The cylindrical rotor structure leads to quiet operation and increased output power and efficiency. Unlike the claw-pole alternator, the length of the machine can be increased to get higher output power at a higher efficiency. The efficiency is higher since the effect of the end windings on the machine performance is less in a machine with a long length. It is also possible to build the machine with a salient-pole rotor instead of a cylindrical rotor. However, a machine with a salient-pole rotor is likely to produce more noise than a machine with a cylindrical rotor.

A machine with a cylindrical wound rotor has similar power electronics and control options as a claw-pole machine. If generation-only operation is required, a diode bridge and field current control is sufficient to regulate the output voltage. Better performance can be achieved by using a switched-mode rectifier in conjunction with field control [37]. If motoring operation is desired (e.g., for starting) or even better performance is desired, a full-bridge (active-switch) converter can be used, as shown in Fig. 32.15. Since this is a synchronous machine, some form of rotor position sensing or estimation is typically necessary. The full-bridge converter allows maximum performance and flexibility but carries a significant cost penalty.

32.6.3.2 Induction Machine

The stator of a three-phase induction machine is similar to that of a three-phase synchronous machine. The rotor is either a squirrel-cage or wound rotor. The machine with the squirrel-cage rotor is simpler in construction and more robust than the machine with a wound rotor in which the three-phase rotor winding is brought outside the rotor through slip rings. The rotor is cylindrical and is constructed from steel laminations. It is also possible to use a solid rotor instead of a laminated rotor. However, a solid rotor leads to higher losses as compared with a laminated rotor. The losses in a solid rotor can be

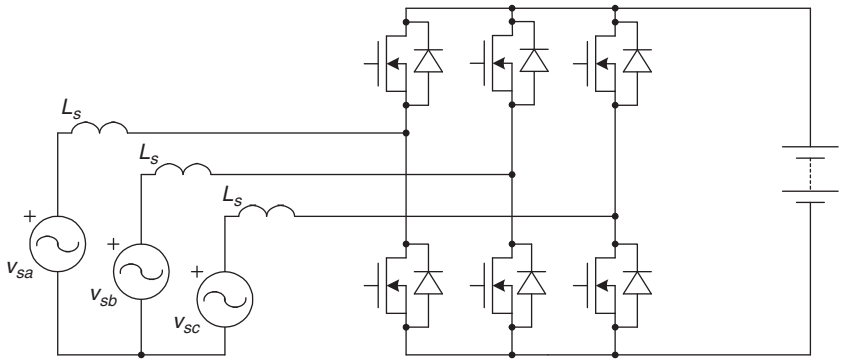

FIG. 32.15 Model of an alternator with full-bridge converter.

reduced by cutting slots in the rotor surface, filling the stator slot openings with magnetic wedges to reduce the field ripple, and placing a copper cage on the rotor.

An induction machine requires a source that can provide the leading reactive power to magnetize the air gap. This means that a three-phase induction generator cannot supply power to a load through a three-phase diode bridge. Capacitor supply of the reactive energy is impractical because of the wide operating speed range. In the most general case (in which both motoring and generating operation can be achieved), a three-phase active bridge can be used. If only generating operation is desired, the power to the load can be supplied through a three-phase diode bridge, and the reactive power can be obtained from a small three-phase active bridge provided for this purpose. This design requires a large number of devices and complex control.

32.6.3.3 Reluctance Machines

The switched reluctance machine is a doubly salient machine. Both the stator and rotor of the machine are made from steel laminations to reduce the iron losses. Only the stator carries windings; the rotor is constructed of steel laminations with a salient shape. The structure of a three-phase switched reluctance machine with six stator poles and four rotor poles is shown in Fig. 32.16A. A winding placed on diametrically opposite stator poles forms a phase winding. When a phase of the machine is excited, a pair of rotor poles tends to align with the excited stator poles to provide a path of minimum reluctance. If the rotor is moving toward alignment with the excited pair of stator poles, then the machine develops a positive torque and acts as a motor. If the rotor is moving away from the excited pair of stator poles, then the machine develops a negative torque and acts as a generator. The advantages of the switched reluctance machine include simple construction, fault-tolerant power electronic circuit, high reliability, unidirectional phase currents, and low cost. The drawbacks of the machine include high levels of torque ripple, vibration and acoustic noise, and a relatively high-power electronic cost.

The synchronous reluctance machine is a singly salient machine. The stator of the machine is similar to that of a synchronous or induction machine. The rotor has a segmented

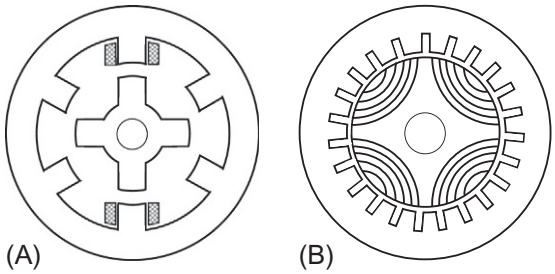

FIG. 32.16 Structures of (A) switched reluctance and (B) synchronous reluctance machines. AA′ represents phase-A winding.

structure with each segment consisting of a stack of axially laminated steel sheets sandwiched with a nonmagnetic material. The structure of a four-pole synchronous reluctance machine is shown in Fig. 32.16B. A synchronous reluctance machine has less torque ripple, lower losses, and higher power density than a comparable switched reluctance machine. Inclusion of permanent magnets in the rotor structure allows both reluctance and magnet torque to be achieved. Such interior permanent-magnet (IPM) machines can achieve very high performance and power density. When permanent magnets are included, however, careful attention must be paid to the effects of shutdown of the power electronics as an uncontrolled back-emf component will exist in this case [41].

The switched reluctance machine, like the induction machine, requires an external source to magnetize the air gap. Several circuits are available to excite the switched reluctance machine. A circuit that is suitable for the automotive application of this machine is shown in Fig. 32.17. A phase leg is needed for each stator phase of the machine. In this case, the switched reluctance machine obtains its excitation from the same bus that it generates into. Unlike the synchronous and induction machines in which the number of wires needed to connect the machines to the power converters is usually equal to the number of phases, the number of wires needed to connect the switched reluctance machine to a converter is equal to twice the number of phases. This is of no particular concern in a switched reluctance machine in which the power converter is integrated with the machine in the same housing. The

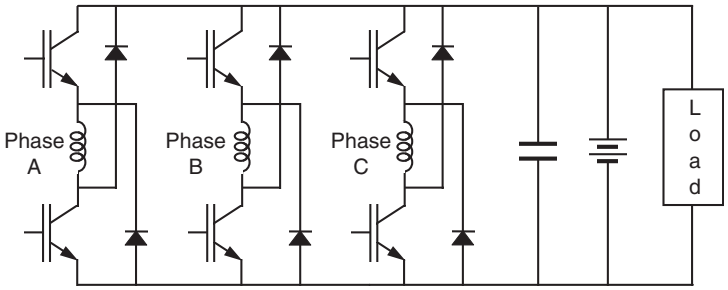

FIG. 32.17 Circuit for a switched reluctance machine.

synchronous reluctance machine also requires an external source to magnetize the air gap. The machine usually employs an active bridge similar to the one used with an induction machine for the desired power conversion. The machine can also employ the converters used with the switched reluctance machine. In this case, the currents through the stator windings are unidirectional. The relative complexity of the power electronics is a disadvantage of these machine types in the case where only generator operation is necessary.

32.6.3.4 Permanent Magnet and Hybrid Synchronous Machines

The permanent-magnet synchronous machine designed with high-energy rare-earth magnets operates with high efficiency, high power density, low rotor inertia, and low acoustic noise. The excitation from the permanent magnets is fixed, and therefore, the regulation of the output voltage of the machine is not as straightforward as in a synchronous machine with a wound rotor. For generator operation, machines of this type can use switched-mode rectifiers to regulate the output voltage [42,43]. The boost rectifier of Fig. 32.14 is one possible implementation of this approach. Alternatively, a diode rectifier followed by a dc/dc converter can be used to regulate the generator system output [44]. Another method proposed for this type of system involves the use of tapped windings and two three-phase SCR bridges [45]. The taps on the phase windings are connected to one bridge, while full-phase windings are connected to the other bridge. The bridge connected to the full-phase windings is used to supply power to the dc bus at low engine speeds, while the converter connected to the taps is used at high speed. The use of a tapped winding and dual bridges helps the system cope with the wide speed range of the alternator and limit the losses associated with the pulsating output currents. In the case when both motoring and generating modes are desired, a full-bridge converter can be used. Again, as this is a synchronous machine, some form of position sensing or estimation is necessary. Also, in all of these systems, the effects of failure of the power electronics must be carefully considered as there is no possibility of regulating the back voltages by field control.

Attempts to develop a simpler voltage regulation scheme for permanent-magnet synchronous machines have led to a permanent-magnet/wound-rotor hybrid synchronous machine in which the rotor consists of two parts, a part with permanent magnets and a part with a field winding [46]. The two parts are placed next to each other on a common shaft. The rotor with the field winding can employ claw-pole, salient-pole, or cylindrical structure. The field current generates a flux that is used to either aid or oppose the permanent-magnet flux and regulate the output voltage of the machine. One possible failure mode of this approach that can lead to catastrophic failure is if the field winding breaks while the machine is operating at high speed. In this case, the generated output voltage will become large and uncontrolled. Some means of mechanically disconnecting the alternator at the input or electrically disconnecting it at the output may be necessary to limit the impact of this failure mode.

32.6.3.5 Axial-airgap Machines

The principle of operation of an axial-air-gap or axial-flux machine is the same as that of a radial-air-gap machine. An axial-air-gap machine is characterized by a short axial length and large diameter. The structure of an axial-air-gap permanent-magnet machine with surface magnets is shown in Fig. 32.18 [47]. The stator of the machine can be slotless or slotted. Two different magnetic circuit configurations are possible. In the NN configuration, the magnetic polarities in one pole pitch on both sides of stator are the same so that there

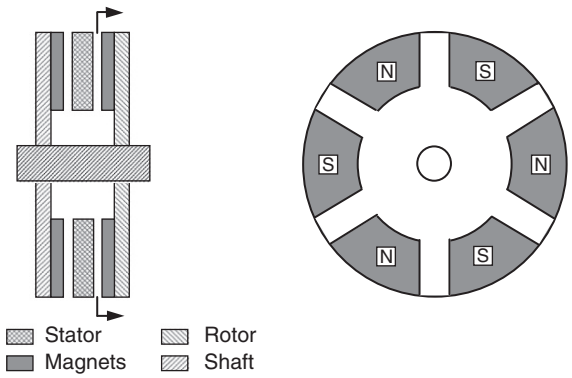

FIG. 32.18 Structure of an axial-air-gap permanent-magnet machine.

are two main fluxes with symmetrical distribution through the stator. In this case, the conductors can be wound into two back-to-back stator slots to make one coil. The machine has a large stator yoke dimension because the flux passes through the yoke but less copper loss because of short end windings. In the NS configuration, the magnetic polarities in one pole pitch on the opposite sides of stator are the opposite of each other so that there is only one main axial flux through the stator. In this case, the stator yoke dimension is small, but the end windings are long because the direction of current in the back-to-back stator slots is the same. The iron losses are small due to small yoke dimension, and the copper losses are high because of long end windings. Heat removal is more challenging due to small stator dimensions. The structure shown in Fig. 32.18 is that of an axial-air-gap permanent-magnet machine with surface magnets. In an axial-air-gap machine with interior permanent magnets, the magnets are embedded in the steel of the rotor.

The axial-air-gap versions of other types of machines, such as the induction and switched reluctance machines, are also possible. The structure of an axial-air-gap induction machine is similar to that of an axial-air-gap permanent-magnet machine except that windings are used instead of permanent magnets.

32.7 Dual/High Voltage Automotive Electrical Systems

The electric system of a 1920s internal-combustion-engine (ICE) automobile had only a few loads: a starter, an ignition device, a horn, and some lamps [48]. The mean power consumption of these loads was less than 100 W. An engine-driven dc generator charged a 6 V lead-acid battery that provided electric power. The power was distributed via point-to-point wiring, with most loads controlled directly by manually operated primary switches located within the reach of the driver. Only the starter was switched indirectly by an electromechanical relay. After the Second World War, the automotive electric system started to grow rapidly in complexity and power consumption as additional features, including radios, multispeed windshield wipers, and power windows, were added. The introduction of higher compression engines stretched the 6 V system beyond its technological limits. The 8.5:1 compression ratio engines required 100%–200% greater ignition voltages than the 6.4:1 engines. As a result, the primary-side current of the ignition coil was doubled or tripled, and the life of the distributor contacts was reduced to an unacceptable level. To overcome this problem, the battery voltage was increased to 12 V in the mid-1950s [49,50].

Over the past four decades, the electric power requirements of automobiles have increased even more rapidly. From a mere 400 W in 1955, the power rating of a luxury vehicle's generator has increased to over 1800 W [51,52]. However, the electric system of a modern automobile is architecturally identical to the 12 V point-to-point system of the 1950s. The only changes that have taken place have been at the component level, such as the replacement of the dc generator by a three-phase alternator-rectifier, the replacement of wound-field dc motors by permanent-magnet ones, and an increased use of relays. The rapid growth in the electric system is expected to continue due to environmental regulations; consumer demand for increased functionality, safety, security, and comfort; and replacement of some mechanical actuators by electric counterparts. The average electric power requirement of a modern luxury vehicle is about 800 W. With the addition of such loads as electric power steering, engine-cooling fan, water pump, and electromechanical engine valves, the average power requirement could increase to 2.5 kW by 2005 [53]. The traditional solution of increasing the size of the alternator and the battery is not practical due to space limitations and fuel efficiency requirements. Furthermore, the peak power requirements of some of the anticipated loads—heated windshield (2.5 kW), heated catalyst (3 kW), electromechanical engine valves (2.4 kW at 3000 rpm), and active suspension (12 kW)—cannot be met economically using the present architecture. These factors have motivated the development of new dual-/high-voltage electric architectures that incorporate a higher-voltage bus in addition to the standard 14 V bus [39,54–56]. A dual-/high-voltage approach allows an efficient supply of power to many loads that benefit from operating at a higher voltage while retaining the 14 V bus for loads (such as lamps and electronics) that do not benefit from a higher voltage. High-voltage architectures that do not retain the 14 V bus are also possible but will require a substantial investment in the design and production of new high-voltage components. This section describes some of the characteristics and preliminary specifications of the new dual-/high-voltage electric system architectures. It also discusses some of the widely considered implementation approaches.

32.7.1 Trends Driving System Evolution

The conventional 12 V automotive electric power system has many defects, including a widely varying steady-state system voltage and large transients, which force the electric functions to be overdesigned. However, these limitations alone have not been a strong enough driver for automotive companies to seriously evaluate advanced alternatives. Now, a number of new factors are changing this situation. The most important of these are future load requirements that cannot be met by the present 12 V architecture.

32.7.1.1 Future Load Requirements

Table 32.6 gives a list of electric loads expected to be introduced into automobiles in the next 10 years [53]. Some of these loads (electrohydraulic power steering, electric engine fan, electric water pump, and electromechanical valves) will replace existing

TABLE 32.6 Electric loads expected to be introduced into automobiles in the next decade [53]

Load	Peak power (W)	Average power (W)
Exhaust air pump	300	10
Electrohydraulic power steering	1000	150
Electric engine fan	800	150
Heated catalytic converter	3000	90

Active suspension	12,000	360
Total		1830

mechanically or hydraulically driven loads. The remaining are new loads introduced to either meet government mandates or satisfy customer needs.

The average electric power requirement of a present-day automobile is in the range of 500–900 W depending on whether it is an entry-level or a luxury vehicle. When the loads of Table 32.6 are introduced, the average electric power requirement will increase by 1.8 kW. Furthermore, if the air-conditioning (A/C) pump was to ever become electrically driven, the peak and average power demands would increase by an additional 3.5 and 1.5 kW, respectively. Distributing such high power at a relatively low voltage will result in unacceptably bulky wiring harnesses and large distribution losses. Since the alternator has to generate both the power consumed by the loads and the power dissipated in the distribution network, its output rating (and hence size and power consumption) will be greater than in an architecture with lower distribution losses. With the large premium attached to the size of the alternator (due to space constraints in the engine compartment), an architectural change in the distribution and generation systems is essential before many of the future loads can be introduced.

There is also an increasing disparity in the voltage requirements of future electric loads. High-pulse-power loads, such as the heated windshield and electrically heated catalytic converter, become feasible only at voltages greater than the current 14 V [57]. On the other hand, incandescent lamps and electronic control units (ECUs) will continue to require low voltages. For example, present-day ECUs have linear regulators that convert the 14 V distribution voltage to the 5 V needed by the integrated circuits. The efficiency of these regulators is equal to the ratio of output to input voltage, that is, 35%. Furthermore, the next generation of higher speed lower power consumption integrated circuits operates at 3.3 V, making the regulators more inefficient. This inefficiency also means that larger heat sinks are required to remove the heat from the ECUs.

32.7.1.2 Higher Fuel Efficiency

A secondary motivating factor for the introduction of a higher system voltage is the challenge of achieving higher fuel economy. The average fuel economy of present-day automobiles in the United States is in the vicinity of 30 mpg. There is little market incentive for automobile manufacturers to increase the fuel economy of vehicles for the US market where the price of fuel is relatively low. The price of gasoline in the United States ($1.70 per gallon) is less than the price of bottled water ($4.00 per gallon when bought by the quart). Although market forces have not been a driver for the development of fuel-efficient vehicles, a number of new incentives have emerged over the past few years. One of these is the fine imposed on the automakers by the US government if the average fuel economy of their fleet falls below the mandated standard. The mandated standard for cars has increased from 24 mpg in 1982 to its 1997 level of 27.5 mpg and will continue to increase. In Europe, the German Automotive Industry Association (VDA) plans to increase the average fleet fuel efficiency to 39.9 mpg by 2005—compared with 31.4 mpg in 1990 [58].

Another driver behind the development of fuel-efficient vehicles is the partnership for a new generation of vehicles (PNGV). This 10-year research program, launched in September 1993, is a collaboration between the US Federal Government and the big three US automakers (General Motors, Ford, and DaimlerChrysler) that aims to strengthen national competitiveness in the automotive industry and reduce dependence on foreign oil. The PNGV has set a goal to develop an 80 mpg midsize vehicle by 2004 [59]. The German Automotive Industry Association is pursuing similar targets. The VDA has undertaken a pledge to introduce a 3 L/100 km (78 mpg) vehicle by the year 2000. This is complemented by the introduction of highly fuel-efficient vehicles (in excess of 50 mpg) in both the Japanese and American markets.

With the present alternator, 800 W of electric power consumes 1.33 L of gasoline for every 100 km driven when the vehicle has an average speed of 33.7 km/h. This represents a 45% increase in fuel consumption for a 3 L/100 km vehicle. Hence, if future high-fuel-economy vehicles are going to have comfort, convenience, and safety features comparable with present-day vehicles, the efficiency of the electric generation and distribution system will have to be substantially improved. Furthermore, as discussed in Section 32.8, one widely considered means of achieving high fuel economy is the use of a hybrid vehicle architecture. In practice, this approach necessitates the introduction of a higher voltage in the vehicle.

32.7.2 Voltage Specifications

A major issue when implementing a high- or dual-voltage system is the nominal voltage of the high-voltage bus and the

TABLE 32.7 Voltage limits for 14 and 42 V buses proposed in Ref. [56]

Voltage	Description	Value
$V_{42,OV-dyn}$	Maximum dynamic overvoltage on 42 V bus during fault conditions	55 V
$V_{42,OV-stat}$	Maximum static overvoltage on 42 V bus	52 V
$V_{42,E-max}$	Maximum operating voltage of 42 V bus while engine is running	43 V
$V_{42,E-nom}$	Nominal operating voltage of 42 V bus while engine is running	41.4 V
$V_{42,E-min}$	Minimum operating voltage of 42 V bus while engine is running	33 V
$V_{42,OP-min}$	Minimum operating voltage on the 42 V bus. Also, lower-limit operating voltage for all noncritical loads (i.e., loads not required for starting and safety)	33 V
$V_{42,FS}$	Fail-safe minimum voltage—lower limit on operating voltage for all loads critical to starting and safety on the 42 V bus	25 V
$V_{14,OV-dyn}$	Maximum dynamic overvoltage on 14 V bus during fault conditions	20 V
$V_{14,OV-stat}$	Maximum static overvoltage on 14 V bus	16 V
$V_{14,E-max}$	Maximum operating voltage of 14 V bus while engine is running	14.3 V
$V_{14,E-nom}$	Nominal operating voltage of 14 V bus while engine is running	13.8 V
$V_{14,E-min}$	Minimum operating voltage of 14 V bus while engine is running	12 V
$V_{14,OP-min}$	Minimum operating voltage of 14 V bus. Also lower-limit operating voltage for all noncritical loads	11 V
$V_{14,FS}$	Fail-safe minimum voltage—lower limit on operating voltage for all critical loads on the 14 V bus	9 V

operating limits of both buses. While there are many possibilities, there is a growing consensus in the automotive industry for a nominal voltage of 42 V for the high-voltage bus (corresponding to a 36 V lead-acid storage battery) [39,56,60]. This voltage is gaining acceptance because it is as high as possible while remaining within acceptable safety limits for open wiring systems (once headroom is added for transients) and it provides substantial benefits in the power semiconductors and wiring harness [61]. Furthermore, this voltage is sufficient to implement starter/alternator systems and "light" hybrid vehicle designs [62,63]. While no vehicles equipped at 42 V are in production at present, availability of 42 V components is rapidly increasing, and 42 V equipped vehicles may be expected early in this decade.

The permissible static and transient voltage ranges in an electric system are important design considerations for power electronic equipment. At present, no universally accepted specification exists for high- or dual-voltage automotive electric systems. However, the preliminary specifications proposed by the European automotive working group, *Forum Bordnetz*, are under wide consideration by the automotive industry [56]. These specifications, summarized in Table 32.7, impose tight static and transient limits on both the 42 and 14 V buses. The upper voltage limit on the 14 V bus is far lower than in the conventional 12 V system. The allowed upper limit on the 42 V bus is also proportionally tight. These strict limits facilitate the use of power semiconductor devices such as power MOSFETs and lower the cost of the protection circuitry needed in individual functions. However, they also require much more sophisticated means for limiting transients (such as load dump) than is found in conventional systems, which imposes a significant cost. Appropriate voltage range specifications for dual-/high-voltage electric systems are thus a subject of ongoing investigation by vehicle manufacturers and will likely continue to evolve for some time.

32.7.3 Dual-Voltage Architectures

Conventional automotive electric systems have a single alternator and battery. Dual-voltage electric systems have two voltage buses and typically two batteries. Single-battery configurations are possible but tend to be less cost-effective [61]. A variety of different methods for generating and supplying energy to the two buses are under investigation in the automotive community. Many of these have power electronic circuits at their core. This section describes three dual-voltage electric system architectures that have received broad attention. In all three cases, the loads are assumed to be partitioned between the two buses with the starter and many of the other high-power loads on the 42 V bus and most of the lamps and electronics on the 14 V bus.

The dc/dc converter-based implementation of Fig. 32.19 is perhaps the most widely considered dual-voltage architecture. In this implementation, an alternator and associated battery provide energy to one bus (typically the 42 V bus), while the other bus is supplied via a dc/dc converter. If a battery is used at the dc/dc converter output, the converter needs to be rated for slightly above average power. Otherwise, the converter needs to be rated a factor of two to three higher to meet peak power requirements [61]. The architecture of Fig. 32.19 has a

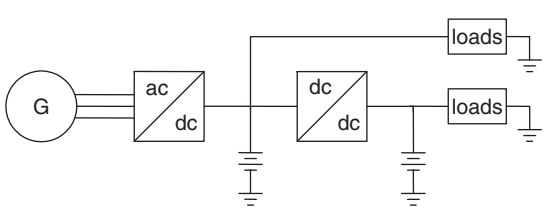

FIG. 32.19 Dual-voltage architecture based on a dc/dc converter.

number of advantages. The dc/dc converter provides high-bandwidth control of energy flow between the two buses, thus enabling better transient control on the 14 V bus than is available in present-day systems or in most other dual-voltage architectures. Furthermore, in systems with batteries on both buses, the dc/dc converter can be used to implement an energy management system so that generated energy is always put to best use. If the converter is bidirectional, it can even be used to recharge the high-voltage (starter) battery from the low-voltage battery, thus providing a *self-jump-start* capability. The major challenge presented by this architecture is the implementation of dc/dc converters having the proper functionality within the tight cost constraints dictated by the automotive industry. Some aspects of design and optimization of converters for this application are addressed in Ref. [64].

The dual-stator alternator architecture of Fig. 32.20 is also often considered for dual-voltage automotive electric systems [65,66]. In this case, an alternator with two armature windings is used along with two rectifiers to provide energy to the buses and their respective batteries. Control of the bus voltages is achieved via a combination of controlled rectification and field control. Typically, field control is used to regulate one output, while the other output is regulated using a controlled rectifier. Fig. 32.21 shows one possible implementation of this architecture. It should be noted that to achieve sufficient output power and power steering from the dual-wound alternator, the winding ratio between the two outputs must be carefully selected. For 42/14 V systems, a winding ratio of 2.5:1 is typical [66]. Advantages of this electric architecture include low cost. However, it does not provide the bidirectional energy control that is possible in the dc/dc converter architecture. Furthermore, there are substantial issues of cross regulation and transient control with this architecture that remain to be fully explored.

In a third architecture, a single-output alternator with a dual-output rectifier is employed. This approach is shown schematically in Fig. 32.22. As with the dual-stator alternator configuration, this architecture has the potential for low cost. One widely considered implementation of the dual-rectified alternator is shown in Fig. 32.23 [65,67–69]. Despite its simplicity, this implementation approach provides less functionality than the dc/dc converter-based architecture, generates substantial low-frequency ripple that must be filtered, and has serious output power and control limitations [66]. An alternative implementation, proposed in Ref. [37] and shown in Fig. 32.24, seems to overcome these limitations and may potentially provide the same capabilities as the dc/dc converter-based architecture at lower cost. Clearly, this architecture has promise for dual-voltage electric systems but remains to be fully explored.

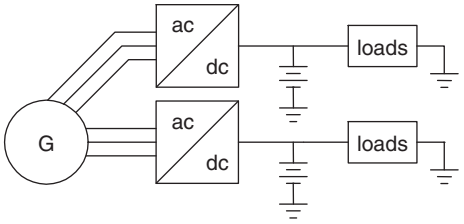

FIG. 32.20 Dual-voltage architecture based on a dual-wound alternator.

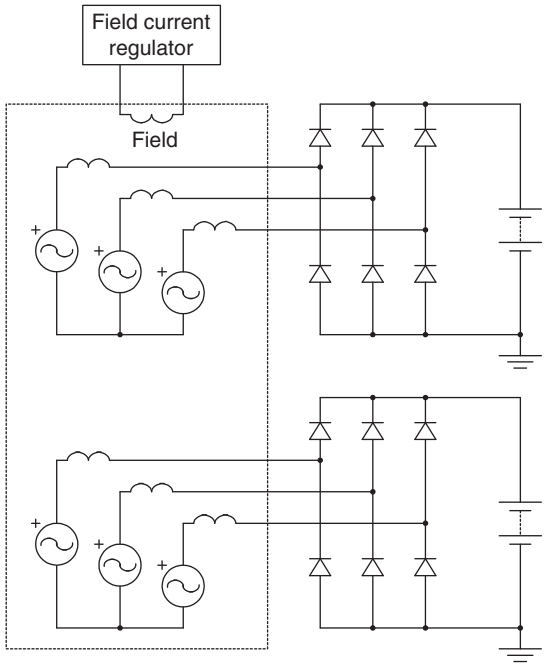

FIG. 32.21 Model for a dual-wound alternator system. The two output voltages are regulated through field control and phase control. For a 42/14 V system, a winding ratio between the two stator windings of 2.5:1 is typical.

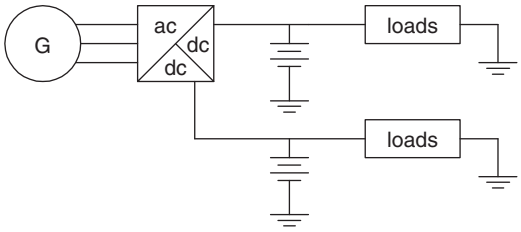

FIG. 32.22 Dual-voltage architecture based on a dual-rectified alternator.

32.8 Electric and Hybrid Electric Vehicles

Battery-powered electric vehicles were first introduced over 100 years ago and continue to incite great public interest because they do not generate tailpipe emissions. Nevertheless, the low-energy-storage density and the high cost of suitable

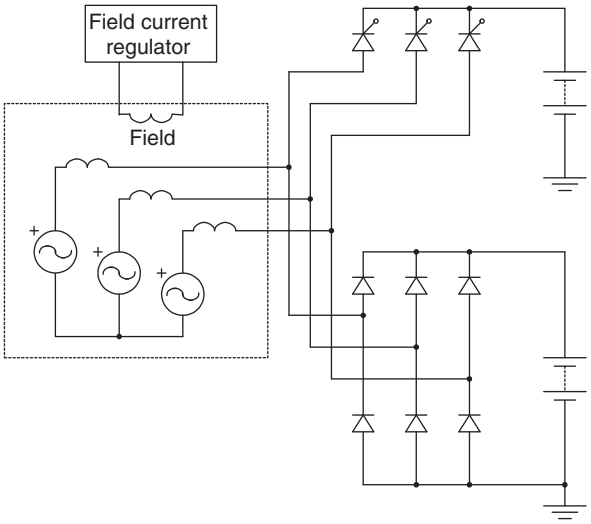

FIG. 32.23 A dual-rectified alternator with a phase-controlled rectifier.

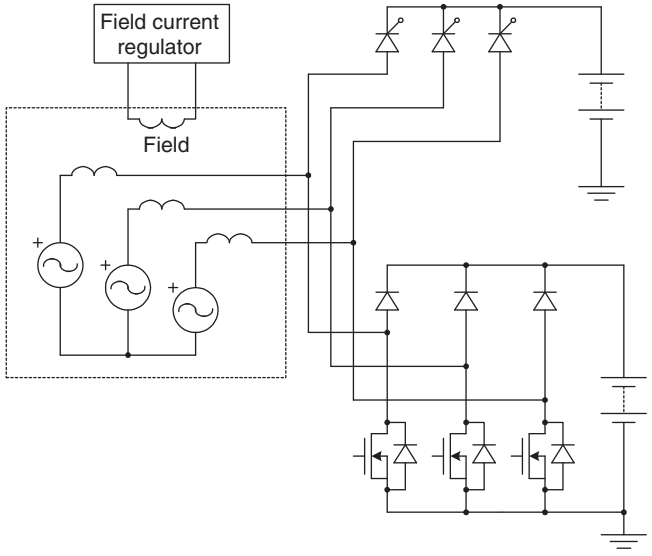

FIG. 32.24 A dual-rectified alternator with a switched-mode rectifier.

batteries make pure electric vehicles noncompetitive with internal-combustion-engine vehicles in most applications. An alternative approach that is generating widespread attention is HEV. An HEV combines electric propulsion with another energy source, such as an internal combustion engine, allowing the traditional range and performance limitations of pure electric vehicles to be overcome [70]. Alternative energy sources, such as fuel cells, are also possible in place of an internal combustion engine.

HEVs can be classified as having either a parallel or series driveline configuration [71]. In a series HEV, all of the propulsion force is produced from electricity; the engine is only used to drive a generator to produce electricity. In a parallel hybrid, propulsive force can come from either the engine or the electric drive. In both cases, batteries or other electric storage devices are used to buffer the instantaneous difference between the power needed for propulsion and that generated by the engine. The selection of a series or parallel driveline depends heavily on the performance requirements and mission of the vehicle.

In a series HEV, all power delivered to the wheels of the vehicle must be delivered through the electric driveline. The electric driveline components, including the batteries, power electronics, and machine(s), must all be rated for the *peak* traction power requirements, making these components relatively large and expensive if performance (e.g., acceleration) comparable with a conventional vehicle is to be achieved. To achieve the required power levels, the electric driveline must operate at hundreds of volts, necessitating the electric subsystem to be sealed from access by the user. The engine, on the other hand, needs only be rated to deliver the *average* power required by the vehicle, which is much lower. In a system that does not require utility recharge of the batteries (i.e., can drive indefinitely on fuel alone), the engine size is set by the power requirements of the vehicle at maximum cruising speed. If utility recharge of the batteries and a battery-limited driving range is acceptable, engine power requirements can be reduced even further. Because the engine does not provide tractive power, it can be designed to run at a single optimized condition, thus maximizing engine efficiency and minimizing emissions. Furthermore, the need for a transmission is eliminated, and there is a great deal of flexibility in the engine placement.

In a parallel HEV, traction power is split between the engine and the electric driveline. One possible approach is to utilize a single machine mounted on the engine crankshaft to provide starting capability along with electric traction power and regeneration [72–75]. This approach can be replaced or complemented with other approaches, such as using of a power-splitting device such as a planetary gear set [70,76] or using different propulsion and generation techniques on different sets of wheels [71,77,78]. In all parallel hybrid approaches, some form of transmission is needed to limit the required speed range of the engine. A wide range of divisions between engine size and electric system size is possible in the parallel hybrid case, depending on structure. Depending on this split, the necessary electric driveline system voltage may be as low as 42 V (which is safe for an open wiring system) or as high as 300 V. Also because the electric subsystem, the internal-combustion-engine subsystem, or both may provide tractive power under different conditions, there exist a wide range of possible operating approaches for a parallel hybrid system. Consequently, the control strategy for a parallel hybrid tends to be substantially more complex than for a series hybrid.

One parallel hybrid approach that is receiving a lot of attention for near-term vehicles is a “light” or “mild” hybrid. In this case, a somewhat conventional vehicle driveline is complemented with a relatively small starter/alternator machine mounted on the crankshaft [62,63,72–75,79]. The electric drive power is

typically below 10 kW average and 20 kW peak. The starter/alternator can be used to provide rapid, clean restart of the vehicle so that the engine can be turned off at idling conditions and seamlessly restarted. This so-called stop-and-go operation of the engine is valuable for fuel economy and emissions. The starter/alternator can also be used to implement regenerative braking, to provide engine torque smoothing (replacing the flywheel and allowing different engine configurations to be used) and to provide boost power for short-term acceleration. At the low-power end, such systems can be integrated directly into the open wiring configuration of a 42 V electric system, simplifying the vehicle electric architecture. System-level control remains a major challenge in realizing the full benefits of such systems. Starter-/alternator-based hybrids are expected to be a significant near-term application of power electronics and machines in automobiles.

The increasing electric and electronic content of automobiles is beginning to stretch the capabilities of the conventional 12 V electric system. Furthermore, there is a desire on the part of vehicle manufacturers to introduce new high-power loads, such as electromechanical engine valves, active suspension, and integrated starter/alternator. These are not likely to be practical within the present 12 V framework. These challenges are forcing the automotive industry to seriously consider high- and dual-voltage electric systems. The ongoing developments in this area were reviewed in Section 32.7

The increasing electric content of vehicles both underscores the need for power electronics and reflects the benefits of their introduction. It is safe to say that power electronics will continue to play an important role in the evolution of automobiles far into the future.

32.9 Summary

Power electronics is playing an increasingly important role in automobiles. It is being used to enhance the output power capability and efficiency of the electric power generation components. Power electronics is also an enabling technology for a wide range of new and improved functions that enhance vehicle performance, safety, and functionality.

The design of automotive power electronic systems is strongly influenced by the challenging electric and environmental conditions found in automobiles. Important factors include the static and transient voltage ranges, electromagnetic interference and compatibility requirements, and temperature and other environmental conditions. Some of the most important design considerations for automotive power electronics were addressed in Section 32.3.

Section 32.4 described some of the vehicle functions that benefit from or are enabled by power electronics. These functions range from lighting to actuation and steering. Power electronic switches also play a central role in multiplexed electric distribution systems. This role of power electronics was addressed in Section 32.5.

The rapid increase in electric power demand in automobiles is motivating the introduction of new technologies for electric power generation and control. Lundell alternators are presently used for power generation in automobiles but are rapidly reaching their power limits. Section 32.6 reviewed the operating characteristics of the Lundell alternator. It also described several techniques for extending the power capabilities of this machine. Meeting the growing demand for electric power, alternative machine, and power electronic configurations may be necessary in the future. A number of candidate machine and power circuit configurations were reviewed in Section 32.6. Such configurations can also be applied toward the design of integrated starter/alternators and hybrid propulsion systems, as was discussed in Section 32.8.

33.1 Introduction

Recently, energy-related concerns have been increasing in terms of many subtopics such as environmental sustainability, population growth, energy independence, energy security, and political imbalance between developed/developing countries. Among these hot topics, environmental sustainability is a major issue as the conventional fossil-fuel-consumption-based energy production results in significant increase in the global greenhouse gas (GHG) emissions, which in turn may cause global warming [1,2]. Many developed/developing countries have set future targets for reduction in GHG emissions for meeting the targets provided by Kyoto Protocol, Paris Climate Conference (COP21, in Dec. 2015), and European Union 2020 perspective. Thus, due to the existing drawbacks of conventional energy sources, utilization has led to the development of new, cleaner energy-based technologies in different areas, such as transportation and power generation. Among these application areas, special emphasis has been given on the development of a new generation of environment-friendly vehicular systems because of their potential to offer reduced emissions in the transportation sector and to reduce the dependence of many countries on imported fuel [3,4]. The automotive industry is one of the largest global industries, and there are around 1 billion vehicles in use. This sector generates a value of more than $3 trillion per year while enabling the employment of nearly 10 million people [5]. In this regard, the transportation sector plays a crucial and growing role in the world energy use, and it is responsible for approximately 15%–20% of overall GHG emissions [1,5]. The abovementioned factors generated renewed interest in the development of alternative vehicle technologies.

In particular, the efforts for technological improvements and innovation in transport and various electrically driven vehicles (EDVs) have been developed by important vehicular system manufacturers around the world supported by public authorities, nonprofit organizations, researchers, and many private companies promoting sustainable development [1,4,6]. EDVs have significant potential for widespread use in the future, which may include battery-based electric vehicles (BEVs), fuel-cell-powered electric vehicles (FCEVs), hydrogen fuel-cell plug-in hybrid vehicles, or plug-in hybrid electric vehicles (PHEVs) [1].

Many studies in the literature are dedicated to examining the economic and environmental impacts of different EDV technologies, which are based on case studies for different places.

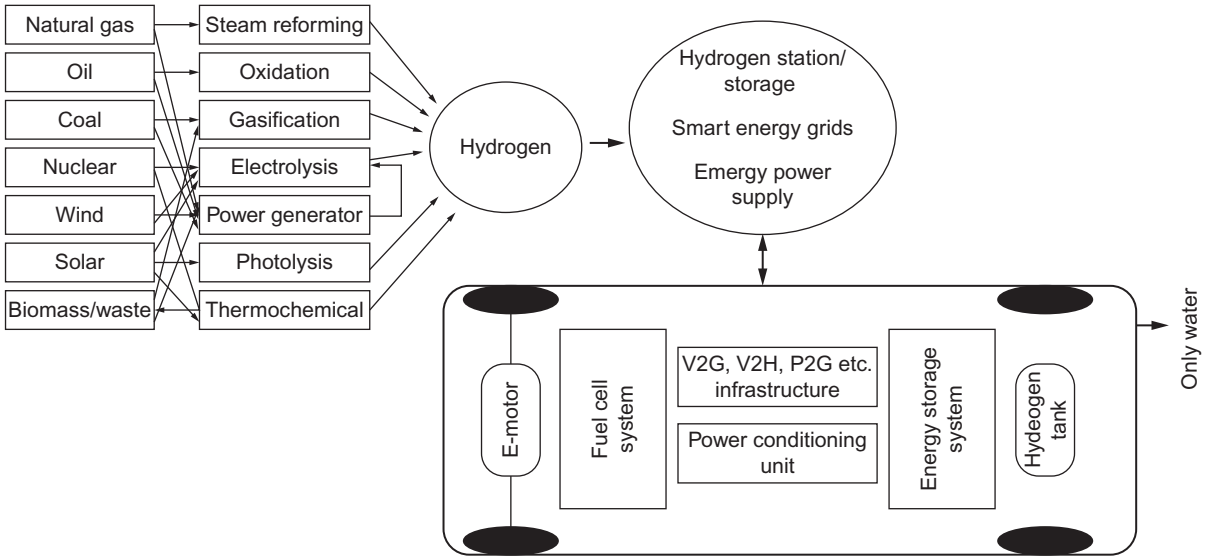

FIG. 33.1 Hydrogen energy chain and FCEV as a part of smart grids for sustainable transportation.

Brady and O'Mahony [7] evaluated the possibility of vehicular system-based emission reduction for the city of Dublin under different EDV market penetration scenarios. The results proved that EDVs could be considered as long-term alternatives to conventional vehicles, with the potential for considerable emissions reduction. The electrification of vehicular systems has the potential to lower the primary energy requirement and CO_2 emissions by 50% per kilometer. Browne et al. [8] focused on the role that can be played by different fuel delivery structures and new EDVs in reducing freight traffic and its environmental impacts in towns and cities. Perujo and Cuiffo [9] found that the vehicle-to-grid (V2G) interaction of EDVs could contribute to the efficiency of the energy distribution system that leads to better environmental results. Görbe et al. [10] described the idea of utilizing EDV batteries as storage devices in a low-voltage grid composed of distributed small-scale renewable power plants to contribute to both grid operation and environmental impact reduction. Moriarty and Honnery [11] explored the efforts promoting the use of EDVs to replace transportation-based fossil-fuel utilization and reduce GHG emissions, with a focus on reducing energy and emissions, and reported the midterm and long-term positive impacts of EDV penetration.

Transportation-specific policies and research & development (R&D) studies are strongly dedicated to find competitive alternative vehicular options to meet the GHG reduction targets in the long term and to enable the political effects of energy independence. Köhler et al. [12] assessed the innovation structures for R&D in low-carbon vehicles in the European Union (EU) automobile industry, which are primarily based on conventional vehicle technologies. This study also compared BEVs with both FCEVs and hydrogen fuel-cell PHEVs. The ever-increasing energy consumption causing the depletion of fossil fuels and rising public awareness for environmental protection resulted in much of the research work to focus on alternative/renewable energy sources. Thus, it becomes a requirement to replace conventional fuels with new energy sources [13]. As a consequence, novel renewable and clean energy power sources must be considered including vehicular systems that are primarily driven by conventional fuel types. Among the possible alternatives, as a part of the change toward the hydrogen-based energy system, hydrogen fuel-cell vehicles are given specific importance and will play a major role to realize sustainable transportation (see Fig. 33.1), improve the quality of life, reduce health-care costs, and promote technological reform in automotive industry [14–18].

An FC is an energy conversion device that converts the chemical energy of a reaction directly into electricity with byproducts of water and heat. There are several types of commercially available FCs, such as polymer electrolyte or proton-exchange membrane (PEM) FCs, solid oxide FCs, alkaline FCs, molten carbonate FCs, phosphoric acid FCs, and direct methanol FCs. Among the various types of FCs, the PEMFC technology has found widespread use, especially in vehicular applications [14].

> The PEMFC technology is still under active R&D investigation for powering systems in many applications. However, the daily operation of systems like vehicular loads and residential units with transient load changes may not be suitable for using a sole PEMFC system. This phenomenon is mainly caused by the limitation of FCs to track fast load variations due to their slow dynamics. These fast energy demand periods frequently occurring in the operation of daily utilized systems to high-voltage drops in a short time, which is defined as starvation phenomenon [16]. In the case of fuel starvation, the FC performance degrades, and cell

voltage drops. This issue may cause a significantly insecure operation for the FC stack. Thus, to utilize an FC in dynamic applications, its current or power slope must be limited to prevent the fuel-starvation problem. Therefore, hybridizing FC system with an energy storage system (ESS) decreases system cost, while sizing improves dynamic performance of overall vehicle system, promotes FC lifetime, and provides fuel economy owing to regenerative braking energy capturing and load sharing. Because of different characteristics of multiple power sources or ESS in a PEMFC-powered hybrid system, the efficiency and the fuel economy of these hybrid units mainly depend on a proper energy management strategy and well-designed power electronics architecture [15]. However, the hybridization with ESS will cause the complexity of the vehicle and the control systems, weight increase, and extra storage cost [5].

Since FCEV is a completely new and complex scientific area with significant capital costs and administrative challenges, it needs systematic approach involving all stakeholders (central and local governments, transportation departments, energy companies, organizations, automakers, auto parts providers, universities, R&D institutes, etc.) [17,19]. Thus, coordination is a requirement about data collection and analysis, policy planning, infrastructure construction, safety, promotion, operation, management, maintenance, finance, etc. Besides, governments should support ambitious plans and incentivize regulations to introduce hydrogen-powered vehicles to the market. Hydrogen, which is one of the key elements of hydrogen-powered vehicles, can be produced from a variety of sources including fossil fuels such as natural gas, oil, and coal and renewable sources such as solar and wind power, biomass, waste, and nuclear energy.

Hydrogen is a future energy carrier, energy transporter, and energy transmitter. By the evaluation of environmental and economic assessments of the hydrogen supply chain, renewable sources, and conversion units such as photovoltaics (PVs), wind turbines (WTs), and FCs have been found to be promising energy sources toward building a sustainable energy economy in the next decade [18,20]. These renewable energy sources, however, suffer from some deficiencies when used as stand-alone energy sources and grid-parallel sources. The power generated by WT and PV systems is highly dependent on weather conditions. In addition, it is difficult to store the power generated by a PV or WT system for future use. To alleviate these problems, WT and PV sources can be integrated with other alternative systems. Therefore, alternative energy conversion systems such as PV cells and wind turbines can be cooperated with fuel cells and FCEVs. Felgenhauer et al. [19] concluded that FCEVs can be used as a part of hydrogen infrastructure may provide hydrogen to the natural gas supply (Power2Gas, P2G). Also, the V2G or vehicle-to-home (V2H) interaction of EDVs can contribute to the efficiency of the smart energy systems (as grid storage and P2G) or stand-alone applications such as emergency power sources [21]. Thus, higher efficiency can be obtained by making the best use of their features while overcoming their limitations [20]. In this case, when power is plentiful, FCEVs can be used both a storage and a flexible load resource [19]. The hydrogen produced by an electrolyzer using renewable power sources is used in the FC system and acts as an energy buffer. Thus, the effects of reduction and even the absence of available power from the renewable energy system can be easily tackled. By using the electrolyzer, hydrogen can be generated and stored for later use in FCV refueling [19].

This chapter focuses on the hydrogen-fueled FC technology, which is used in vehicle applications as an alternative energy converter (hydrogen to electric) for environment-friendly sustainable transportation. This chapter is organized as follows: First, hydrogen infrastructure, hydrogen production methods, and hydrogen storage systems are described. Second, the main types of fuel cells are described in detail. Third, fuel-cell system components and their properties are explained. Fuel-cell-powered automotive applications, their design and energy management architectures, current status and future trends, and safety issues are discussed in the final section.

33.2 Hydrogen Infrastructure and Vehicle Hydrogen Storage System

Hydrogen, which is the simplest and most abundant element in the universe, was discovered in the 1700s. The element is colorless, odorless, tasteless, and 14.4 times lighter than air. Hydrogen does not occur free; it is found in compounds in nature. The most well-known compound is water. Hydrogen is not found naturally; it comes from fossil fuels, renewable sources, and nuclear energy by using reformer, electrolyzer, or fuel processor.

When comparing with other energy sources, hydrogen has the highest energy content in terms of weight. For instance, 1 kg of hydrogen approximately has the energy of 2 kg natural gas or 3 kg oil. However, hydrogen has very low volumetric energy content that requires costly production, storage, and delivery of hydrogen. The capital cost of hydrogen production needs to be solved economically and environment-friendly for a successful hydrogen economy [5]. Recent advancements in hydrogen-powered applications make hydrogen as an indispensable source of energy for the hydrogen economy.

In future energy systems, renewable energy sources will be used to generate hydrogen, and power demand might be satisfied using renewable sources and fuel cells since the hydrogen economy is a vision of the future. Therefore, alternate energy conversion systems such as PV cells and WTs can be cooperated with FCs. Here, to sustain the power demand and solve the energy storage problem when too much renewable electricity is being produced compared with the demand that exists at that moment, electric energy can be stored in the form of hydrogen. By using an electrolyzer, hydrogen can be generated and stored

for future use. Since the process is providing hydrogen to the natural gas supply (Power2Gas, P2G) and combined heat power (CHP) approach, in the near future, they can be a competitive and convenient solution. It has been reported that with the growth in demand, the fuel-cell vehicle infrastructure would substantially reduce the cost [19].

33.2.1 Hydrogen Production Methods

Hydrogen can be produced from both renewable (hydro, wind, solar, biomass, and geothermal) and nonrenewable (coal, natural gas, and nuclear) resources [22]. Hydrogen is mainly produced through fossil-fuel processing. In the entire world, 48% of hydrogen is produced from natural gas, 30% from oil, 18% from coal, and only 4% from renewable sources [23].

The main hydrogen production methods are steam reforming, gasification, partial oxidation, thermochemical cycling, photolysis, and electrolysis. Steam reforming may be used with natural gas, gasification with coal and waste, partial oxidation with oil, thermochemical cycling with nuclear and solar, photolysis with solar, electrolysis with wind and solar, etc. [23,24]. Producing hydrogen with a low cost means reforming it from fossil fuel such as natural gas, which may give rise to pollution by forming carbon dioxide. Manufacturing hydrogen is relatively more expensive [18,25].

Hydrogen production through electrolysis of water is more promising as it avoids carbon emission. Water can be decomposed into its elementary components by passing electric current between two electrodes separated by an electrolyte. According to Faraday's law, hydrogen production rate of an electrolyzer cell is directly proportional to the electric current in the equivalent electrolyzer circuit.

Electrolysis process has been proposed especially for renewable systems. The power generated by these systems highly depends on weather conditions. For example, during cloudy periods and at night, a PV system would not generate any power. In addition, it is difficult to store the power generated by a PV system for future use. To overcome this problem, a PV system can be integrated with other alternate power sources and/or storage systems, such as electrolyzer, hydrogen infrastructure, and FC systems [26]. When assessing recent developments in hydrogen applications, renewable energy sources have been used to generate hydrogen. Besides, energy demand/supply management can be satisfied using renewable sources and hydrogen infrastructure by including FCEVs, smart grids, and hydrogen-fueling systems. The renewable hydrogen cycle coupled with smart grids is shown in Fig. 33.2.

33.2.2 Hydrogen Storage

The driving range of the FCEVs depends on its onboard hydrogen storage capability and other energy management systems. According to the improvements of the hydrogen storage tanks, FCEVs can meet to match driver expectations [5,23]. The use of hydrogen as a vehicle fuel requires an onboard storage that offers inherent safety and both volumetric and gravimetric efficiencies. Onboard storage in vehicular systems is one of the major barriers to the acceptance of hydrogen-powered vehicles

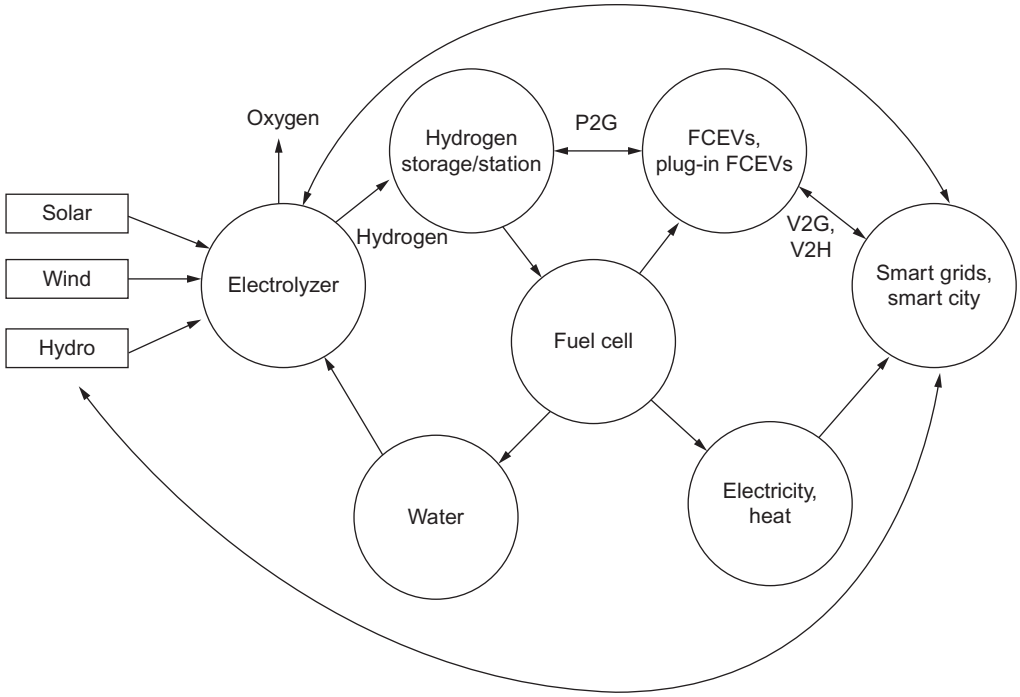

FIG. 33.2 Renewable hydrogen cycle coupled with smart grids.

[27]. Since onboard storage systems increase safety concerns especially for drivers and passengers during dangerous situations such as car accidents, the storage system gives a hazardous impression. The problems associated with hydrogen storage change from one storage technology to another. Thus, hydrogen storage technologies are evaluated as the first step of the current deliverable presentation. There are four technologies available today to store hydrogen aboard vehicles [16,17,28]:

- Compressed hydrogen gas in high-pressure tanks
- Liquefied hydrogen
- Metal hydrides
- New methods currently under development

The most used technique for hydrogen storage is compression of hydrogen into different kinds of high-pressure tanks [16]. According to the Department of Energy (DoE), compressed hydrogen technique will continue to be the most popular type of hydrogen storage for vehicular systems until 2020. Most vehicles currently in the on-road testing phase and on the road commercially are equipped with such a composite high-pressure tank. This is because of its simple structure and charge-discharge easiness. In general, vehicular pressurized hydrogen storage tanks made of very light and robust composite materials [29]. Storage density (gravimetric ratio) of above 0.05 kg of hydrogen per 1 kg of total weight, which means a stored hydrogen ratio of 5%, is easily achievable [16]. This ratio can reach up to 11.3% in this approach. There are two working pressures commonly used in commercialized vehicles such as 350 bar (35 MPa–5000 psi) and 700 bar (70 MPa–10000 psi) [17]. Leading FCEV automakers have mounted the high-pressured storage tanks on their models with their own preferences. For instance, while Toyota, Honda, and Hyundai use 700 bar (10,000 psi), Nissan uses 350 bar (5,000 psi) pressurized tank [5,21].

In another approach, the hydrogen gas is liquefied and stored under lower temperature and pressure compared with the high-pressure approach in liquefaction technique [16]. In this method, the ratio of stored hydrogen per tank weight is around 26%. However, the usage of liquid hydrogen storage system is limited because of its properties, cost of the manufacturing material, and cost of the tank. Besides, the whole process is relatively inefficient because a lot of energy is already consumed in the first stage of hydrogen liquefaction [30]. In this technique, nearly 26% of the stored hydrogen energy is consumed during the hydrogen liquefaction process [28]. In addition, liquid hydrogen tanks suffer from hydrogen leaks due to the unavoidable thermal losses that lead to pressure increase in the tank. This hydrogen self-discharge of the tank may reach to 3% daily, which means a 100% self-discharge in 1 month [31]. Hydrogen liquefaction and use of liquid hydrogen are usually practiced only where achieving high storage density is absolutely essential, such as in aerospace applications [28,16]. Some prototype hydrogen-powered automobiles also use specially developed liquefied hydrogen tanks [16].

Metal hydrides offer alternatives to the storage of hydrogen in gaseous and liquid form. Storing hydrogen as hydride in metals provides some advantages especially for safety in many applications. However, the tank weight provides a significant problem in this approach especially for applications like vehicular systems. The commercially available metal hydride hydrogen tanks offer a stored hydrogen ratio of 4.5% [27]. Besides, the repetition of hydrogen storage (absorption)/release (desorption) further decreases this ratio. Moreover, heat is released during the absorption process, which must be removed in order to achieve the continuity of the reaction. Similarly, during the hydrogen desorption process, heat must be supplied to the storage tank [16]. To overcome these limitations, some new techniques in metal hydride hydrogen storage approach are under investigation, which is expected to reach a hydrogen storage ratio of 10.5% in the near future [31].

New hydrogen storage methods have potential for providing higher energy densities than the conventional methods. These methods contain hydrogen storage in carbon nanotubes, storage in glass microspheres, boron-based storage, or storage in polyhydride chemical complexes [29]. Among them, the nanotube technique seems to be promising according to the recent developments in nanotechnology, which is anticipated to reach to a hydrogen storage ratio of 68% [17]. As another novel hydrogen storage method, boron-based chemical storage materials (like borohydrides and ammonia borane) are promising compounds with their high-hydrogen capacities. However, these hydrogen storage materials create ongoing problems from the kinetic and thermodynamic limitations in practice [32]. Besides, the current costs of these methods are extremely high that prevents the commercial utilization of these approaches [33,34].

33.2.3 Hydrogen Delivery and Fueling Station

It is expected that the FCEVs will have a significant market share in upcoming years. To that end, an effective and efficient utilization of the currently existing hydrogen infrastructure should be reconsidered for widespread penetration of FCEVs. Considering that proof-of-concept experiment with R&D studies for hydrogen generation has been already shown; construction of hydrogen generation and distribution infrastructure is a requirement for commercialization of FCEVs to achieve a sustainable process [19,21].

Hydrogen has poor volumetric energy density, and hence, FCEVs have a limited storage capacity, which makes hydrogen generation and distribution infrastructure a must-have. In addition, to ensure acceptance by public, hydrogen-refueling stations should be constructed and mounted.

Despite the expensiveness and complexity of hydrogen storage, it has been reported that delivering hydrogen by pipeline or tanker trucks to the refueling stations is possible with some adaptive alterations to the current infrastructure [17]. It is significantly important for both developed and developing

countries to realize these studies in a timely manner in order to prevent/reduce the possible future technological dependence on other countries about this issue. Several such studies are realized worldwide, especially in countries such as Japan, the United States, Germany, China, South Korea, and Italy, where renewable sources are used with a high ratio with a vision of future hydrogen economy and hydrogen generation, and distribution infrastructure has been already established or planned [17,19].

If hydrogen-fueled vehicles are used instead of natural gas delivery systems, using central hydrogen delivery system would be more convenient. Furthermore, decentralized and distributed hydrogen stations combined with electrolyzers and renewables will be built to meet the variable demands for hydrogen [5].

In this regard, the fueling and P2G operations of FCEVs should be controllable under the smart grid umbrella. Besides, hydrogen storage of FCEVs in parking condition can be utilized as a backup gas unit when the gas demand increases or fuel cells of FCEVs with suitable power-conditioning unit can supply power to electric loads and appliances. Thus, FCEVs can be considered as multicarrier energy sources. Likewise, BEVs and PHEVs are also considered as both storage and a flexible load resource with a connection to smart grids (including renewables) under a suitable smart charging and discharging approach. Furthermore, smart grids have the potential of exploiting renewable sources and providing the required infrastructure for BEVs and FCEVs [19]. Additionally, CHP of the electrolyzer can be considered as a supplementary.

In this context, Honda proposed and developed novel and efficient complementary applications of hydrogen value chain such as FCEV, compact/smart hydrogen station (SHS), high-pressure storage tank, fuel cell stack, electrolyzer, and power-conditioning units. After accomplishing their proof-of-concept experiments, commercialization by Honda has already started and currently being deployed in some regions [21]. To this end, some governments and automakers are cooperating, aiming to support hydrogen infrastructure development by methods by partially subsidizing operation costs of infrastructure firms [21,35]. However, the abovementioned issues cannot be evaluated independent from smart energy technologies.

33.3 Fuel Cells and Types

The fundamental principles of FC concept were described in 1838 by a Swedish scientist Christian Friedrich Schönbein. Sir William Grove, called the father of the FC, generated electricity by reversing the electrolysis of water in 1839, thus inventing the first FC system. In 1950, Francis Bacon from Cambridge University demonstrated the first 5 kW alkaline FC system. After the successful commercialization of alkaline FC technology, National Aeronautics and Space Administration (NASA) also started working on a weightless power system. In the 1970s, NASA developed a 12 kW alkaline fuel-cell (AFC) system for use with the space shuttle. Furthermore, researchers started R&D studies to use different types of fuel cells on applications like transportation systems. Currently, it is the most important development in the history of decentralized energy supply [5,24,36].

FC is an electrochemical device that generates electricity through a chemical reaction. It is an energy conversion device operating at high temperatures and using chemical energy stored in fuels, such as hydrogen, hydrocarbons, and alcohols without any direct combustion processes. Since the fuel-cell device is producing electricity and heat while altering hydrogen and oxygen into water, it emerged as one of the most promising power sources offering higher energy densities and energy efficiencies without any pollution [5,37,38].

FC is a converter, generating electric and heat energy with the electrochemical combination of hydrogen fuel and oxidant. This reaction emits only water. A fuel-cell system and chemical battery have a structural similarity. Unlike battery systems, the operation of fuel cells is restricted only by the existence of fuel, and there is no charging limitation [13]. Since FCs convert the chemical energy directly into the electric energy, FC efficiencies are not limited by theoretical Carnot efficiencies. Thus, FC has a high conversion efficiency compared with mechanical and combustion processes [38]. If the waste heat/exhaust can be cogenerated with the purpose of heating and cooling (can be used in residential, commercial, and industrial applications), typical values of efficiency would range up to 85% [37].

The main advantages of the FCs are as follows [5,37,39]:

- Potential to provide high operational efficiency and low operational maintenance
- Different fueling options
- Highly modular structure
- Offer zero or low environmental emissions and quiet operation
- No moving parts, except ancillaries (fans and pumps)
- Potential for high reliability

Barriers to more widespread adoption of the FC systems are the following [39]:

- Cost of FCs and the hydrogen infrastructure
- The lack of manufacturing and practical operating experience

FCs are generally classified depending on the type of electrolyte they use. Six main types of FCs are available in the market as listed below:

- Alkaline fuel cells (AFC)
- Molten carbonate fuel cell (MCFC)
- Polymer electrolyte fuel cell (PEMFC)
- Direct methanol fuel cell (DMFC)
- Phosphoric acid fuel cell (PAFC)
- Solid oxide fuel cell (SOFC)

The classification with some technical characteristics is shown in Table 33.1.

TABLE 33.1 Main types of fuel cells with some technical characteristics [5,25,37,40,41]

Types of FC	Operating temperature [°C]	Fuel	Charge carrier	Electrolyte	Oxidant	Start-up time (h)	Efficiency (%)
AFC	50–200	Pure H_2	OH^-	Liquid solution of KOH ($LiAlO_2$)	O_2 in air	<0.1	50–70
MCFC	650	H_2, CO, CH_4, other hydrocarbons	CO_3^{-2}	Lithium and potassium carbonate	O_2 in air	5–10	40–85 with cogeneration
PEMFC	50–100	Pure H_2	H^+	Solid polymer membrane (Nafion)	O_2 in air	<0.1	40–60
DMFC	60–200	CH_3OH	H^+	Solid polymer membrane	O_2 in air	<0.1	35–50
PAFC	160–210	Pure H_2	H^+	Phosphoric acid (H_3PO_4)	O_2 in air	1–4	35–85 with cogeneration
SOFC	800–1000	H_2, CO, CH_4, other hydrocarbons	O^-	Stabilized solid oxide electrolyte (Y_2O_3,ZrO_2)	O_2 in air	1–5	45–60 with cogeneration

33.3.1 Alkaline Fuel Cell

Alkaline fuel-cell system is one of the first developed fuel-cell technology with the simplest structure. It is the first type widely used on space applications [37,41]. AFCs use a liquid solution of potassium hydroxide (KOH) as an electrolyte that conducts ions between two electrodes: anode and cathode. Because the electrolyte is alkaline, the ion conduction mechanism has differences from PEMFCs [24]. At the basic structure of AFCs as given in Fig. 33.3, at the anode side, hydrogen undergoes oxidation reaction that turns hydrogen into a positively charged ion and negatively charged electron. The negatively charged electrons travel through an external circuit that generates electricity and unifies with oxygen atoms at the cathode side [42]. The alkaline electrolyte only lets the composed hydroxyl (OH^-) go through the anode side. By this reaction, hydrogen ions and hydroxyl reunite producing water. Eventually, water, heat and the electricity will be obtained.

Some key advantages of AFC systems can be specified as [43] the following:

- Low operation temperatures (50–200°C)
- Quick start-up range (<0.1 h)
- High efficiency (50%–70%)
- Low catalyst requirement reducing content costs
- Simple structure
- Low weight and volume

Some key disadvantages of AFC systems can be specified as [13,43–45] the following:

- Short operating life since they use a liquid solution of potassium hydroxide (KOH) as an electrolyte that is highly corrosive, thus eroding its parts
- Required oxygen must be provided after purification since they are very intolerant to carbon dioxide
- High cost for commercialized applications and current R&D studies are focusing on reducing costs

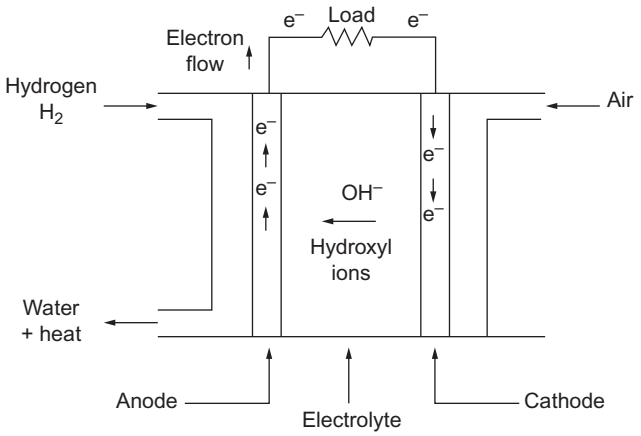

FIG. 33.3 Basic structure of an AFC.

33.3.2 Molten Carbonate Fuel Cell

The main principles of MCFCs are based on SOFCs and the other types of fuel cells. In the mid-1960s, Texas Instruments developed several MCFCs for US Army that led to a widespread use of MCFCs in the field [43].

MCFCs use lithium potassium carbonate salts as an electrolyte as shown in Fig. 33.4. They operate at high temperatures (650°C); therefore, catalysts can be made of low-priced metals to reduce cost, and the heat/exhaust can be utilized [37]. If the heat/exhaust can be utilized (with CHP), the efficiencies of MCFCs can be increased from 60% to 85%. Additionally, higher temperature makes the FC system more tolerant to poisoning (carbon monoxide) than lower temperatures. These systems can use either carbon dioxide or oxygen as a fuel. Currently, there are many molten carbonate systems available with capacities ranging from 100 kW up to 2 MW.

MCFCs do not demand an external reformer; thus, the primary fuel used may not be hydrogen gas. The basic components of natural gas, methane, and steam are processed at a reformer in the MCFC system, and electricity will be produced. The internal reformer reduces the costs compared with the other FC technologies with external reformers.

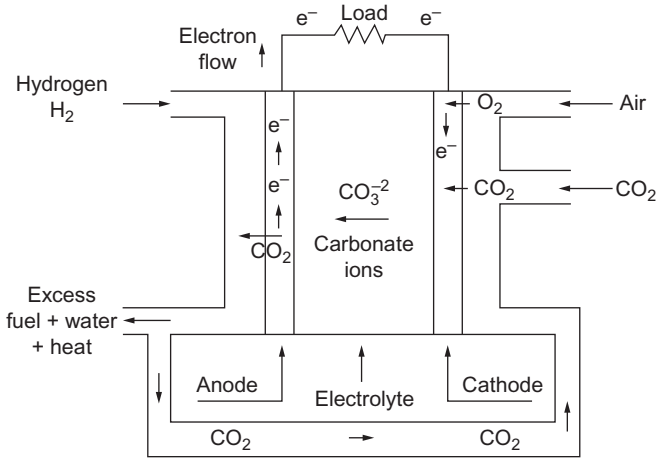

FIG. 33.4 Basic structure of a MCFC.

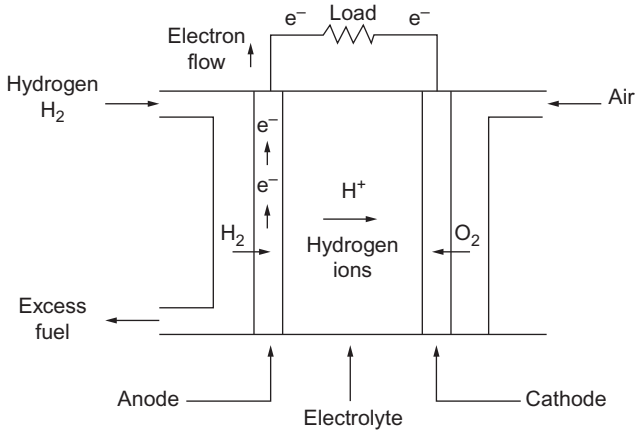

FIG. 33.5 Basic structure of a PEMFC system.

Some key advantages of MCFC systems are specified below [43,46]:

- Using the fuel converted in the system
- Producing so much heat/exhaust that can be cogenerated
- High efficiencies
- Relatively fast response to load changes in steady-state conditions
- Require low-cost catalysts
- Lower sensitivity to poisoning

Some key disadvantages of MCFCs include the following [46]:

- Slow start-up range (5–10 h)
- Demand redesigning with more resistant components to corrosion
- Problems in contenting the liquid electrolyte in the structure
- Requirement of preheating before starting work
- Short operating life especially when using for high-power production systems

33.3.3 Polymer Electrolyte Fuel Cell

Among the various next generation power supplies, the polymer electrolytes or PEMFCs have been found to be one of the most promising energy sources due to their high efficiencies and environment-friendly operations [47].

The basic structure of PEMFC, shown in Fig. 33.5, consists of three segments: the anode (negative characteristic electrode), the cathode (positive characteristic electrode), and the electrolyte membrane sandwiched between the two that allows only positively charged ions/protons to move between the two electrodes. The anode and the cathode have a catalyst, which speeds up the reactions at the electrode. Hydrogen goes to the anode side, and oxygen from the air flow goes to the cathode side. At the anode side, hydrogen undergoes oxidation reaction that turns hydrogen into a positively charged ion and negatively charged electron. After the reaction, protons are being transferred from anode to cathode through the electrolyte membrane, while the electrons travel through an external circuit. When the ions/protons reach the second electrode cathode, they will unify again with electrons and react with oxygen to form water. Eventually, electricity, water, and heat will be generated [39].

Some key advantages of PEMFCs include the following [16]:

- Low operation temperatures (50–100°C)
- Quick start-up range (<0.1 h)
- High efficiencies (40%–60%)
- Structure of electrolytes is more reliable, secure, and stable than other FCs
- High power density is the highest among all the available types of FCs
- High tolerance capability to differential pressures of the reactants
- Robust and simple structural design

Some key disadvantages of PEMFCs are listed below:

- Possess a structure highly depending on the purity of hydrogen
- Very poor tolerance to carbon monoxide and sulfur particles
- Gases require to be moisturized before reacting
- Comprised of a fairly expensive platinum catalyst and a solid polymer membrane

PEMFCs are a good candidate to substitute conventional technologies with their higher efficiencies and lower environmental impacts. The cost of PEMFCs is expected to down to consumer affordable levels in the near future [13].

Many advantages of PEMFCs, including fast response time, low operating temperature, high power density, and life cycling, have made the PEMFCs attractive and promising energy devices from the transportation and mobile applications to

stationary applications as a distributed generation [5,16]. Therefore, lots of big companies such as Ballard, UTC, Nuvera, PlugPower, General Electric, Toshiba, and Sanyo produce PEMFCs commercially. Leading automaker companies such as Honda, Toyota, Daimler-Chrysler, General Motors, BMW, Nissan, Ford, Hyundai, and Renault and worldwide brand-mark companies like Samsung and IBM use this shining technology for their own commercial applications [48].

33.3.4 Direct Methanol Fuel Cell

FCs either use hydrogen directly or reform hydrocarbon fuels like methanol, which is the simplest organic fuel that can be most economically and efficiently produced from relatively plentiful fossil fuel [24]. Thus, the operation of the DMFC is based on oxidation of water mixed with methanol. After the oxidation, methanol goes to the FC anode side [37]. DMFCs use a liquid fuel methanol, which is easier to transport for public using with current infrastructure [41]. DMFCs are often used to supply power for portable electronics and emergency power supply.

Recently, concerns about the poisonous effects of methanol have emerged; thus, companies prefer using ethanol instead of methanol [37]. DMFCs have immature technology, low power density, slow power response, and low efficiency compared with direct hydrogen FCs [24].

33.3.5 Phosphoric Acid Fuel Cell

Phosphoric acid fuel cell is the first developed FC technology and first to be used commercially. They are considered as first generation of modern FC. PAFCs use liquid phosphoric acid as an electrolyte. The PAFC systems have about 40% energy production efficiency and high operating temperatures (150–220°C) [42]. With cogeneration of heat/exhaust, the efficiency can be increased up to 85% [43]. Currently, there are PAFCs with capacities ranging from 200 kW to 11 MW. Necessary improvements for widespread use of PAFCs will require reducing the operating cost while increasing the operating life.

These FC systems have a drawback of weight; therefore, these FCs are not preferable on transport applications. Some key advantages of PAFC systems can be specified as follows [43,46]:

- Tolerant till 30% carbon dioxide content, hence direct usage of atmosphere air
- High efficiency (85%) with cogeneration of heat/exhaust (CHP)
- Operate trouble-free at temperatures (150–220°C)

Some key disadvantages of PAFCs include the following [42,43]:

- Slow start-up range (1–4 h)
- Low tolerant to carbon monoxide component
- Exhausting water content can damage acidic electrolyte (corrosion)
- Massive and heavy structure
- Requirement of external reformer
- Requirement of preheating before starting to operate

33.3.6 Solid Oxide Fuel Cell

SOFCs operate at high temperatures (700–1000°C), and every single solid oxide cell produces 0.8–1 V voltages [43]. The heat/exhaust (around 500–850°C) generated by SOFCs is attractive for cogeneration. SOFC systems are currently used in stationary applications such as backup power units. Furthermore, recent R&D studies are focusing on feasibility of SOFCs at transportation appliances [49,50].

Solid oxide fuel cells are promising with their inherent advantages for industrial applications such as its independence from pure fuel. Therefore, hydrogen and CO, CH_4, and other hydrocarbons can be used as fuel [37] in a SOFC. Since SOFCs operate at high temperatures, these systems can use low-cost catalyst components to enhance operational performance. SOFCs use a solid electrolyte, generally a ceramic material called yttria-stabilized zirconia (YSZ). Because the electrolyte does not involve a liquid-phased reaction, a problem such as fuel flooding does not occur. Also, SOFCs can be manufactured for many configurations, although other FC types with liquid electrolyte cannot [46].

In SOFCs, fuel is supplied to the anode side, and oxygen from the air flow goes to the cathode side as shown in Fig. 33.6. At the anode side, hydrogen undergoes oxidation reaction that turns hydrogen into a positively charged ion and negatively charged electron. The separated electrons travel through an external circuit from anode to cathode to produce electricity and oxygen atoms absorb the electrons. The solid electrolyte membrane only permits the transition of negative charged oxygen ions from cathode to anode. When oxygen ions reach anode, they react with hydrogen ions to form water.

SOFCs have about 45% efficiency that can reach 85% by capturing and utilizing the heat/exhaust. Additionally, the SOFC systems have low gas emissions [51].

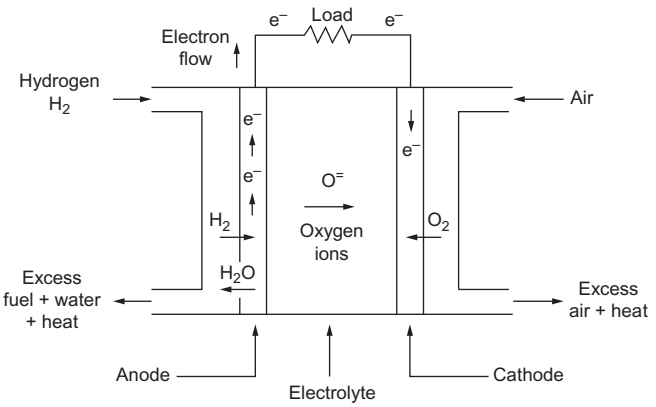

FIG. 33.6 Basic structure of a SOFC system.

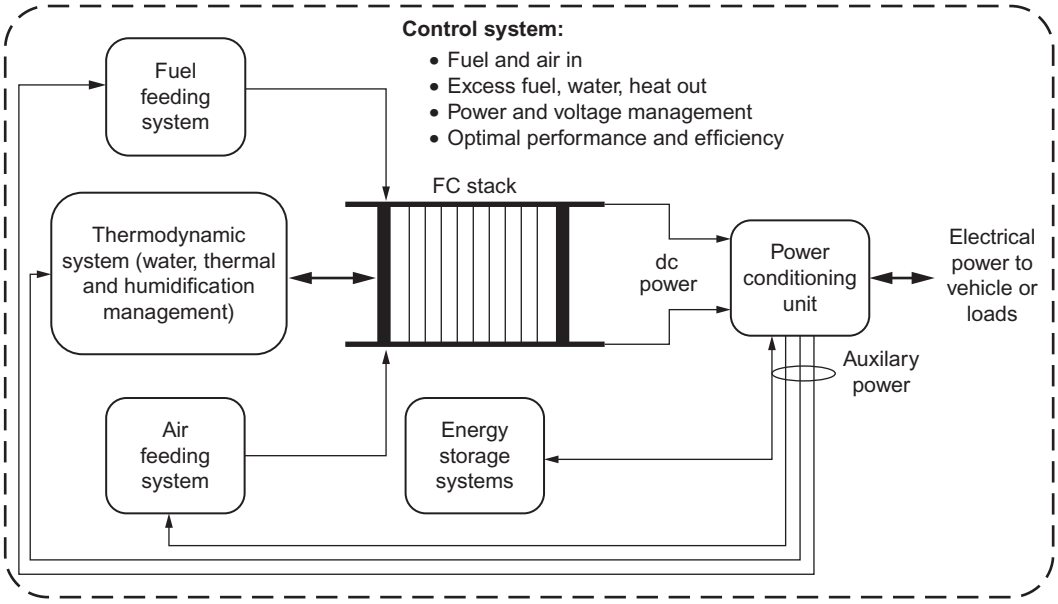

FIG. 33.7 FC system components.

Some key advantages of SOFC systems can be specified as follows [42,45,46]:

- Producing massive amount of heat/exhaust that can be utilized
- Fast chemical reactions
- High efficiency
- The solid electrolyte is more reliable than a liquid electrolyte
- Nonrequirement of external reformer
- No corrosion problems

Some disadvantages of SOFC systems include the following:

- Slow start-up range (1–5 h)
- Requirement of R&D studies on decreasing volumetric and gravimetric parameters
- Low tolerant to sulfur element
- Requirement of long-term proof-of-concept studies

33.4 Fuel Cell System Components

Among the various types of fuel cells, PEMFC has drawn the most attention due to its simplicity, viability, quick start-up range, higher power density, long cycle life, and low operational temperature (80–100°C). Since PEMFCs are the best candidate for vehicular and commercial applications, in this section, PEMFC system components are discussed in detail.

In practice, FC systems need auxiliaries (blowers, pumps, fans, ejectors, motors, turbines, compressors, valves, and regulators) to support their operation [24,52]. The main components of the FC system include the FC stack, fuel feeding, air compressors, humidifiers, power-conditioning unit with control systems, and energy storage system as shown in Fig. 33.7 [25]. All of these components work together to provide power to an electric load while regulating the proper amounts of fuel and ensuring system safety [52].

(i) *Fuel cell stack.* Although the FC stack is the main component of the fuel-cell system, for the required electric energy, all fuel-cell components must work in harmony. To that end, hydrogen fuel and air must be loaded into the stack as pressured gas. Thereafter, the excess hydrogen will be purged, and excess heat will be removed by circulating cooling water through the stacks during processing [23]. During operation, an FC produces dc electricity and water and heat through electrochemical process.

A fuel cell stack is made by assembling cells to deliver the required amount of voltage and power. Since a single cell produces less than 1 V, this voltage ratio is insufficient for most of the applications [21,41]. A single fuel cell consists of three metal plates called separators and two membrane electrode assembly (MEA) plates, which generates electricity. Innovative MEA design can provide effective and efficient fuel flow [21]. The cell generates electricity in the form of direct current (dc) by reacting hydrogen and oxygen in the air at the MEA.

The ideal potential of a hydrogen/oxygen FC under standard state conditions (25°C and 1 atm) is 1.229 V with liquid water product. However, the actual FC potential is lower than the ideal potential value due to the irreversible voltage drops that occurs in the FC system. There are three types of irreversible voltage drops, namely, activation overvoltage, ohmic overvoltage, and concentration overvoltage. At low current densities, the

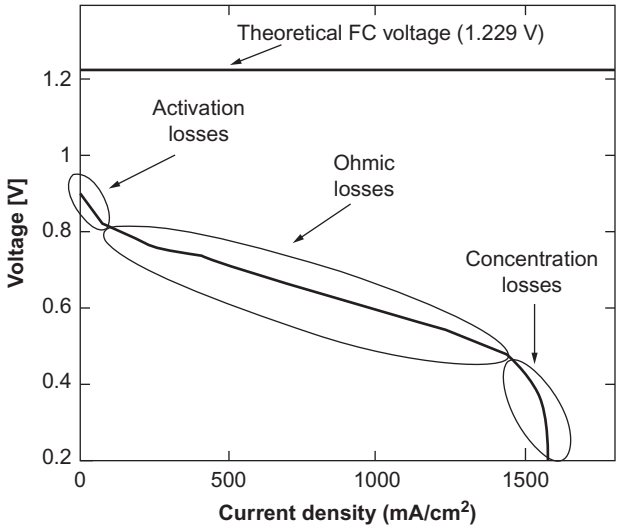

FIG. 33.8 Typical FC polarization curve.

activation overvoltage is responsible for the voltage drop of the FC. Besides, concentration overvoltage becomes more significant at high current densities. The effects of these voltage drops and the corresponding variance of FC voltage can be seen from the FC polarization curve shown in Fig. 33.8 [53]. Operating FC in this linear region is quite important for ensuring overall system efficiency.

The fuel cell stack from combined assembling cells is the most important part of a fuel-cell power system, like an engine in the conventional vehicle. The FC stack provides the current required by governing of a fuel flow rate through the anode channels, that is, the fuel flow rate varies according to the system power requirements [5]. The auxiliaries of FC system also consume 10%–15% of the total power output of the fuel cell stack [24]. The amount of power produced by fuel cell and its performance depends upon several factors, such as cell size, operating temperature, reactant gas stoichiometric flow rates, pressure of gases supplied to the cell, and anode and cathode humidification parameters [41,52].

(ii) *Fuel- and air-feeding systems.* Automotive applications with onboard hydrogen storage tank have control systems consisting of pressure regulators, relative humidity, fuel purity grade, and fluid-dynamic conditions [23]. As mentioned before, FCs have some limitations to track fast load variations, such as acceleration and deceleration for vehicular application, due to their relative slow dynamics, which is defined as FC starvation and flooding phenomenon. Thus, to utilize an FC in dynamic applications, both the air- and fuel-feeding control systems must be well managed and supported by a proper fuel cell energy storage system. To improve FC performance and efficiency, design and control of the air compressor are very important in order to accumulate and efficiently remove water produced from the reaction [21,23,41]. However, some automakers like Hyundai use different design as near-ambient air pressure to provide oxygen to the FC stack [54].

(iii) *Thermodynamic system.* In an FC system, water management, thermal management, and humidification can be increased to optimize overall system performance and improve power generation [23]. These three components must be efficient and reliable for optimum functioning of overall system, which require proper design, control, and water balance. If these conditions cannot be achieved, problems such as membrane drying out, electrode flooding and conductivity inadequacy, and excess water accumulation in the anode side would occur [23,25].

(iv) *Power-conditioning unit.* Another part of FC system is the power-conditioning unit (PCU). Because an FC produces dc electric energy, it must be converted from unregulated low-voltage level (voltage varies in a wide range depending on the load current) to regulated high-voltage level using a dc/dc converter and/or inverted to alternating current (ac) using dc/ac inverter for ac electric loads/drivetrains. The power-conditioning unit in such a vehicular system is mainly composed of dc/dc converters and an inverter unit. The inverter and propulsion motor are emulated using the dc load bank; therefore, only dc/dc converters are designed and built. The dc/dc converters used in FCEV topologies are the essential power-train components as they allow load sharing between main energy source and energy storage systems (ESSs) by using PCU. For example, the FC power stage is assigned for a power-tracking process to supply the determined power value from the FC system. Besides, ESS power stage can be devoted to DC link voltage control. Both power tracking and DC link voltage control processes can be implemented using a controller. Thus, this hybrid system topology provides the capability of delivering the desired power value from the FC system while keeping the bus voltage at desired intervals [55]. The driving motor can either be ac or dc motors such as induction motors, permanent magnet brushless motors, and switched reluctance motors [56]. The proper response of the FC system to the overall load dynamics can be achieved by generating appropriate power-switching signals to the converters [47]. While these converters design and operate, they must be preferred with high voltage ratio, high efficiency, low electromagnetic interference (EMI), and high compactness while keeping low cost [37].

(v) *Energy storage systems.* A stand-alone FC system integrated into an automotive powertrain is not always sufficient to satisfy the load demands of a vehicle. Although FC systems exhibit good power capability during steady-state operation, the response of

fuel cells during transient and instantaneous peak power demands is relatively poor. Therefore, when utilizing a PEMFC, it is recommended to associate it with an auxiliary power source to improve the dynamic performance of the whole system. There are many types of auxiliary units for compensating the slow response characteristics of the PEMFC unit and increasing the efficiency of the overall system. Energy storage units such as batteries, ultracapacitors (UCs), and flywheels, can be classified in the auxiliary power units group for use in hybrid systems including PEMFC. Specifically, not only energy storage units compensate the slow response phenomenon of PEMFC system, but also it provides the advantage of recovering the reusable kinetic energy that occurs in vehicular applications during braking periods. Thus, the consumption of hydrogen for FC units can be significantly decreased.

In many applications, batteries are utilized as ESS. Among the various existing rechargeable batteries, lithium-ion batteries appear to occupy a prime position in various aspects. A battery is needed in an FC system to supply power during the time after a change in the flow of reactants occurs. An auxiliary power source such as a battery bank can be used to improve the FC dynamics. In addition, the use of batteries reduces the size and cost of the FC, increases the lifetime, and avoids overloading. The battery bank supplies auxiliary power during cold start of the FC and supports peak demand periods or transient events. They also compensate the tracking delays of FC system. The state of charge (SoC) is an indicator showing the emptiness or fullness of the battery. The battery current can either be negative or positive, with respect to the mode of operation, for example, charging or discharging [57].

When the load power exceeds the maximum output of FC, battery starts to discharge through a converter located in the PCU and keeps discharging until the overloading ends. Also, if a step or ramp increase in the load demand occurs (even there is no overloading), battery bank helps the FC system until the FC power increases and matches the demanded power. The FC system has a relatively slow response in both step-up and step-down load conditions. When a step-down loading occurs, the output power of the FC slowly matches the reference power. In these conditions, the battery bank captures the differing power to successfully meet the load demands. These recaptured energies sometimes might not be sufficient to keep the battery SoC above a predefined level. Thus, another control loop is used to directly charge the battery bank from FC power plant with respect to the final SoC. The charge and discharge conditions of the battery are controlled with the aid of a dc/dc converter [57]. In the battery discharge current control, the key point is how good the FC power matches the active power requirement of the load. Thus, the positive difference between the FC reference power and the actual FC output power is processed to force the dc/dc converter to draw the reference current from the battery. The discharge current is limited using a saturation system to avoid battery overloading.

The battery can be charged when the FC reference power is above the power demand due to its slow response. While this can be evaluated as a naturally charging condition, another charging control loop is also employed. If all these conditions conforms the respective criteria, battery can be charged. In the battery charge current control, the key point is instantaneous SoC of the battery when compared with its nominal SoC. The battery charge current should be inversely proportional to the depth of discharge [57]. Also, the battery has some effect on meeting the reactive power demand. We can express the reactive power as the oscillating power between source and load buses. In systems including dc/ac conversion such as fuel cells, we observe that the reactive power oscillates between the reversible device (battery or UC) of the dc bus and the ac load bus. The reactive power passes through the antiparallel diodes of the inverter circuit to reach the rechargeable device and then passes to the load side through the next alternant. However, due to the reactive power losses on the contactors and the equivalent system impedance, there is always a dc power to be converted to the reactive power, which results in hydrogen consumption, stack dc voltage drop, and load bus voltage drop [57].

Ultracapacitors are also ESS devices that offer significantly better energy densities than conventional capacitors, better power densities than conventional batteries and can be constructed in modular and/or stackable format. The charge and discharge time of an UC varies from fractions of a second to several minutes, while providing maintenance-free operation. UCs provide the lowest cost per farad and extremely high cycling capability and prove to be environmentally safe [47]. The capacitance of UCs may vary from a few farads to several thousand farads per cell. Because of the aforementioned unique characteristics, UCs are utilized for a wide range of applications. Therefore, a UC bank can effectively serve as a cost-effective alternative to batteries, especially during short peak demand periods.

The natural structure of ultracapacitors is appropriate to meet transient and instantaneous peak power demands. The UC bank is designed to provide the difference between the load demand and the output power generated by the FC system. Without the UC bank, the FC system must supply all power demand, thus increasing the size and cost of the FC system.

The amount of energy drawn from the UC bank is directly proportional to the capacitance and the change in terminal voltage. The effective specific energy for a prescribed load can be supplied by various UC bank configurations. In practical applications, the required amount of terminal voltage and energy or the capacitance of UC storage system can be built using multiple UCs in series and parallel. The terminal voltage determines the number of capacitors, which must be connected in series to form a bank, and the total capacitance determines the number of capacitors, which must be connected in parallel

in the bank. The natural structure of UC is appropriate to meet transient and instantaneous peak power demands.

As a result, while choosing an ESS, the following characteristics should be considered [5,57]: specific energy and energy density; electric power, that is, the electric load required; volume and mass; storage capacity; reliability; durability; safety; cost; recyclability; environmental impact; response time; efficiency; self-discharge rate/charging cycles and excess discharge; sensitivity to temperature; charge-discharge rate lifetime; environmental effects; investing/operating cost; maintenance; availability; design complexity/voltage range; life cycle; and recharge rate of storage element.

33.5 Fuel Cells in Automotive Applications

FCs offer many advantages over the internal combustion engines (ICE) for vehicular applications because they are energy efficient, clean, and fuel flexible. Today, FCs have become smaller, more powerful, and more durable [54]. Since FCEVs provide much better air quality, health problems, such as incidence of asthma and other chest complaints, will decrease [25]. Hydrogen FC systems have the potential to reach 60% peak efficiency [15]. Onboard the vehicle, conversion of hydrogen produces electricity for power train of vehicle and water. Hydrogen can be obtained from various sources with different methods [58]. Leading automobile industries are making every effort to make hydrogen-powered vehicles affordable, environment-friendly, and safe [25,41].

Automobiles, buses, scooters, golf cars, utility vehicles (such as forklifts and airport vehicles), locomotives, tramways, boats, airplanes, and underwater vehicles can be considered as some of the applications of PEMFC systems in transportation area [15]. In automobile systems, almost all major automakers have demonstrated prototypes and commercially available FC vehicles and announced future plans for production and commercialization in the near future. On the other hand, buses seem to be the most likely type of road vehicles for an early market introduction of the FC technology. Also, scooters may be a significant market for FC technologies, especially in developing countries. To conclude, the transportation area seems to be the most promising sector of PEMFC technology.

The need to reduce emissions through the improvement of vehicle efficiency and the depleting fossil fuels has motivated researchers to investigate alternatives to conventional ICE-based vehicular systems. Among the alternatives, FC-powered electric vehicles using hydrogen as fuel are considered as the ultimate route to achieving sustainable long-term alternative propulsion systems [16]. Hydrogen is an energy carrier with many important unique features. It is considered as the lightest, most efficient, and cleanest fuel. One of its unique features is that it can be converted to electricity in FCs through electrochemical processes with higher efficiencies than conversion of fossil fuels to mechanical energy in ICEs. Thus, this particular characteristic allows higher efficiency and practically null emission of polluting agents for FC-powered vehicles compared with ICE-based vehicular systems. Particularly, these efficiency and environmental friendliness advantages become more significant when renewable energy sources such as wind and solar are used for hydrogen production. In particular, passenger vehicles are mostly operated at part loads significantly below their rated power; thus, vehicle running in urban or suburban areas demands a small fraction of the rated FC power most of the time. Thus, the efficiency of the overall system becomes higher as the FC is operated most efficiently. This issue is exhibited by Villatico and Zuccari [59] by comparing the performance of FC and ICE in real driving cycles. Moreover, FC-based vehicles have medium- and long-term potential to be the mainstream vehicle in the future because they have almost zero emission and compatible driving range to ICE-based vehicles [1,5,55]. For real utilization of EVs, many features should be considered, such as performance, cold start, reliability, durability, cost, and fueling/charging times, availability, and infrastructure [13,18]. Both FC and battery EVs have similar components, like driving motors, power conditioners; also, they will coexist in the future. The FCEV is a promising solution because of faster refueling, cold starting, faster warming up to operating temperature and longer driving range features compared with BEV [24,25,60]. Generally, the FCEVs are proper for midsize and long-range vehicles, while the BEV is suitable for small-size and short-range vehicles [5].

Among the various available FC types, PEMFC is the most likely candidate for automotive applications, thanks to its several attractive features, such as low operating temperatures, relatively low cost and quick start-up, simplicity, viability, packaging under the hood of vehicle, and high efficiency [55]. However, the unsteady operation of a vehicle may not be appropriate for the usage of a sole FC system. Moreover, a FC system (in the power train of an automotive) needs to be equipped with the combination of ESS, driving motor, converters, and various auxiliary devices [23]. The power demand of a vehicle motor undergoes significant variations due to acceleration, changes in road surface and traffic conditions. Thus, a sole FC system may not totally satisfy the power demand of a vehicle due to the limitation of fuel cells to track fast load variations because of their slow response dynamics. Besides, load demand fluctuations in vehicle operation may cause fuel starvation, flooding, membrane drying, and pressure imbalance across the FC membrane, which may damage the FC stack and decreases its lifetime [61]. Moreover, an advanced energy management strategy is necessary to split the power demand of a vehicle in a suitable way for the onboard power sources in order to maximize the performance while promoting the fuel economy and endurance of hybrid system components.

33.5.1 Design Architectures for PEMFC Powered Hybridizations

In general, FCEVs are configured as series vehicles [60]. However, the architecture of a FCEV can be configured in series, series-parallel, and parallel. The selection of the hybrid power-train topology is very important for an efficient operation and better market penetration of FCEV systems. Effective and efficient power conversion technologies are strategic for the progress of FCEVs [62]. Interfacing the load/power-train unit requirements with the different operational modes of onboard generation and storage systems call for suitable power electronic converter configuration and control. The selection of power-conditioning unit for hybrid systems including PEMFC is based on some significant factors like lower cost, space requirement, compact structure, higher efficiency, electric isolation, and ripple-free and reliable operation [15,62].

Despite the fact that hybridization concept brings remarkable benefits, the main challenge is to find the appropriate combination of energy sources. Each energy source has unique characteristics and energy conversion efficiency. Thus, each combination is expected to show different performance, efficiency, and fuel/energy consumption. Moreover, in a hybrid topology, these energy sources can be connected to dc bus either directly or via a power converter. In case of utilizing a power converter, which allows higher flexibility in load sharing, an improved hydrogen economy may be expected. However, system efficiency may decrease due to additional conversion stage, which might worsen the equivalent fuel economy.

Considering the abovementioned factors and the load/drive-train requirements, various topologies may be used for the operation of PEMFC hybrid systems. One of the simplest architectures for the parallel operation of PEMFC hybrid systems includes the direct integration of PEMFC system with the auxiliary power unit as shown in Fig. 33.9. During low power demand, the FC system generates up to its load limit, and the excess energy between the load demand and the FC output power is used to charge the auxiliary unit. In this period, the S1 switch is closed, and S2 switch is open. During high-power-demand periods, both the FC system and the auxiliary units supply the load demand. During this period, S1 switch is kept open, and S2 switch is closed. The direct integration topology is attractive, because it does not require a high-power dc/dc converter; thus, the complexity, cost, weight, and volume of the system are significantly reduced [15]. For example, the UC system integration can be achieved with or without power electronic converter via series and parallel connection. Because of the high specific power and power density of UC bank, it may be possible to eliminate the dc/dc converter for voltage regulation so that it can deliver higher output. This topology is proposed by Honda [63] for a combined PEMFC-/UC-powered vehicular system. Also, the direct integration of the FC with the UC bank is possible for relatively low-voltage applications with a dc bus of less than 50 V [64]. The UC bank and the load terminal voltages depend on the FC system terminal voltage, which prevents the power capability of the UC bank from being fully utilized. Therefore, the UC bank size is restricted by the terminal voltage of the FC system, as in the battery/UC hybrid system of Ref. [65].

Different designs of a topology with only one dc/dc converter unit are shown in Figs. 33.10 and 33.11. The topology in Fig. 33.10 regulates the output power of the FC system, while the rest of the energy between the load demand and the FC output power is naturally supplied by the auxiliary unit. Besides, the topology in Fig. 33.11 is based on the regulation of the auxiliary system output power or the regulation of the DC bus voltage. There are many studies in the literature using these two topologies. Some previous studies on these topologies are reviewed and summarized in Ref. [15].

The most common topology for hybrid systems is composed of multiple dc/dc converters as shown in Fig. 33.12. In this kind of topology, the dc/dc converter of one of the available power sources is employed for the dc bus voltage regulation, which is called voltage-oriented-control, and the rest of the converters are controlled for power tracking by power-oriented-control methodology. Thus, the proposed power-conditioning unit provides the capability of delivering the desired power value from the hybrid power sources while keeping the bus voltage

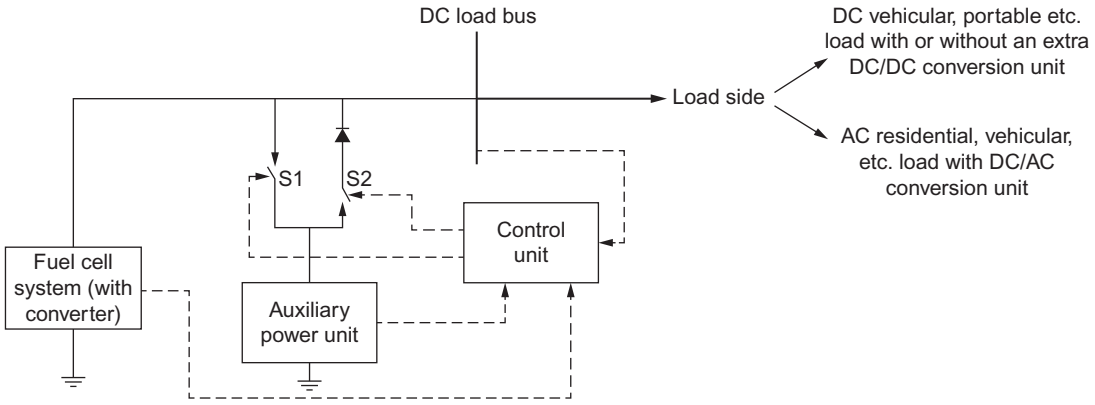

FIG. 33.9 Direct integration topology [15].

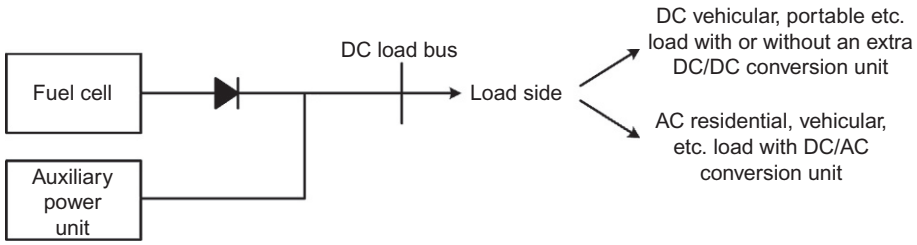

FIG. 33.10 Single converter-based topology [15].

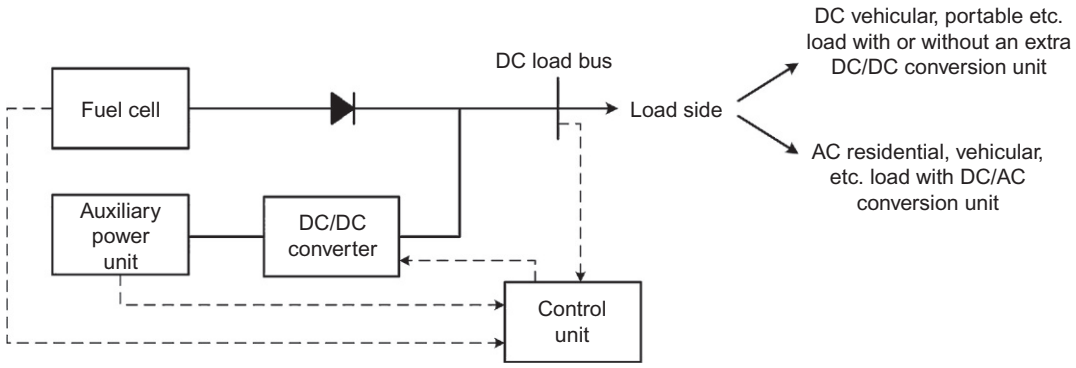

FIG. 33.11 Single converter-based topology [15].

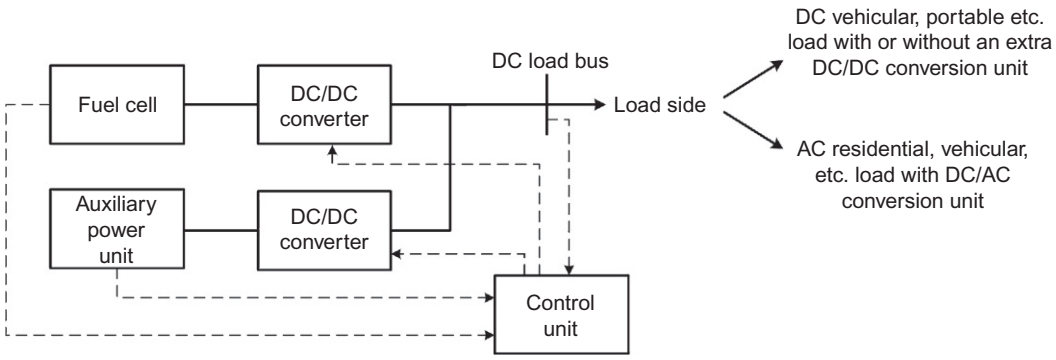

FIG. 33.12 Multiple converter-based topology [15].

at a desired level. Additional architectures for the usage of multiple converter topologies for transportation area are available in Refs. [53,66–70].

Combining the features of multiple converter-based topology, some researchers focused on utilizing multiple-input single-output design architecture as depicted in Fig. 33.13. This topology provides the advantage of reduced number of elements (multiple inputs of power sources can be connected to a dc bus via only one output capacitor) used in power electronics interface design. For example, Ferreira et al. [71], Perez et al. [72], and Napoli et al. [73] utilized the multi-input converter topology for an electric vehicular system consisting of PEMFC, battery, and UC.

The design of the abovementioned single- or multi-input converters can be realized as insulated or uninsulated, unidirectional, or bidirectional according to the area of application. The basic uninsulated unidirectional and bidirectional dc/dc converter topologies are shown in Fig. 33.14. The proposed multi-input and bidirectional converter-based PCU offers the following advantages:

- Voltage levels of the input power sources can be different.
- The input sources can deliver the requested power individually and simultaneously.
- Electrically isolation prevents damage on input sources.
- The proposed PCU can work bidirectionally, that is, the power can flow in either direction between individual input and output.

However, there are different advanced, more advantageous but complex topologies developed by power electronics researchers [15].

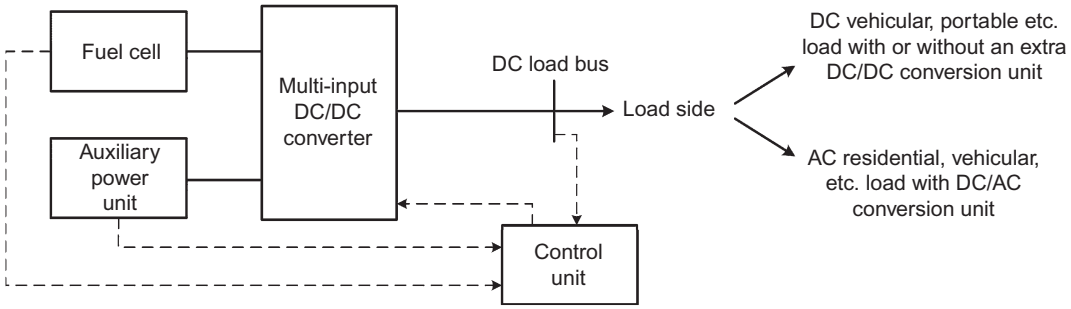

FIG. 33.13 Multi-input converter-based topology [15].

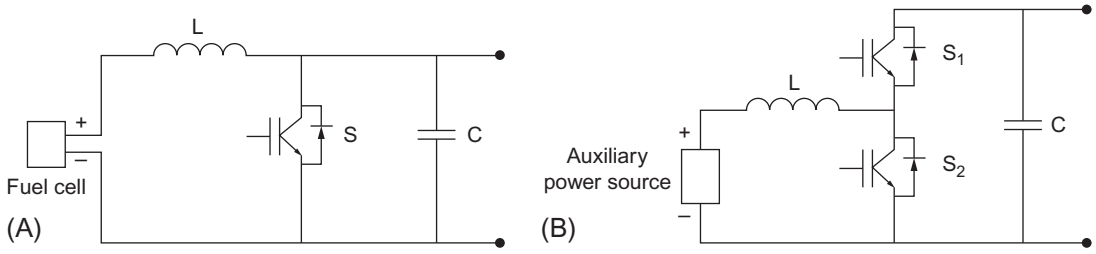

FIG. 33.14 Structures of the basic dc/dc converter topologies: (A) boost converter topology and (B) bidirectional converter topology [15].

33.5.2 Vehicular Power Control Strategy and Energy Management

Due to the different characteristics of multiple power sources, the efficiency and the fuel economy of hybrid systems mainly depend on proper energy management strategy (EMS), which is very important for PEMFC-powered hybrid systems.

An FCEV energy control system must provide good acceleration and high recovery of braking energy. The power sharing between the FC system and energy storage system (battery or UC bank) is determined according to the load sharing and control algorithm. Main requirements of the control algorithm are satisfaction of the power demand and management of the power flow in accordance with efficient operation of the different power sources. Coupled with this, the control system should utilize the FC system and energy storage system to match the vehicle load profile by considering different features of power sources.

Since stable operation of the FC system is vital for efficiency, lifetime and cost, FC system should deliver the base load power without responding to peak power demand. Another purpose of the control system is to adopt the battery or UC bank in stabilizing the dc link voltage. This enables power transfer to/from battery or UC bank and improves the driving performance.

Hybrid systems can provide improved efficiency when a well-designed energy splitting algorithm that considers the individual characteristics of each hybrid system is applied. There are many techniques for energy management that have been investigated in the literature, such as intelligence-based strategies, optimization-based strategies, and frequency decoupling strategies [74].

33.5.2.1 Intelligence-based Energy Management

Recently, many intelligence-based energy management strategies such as fuzzy logic, and neural networks for use in PEMFC-powered systems, have been reported in the literature [15]. Among them, fuzzy logic controller (FLC)-based methodology plays a dominant role due to its independence of a full mathematical plant model and training procedure. Nonlinearity and difficulties in proper identification of parameters of the plant mathematical models limit the use of model-based conventional control approaches.

Fuzzy logic provides suitable structure compared with conventional control methods especially for the systems comprising nonlinear behaviors where an overall mathematical model is difficult to obtain. Moreover, there is no need for historical data, which is an important advantage over other types of intelligent controllers such as neural networks. Thus, FLC provides a suitable structure especially for systems composed of nonlinear behaviors.

In the literature, many researchers applied fuzzy logic approach for hybrid systems with PEMFC for different applications. Among them, Gao et al. [75] provided the power distribution in a hydrogen-powered hybrid bus composed of PEMFC as the main power source and battery/UC combination as the auxiliary unit. In [15], FLC utilized the SoC values of auxiliary units and the required power demand of the bus as inputs for determining the output power values of FC and UC systems. Erdinc et al. [53,67] regulated the energy management in PEMFC/UC and PEMFC-/battery-/UC-powered hybrid vehicular systems using fuzzy logic. The aforementioned architectures [53,67] utilized the SoC values of battery and/or UC

units and a transient-free form of the vehicular power demand, provided by a load-sharing algorithm, based on standard drive cycles as inputs and gave the requested power value from PEMFC system as output. Li et al. [76] proposed a FLC design for a PEMFC/Battery hybrid system with a similar structure to Erdinc et al. [67]; however, they optimized the parameters of their FLC for an optimal energy control. As a contribution to the studies of Erdinc et al. [53,67] and Li et al. [76], Eren et al. [77] inserted the control of internal dynamics of PEMFC system in the fuzzy-logic-based energy management approach in order to provide a safe and efficient operation for PEMFC. Kisacikoglu et al. [78] directly controlled the duty cycles of the converters of PEMFC and UC as the outputs of the FLC in a PEMFC/UC hybrid vehicular system.

Another intelligent method used for the control of hybrid system is the neural network approach. Comparing neural network with one of the most popular intelligence-based technique, fuzzy logic, this quick-response capability provides a significant advantage. Fuzzy logic approach does not need a training procedure; however, the rule-based fuzzy structure makes it longer to respond compared with neural network approach. Thus, neural network control may be a competitive approach with fuzzy logic for some applications. Besides, the abovementioned features would lead the neural networks to solve complex problems precisely and flexibly and provide a suitable basis for the control of complex systems. Consequently, neural network has demonstrated remarkable success in control area [15].

33.5.2.2 Optimization Based Strategies for Energy Management

Power management and control system is very important for improving energy efficiency, vehicle performance, and for reducing the weight, size, and cost. Various flexible control methods and intelligent techniques are used for optimization, subject to system constraints. The power management system not only optimizes the available sources but also manages the load dynamically, based on the need and priority of the demand. In these types of energy management approaches, the optimal reference power signals for onboard power sources are calculated by the minimization of a cost function. This cost function generally represents the fuel consumption or emissions especially for vehicular applications. If this optimization is performed over a fixed driving cycle, a global optimum solution can be found. Many approaches such as optimal control theory, linear programming, dynamic or stochastic programming, genetic algorithm, simulated annealing, linear and nonlinear predictive model, and game theory are utilized for solving the aforementioned global optimization problem.

There is significant number of studies dealing with the energy management of an FC-powered hybrid system utilizing an optimization-based methodology [79,80]. For example, Rodatz et al. [79] presented an experimentally applied equivalent fuel consumption minimization strategy aiming at minimizing the hydrogen consumption while maintaining drivability in a PEMFC/UC hybrid vehicular system. Xu et al. [80] performed a similar optimization approach for an FC/battery hybrid bus. Similar fuel consumption minimization-based approaches were also utilized by Paladini et al. [81] for FC/battery/UC hybridization for a vehicle in a simulated environment.

33.5.2.3 Frequency Decoupling Based Energy Management Strategies

During the daily operation of a system, load transitions may occur frequently. The load power profile is a nonstationary signal and consists of transients. The wavelet transform can be effectively used for analyzing power transients in FCEV power demand profile, because of its ability to deal with nonstationary and/or transient signals. A given signal can be decomposed into transients and desired characteristics can be extracted simultaneously in both the time and frequency domain by using the wavelet transform (WT). The WT decomposes into various components at different time intervals and frequency bands as a windowing technique. In wavelet analysis, long windows are used at low frequencies, and short windows are also used at high frequencies.

One of the most popular mother wavelets is Haar wavelet for detecting and localizing of transients. The Haar basis has the shortest filter length in the time domain in comparison to other wavelet bases. Because of the abovementioned features, the Haar wavelet transform is the most suitable functions for filtering HEV power demand load profile, which consists of transients corresponding to sharp peak power demand. The transients of the HEV power demand signal is clearly observed from the short-term frequency and component magnitude changes.

For some applications like vehicular systems, these transient changes in load demand may occur significantly, which pose dynamic stress onto the FC membrane due to pressure oscillations and possible fuel starvation, which may reduce the lifetime of the FC system. Thus, to ensure FC lifetime prolongation by preventing the FC system from load changes with high frequencies, researchers applied different frequency decoupling techniques. The basic approach for this issue is inserting a transfer function for a delay with a suitable time constant (first-order low-pass filter). Liu et al. [82] proposed such a first-order filter for PEMFC system. Besides, some conventional filtering techniques like Butterworth high- and low-frequency filters have been utilized. These conventional filters decouple the main signal with a predefined cutoff frequency; thus, the FC system can be prevented from transient variations. However, the loss of important edge information is a significant phenomenon in conventional filtering techniques. Considering this issue, some researchers applied a wavelet-transform-based frequency decoupling strategy for PEMFC-powered systems. Wavelet transform is a signal processing method that is well known for its capability to treat transient

signals. The advantage of wavelet analysis, as opposed to conventional techniques, is that wavelet transform decomposes a signal into a series of short duration waves or local basis functions (wavelets) on the time axis, which allows the analysis of local phenomena in signals consisting of many transients. Besides, wavelet transform provides a quadratic mirror filtering application and the loss of important edge information is minimized compared with conventional filtering techniques. Considering these features of wavelet transform, Uzunoglu and Alam [83] applied a wavelet-based energy management strategy for a PEMFC/UC hybrid vehicular system. A similar wavelet-based approach was utilized by Zhang et al. [66] for a PEMFC/battery/UC hybrid system.
