33.3.3.9.1 The Cleaner Step. The cleaner is composed of a solvent, an acid and a surfactant. The solvent removes organic surface residues by dissolution. The acid removes oxidation and the surfactant wets the surface. The wetting is very important when plating small high aspect ratio holes or blind vias; a well wetted surface will not trap air. Intermittent vibration in this step is helpful to ensure that all air is dislodged from tight spaces. Follow vendor’s recommendations of concentration, temperature, dwell time

and dump and remake schedule to ensure the cleaner functions as intended. Good two-step rinsing is important after the cleaner as its components in trace amounts, if dragged down the line may adversely affect the plating.

33.3.3.9.2 The Microetch Step. The microetch is made up with a strong oxidant like sodium persulfate or hydrogen peroxide in a sulfuric acid medium. The microetch oxidizes the surface copper and literally etches it away exposing a fresh copper surface for plating. If the metallization used is electroless copper; the concentration and dwell time should be controlled to ensure that the electroless copper is not etched away. In addition the microetch can undercut minute stubborn residues that the cleaner did not remove. Concentration, temperature, dwell time and dump and remake schedule must be adhered to. The panels are double rinsed after the microetch.

33.3.3.9.3 The Predip Step. The predip is made up with sulfuric acid at 5 to 10 percent. This step ensures that the surface is oxidation free and is acidic to match the acidity of the electrolyte. There is no rinse between the predip and the acid copper bath.

33.4 TIN ELECTROPLATING

The primary use of tin electroplating in printed wiring board (PWB) manufacturing is as an etch resist after panel or pattern plating. The tin plate is the final step in pattern definition. The process starts with defining the pattern to be copper plated using a photoimageable resist. The plated copper pattern is then plated with a coating of tin. The panel is then resist stripped and the exposed laminate copper is then etched away, leaving the desired circuit with its tin coating. The final circuitization step is tin stripping.

33.4.1 Acid Tin Sulfate

This is the most widely used system. The key here is to ensure complete coverage; usually 0.3 mil (7.5 µm) of tin are deposited on the traces and the holes. This is a sacrificial layer that is not part of the finished PWB. After final etch the tin is stripped. Table 33.3 describes the operation and control of the tin sulfate bath.

TABLE 33.3 Acid Tin Sulfate
Operation and control

Operating conditions:	
Tin	2 oz/gal
Sulfuric acid	10–12% by volume
Carrier, additives	Replenish based on Ah usage or spectrophotometric analysis
Temperature	65–85°F
Cathode current density	10–30
Current efficiency	100%
Plating rates	7.8 Ah for 1.0 mil/ft^2
Anodes:	
Type	Bars
Composition	Pure tin
Bags	Polypropylene
Hooks	Monel or titanium
Length	Rack length minus 2–3 in
Current density	5–20 A/ft^2

33.4.1.1 Process Controls

33.4.1.1.1 Agitation. A filter pump circulates the solution without allowing air to be introduced. Cathode rod agitation is recommended for thru hole plating.

33.4.1.1.2 Filtration. A 3- to 10-µm polypropylene filter is needed to control excess cloudiness and sludge formation.

33.4.1.1.3 Temperature. Operate at the temperature recommended by the supplier.

33.4.1.1.4 Carbon Treatment. Continuous carbon filtration at room temperature is recommended to remove organic contaminants/buildup.

***33.4.1.2 Common Contaminants*.** These include three groups of contaminants.

- *Organic :* These come from additives and breakdown of resist. The solution may require carbon filtration or treatment; based on its carbon content.
- *Metal:* The effects of metallic contaminants on the plated deposits and the maximum levels allowable are as follows: copper darkness, 5 to 10 ppm; cadmium dullness, 50 ppm; zinc dullness, 50 ppm; nickel streaks, 50 ppm; iron dullness, 50 to 120 ppm; and chromium dullness, 5 ppm. Metallic contaminants may be removed by dummy plating at low current density (2 to 5 ASF).
- *Nonmetal:* The maximum allowable level for the chloride ion is 75 ppm.

33.4.1.3 Solution Controls

- Use electronic grade chemicals to avoid metallic impurities like Cd, Zn, or Fe.
- Maintain the appropriate levels for the organic additives.
- Ensure adequate rinsing after plating.
- Ensure the tin has a visual lustrous finish.

33.4.1.3.1 Bath Control. Stannous sulfate and sulfuric acid are maintained by chemical lab analysis. Additives may be controlled by spectrophotometric analysis, Ah usage, or hull cell.

33.4.1.4 Problems with Tin Electroplating

33.4.1.4.1 Dull Deposits. These are due to an out-of-balance condition of the main solution constituents, that is, low acid (<10 percent), high tin (>3 oz/gal), improper additive levels, contamination by metals or chlorides, or high temperatures (>65°F).

33.4.1.4.2 Peeling Tin. Tin peeling is attributed to low acid concentration (<10 percent) and or organic contamination.

33.4.1.4.3 Slivers. These are caused by overetching. A review of etching practice is indicated, as well as the use of reduced thickness copper foil.

33.4.1.4.4 Pitting. If the substrate is not the cause, check precleaning, solution balance and contaminants, current efficiency, and current densities. High-current densities may cause pitting.

33.5 NICKEL ELECTROPLATING

Nickel plating is used as an undercoat for precious and nonprecious metals. For surfaces such as contacts or tips that are normally subjected to heavy wear, the uses of nickel under a gold plate will greatly increase wear resistance. When used as a barrier layer, nickel is effective in preventing diffusion between copper and other plated metals. Nickel-gold combinations are frequently used as final finishes for soldering, contacting and wire bonding. MIL-STD-275 calls for a low-stress nickel with a minimum thickness of 0.0002 in. Low-stress nickel deposits are generally obtained using

nickel sulfamate baths in conjunction with wetting (antipit) agents. Additives are also used to reduce stress and to improve surface appearance.

33.5.1 Nickel Sulfamate

Nickel sulfamate is commonly used both as an undercoat for through-hole plating and on gold finger tabs.

Conditions given in Table 33.4 are applicable for through-hole and full-board plating.

TABLE 33.4 Nickel Sulfamate
Operation and control

Operating conditions:	
pH	3.5–4.5 (3.8)
Nickel	10–12 oz/gal
As nickel sulfamate	43 oz/gal
Nickel chloride	4 oz/gal
Boric acid	4–6 oz/gal
Additives:	
Brightener	As required
Antipit (Wetter)	As required
Temperature	130 ± 5°F
Cathode current density	20–40 ASF
Anodes:	
Type	Bars or chunks
Composition	Nickel
Purity	Rolled depolarized, cast, or electrolytic; SD chips in titanium basket
Hooks/baskets	Titanium
Bags	Polypro, or Dynel
Length	Rack length minus 3–4 in

33.5.1.1 Process Controls

33.5.1.1.1 pH. With normal operation, pH increases. To lower pH, use sulfamic acid (not sulfuric acid). A decrease in pH signals a problem; anodes should be checked.

33.5.1.1.2 Temperature. The preferred temperature is 125°F. Low temperature may cause stress and high current-density (CD) burning. Higher temperatures decrease the hardness of the nickel deposit.

33.5.1.1.3 Agitation. Solution circulation between panels is achieved through the filter pump and/or cathode rod agitation.

33.5.1.1.4 Filtration. This is done continuously through 5 to 10 µm polypro filter, which is changed periodically based on utilization.

33.5.1.1.5 Deposition Rate. For 0.5 mil, plate 25 to 30 min at 25 A/ft^2. For 0.2 to 0.3 mil, plate 15 min at 25 A/ft^2.

33.5.1.1.6 Common Contaminants

Metals: The following are the maximum allowable metal contaminants: iron, 250 ppm; copper, 10 ppm; chromium, 20 ppm; aluminum, 60 ppm; lead, 3 ppm; zinc, 10 ppm; tin, 10 ppm; and calcium, 0 ppm. These metal contaminants lower the deposition rates and cause nonuniform plating. Copper and lead cause dark, brittle deposits at low CD. Dummy-plate at 3 to 5 A/ft^2. Iron, tin, lead, and calcium cause deposit roughness and stress.

Organics: These cause pitting, brittleness, step plating, and lesser ductility.

Sulfates: These cause solution breakdown and should not be added.

33.5.1.1.7 Carbon Treatment. This process is used to reduce the organic contamination in the electrolyte.

Circulate through a carbon canister for 4 h (more than one canister may be required) or batch-treat to remove organics. The basic six steps to batch-carbon-treat are as follows:

1. Transfer to the treatment tank. Do not adjust pH.
2. Heat to 140°F.
3. Add 3 to 5 lb carbon per 100 gal of solution.
4. Stir 4 h at temperature.
5. Let the solution settle 1 to 2 h.
6. Filter the solution back to plating clean tank.

33.5.1.2 Common Problems. A Hull cell Plated at 2 A for 10 min. with gentle agitation is a useful tool for evaluating the deposit, the condition of the bath and contaminants.

33.5.1.2.1 Visual Observation. The plated metal has a matte, dull finish. Burned deposits are caused by low temperature, high-current density, bath imbalance, and poor agitation. Rough deposits are due to poor filtration, pH out of spec, contamination, or high-current density.

33.5.1.2.2 Pitting. This is caused by low antipit, poor agitation or circulation, boric acid imbalance, or the presence of organics. In testing for antipit, the solution should hold bubble for 5 s in a 3-in wire ring and for less than 5 s in a 5-in ring. In the case of severe pitting, cool to room temperature, add 1 pt/200 gal hydrogen peroxide (35 percent), bubble air, and reheat to 140°F. Carbon-treat the solution to remove additional organics. Adjust pH before restarting.

33.5.1.2.3 Stress. This refers to the cause of deposit cracking. Although low nickel chloride causes poor anode corrosion (a rapid decrease in nickel content), high chloride causes excess stress. To prevent this, maintain pH, current density, and boric acid for control below 10 kpsi.

33.5.1.2.4 Burns. A low concentration of nickel sulfamate causes high-current-density “burns.”

33.5.2 Nickel Sulfate

This is typically plated with an automatic edge connector (tab) plating machine. Table 33.5 gives the operating conditions that apply to these systems. For additional instruction, follow the details in nickel sulfamate section above.

TABLE 33.5 Nickel Sulfate
Operation and control

Operating conditions:	
pH	1.5–4.5
Nickel	15–17 oz/gal
Nickel chloride	2–4 oz/gal (with soluble anodes)
Boric acid	5–7 oz/gal
Stress reducer	As required
Antipit	As required
Temperature	130 ± 5°F
Cathode current density	100–600 A/ft^2
Current efficiency	65%
Anodes:	
Composition	Nickel or platinized titanium

Nickel anodes are preferred in tab plating equipment because the pH and the metal content remain stable. The pH will decrease rapidly when insoluble anodes are used. The pH should be maintained at 1.5 or higher with additions of nickel carbonate. Stress values are higher than in sulfamate baths, with values of about 20 kpsi.

33.6 GOLD ELECTROPLATE

Early PCB technology used gold extensively. In addition to being an excellent resist for etching, gold has good electrical conductivity, tarnish resistance, and solderability after

storage. Gold can produce contact surfaces with low electrical resistance. In spite of its continued advantages, the high cost of gold has restricted its major application to edge connectors (tabs) and selected areas, with occasional plating on pads, holes, and traces (full build). Both hard-alloy and soft, pure gold, are currently used. Plating solutions are acid (pH 3.5 to 5.0) and neutral (pH 6 to 8.5). Both automatic plating machines for edge connectors and manual lines are in use.

33.6.1 Acid Hard Gold

To a large extent, acidic gold solutions are used for compliance to MIL-STD-275, which states that gold shall be in accordance with MIL-G-45204, Type II, Class 1. The minimum thickness shall be 0.000050 in (50 µin); the maximum shall be 0.000100 in. Nonmilitary applications require 25 to 50 µin. A low-stress nickel shall be used between the deposited gold and copper substrate. Deposit hardness and wear resistance are made possible by adding complexes of cobalt, nickel, or iron to the bath makeup. Type II hard gold is not suited for wire bonding. These systems use potassium gold cyanide in an organic acid electrolyte. Automatic plating equipment are being used increasingly because of the enhanced thickness (distribution) control, efficient gold usage, productivity, and quality. A comparison of automatic versus manual plating methods for edge connectors is given in Table 33.6.

TABLE 33.6 Acid Gold-Cobalt Alloy
Operation and control

	Manual	Automatic
Gold content, troy oz/gal	0.9–1.1	1–3
pH	4.2–4.6	4.5–5.0
Cobalt content	800–1000 ppm	800–1200 ppm
Temperature	90–110°F	100–125°F
Solution density	8–15 Be°	12–18 Be°
Replenishment per troy oz gold	8 Ah	6.5 Ah
Current efficiency	50%	60%
Agitation	5 gal/min	50 gal/min
Anode-to-cathode distance	3–5 in	1.4 in
Anodes, composition	Platinized titanium	Platinized titanium
Cathode current density	1–10 A/ft^2	50–100 A/ft^2
Thickness	40 ± 10 µin	40 ± 2 µin
Deposition rate for 40 µin	3–6 min	0.3–0.6 min
Deposition composition	99.8% gold, 0.2% cobalt	99.8% gold, 0.2% cobalt
Hardness	150 Knoop	150 Knoop

Gold solution: Maximum allowed metal contaminants

Metal	Maximum ppm	Metal	Maximum ppm
Lead	10	Iron	100
Silver	5	Tin	300
Chromium	5	Nickel	300–3000
Copper	50		

33.6.1.1 Process Controls

33.6.1.1.1 Analysis. Gold content, pH, and density should be maintained at optimum values. Operation at very low gold content causes early bath breakdowns with loss of properties, less current efficiency, and less cost savings. The pH is raised by using potassium hydroxide and is lowered with acid salts. Solution conductivity is controlled by density, which is adjusted with conductivity salts. Hull cell is not recommended for this purpose.

33.6.1.1.2 Anodes. Platinized titanium should be replaced when operating voltages are excessive or when thick coatings develop on the anode surfaces.

33.6.1.1.3 Recovery. Plating solutions should be replaced when contaminated, when plating rates decrease, or after about 10 total gold content turnovers.

33.6.1.1.4 Problems. Difficulties can be controlled by proper gold bath and equipment maintenance. Some typical situations follow:

Discolored deposit: This may be due to low brightener; to metal contaminants such as lead, low pH, low density, or organic contaminations; or to leaking from tape. Gold plate is stripped to evaluate nickel. For these problems, first try to lower the pH, raise the density, or increase the brightener before replacing the bath or using decreased current densities.

Gold peeling from nickel: This is generally due to inadequate solder stripping, leaky tape, or poor nickel activation. Methods to increase nickel activation include increasing acid strength after nickel plating and using a fluoride activator, or the use of a gold strike. A gold strike that is compatible with gold plate and has low metal content and low pH is available. Its main purpose is to maintain adhesion to the nickel substrate.

Wide thickness range: To improve thickness distribution of the gold deposit; improve the solution movement between panels; clean, adjust, or replace anodes; and adjust or replace the solution.

Low deposition rate: This is characterized by excessive gassing and low efficiencies. To correct this condition, adjust solution parameters and check for contaminants such as chromium.

Pitting: Strip gold and evaluate the underlying nickel by cross-sectioning.

Resist breakdown: Low current efficiencies cause this condition. Use solvent-soluble screened or dry film for best results.

33.6.1.2 Pure 24-Karat Gold. High-purity 99.99 percent gold processes are used for boards designed for semiconductor chip (die) attachment, wire bonding, and plating solder (leaded) glass devices, for their solderability and weldability. These qualities comply with Types I and III of MIL-G-45204. The processes are neutral (pH 6 to 8.5) or acid (pH 3 to 6).

Table 33.7 gives typical conditions for a neutral bath.

TABLE 33.7 Neutral Pure Gold
Operation and control

Gold content	0.9–1.5 troy oz/gal
pH	6.0–7.0
Temperature	150°F
Agitation	Vigorous
Solution density	12–15 Be
Current efficient	90–95%
Cathode current density	1–10 A/ft^2
Deposition rate @5 ASF	100 µin in 8 min
Deposit composition	99.99% + gold
Hardness	60–90 Knoop

33.6.2 Alkaline, Noncyanide Gold

Various processes for alloy and pure gold deposits are available. Solutions are based on sulfite gold complexes and arsenic additives and operate at a pH of 8.5 to 10.0. A decision to use this process is based primarily on the need for uniformity (leveling), hardness (180 Knoop), purity, reflectivity, and ductility. PC board use is limited to body plating, since wear characteristics of the sulfite-gold are not suitable for edge connector applications. The microelectronics industry uses these processes for reasons of safety and gold purity. Semiconductor chip attachment, wire bonding, and gold plating on semiconductors are possible applications and are enhanced by using plating without metallic additives.

33.6.3 Gold Plate Tests

Several routine in-process and final quality control tests are performed on gold:

- *Thickness:* Techniques are based on beta-ray backscattering and x-ray fluorescence. Thickness and area sensitivity are as low as 1 µin with 5-mil pads.
- *Adhesion:* Standard testing involves a tape pull test.
- *Porosity:* Tests involve nitric acid vapor and electrographics.
- *Purity:* Lead is a common impurity that must be controlled to <0.1 percent. Other tests included discoloration by heating, electrical contact, and wear resistance.

CHAPTER 34
DIRECT PLATING

Hayao Nakahara
N.T. Information Ltd., Huntington, New York

34.1 DIRECT METALLIZATION TECHNOLOGY[a]

For 40 years the PTH process of choice has been palladium followed by electroless copper, but there have been at least 12 DMT processes challenging that established process, with several hundred installations, a significant percentage of the total number of PCB shops. The basic idea for the palladium systems dates back to the Radovsky patent of 1963,[1] which claimed a method of using an electrically nonconductive film of palladium in a semicolloidal form to directly metallize through holes in printed circuit boards. Radovsky's invention was never commercialized. The basic idea for the carbon/graphite systems dates back to the very early days of eyelet boards when Photocircuits was experimenting with graphite, silver, and other media to turn their single-sided PCBs into reliable double-sided boards.

34.1.1 Direct Metallization Technology Overview

From the many media and technical variations, some common elements have evolved.

34.1.1.1 DMT Common Elements. There are two elements common to all DMT:

1. Holes must be conditioned more specifically and thoroughly than for electroless copper.
2. Conductive media must be removed from the copper foil in a majority of the techniques (an exception is DMS-E).

It is understood that additional desmear steps are necessary or advisable when processing multilayer PCBs. Common elements to all horizontal conveyorized DMT systems are:

- Throughput is typically 6 to 15 min for a panel, with the next panel following 1 in behind
- Tremendous economies in rinse water use
- Lower consumption of chemicals
- Fewer steps than in its vertical mode
- Panel-to-panel uniformity

Many DMT processes work better than electroless copper on substrates with “difficult” resin systems such as PTFE, cyanate ester, or polyimide.

34.1.1.2 Direct Metallization Categories. DMT falls into four broad categories:

1. Palladium-based systems
2. Carbon or graphite systems
3. Conductive polymer systems

4. Other methods

34.1.2 Palladium-Based Systems

34.1.2.1 Palladium/Tin Activator with Flash Electoplating. EE-1,[2] the first commercialized direct metallization technique was invented in 1982 at Photocircuits and PCK. It uses a palladium/tin activator followed by mandatory flash electroplating. The flash-plating bath contains a polyoxyethylene compound to inhibit the deposition of copper on the foil surface without inhibiting deposition on palladium sites on nonconductive surfaces (holes, edges, substrate). Deposition occurs by propagation from the copper foil and grows epitaxially along the activated surface of the hole. Coverage takes about 5 to 6 min. This flash is pattern- or panel-plated subsequently to full thickness in any electroplating bath. Microetching is incorporated in the accelerator to remove palladium sites and nail heads from innerlayers. A special cleaner/conditioner is used. This process has never been adapted to horizontal equipment. (See Fig. 34.1.)

34.1.2.2 Palladium/Tin Activator with Vanillin. DPS[3] was invented in Japan in the late ’80s. This method uses a palladium/tin activator with vanillin, followed by pattern or panel electroplating. It employs a special cleaner/conditioner and a carbonate accelerator. The three key solutions—cleaner/conditioner, activator, and accelerator—all operate at elevated temperatures. DPS has recently been adapted to horizontal equipment, but works well in the vertical mode, both manual and automatic. Following the last step, the *Setter*, DPS yields a stable, grayish conductive palladium film in the holes. It is believed that the cleaner/conditioner slightly solubilizes the activator, attracting it to the nonconductive surface, and that the vanillin lines up the palladium molecules, and directs them towards the work, hence giving lower electrical resistance and better adhesion to nonconductive surfaces. It is also claimed that there is little palladium/tin left on the copper foil, so it is easily soft-etched away in the normal electroplating preplate cycle. (See Fig. 34.2.) DPS was the first DMT process to suggest an Ω meter as the standard quality assurance (QA) tool.

34.1.2.3 Converting Palladium to Palladium Sulfide.

Crimson,[4] invented by Shipley, employs a conversion step after the activator where palladium is changed to palladium sulfide, which is claimed to be more conductive for subsequent electrolytic copper plating. The *enhancer* stabilizes the conductive film so that it is chemically resistant to imaging steps. The *stabilizer* neutralizes residues from the enhancer, thereby preventing contamination of subsequent steps. The *microetch* selectively removes activator from copper surfaces to achieve optimum copper-to-copper bond and reliable dry film adhesion. The process works best in conveyorized horizontal equipment and can be followed by pattern or panel electroplating. (See Fig. 34.3.)

34.1.2.4 Process Variations. ABC,[5] invented in Israel by Holtzman et al., is similar to EE-1. It has been adapted to conveyorized horizontal equipment, but must be followed by a flash electroplating in a proprietary bath.

Conductron, from LeaRonal, is similar to DPS with the addition of a special cleaner/conditioner and a glass-etch step. It has been adapted to conveyorized horizontal equipment and can be followed by pattern or panel electroplating.

Envision DPS, from Enthone-OMI, and Connect, from M & T (now Atotech), are fairly similar to each other, and to DPS, though each has a specific cleaner/conditioner and modified accelerator. No adaptation has been made to horizontal processing. Both processes can be followed by pattern or panel electroplating.

Neopact,[6] from Atotech, uses a tin-free palladium activator in colloidal form. The subsequent postdip removes the protective organic polymer from the palladium, leaving it exposed and with increased conductivity. It has been adapted to conveyorized horizontal equipment, works well in vertical, and can be followed by pattern or panel electroplating. (See Fig. 34.4.)

34.1.3 Carbon/Graphite Systems

34.1.3.1 Carbon Suspensions. Black Hole,[7] the second direct metallization technique, was patented by Dr. Carl Minten in 1988 and pioneered by Olin Hunt, who sold their technology to MacDermid in 1991. MacDermid improved the process considerably and called it Black Hole II. Instead of palladium activator, Black Hole II uses carbon suspensions as its conductive medium. Polyelectrolyte conditioned nonconductive surfaces absorb carbon sites, and they "line up" after heating. To ensure sufficient conductivity, the carbon treatment is performed twice. Residues of carbon sites must be removed from the copper foil surface by a microcleaning step. Black Hole II has been well adapted to conveyorized horizontal equipment and can be followed by pattern or panel electroplating. (See Fig. 34.5.)

34.1.3.2 Graphite. Shadow[8] is from Electrochemicals (division of LaPorte Industries, UK, then OMG and now Platform Speciality) and uses graphite as its conductive medium. The process sequence of Shadow is very simple and involves fewer steps than most DMT. Electrochemicals and one of their fabricators, Eidschun Engineering, made the breakthrough in inexpensive, compact, conveyorized horizontal equipment, and the Shadow process is well adapted to this mode. It can be followed by pattern or panel electroplating.

34.1.4 Conductive Polymer Systems

34.1.4.1 DMS-E. DMS-E[9] from Blasberg is a second-generation DMS-2 process with which they pioneered in this field. DMS-1 was similar to EE-1. After microetch and conditioning, a potassium permanganate solution forms a manganese dioxide coating in the holes which acts as an oxidizing agent during subsequent synthesis reaction. In the catalyzing step, an EDT[b] monomer bath wets the manganese dioxide surfaces especially well. During the sulfuric acid fixation step, a spontaneous oxidative polarization takes place, forming a black conductive poly-EDT film on the nonconductive areas of the PCB. This technique is very suitable for use in conveyorized, horizontal equipment, since the oxidative conditioning step is very hot (80 to 90°C), and there are solvents involved. It can be followed by pattern or panel electroplating. (See Fig. 34.6.)

34.1.4.2 Compact CP. Compact CP[10] was developed by Atotech in 1987 and is essentially similar to DMS-E, except that it combines the catalyzing and fixation steps, it uses an acid permanganate, and the conductive film is a polypyrrole. The technique is very suitable for use in conveyorized, horizontal equipment. It can be followed by pattern or panel electroplating.

34.1.5 Other Methods

There are several other novel ways to metallize holes in PCBs, such as Phoenix and EBP from MacDermid, Schlötoposit from Schlötter. There are conductive ink and laser scribing/filling techniques; there are sputtering and sequential plating, to name a few, but they do not fall within the scope of this chapter.

34.1.6 Comparative Steps of DMT Process

34.1.6.1 DMT.1: Palladium-Based Systems. All vertical modes only, for comparison purposes, are shown in Table 34.1.

34.1.7 Horizontal Process Equipment for DMT

Although many DMTs fit easily into existing electroless copper lines, whether manual or automatic, and perform well in a vertical mode, DMT is becoming inextricably linked to horizontal processing in a conveyorized machine. Like so many inventions, necessity was its mother. Certain DMT processes are marginal in the vertical/basket mode, and handling each panel individually was the only solution. The advent of compact and inexpensive horizontal DMT equipment has been a catalyst. Although Atotech pioneered horizontal electroplating equipment with their Uniplate system, until the development of horizontal DMT machines it was not feasible to engineer a horizontal PTH machine. Now, however, for those who want only flash plating, or even full electroplating, the entire process—both PTH and galvanic—may be horizontal, conveyorized, and automated with the advantages of reduced chemical consumption; radically reduced use of rinse water; panel-to-panel uniformity, reliability, and quality; reduction in operating personnel; reduction of handling; a fully enclosed operating environment; and JIT delivery. Stackers/accumulators further minimize handling and optimize efficiency.

34.1.8 DMT Process Issues

Anything brand new experiences some “teething problems” at the beginning, and DMT is no different. But most of the processes referred to in this chapter are in at least their second generation and some are already in their third, so there are no serious contraindications to the use of DMT. However, there are a few caveats:

1. Esoteric base material does not run well with all DMT.
2. Not all DMT performs as well in the vertical mode as in the horizontal.
3. Certain DMT is better suited to the rigors of multilayer production.

4. Some perform better than others with very small holes.
5. Some processes are cleaner than others.
6. Certain DMT is more sensitive than electroless copper to organic contamination in electrolytic copper plating.
7. Rinsing is important, and some DMT needs special rinsing.
8. Rework is simple in most DMT, but it can be abused, i.e., it changes the cost structure.
9. Quality assurance tools for DMT (how do you know that holes will plate void-free?) are being developed, but at the moment, the only absolutely certain method is to flash electroplate, because, unlike electroless copper, there is not much to see in the hole after DMT.
10. Some DMT analyses and operating controls are rudimentary.

34.1.9 DMT Process Summary

Strong ecological and health reasons will drive the use of DMT for the manufacture of PTH boards. Since the cost of PTH metallization constitutes only 2 to 3 percent, at most, of the total process cost of a PCB, the direct saving resulting from DMT is very small. However, the fringe benefits of this technology are rather significant: water conservation, no noxious chemicals, minimal panel handling, reduced waste treatment, lower labor costs, fewer rejects, etc.

CHAPTER 35

PRINTED CIRCUIT BOARD SURFACE FINISHES

George Milad

Uyemura International Corporation, Southington, Connecticut

35.1 INTRODUCTION

35.1.1 Purpose and Functions of Surface Finishes

The printed circuit board (PCB) conductor surface finish is a critical element in the formation of the interface between the component and the interconnection circuitry. As its most essential function, the final finish process is intended to provide exposed copper circuitry with a protective coating in order to preserve solderability. In addition certain surface finishes provide a suitable wire bonding surface as well as an electrical contacting surface. Perhaps no other step in the PCB manufacturing process has undergone more change in the era of surface mount manufacturing than the final finish chemical process. A wide variety of functional,

environmental, engineering, cost, and productivity have contributed to this frequent change.

35.1.2 The Impact of Lead-Free Manufacturing

The impact of lead-free manufacturing, as a result of the Waste Electrical and Electronic Equipment (WEEE) directive and Restriction on Hazardous Substances (RoHS), has changed surface finish specifications for PCBs and the soldering of those surfaces at assembly. Lead-free assembly has changed just about every aspect of the surface finish technology. The elimination of lead (Pb) in most designs has rendered the standard surface finish hot air solder level (HASL) increasingly obsolete. At assembly, the use of new solder alloys affects the compatibility of the finishes with the metallurgy of the final solder joint. Many of the assembly issues related to surface finishes, such as surface-mount technology (SMT) pad wettability, plated through hole (PTH) fill, and voiding are exacerbated by the Pb-free assembly process. Finally, the higher temperature of Pb-free soldering has a major impact on the shelf-life and solderability of the Pb-free finishes.

35.1.3 Technology Drivers

Each company in the manufacturing supply chain has needs specific to its manufacturing step. The methods used to achieve these goals have evolved with developments in PCB technology. Historically, technicians were able to solder components directly to copper using very active fluxes. When PCBs were first made in large production quantities, chemists devised ways to protect the copper using metal or organic coatings. Electroplated tin-lead became a popular

coating as a metallic layer that could be subsequently reflowed. Design changes forced the era of solder mask over bare copper (SMOBC). With SMOBC, reflowed plated tin-lead was no longer possible because the tin-lead liquefies under the soldermask during the soldering process. HASL, the successor to plated tin-lead, became the surface finish of choice worldwide.

Increasing PCB circuit density and the need for co-planarity, inspired the reemergence of organic coatings, such as organic solderability preservatives (OSPs) and metallic layers such as electroless nickel/immersion gold (ENIG), immersion silver and immersion tin. For the highest functionality electroless nickel electroless palladium and immersion gold ENEPIG offers an even better alternative.

The environmental initiative to eliminate ozone-depleting chemicals led to the next change in surface finish preference. Use of no-clean assembly operations prompted a decline in OSP and an increase in metallic finishes.

35.1.4 Fabrication Requirements

The company producing the bare printed circuit board––that is, the PCB fabricator––has needs that are specific to that business, as follows:

- Inexpensive processing equipment and high throughput
- Electrically testable surface
- No attack on the soldermask
- No toxic chemicals (waste should be easily treated)
- Availability of technical service from supplier
- Reworkability
- Measurable performance
- No sensitivity to poor handling
- Long shelf-life

- Specified by most original equipment manufacturer (OEM) customers

35.1.5 Assembly Requirements

The assembly engineers, whether contract Electronics Manufacturing Services (EMS) provider, or independent original design manufacturer (ODM), have requirements that are very different from those of the PWB fabrication customer:

- Flat surface for stenciling paste
- Low contact resistance for in-circuit test (ICT)
- Tolerance for paste misprint cleaning
- Long incoming shelf-life (more than 1 year)
- Long mid-assembly shelf-life (more than 2 weeks)
- Compatibility with all pastes and fluxes
- Capability of bonding with Al and/or Au wire
- The ability to be visually inspected
- Ease of handling
- Excellent and predictable wettability
- Fiducial recognition
- No warp and twist of the PCB
- Good compliant pin and connector contacts
- Good Pb-free soldering with no need for nitrogen
- No solder bridging or plugged holes

35.1.6 OEM Requirements

The original equipment manufacturer has the following additional requirements:

- Best solder joint reliability; strong intermetallic

- Minimum impact on cost of bare board
- Corrosion resistance in uncontrolled field environments
- Usefulness as an electrical test point and EMI shield
- Functionality as a touchpad/keypad contact
- Good electrical performance of high-speed signals
- Adherence to industry specifications
- Complete documentation from the chemical supplier
- Established supply base of installed fabricators
- Audited fabricators

35.2 PWB SURFACE FINISHES

35.2.1 Surface Finishes Available in the PCB Industry

- HASL
- Reflowed tin-lead
- ENIG
- ENEPIG
- OSP
- Immersion silver
- Immersion tin
- Electroless palladium (Pd)
- Electrolytic nickel/electrolytic gold
- Electroless gold
- Direct immersion gold

Table 35.1 shows the common finishes and their typical thicknesses.

TABLE 35.1 Common Surface Finish Options with Typical Thickness

PCB Surface Finish		Typical Thickness
Hot air solder level		2–40 µm (80–1600 µin)
Organic solderability preservative (OSP)		0.1–0.6 µm (4–24 µin)
Electroless nickel/immersion gold (ENIG)	Nickel:	3–6 µm (120–240 µin)
	Gold:	0.04–0.12 µm (1–3 µin)
Electroless Ni/electroless Pd/immersion gold (ENEPIG)	Nickel:	3–6 µm (120–240 µin)
	Palladium:	0.08–0.3 µm (2 – 12µin)
	Gold:	0.04–0.12 µm (1–3 µin)
Immersion silver		0.1–0.4 µm (4–16 µin)
Immersion tin		0.6–1.2 µm (24–48 µin)

35.3 HOT AIR SOLDER LEVEL

Hot air solder level (HASL or HAL) is the process of immersing a circuit board into molten solder, immediately followed by blowing the excess molten solder out of the holes using hot air under high pressure. For the vast majority of HASL applications, the solder alloy is tin-lead. For Pb-free applications, the main alloys include tin-copper, tin-silver-copper, tin-copper-nickel, and tin-copper-nickel-germanium alloys. The thickness and texture of the HASL surface result from the surface tension of molten solder. As such, the thickness varies from 2 to 20 µm or more.

HASL boards demonstrate excellent shelf life, solderability protection, and resistance to poor handling, but they do tend to have higher levels of residual ions left over from fluxing. The HASL operation forms an intermetallic with copper circuitry at the PCB shop.

This extra thermal step, with the associated loss in copper, is a concern for Pb-free assemblies. Expansion of the PCB substrate at high temperatures can warp and/or twist the board. The dimensional movement, along with uneven pad flatness and plugged vias, makes assembling dense circuitry (less than 0.5 mm pitch) difficult or impossible. The worldwide decline of HASL is partly due to assembly concerns and partly due to Pb restrictions.

35.3.1 Fabrication Process

HASL can be applied in vertical or horizontal equipment. As a pretreatment, the copper is cleaned, microetched, and fluxed. It is common for the HASL pretreatment steps to be carried out in conveyorized equipment, and then the panel to be transferred to a vertical machine that dips the individual panel into molten solder. As the panel is raised, air knives blow off excess solder. Surface finishing engineers must be aware of safety concerns, such as exposure to Pb and the possibility of equipment fires. Newer horizontal conveyorized equipment provide a safer environment as well as a more planar surface.

To handle the very high temperatures of the molten alloy, equipment is manufactured from stainless steel, titanium, and other alloys. Aggressive rinsing is needed to remove flux residues, as the HASL process uses aggressive acid fluxes as compared to no clean fluxes used in other surface finish processes.

35.3.2 Benefits and Limitations

Benefits

- Inexpensive as compared to other finishes
- Forms the more reliable Cu/Sn intermetallic solder joint

- Widely available

Limitations

- It is a nonplanar finish
- Increases the overall thickness of the IMC
- May form solder bridging (fine pitch)
- High temperature immersion may damage the PWB

35.4 ELECTROLESS NICKEL IMMERSION GOLD

Electroless nickel immersion gold (ENIG) is an electroless nickel layer capped with a thin layer of immersion gold. It is a multifunctional surface finish, applicable to soldering, aluminum and copper wedge wire bonding, press fit connections, and as a contact surface. The immersion gold protects the underlying nickel from oxidation/passivation over its intended life.

The nickel layer forms a diffusion barrier preventing the diffusion of the underlying copper into the gold overcoat. The nickel also strengthens the thru hole by acting as a rivet. In addition the nickel protects the copper from dissolution into molten solder at assembly.

Chemically, gold is the ideal element for the external coating of PCBs. Gold does not form an oxide, so it is virtually unaffected by temperature and storage conditions that might reduce the shelf-life of other finishes. In addition, gold dissolves readily into solder, promoting superior wettability to the nickel substrate.

35.4.1 IPC-4552 ENIG Specification (2002)

The ENIG IPC-4552 Specification was issued in 2002, at that time the idea of lead free (LF) had not taken hold in the industry and tin lead was the dominant assembly solder in use.

For thickness IPC-4552 stated:

> The electroless nickel thickness shall be 3 to 6 µm [118.1 to 236.2 µin].
>
> The minimum immersion gold thickness shall be 0.05 [1.97 µin] at four sigma (standard deviation) below the mean; the typical range is 0.075 to 0.125 µm [2.955 to 4.925 µin]. There was no upper limit set.

No thickness upper limit was set for the immersion gold. The stated “typical range” was erroneously interpreted as the upper and lower limits of the specification.

The IPC ENIG Specification 4552 is presently under revision. The reason for the revision is related to present practices that expect immersion gold thickness in excess of 3 µin. IPC 4552 Rev A is presently in its final draft format awaiting peer review before issuance. The IPC4552 Rev A draft sets limits for immersion gold with a minimum of 1.6 µins to a maximum of 4.0 µins. The revision also contains a nickel corrosion (Black Pad) chart. The chart shows examples of acceptable corrosion, debatable corrosion and rejectable corrosion.

35.4.2 Chemical Definitions

35.4.2.1 Electroless Process. This chemical process promotes sustained deposition of a metal or metal alloy onto the PCB surface through an oxidation-reduction chemical reaction, without the application of an external electrical potential. Reducing agents, such as sodium hypophosphite or sodium formate, react at catalytic surfaces to release

electrons, which immediately reduce the positively charged metal ions (e.g., nickel ions in ENIG and ENEPIG and palladium ions in ENEPIG), promoting their deposition onto the PCB.

This type of reaction is described as “autocatalytic,” as the deposition process will continue even after the substrate is completely covered by a continuous layer of the plated deposit. The deposit thickness will therefore continue to rise in the presence of source metal ions and a reducing agent, until the board is removed from the plating bath. The thickness of plated deposits will vary depending on the bath temperature, chemical parameters (such as solution pH) and the amount of time spent in the plating bath.

35.4.2.2 Immersion Process. This chemical process uses a chemical displacement reaction to deposit a layer of a second metal onto a base metal surface. In this reaction, the base metal dissolves, releasing the electrons that reduce the positively charged ions of the second metal present in solution. Driven by the electrochemical potential difference, the metal ions in solution (e.g., gold ions in ENIG or ENEPIG process) are deposited onto the surface of the board, simultaneously displacing ions of the surface metal into solution.

This type of reaction will continue as long as the base metal is available to supply electrons to the displacement reaction.

35.4.3 ENIG Fabrication Process Sequence

1. *Cleaner:* The purpose of this step is to clean the copper surface in preparation for processing. The cleaner removes oxides and light surface contaminants, and ensures that the surface will be in a condition allowing it

to be uniformly microetched. Vendor specifications for temperature, dwell time, agitation and bath chemical control should be followed.

2. *Microetch:* The purpose of this step is to produce a surface that may be uniformly catalyzed and plated with good deposit adhesion by removing some copper from the surface. A variety of different etchant types may be used (e.g., sodium persulfate, peroxide/sulfuric). Vendor specifications for temperature, dwell time, agitation and bath chemical control should be followed.
3. *Catalyst:* The purpose of this step is to deposit a material that is catalytic to electroless nickel plating on the copper surface. The catalyst lowers the activation energy for nickel deposition and allows plating to initiate on the copper surface. Examples of metal catalysts include palladium and ruthenium (deposited by an immersion reaction with the copper surface). Vendor specifications for temperature, dwell time, agitation, and bath chemical control should be followed.
4. *Electroless nickel:* The purpose of this bath is to deposit the required thickness of electroless nickel on the catalyzed copper surface. The nickel thickness should be adequate to cover the copper with a substantially pore-free coating, to create a diffusion barrier to copper migration, and also serve as a solderable surface, depending on the intended application.

   The nickel bath has a relatively high deposition rate and its active chemical components must be maintained in balance on a continuous basis, by addition of appropriate replenishment components. Electroless nickel baths typically run at high temperatures and extended dwell times to achieve the required deposit thickness. It is therefore important to ensure that compatible PCB substrate and solder mask materials are used. Vendor

specifications for temperature, dwell time, agitation, and bath chemical control should be followed.

5. *Immersion gold:* The purpose of this step is to deposit a thin, continuous layer of immersion gold. The gold protects the underlying electroless nickel layers from oxidation or passivation, and also serves as a contact surface, depending on the intended application. This bath runs at relatively high temperatures and dwell times. Vendor specifications for temperature, dwell time, agitation, and bath chemical control should be followed.
   - *Rinsing:* The purpose of these steps is to remove residual process chemicals from the PCB surface after each chemical processing step. This may be achieved in either a single step or with multiple rinses. In some instances, predip and/or postdip process steps may also be required for optimum process performance. Vendor specifications for temperature, dwell time, agitation, and turnover rate should be followed.
   - *Drying:* The purpose of this step is to ensure the boards are completely dry. This may be achieved by use of either in-line vertical, or off-line horizontal drying. Off-line horizontal drying should be preceded by a horizontal rinsing step and should be dedicated to the boards from the ENIG processes. The time and temperature should be optimized to suit the type of product.

Due to the long dwell times, high operating temperatures, the ENIG process is always conducted in vertical tanks. To achieve the throughput required in production, many ENIG systems make use of two electroless nickel (EN) tanks, which allows for heating new baths or nickel stripping. Using two active EN tanks greatly improves throughput.

In addition to the normal plastic materials used in tank construction, stainless steel can be used for EN tanks. This is possible only with the use of anodic passivation, which

employs an electrical bias applied to the steel to prevent reduction of nickel ions on the steel. By using steel tanks, fabricators avoid the frequent stripping of plastic tanks required due to the slow plate-out of nickel on rough surfaces and localized hot spots.

35.4.4 Benefits and Limitations of ENIG Surface Finish

Benefits

- Flat co-planar surface, ideally suited for fine pitch surface mount applications
- Solderable surface forms a Ni/Sn intermetallic
- Aluminum and copper wire bondable
- Excellent contacting surface
- Shelf life exceeds 12 months
- Strengthens the PTH
- Protects the underlying copper from dissolution in the solder
- Does not require connectivity during the deposition process, like electrolytic Ni/Au
- Widely available

Limitations

- Complex process requiring good engineering and lab support
- Thicker nickel deposits may interfere with high frequency signal propagation
- Difficult to rework
- More costly compared to other finishes
- Susceptible to “nickel corrosion” or black pad*.

The term “black pad” (BP) occasionally referred to as “black nickle” describes a very specific phenomenon that

may occur in ENIG finished boards. It describes a corroded nickel surface under the immersion gold. If this corrosion is *excessive*, soldering fails (poor wetting, and poor solder joint strength). If a solder ball soldered to a highly corroded Ni surface is subjected to a pull force it would come apart at the Ni solder interface leaving behind a pad with a darker almost black Ni surface.

The BP occurs with an extended dwell time in an aggressive gold bath depositing on a compromised nickel surface. An aggressive gold bath is one where the plating parameters particularly the concentration of the gold is below the recommended supplier operating range. A compromised nickel deposit is uneven and has deep crevices, mostly a result of uneven catalyzation/initiation of nickel deposition. It can also be the result of running the bath outside the recommended ranges.

Following supplier's specification a pristine copper pad would be evenly catalyzed, the nickel will initiate uniformly and will produce a flat crevice free deposit. Under these conditions running the gold bath within its operating range will never produce BP or nickel corrosion.

35.5 NICKEL PALLADIUM GOLD

Electroless nickel/electroless palladium immersion gold (ENEPIG) is sometimes referred to as the "universal" finish, because of the versatility of its applications. ENEPIG is suitable for soldering, gold wire bonding, aluminum wire bonding, and contact resistance. ENEPIG is formed by the sequential deposition of electroless Ni (120 to 240 µin) followed by 2 to 12 µin of electroless Pd with an immersion gold flash (1 to 2 µin) on top. It is a multifunctional surface finish, applicable to soldering and to gold, aluminum and copper wire bonding. In addition, it is also suitable as the

mating surface for soft membrane and steel dome contacts, “low insertion force” (LIF) and “zero insertion force” (ZIF) edge connectors and for press-fit applications.

ENEPIG has the advantage over ENIG of being a gold wire bondable surface. ENIG is not an ideal gold wire bonding surface because over time the electroless nickel will diffuse thru to the surface along the crystal boundaries of the immersion gold and the bonding would fail. ENEPIG’s palladium layer is a diffusion barrier to the nickel, the gold remains unadulterated and is bondable with gold thickness as low as 1.2 µin or 0.03 µm.

A thicker gold coating as thick as 0.1 to 0.2 µm or 4 to 8 µin would open the wire bonding operating window. Thicker gold is beyond the capability of standard immersion gold. If a thicker gold is specified then a modified immersion gold like a “reduction assisted immersion gold” would be the preferred choice.

The electroless palladium requires a reducing agent. The most commonly used reducing agent is sodium hypophosphite, this produces a phosphorus palladium deposit with 4 to 5 percent phosphorous in the deposit. The presence of phosphorous renders the palladium deposit amorphous (noncrystalline), making it the ideal diffusion barrier. Other reducing agents may produce a nonphosphorus palladium which tends to be crystalline in structure.

35.5.1 The ENEPIG IPC-4556 Specification 2013

For thickness IPC-4556 stated:

The thickness specification for ENEPIG states:

Nickel: 3 to 6 µm [118.1 to 236.2 µin] at ± 4 sigma (standard deviations) from the mean. Palladium: 0.05 to 0.15

µm [2 to 12 µin] at ± 4 sigma (standard deviations) from the mean.

Gold: 0.025 µm *[1.2 µin] at −4 sigma (standard deviations) below the mean*.

All measurements to be taken on a nominal pad size of 1.5 mm × 1.5 mm [0.060 in × 0.060 in] or equivalent area.

An amendment is presently in final draft for peer review. The amendment is setting an upper limit for gold thickness for ENEPIG at 2.8 µin (0.7 µm). The amendment was necessary because too many designers were specifying a much higher immersion gold value. The higher thickness involved increased dwell time in the gold bath resulting in nickel corrosion under the palladium layer.

35.5.2 Process Sequence

The ENEPIG process sequence differs from the ENIG sequence only in the addition of the electroless palladium and its subsequent rinses between the electroless nickel and the immersion gold process steps.

35.5.3 ENEPIG Specific Attributes

ENEPIG has specific attributes that are attractive to designers that call out PWB surface finishes:

35.5.3.1 Soldering. ENEPIG forms the most robust solder joint with SAC type lead free solder. The copper and the palladium are incorporated in the intermetallic (IMC) Ni/Sn layer (Sn tin, Ag silver Cu copper). This limits the propagation of the IMC with thermal stressing or extended shelf life, resulting in a solder joint of superior strength.

35.5.3.2 Wire Bonding. ENEPIG is a gold wire bondable surface in spite of the reduced immersion gold thickness. The palladium layer is a diffusion barrier to the nickel, resulting in an unadulterated gold surface layer for bonding.

35.5.4 Benefits and Limitations of ENEPIG Surface Finish

Benefits

- Gold wire bondable
- Aluminum and copper wire bondable
- Solderable surface forms a Ni/Sn intermetallic
- Produces the most robust solder joint with lead free SAC type alloys
- Ideally suited for fine pitch surface mount applications
- Excellent contacting surface
- Shelf life exceeds 12 months
- Strengthens the PTH
- Protects the underlying copper from dissolution in the solder
- Does not require electrical connectivity like electrolytic Ni/Au

Limitations

- Complex process requiring good engineering and lab support
- Thicker nickel deposits may interfere with high frequency propagation
- Difficult and costly to rework
- More costly compared to other finishes

35.6 ORGANIC SOLDERABILITY PRESERVATIVES

As the name implies, organic solderability preservatives (OSPs) are very thin organic coatings used to preserve the solderability of PCB surface copper. OSPs form a complex organo-metallic compound with the copper surface of the PCB. The primary function of OSP is to provide a solderable surface finish, suitable for all surface mount and through-hole assembly applications and with an appropriate shelf life. The coating has demonstrated the ability to meet category 3 coating durability (shelf life of 12 months per J-STD-003 and industry data), when produced per the required vendor specifications. Some OSP coatings, may not necessarily meet this requirement, but may meet category 2 or 1 coating durability. In spite of OSPs being limited to solderability preservation, OSPs are widely used worldwide on products that are not fine pitched or with high aspect ratios holes.

There is a wide variety of OSPs that have evolved with the increasing complexity of the PCB. OSP products include benzotriazoles, imidazoles, benzimidazoles, and phenyl benzimidazoles (see Fig. 35.1). Initially all that was required was a single thermal excursion for soldering leads into component holes, Then came surface mount that required at least two thermal excursions (one per side), This later evolved into surface mount with through hole, and eventually to high aspect through holes in multilayer boards with heavy ground planes that act as heat sinks. Add on top of that the need to hand solder an occasionally rework.

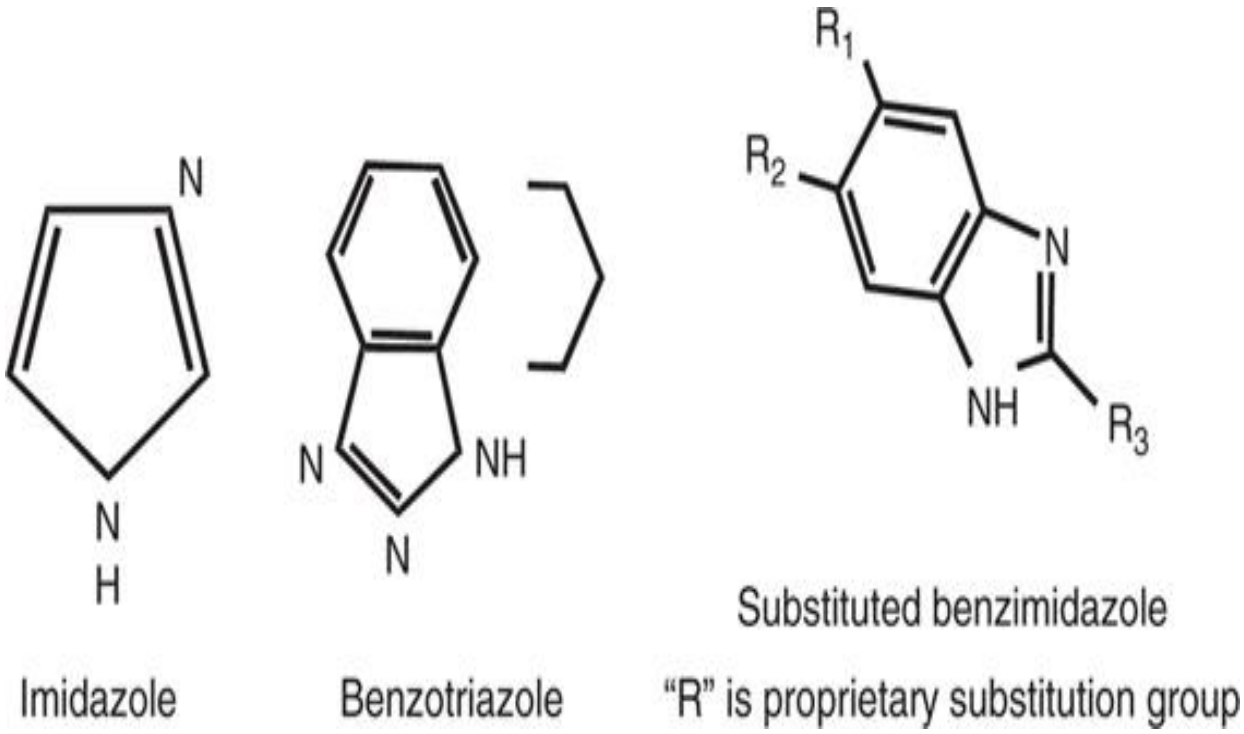

FIGURE 35.1 OSP molecule types.

The biggest relevant evolution is "lead free" (LF) assembly. LF assembly temperatures at 260°C are 35°C higher than eutectic soldering at 225°C. The more thermally robust coatings have significantly higher decomposition temperatures than the peak reflow temperature. They require contact with appropriate flux and or molten solder to penetrate the coating. They have longer shelf life, survive multiple reflow cycles and are more lead-free assembly compatible. Some of the newer OSPs have additives occasionally referred to as "oxygen scavengers." These additives can "open" the performance window of the specific OSP.

A newer generation of OSPs is designed to survive exposure to multiple high-temperature soldering operations. These chemicals are normally based on benzimidazole with attached functional groups to add molecular weight and thermal resistance. Substituted phenylimidazole and OSP systems with metal co-deposits have been used as well. The

intent of the new generation of OSP is to withstand Pb-free soldering temperatures. These “high-temperature” OSP coatings, made for use with Pb-free alloys and the associated fluxes, can be deposited at higher thicknesses and may be measured as high as 1.0 µm.

35.6.1 Fabrication Process

Table 35.2 shows the fabrication process for OSP, including chemicals and dwell times.

TABLE 35.2 Process Flow for Organic Solderability Preservative

Process	Chemicals	Time, min
Cleaner	Aqueous solvents, acids, and surfactant. The solvent removes organic residues. The acid removes oxidation and the surfactant wets the surface.	1–4
Microetch	1–2 µm of Cu is oxidized to Cu^{++} and dissolved.	1.0
Predip	Normally, the predip employs ingredients of the OSP bath without the OSP chemical itself.	0.5
OSP	OSP, acetic or formic acid, source of copper or other metals.	0.5–1.0

OSP is usually applied using conveyorized equipment. The cleaner and microetch may use flood or spray application, but OSP is applied using only a flood module. Rinsing is very important to ensure that contamination from all prior fabrication steps is removed. Often, OSP is applied when the PCB is in individual circuit form after the PWB has been electrical tested, routed, and depanelized. This is to preserve the fragile OSP surface, which is sensitive to handling,

contamination, and fingerprints. The OSP parts should stabilize at room temperature and controlled humidity before packaging, as any moisture in the package can cause different levels of discoloration.

OSP thickness is normally determined by indirect sampling. A sample coupon is processed along with the production parts. The coupon is immersed in an acid/solvent solution that dissolves the coating. The thickness of OSP is calculated by comparing the degree of UV light absorbance of the sample against a standard of known concentration using a spectrophotometer. That measurement is used as a quality control for the production boards.

Another method relies on “optical reflectivity” and resolves thin-film thickness by analysis of spectral interference observed by reflecting light over a range of optical wavelengths from layered samples. For OSP on PCBs, light reflected from the air/OSP interface and the OSP/Cu interface exhibits phase differences that create intensity oscillations across the wavelength range. The intensity oscillation is dependent upon the wavelength of the light, OSP thickness, and the physical properties of the coating. By analyzing the frequency and amplitude of these intensity oscillations, the thickness of the OSP coating can be determined.

35.6.2 Benefits and Limitations of OSP

Benefits

- Simple process
- Flat planar surface
- Widely available
- Forms a Cu/Sn intermetallic
- Easy to rework
- Cost effective

- High productivity at Fabrication

Limitations

- Handling sensitive
- Only applicable as a soldering finish
- Limited shelf life
- Exposed copper after final assembly
- Not easy to inspect or verify thickness
- Problematic for paste misprints
- A nonconductive surface

35.7 IMMERSION SILVER

Immersion silver (IAg) forms a thin immersion deposit over copper. It is a multifunctional surface finish, applicable to soldering, press fit connections and as a contact surface. It has the potential to be suitable for aluminum wire bonding. The immersion silver protects the underlying copper from oxidation over its intended shelf life.

Immersion silver is a galvanic displacement process with a typical thickness range of 0.1 to 0.4 µm. The fabrication process is easy, but the coating can suffer from tarnish when left exposed after assembly in field use. Heavy tarnish can be a predictor for corrosion and functional loss.

Thickness Specification of Immersion Silver IPC-4553 A (2009) states:

The thickness of the immersion silver deposit should be 0.12 µm [5 µin] minimum to 0.4 µm [16 µin] maximum at ± 4σ from process mean as measured on a pad of area 2.25 mm^2 or 1.5 mm × 1.5 mm [approximately 0.0036 in^2 or 0.060 in × 0.060 in]; typical value between 0.2 µm [8 µin] to 0.3 µm [12 µin].

Note: The original IPC-4553 silver specification issued in 2005 is outdated and should not be called out.

Chemical Coating

The PCB copper is prepared using separate cleaning and micro etch steps. Over time, these steps can be taken for granted, but improper use can cause many defects. The predip bath removes excess acidity from the PCB and prevents chlorides from entering the silver bath, where silver chloride would quickly precipitate. The silver bath relies on the galvanic displacement of less noble copper with two atoms of more noble silver. Proper rinsing and drying is essential.

35.7.1 Fabrication Process

Table 35.3 shows the fabrication process for immersion silver surface finish, including the chemicals used and dwell times.

TABLE 35.3 Process Flow for Immersion Silver

Process	Chemicals	Time, min
Cleaner	Aqueous solvents, acids, and surfactant. The solvent removes organic residues. The acid removes oxidation and the surfactant wets the surface.	1–4
Microetch	1–2 µm of Cu is oxidized to Cu^{++} and dissolved.	0.5–1.0
Predip	Normally, the ingredients of the silver bath without the silver metal itself.	0.5
Silver	Silver, acid, grain refiners, chelating agents $Ag^{+} + Cu(0) \rightarrow Ag(0) + Cu^{++}$	0.5–3.0
Postdip (optional)	Can be an antitarnish or an extra cleaner for demanding ionic cleanliness applications.	

Most immersion silver in large production is applied in conveyorized equipment. The cleaner and micro etch may use flood or spray application, but the silver solution is applied using flood. Rinsing is very important to ensure that contamination from all prior fabrication steps is removed. In smaller-scale production and prototype manufacturing, silver can be applied in vertical process tanks. Often, silver is deposited on individual circuits, after the PCB has been routed, depanelized, and electrically tested. This is to preserve the silver surface, which can be sensitive to handling, contamination, and fingerprints.

35.7.2 Benefits and Limitations

Benefits

- Planar surface finish suitable for fine pitch assembly
- Relatively simple process, with high productivity at fabrication
- Forms a Cu/Sn solder joint
- Suitable for use as a contacting surface
- Compatible with lead free soldering
- Widely available

Limitations

- The surface will tarnish over time
- Handling sensitive
- Exposed silver after assembly can exhibit creep corrosion
- May attack the soldermask interface during deposition
- Requires special packaging for extended (12 months) shelf life

Design considerations for IAg:

The following should be part of the original design for immersion silver surface finish:

- Use anti-tarnish overlay
- Eliminate soldermask defines pads (SMD) pads
- Filled vias must be completely filled
- At assembly, print paste to cover entire pad
- Keep test pads apart (min 80 mils)
- Paste and reflow test pads

35.8 IMMERSION TIN

Immersion tin is a thin coating of pure tin, typically 0.6 to 1.2 µm thick, which protects the underlying copper from oxidation and provides a highly solderable surface. Tin is deposited using a galvanic displacement process and can be applied in vertical or conveyorized equipment. Tin boards are used primarily for solderability and have very good compliant pin connector functionality.

IPC-4554 Immersion Tin Specification 2007

For immersion tin the committee only specified a lower limit for thickness. The relatively thick value of 1 µm was chosen to ensure that enough virgin tin would be available at the surface for soldering after storage. It is well understood that tin forms an intermetallic (IMC) layer with the underlying copper, and that this layer continues to grow in thickness over time.

The immersion tin thickness will be:

1.0 µm (40 µ”) minimum at –4σ from process mean as measured on a pad of area 2.25² µm (3600² mils). Typical value of 1.15 µm ((46 µ”) to 1.3 µm (52 µ”).

The immersion tin Specification IPC-4554 was amended in 2011. The amendment addressed solderability testing and specified the allowed stress testing conditions for the deposit and the type of fluxes to be used for both tin/lead and LF testing.

35.8.1 Immersion Tin Deposit

As with all immersion metal systems, the copper needs to be perfectly clean and textured before the tin plating step. A predip is used to maintain proper chemical balance in the tin bath and prevent contamination. The tin deposition is not a direct galvanic displacement, since tin is more electronegative than copper. Thiourea is used in tin chemical formulation to create a copper-thiourea complex on the surface. This complex becomes more electronegative than tin, and can be displaced in the immersion reaction. Because of the need to drive the reaction, the tin bath contains relatively high concentrations of chemicals, which must be thoroughly rinsed. Allowance must be made at waste treatment for the presence of thiourea.

35.8.2 Fabrication Process

Table 35.4 shows the fabrication process for the immersion tin surface process, including chemicals used and dwell times.

TABLE 35.4 Process Flow for Immersion Tin

Process	Chemicals	Time, min
Cleaner	Aqueous solvents, acids, and surfactant. The solvent removes organic residues. The acid removes oxidation and the surfactant wets the surface.	1–4
Microetch	1–2 µm of Cu is oxidized to Cu^{++} and dissolved.	0.5–1.0
Predip	Normally, the ingredients of the tin bath without the tin metal.	1.0
Tin	Tin, thiourea, acids, whisker inhibiting trace metals, chelating agents.	4.0–12.0
Postdip (optional)	Can be an extra cleaner for demanding ionic cleanliness applications.	

Some production installations use immersion tin in horizontal conveyorized applications. Conveyorized lines are long and therefore expensive and are only used in high productivity fabrication sites. The use of vertical tanks carrying baskets of panels for immersion tin plating makes better use of production floor space. Due to the high sulfur reactivity of the thiourea ingredient, tin lines should be dedicated to the tin process only and not mixed in with OSP, silver, or ENIG lines where sulfur can harm the surfaces.

35.8.3 Benefits and Limitations

Benefits

- Planar surface finish suitable for fine pitch assembly
- Relatively simple process, with high productivity at fabrication
- Forms a Cu/Sn solder joint
- Excellent compliant tin functionality
- Compatible with lead free soldering
- Reworkable
- Widely available

Limitations

- The surface will oxidize with exposure to moisture and air
- Susceptible to whisker formation
- Handling sensitive, a soft metal
- May attack the soldermask interface during deposition
- Cu/Sn intermetallic (IMC) is formed after deposition and continues to grow with time and temperature
- The IMC may interfere with accurate thickness determination

35.9 OTHER SURFACE FINISHES

Other surface finishes include reflowed tin-lead, electrolytic nickel/electrolytic gold, electroless palladium, electroless gold, direct immersion gold,

35.9.1 Reflowed Tin-Lead

Before the widespread use of solder mask, a primary method for protecting copper circuitry was to electroplate a coating of tin or tin-lead on the copper. After component insertion, the tin plating could be liquefied with oven or vapor-phase reflow to form solder joints. The use of solder mask over bare copper to take advantage of surface mount, wave soldering, and mixed assembly restricted the use of tin plate finishing. For simple technology product, tin or tin-lead plate and reflow remains a viable fabrication and assembly method.

35.9.2 Electrolytic Nickel/Electrolytic Gold

The electrolytic nickel-gold process employs galvanic electroplating. The circuit board is placed on a rack and electrically connected to a power supply (rectifier). When immersed in a solution of metal ions, the metals are reduced as a metal coating on the PCB by the supply of electrons. The metal thickness grows in a very predictable way depending on the time, current, area plated, and efficiency of the reaction. More frequently, the coating is applied selectively in combination with another finish such as OSP.

Electrolytic nickel gold is commonly used on features requiring high-force physical connections or gold wire-bonding. Several micrometers of nickel are deposited, and 0.50 to 1.5 µm of gold as the final mating surface. It is not a recommended soldering surface as the thicker gold will create embrittlement within the intermetallic phase of the solder joint.

If the surface is designed as a contacting surface with multiple insertions hard gold must be used. Gold is hardened by alloying the deposit with ~3 percent of nickel, chromium, or iron. For a large number of PCBs that employ edge tab connection, the PCB is electroplated in a special plating line where only the exposed edge features are immersed into the plating cell.

If the application is gold wire bonding, only soft gold (99.99) must be used. For gold wire bonding a thick gold layer ensures that the underlying nickel will not defuse all the way to the surface where it would have an adverse effect on the bonding process.

35.9.3 Electroless Palladium

As a precious metal palladium is resistant to oxidation, and can offer a good physically strong deposit for electrical contacts and soldering. A thin coating of 0.1 µm or 4.0 µin was successfully utilized as a solderable and contacting

surface in the mid to late 1990s. As the price of palladium soared, it became less attractive and for this application immersion silver was a more attractive alternative.

35.9.4 Electroless Palladium/Immersion Gold

As electroless palladium/immersion gold (EPIG) begins to get a foothold in the industry as a surface finish with unique attributes; the question was what about very fine pitch applications where the thickness of the nickel may reduce the spacing between the pads? And what about high-frequency signal propagation where the thicker nickel layer “skin effect” may create a degree of signal loss? These have led to the emergence of EPIG, as a surface finish that could resolve these issues. It is a solderable contacting surface that is also gold wire bondable.

Suppliers who offer this finish have specific recommendation for the thickness of the palladium and the gold depending on the intended use. No IPC specification for this finish exists as yet.

35.9.5 Electroless Gold

Gold can protect copper and resist oxidation like no other metal. Electroless nickel with a cover layer of electroless gold is a viable surface finish and has been in use as a gold wire bondable surface. For this specific application the electroless gold is deposited on a layer of immersion gold. Both gold layers are soft/pure gold (99.99 pure). As with ENIG, electroless nickel under layer is needed as a barrier layer to prevent copper to gold interdiffusion. Electroless gold can achieve a sufficient thickness to allow gold wirebonding and some physical connection functions. It also deposits much

more uniform thickness than electrolytic gold. Better thickness control allows somewhat thinner coatings, so gold embrittlement can be prevented, if the finish doubles as a soldering surface. Cost and process control considerations prevent more widespread use as a PCB finish.

35.9.6 Direct Immersion Gold

Because electroless nickel is the cause for many of the disadvantages of ENIG, some designers have considered the use of immersion or electroless gold directly on top of underlying copper. This process works for boards that are assembled without a long shelf life and do not require multiple thermal excursions. Without the barrier coating of nickel, however, the copper and gold soon dissolve into each other creating a discolored gold finish. The solderability of the finish, however, is unaffected by this discoloration. The finish remained solderable after 3+ years in an ambient environment.

Printed circuit board designers have at their disposal a large variety of surface finishes. Each surface finish is unique in some aspect like cost, material compatibility, signal integrity, assembly attributes, intended use, life expectancy, environment of use, reliability, and the list goes on.

Newer designs like continuous miniaturization and high frequency signal propagation, are creating opportunities for supplier’s R&D departments to seek innovative surface finish solutions to meet the continuous evolution of the electronics industry.

CHAPTER 36
SOLDER MASK

David A. Vaughan
Taiyo America, Inc., Carson City, Nevada

36.1 INTRODUCTION

36.1.1 Definition and Terminology

The term *solder mask*, as used in this chapter, is the same as the terms *mask, soldermask*, or *solder resist*, which are frequently used interchangeably in the printed circuit board (PCB) fabrication industry. The Association of Connecting Industries (IPC) has standardized on the use of *solder mask*, since that is the term most widely used in the industry. The existing definition for “Solder Resist” from IPC-T-50 is, “A heat-resistant coating material applied to selected areas to prevent the deposition of solder upon those areas during subsequent soldering.” With the evolution of PCB technology, solder mask coatings are now asked to provide much more functionality than simply a soldering aid.

36.1.2 Purpose

When solder masks were first used, their purpose was to protect the circuitry of the PCB from solder during the assembly operation. Eliminating short circuits was the main objective. As the use of solder mask became more prevalent and the material properties improved, solder mask was used for other functions, such as to provide environmental protection to the assembled board, and to serve as a plating resist for final finishes, dielectric protection, and other functions that take advantage of the properties of the cured mask.

36.1.3 History

Solder mask began with the use of two-part epoxy, thermally curable inks that were an offshoot of inks that were used in the printing industry. These inks were applied by screen printing with the use of a patterned screen, since these materials were not photoimageable. One-part inks that were ultraviolet (UV) curable were available soon after, but these also had to be applied by a patterned screen because they could not be imaged and developed.

Photoimageable solder masks were developed in the mid-1970s and were offshoots of photoresist materials used for patterning the circuitry. Photoimageable solder masks were developed in both liquid (LPI) and dry film (DFSM) and both were used widely. Today, more than 98 percent of the solder mask used is applied in liquid form, and most is photoimageable.

36.2 TRENDS AND CHALLENGES FOR SOLDER MASK

The use of solder mask continues to evolve with the technology. This section discusses some of the issues involved.

36.2.1 Circuit Density

Since the development of circuit boards, the dimensions of the holes and features have been decreasing. Smaller component attachment dimensions require corresponding decreases in solder mask features that challenge the solder mask materials and processes.

36.2.1.1 Feature Size. Smaller solder mask features have eliminated non-photoimageable solder masks from all but the lowest technology designs, and continue to require ongoing improvements in resolution and image reproduction. A very high percentage of solder mask being used is photoimageable.

36.2.1.2 Hole Size. Holes in boards that have been coated with LPI solder mask will have some solder mask material in the holes after application. Typically this material must be removed in the development process. There are very significant differences in how easily different solder mask materials develop from holes. There is also a difference in the amount of solder mask material that is in the holes between application methods, with spray and curtain coating leaving less material than screen printing.

36.2.2 Component Attachment in a Lead-Free Environment

As many PCB fabricators and assemblers transition to lead-free processing, they are faced with solder alloys that have

an operating temperature up to 30°C (54°F) hotter than the traditional eutectic tin-lead solders. These increased soldering temperatures raise concerns about the ability of the solder mask (as well as all other materials) to resist embrittlement, discoloration, loss of adhesion, and cracking with repeated exposures to the higher temperatures. Some existing products may not be acceptable for lead-free processing.

36.2.3 High-Density Interconnection

High-Density Interconnection (HDI) technology creates small blind microvias that are plated to provide interconnects to buried layers of circuitry. These small holes can either be coated with solder mask or filled and plated over so that the real estate of the hole can be utilized for a circuit or a component mounting pad (via-in-pad).

If the hole is simply coated with solder mask and the solder mask is not developed from the hole, the air trapped in these small holes may expand and create a bubble or blister, or may erupt, exposing the copper in the hole to potentially corrosive chemistries. These holes should be developed cleanly so that they receive the final finish, should be protected before solder mask application with an inert final finish or be completely plugged.

Plating over microvias requires that they are totally filled, planarized, roughened, and catalyzed before the plating process. If a conductive plugging material is used, the catalysis step typically can be eliminated. Material selection for this application is particularly important because not many materials can withstand the roughening and plating and still maintain good adhesion of the copper to the plugging material after exposure to soldering temperatures. If the via is in a component mounting pad (via-in-pad), the plugging material must not shrink and cause a significant

depression (dimple) in the pad. This is especially true for wire bonding applications that require a very flat planar surface.

36.2.4 Environmental

The Restriction of Hazardous Substances (RoHS) Directive 2002/95/EC places restrictions upon specific materials that may be included in PCB fabrication materials, including solder masks. These requirements may require some products to be reformulated. Some products and/or markets may require low-halogen materials to comply with company or industry specifications. Again, these requirements have required some solder masks to be reformulated or new products to be developed.

Many localities have strict air emissions regulations that limit the materials and the amount that may be exhausted to the atmosphere. Individual processes or pieces of equipment may require a permit to exhaust any volatile materials. Hazardous air pollutants (HAPs) and volatile organic components (VOCs) are of particular concern. Limits on these parameters can limit mask selection and application processes. For example, curtain coating and spray mask application are not viable in some areas due to the higher percentage of solvent needed for proper application. Screening utilizes solder mask at a much higher percent solids (less dilution), so air emissions may be only half that of other methods.

36.2.5 Technical Service and Troubleshooting

The solder mask process is quite complex. It relies upon all PCB fabrication processes that preceded it and plays a key

role in all processes after it has been applied, through assembly and the life of the PCB. As a result, it is recommended that the specifying authority choose companies that can provide technical expertise and troubleshooting assistance. Companies that offer service and experienced engineering personnel in the PCB fabricators are becoming scarcer, making the supplier's ability to provide service a key issue in solder mask selection.

36.3 TYPES OF SOLDER MASK

36.3.1 Non-Imageable

Early solder masks could not be photoimaged—that is, placed in its exact location with a photographic process. They could not be hardened selectively in one area and then be removed from other areas. These masks had to be applied in the final pattern desired, typically through a patterned screen. The "silk screening" process (the screens are actually nylon) is limited in that it can neither resolve the fine features nor meet the registration requirements and tolerances needed for today's PCB designs. The use of these materials is limited to lower technology products.

36.3.2 Imageable

Higher-density circuitry, with its close tolerances and image reproduction requirements, has mandated the use of photoimageable solder mask. Assemblers need fine dams (or "webs") of solder mask between fine-pitch component leads (see Fig. 36.1) to enable assembly with low defect rates. These webs are frequently as narrow as 0.003 in. and can be as narrow as 0.001 in. A photoimageable mask is required to meet these needs.

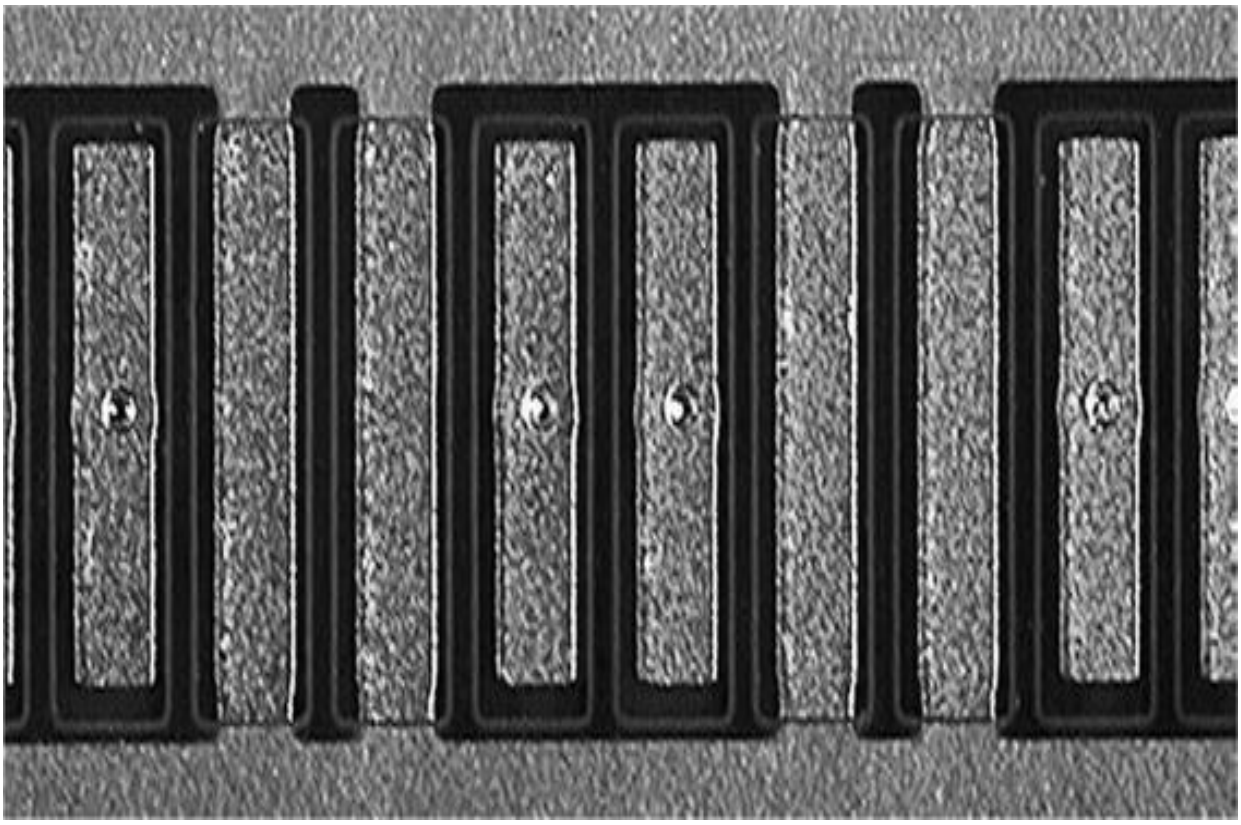

FIGURE 36.1 An example of fine solder dams, or “webs,” imaged between fine pitch SMT pads.

Photoimageable masks are available in either liquid or dry-film forms. Liquids account for more than 98 percent of the products used, due to their lower cost, greater availability, ease of use, and acceptability in assembly processing. Dry-film masks require special application equipment, are expensive, are often not robust when used as a resist for final finishes such as ENIG or immersion tin, and are too thick for use in some assembly processes.

36.3.3 Temporary

A number of temporary masks are used in PCB fabrication and assembly processing. The properties of these masks vary considerably depending upon the purpose for which they have been used. The typical application for these masks

is to protect circuitry from plating and/or soldering. Various products can be removed mechanically by peeling (“peelable mask”) or by dissolving in cleaning chemistry. Since they do not become a permanent part of the finished assembly, there are no industry standards for these products. PCB fabricators and assemblers should be careful to verify the compatibility of any temporary mask with their solder mask(s) to avoid problems such as swelling, blistering, and so on.

36.4 SOLDER MASK SELECTION

36.4.1 Availability and Consistency

There are ongoing changes in the makeup of the supplier base of electronic materials, including solder mask. Many acquisitions have taken place and several products eliminated in the recent past, so users must have confidence that they will have a continued source of supply of solder mask that is the same lot to lot for the future. International Organization for Standardization (ISO) qualification for the manufacturing operation as well as for environmental considerations are good indicators of a supplier with a long-term view.

36.4.2 Performance Specifications

36.4.2.1 IPC-SM-840. This is the predominant solder mask material specification used globally. Most manufacturers test their products to verify that their products are capable of meeting the requirements of this document. The SM-840 includes physical, chemical, thermal, and electrical requirements for two classes of application.

36.4.2.2 Underwriters Laboratories UL94. This specification defines the degree of flammability of a material. Solder mask suppliers generally test their products for flammability according to UL94. The solder mask is applied to a specific type of base material or construction before burn testing. The main variables in this test are the specific base material and construction, the mask type, and the thickness of each. Since most solder mask has no flame retardant, thinner mask and thicker base material will give better results.

36.4.2.3 Telcordia GR-78-CORE. This specification, from Telcordia, is commonly referred to by its previous name, BellCore. With the introduction of the C Revision to IPC-SM-840, the Class T requirements were accepted by the BellCore as equivalent to meeting the GR-78-CORE specification. This specification is still available as part of a package of documents from Telcordia that is quite expensive. However, since Telcordia recognizes the IPC-SM-840 Class T specification for solder mask, it is typically not necessary to purchase a copy of the GR-78 specification.

36.4.2.4 Military Applications. The military specification that applies to solder mask is MIL-P-55110. Since the mid-1990s, the revisions of this document refer to the IPC-SM-840 specification for solder mask requirements.

36.4.2.5 NASA Outgassing. Materials that will be used in space applications are tested under extremely high vacuum conditions. To be acceptable, they must exhibit a maximum total mass loss (TML) of 1.0 percent and have a maximum collected volatile condensable material (CVCM) of 0.10 percent. A list of tested products is available from the NASA website at http://outgassing.nasa.gov. This site features “Outgassing Data for Selecting Spacecraft Materials,” which lists products that the Goddard Space

Center has tested (and the tests' results). Not all materials tested have passed the TML and CVCM specifications. Independent test labs can also be used to test for this property.

36.4.2.6 Other Customer Industry Application Specifications (AABUS). Often PCB customers have special requirements for their solder mask. These can be a modification of the IPC criteria or some additional requirement not included in the SM-840 document. There is a term used to describe these requirements: as agreed between user and supplier (AABUS). The key word here is "agreed," since both parties must be completely aware of the requirement and what it takes to achieve the required result.

36.4.3 Environmental and Health Considerations

36.4.3.1 RoHS Compliance. Most PCB fabricators now insist that any solder mask products they use be compliant with Directive 2002/95/EC of the European Parliament and of the Council of 27 January 2003 on the restriction of the use of certain hazardous substances in electrical and electronic equipment, the RoHS directive, and Directive 2003/11/EC, the 24th amendment to Council Directive 76/769/EEC. This directive places requirements on specific materials and amounts of each that may be included in a formulation. Meeting this criterion is essential for most printed wiring board (PWB) fabricators.

36.4.3.2 Lead-Free. One of the materials eliminated with RoHS compliance is lead. The largest impact of eliminating lead is the higher soldering temperatures required for lead-free solders. Soldering temperatures for

these alloys are typically 10 to 20°C hotter than for eutectic tin-lead solders. For example, one of the current alloys of choice is SAC-305 (tin-silver-copper solder) has a melting point 34°C higher than eutectic solder. Higher temperatures place additional stress upon the solder mask and could potentially lead to adhesion loss, color change, embrittlement, or cracking.

Organization	Spec-test Method	Chlorine	Bromine	Total Halogen
JPCA	JPCA-ES-01-1999	<900 ppm	<900 ppm	
IEC	IEC 61249	<900 ppm	<900 ppm	<1,500 ppm

36.4.3.3 Low Halogen. The low-halogen requirement came about due to concerns about incineration of scrap PCBs generating dioxins under some conditions, and originally centered on some brominated flame retardants used in base laminates. It progressed from that into an additional concern over the chlorine content. This requirement is sometimes referred to as “halogen-free,” but in reality, the true requirements place a limit on the amount of bromine, chlorine, and their sum in the content of the material. Current low-halogen requirements on the cured solder mask are as follows:

Although solder masks do not typically contain flame retardants, and hence no bromine, they often contain chlorine. The chlorine generally comes from pigments that give the mask its desired color, and also from residual catalyst from the resin (solder mask raw material) manufacturing process. A number of manufacturers offer low-halogen solder mask materials that meet the specified criteria.

36.4.4 Circuit Density Issues

As the pitch of circuitry and packages has decreased, it has also generated the demand for smaller holes and finer solder mask features.

36.4.4.1 Hole Size. As mentioned in Sec. 36.2.1.2, small hole sizes are a significant challenge for the solder mask process. All application processes introduce some solder mask into the holes, and this material must be removed (developed) from the holes before curing. There are two primary considerations in achieving finished PCBs with no mask in the holes. First, it is easier to achieve mask-free holes when less solder mask is introduced into the holes during the application process. In general, spray applications put the least mask into holes, and single-sided screening introduces the most. Curtain coating and simultaneous double-sided screen printing produce more moderate levels of solder mask in holes.

The ability to remove all solder mask from the holes is dependent upon the solder mask material itself, the tack drying, and the developing processes. Some solder masks inherently develop faster than others, so the choice of products has a significant impact on development. If the solder mask is subjected to an overly aggressive (too hot and/or too long) tack drying process, the mask may not develop at its optimum speed. The developing equipment and process should be set up according to the solder mask manufacturer's recommendations. This includes the chemistry, pressures, flow rates, nozzle type(s), process cycle times, and so on.

36.4.4.2 Solder Dams ("Webs"). To reduce soldering defects in assembly, designers have placed fine solder dams, or "webs," between attachment pads. The width of these dams is frequently in the 2.5 to 3.0 mil range, with some

designs requiring dams as narrow as 1.0 to 1.5 mils wide. Producing features this fine is not possible with all solder mask materials, and the imaging process for very fine features will typically be modified from normal production with wider dams.

36.4.5 Assembly Considerations

36.4.5.1 Thickness. When PCBs had all through hole components, solder mask thickness was not of much concern. However, with the advent of surface-mount technology in the 1980s, excessive solder mask thickness caused assembly problems, including:

- Tombstoning of discrete devices in reflow soldering
- Excessive opens with discrete devices in wave soldering
- Solder paste printing problems (excessive paste, solder balls, paste on back of stencil, etc.)

Flip-chip assembly, with its finer pitch, has placed further restrictions on the maximum mask thickness. These thickness restrictions effectively eliminated dry film solder mask in most applications and relegated it to a specialty product for special applications.

36.4.5.2 Cleanliness. After PCBs have been assembled, they must meet specific ionic and visible cleanliness requirements. It is important that PCBs produced with the specific solder mask through the normal process be qualified through the assembly process to ascertain whether the production parts will meet expectations. Each solder mask and flux combination throughout the assembly process may give a different cleanliness result.

36.4.5.3 Solder Balls. Some assembly processes are more prone to generate solder balls than others.

Prequalification of the solder mask with the assembly chemistries and processes is essential to predict production performance. If solder balls occur during assembly, in some cases they can be reduced by using a mask with a different surface finish. Satin or matte products sometimes have less of a tendency to have solder balls. Modifying the solder mask cure can have an effect on the level of solder balls also—consult with the solder mask supplier before deviating from its recommended cure process.

36.4.5.4 Assembly Material and Process Compatibility. When qualifying a new solder mask or new PCB supplier, it is critical that all existing materials and processes be evaluated for compatibility before production is scaled up. This should help avoid major issues where there is a large quantity of PCBs awaiting assembly that cannot be assembled with the existing assembly materials and processes. Care should be taken to include evaluation of:

- Soldering fluxes and pastes
- Cleaning agents
- Multiple heat exposures
- Adhesives
- Underfills
- Temporary solder masks
- Tapes
- Anything else in assembly that depends upon the surface of the solder mask

36.4.5.5 Conformal Coating Compatibility. Again, qualification of the solder mask, through all of the fabrication processes, is required to ensure that no problems with production boards arise. Since conformal coating is applied after assembly, a significant amount of processing and exposure to other chemistries will have happened since the

solder mask has been applied. The conformal coating compatibility testing should be done on a board that has been through all of the assembly processing. The cleanliness of the PCB surface after the final assembly process has a great impact upon the adhesion of the conformal coating. One cannot expect conformal coating to adhere well to a dirty board. These coatings were not meant to be applied over a no-clean flux, but over a clean substrate.

36.4.6 Application Method for Installed Equipment

Choose solder mask that is compatible with the existing or proposed application method. Not all solder masks can be screen printed, sprayed, and curtain-coated. Consult with the solder mask supplier for the appropriate solder mask for your application method.

36.4.7 Gloss

Solder masks are available in different levels of gloss. Typical terminology for finishes includes gloss, semigloss, satin or semimatte, and matte. These finishes represent a certain level of reflectivity of light and microroughness. Gloss level is generally specified by end users for assembly or cosmetic reasons.

36.4.8 Color

Likewise, different levels of color may be available. Most solder mask is green, but many other colors, such as red, blue, black, yellow, and white, are often specified. Some solder masks are specified to be clear.

36.4.9 Packaging versus PCB

When solder mask is used on substrates that will become part of a semiconductor package. The JEDEC Solid State Technology Association (once known as the Joint Electron Device Engineering Council) specifications apply in addition to the IPC specifications. JEDEC specifications include additional, more aggressive testing that generally requires a more robust solder mask. Low moisture absorption is important for a mask used in packaging applications.

36.4.10 Surface Finish Compatibility

The choice of the final surface finish for the copper has an effect upon how the solder mask performs. And, with the elimination of lead in solder, the compatibility of new final finishes needs to be confirmed before their implementation. Most of these finishes are applied after the solder mask so the process for mask application can have a significant impact upon final quality of the PCB:

- *Hot air solder leveling (HASL)* This has been the most common final finish, utilizing 63/37 eutectic or 60/40 tin/lead (Sn/Pb) alloys. The PCB is coated with flux, immersed into molten solder, and withdrawn through air knives to remove excess solder. Lead-free solders are expected to require solder temperatures significantly hotter than what has been required for eutectic solder. The higher temperatures are expected to place higher stress on the solder mask and may also present more difficult post-HASL cleaning challenges.
- *Electroless nickel/immersion gold (ENIG)* ENIG is typically applied to the metal surfaces of the PCB after the solder mask process. Each plating chemistry supplier has its own ENIG bath, and each has a different level of

aggressiveness to the solder mask. Consequently, the solder mask and ENIG chemistry must be qualified together to avoid breakdown of the solder mask over circuits or around openings on metal. A thicker coating of solder mask may alleviate solder mask breakdown problems. Excessive microetching before plating can undermine the solder mask and induce tape test failure as the overhanging mask is broken off.

- *Immersion tin* The same comments from ENIG also apply to immersion tin.
- *Immersion silver* Immersion silver is relatively benign to the solder mask, and few, if any, issues are known as of the writing of this book.
- *Organic solderability preservative (OSP)* This is another process and chemistry that has little impact on the solder mask.

36.5 SOLDER MASK APPLICATION AND PROCESSING

36.5.1 Surface Preparation

Solder mask should be applied to a clean, dry surface. The cleaning step should remove all particulates, oils and greases, and unwanted oxides. In the case of bare copper, this step should provide some “tooth” to the copper to enhance the mechanical bond of the mask to the copper. The cleaning step is followed by a rinse and drying step that leaves the panels ready for coating with mask. The surface preparation technology chosen is dependent upon the metallization of the circuitry and, to a lesser extent, the base laminate material.

36.5.1.1 Copper Circuitry. A large majority of panels produced have solder mask coated over bare copper (SMOBC). The goals of the surface preparation process are to remove all unwanted oxides and contaminants from the copper and to impart a microroughness or “tooth” to the surface, and to leave a clean, dry surface for coating.

36.5.1.1.1 Incoming Copper. The quality of the surface of the copper is very important for achieving good solder mask adhesion. All traces of the etch resist metallization, typically tin or solder, must be removed prior to the solder mask surface preparation process. Solder mask does not adhere well to tin or solder residues or tin-copper intermetallic surfaces.

36.5.1.1.2 Preparation Methods. The most common surface preparation method is pumice scrubbing with either a silica or aluminum oxide media. Most equipment in use is brush pumice, but jet pumice may be used also. With this method, the main considerations are keeping the pumice concentration within recommended levels, periodic changing of the media, and good equipment maintenance. A prepared surface from a proper pumice cleaning will have a uniform rosy pink, matted surface that is free from stains. Considerations in pumice-based preparation techniques include the following:

- *Brush pumice versus jet pumice* Both techniques utilize a slurry of pumice in water. With brush pumice the slurry is pumped onto the panel surface under low pressure, and rotating brushes scrub the pumice against the panel surface to clean and roughen it. With jet pumice, the slurry is sprayed through nozzles at high pressure onto the panel surface; the impact of the particles against the panel surface provides the cleaning and roughening.
- *Silica versus aluminum oxide* The media used in pumice scrubbing degrades with usage. Silica pumice is softer than aluminum oxide and must be changed more

frequently, but it is much less expensive; thus relative cost differences in operation may not be significant. Silica pumice particles degrade by fracturing into smaller pieces and not providing the needed impact to roughen the surface. Aluminum oxide particles become rounded with age and will “peen” the surface instead of roughening it. Both conditions lead to a less than optimum solder mask adhesion.

Chemical cleaning, usually in the form of a microetch, may be used to prepare the copper surface. Not all microetch chemistries will provide the proper tooth for best adhesion, so a product should be selected that provides some tooth (a matte surface is a good indicator) instead of a bright shiny surface. Good rinsing and drying, and possibly a passivation chemistry, are important to avoid rapid staining of the copper since it is very active after chemical cleaning.

Abrasive brush or compressed pad technology is generally acceptable for solder leveled panels, but if other final finishes such as ENIG or immersion tin are used, it may not provide sufficient adhesion. The abrasive in the brushes leaves directional scratches in the copper that can lead to the wicking of plating chemistries under the mask that will cause loss of adhesion around mask openings on copper. If this method is to be used, it should be followed by a chemical cleaning that will provide the microroughness needed for good adhesion.

A very good alternative to abrasive or chemical cleaning is to impart an oxide to the copper surface. If the copper has not been cleaned or if there are residual etch resist metals on the surface, the copper will not oxidize. The oxide provides a fine structure and microroughness for very good adhesion. When using this technique, the fabricator should use a “reduced oxide” so that cleaning chemistries in subsequent processes will not attack the oxide layer and cause adhesion loss at the mask-copper interface.

36.5.1.1.3 Rinsing and Drying. After the cleaning step, the panel surfaces must be thoroughly rinsed with good quality water. City or well water is often inadequate due to high levels of minerals, particulates, and other contaminants. Poor water quality can lead to blistering of the mask and/or discoloration of the copper under the solder mask. Deionized (DI) water is the best rinsing agent, but reverse osmosis (RO)-treated water is also used effectively.

After the panels have been rinsed, the drying step should remove the water from the panels—both from the surface and from the holes. Air knives should be incorporated to blow out the holes and sweep the water from the surface. It is undesirable to dry water on the boards since any droplets that are dried will leave behind any dissolved minerals and other contaminants that had been in the water.

36.5.1.2 Other Metals

36.5.1.2.1 Gold, Tin, or Solder. If the gold-plated surface is perfectly clean, no surface preparation is required. However, if there is any question about cleanliness, or if the panels have been exposed to any chemical vapors or particulates, or have been awaiting solder mask for any appreciable time, they should be cleaned. Depending upon the extent of surface contamination, the panels can be only rinsed and dried, or may be cleaned in a mild detergent solution before rinsing and drying. Abrasive cleaning is not recommended.

36.5.1.2.2 Mixed Metals. Two good examples of the use of mixed metals are for panels that have been selectively solder-stripped and for panels that have had fingers or contacts plated with gold before the solder mask process. The surface preparation process must be selected based upon the most delicate of the metals on the panel.

36.5.2 Solder Mask Application

36.5.2.1 Liquid Masks. Solder masks applied in liquid form can be either photoimageable or not. Most solder mask in use today is photoimageable, meaning that after application it will be patterned in a photolithographic process. A non-imageable product must be applied only to those areas to be coated, and areas where metal or base material must be exposed cannot be coated.

36.5.2.1.1 Application—Liquid Photoimageable (LPI) Solder Mask. LPI solder masks are applied typically by screen printing, spray, or curtain coating. Although each method has pros and cons, all are used successfully in the industry.

Screen printing is the most common technique of applying solder mask. This technique utilizes a non-imaged, tightly stretched screen of precise construction and a squeegee to apply the solder mask through the screen onto the panel. The screening technology includes a wide range of equipment and techniques, from single-sided hand screening to fully automated double-sided equipment:

- *Single-sided coating (hand or flat bed)* In this application, each side of the panel is fully coated (except for a border on each side) with solder mask, one side at a time. The panel may be tack dried between coating the two sides, or the second side may be coated immediately using a dimple plate to protect the coating on the first side. It is advantageous to coat both sides of the panel before tack drying so that both sides see the same tack-drying cycle. One concern about this technique is the amount of solder mask that is pushed into the holes. Since this is a single-sided process, there is nothing to restrain the amount of mask that gets pushed into the holes, so it may be more difficult to develop all of the mask out of the holes.

- *Double-Sided Coating* Vertical double-sided screen printing applies solder mask to both sides of the panel or panels simultaneously. The screening units used are available in various levels of automation, up to fully automated screening units that are integrated with tack drying ovens. Because they apply mask to both sides at the same time, the units put less mask into holes, making it easier to develop mask out of holes—a particularly important consideration when working with small holes that must be free of solder mask. Front-to-back squeegee alignment is critical for putting the least amount of solder mask into the holes.

A key variable in screen printing is the screen mesh. Most applications utilize a non-calendared, nylon mesh material. These products are designated with the number of threads per inch and the diameter of the threads in microns. Typical examples of commonly used mesh counts are 86-120, 83-100, 86-100, 92-100 or 110-80. Supplier literature will provide a theoretical ink volume for each type that can be used to determine the relative difference in coating weight to be applied to the panel.

Table 36.1 provides an overview of the screen process key variables and the effect of operating a process at the extreme of that variable.

TABLE 36.1 Screening Process Variables and Effect Operating at the Extremes

Process Variable	Effect of Low	Effect of High
Mesh Tension	Mesh sticking to screen Poor quality printing Low coating thickness	Nonuniform coating across panel
Squeegee Pressure	Skips (areas with no solder mask)	Low coverage over circuits
Squeegee Speed	Lower circuit coverage	Higher coverage
Squeegee Shape	Very sharp edge, lower coverage	Slightly rounded edge, higher coverage
Squeegee Angle (from panel surface)	Lower coverage, Less ink in holes	Higher coverage, More ink in holes
Snap-off	Screen sticking to panels	Skips or difficult printing
Ink Viscosity	Lower coverage, More flow or sagging if too low	Higher coverage, Bubbles if too high

Spray coating accounts for a limited percentage of the solder mask coating. There is renewed interest in spray coating since it can allow more latitude in removing solder mask from holes. As the holes become smaller, some solder masks and processes have difficulty achieving clean holes after development. At the same time, because the solder mask is sprayed at reduced viscosity, the amount of solvent (VOCs) that is exhausted to the environment is significantly higher than for screen printing, the use of spraying may be limited in some localities.

Two basic types of spray equipment have been used for spray coating PCBs with solder mask, HVLP (high volume, low pressure), and electrostatic. HVLP spray systems are most common. Single- and double-sided spray units are available.

The solder mask is sprayed at a reduced percent solids compared to screen printing, so circuit coverage and tack

drying can be more of a problem, especially if the ink and/or spray guns are not heated. Heating of the ink allows more solvent to evaporate between the nozzle and the panel, resulting in a higher viscosity liquid on the panel. The higher viscosity theoretically allows greater circuit coverage with less ink.

The conventional HVLP spray process utilizes a low pressure stream of solder mask liquid that is atomized by a high volume stream of air. The atomized solder mask is directed to the PCB surface in a specific pattern so that as either the panel or the spray head(s) move, a uniform coating is applied to the panel. In some systems, the ink is heated just before spraying to lower its viscosity and aid in the evaporation of solvent between the spray nozzle and the panel. Typical process variables for HVLP spray include ink viscosity, ink (pot) pressure, atomization air pressure, conveyor speed, and ink and atomization air temperatures.

In a typical electrostatic spray application, the ink is atomized and given an electrostatic charge while the PCB panel is grounded to attract the ink particles. The intent is to limit the amount of overspray and provide a more even coating. In reality, with the infinitely variable PCB designs to be coated, there are often many ongoing adjustments required to minimize Faraday effects that cause uneven distribution of the spray. Often solder mask formulations need to be modified for effective use in electrostatic spray applications. The main process variables in electrostatic spraying are solder mask temperature and viscosity (dilution), bell speed and voltage, back plane voltage, and shaping air pressures. These variables are adjusted to provide a uniform coating of the desired thickness or weight.

Table 36.2 lists the process variables and the effect of operating at the extremes of that variable.

TABLE 36.2 Key Variables for Spray Coating and Effect of Low and High Levels for Each Variable

Process Variable	Effect of Low	Effect of High
Ink Viscosity	Low circuit coverage, Tack drying difficulties	Mottled or "orange peel" coating, excessive atomization, and overspray
Ink Temperature	Low circuit coverage	Possible clogging of lines or nozzle
Ink (Pot) Pressure	Thin coating, low coverage	Thick coating, drying problems
Atomization Air Pressure	Mottled surface	Excessive overspray
Wet Weight or Wet Film Thickness	Low circuit coverage	Thick coating, insufficient drying, and/or bubbling

Curtain coating is an application method where the panel to be coated is rapidly passed through a continuous falling "curtain" of solder mask. The curtain is created by pumping the solder mask through a die with a slot of controlled opening. The curtain falls vertically through an opening between two conveyors that carry the panels horizontally through the curtain, thus coating the panel on its upper side. Solder mask that is not coated onto the circuit board panels falls into a trough between the conveyors and is recirculated. The pump and conveyor speeds and the gap in the die control the coating thickness. Solder mask used in curtain coating applications must be coated at reduced viscosity or percent solids (as in spray applications), so the increased VOCs emitted to the atmosphere may limit curtain coating's acceptability in some localities.

Curtain coating is a highly productive process that gives uniform coating across panels. It has good flexibility for coating panels of different sizes (above a minimum) and gives very high material utilization.

The quality of the coating from this process is highly dependent upon the ability to maintain a uniform, stable

curtain of solder mask. The solder mask must be maintained at the specified temperature and viscosity to avoid coatings that are too thick or thin, streaks, skips, or breaks in the curtain that cause no coating in localized areas, commonly referred to as “blips.” Curtain coating is sensitive to circuit height and typically requires process changes as height increases to avoid skips in the coating. Thin panels may become airborne at high conveyor speeds, and thick panels may slip on the conveyor and not accelerate to proper coating speed.

Typical process variables for curtain coating include solder mask viscosity and temperature, pump pressure, die (gap) opening, conveyor speed, and air flow. Table 36.3 lists the key variables for curtain coating and the effect of operating the process at the extremes of each variable.

TABLE 36.3 Key Variables for Curtain Coating Solder Mask Application and the Effect If the Process is Operated at the Extremes of That Variable

Process Variable	Effect of Low	Effect of High
Ink Viscosity	Low circuit coverage, dewetting, Streaks or breaks in the curtain ("blips"), Sagging of the coating	Unstable curtain, streaks, improper leveling, skips
Ink Temperature	Coat at incorrect percent solids, Sagging of the coating, Thin coverage	Unstable viscosity, high solvent evaporation, Inconsistent leveling
Pump Pressure	Thin coating, low coverage	Thick coating, drying problems
Conveyor Speed	Excessive coating	Insufficient coating, Ink in holes, Teardropping on bottom side
Wet weight or wet film thickness	Low circuit coverage	Thick coating, Insufficient drying and/or bubbling, Sagging of coating
Air flow around the curtain	None	Unstable curtain, "blips," Nonuniform coating

36.5.2.1.2 Tack Drying—Photoimageable Solder Mask. LPI solder mask inks received from the supplier contain solvents to control the viscosity in the correct range for their intended application process. These solvents must be removed to harden the surface of the coating so that it may be handled and processed through the exposure step. Because the coated solder mask is wet and tacky, tack drying should closely follow the mask-coating process to reduce the possibility of handling damage and airborne debris becoming embedded in the wet ink. Care must be taken that panels do not touch each other in tack drying because they will mark each other and will not dry properly due to localized inadequate air flow across the panel surface. (Dry film, UV, and thermally cured solder masks do not require tack drying.)

Panels that have had insufficient tack drying will be sticky (phototools will stick to the solder mask); they may also exhibit “artwork marking,” where the pressure from the exposure process causes the mask surface to be smoothed, changing the cosmetic appearance of the surface. If solder mask has excessive tack curing, it will become difficult or impossible to develop—a condition called “lock-in.”

Oven types used for tack drying include batch ovens, tunnel ovens, and infrared (IR) ovens.

Batch ovens can be as small as a bench-top unit where panels may be inserted individually or as large as a walk-in oven that may be loaded with many panels in racks or carts. The wet panels are loaded through a door or doors that are gasketed or sealed to the operating area so that the vapors emitted are not exhausted into the work environment.

Total tack drying time in a batch oven is the sum of the ramp-up time plus the desired time at temperature. Ramp-up time of the panels is dependent upon the initial temperature of the oven, the heating capacity of the oven, the amount of makeup or purge air, and the loading (thermal mass) of the panels, racks, and carts placed in the oven at start-up.

Cure times are generally specified to be a specific time at temperature. Once the ramp-up time has been determined for the specific temperature and worst-case loading (generally a full oven load), the total time for the cure process is the ramp-up time plus the cure time. Oven doors should not be opened during a cure cycle because cure volatiles may escape into the environment and temperature will be lost and potentially cause incomplete curing.

Pros of using batch ovens include the ability to load large quantities of panels of any thickness or design at one time with minimal labor. Cons include having to wait for the oven to be empty before starting a new cycle. Opening of doors causes significant drop in temperature and may cause under

curing if the time is not adjusted for the time below curing temperature.

In conveyorized *tunnel ovens*, panels are generally placed in slots in the conveyor or in racks that ride on the conveyor. The main controls are temperature and conveyor speed. Exhaust from the oven serves the same purpose as purge air and should be regulated per the oven manufacturer's specification. Curing is typically uniform and is independent of panel design and construction.

With IR ovens, panels typically lay flat and are processed one at a time, and cure times are very rapid. Multiple cure recipes are usually needed to compensate for differences in panel design, materials, and construction. Proper handling of the exhaust is important, as with all curing ovens.

Several issues must be considered in the tack drying process:

- *Time at temperature* Proper curing requires specified time at temperature. Ovens should be set up with a profiler to ensure that variables such as oven loading, heating capacity, ramp-up time, and so on, compensated for when establishing process conditions.
- *Air flow* Air flow in ovens must be parallel to the panel surface so that there is uniform temperature across the panels and the solvent is swept away from the coated surface.
- *Debubbling time* With some solder mask applications, it is important to have some time (usually 5–10 min. maximum) for the coating to debubble before the tack drying occurs. This allows time for the bubbles to break and for the coating to heal itself.
- *Purge air* All ovens need fresh air to be drawn into the oven to replace solvent-laden air that is exhausted. Without sufficient purge, air panels will not dry properly.

- *Condensate* Volatiles from the solder mask can condense on cool surfaces of the oven and ductwork. This material must be cleaned periodically so that it does not plug air passages. Proper safety equipment should be worn during cleaning.

See Table 36.4 for a list of oven types and their advantages and disadvantages.

TABLE 36.4 Solder Mask Drying Ovens and Their Associated Advantages and Disadvantages

Oven Type	Pros	Cons
Batch	Productivity—large quantities with minimal manpower	Potential for nonuniform temperature
	Low investment	Opening oven doors causes temperature to drop
	Not dependent on panel design, materials, or construction	Cure time may be oven-loading dependent
	Consistency	
Tunnel	Consistency	More handling
	Uniformity	Higher investment
	Not dependent on panel design, materials, or construction	Thin panels may need a fixture to prevent them from bending
Infrared (IR)	Very fast cycle time	Multiple recipes usually required to compensate for different materials, designs, and constructions
	Productivity	Cannot cure every PCB design/construction
		Requires automation or extra handling
		High investment

36.5.2.1.3 Exposure. Exposing photoimageable solder mask requires equipment that provides the needed intensity of light of the proper wavelength to expose the solder mask to an extent that the exposed mask will withstand the developing process without washing away, lifting, or getting surface attack.

Exposure equipment must provide a means of holding a phototool in intimate contact with the surface of the panel being exposed and provide the required amount of light (millijoules/cm^2) of the needed wavelength distribution (which may depend on the solder mask) at the appropriate intensity (mW/cm^2). Unfortunately, many exposure devices that are used for exposing solder mask are substandard, including many units that were designed many years ago for exposing primary imaging photoresist. Modern units have high-intensity lamps (7 kW or higher) and sufficient lamp and exposure frame cooling to provide a high-quality image very quickly.

Lamp intensity and energy output should be monitored routinely with a radiometer sensitive to the appropriate wavelength to verify that the lamps are performing as expected. Intensity will decrease with lamp hours, making exposure times become longer. At the same time, the infrared output will increase, potentially causing frame cooling issues. Hot exposure frames cause artwork to stick to the mask, resulting in artwork marking or mask to transfer to the phototool.

Laser units are available for exposing photoresist that have been used for exposing solder mask. These solder masks may be specially formulated to be sensitive to the laser wavelength. Laser imaging eliminates solder mask registration problems, but is not as productive as conventional exposure. Equipment cost is very high compared to conventional lamp exposure equipment.

Underexposure will result is insufficient polymerization to withstand the development process properly without damage to the solder mask. Typical symptoms may include a dull or chalky surface, lifting of small features (e.g., solder dams), excessively undercut sidewalls, or lifted mask.

Overexposure causes image growth where the exposed feature is larger than on the artwork and openings in the solder mask will be smaller. If the growth is excessive, the mask may grow onto the pads.

36.5.2.1.4 Development. Development of the unexposed solder mask material must be sufficient to clean out completely the smallest holes that must be free of mask.

Photoimageable solder masks may be developed in either aqueous or solvent chemistries. The developer chemistry needed depends on the mask formulation. In the development process, solder mask that has not been exposed to UV light and polymerized is washed away, or developed, from the PCB panel to reveal the desired pattern of solder mask.

For aqueous development, the chemistry is a warm, mildly alkaline (pH 10.6–11.3) solution of sodium carbonate (Na_2CO_3) or potassium carbonate (K_2CO_3). Proprietary chemistries are also available. Antifoam is generally used to control foaming as the development solution loads with developed mask.

Solvent-developing chemistry typically uses gamma-butyrolactone (also known as “GBL” or butyrolactone) or butyl carbitol (2-(2-Butoxyethoxy)ethanol) solvent.

The development process must be set up to ensure that the smallest holes are free of undeveloped solder mask. This is very different from photoresist because the breakpoint will often be 10 to 15 percent of the development chamber instead of nearly 50 percent with photoresist.

Key process variables for the development process are the time in the developer and rinse sections; solution

temperature, pressure, and nozzle type; flow rate; and configuration.

It is very important to have an inspection step immediately after development to check for registration, mask in holes, feature resolution, dam retention, lifting, and so on. Once the panels have been cured. it is significantly more difficult to strip and rework the solder mask, and the rework process is more likely to cause the panels to be scrapped.

36.5.2.2 Dry-Film Solder Mask (DFSM) Application.

The process for DFSM differs from LPI solder mask only in the application step. Surface preparation, exposure development, and cure are the same as for LPI solder masks.

36.5.2.2.1 Application with Vacuum Lamination. DFSMs typically have no solvent in them to enable them to conform to circuits without entrapping significant amounts of air along or between circuit traces. To apply these films to circuit topography, a laminator must be able to laminate panels in a vacuum chamber. The predominant type of vacuum laminator has heated upper and lower platens. The panel or boards to be coated will have DFSM gently applied (without any pressure) to one or both sides and are placed into the vacuum chamber formed between the upper and lower platens. The platens are closed together and a seal is formed. Vacuum is drawn in the chamber. When a specified time has been reached (determined by the board type and thermal mass, DFSM type and thickness, and board/panel plated circuit height), the flexible diaphragm on the upper platen (which had been held tightly against the upper platen surface by vacuum) is released to slap down onto the panel surface. The heat will have made the DFSM plastic so that it will conform to the circuits, and the vacuum prevents poor lamination along circuits. The lamination is completed when the platens separate and atmospheric pressure forces the DFSM into all voids.

36.5.2.2.2 Roll Lamination. Lamination of DFSM with a standard hot roll laminator is unacceptable for all except the least demanding applications. It is impossible to laminate a flat film of solder mask to PCB topography without trapping air along circuits. There are vacuum hot roll laminators that will work satisfactorily, but these are not widely available.

36.5.2.3 Non-Imageable

36.5.2.3.1 UV and Thermally Curable Solder Masks. Because these products are not photoimageable, they must be applied with patterned screen printing in the exact pattern that is needed on the finished PCB. After their application, they are cured by the appropriate cure recipe as dictated by the supplier. There is no opportunity to develop off solder mask from areas where it is unwanted, so registration of the screen to the panel is very important.

36.5.2.3.2 Ink Jet Application. This technique utilizes digital data and ink jet technology to coat solder mask only in areas where it is wanted. This eliminates the photoimaging steps and should reduce or eliminate registration problems. Several machines are now being used in production and the application is growing. Most are UV-cured machines are being used in production for solder mask application.

36.5.3 Curing

36.5.3.1 Cure Purpose. All solder mask products require a cure step or process for the solder mask to achieve the desired material properties. Curing typically increases hardness and the thermal and chemical resistance. The desired curing process is determined by the specific solder mask used. Consult the technical data sheet for the product and follow the supplier’s recommendations for the appropriate cure.

36.5.3.2 Types of Cure—UV, Thermal, IR.

36.5.3.2.1 Thermal Cure. Nearly all solder masks require a thermal cure. It is generally specified as a specific time at temperature. When calculating the correct time, the fabricator must add the temperature ramp-up time to the required time at temperature to arrive at the total time in the oven. For a conveyorized oven, a thermal profile will show the time above the minimum temperature.

If the thermal cure is to be accomplished with an infrared oven, the time will be much shorter but temperatures will be far greater than for a convection oven. Also, a number of recipes are usually needed to compensate for materials with different IR absorbance and panels with different thermal mass or thickness.

36.5.3.2.2 UV Cure. Some solder masks require high-intensity UV light to cure. This is typically applied in a conveyorized UV curing unit. Calibration of the curing unit is important to ensure the solder mask is cured properly.

36.5.3.3 Effects of Undercure and Overcure.

Improperly cured solder mask can exhibit poor properties that will become apparent in subsequent processing. Care must be taken to ensure that the solder mask is cured according to the supplier’s recommendations. The following are some of the potential problems caused by improperly cured solder mask.

Undercure problems include:

- Blistering or adhesion loss in final finish or assembly
- High ionic contamination
- Residues from assembly soldering
- Solder balling
- Handling damage and soft coating

Overcure problems include:

- Embrittlement and cracking
- Adhesion loss

36.5.4 Stripping Solder Mask

Stripping of solder mask is something to be avoided, but at times is required due to problems such as misregistration, incorrect or wrong sized artwork, handling damage, and so on. It is important to recognize problems as early in the process as possible since the stripping process must be more aggressive after each process step.

36.5.4.1 Stripping after Coating. At this stage, the solder mask may be removed easily. An LPI solder mask can simply be developed off. (*Note:* The mask should be tack dried first to avoid contaminating the developer with wet mask and/or solvent.). UV and thermal mask must be removed manually with an appropriate solvent.

36.5.4.2 Stripping after Photoimaging. The stripping task becomes more difficult. Aggressive chemistries, typically highly caustic and at high temperature, are required. These chemistries are aggressive and the process, if not controlled, can damage the butter coat of the laminate and render the panel scrap. Small holes filled with solder mask may not be able to be cleaned out in the stripping operation without damaging the panel.

36.5.4.3 Stripping after Cure. Stripping solder masks is most difficult at this stage, and doing so in fact may be impossible for some solder masks. The time required to strip the solder mask may allow exposed portions of the laminate to become damaged and cause the panel to be scrapped. Every effort should be made to identify panels needing stripping before curing.

36.6 VIA PROTECTION

Via protection is an increasingly complex issue for PCB designers and fabricators. There are multiple options for protection—organic and conductive, platable or not, before or after final finish, and more. The materials and processes for each type are not the same, so there is no single answer, and few answers that are easily performed with high productivity. Inks for plugging come in a variety of processing types, including thermal cure, UV cure, photoimageable, conductive, platable, and so on. The panel design will narrow the choice for the specific application.

36.6.1 IPC-4761, "Design Guide for Protection of Printed Board Via Structures"

IPC-4761, published in July 2006, gives excellent guidance for how best to protect vias and what not to do. It does not give specifications for the plugging materials themselves, but a future document is expected to do so. This document calls out a number of classes of via protection that can be used by designers and fabricators.

One very important message from this document is that vias should be protected from both sides, not only one side. If single-sided protection is used before an "inert" final finish, a ring void of copper results at the barrel-plug interface that is subject to corrosion due to entrapped microetch, flux, or other corrosive chemistry. Also, some of these materials leach out in subsequent processes and can kill plating baths, cause high ionics, induce electrochemical migration, or present other long-term reliability concerns.

36.6.2 Material Specifications

Although there are no “official” specifications for the materials used for plugging, there are some specifications that apply to solder mask that should be considered when using a material other than solder mask to protect vias. UL94 flammability and IPC-SM-840 tests—including especially resistance to solvents and cleaning agents, as well as non-nutrient testing—may be necessary. Dependent upon the specific circuitry design, other specific tests from IPC-SM-840 or other specifications may be appropriate.

36.6.3 Material Selection Considerations—Solder Mask versus Specialty Inks

36.6.3.1 Shrinkage—Percent Solids. LPI solder masks have solvent in the formulation to control viscosity and tackiness. Drying the solvent causes the plug of mask in the via to shrink, typically causing a dimple and some thinning of the coverage on the knee of the hole. This may not be a problem if the plug is covered with another coating of solder mask or if the annular ring of the via does not pick up solder or other final finish. Specialty hole plugging inks are available that are very high in solids and shrink very little, as are 100 percent solid inks that eliminate this concern.

36.6.3.2 Platability—Cu Adhesion. More frequently, designers are specifying that the material used to plug the hole be platable so the real estate can be reclaimed as in via-in-pad designs or in subcomposite structures. Such applications require a material that can be roughened, catalyzed, and plated with good copper adhesion.

36.6.3.3 Image Definition. If the vias to be filled are in very close proximity to areas that must be solderable (e.g., surface-mount technology [SMT] pads) it may be desirable or, mandatory to utilize a plugging product that is photoimageable to ensure the ink does not encroach upon solderable surfaces.

36.6.3.4 Other Properties. One property important for vias needed to conduct thermal energy is thermal conductivity. Products used to fill such vias are generally highly loaded with a material with good conductivity such as silver or copper. Some designers believe that boards that must operate at high temperatures should have plugging materials with low coefficient of thermal expansion (CTE) and high glass transition temperature (T_g), but there is little data to substantiate benefits of such materials.

36.7 SOLDER MASK FINAL PROPERTIES

Final properties are often characterized into physical, electrical, mechanical, and chemical properties. Most people who specify solder mask utilize the criteria in the IPC-SM-840 document when specifying desired mask performance. There are other industry and regional specifications but the IPC specification is recognized worldwide.

36.8 LEGEND AND MARKING (NOMENCLATURE)

Many boards still require legend and marking to identify part numbers and component locations, for company logos, date

codes, and a multitude of other reasons. These can be etched into the copper or, more typically, added in a separate process after solder mask. For good legibility, materials are of a color that contrasts with the solder mask color.

36.8.1 Types

36.8.1.1 UV. These materials are not photoimageable, but are applied in the specific desired pattern through a patterned screen and then are cured with high-intensity UV light.

36.8.1.2 Thermal. These materials are not photoimageable, but are applied in the specific pattern desired through a patterned screen and then are thermally cured, generally in a batch or conveyorized oven.

36.8.1.3 Photoimageable. These inks are applied to large areas of panels or over complete panels, as with an LPI solder mask. They are tack dried, imaged, developed, and cured, often at the same time as the solder mask is cured. The advantages of these products are that they eliminate expensive screen making and achieve excellent resolution, even over the topography of circuits.

Special inks have been formulated for LPI legend applications that have higher pigment loading. The advantage of these inks is that they can be coated much thinner while achieving good color contrast. This increases the productivity through the tack and developing processes and gives a more robust finished product since it is thinner and less likely to be chipped. Standard solder masks of contrasting color may be used but they will have to be coated thicker to achieve similar contrast. The higher

sidewall thickness makes the legend more susceptible to chipping.

36.8.1.4 Ink Jet. These are actually UV and/or thermal inks that are applied with an ink jet. A limited number of these machines are in production as of early 2007. Initial equipment cost is very high, as is the price of ink, and progress in productivity is expected in the future.

36.8.2 Legend Specifications

36.8.2.1 IPC. No approved IPC specification exists for legend inks. A committee is drafting a specification, IPC-4781, that should be issued in 2008.

36.8.2.2 Military. The military has an obsolete specification that was written years ago around a two-part epoxy ink that most MIL applications still specify. Many of the criteria (such as shelf life, pot life, composition, etc.) in this specification are irrelevant to the final legend performance, but they are still enforced as long as the specification is used. More recently the specification for legend ink called out for many military applications is CID A-A-56032D, entitled “Commercial Item Description—Ink, Marking, Epoxy Base.” Although military specifications call out epoxy-based marking inks, a number of fabricators have had other inks approved on a waiver basis for military applications.

36.8.2.3 UL94. When areas of legend ink on the board are larger than a UL flame strip (½ × 5 in.), it is treated as if the legend is another coating that needs UL qualification. If all areas are smaller than the flame strip dimension, no separate UL qualification is needed.

36.8.3 Legend Performance

36.8.3.1 Legibility and Resolution. The legend must be readable to be useful. As circuitry becomes more dense, the feature sizes needed for legend become smaller also, causing processes to be reestablished to give the desired quality. Some fabricators have switched to a photoimageable (LPI) legend to give the desired resolution for the legend on high-density circuitry.

36.8.3.2 Adhesion. The legend must be applied to a clean, dry surface and be properly cured to achieve optimum adhesion. This can be a challenge when legend is applied after HASL or other final finish that could leave a residue (such as HASL flux) on the surface. Legend adhesion must be evaluated in combination with the solder mask and its processing. Different legend materials have different adhesion to different solder masks.

36.8.3.3 Final Finish Compatibility. Like solder mask, legend materials that are applied before the final finish must survive the final finish processes and chemistries. Not all legend materials will survive all finishes and these must be qualified together, the same as with solder mask.

CHAPTER 37
ETCHING PROCESS AND TECHNOLOGIES[a]

Gareth Parry
Draig Technologies Inc., Stouffville, Ontario, Canada

37.1 INTRODUCTION

One of the major steps in the chemical processing of subtractive printed boards is *etching*, or removal of copper, to achieve the desired circuit patterns. Etching is also used for surface preparation with minimal metal removal (microetching) during innerlayer oxide coating and electroless or electrolytic plating. Technical, economic, and environmental needs for practical process control have brought about major improvements in etching techniques. Batch-type operations, with their variable etching rates and long downtimes, have been replaced completely with continuous, constant-etch-rate processes. In addition, the need for continuous processing has led to extensive automation along with complete, integrated systems.

The most common etching systems are based on alkaline ammonia and cupric chloride. Other systems include peroxide–

sulfuric acid, persulfates, and ferric chloride. Process steps include resist stripping, precleaning, etching, neutralizing, water rinsing, and drying. This chapter describes the technology for etching high-quality, fine-line (0.0015- to 0.003-in) circuits in high volume at a practical cost, as well as continuous processing, constant-etch rates, and control at high dissolved copper capacities. Increasingly, the production of uniform and constant feature geometries calls for precision and statistically robust control of the circuitization processes and materials.

There remains the ever increasing need to balance the process selection according to the factors of cost, environmental and regulatory compliance, stable factory productivity, low worker intervention requirements, compatibility with board design, and construction innovations. It is significant that environmental concern has eliminated the use of chromic–sulfuric acid and ammonium persulfate etchants and chlorinated solvents. Limitations on chlorine gas and volatile organic emissions loom as a significant factor in determining future process choices, and pressure to eliminate brominated compounds and lead content may have consequences for processing mandated by material developments. More than ever, the simplification of process selection and vendor support appear to drive process selection in the industry.

Typical procedures are given for etching organic (i.e., dry film) and metal-resist boards, and for innerlayers. Strippers and procedures for resist removal are described based on resist selection, cost, and pollution problems. The properties of available etchants are also described in terms of resist compatibility, control methods, ease of control, and equipment maintenance. Other considerations include chemical and etchant effects on dielectric laminates, etching of thin-clad copper and semiadditive boards, solder mask on bare copper (SMOBC), equipment selection techniques, production capabilities, quality attained, and facilities.

37.2 GENERAL ETCHING CONSIDERATIONS AND PROCEDURES

Good etching results depend on proper image formation in both organic innerlayer print-and-etch and plated-metal etch resists. Etch personnel must be familiar with screened, photosensitive, and plated resists commonly used. The etching of printed boards must begin with suitable cleaning, inspection, and preetch steps to ensure acceptable products. Increasingly, metal foil or plating uniformity in structure thickness and freedom from coatings and defects must be maintained to achieve uniform small-feature definition. Plated boards also require careful and complete resist removal. The steps after etching are important because they remove surface contamination and yield sound surfaces. This discussion considers the various types of resists and outlines typical procedures used to etch printed boards using organic and plated resist patterns.

37.2.1 Screened Resists

Screen printing is a common method for producing standard copper-printed circuitry on metal-clad dielectric and other substrates. The etch-resist material is printed with a positive pattern (circuitry only) for copper etch-only boards or with a negative image (field only) when plated through-holes and metal resist are present.

The type of resist material used must meet the requirements for proper image transfer demanded by the printer and for stripping chemistry compatibility. From the metal etcher’s point of view, the material needs to provide good adhesion and etch-solution resistance; be free of pinholes, oil, or resin bleed-out; and be readily removable without damage to substrate or circuitry.

Typical problems are excessive undercutting, slivers, unetched areas, and innerlayer shorts in multilayer boards. In addition, conductor line lifting may occur when the copper-to-laminate peel strength (or surface contamination) is below specification.

37.2.2 Hole Plugging

Plugged-hole, copper-only boards use alkaline-soluble screen resists in a unique manner. The technique, called *hole plugging*, makes the SMOBC board possible. This technique can be used with screened images and to augment *tent-and-etch* processing for small annular ring structures.

37.2.3 UV-Cured Screen Resists

Ultraviolet-cured solventless systems are available for print-and-etch and plating applications. These products are resistant to commonly used acidic plating and etching solutions. Stripping must be evaluated carefully.

37.2.4 Photoresists

Dry-film and liquid photoresist materials are capable of yielding the fine-line (0.0015 to 0.003 in) circuits needed for production of surface-mount circuit boards. Like screened resists, photo-sensitive resists can be used to print either negative or positive patterns on the metal-clad laminate. Although dry-film and liquid materials differ in both physical and chemical properties, they are considered together for our purpose.

In general, both positive- and negative-acting resists offer better protection in acidic rather than alkaline solutions; however, negative-acting types are more tolerant of alkaline solutions. Negative resists, once exposed and developed, are

no longer light sensitive and can be processed and stored in normal white light. The positive resists remain light sensitive even after developing and must therefore be protected from white light. Liquid photoresists, although less durable, are capable of finer line definition and resolution.

Positive-acting resists are subject to the same problems as are negative-acting resists, although they may be easier to remove cleanly, after exposure, from areas to be etched or plated. Problems related to plating photoresist-coated boards are reviewed in Chap. 33.

37.2.5 Plated Etch Resists

At present, the most extensive use of metal-plated resists is found in the production of double-sided and multilayer plated-through-hole circuit boards. The most commonly used resists are tin (matte and bright surface). Solder plate (60 percent Sn, 40 percent Pb) continues to be used on some reflow-treated solderable coating situations, but it is not favored for a sacrificial resist that is to be removed for SMOBC processing. Nickel, tin/nickel, and gold are occasionally used. Silver is used to some extent for light-emitting and liquid crystal applications. Details concerning the deposition of these metals are given in Chap. 35. The use of these resists is described in the following paragraphs.

37.2.5.1 Tin Plating. Thin tin deposits (0.0002 in) are used to make SMOBC boards where the tin etch resist is stripped after etching. Alkaline ammonia etchants are usually favored. Other etchants, such as sulfuric acid–hydrogen peroxide and ammonium persulfate–phosphoric acid, have been especially formulated for bright tin. Tin plating (directly over barrier layers of nickel or tin/nickel) has been used because of its optimum solderability. Cupric and ferric chloride etchants attack tin and are not used.

37.2.5.2 Solder Plate. Tin/lead solder (0.0003 to 0.001 in thick) is the plated etch resist for “fusing” into a solderable finish. The 60Sn/40Pb alloy offers good etchant resistance with few problems but must be treated with a brightening solution to retain solderability. Increased reliability may be achieved by the use of solder plate over tin/nickel.[1] Thin solder deposits (0.0002 in) can be used for the SMOBC process but have no benefit over tin plating for this purpose. The most suitable etchants are alkaline ammonia and sulfuric acid–hydrogen peroxide. Ferric and cupric chloride acid etchants cannot be used because of solder plate attack. Postetch neutralization rinses are needed, especially with alkaline systems, to rinse away etchant residues and to maintain optimum surface properties.

37.2.5.3 Tin/Nickel and Nickel. Tin/nickel alloy (65 percent Sn, 35 percent Ni) and nickel plate, used as is or overplated with gold, solder, or tin, are also capable metal resists for etching copper in alkaline ammonia, sulfuric acid–hydrogen peroxide, and persulfates.

37.2.5.4 Gold. With an underplate of nickel or tin/nickel, gold provides excellent resistance to all the common copper etchants. Some etchants have a slight dissolving effect on gold.

37.2.5.5 Precious Metals and Alloys. Rhodium has been described as being a suitable resist for edge connectors on boards; however, the plating process is difficult to control. When plated over nickel, rhodium tends to be thin and porous and to lift during etching. Because of varying surface properties, 18-karat alloy gold and nickel/palladium must be evaluated carefully when used as substitutes for pure gold systems.

37.2.5.6 Silver. Although silver is not used on most printed boards (MIL-STD-275 states that it shall not be used), it has found some applications for camera, light-emitting, and liquid

crystal devices. Copper etching using silver as resist can be done with alkaline ammonia solutions. Silver loss is about 0.0001 in/mm.

37.2.5.7 Etching Procedures for Plated-Metal Resists. Etching of the metal-resist-plated boards begins with removal of the plating resist using commercial strippers. The stripping process must be sufficient to remove resist trapped under plating edges. Gold, solder, and tin resists must be handled carefully because they scratch very easily. Tin/nickel alloy and nickel plate, however, are very hard and resistant to abrasion.

The procedure after etching includes thorough water rinsing and acid neutralizing to ensure removal of etchant residue on the board surface and under the traces. Alkaline etchants are followed by treatment with proprietary ammonium chloride acidic solutions, ferric and cupric chloride with solutions of hydrochloric or oxalic acid, and ammonium persulfate with sulfuric acid. Alkaline cleaning is used for tin/lead boards etched in chromic–sulfuric acid. Etchant residue not removed before drying or reflow results in lowered electrical resistance of the dielectric substrate and in poor electrical contact and soldering on the conductive surfaces.[2] Care must be taken to minimize undercutting and overplating to eliminate slivers of plating breaking off and bridging circuitry.

A problem common to etching printed boards is not having the entire area etch clean at the same time. This occurs when etch action is more rapid at the edges of printed areas than in a broad expanse of copper. If very fine patterns and lines are required, the result can be loss of the pattern due to undercutting, especially when the board is left in the etcher until all the field copper has etched away. Modern etchers with reduced pooling of etchant have reduced this problem.

Fine-line boards in high-volume production may require special fine-line etchants, high-resolution photoresists, thin-clad laminates, controlled plating distribution, and thin base foil processing. Care must be taken to balance etching and

thickness factors. In some cases, fine-line etchant additives have actually made cleanout more difficult in spaces of 0.003 in and narrower.

37.3 RESIST REMOVAL

The method used for resist stripping must be carefully evaluated when a resist is selected. The effect on board materials, cost and production requirements, and compliance with safety and pollution standards must be taken into account. Solvent-based stripping solutions are under significant environmental pressure. Chlorinated solvents and cyclic compounds (toluene, xylenes, etc.) have been banned, and many glycol ethers are restricted. In spray applications, care must be taken to capture or eliminate VOC emissions. For these reasons, aqueous or primarily aqueous stripping systems are necessarily widely used.

37.3.1 Screen Resist Removal

Alkali-soluble resist inks are generally preferred. Stripping in the case of thermal and UV-curable resists is accomplished in 2 percent sodium hydroxide or in proprietary solutions. The resist is loosened and rinsed off with a water spray. Adequate safety precautions must be taken, since caustics are harmful.

Conveyorized resist-stripping and etching machines use high-pressure pumping systems that spray hot alkaline solutions on both sides of the boards. Certain laminate materials such as the polyimides may be attached by alkaline strippers. Measling, staining, or other degradation is noted when strippers attack epoxy or other substrates. Control of concentration, temperature, and dwell time usually can prevent serious problems.

Screened vinyl-based resists are removed by a dissolving action in solutions of chlorinated, petroleum, or glycol ether

solvents. Methylene chloride and toluene (both currently not usable) were used extensively in cold stripper formulations. The most common strippers are acidic formulations that contain copper brighteners and swelling, dissolution, and water-rinsing agents. The usual procedure for static tank stripping involves soaking the coated boards in at least two tanks of stripper. Excessive time in strippers is to be avoided because of attack on the butter (top epoxy) coat, especially on print-and-etch or single-sided boards. Water is a contaminant in most cold strippers.

37.3.2 Photoresist Removal

37.3.2.1 Dry Film. Dry-film resists have been formulated for ease of removal in aqueous alkaline solutions. Strippers are available for both static tank and conveyorized systems, although conveyorized systems are preferred because the spray action aids in separating the resist from the copper surfaces and washing it off the panel. Prompt processing after etching avoids resist adhesion “lock-in,” which can make removal difficult. Aqueous-alkaline stripping results in partially undissolved residues of softened resist films. These residues are captured in a filter system and disposed of in accordance with waste-disposal requirements. Design and availability of specific filters to match the character of the “skins” can be a significant factor in the selection of the proper resist. Environmental caution must be taken to properly evaluate and dispose of resist residues. Metal content (particularly lead) may lead to classification of these residues as toxic waste.

37.3.2.2 Negative-Acting Liquid Photoresist Removal. Negative-acting, liquid-applied photoresist can be readily removed from printed boards that have not been baked excessively. Baking is critical to removal because it relates to the degree of polymerization. Since overbaking is also damaging to the insulating substrates, processes should stress minimal baking—only enough to withstand the operations

involved. The negative-acting resists are removed by using solvents and commercial strippers. In this case, the resist may not dissolve; instead, it softens and swells, breaking the adhesive bond to the substrate. Once that has taken place over the entire coated area, a water spray is used to flush away the film.

37.3.2.3 Positive-Acting Photoresist Removal. Positive-acting photoresists are removed in commercial organic and inorganic strippers if baking has not been excessive. Removal by exposure to UV light and subsequent dipping in sodium hydroxide, TSP, or other strong alkaline solutions is also effective. Overbaking makes removal difficult. Machine stripping is done in a solution of 0.5*N* sodium hydroxide, nonionic surfactants, and defoamers.

37.3.3 Tin and Tin/Lead Resist Removal

In SMOBC processing, the metal-plated resist is removed to present a flat, clean copper surface for solder mask definition. Tin/lead alloys can be stripped in oxidizing fluoride solutions such as fluoboric acid and hydrogen peroxide or ammonium bifluoride with hydrogen peroxide or nitric acid. (Caution: machine construction must be made compatible with fluorides by elimination of titanium and glass components.) Commercial formulations are available to be used inline after the etch machine rinses. Accumulations of spent solution or filtered lead fluoride deposits must be treated as hazardous waste and have been accepted by solution vendors for treatment and disposal costs. Modern applications usually use lead-free tin plating resists, which can be fluoride containing as previously discussed, or compounds of ferric chloride followed by nitric acid. In either case, feed-and-bleed solution management with filtration and periodic chamber cleanout has been successful.

37.4 ETCHING SOLUTIONS

This section is a survey of the technology and chemistry of the copper etching systems in common use. Selection of practically available etchants has been limited by economic, operational, and (environmental) regulatory concerns. Fabricators have been forced into practical trade-off decisions to suit situations. Two etchants in particular, chromic–sulfuric acid and ammonium persulfate, are no longer practical considerations due to environmental pressures. Other formulations and choices have been modified to suit these pressures.

There are two basic etchant needs to be met. The first is traditional foil etching for print-and-etch, plate/tent and etch, and pattern plate and etch. Virtually all processes use constant-rate systems for alkaline ammonia or cupric chloride etchants for this purpose or ferric chloride. The second need is developing technology for specific precision very fine-line etching—including foil thinning and thin metallization clearout for HDI constructions and fine features. (See Sec. 37.7 for additional discussion and mention of additional chemistries that may be useful for these applications.)

Continuous constant-rate systems with process automation represent current practice in production etching. These systems feature feed and bleed of replenishment chemicals under control of process instrumentation that monitors and responds to real-time changes in properties of the working solution. The “bleed” stream of the working composition etchant is usually returned to suppliers for copper reclamation and chemical recycle. The resulting degree of constant etching rate allows for stable and repeatable performance to achieve practical manufacturing processes. However, as demands for higher precision increase, further sophistication in controls will be necessary.

Key factors for selecting an etching chemistry include

- Board design requirements
- High yield
- Compatibility with resist
- Etch rate (speed)
- Difference of speeds and sidewall topography with respect to ammonia/cupric/ferric etchants
- Equipment required for process control of etch rate, regeneration, and replenishment
- Ease of equipment maintenance
- By-products disposal and pollution control
- Operator and environmental protection

The preceding factors serve to evaluate copper etchants to be used. Introduction, chemistry, properties, and problems are given in this section, along with suggestions for selection and control.

37.4.1 Alkaline Ammonia

Alkaline etching with ammonium hydroxide complexing is increasingly used because of its continuous operation, compatibility with most metallic and organic resists, high capacity for dissolved copper, and fast etch rates. Continuous (open-loop) spray machine chemical control systems are universally used. This operation provides constant etch rates, high work output, ease of control and replenishment, and improved pollution control. However, rinsing after etching is critical, and the ammonium ion introduced to the rinses presents a waste-treatment problem. On-site closed-loop regeneration with chemical recycling is commercially available but not routinely practiced because of facility requirements, capital cost, fluctuating economics depending on copper commodity pricing, and worker requirements. The general economical and environmentally appropriate operating strategy is to recycle the by-product etchant products under

contract to a supplier who reclaims or reconstitutes the copper contained and regenerates the ammoniacal constituents into a reformulated replenisher solution for return to fabricators.

37.4.1.1 Chemistry. The main chemical constituents function as follows:

1. Ammonium hydroxide (NH_4OH) acts as a complexing agent and holds copper in solution.
2. Ammonium chloride (NH_4Cl) increases etch rate, copper-holding capacity, and solution stability.
3. Copper ion (Cu^{2+}) is an oxidizing agent that reacts with and dissolves metallic copper.
4. Ammonium bicarbonate (NH_4HCO_3) is a buffer and as such retains clean solder holes and surface.
5. Ammonium phosphate [$(NH_4)_3PO_4$] retains clean solder and plated through-holes.
6. Ammonium nitrate (NH_4NO_3) increases etch rate and retains clean solder.
7. Additional additives are included in most formulations to enhance speed and/or sidewall protection. Thiourea or its derivatives are often used, although a newer thiourea-free formulation with improved undercut protection is available.
8. Continuous operations consist of single-solution makeup buffered to a pH of 7.5 to 9.5.

Alkaline etching solutions dissolve exposed field copper on printed boards by a chemical process of oxidation, solubilizing, and complexing. Ammonium hydroxide and ammonium salts combine with copper ions to form cupric ammonium complex ions [$Cu(NH_3)_4^{2+}$], which hold the etched and dissolved copper in solution at 18 to 30 oz/gal.

Typical oxidation reactions for closed-loop systems are shown by the reaction of cupric ion on copper, and air (O_2) oxidation of the cuprous complex ion:

$$Cu + Cu(NH_3)_4^{2+} \rightarrow 2Cu(NH_3)_2^{+} \quad (37.1)$$

$$2Cu(NH_3)_2^{+} + 2NH_4^{+} + 2NH_3 + \tfrac{1}{2}O_2 \rightarrow 2Cu(NH_3)_4^{2+} + H_2O \quad (37.2)$$

There is strong evidence that the etching rate is dependent on the diffusion of $Cu(NH_3)_2^{+}$ from the copper surface [Eq. (37.1)] into the bulk of the active solution, where oxidation per Eq. (37.2) occurs.[3] Etching can be continued with the formation of $Cu(NH_3)_4^{2+}$ oxidizer from air during spray etching and as long as the copper-holding capacity supported by Cl^- ions is not exceeded.

37.4.1.2 Properties and Control. Early versions of alkaline etchants were batch operated. They had a low copper capacity, and the etch rates dropped off rapidly as copper content increased.[4–6] It was found to be necessary to add controlled amounts of dissolved oxidizing agents to speed up the rate and increase copper capacity at a constant temperature. Batch operation is no longer supported by commercial suppliers.

Etching solutions are operated at 120 to 130°F and are well suited to spray etching. Efficient exhaust systems are required because ammonia fumes are released during operation.[7] Etching machines must have a slight negative pressure and moderate exhausting to retain the ammonia necessary for holding dissolved copper in solution. Care must be taken that sufficient fresh air to supply needed O_2 is introduced to balance the extraction. Currently available solutions offer constant etching of 1 oz (35 µm) copper in 1 min or less, with a dissolved copper content of 18 to 24 oz/gal.

37.4.1.3 Continuous Systems. A practical method of maintaining a constant etch rate with minimal pollution uses automatic feeding controlled by specific gravity or density.[6] The process, which is generally referred to as *bleed and feed*, is illustrated in Fig. 37.1. As the printed boards are etched,

copper is dissolved, and the density of the etching solution increases. The density of the etchant in the etcher sump is sensed to determine the amount of copper in solution. When the density sensor records an upper limit, a switch activates a pump that automatically feeds replenishing solution to the etcher and simultaneously removes etchant until a lower density is reached. An elegant by-product of this technique is the introduction of the replenisher into the first rinse stage following the etcher. The rinse captures the copper from the panel and reintroduces it to the etcher, where it is eventually eliminated to the by-product tank with the rest of the copper. When used with aqueous processing photoresists, it has been found that low pH (7.9 to 8.1) aids etch reliability. However, maintaining this pH by adjustment of exhaust extraction has been difficult. Measurement of pH and controlled addition of anhydrous ammonia into the etchant has improved consistency. It has been established that control of free ammonia as well as ammonium chloride and oxygen levels are needed to stabilize etching rates. Direct injection of oxygen has also been attempted to stabilize the etching rates between low and high copper etching demand process utilization periods. Typical operating conditions are as follows:[b]

Temperature	120 to 130°F (49 to 50°C)
pH	8.0 to 8.8
Specific gravity at 120°F (49°C)	1.207 to 1.227
Baumé, Be°	25 to 27
Copper concentration, oz/gal	20 to 22
Etch rate, 0.001 in/mm	1.4 to 2.0
Chloride level	4.9 to 5.7 mol/L

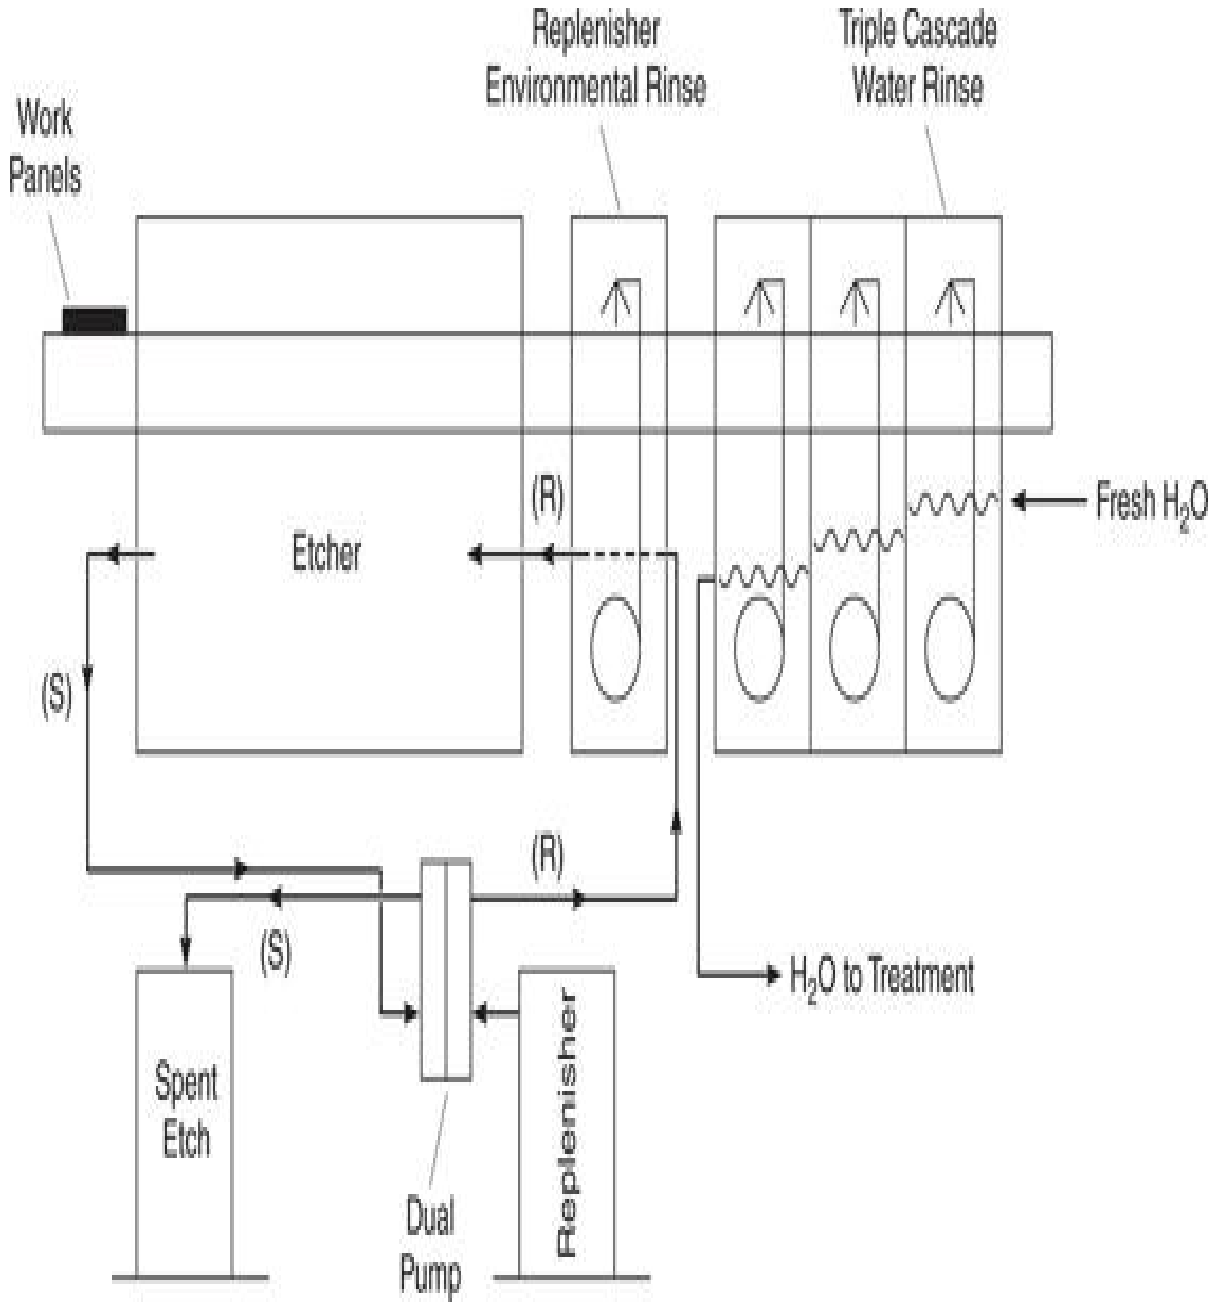

FIGURE 37.1 Automated flow-through alkaline etching system.

A study of the etching rate versus dissolved copper content shows the following effects:

0 to 11 oz/gal	Long etching times
11 to 16 oz/gal	Lower etch times but solution control difficult
18 to 22 oz/gal	Etch rates high and solution stable
22 to 30 oz/gal	Solution unstable and tends toward sludging

All work must be thoroughly rinsed immediately upon leaving the etching chamber. Techniques such as replenisher rinsing and multiple cascade water rinsing assist in thorough rinsing with controlled effluent and limited water use.[8] Do not allow the boards to dry before rinsing. Typical plated resist is tin. On occasion, tin/lead solder resist is plated for fused tin/lead applications. Etched circuitry with plated tin/lead solder resist also requires an acid application of solder brightener for reflow of the coating. Thiourea-containing brighteners have largely been eliminated due to use of sacrificial plating resist (SMOBC) and environmental pressures. Rinsing must be sufficient to remove etchant from under circuit edges and to completely clean the circuit surfaces and plated through-holes.[8] Multiple-stage cascading water rinsing and air knife drying result in clean, stain-free surfaces (see Fig. 37.1). Modern processes often follow the etching rinse with metal-resist stripping and rinsing chambers before exiting the machine conveyor.

37.4.1.4 Closed-Loop Regeneration. True regeneration requires the following:

1. Removal of portions of the spent etching solution from the etcher sump under controlled conditions, according to the amount of copper added to the etch bath.
2. Chemical restoration of spent etchant (i.e., removal of excess by-products and adjustment of solution parameters for reuse).
3. Replenishing of etchant in the etching machine, balancing the actual production use demands. Constant etching conditions are achieved when regeneration is continuous. Regeneration by these methods is expensive and is thus

limited to large printed-circuit facilities. The principal methods of regeneration are crystallization, liquid–liquid extraction, and electrolytic recovery.

- Crystallization reduces the copper level in the etchant by chilling and filtering precipitated salts. This is followed by refortification and adjustment of operating conditions.
- Liquid–liquid extraction[9,10] is gaining acceptance because of its continuous and generally safe nature. The process involves mixing spent etchant with an organic solvent (i.e., hydroxy oximes) capable of extracting copper. The organic layer containing copper is subsequently mixed with aqueous sulfuric acid, which extracts copper to form copper sulfate. The copper-free etchant is restored, and the copper sulfate is available for acid copper electrowinning. Closed-loop regeneration systems reduce chemical costs, sewer contamination, and production downtime, but require floor space, resources, and technical attention. Economics are directly affected by copper market prices.
- Electrolytic recovery of copper directly and through membrane cells from an ammonia-complexed copper sulfate etchant yields possible benefits such as reduced waste shipments and cost savings.[11,12]
- These processes are usually employed by the large-scale vendor/recycling plants that offer a spent removal and replenisher replacement service as part of the product contract. This practice allows for economies of scale and environmental responsibility to be removed from the fabrication plant site.

37.4.1.5 Special Problems Encountered during Etching[13]

1. *Low etch rate with low pH, <8.0*. This is caused by excessive ventilation, heating, downtime, and spraying when the solution is hot, under conditions of adequate replenishment or low ammonia. The pH must be raised with

anhydrous ammonia. Automatic replenishment equipment must be checked.

2. *Low etch rate with high pH, >8.8*. This is caused by high copper content, water in etchant, or underventilation.
3. *Low etch rate with optimum pH*. This is due to error of copper thickness, oxygen starvation in the etcher, or contamination of the etchant.
4. *Solder attack*. This is caused by excess chloride in the etchant, improper tin/lead deposits, or insufficient phosphate content.
5. *Residue on solder plate, holes, and traces*. These may be caused by etchant solution imbalance or by spent finisher.
6. *Under- or overetching*. This may be due to improper pH or equipment adjustments.
7. *Sludging of etch chamber with low pH, <8.0*. See special problem 1. Sludge will be gritty and dark blue. This may be corrected by the addition of anhydrous ammonia.
8. *Sludging of etch chamber with high pH, >8.8*. See special problem 2. Sludge will be light blue and fluffy. This may be due to the copper concentration exceeding the capacity of the chloride concentration. It may be corrected by adding ammonium chloride. It may also be due to water added to the etchant.
9. *Presence of ammonia fumes*. The cause of this is leaks in the etcher. Ventilate for operator safety.
10. *Pollution*. This results when water coming from the etchers contains dissolved copper. If so, it must be chemically treated and separated from ammonia-bearing rinses. Thin-clad copper laminates present a further problem because their faster movement through the etcher increases the transport of etchant into the rinses. Evaluate isolation roller placement and cleanliness, internal etcher overspray, and proper chemical and water rinsing.

37.4.2 Cupric Chloride

Cupric chloride is the second mainstream etchant of choice. (See Table 37.1 for characteristic cupric chloride solutions.) It is more compatible with photopolymer resists and is the etchant of choice for precision etching of small features. Because the cuprous ion buildup renders the etchant impractically slow, this etchant must always be used as a regenerative system with continuous oxidizer management and control. These systems have been the subject of many innovations to achieve continuous regeneration, lower costs, and a constant, predictable etch rate. Steady-state etching with acidic cupric chloride permits high throughput, material recovery, and reduced pollution. Regeneration in this case is somewhat complex but is readily maintained. Dissolved copper capacity is high compared with that of batch operation. Cupric chloride solutions are used mainly for fine-line multilayer inner details, print-and-etch boards, and panel-plate/tent-and-etch boards.[14] In addition to photoresists, screened inks, gold, and tin-nickel have been used. Solder and tin resists are not compatible with cupric chloride etchant.

TABLE 37.1 Characteristic Cupric Chloride Etching Solutions

Component	Solution 1[15]	Solution 2[16]	Solution 3[17]	Solution 4[18]
$CuCl_2\ 2H_2O$	1.42 lb	2.2 *M*	2.2 *M*	0.5–2.5 *M*
HCl (20° Be)	0.6 gal	30 mL/gal	0.5 *N*	0.2–0.6 *M*
NaCl		4 *M*	3 *M*	
NH_4Cl				2.4–0.5 *M*
H_2O	*	*	*	*

*Add water to make up 1 gal.

37.4.2.1 Chemistry. The etching reaction is as follows:

$$Cu + CuCl_2 \rightarrow Cu_2Cl_2 \quad (37.3)$$

Chloride ions, when added in excess as hydrochloric acid, sodium chloride, or ammonium chloride, act to solubilize the relatively insoluble cuprous chloride and thereby maintain stable etch rates. The complex ion formation can be shown as

$$CuCl + 2Cl^- \rightarrow CuCl_3^- \quad (37.4)$$

The formation and diffusion of this chloro-complex form of the Cu(I) ion determine the etching rate for cupric chloride. Thus, the rate is affected by chloride ion concentration as well as the typical diffusion concentration and film thickness variables.

The etchant is regenerated by reoxidizing the cuprous chloride to cupric chloride by several chemical choices as illustrated by the following equations:

$$Air\ 2Cu_2Cl_2 + 4HCl + O_2 \rightarrow 4CuCl_2 + 2H_2O \quad (37.5)$$

This method of regeneration is not used because the oxygen reaction rate in acids is slow and the solubility of oxygen in hot solution is low (4 to 8 ppm). Spray etching induces air oxidation, but is not sufficiently reactive to support practical etching rates. An additional option of using ozone can accelerate the rate of this process, but ozone concentrations in an oxygen stream are difficult to maintain at above 3 percent, thus limiting utility.

Direct chlorination

$$Cu_2Cl_2 + Cl_2 \rightarrow 2CuCl_2 \quad (37.6)$$

As the traditional regeneration choice, the chlorine reaction is rapid, positive, and easily controlled. Liquefied chlorine gas has been generally available, and standardized commercial addition systems have been available. Recently, pressure on chlorine distribution and use due to safety and environmental regulations have made availability and implementation more

expensive and difficult. It is significant that the reaction simplicity indicates that all etched copper is converted directly to cupric chloride [combination of Eqs. (37.3) and (37.6)]. Thus, there is no effect on water or acid balances from the etching reaction itself.

Hydrogen peroxide

$$Cu_2Cl_2 + 2H_2O_2 + 2HCl \rightarrow 2CuCl_2 + 2H_2O \qquad (37.7)$$

This process is more complicated because both hydrogen peroxide and hydrochloric acid add water in the reaction process. Since hydrogen peroxide is unsafe to store and handle in concentrations above 35 percent, there is considerable water added with both the oxidizer and the hydrochloric acid. The result limits the copper-holding capacity of the etchant. The addition is reasonably and simply controlled as a direct ratio of HCl, and peroxide is added to the bath to maintain the copper oxidation. This formulation has been favored in Europe and to some extent in Asia.

Sodium chlorate

$$3Cu_2Cl_2 + NaClO_3 + 6HCl \rightarrow 6CuCl_2 + NaCl + 3H_2O \qquad (37.8)$$

Sodium chlorate has become one of the most widely used formulations. The oxidizer solutions can be mixed from powder and are also commercially supplied as 45 percent solutions. The water balance must also be carefully controlled with this oxidizing plan, and the amount of sodium chloride in the working bath can be boosted by addition with the oxidizer. This can be a rate enhancer by supplying chloride ions needed by Eq. (37.6), and since the chloride ion is separately added from the hydrochloric acid, the free acid can be maintained at very low levels (<0.1 normal).

Electrolytic

$$\text{(Cathode)} \qquad Cu^+ + e^- \rightarrow Cu \qquad (37.9)$$

$$\text{(Anode)} \qquad Cu^{+} \rightarrow Cu^{2+} + e^{-} \qquad (37.10)$$

Electrolytic systems of direct and membrane cell design have been employed. However, this technology is not a major factor in current manufacturing practice.

37.4.2.2 Properties and Control. Early cupric chloride formations had slow etch rates and low copper capacity and were limited to batch operation.[15–21] Regenerated continuous operation using modified formulations has brought useful improvements. Etch rates as high as 55 s for 1 oz copper are obtained from cupric chloride–sodium chloride–HCl systems operated at 130°F with conventional spray-etching equipment. Copper capacities are maintained at 20 oz/ gal and above. However, more recently, higher copper contents and adjusted chemistries at 125°F typically etch at 75 to 90 s for 1 oz copper.

37.4.2.3 Continuous Etching and Regeneration. Systems in use include chlorination, sodium chlorate, hydrogen peroxide, and electrolysis.

37.4.2.3.1 Chlorination. Direct chlorination has been the preferred technique for regeneration of cupric etchant because of its historically low cost, high rate, efficiency in recovery of copper, and pollution control. The cupric chloride–sodium chloride system (Table 37.1, no. 3) is suitable. Figure 37.2 shows a generalized process.[17] Chlorine, hydrochloric acid, and sodium chloride solutions are automatically fed into the system as required. Sensing devices include oxidation-reduction instruments (Cu oxidation state), density (Cu concentration), level sensors, and thermostats. Chlorination is reliable and controllable. Other factors are safety and solution control. Optical colorimetric sensors can be used to detect Cu(I) levels. However, these cells are subject to fogging by organic contamination and crystalline buildup with the hazardous defect of continuing to add chemicals past the proper control points and liberating chlorine into the work area.

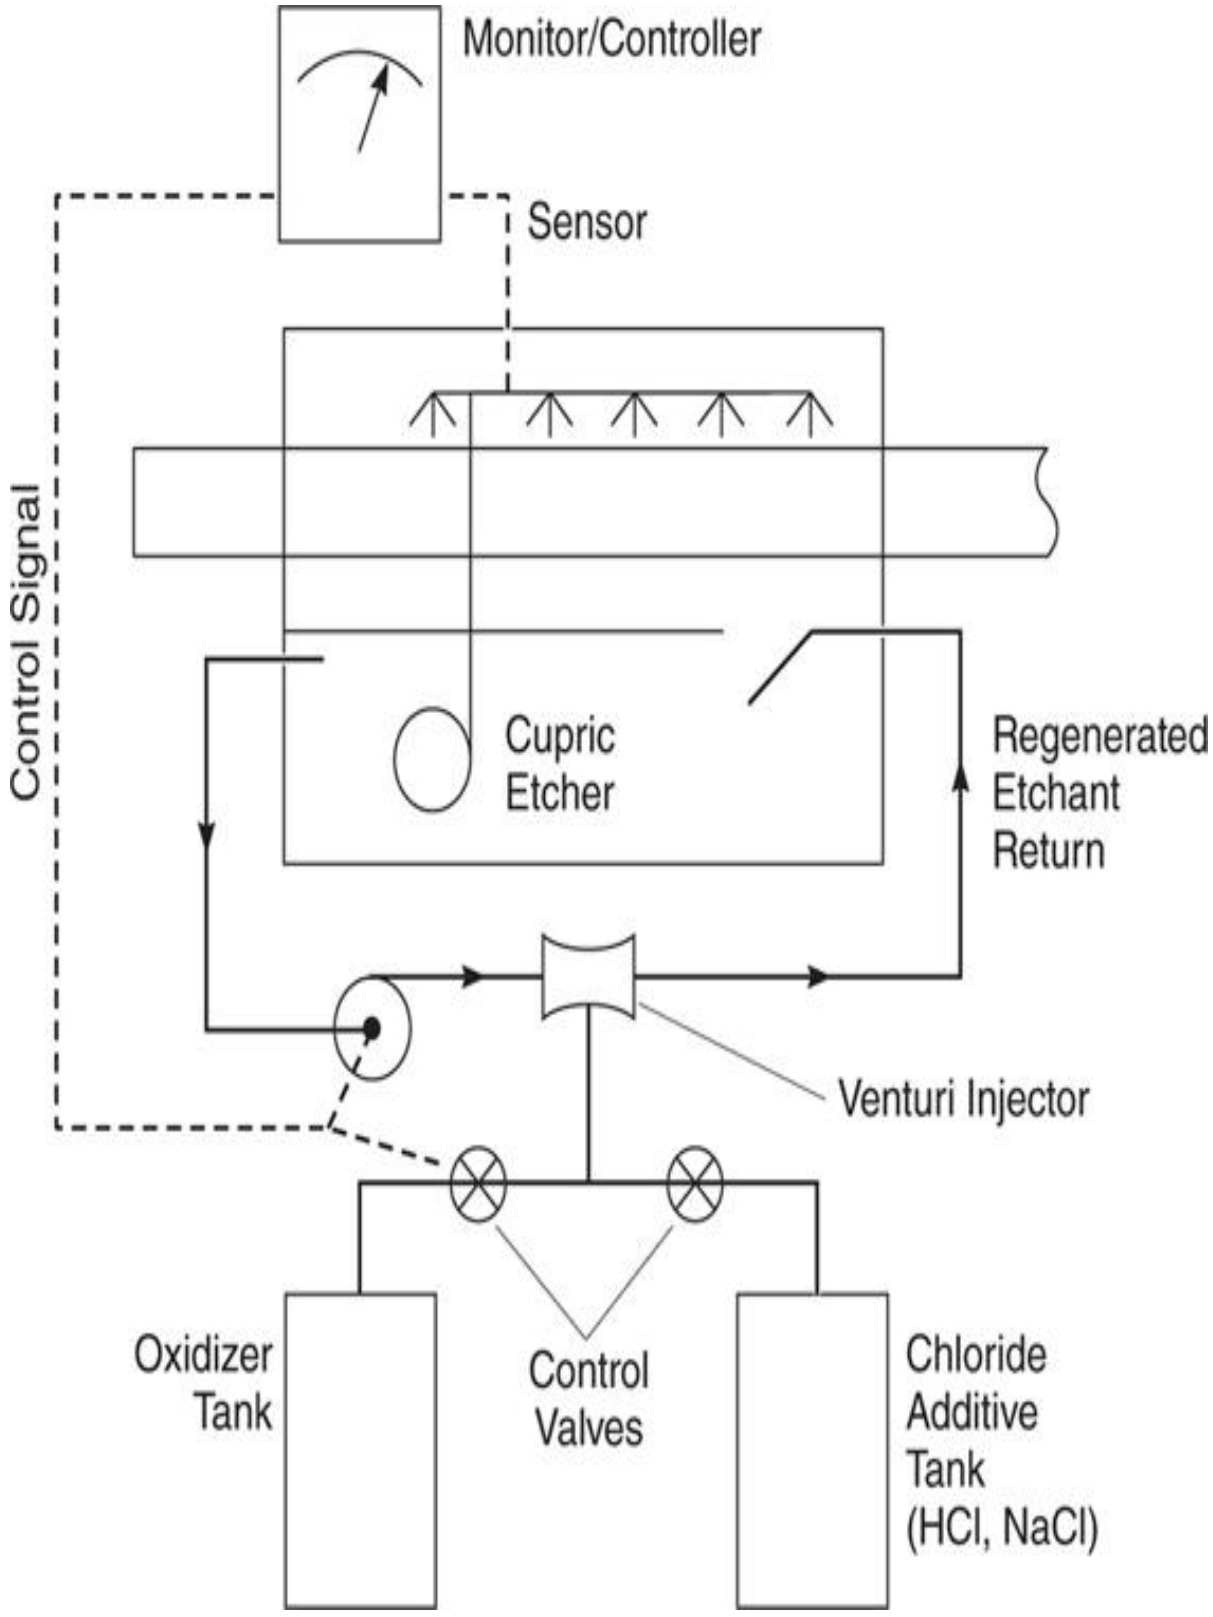

FIGURE 37.2 Cupric chloride chlorination regeneration system.

1. *Safety:* Use of chlorine gas requires adequate ventilation, tank and cylinder storage, leak-detection equipment, emergency protocols, personal protective equipment, operator training, and fire department approval and inspection of installations.
2. *Solution control:* An increase in pH will cause the copper colorimeter to give erroneous readings caused by turbidity in the solution. Organic deposits can also foul controls. Excess NaCl at 18 to 20 oz/gal copper causes coprecipitation of salts when the solution is cooled. Solution filtration and etch tank cleanliness must be maintained. Replacement of electrodes, instruments, and metering devices should be scheduled regularly.

37.4.2.3.2 Chlorate Regeneration. This method, currently widely supported, uses sodium chlorate, sodium chloride, and hydrochloric acid and is an alternate method similar to chlorination. A control sequence similar to the one shown in Fig. 37.2 may be used. Sodium chlorate is available in commercial solutions of several strengths with some degree of formulated agents (usually sodium chloride) added to the mixture. These solutions are added with hydrochloric acid either as a coordinated addition or in a special control logic sequence that allows very low free acid. This control system uses a multiple sensor color or turbidimetric optical system. The addition of one component (e.g., oxidizer) to a flowing sample cell occurs when the primary cell senses are triggered. A second cell allows this addition so long as there is a change from the first cell input. When there is no longer a change response and the first cell is still in “triggered” condition, the second component (e.g., HCl) is added. The logic continues to flip-flop until the first cell is satisfied. The etch sump conditions seem to have a partially delayed response to the chemical addition reaction such that oxidizing seems to occur over a longer period. Therefore, proper addition and mixing in the sump must be considered for stable control operation.

1. *Safety:* Sodium chlorate is a potent oxidizing agent that can support combustion. It is necessary to ensure that solution spills are completely cleaned up and that the rags or other materials are not allowed to dry out. Excess addition of reagents above amounts to support the actual copper etched may form chlorine gas that will be liberated into the etch machine and environment. Proper instrumentation and training for this eventuality must be implemented.
2. *Solution control:* If there is insufficient free acid content in the etch sump to react with the oxidizer and copper [Eq. (37.8)], a dangerous imbalance can occur. First, the instruments and controls may not respond properly, and the etch reaction may slow down. Second, any subsequent addition of acid or mixing with acid-containing wastes can liberate chlorine gas in an uncontrolled and dangerous manner. Proper chemical balance is another issue. Water is added in all of the chemical streams and is produced in the chemical reaction. Therefore, any excess chemical addition can dilute the chemistry and change the copper-holding ability of the etchant.

37.4.2.3.3 Hydrogen Peroxide Regeneration. Hydrogen peroxide uses a two-part chemistry much like sodium chlorate. ORP instrumentation is identical in the control of adding proportional amounts of oxidizer and hydrochloric acid. Peroxide tends to decompose on sitting so that the spills are not as dangerous. Older application of colorimetric cells for the control of dosing has largely been eliminated.

1. *Safety:* Hydrogen peroxide solutions can become unstable and disassociate into oxygen and water with the liberation of heat. This can occur with explosive force in a confined vessel such as a drum stored in sunlight or heat. It can also occur in plumbing with closed valving. The decomposition is catalyzed by many metals, including Cu, Ni, and Fe. If traces of metal or metal salts are allowed to contaminate

piping runs, the piping may also rupture explosively. Facilities should be constructed with pressure relief capabilities.

37.4.2.3.4 Electrolytic Regeneration. The electrochemical reversal of the etching of copper shown in Eq. (37.9) and (37.10) is claimed to be effective and economical. Descriptions of this system are given in the literature.[15] On a large scale, electrolytic regeneration requires a high investment in equipment and materials, as well as high power consumption. The chemical formulation is relatively high in acid content and low in copper, a condition not optimized for etching effectiveness or plating efficiency.

The etchant is a solution of cupric chloride and hydrochloric acid (Table 37.1, no. 1). Etchant flows continuously between spray-etching machines and a plating tank. In the plating machine, two processes take place simultaneously: copper is plated at the cathode, and regeneration of the spent etchant occurs at the anodes. Copper recovery may not return copper value and may be expensive, inconvenient, and cause difficulty with recycling.

37.4.2.4 Problems with Cupric Chloride Systems

1. *Slow etch rate:* Depending on chemical formulation, cupric chloride is inherently slower than ammonia and must be properly evaluated before production expectations are established. Check to ensure no resist residues or chromate coatings remain on the panel surface before etching. A slower than usual rate is frequently due to low temperatures, insufficient sump mixing, or poor solution chemical control. If temperature and agitation are under control, slow etching with a dark green solution may result from a low cupric ion content, indicating insufficient oxidizer. Acid must also be added to clarify cloudy solutions. (Before acid addition, make sure excess oxidizer is not present.) In regenerative systems, the source of oxidation

may be depleted. It is advisable to analyze specific gravity, free acid, and total chloride on a regular schedule and maintain control charts to ensure that bath controllers are consistent and operating properly.

2. *Sludging:* This occurs if acid is low or if water dilution occurs.
3. *Etcher goop:* This is a common floating accumulation of photoresist compounds leached into and precipitated from etch baths. Accumulations appear to increase with higher acid formulations. Formation can be limited by proper exposure of photoresists and continuous recirculation of the etch bath through carbon filtration. Periodic, complete drain-down of the etching machinery and thorough mechanical and chemical equipment cleaning with a sulfamic acid–type commercial cleaner can minimize problems.
4. *Yellow or white residues on copper surface:* Yellow residue is usually cuprous hydroxide. It is water insoluble and is left when boards are etched and alkali-cleaned. A white precipitate will probably be cuprous chloride, which can remain after etching in solutions that are low in chloride ion and acid. To eliminate both conditions, the solution in which the board is rinsed just before final water-spray rinsing should be 5 percent by volume hydrochloric acid.
5. *Waste disposal:* Spent or by-product etchant is usually sent off-site for copper reclamation. There is usually a fee for this service depending on copper content and distance to the reclamation facility. The solutions must be free of unreacted oxidizer (see previous chlorate system discussion). Etchant can contain traces of zinc, chromium, and arsenic from the foil treatments.

37.4.3 Sulfuric Acid–Hydrogen Peroxide

Sulfuric-peroxide systems are used extensively for copper surface preparation by microetching the surface to provide texture and active surfaces. These formulations have been used in the past for primary circuitization etching but are no longer favored because of slow etch rate and needs for accompanying control of exotherm and copper crystallization. However, the increasing need for fine-line etching has renewed use possibilities for this and other etchants (see Sec. 37.7.4). In essence, these call for etching foils thinner than ½ oz and the control precision offered by slower etchants. They are compatible with metal resists and many organics.

37.4.3.1 Chemistry. Typical constituents of both immersion and spray etchants and their functions are as follows:

1. Hydrogen peroxide is an oxidizing agent that reacts with and dissolves metallic copper.
2. Sulfuric acid makes copper soluble and holds copper sulfate in solution.
3. Copper sulfate helps to stabilize etch and recovery rates.
4. Molybdenum ion is an oxidizing agent and rate exaltant.[22]
5. Aryl sulfonic acids are peroxide stabilizers.[23]
6. Thiosulfates are rate exaltants and chloride ion controllers that permit lower peroxide content.[24]
7. Phosphoric acid retains clean solder traces and plated through-holes.[25,26]

The etching reaction is as follows:

$$Cu + H_2O_2 + H_2SO_4 \Rightarrow CuSO_4 + 2H_2O \qquad (37.11)$$

37.4.3.2 Properties and Control. The earlier technical problems of slow etch rates, peroxide decomposition, and foaming in spray systems have been solved, but critical concerns still remain. Among these are process overheating, etchant composition balance with by-product recovery, etchant

contamination, and the dangers of handling concentrated peroxide solutions. The specific problem of decomposition of peroxide during idle hours has caused disastrous equipment meltdowns, and thus requires thermal management while equipment is otherwise not in operation.

37.4.3.3 Closed-Loop Systems. Production facilities require continuous recirculation of the etchant through the etching tank or machine and the copper sulfate recovery operation. Etchant replenishment is controlled by chemical analysis and by additions of concentrates.

Copper sulfate recovery is based on lowering the solubility of $CuSO_4$ $5H_2O$ by decreasing the etchant temperature to 50 to 70°F. Crystallizer equipment and conveyorized discharge has been available for this process.

37.4.3.4 Problems Encountered with Peroxide Systems

1. *Reduced etch rates:* This problem can be caused by operating conditions, solution imbalance, or chloride contamination.
2. *Under- and overetching:* A review of etching conditions, solution control, and the resist stripping process may show deviations from normal. In the case of immersion etching, the solution and panel agitation may need to be increased. When spray-etching, a check of nozzles and line clogging is indicated.
3. *Temperature changes:* Recirculating water rates and thermostats need to be examined regularly. Overheating may be due to high copper content, contamination, or rapid peroxide decomposition.
4. *Copper sulfate recovery stoppage:* Examine solution balance, heat exchanger, and other recovery equipment. Exit conveyor jamming difficulties from thermal excursions and varying crystal size and liquid content cause major shop floor problems.

37.4.4 Persulfates

Ammonium, sodium, and potassium persulfates modified by certain catalysts have been adopted for the etching of copper in PC manufacturing. Continuous regenerative systems and a batch system using ammonium persulfate are no longer used. Wide use is made of persulfates as a microetch for innerlayer oxide coating and copper electroless and plating processes. Persulfate solutions allow all common types of resists on boards including solder, tin, tin/nickel, screened inks, and photosensitive films. Formulations of ammonium persulfate catalyzed with mercuric chloride are no longer used, primarily because of environmental issues, costs, and improved alternatives. In general, persulfate etchants are unstable and will exhibit decomposition, lower etch rates vs. copper content, and lower useful copper capacity.

37.4.4.1 Chemistry. Ammonium, potassium, and persulfates are stable salts of persulfuric acid ($H_2S_2O_8$). When these salts are dissolved in water, the persulfate ion ($S_2O_8^{2-}$) is formed. It is the most powerful oxidant of the commonly used peroxy compounds. During copper etching, persulfate oxidizes metallic copper to cupric ion as shown:

$$Cu + Na_2S_2O_8 \rightarrow CuSO_4 + Na_2SO_4 \qquad (37.12)$$

Persulfate solutions hydrolyze to form peroxy monosulfate ion (HSO_4^{1-}) and, subsequently, hydrogen peroxide and oxygen. This hydrolysis is acid catalyzed and accounts for the instability of acidic persulfate etching solutions.

Ammonium persulfate solution, normally made up at 20 percent, is acidic. Hydrolysis reactions and etchant use cause a reduction of the pH from 4 to 2. The persulfate concentration is lowered, and hydrated cupric ammonium sulfate [$CuSO_4$ $(NH_4)_2SO_4$ $6H_2O$] is formed. This precipitate may interfere with etching.

Solid persulfate compounds are stable and do not deteriorate if stored dry in closed containers. Solution makeup composition includes various catalysts, including organic matter and transition metals (Fe, Cr, Cu, Pb, Ag, etc.). Materials for storage must be chosen carefully. Persulfates should not be mixed with reducing agents or oxidizable organics.

The useful capacity of the etchant is about 7 oz/gal copper at 100 to 130°F. Above 5 oz/gal of copper, it is necessary to keep the solutions at 130°F to prevent salt crystallization. The etch rate of a solution containing 7 oz/gal of dissolved copper is 0.00027 in/min at 118°F.

37.4.4.2 Batch Operation. Sodium persulfate is preferred because it has minimal disposal problems and somewhat higher copper capacity and etch rates. A composition of 3 lb/gal sodium persulfate with 15 ppm of $HgCl_2$, 1 gal of proprietary additive, and 57 ml/gal of H_3PO_4 has been successfully used for batch-type spray etching.[27] Etch rates vary throughout bath life and range from 0.0018 to 0.0006 in/min for copper content of 0 to 7 oz/gal. Prepared solutions must be aged for 16 to 72 h before etching when proprietary additives are used.

37.4.4.3 Problems with Persulfates

1. *Low etch rates:* Since the solution may decompose, it will be necessary to replace the bath. If solution is new, add more catalyst and check for iron contamination.
2. *Salt crystallization:* Salts crystallize on the board and cause streaks, damage the solder plate, and plug the spray nozzles or filters. When copper content is high, blue salts may precipitate.
3. *White films on solder surface:* This may occur normally or when the lead content in the solder plate is too high.
4. *Black film on solder:* This condition can result when the solder alloy is high in tin. If solder reflow or component soldering is to follow, activate by tin immersion or with

solder brighteners. Adjust phosphoric acid content in etchant and solder-plating conditions.

5. *Spontaneous decomposition of etch solution:* This breakdown is due to contaminated, overheated, or idle solutions. Ammonium persulfate etchants are unstable, especially at higher temperatures. At about 150°F, the solution decomposes quickly. Use it soon after mixing.
6. *Disposal:* The exhausted etchant consists mainly of ammonium or sodium and copper sulfate with a pH of about 2. Two methods for disposal are
   a. Electrolytic disposition of the copper on the surface of passivated 300 series stainless steel is one disposal method. The spent etchant is acidified with sulfuric acid prior to electrolysis. Once the copper has been removed, the remaining solution can be diluted, neutralized, checked, and discarded. The copper can be removed from the cathode. Spent sodium persulfate can be treated with caustic soda.
   b. Addition of aluminum or iron machine turnings to a slightly acidified solution is another practical but possibly more difficult means of removing the dissolved copper. The reaction, especially in the presence of chloride ions, will be violent, and considerable heat will be given off if the solutions are not diluted.

37.4.5 Ferric Chloride

Ferric chloride solutions are used as etchants for copper, copper alloys, Ni/Fe alloys, and steel in PC applications, electronics, photoengraving arts, and metal finishing. Current use of ferric chloride etchant in printed wiring fabrication is extremely limited in the United States because of costly disposal of the copper-containing etchant, and the much better commercial support for ammoniacal and cupric chloride etchants. There is still considerable use for alloy etching and photochemical machining applications.

Ferric chloride can be used with screen ink, photoresist, and gold patterns, but it cannot be used with tin or tin/lead resists. However, ferric chloride is an attractive spray etchant because of its ease of use, holding capacity for copper, and ability to be used on an infrequent batch application basis.

The composition of the etchant is mainly ferric chloride in water, with concentrations ranging from 28 to 42 percent by weight. Free acid is present because of the hydrolysis reaction and the need to maintain an acid environment. The natural acidity is usually supplemented by additional amounts of HCl (up to 5 percent) to prevent formation of insoluble precipitates of ferric hydroxide. Commercial formulations for copper alloy etching are usually 36 Be, or approximately 4.0 lb/gal $FeCl_3$, and may contain antifoam and wetting agents. Customary acid operating HCl content is 1.5 to 2.0 percent.

The effects of ferric chloride concentration, dissolved copper content, temperature, and agitation on the rate and quality of etching have been reported in the literature.[28,29]

37.4.6 Chromic-Sulfuric Acids

These etchants for solder- and tin-plated boards were preferred for many years. More recently, their use has been completely eliminated due to Cr(VI) listing as a critical environmental hazard. Other problems with chromic-sulfuric etchants are difficulty in regeneration, inconsistent etch rate, the low limit of dissolved copper (4 to 6 oz/gal), and dangerous degradation of PVC and polypropylene equipment. Chromic acid etchant is suitable for use with solder, tin/nickel, gold, screened vinyl lacquer, and dry or liquid film photoresists. Chromic-sulfuric mixtures etch copper slowly, and additives are needed to increase the etch rate. For example, sodium sulfate and iodine have been used for rate increase. Alkaline etchants have become so well controlled that there is no justification for the risks and costs of chromic acid formulations.

The following listing demonstrates some of the operational difficulties with chromic-sulfuric etchants.

1. *Solder attack:* The protective value of solder depends on the formation of insoluble compounds on the surface. Solder is attacked if the sulfate content of the bath becomes very low or contains chloride or nitrates. The solder plate composition can also cause etchant attack. When the lead content becomes low, the sulfate film protection is lowered, and protection is lost.
2. *Slow or no etching of copper:* This can be caused by low chromic content, low temperature, insufficient acid, or high copper content. The solution is maintained as close as possible to 30 Baumé (pH about 0.1, temperature 80 to 90°F) and should be discarded when copper metal content exceeds 5.5 oz/gal.
3. *Staining of board materials:* The surfaces of dielectric substrates such as paper-based phenolics are attacked by chromic acid etchants. Removal is difficult, and the boards are generally rejected.
4. *Disposal:* Spent chromic acid etchants present a serious disposal problem. Disposal must comply with pollution standards and approved practice.
5. *Safety hazards:* Chromic acid is an extremely strong oxidizing agent. It will attack clothing, rubber, plastics, and many metals. Safety measures require adequate ventilation to keep fumes out of room air, synthetic rubber gloves, aprons, face and eye shields, and storage away from combustible materials. Dermatitis and nasal membrane damage are possible dangers.[7]

37.4.7 Nitric Acid

Etchant systems based on nitric acid have not found extensive application in PC manufacture. Copper etching is very exothermic, which may lead to violent runaway reactions.

Problems with this system include solution control, attack on resists and substrates, and toxic gas fuming. However, nitric acid has certain advantages. These include rapid etching, high dissolved copper capacity, high solubility of nonsludging products, availability, and low cost.

37.4.7.1 Chemistry. Reaction in strong acids is shown by the following equation:

$$3Cu + 2NO_3^- + 4H^+ \rightarrow 3Cu^{2+} + 2NO_2 + 2H_2O \qquad (37.13)$$

Recent work shows that process improvements are possible.[30,31] Controlled etching has been attained in solutions containing 30 percent copper nitrate, water-soluble polymers, and surfactants. Dry-film resists work well in this etchant. An important finding was that straight wall trace edges were achieved using nitric acid. This could result in higher yields and density of fine-line boards. The major difficulty in obtaining the sidewall results is the requirement for specific crystollagraphic grain structure to the copper foil that has been difficult to reproduce in production quantities.

37.5 OTHER MATERIALS FOR BOARD CONSTRUCTION

Printed board laminates are usually composed of copper foils bonded to organic dielectric materials, ceramics, or other metals.

1. *Organic dielectrics:* These are thermosetting or thermoplastic resins usually combined with a selected reinforcing filler. Thermoset-reinforced materials used for rigid and flexible boards provide overall stability, chemical resistance, and good dielectric properties. Thermoplastic materials are also used for flexible circuit applications. A

factor in material selection is the effect of process solutions, etchants, and solvents on the material. In addition, the adhesives used in laminating metal to substrate can be softened, loosened, and attacked by some solutions. Flat-surface planarity is an aid to precision etching. This can be improved by selection of laminate with fine glass woven structures that do not express a waviness to the free copper foil surface.

2. *Thin-clad copper:* Etched printed boards with epoxy laminate of ¼ oz (9 µm) copper or less show minimal lateral etching, thus enabling higher fidelity to pattern-plated traces. The problem with very thin copper foils is pinhole density and fragility in the laminate manufacturing process. One method of avoiding these problems is to start with a more conventional ½-oz (18-µm) foil and reduce its thickness by etching to a thinner state (3 to 9 µm).[32] This technique depends on a uniform starting foil and a very well-controlled etching process. Although the particulars of the published process were not disclosed, cupric chloride and sodium persulfate formulations have been used for this process.
3. *Reverse foil laminate:* This construction is receiving attention for improving precision and control of etched lines. In order to achieve this foil structure, the *tooth* or crystalline roughness must also be controlled in the foil. The tooth side is usually placed on the dielectric interface of the laminate to increase peel strength and present a flat surface for processing. However, one variation is to place the *drum* or flat side of the laminate toward the dielectric and leave the tooth side upward. This forms a flat interface so that the etching stops at this surface, instead of the conventional extra etching to remove the teeth that are buried in dielectric.
4. *Semiadditive copper:* A copper thickness of 0.000050 to 0.000200 in with subsequent copper and resist metal plating shows no overhang or sliver formation. These layers must be of sufficient thickness and uniformity to withstand

the cleaning and preparation steps for plating the required conductors.

37.6 METALS OTHER THAN COPPER

37.6.1 Aluminum

Aluminum-clad flexible circuits find use in microwave stripline[33] and radiation-resistance applications. Aluminum and its alloys have good electrical conductivity, are lightweight, and can be plated, soldered, brazed, chem-milled, and anodized with good results. Laminate dielectrics include PPO,[33] polyimide,[37] epoxy-glass, and polyester.

Precleaning for resist application includes nonetch alkaline soak, water rinsing for 5 to 10 s in chromic-sulfuric acid, rinsing, and drying. Preferred etchants include ferric chloride (12 to 18° Baumé), sodium hydroxide (5 to 10 percent), inhibited hydrochloric acid, phosphoric acid mixtures, solutions of HCl and HF, and ferric chloride–hydrochloric acid mixture.

Screen-printed vinyl resists and dry-film photoresist are the most durable for deep etching or chem-milling. A dip in a 10 percent nitric or chromic acid solution will remove residues from the surface or edges of conductor lines that may be left on some alloys. Dilute chromic acid has also been used for this purpose. Spray rinse thoroughly with deionized water after etching.

37.6.2 Nickel and Nickel-Based Alloys

Nickel is increasingly used as a metal cladding, electroplated deposit, or electroformed structure for printed wiring because of its welding properties. Nichrome- and nickel-based magnetic alloys are other examples of materials requiring special etching techniques.

The methods previously described are adaptable to image transfer and etching of nickel-based materials. Etching uses ferric chloride (42° Baumé) at about 100°F. Other etchants include solutions made from one part nitric acid, one part hydrochloric acid, and three parts water, or one part nitric acid, four parts hydrochloric acid, and one part water.

37.6.3 Stainless Steel

Alloys of stainless steel are used for resistive elements or for materials with high tensile strength. Etching of the common 300 to 400 series can be done with the following solutions:

1. Ferric chloride (38 to 42° Baumé) with 3 percent HCl (optional).
2. One part HCl (37 percent) by volume, one part nitric acid (70 percent) by volume, one to three parts water by volume. Etch rate is about 0.003 in/min at 175°F, useful for high 300 to 400 series alloys.
3. Ferric chloride + nitric acid solutions.
4. One hundred parts HCl (37 percent) by weight, 6.5 parts nitric acid by weight, 100 parts water by weight.

37.6.4 Silver

Silver, the least expensive precious metal, has excellent properties, including superior electrical and thermal conductivity, ductility, visible-light reflectivity, high melting point, and adequate chemical resistance. As such, it is widely used throughout the electronics industry. Flexible circuit structures with silver are used in electronic cameras and LED products.

Standard image-transfer methods are suitable. Preetch cleaning should include a dip in dilute nitric acid. Mixtures of nitric and sulfuric acids are effective etchants. With silver on

brass or copper substrates, a mixture of 1 part nitric acid (70 percent) and 19 parts sulfuric acid (96 percent) will dissolve the silver without attacking the substrate. The solutions should be changed frequently to prevent water absorption and the formation of immersion silver on the copper.

Etching can be done with a solution containing 40 g chromic acid, 20 mL sulfuric acid (96 percent), and 2000 mL water.[35] This is followed by a rinse in 25 percent ammonium hydroxide. Thin films of silver are etched in 55 percent (by weight) ferric nitrate in water or ethylene glycol. Solutions of alkaline cyanide and hydrogen peroxide will also dissolve silver. Use extreme caution. Electrolytic etching is also possible with 15 percent nitric acid at 2 V and stainless-steel cathode.

37.7 BASICS OF ETCHED LINE FORMATION

The basic process of chemical etching to form features has been studied and modeled extensively. However, the best scientific knowledge can only proceed to an understanding of factors influencing the process. The practical execution of the process to manufacture useful circuits contains elements of experience in the best practice of several processes and choices in the selection of materials and process variations to achieve technically sound, cost-effective, and manufacturable results. In order to make fine-line circuit products, it is necessary to understand the process fundamentals so that the limitations may be understood and then overcome. The intent of this section is to briefly review the underlying science and discuss factors and practices for precision etching.

37.7.1 The Image

37.7.1.1 Phototools. It seems obvious that artwork is the first defining step of the image. If the phototool lacks definition, integrity, or dimensional stability, there is no possibility of improving the image in subsequent processing. The edge definition and contrast are particularly important. Images of multiple pulses or *spots* must be overlapped so that there is minimum waviness of edges. As the feature to be resolved becomes smaller, the image must have better and cleaner integrity. It is desired that the artwork be at least an order of magnitude (factor of 10) better than the final tolerance required for the final product. Therefore, if the line tolerance is 0.0001 in, then the artwork should be 0.00001 in.

37.7.1.2 Image Integrity. The effectiveness of the image translated from the artwork/ exposure process can be best achieved by optimization through all of the processing. Surface preparation, resist application, exposure, handling, development, and cleanliness must be maintained sufficiently to produce images with proper integrity. Image integrity may be gauged periodically with a resource such as the Conductor Analysis Technologies etch evaluation protocol. Defects such as shorts and opens have been determined to be related to resist integrity, and persistent linewidth repeating patterns may be image related. General concepts indicate that the thinner the resist, the shorter the light path; and the less optical interface layers between the light source and the copper surface, the better fidelity of the image to the phototool. However, constant improvement in film, exposure, and phototool products makes fine-image options dependent on proper optimization and constancy of technique and cleanliness as well as choice of technology.

37.7.2 Basics of Processing

37.7.2.1 Diffusion—The Controlling Mechanism. In Sec. 37.4, the chemical reactions of the etching process are discussed. In order to understand the formation of the actual

shapes of the foil cross section, the influences of diffusion and fluid flow must be understood.[32] As a result of the etching reaction at the reaction point on the copper surface, a complex ion concentration is built up and active etching chemicals are depleted. In order to complete the reaction, this complex ion must move through a static *boundary layer* into a place where there is fresh etchant supplied to complete the reaction and carry away the etched product (see Fig. 37.3). This boundary-layer shape is dependent on the specific shape of the resist and etching wall, the fluid flow over the surface, and the critical fluid flow in the channels formed by the resist and the etched side wall.

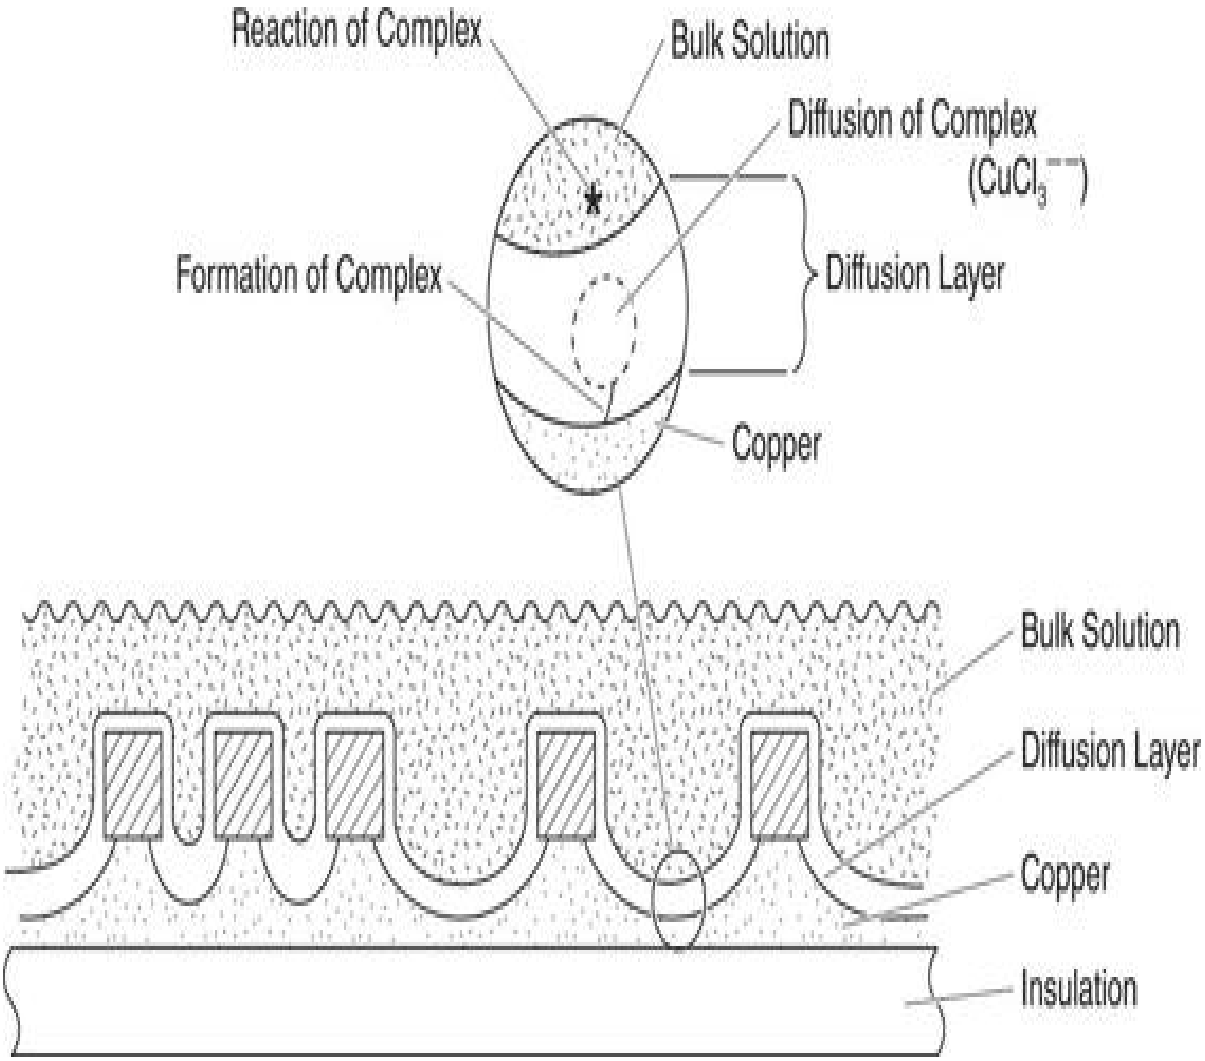

FIGURE 37.3 Etching dynamics for diffusion.

37.7.2.2 Fluid Flow Contribution. Examination of Fig. 37.3 shows that the contour of the boundary layer and its thickness vary with the shape and narrowness of the channel. If the surface is flat with no resist image, the boundary layer is thin and only dependent on the fluid properties and velocity across the surface. On the other hand, with resist images forming channels with depth, and the etched copper forming further channels, it is easy to see how the flow of fluid in the channel can be much different than the surface flow. In order to make matters even more confusing, the circuit traces and resist images form actual channels in the surface.

Much like a river bottom, the fluid flow in these individual channels is influenced by but different from the overall surface flow. In general, the narrower and deeper the channel, the slower the flow; and, critically, the diffusion boundary layer is more significant and etchant slows. In general terms, this is the reason that the middle section of a group of parallel, closely spaced lines etches slower than the outside lines. Similarly, this is the reason why a sharp 90° angle has a slower-etching section in the inside edge of the bend.

The concept of spray etching adds another dimension to the fluid dynamics. The surface of the panel is never really free of a liquid film. The top side of a panel has the etch liquid held up between delivery by the sprays and removal by flow off the edges. This flow is influenced by the number, flow, and pattern of the nozzles, the interaction of the flow between the sprays, the motion of the panels, and the effects of rollers and other contacting and shadowing objects. Even the bottom side retains fluid by surface tension and is influenced by the amount of liquid moving under the direction of the nozzles. The end result is complicated flow patterns that are the result of testing and optimization by the machine manufacturers.

37.7.3 Trace Shape Development

37.7.3.1 Etched Trace Shape Description. During etching, the gap between resist areas is removed evenly at first, and then progressively cup-shaped until the center area is broken through. After this, the area of exposed laminate opens progressively and the etching works on the side walls, etching in and under the resist as the side wall is relieved to expose more insulation and isolate the desired feature. (It has been noted that very little undercutting is apparent until the center is opened.) Figure 37.4 illustrates the attack with standard definitions for R (resist width), B (base of trace), T (top of trace), and t (foil thickness). There are two descriptive measures of the etching process—undercutting and etch factor—which are defined in Eqs. (37.14) and (37.15). These definitions are not universal, so it is necessary to clarify the definitions to correctly interpret discussions using these factors. Undercutting defines the average overhang of resist after top width reduction, and etch factor defines the average side wall inward taper of the etched feature per unit thickness. Occasionally, the etch factor is inverted or different measured values are used.

$$\text{Undercut:} \qquad U = (R - T)/2 \tag{37.14}$$

$$\text{Etch factor:} \qquad F = 2t/(B - T) \tag{37.15}$$

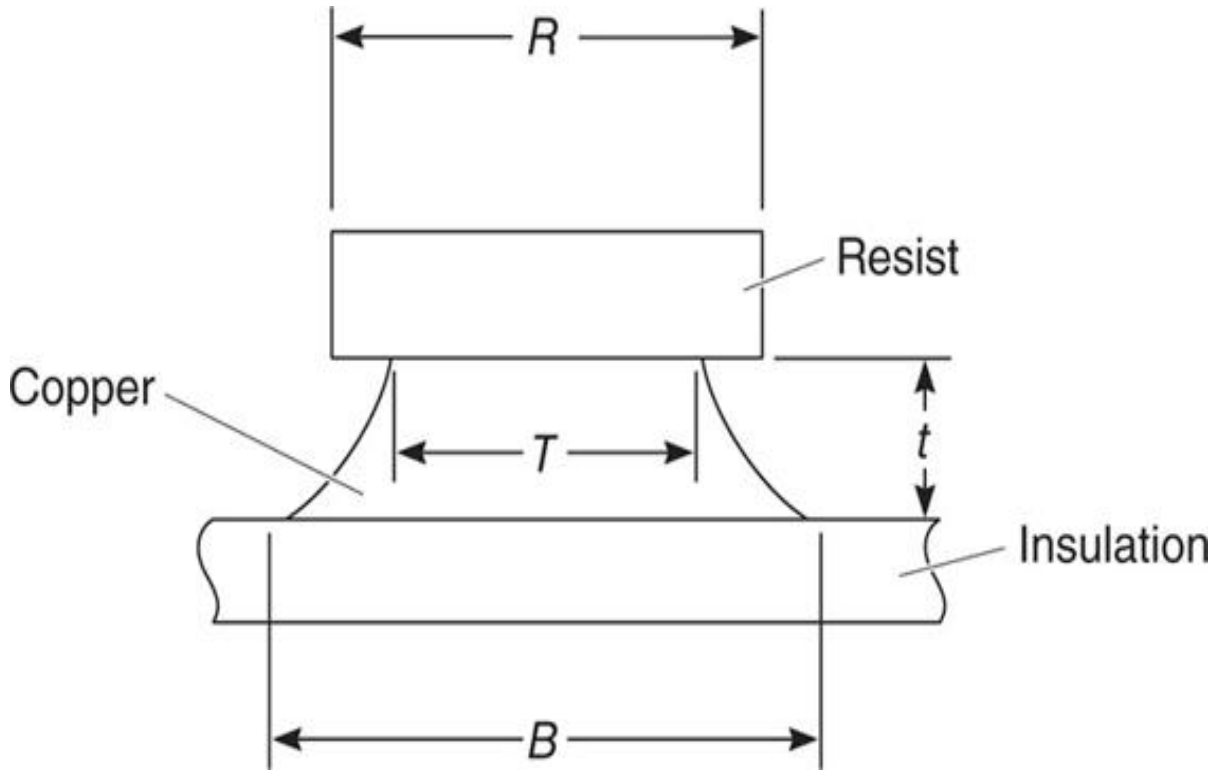

FIGURE 37.4 Trace cross-section measurement.

It is significant that these two units of measure are useful in describing the development of the shape of an etched part. It is desirable that *U* be minimized and *F* maximized for best feature definition.

37.7.3.2 Undercut and Etch Factor Development. The development of trace shapes has been studied by observing etched traces at progressive times.[36, 37] This allows one more parameter to be developed, the extent of etch, which is the ratio of *R/B*. This factor equals 1.0 when the bottom of the trace equals the resist width, one measure of ideal etching. Note that if $R < B$, this implies that the trace is underetched, and $R > B$ indicates overetching. The traces were etched in cupric chloride using 3.0-mil line and space patterns of 1.0-mil resist on 1-oz (1.4-mil) copper foil. The progression of etch values is found in Table 37.2 and Fig. 37.5.

TABLE 37.2 Etch Progression

Etch Time, s	Undercut, *U* mil	Etch Factor, *F*	Extent of Etch, *R/B*
90	0.05	0.90	0.5
110	0.30	1.75	0.75
125	0.45	2.33	1.1
140	0.525	2.67	1.0
165	0.75	3.11	1.25

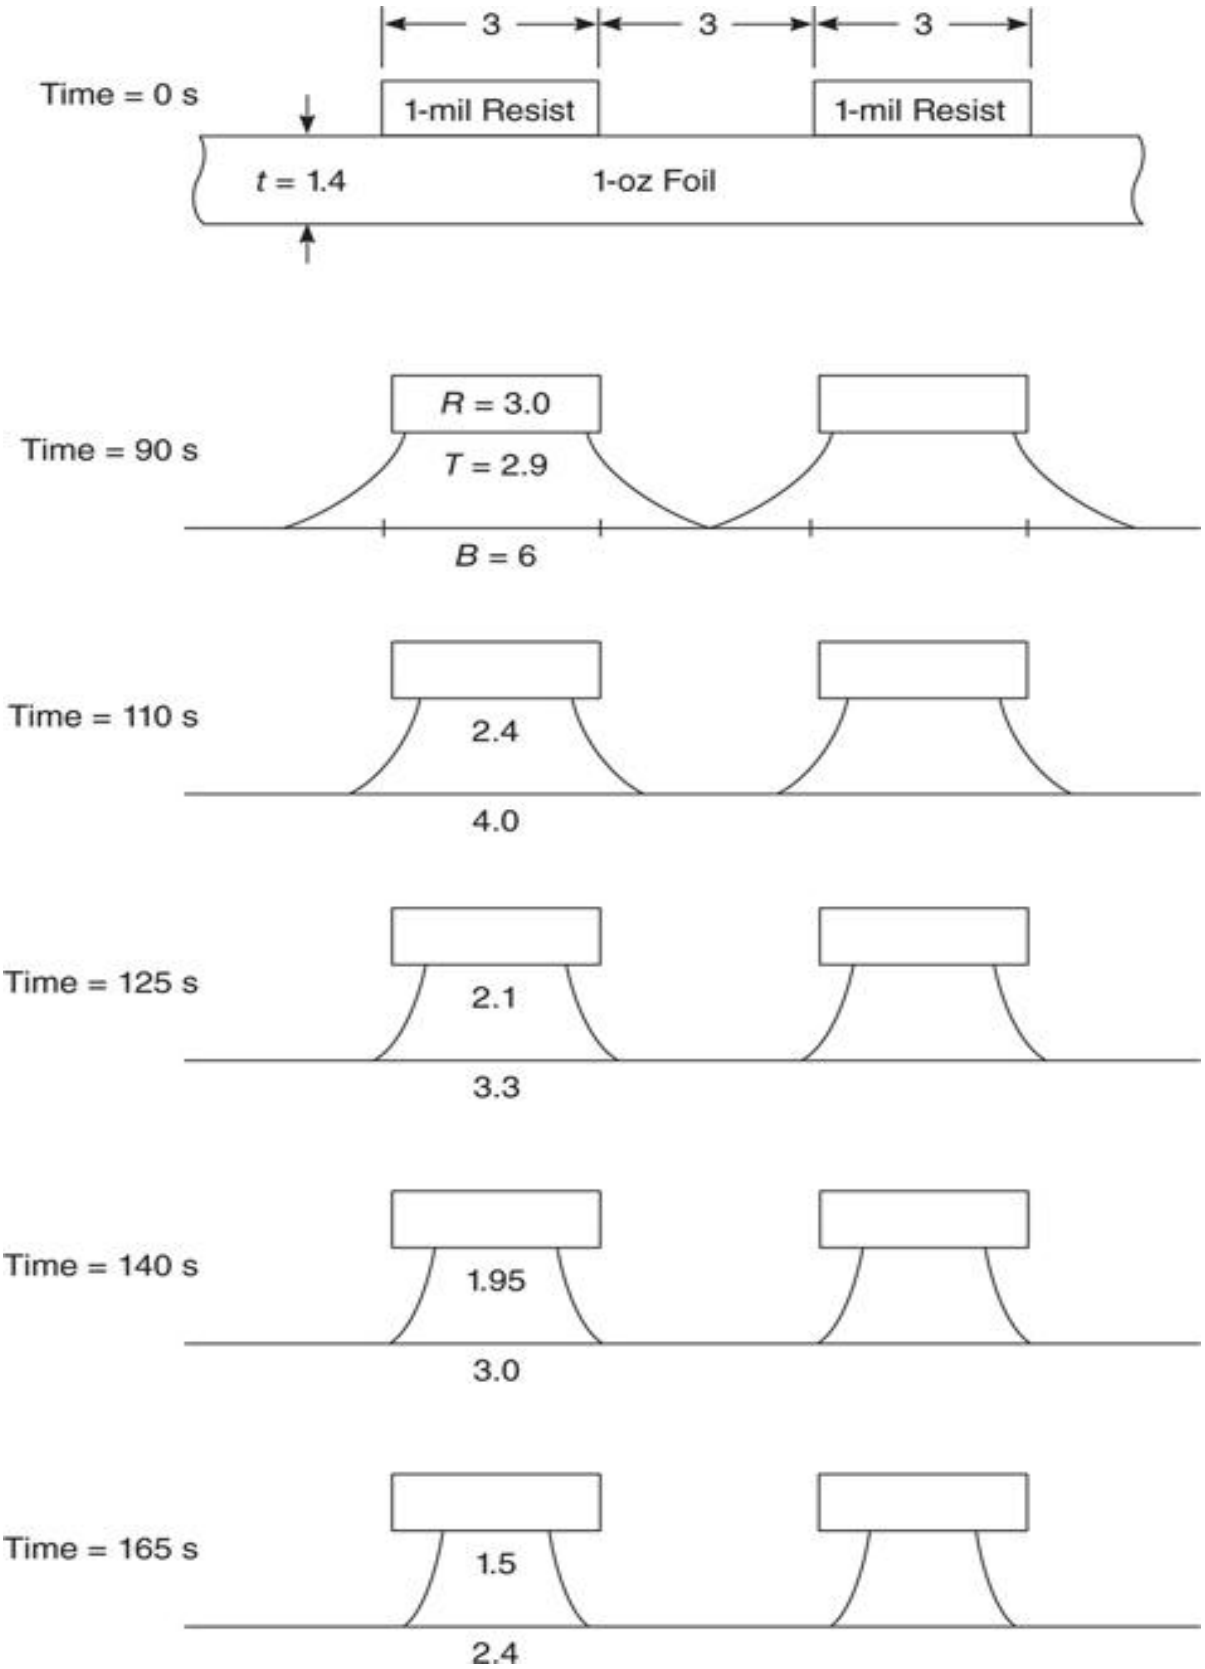

FIGURE 37.5 Line formation development.

There is an important conclusion to be drawn from these data. In order to compare or characterize an etch process (etcher to etcher, etchant to etchant, condition to condition, etc.), it is not sufficient to only use the undercut or etch factor alone. The data must be evaluated at a given *R/B* point for the same foil, resist, artwork, and panel size. If these factors are not held constant, the statement that "process A gives less undercut" has little meaning—additional etching gives more undercutting and straighter side walls.

37.7.3.3 Sensitivity Analysis. One of the extensions of the previous analysis is the ability to evaluate the sensitivity of the process. This is a study of the change in the result (*R/B*) due to the additional etching (relative time). Relative time is the ratio of the actual etching time to the nominal etch time taken to reach *R/B* of 1.0. In Table 37.2, it took 140 s to reach *R/B* = 1, but only 25 s (18 percent) more etching to achieve 25 percent overetching (*R/B* = 1.25). This sensitivity indicates that a small amount of overetch time could cause overetched 3-mil circuits. In this example, the etching process is slow enough to be controlled with the adjustment of the conveyor speed in the etcher. However, if the etchant were twice as fast (alkaline, for example) with the same sensitivity, it would be difficult to accurately "dial in" the proper result. Further evaluation of the cumulative variation from several variable properties on the overall product capability statistics can be found in the literature.[38]

37.7.3.4 Implication for Improved Processes. As a practical process application, it is often desirable to improve the etch factor to get a more square shape of the etched profile. One method for accomplishing this is to design the phototool for wider lines than desired, and then overetch to the desired endpoint. This practice increases *F* at the expense of also increasing *U*. However, as spaces get smaller, there is no space available for additional resist linewidth, because the fluid activity is restricted so that the etchant is stagnant

between the traces. Therefore, resist width near the final line specification and precise control of the etch process are required to obtain desired shape profiles within the $R/B = 1$ degree of etching. As feature specifications tighten, the process to do this may need to be altered. One patented approach is to finish the etch with a specific slower-speed fine-tune etching chemistry to be able to stop the etching process at precisely the correct point.[39]

37.7.4 Fine-Line Formation Etching Requirements

37.7.4.1 Fine-Line Definition. The term *fine line* is a relative one because the current state of processing by conventional available technology is constantly improving. Therefore, fine lines can be considered the next extension of capability that requires precision higher than that afforded by available technology. This is understood by means of statistics and standard gauging tools. The measure C_p (simple process capability) evaluates the variability of output results ($6s$, where s is the standard deviation of the linewidth distribution) to the specification limits of variation.[40] The data for the performance can be obtained by using a standardized test vehicle (IPC-9251) or a commercial testing program by CAT (see Chap. 36). In general, fine lines can then be defined as the linewidth point at which yield performance begins to drop below the run of production. Note that it is up to the customer and shop to determine what product line variation (usually a percent of line dimension) is allowed. It is apparent that this definition depends on the available technology and operation of the individual shop.

37.7.4.2 Limitations—Practical Rule of Thumb. It is useful to have a practical limit to express an understanding of where the technologies may limit performance. In the case of etched linewidth, it has been expressed that the total of the

resist thickness plus the etched foil thickness would limit the gap between the etched features. Therefore, for 1.2-mil dry-film resist over 1-oz copper foil, the total thickness is 2.6 mils. This could be used as a practical limit for both the trace and gap. Further limits can be determined by the undercut and etch factor experienced for the same type of etched features. Therefore, using the $R/B = 1$ data from Table 37.2 ($U = 0.525$ mil), a 2.6-mil resist line would be 2.6 mils at the trace bottom and would have a 1.5-mil etched top reduction, leaving only a 1.1-mil top surface. It must then be determined if these dimensions (with allowance for variations) are sufficient for the design functionality.

37.7.4.3 Thinner Is Better. In general, it follows that thinner foil and thinner resist allow for smaller features. However, if thin foil (9 µm, ¼ oz) is used, the traces may be plated to achieve better current capability. Thin resist may be used, but the image may be susceptible to handling damage or damage in the process equipment. However, for coated resists of 0.4 mil and ¼-oz foil (0.35 mil), the result could indicate a limit of 0.75 mil (19 µm). In fact, there has been a process using 3- and 5-µm foil to produce 30-µm line- and spacewidth patterns with 14 µm additional plated copper (total trace height of 17 and 19 µm). This method uses both panel and pattern plating.[41] The original foil was etched from thicker commercial foil laminate to the working thickness.

37.7.4.4 Changing the Microchannel Flow. As previously explained, the flow in the microchannels surrounding the features is critical in achieving uniform and accurate etching results. There is a unique process development using fibers to affect localized fluid mixing in these channels.[42] This approach requires specific patented equipment and processing methods.[43] Reported results down to 50-µm (2-mil) lines and spaces in 1-oz (37-µm) copper have been produced with 1.4-mil (37-µm)-thick resist. This is a very unique and important result because conventional foil and

resist technology can be used to make features significantly smaller than conventional capability through improved fluid application mechanics.

37.7.4.5 Beyond Fine? HDI Impacts. High density interconnect (HDI) technology involves several technology changes to form the circuitry. The highlight, as the name implies, is small via structures made in a layer-by-layer methodology with a built-up thin insulator and thin foil structure. To achieve the interconnection, thin and precisely controlled traces are required. The technologies, such as the two previous items, are becoming available to attack the needs of the products. As layer counts increase, the accumulating yield implications are significant, so that each process must produce minimum defects. For etching, one of the challenges is to make the resist conform to the surface—which forces the structural materials and processes to engage planarity of the end stage process as an issue. Etching capability requires improving the precision, stability, and capability of processing. The flowchart in Fig. 37.6 graphically illustrates the effects required for etching concerns and approaches to address these.[44] It is significant that there are no new concerns added to previous discussions.

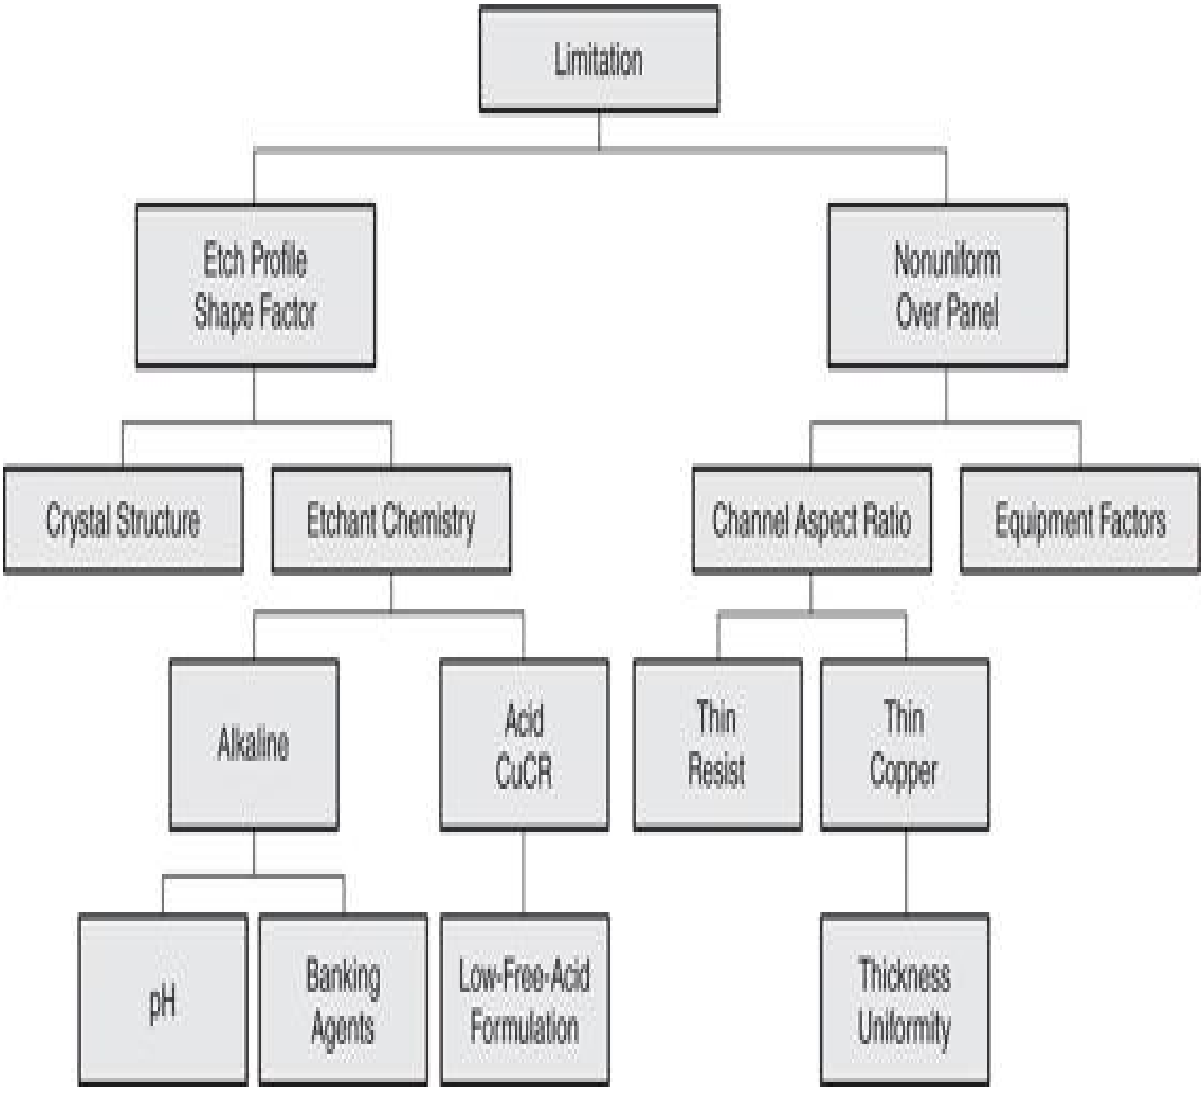

FIGURE 37.6 Flowchart for study of resolution of HDI etched product limitations. Profile and uniformity limitations may be studied for process improvement by progressing down the chart for contributing elements.

37.7.4.6 Stability and Control. It is important to measure and understand sources of variation in order to eliminate them. The gauging tools mentioned previously are very useful for collecting the data for analysis. One important feature is the positional and orientational variation in line geometry. Various conclusions can be taken from feature variation by location across the panel and orientation relative to the direction of motion. Repeating the gauging technique on a regular basis can allow observation of changing conditions within the process (such as plugged nozzles and other defects).

Another type of variation can be obtained by examining a series of gauge panels progressively processed with specific time-lag variations. If etching chemical controls are not adequate, the etch rate may vary in the sequence and therefore cause line variation with time. Usually, regeneration equipment can be adjusted or modified to minimize these variations, but the value of such instrument upgrades can be determined easily by data recorded about the type and extent of defects incurred.

37.8 EQUIPMENT AND TECHNIQUES

Etching equipment for circuit line formation has developed many variations on spray processing equipment. Often, as members of a coordinated automatic immersion plating process line, there are immersion etching tank varieties for microetching and surface preparation. However, for individual panels, conveyorized spray processing is clearly established because of efficient part handling and processing effectiveness.

37.8.1 Spray Equipment Basics

37.8.1.1 Construction. Etching equipment must be made from materials for long life, good dimensional stability, and resistance to chemicals and temperatures (130°F and higher). The basic construction includes rigid plastics (PVC, polypropylene, CPVC, and PVDF), metals (titanium, Hastalloy C), elastomers (vinyl, Viton A, Kel F, ethylene-propylene), specialized composites (epoxy-glass, graphite, and carbon-filled polymers, and other specialized formulations), and glass or clear and translucent polymers for visibility. The challenge is to select proper grades, compositions, and properties for mechanical strength, functionality, and durability. Equipment manufacturers perform these tasks in their design process.

37.8.1.2 Controls. Controls and electronics are significant because the increasing robustness and precision can have a large impact on cost. Therefore, the compromise on cost-effectiveness/technology trade-off often is made with a market-price primary goal. Therefore, cost-benefit analysis must be made by purchasers to evaluate available upgrades in instrumentation. The key controls are temperature, pressure, conveyor speed, and safety interlocks. Temperature is especially important because the etching reactions are usually exothermic and heat must be removed by cooling water coils to maintain stable rates. Conductivity, pH, density, ORP, and other process chemical control instruments may be added to monitor and control the processes. These instruments may be integrated into a PLC or computerized control system or may be individual control-panel stand-alone instrumentations. The wiring and the control cabinet itself must be suitably fume and hazard protected for water and chemical splashes as well as corrosive fumes. It is desired to have critical condition displays available to operators in the machine environment as well as some means of monitoring and recording process information.

37.8.1.3 Spray Strategies. Individual equipment designers have implemented very different types and mechanisms of spray attack on the panels. It is important to realize that the spray system design must be carefully integrated with the conveyor and mechanical design to minimize the effect of rods, wheels, panel control devices, and other mechanisms to achieve both uniformity and geometry of the features produced. It must be realized that the effect of the sprays is not merely the attack by droplets on the surface, but that the sprays are the prime drivers of the direction and effectiveness of the microchannel fluid flow on the panels. Therefore, separate controls and gauges must be provided for top and bottom spray arrays. For maximum precision, four quadrant controls are often beneficial. The mechanical spray arrays can be described as a variation of the following types.

37.8.1.3.1 Fixed Spray Array. This is a system of spray tubes containing multiple nozzles connected transversely across the conveyor to a header pipe on one or both sides. The spray nozzles are placed into the tubes in a pattern designed to optimize the effect. Care must be taken to install and orient the nozzles properly for designed effect. Mechanical intervention to selectively activate (or deactivate) portions of the design to effect the fluid dynamics of particular patterns should be included.

37.8.1.3.2 Oscillating Sprays. This system uses spray tubes that are connected generally to be aligned with the conveyor direction (often at a slight angle). The ends of the spray tubes are made with rotating seals so that the tubes can be moved back and forth by an oscillating crank or gearing mechanism. The nozzles move the liquid in a pattern generally across the conveyor travel. Individual spray tubes may be throttled and/or selectively activated.

37.8.1.3.3 Reciprocation. These nozzles are usually placed in an array similar to the fixed system, and the entire array is moved by a cranking mechanism in a direction across the conveyor. Maximum precision offerings include various patterns of nozzles that can be separately valved and selectively activated by computer controls.

37.8.1.3.4 Spray Nozzles. Spray nozzles are available in several types, sizes, and materials. For etching it has been established that PVDF nozzles are robust and consistent. The nozzle patterns are flat fan, full cone (round and squared), and open cone designs. Generally, flat fan nozzles have large openings and high impact for a given flow rate, while round cones have lower impact and orifice restrictions to ensure the pattern is filled. One of the principal failings of nozzles is simply clogging. The best array design can become dangerously nonuniform simply by plugging a small number of sprays. There is a commercially available nozzle that has a self-clearing fan design. Many are installed. For some applications, filtration between the pump and sprays has been installed to prevent plugging.

37.8.1.3.5 Selection. All of these combinations of nozzles, arrays, and mechanisms offer benefits and drawbacks that are often counterintuitive to the end user. It is necessary, therefore, to test and evaluate the performance of the spray systems for the work type and working environment. Testing of performance must be evaluated in a carefully controlled trial or by comparison with a standardized gauging tool.

37.8.2 Spray Equipment Options

37.8.2.1 Vertical Panel Orientation

37.8.2.1.1 Batch Operation. Some of the earliest equipment is still useful for prototype manufacture. This equipment holds a single panel on a workpiece that is generally rotated about an axis and sometimes oscillated as well. The sprays are addressed from one or both sides of the work and may be fixed or oscillating. This type of equipment usually is limited to small panels. The liquid all drains off the panel and falls into a collection sump. The panels must be removed after etching is complete and placed into a separate rinse vessel. (Some equipment has been designed to divert the drain and spray water onto the same work orientation.) This equipment is not capable of high capacity but has been able to etch high-quality work.

37.8.2.1.2 Conveyorized Operation. There are several versions of large machines that accept vertically oriented workpieces, convey them on a series of rollers from beneath the panel, and stabilize the work with rollers or wires. There are some machines that suspend the panels from the top surface. Vertically oriented nozzle arrays, either stationary or moving, spray the panel surfaces. These machines have been more successful in developing than etching because the depth of the image to be developed is formed by the exposure rather than completely depending on the etching fluid dynamics. All the liquid sprayed on the panels is removed by running downward off the bottom panel edge; therefore, the nozzles

must be specifically designed to offset the effects of higher amounts and speeds of down flowing etchant progressively toward the panel's lower edge. It is obvious that very thin workpieces can have difficulty being conveyed through this design.

37.8.2.2 Horizontal Panel Orientation

37.8.2.2.1 General Operation. The most widely used configuration of etching equipment handles the panels horizontally on a roller table support. The panels placed on the rollers move constantly through arrays of sprays above and below the work. One of the principal design challenges is the fluid flow control of the liquid pool that builds up on (and runs off) the top surface of the panel. The various designs of the spray system must allow equally good and equally fast etching beneath the panel as on top. In a well-conceived design, the simple adjustment of spray pressures can achieve this balance.

37.8.2.2.2 Conveyance. The conveyor design is particularly critical. Rollers must turn at constant speed to ensure that the surfaces are not rubbed and damaged. Chains and gear designs have been successfully used. The potential problem areas are the entrance and exit squeegee rollers and the changes from one machine drive section to another. The roller wheels themselves need to be made of compliant materials that have flat area contact with the panels (rounded contact areas allow points that can cause resist damage, especially if the rollers harden with age). The wheels must be spaced far enough apart to allow the bottom spray to hit the panel with minimum shadowing, but close together enough to convey thin work without sagging or deforming.

Thin panels (0.0015- to 0.003-in insulation core) are difficult to convey because the leading edges must feed consistently from one roller to the next in spite of the downward force of the fluid. In addition, the deflection of the panels between rollers due to fluid loading can cause lack of uniformity in etching. Often, special mechanical guides such as clips or wires are used to overcome these difficulties. Problems occur

when the guides stretch or are misplaced during production. If one panel jams, then the others behind it continue to jam and pile up, resulting in a major problem when discovered. The clearing of the jam often requires removal of rollers that are usually enmeshed in the mass of displaced guides and work. Not only are damaged panels costly, the downtime to renew the equipment and reestablish production causes significant production delay. One particular patented design features a combination of rollers and spray force that assures robust transport while simultaneously improving planarity for spray action.[45]

Truly flexible circuitry requires even more enhancements for reliable transport. Frames and screens have been used in the past, but these fixtures require extra handling and cause drag-over and cleaning problems. For sheet-cut panels, the best solution is a leading edge support attached to the panel by tape or mechanical clips. Usually these panels are attached and removed manually, but automatic systems could be provided. Flexible circuits can also be manufactured in continuous rolls that can be threaded through multiple processes. In addition to the previous difficulties with planarity and drag-over, the precise synchronization of roller speed throughout all the processes is mandatory. Therefore, machine and processing speeds must be carefully planned at original manufacture to allow proper dwell settings and latitudes. Rinsing and drag-over present problems.

37.8.3 Rinsing

Rinsing is a process technology that needs particular attention because of the multiple needs of uncontaminated panels, conservation of rinse waters, and environmental discharge limitations. It is no longer sufficient to flood the panel with large amounts of water that are then discharged to sewers. The capability of technical analysis of this process has been published.[46]

37.8.3.1 Cascade Rinsing. The principal tool to effect the required change is the concept of multiple-stage cascade rinsing. This process includes the concept that a robust flow recirculated on a panel can reduce the concentration to a level in equilibrium with a much lower circulated water stream. The lower stream passes through a series of chambers of increasing concentration, while the work passes through a series of chambers of increasing cleanliness (in reverse order from the water). The end result is a small use of water capturing a relatively high level of contamination. The contamination level is many times the discharge limit for direct environmental discharge. However, the fact that the stream is relatively small and highly concentrated allows for reasonable treatment and recovery of by-products by ion exchange, direct electrowinning, or membrane cell concentration. In certain circumstances, the waste stream may be comingled with a main process stream for recycling (see Fig. 37.1).

37.8.3.2 Drag-Over Minimization. All of the contamination that eventually ends up in the water stream is that introduced by drag-over from the process itself (or from a recirculated environmental rinse). Therefore, the first step in successful rinsing is the reduction or prevention of materials from the panel. The conventional means of attempting this is by a set of pinch or squeegee rollers at the output of the chemical module. These rollers may be increased in effectiveness by softness or by pressure. Often, rollers made of PVA foam have been employed effectively. However, these rollers must be kept clean and moist to be effective. Other methods include improved baffling, ensuring capture of overspray, and low-velocity air blow-off. Proper management of drag-over on conveyorized equipment has reduced residues by a factor of 10 or better. Thin panels cause difficulties because the compromise made between conveying reliability devices and planarity and contact of squeegee rollers and surface tension reduces effectiveness of retention. Thick panels (over 0.125 in) also cause problems because squeegee

rollers and baffles must lift to clear the panels, allowing gaps for solution escape. It is therefore a subject for engineering study and process management trade-off decisions that must be considered during the specification process.

CHAPTER 38
ROUTING AND V-SCORING

Matthias Stickel
KSG Leiterplatten GmbH, Gornsdorf, Germany

38.1 INTRODUCTION

The routing and v-scoring operations have predominantly the function to give the printed circuit board (PCB) the final outline dimensions or to transform the shape and size from the production format of the PCB manufacturer to the required shape and size of successive processes (e.g., assembly). Especially for small parts are there big advantages in handling, when the single PCB is not cut out entirely, but left in a “subpanel” together with other PCBs. In addition to the reduced amount of handling is the efficiency of several steps requiring “alignment” increased at the PCB manufacturer (e.g., electrical test) and at the assembly process. Pre-cuts with tabs or other break-away features enable an easy manual or tooled singulation at any stage. As the routed features have multiple requirements concerning the alignment (to drilled holes, to the image, to the inner layers), several functions were added to CNC machines over the years. Examples are

- Routing of plated slots (instead of slot drilling)

- Routing of big holes (instead of circular slot drilling)
- Routing of larger diameters for unplated through holes to avoid broken tents
- Routing with camera alignment for critical alignments to the outer layer image
- Depth controlled routing
  - To reduce the thickness on the board edges for insertion applications
  - For cavities
  - To break electrical connections
- Pre-cutting to enable break-out after assembly
- Routing with special tools (v-groove cutters, chamfering, counter sink vias)

38.2 THE ROUTING OPERATION

In opposite to the drilling operation, in which the main material removal is made in the *z* axis leading to an axial force onto the spindle, the main material removal in the routing operation is made in the *x* and *y* axis, leading to a radial force onto the spindles. This requires not only different bearings of the spindles, but also a different focus on the movements of the table and the traverse holding the spindle as they heavily contribute to the material removal and with that the achieved speeds and quality levels.

There are several key elements involved in a routing operation:

- Alignment
- Router/router tool
- Machine
- Product
- Program/coordinates/hole locations

- Parameters/cutting conditions
- Supporting materials

All of them will be covered in this chapter in detail.

38.2.1 The Basic Principle of Routing

Routing, as subtractive manufacturing operation, belongs to the group of “cutting with geometrically well-defined tool edges.”[1] A relative motion of a rotary cutting tool and the workpiece is required to remove material from the workpiece to bring it to a desired shape, where the feed of the cutting wedge parallel to the surface generates a chip.[2]

Goals of this operation are

- Smooth surface
- Low force
- Short time/fast processing
- Long tool life

These goals typically need to be compromised and can be influenced with the selection of different, dependent angles of the cutting tool and the parameters. The angles and geometries contributing to the material removal when the tool penetrates the workpiece can be seen in Fig. 38.1.

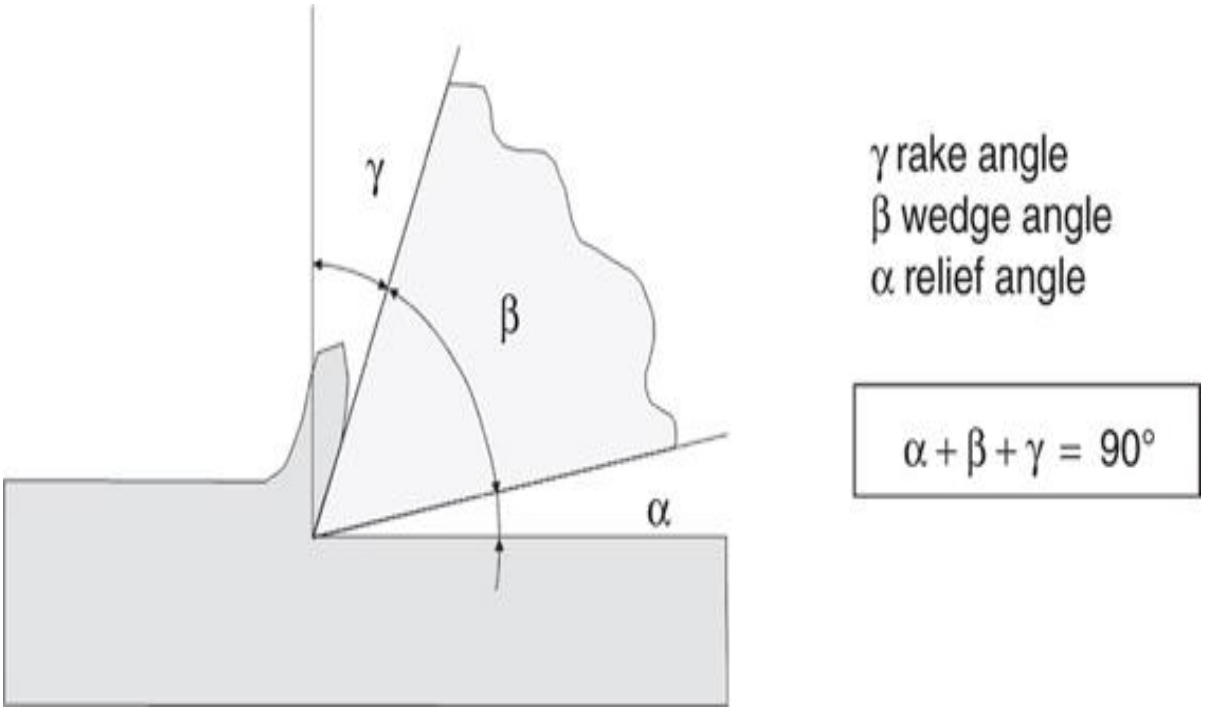

FIGURE 38.1 Geometries during a chip generation/formation.

Looking at the different angles are some general statements possible:

The smaller the wedge angle, the lower the required force to generate the chip. However, needs the wedge angle to be matched with the material that is to be removed. If it is too small for the selected application, the result is excessive wear or break outs of the cutting edge. The harder the material, the bigger needs the wedge angle to be. The relief angle determines the amount friction and generated heat. The softer the material, the bigger the relief angle needs to be, as soft materials generate more friction and heat. The rake angle determines and influences the type and size of the chip. Large rake angles can generate a continuous chip (depending on the material). A negative rake angle leads to scraping and a very small amount of material removal.

The quality of the routing operation is not only defined by the materials, the selected geometries and the cutting conditions, but also to a large extend by the selected method or for peripheral routing by the considered side, as the chip

formation is totally different for the sides. The basic cutting principals are shown in Fig. 38.2.

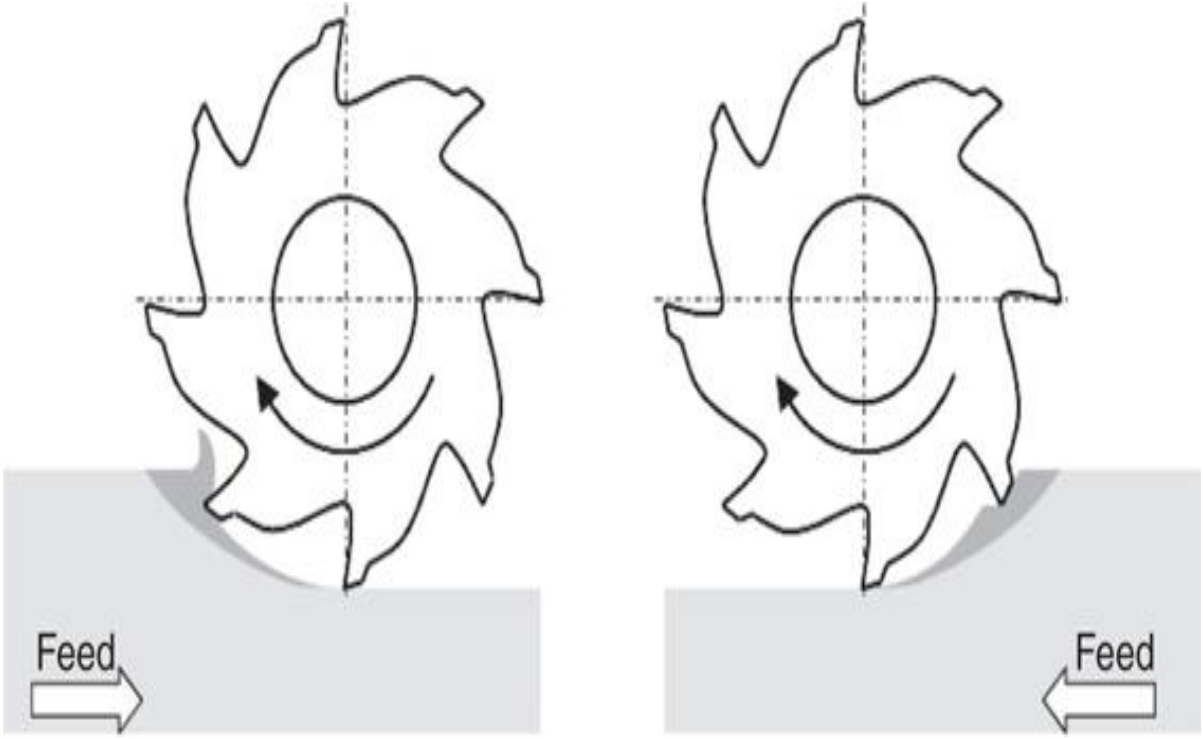

FIGURE 38.2 Routing operations: conventional milling (*left*) and climb milling (*right*).

While for “conventional” or “up” milling the chip starts at zero and ends at the maximum thickness, the chip formation for “climb” or “down” milling is in a way that it starts at the maximum thickness and ends at zero.

Looking at the routing operation in the PCB industry, where there is a relative movement between the rotating tool perpendicularly to solid material, both principles are present in the same operation. These different cutting conditions on both sides result in different quality levels and a “good” and a “bad” side. As the result the conventional or up milling leads to a better edge and can be considered as “good” or product side and the side with the “climb” milling as the “bad” or scrap side (Fig. 38.3).

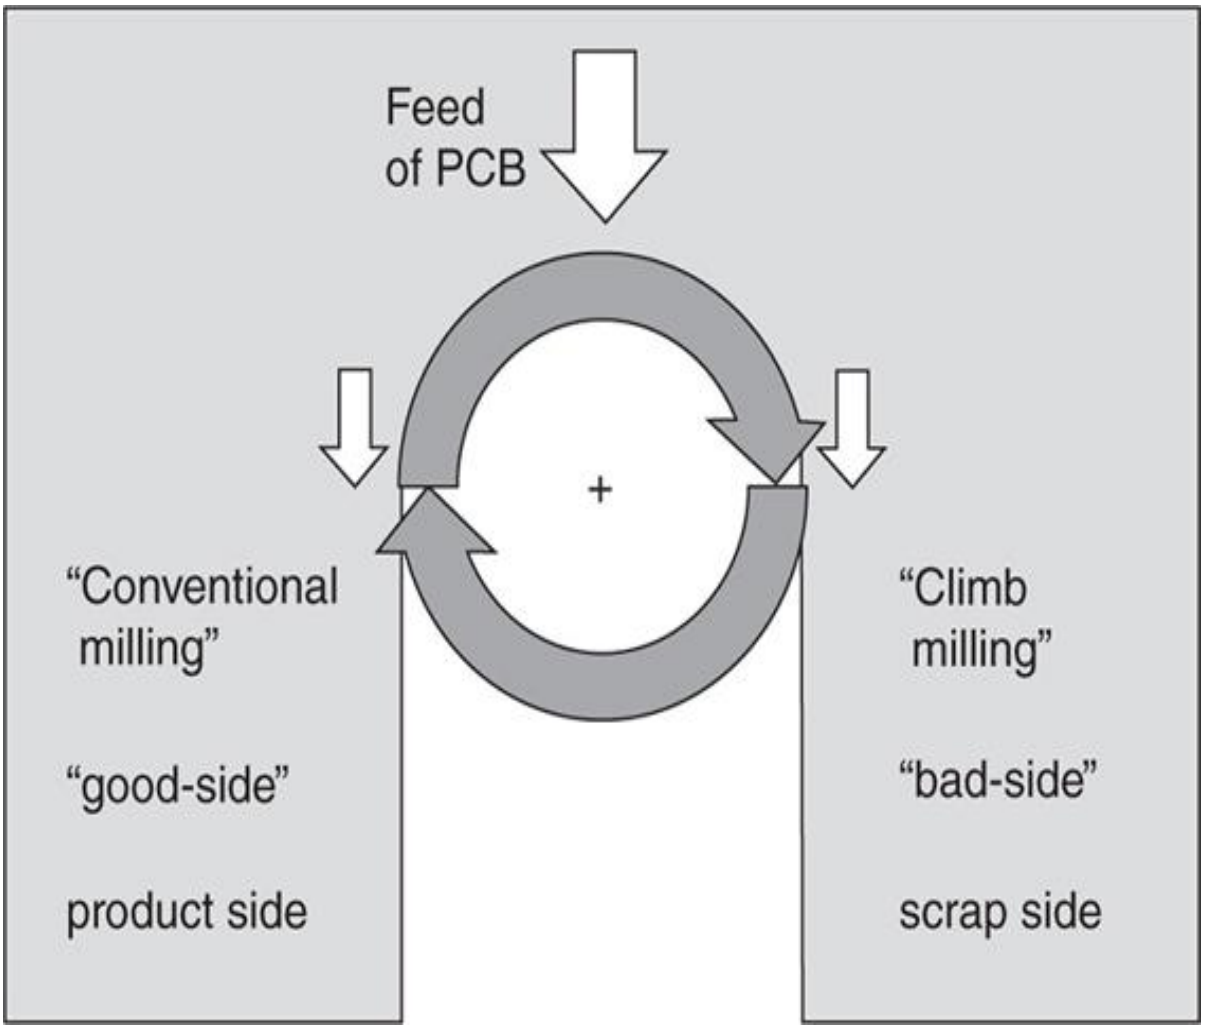

FIGURE 38.3 Cutting conditions routing into solid material.

This is the reason why the orientation of the motion of the tool to the PCB is performed counterclockwise for depanelization, singulation, profiling or outer contours of the PCB and clockwise for cutouts within a printed circuit board always leaving the side with "conventional" milling cutting conditions on the product.

Figure 38.4 also demonstrates another aspect which needs to be considered during the routing operation: the tooling or design data of a specific layout show the outline dimensions after processing. If this would be the path of the router, the PCB would turn out to be too small, as for each routed line additionally the radius (or half the diameter) would be taken away. Special machine commands compensate this defining if

the router tool is to the left or to the right of the structure. In doing so is the radius “compensated,” meaning that the center line of the tool is shifted accordingly by the radius to one side.

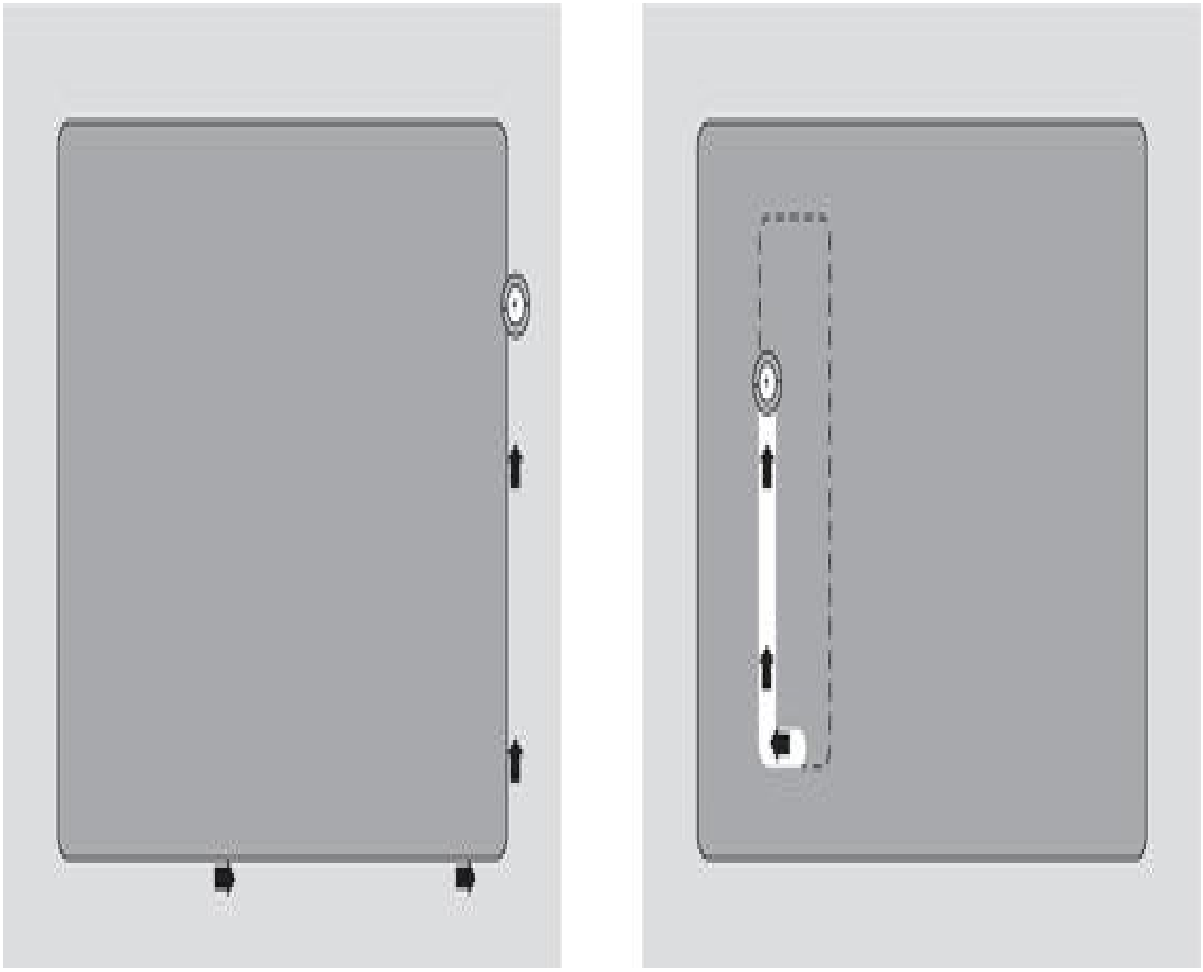

FIGURE 38.4 Selection of cutting orientations: counterclockwise (*left*) and clockwise (*right*).

In addition to the general compensation of the radius (also “cutter offset”) which is required due to geometrical aspects, is also a product and process related compensation required. Based on the combination of the table feed and the rotating tool is there an additional force to the side resulting in a deflection of the router. This deflection will change the effective dimensions and needs to be compensated (for inner and outer contours) as well. The amount depends on the tool (diameter, length, material, geometry), the stack (height,

material) and the selected cutting conditions (feed, speed) and with that is so individual, that it needs to be determined in a pre-run for every new product for best results.

38.2.2 Alignment/Stacking/Pinning

The alignment in the routing operation can be done in several ways. Selection criteria are the outline tolerances and the degree of automation which is practiced in the manufacturing shop. Considering manual loading and unloading are the production panels aligned with two pins (in the center of the short axes) or four pins (in the corners) in the area of the panel frame. With that, is the alignment done outside of the active area so that the panel frame, including the pins, remains fixed to the table, while the cutout boards which are loosely on the table can be removed from the machine after the program is run. The pins are either fixed into plastic inserts or fixtures on the table, so that the stack of multiple PCBs is generated manually by piling one panel after the other, after putting a backup material on the table.

Another option is to generate the stack in a separate operation by pinning the defined number panels together. This is done with two to eight pins. The entire stack is then aligned by inserting the pins into holes in subtooling plates manually on the table (with a backup material in between).

In an automated loading system for which the stacks are also generated in a separate operation, there is only an alignment with two pins possible. These pins need to be on one axis (typically in the center of the short axis) and are fixed with a prism slot clamping system. As the PCBs or subpanels are cut out of the panel frame is the unloading done manually.

Another option is to have multiple pins in a fixture, so that each board is aligned with pins when the stack is generated and not only each panel. The advantage is, that after the program is run, the boards are not loosely on the table, but stay fixed on their pins until they are removed. The

disadvantage is that this type of alignment requires product/layout specific fixtures which need to be generated in advance. This is the reason why especially for small volume productions usually the other alignment approaches are selected and in case of concerns the boards are additionally fixed with tape to prevent damage after being cut out.

38.2.3 Machine Preparation

Before the entire lot can be processed in the routing operation, the machine has to be set up by

- Loading the program (coordinates and diameter information)
- Loading the parameters or parameter files
- Loading (additional) tools
- Performing a first run
- Measuring the actual dimensions
- Doing additional RC (radius compensation) adjustments

The routing programs are generated with a CAD/CAM system, similar to the drilling programs, by adding board shop specific routines (pilot holes, definitions of the routing path, or tool direction, etc.), to the outline dimensions. The set up (loading the program and the tools, etc.) is also in the same way as for the drilling operation.

38.2.4 Loading/Stacking

For the peripheral routing, when the PCBs are cut into single pieces or subpanels, much bigger diameters are used compared to the drilling operation. This is why stacking, putting several PCBs on top of each other to cut them out simultaneously to increase efficiency, can be practiced in a greater extend. The stack height should not exceed 75 to 85

percent of the effective flute length or the flute length should be chosen accordingly whereas the depth in the backup material and the optional entry material needs to be considered part of the stack as well.

38.2.5 De-Stacking

After the program is run the singulated parts need to be taken out of the machine regardless, if the product is cut out into single pieces or in subpanels. Additionally need the panel frames to be taken out and the pins removed. The PCBs need to be checked for scratches, burrs, or tips.

38.3 MATERIALS

The materials involved in the routing operation are defined by the quality level that needs to be achieved. The main materials that can and need to be selected are

- Router
- Entry material
- Backup material
- Pins, tooling pins
- Soft tools

38.3.1 Entry Material

As there is much less movement in the *z* direction compared to the drilling operation there is no real need to center the router when it penetrates the stack or to clean the router when it leaves the stack. But there are other aspects that might require an entry material:

- To protect the metal surface during the routing operation

- To prevent burr on the entry side
- To transfer and spread heat off the router

Routing is one of the last manufacturing operation steps of a PCB and with that almost all value is added to the product at this stage. This typically also includes the final surface finish which can be sensitive for scratches. As the tool moves in *x* and *y* direction during the operation, the challenge for the pressure foot is to press the stack together, without damaging the surface. This is realized with circular or donut shaped brushes around the cutting tool. The brushes have to have a certain rigidity to press the stack together, but on the other hand they have to be flexible enough to accommodate/compensate changes in the topography due to the circuitry on the outside of the PCB. For sensitive surfaces or critical applications might an entry material be required, as already a small burr caught in the brush can lead to scratches and with that to violations of the acceptability.

The material can be a melamine phenolic. As an alternative are sometime laminates or cores used and the copper in an etching step removed, which makes this type of an entry a fully cured, glass reinforced epoxy material.

38.3.2 Backup Material

The backup materials main function is to protect the machine table from being damaged. Burr on the bottom side of the stack or where the tool exits the stack is also something that has to be paid attention to. But as this is most critical in the *z*-axis direction, conservative/moderate infeed rates can be chosen for the routers as the number of *z*-axis movements is rather low. The backup material is typically made of wood-chip composites. But in opposite to the drilling operation in which for every run a new backup side is used, are the backups in the routing operation used multiple times. This has not only economic advantages, but is also beneficial for the quality as

additional room for the swarf is available and together with a good vacuum reduces the heat generated during the operation. In cases in which there are product specific challenges with burr, regardless if in the area where the router enters the stack or along the routing path might unused backup material be required. This backup material should ideally be processed and structured with the same program before the stack is added and the program run a second time. The diameter for the prerouting of the backup material should be chosen smaller than the router of the conventional program, ensuring that the tools of the conventional always hit solid materials on the edges. In this case can the backup material be used only twice (once per side).

The routing depth into the backup material needs to be compromised between a maximum generating much room for the swarf and a minimum to reduce the additional heat generated on the router. Typical values are 1 to 2 mm, with smaller values for smaller diameters.

38.4 MACHINES

There are no major differences between the CNC routing machines and the drilling machines used in the PCB industry. The selection of different elements, options and components are enough to optimize a machine for routing applications. For example is the higher side or radial force something to consider in the section of the spindles. Since the tool diameter range is much smaller for the routing, including the much bigger minimum diameter, is the maximum spindle speed also not as relevant compared to drilling? The major elements are shown in Fig. 38.5.

Spindle

FIGURE 38.5 Key elements of a routing machine.

The number of stations on which different stacks are routed at the same time defines the size and drives the weight. The range can be anywhere between 1 (for special applications, prototyping, etc.) and 6 stations (for mass production). The machine base and the traverse holding the routing heads are made of granite or mineral cast. The drives for the *x* direction (moving jointly all router heads) and the *y* direction (moving jointly all stacks) are linear. The *z* axes, moving the spindles up and down, either move jointly or independently from each other, depending on the configuration. The *z* axes can either be driven by ac motors with lead screws or linear drives.

Each station has a subtooling and up to three clamps on the long side (*y* direction) either fixing and holding each stack in place during operation or as additional clamping system for the subtooling plate in which the pins of the stack are inserted. The general alignment of each stack is done with pins. These can either be inserted into the subtooling (for example in interchangeable plastic inserts) for manual loading and stacking or are integrated in the stack, in case the stack is generated outside the machine in separate operation. In this case is there an integrated prism slot tooling in the table.

Each station is typically equipped with a laser measurement station controlling the tools prior and after use for length diameter and run out. In doing so, can tools with a wrong diameter or broken tools (after achieving the predefined maximum distance in the material) be detected. The tool storage is either done in cassettes or in a chain. Some PCB manufacturing shops still use routing machines using tools with plastic “rings” on the tool shank. These can define the distance in the backup and also protect the collet from swarf.

There are different types of pressure feet. On top the standard pressure foot, is one available especially developed for web and burr free routing. The function, also called “pressure foot routing,” can be activated with a special command in the program. Before the very last distance when a

PCB is singulated, the pressure foot remains in the same position and the router moves within the pressure foot. This enables a clean cut at the end. Without this function is there a chance the PCB moves slightly when it is separated from the frame leaving a small tip, which needs to removed manually. The last type of pressure foot is one with multiple functions. It has a special plastic or Teflon coating with which the surface can be detected very precisely (see mapping). For all applications (drilling, routing, mapping, “pressure foot routing”) should different pressures of the foot be selected, as the pressure can be of course higher when there’s no movement in *x* and *y*.

Special attention should be taken to the vacuum removing swarf and debris and with that contributing heavily to the resulting quality of the routing operation. Values of 80 to 120 mbar should be achieved to have good conditions. Additionally should the vacuum be shut off when the spindle moves from one PCB to the next to avoid that the cutout PCBs are dragged along. Small pieces which could clog the exhaustion need to be avoided by optimizing the routing path accordingly.

38.5 ROUTERS

38.5.1 Router Material

Similar to the drill bits used in the PCB industry are the routers predominantly made of solid tungsten carbide. To increase tool life are also routers with a diamond coating (PCD = **p**olycrystalline diamond) available.

38.5.2 Router Geometry

There are several basic types of routers for specific applications (Fig. 38.6).

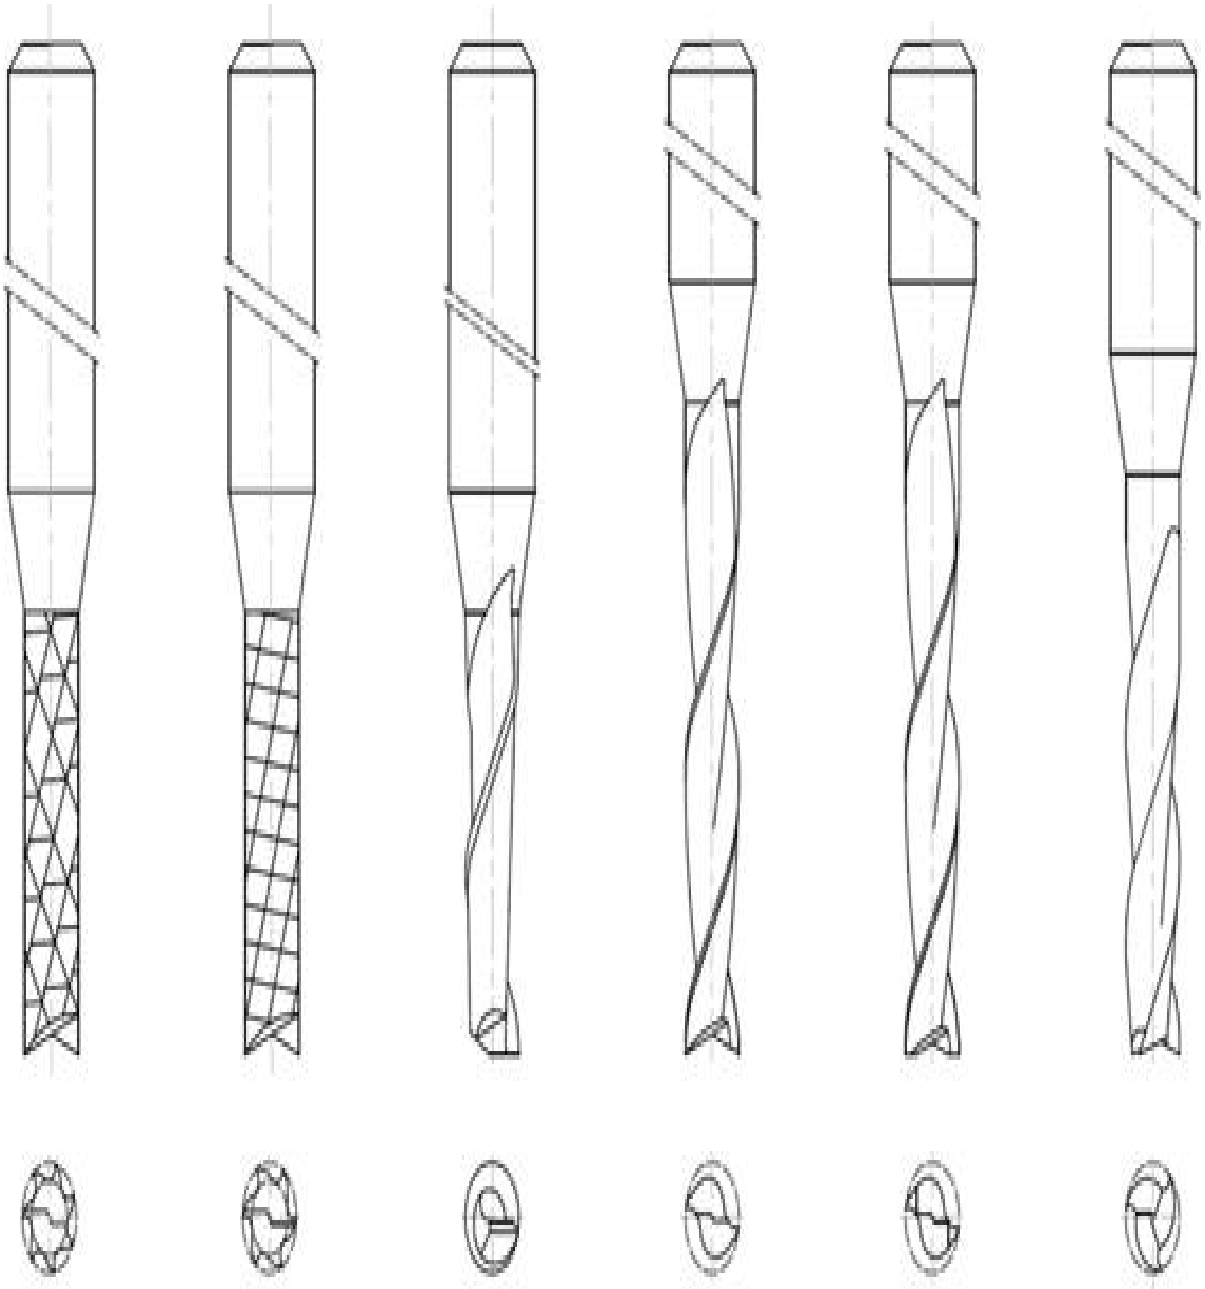

FIGURE 38.6 Router types (*left-to-right*): diamond cut, spiral cut, 1-flute, 2-flute, 2-flute, 3-flute. (Picture courtesy of HPTEC.)

- Diamond cut
- Spiral cut (with or without chip breakers)
- 1 flute
- 2 flute
- 3 flute

All of these tools are available with different orientations of the flute:

- Right-hand spiral/right-twisted flute: in case of conventional clockwise rotating spindles => up cut forcing the material upward out of the slot, toward the vacuum
- Left-hand spiral/left-twisted flute: in case of conventional clockwise rotating spindles => down cut forcing the material downward, pushing the stack together

In case the spindles are rotating counterclockwise is the effect in an opposite way:

- Left-hand spiral flute => up cut
- Right-hand spiral flute => down cut

Most router types are available with a variety of point geometries:

- Drill point
- Double drill point/M-cut
- Fishtail/fishtail with flat end
- Flat end

A special type of router is a v-groove cutter. This tool is not only used for conventional v grooves (v scores) for sophisticated patterns, but also to add chamfers (e.g., for connector insertions).

38.6 PARAMETERS

For the selection of the parameters is the main aspect on top economic considerations the quality level that needs to be fulfilled. Key drivers are the stack height and material that is to be routed along with the selected router (type and geometry). A big influence can be if a predrilling step in the area where

the router enters and exits the stack is done. This can improve the accuracy and due to the additional room for debris, also the quality level. A first starting point for the main parameters is typically provided by the router suppliers who develop general settings for their specific geometries.

Parameters

- Speed or RPM (revolutions per minute) n
- Infeed F_Z
- Table feed F_{XY}
- Chip load (XY) or depth of the cut
- Chip load (Z)
- Tool life

38.6.1 Speed

The cutting speed or surface speed is the speed of a point on the outside of the router. This speed is generally determined by the base material and if necessary adjusted for specific constructions or product groups. As this speed should be kept constant over the whole router bit diameter range, the spindle speeds need to be increased with reduced diameters and decreased for larger diameters.

Cutting speed	$V = n \times \pi \times d/1000$	V [m/min], n [rev/min], d [mm]
Spindle speed	$n = V \times 1000 / (\pi \times d)$	n [rev/min], V [m/min], d [mm]

38.6.2 Chip Load/Depth of Cut

The chip load or “depth of cut” as it is called for routing describes the feed or penetration of the router per revolution. As the routing operation can be performed in three axes in the material, there are two relevant chip loads and feeds (z axis; x

and *y* axis). The chip load is determined by the stack height, the materials that are to be routed and the router geometry (type, diameter, etc.) defining the material volume that can be removed per revolution. If the chip load is chosen too low and the teeth and cutting edges don’t penetrate enough, it leads to “scraping” and excessive generation of heat, influencing the result negatively. If the chip load is chosen too high it will lead to high(er) deflections and worst case to tool breakage.

Chip load (Z)	$f_z = F_z \times 1000/n$	f_z [mm/rev], F_z [m/min], n [rev/min]
Chip load (XY)	$f_{xy} = F_{xy} \times 1000/n$	f_{xy} [mm/rev], F_{xy} [m/min], n [rev/min]

38.6.3 Infeed

The infeed is the *z*-axis speed in which the router moves into/through the stack. The possible speeds depend on if “predrilling” is applied or not.

Infeed rate	$F_z = (f_z \times n)/1000$	F_z [m/min], f_z [mm/rev], n [rev/min]

38.6.4 Table Feed

The table feed is the speed in which the table and the traverse holding the spindles move in the *x* and *y* direction. It more results out of the cutting speed and the chip load.

Table feed	$F_{xy} = (f_{xy} \times n)/1000$	F_{xy} [m/min], f_{xy} [mm/rev], n [rev/min]

38.6.5 Tool Life / Router Life

Equivalent to the number of hits that a drill bit can perform is for routers the “distance in the material” defined and limited. As already mentioned above is the quality level that needs to

be achieved for the tool life the main driver. The wear, driving the quality, is in addition to the selected tool, heavily influenced by the cutting speed, the chip load/table speed, the vacuum and the product stack (materials, stack height, etc.). For standard FR-4 type materials is the maximum distance in the range of 40 to 60 m for a 2.0-mm diameter for a stack of 4.5 mm. For materials containing fillers is the distance reduced to 30 to 50 percent, depending on the type and amount of fillers.

38.6.6 Parameter Example

The example (Fig. 38.7) shows selected diameters to highlight some general items in a parameter table:

DRM [mm]	Speed / RPM [rev/min]	Cutting-Speed [m/min]	Table-Feed F_{XY} [m/min]	Chip-Load [mm/rev]	In-Feed Fz [m/min]
0,50	100000	157	0,3	0,002	0,1
0,60	100000	188	0,4	0,003	0,1
0,70	91000	200	0,4	0,004	0,1
0,80	80000	201	0,6	0,007	0,1
0,90	71000	201	0,7	0,009	0,1
1,0	64000	201	0,8	0,012	0,2
1,1	58000	200	0,9	0,015	0,2
1,2	54000	204	0,9	0,016	0,4
1,3	49000	200	1	0,020	0,4
1,4	46000	202	1	0,021	0,4
1,5	43000	203	1,1	0,025	0,6
1,6	40000	201	1,1	0,027	0,6
....	....	....	....		....
2,0	32000	201	1,1	0,034	0,6
....	....	....	....		....
2,5	26000	204	1,2	0,046	0,6
....	....	....	....		....
3,0	21000	198	1,2	0,057	0,6
3,175	20000	199	1,2	0,057	0,6

FIGURE 38.7 Example of a routing parameter file with a target cutting speed of V = 200 m/min.

- The maximum spindle speed is 100,000 RPM. This maximum RPM is required for diameters being smaller than 0.7 mm, resulting in a cutting speed deviating from the targeted 200 m/min for 0.6 mm smaller diameters.
- The minimum spindle speed is 20,000 RPM. This minimum RPM speed is required in the example at a diameter of 3.175 mm (which is equal to the shank diameter). If a smaller

cutting speed was chosen, the theoretically required minimum spindle speed would not be achievable with this spindle, resulting in a deviating from the ideal cutting conditions.

Properly chosen parameters not only avoid mechanical damage (on the tool or the product) but also have a big influence on the quality, where in most cases the quality level and economic aspects are compromised.

38.7 DEPTH CONTROLLED ROUTING

In addition to peripheral or contour routing are there more and more applications which require only partial removal of the material. Typical applications are areas of reduced board thickness along two sites supporting the insertion of the boards in rails. These features were realized in the past with conventional milling machines. Other applications are “cavities” in the PCB. These are areas where the all material above certain inner layer locations are removed, enabling direct access for the assembly of critical components and or simply reducing the overall height of the PCBA after assembly.

38.7.1 Mechanical Contact

One common approach for the routing in relation to the board surface is to detect the surface via mechanical contact or physical pressure. Required is the laser measurement station measuring the location of the tip of the router in relation to the pressure foot. When the spindle moves downward, the brush passes a physical pressure to the system. Once a certain level is reached is the surface determined. As the location of the tip has been logged, can the relative movement to the surface be started with a secondary measurement system.

38.7.2 Electrical Contact

Another approach is to detect the surface via electrical contact. This requires a conductive surface. It can be electrically detected when the router hits the surface and a relative movement to the “new zero” can be started with a secondary measurement system. The principle can also be applied for referencing to a copper inner layers. Additional holes and traces or bus bars to bring the connection from a conductive board or panel edge to the inner layer. The big advantage is that tolerances caused by thickness variations of the locally different resin flow of the pregregs in the lamination process become irrelevant.

38.7.3 Mapping

Another approach is to detect the surface of the board or the construction under the board physically at multiple predefined points. The relative *z* height is detected and put into a map and considered in the depth controlled routing program. In addition to the laser measurement station, the secondary measurement system and the mapping software option is a special pressure foot required to eliminate the additional tolerances of the brushes.

38.8 V-SCORING

V-scoring is a special form of routing, for the generation of breakaway areas as an alternative to conventional, peripheral routing with reduced requirements on the edge quality. The material is removed with cutting tools from the top and bottom side of the workpiece (PCB) simultaneously, leaving grooves with a v shape on both sides. The remaining material in between the grooves, the web, predominantly defines the force which is required to break the two pieces apart (see

Figure 38.8). The breaking or separation can be done manually in case of thin webs or with special separation tools for thicker webs. The latter is, for example, practiced when additional processing steps (during the manufacturing operation or at the assembly) between the cutting and the breaking are done, for which a certain stability of the production unit is required. A separation with machines improves the edge quality compared to manual breaking.

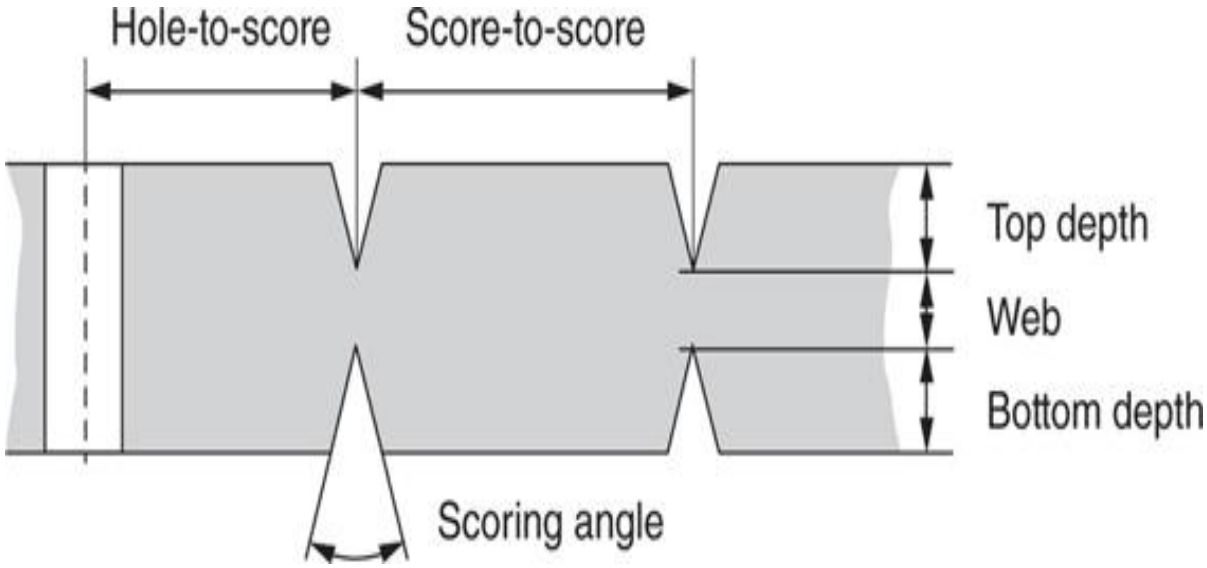

FIGURE 38.8 Key tolerances on products with v-scoring.

The v grooves can be generated parallel to the short and long production panel sides, requiring a 90° rotation during the operation if grooves in both directions are required. Interrupted grooves, so called jump-scores, can be generated as well. In case of round corners or other structures deviating from the orthogonal grooves are routing and scoring combined. Key tolerances are shown in Fig. 38.8.

38.8.1 Scoring Tools

The cutting tools, blades, or saws are available in solid carbide with or without coating and in PCD, with the PCD tools having typically 24 teeth and the solid carbide tools having 100 or 120

teeth (see also Fig. 38.9). The scoring angle (20° to 30°, 90°), defines the material volume which needs to be removed to achieve a certain depth. Additionally is also the groove width and with that, the minimum distance to the next feature defined by the angle. Tools with bigger scoring angles (100° to 140°) are also available if the application requires special geometries for edge beveling or chamfering.

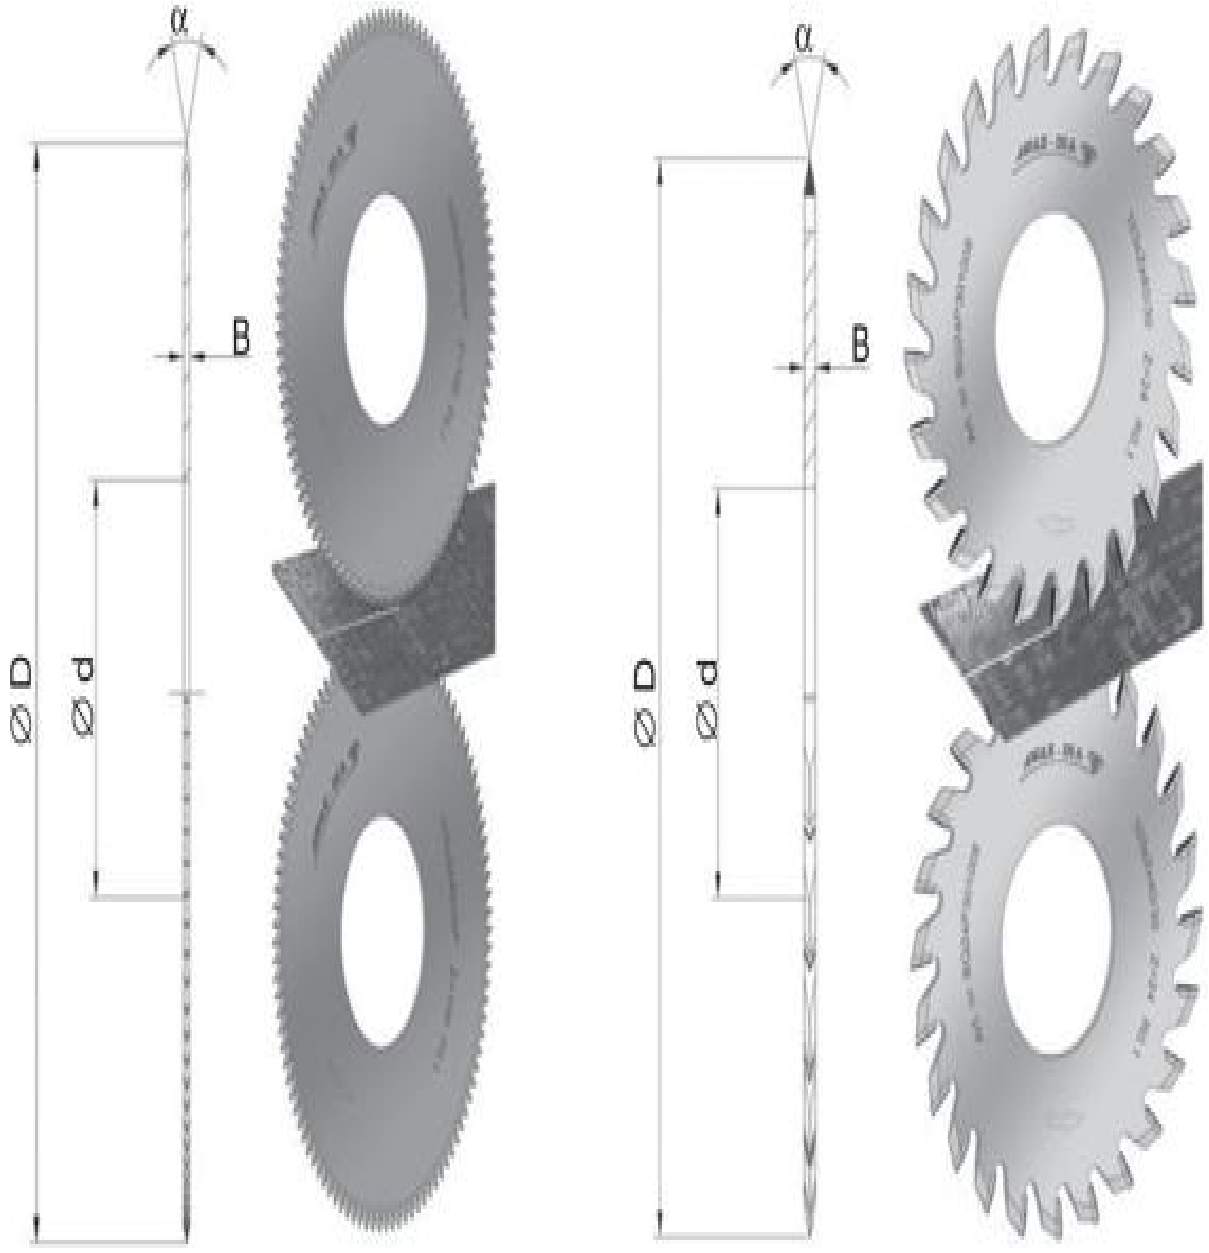

FIGURE 38.9 V-scoring with solid carbide blades (*left*) and PCD blades (*right*). (Pictures courtesy of Awax-Dia.)

To increase the tool life, defined by the distance in the material similar to conventional routing tools, is the tip intentionally removed to reduce wear and avoid fast breakage. For solid carbide tools is that achieved with a chamfer, whereas PCD-tools have a defined radius.

Blades can be repointed, similar to drill bits. However, it is the general wear during operation that needs to be monitored. As the main attribute in the production environment is the web or web thickness, the tool diameter which decreases with the wear, needs to be adjusted to keep the web constant. In this case is the cutting area of the blade penetrated deeper into the product increasing the width of the groove slightly.

The tool life or distance in the material, like in any mechanical subtractive machining operation, is dependent on the material and the cutting conditions. The number of revolutions of the blades is in ranges of 4000 to 8000 RPM. The relative motion of the cutting tools to the material is 20 to 40 m/min. With these settings can PCD tools achieve a distance in the material of up to 80,000 m but also be as low as 10,000 m for heavily filled base materials.

38.8.2 Alignment and Machine Types

There are different types of machines available, varying in the number of CNC axes and the type of alignment. The standard alignment in the v-scoring operation is a “pin-alignment” in which the position or location of the printed circuit board to the v-scoring machine is defined over two mechanically drilled holes in one axis of the board and a corresponding pair of pins in the machine. The PCB is then moved in a relative motion through the two cutting blades which are set in a defined distance resulting in the required web. An additional controlled axis is able to move the board to the location of the next groove. With that, all (parallel) grooves in one axis of the PCB can be generated. With another machine axis can the PCB be rotated 90° and all grooves in the other board axis can be

generated. The next higher level in automation also has a controlled *z* axis with which the distance of the tools (defining the web) can be set in the program. By moving the cutting tools so far apart that they leave the material, can interruptions of the grooves be generated. These technique or technology is also referred to as “jump scoring.”

Due to the increased requirements concerning the alignment of the grooves to the outer layer image can modern CNC v-scoring machines additionally be equipped with a camera system. This allows adjustments in the angle in which the score is generated and also in the positioning of the grooves to each other. After the camera measures metal features (fiducials) or holes in all four corners can the v-scoring pattern be stretched or shrunk to mitigate dimensional changes of the PCB. For the alignment to fiducials might multiple light sources be required as the different final surface finishes reflect the different wavelengths in a different way, giving alternatives for a good recognition of the fiducial enabling a perfect alignment.

38.8.3 Scoring

In a CNC scoring operation is the printed circuit board fed (manually or automated) into the v-scoring machine, after a program with the locations and depth of the grooves and if required the coordinates of the fiducials, is loaded and started. A first rough alignment of the PCB against a mechanical stop is followed by a clamping system which fixes the PCB and defines the location in relation to the machine. In case of “camera alignment” is the camera moved to detect the fiducials at predefined locations. Once the fiducials are detected, additional fine adjustments of the locations of the PCB can be performed. If necessary and defined in such way, is it also possible to stretch or shrink the distance of the v grooves to each other (based on the information gained during the measurement of the features) to compensate dimensional changes of the printed circuit board.

The two blades (one on the top side of the PCB one on the bottom side of the PCB) are accelerated to the defined cutting speed. A relative motion moves the blades across the PCB for the first groove. As the blades only move in one axis back and forth, is the PCB moved to the next groove location, so that the second groove is generated while the blades move back to their original location.

As the blades have cutting “teeth” for the material removal, are the cutting conditions similar to the conventional routing operation. If not defined differently, will one groove be generated in “conventional milling” and one in “climb milling” leading to different results concerning the edge quality of the groove. For critical applications can the direction of the movement of the blades be defined for each individual groove. It has to be considered that the choice of only one cutting direction will have a negative impact on the efficiency as the blade will need to be moved to the original position relative to the PCB after each groove. With that, material is only ablated in every pass.

38.8.4 Depaneling

The separation of the parts after the generation of the groove can either be done manually or with additional (cutting) tools. The parameters defining the force which is required for the manual separation are

1. The web or web thickness
2. The blade or scoring angle
3. The width of the separation partners

The angle and the width of the elements define the lever in which the separation can be done and with that another big element to the web, which defines the general force which is required to separate the elements.

Especially for the manual depanelization or singulation has to be considered that the parts turn out to be bigger than the inner edge of the material. This increase is caused by the broken web exposing glass fibers.

The separation can also be done with tools, in the simplest way a cutter knife looking like a pizza cutter. There are also depaneling machines available having blades, saws, round cutters or linear cutters on one or both sides (top and bottom) looking similar like the actual v-scoring machine. Common is also a single cutting blade (like a saw) with manual feeding of the pre-cut products. The grooves which are already in the product guide the operation and make an additional alignment obsolete.

Very effective can be to combine “routing” and “scoring” enabling complex structures and perfect edge quality (only) where needed and being cost effective and fast on the other areas (see Fig. 38.10).

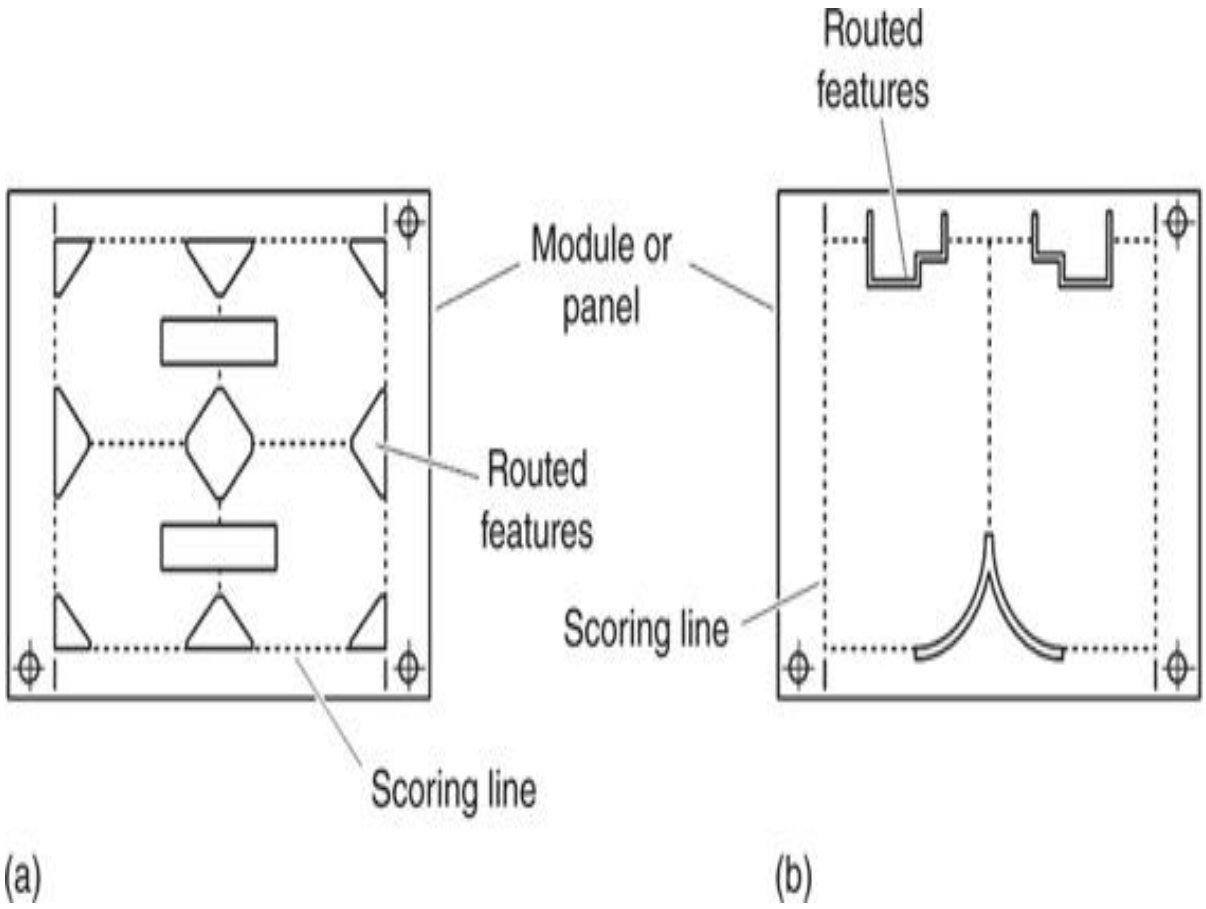

FIGURE 38.10 (*a*) Panel with typical scoring lines and routed corners; (*b*) scoring lines and routed complex features.[3]

38.8.5 Process Control

Controlling the v-scoring operation in a production environment can be manifold. Key elements are

- The edge quality of the groove, for proper parameters and tool life.
- The location of the groove, typically in relation to fiducials or other features on the board.
- The web or web thickness; this is a critical attribute especially if the separation is not done “in-house”. Measurements can either be done visually by looking at the

board edge or mechanically with a caliper gauge or combinations of the two.

- The outline dimensions after separation (visually or mechanically).

To reduce human errors in a manufacturing environment like skipping the entire v-scoring step or to double check the v-scoring machine itself for missing scoring lines, can small coupons in the shape of “I” or “U”-shaped copper traces with test points at both ends be added. These need to be cut once (I-shape) or at least once (U-shape) and can be included in the electrical test. In the example would the pass-criteria be an “open” and a fail-criteria be a “short” indicating that the entire process step or single lines were not performed and the copper traces in the coupon are not cut.

38.8.6 Trouble Shooting V-Scoring

The two main issues in the v-scoring operation are shown in Fig. 38.11. In this figure (1) shows a web which is off center, leading to a deeper and wider score on one side. Usually is the increased width the bigger problem, potentially violating a minimum distance to adjacent features. Root cause is a wrong thickness of the board or a mismatch of the actual or planned thickness. This thickness needs to be entered manually or is part of the NC program. On the other hand can a shape like that be achieved by purpose by entering a thickness deviating from the actual thickness.

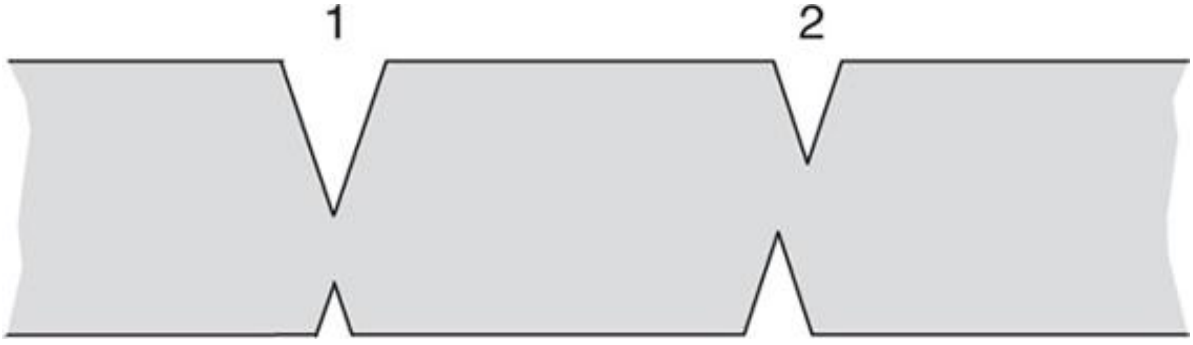

FIGURE 38.11 Issues around the v-scoring process; (1) web-off-center, (2) offset between top-and-bottom cutter tool.

Issue (2) shows an offset of the top cutter to the bottom cutter. Problems can occur in the separation process and the final edge quality. The offset needs to be adjusted in the machine as part of a process control.

PART 7

BARE BOARD TEST

CHAPTER 39

BARE BOARD TEST OBJECTIVES AND DEFINITIONS

David J. Wilkie

Everett Charles Technologies, Pomona, California

39.1 INTRODUCTION

Advances in packaging technology resulting in finer board geometry, including the various forms of high-density interconnection (HDI), have combined with increasing data rates to put significant pressure on the electrical test area. Fixture construction is more expensive and requires improved process control. Advanced test methods, such as radio frequency (RF) impedance testing, are more often required. Global price competition demands reduced costs. Meanwhile, original equipment manufacturers (OEMs) demand that board manufacturers accept increased liability for defective product—thereby demanding improved fault coverage. This chapter is devoted to the why, what, where, when, and how of current electrical test methods useful in meeting these requirements.

39.2 THE IMPACT OF HDI

Test engineers are currently confronting significant changes in test requirements that derive from changes in the product itself. Notable among these changes are those driven by the growth of various HDI technologies. Examples of common HDI applications are direct chip attach (DCA), high-density ball grid array (BGA), and variants of these often referred to as chip scale packaging (CSP). In addition, higher-density input/output (I/O) connectors are commonly applied. In addition to the changes in physical geometry, HDI also implies increasingly high data rates and clock speeds. Advanced means are being applied that verify not only the ability of the product to interconnect electronic components, but to do so in a manner that guarantees signal fidelity.

An analogy is possible comparing the impact of HDI on board technology with the impact of the sound barrier on aerodynamic flight. This analogy is readily applied to final electrical testing. It was popularly imagined that the sound barrier was impassible, or could be passed only by Buck Rogers in his silver rocket—that beyond the speed of sound was no place for an airplane to go. As it turned out, passing the sound barrier *was* difficult, and required rethinking many aerodynamic principles. But the resulting vehicles are still recognizable as aircraft. They have wings, they burn fuel. They meet all of the objectives of earlier craft, and do so in a superior manner. The test processes that are resulting from the impacts of HDI upon final electrical testing are similarly recognizable evolutions of previous methods, employing familiar base technologies, but in new combinations and with added features that actually improve test coverage rather than diminishing it.

Proposals have circulated for radical new measurement approaches to electrical testing. These have included the use of electron beams, laser-stimulated photoelectric

effects, and gas plasma techniques in configurations similar to existing flying probers. In each case, the board is scanned without use of a custom test fixture. To date, all of these methods involve compromise of fault coverage, or add little or no fine-pitch performance beyond conventional methods. Relaxation of test criteria is not a relief available to most users. HDI product types demand increased fine-pitch capability. These finer trace and via geometries increase the risk of latent defects and increase interest in measurement methods most sensitive to precursor symptoms of such defects. As a result, none of these approaches has seen widespread adoption.

Rather than witnessing radical breakthroughs, the market has seen a steady improvement in the availability of software and hardware tools that provide for the effective combination of the best features of conventional test systems and increased availability of test systems dedicated to specialty markets, in particular the small-format laminated chip carrier product type.

39.3 WHY TEST?

Why pay for testing? Why do we need to test? The answer has several components. The primary assumption is that not all boards produced are good. If we could look at the yields through the history of the industry in printed wiring boards using similar technology, we would see exponential reductions in the percentage of bad boards produced. Process improvements and a wide variety of quality improvement programs continue to make a difference. In spite of these improvements, the need for electrical testing remains.

39.3.1 The Rule of 10s

One reason to test is to block the addition of further value to defective product. Consider the printed wiring board as a component of a completed assembly. A commonly accepted relative measure of the cost of faults in a completed electronic assembly can be expressed by the rule of 10s (see Fig. 39.1). The idea is that the earlier a fault is caught, the less it will cost. An example might be an open in a bare board that is not found at bare board test. The faulty bare board is now loaded with the components, soldered, and tested. If the fault is found at the loaded board level, repair or scrapping of the assembled board is much more expensive than repair or scrapping at the bare board level. There are situations where the assembler of the board charges back to the manufacturer of the bare board some portion of the cost of the scrapped components, assembly labor, and/or production cost. This is increasingly true with the high-cost and high-capability integrated circuits (ICs) present in so many designs. A fault that passes a system-level test and makes it to the end user entails even higher cost. Some of these costs are very tangible in the form of field service labor, downtime, parts, and labor. Other costs are counted in lost business and reputation.

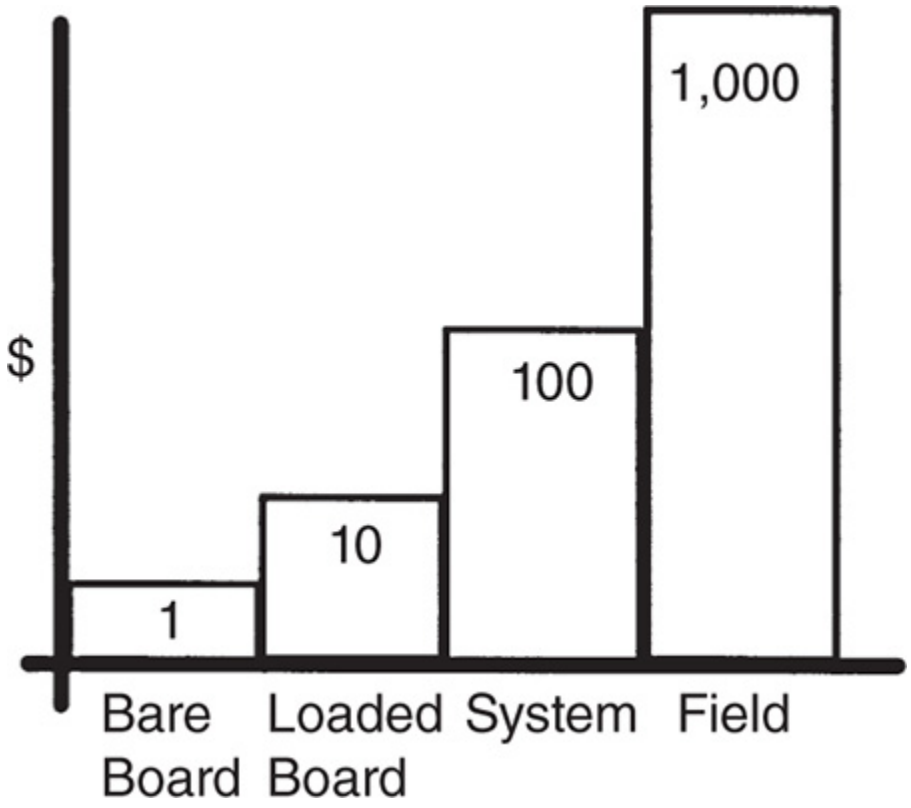

FIGURE 39.1 Rule of 10s: cost of a found fault.

39.3.2 Satisfying Customer Requirements

Where the rule of 10s is a logical big-picture approach to the necessity of testing, requirement from a customer is quite the opposite. The board user has already determined that electrical testing is appropriate and necessary and has made it a requirement as part of supplying the board. It is the obligation and responsibility of the bare board manufacturer to meet this requirement of purchase contracts. In practice, we find such customer requirements stated in various ways.

39.3.2.1 Generic or 100 Percent Board Test. Unfortunately, this requirement may be nothing more than the words “100 percent electrical test” appearing

somewhere in a purchase order or a larger package of documentation. Not only is such a specification relatively meaningless, but the issuer of such a requirement is led to believe that the boards will be tested to the most stringent requirements—that it will not be possible for a single bad board to be delivered. Nothing could be further from the truth. Such a specification fails to define what a 100 percent test consists of. The purchaser of the bare board will certainly be dissatisfied when he or she receives a bad board. Although the specific fault on the bare board in question may have a perfectly viable explanation (might not be detected electrically, or may be undetectable by the specific methods employed), the 100 percent test specification implies that no explanation is acceptable. In many cases, application of this general sort of specification is combined with a customer-imposed limitation on test cost, which in turn requires cost-driven limits on the thoroughness of electrical testing performed by the board manufacturer.

39.3.2.2 Written Test Specification. It is the responsibility of both the bare board manufacturer and the bare board purchaser to agree upon a test specification that is specific in terms of test thresholds and method of testing while keeping in mind the appropriateness to the application for the bare board design. Some limits on test thresholds and test methodology may be due to equipment and capabilities of the manufacturer. It is the responsibility of the bare board manufacturer to educate the end user as to the implications of test specifications in thoroughness and cost of testing. A matrix of test options, fault detection capabilities, escape risks, and associated costs should be presented to the end user. It is the responsibility of the end user to work with the bare board manufacturer to develop specifications appropriate to the bare board being produced and to accept and plan for any testing compromises

imposed by cost or specification limits. Areas that should be covered in the specification are:

- Data-driven testing, source of data, format, and integrity
- Test thresholds: maximum allowable for continuity verification
- Test thresholds: minimum allowable threshold and applied voltage for isolation verification
- Test fixture methods: single fixture with simultaneous access of all test points versus split-net fixtures versus flying probe
- Test point optimization
- Board marking indicating electrical test satisfaction
- Resolution of discrepancies in process (contacts and procedures)
- Requirements for special test methods (time domain reflectometry [TDR], embedded passives, etc.)
- Resolution of escapes

Such agreements make for good communication, clear understanding, happy customers, good reputation, and good business.

39.3.2.3 Using Available Standards. Industry standards or guideline documents such as IPC-9252, “Guidelines and Requirements for Electrical Testing of Unpopulated Printed Boards” (which replaces IPC-ET-652), are useful in developing agreed-upon written specifications for a particular product.

Standards documents must be applied in consideration of the target application. An excessively rigorous specification would result in unacceptable test cost with little quality improvement.

Arbitrarily high isolation voltages or continuity test currents can actually lead to product damage. Conversely,

relaxing isolation resistance specifications on boards containing sensitive amplifiers would be inappropriate. These are but a few examples. In IPC-9252, the IPC has made efforts to distinguish between general classes of board applications, suggesting specific electrical test requirements that attempt to recognize different levels of criticality in testing.

Final determination of the suitability of a given set of requirements must be made in cooperation with technical representatives of the bare board purchaser.

39.3.3 Electrical Testing as a Process Monitor

A third benefit of testing is the improvement of processes and the resultant reduction in costs. To raise yields, reduce scrap, or generally improve quality, there must be a system of measurements able to express results of changes. One of the best areas to collect data is electrical testing. This usually requires an integration of testing and repair data. While the test system can identify a bad board and the location of a fault, a repair operator can further classify the fault to associate it with a specific process (imaging, plating, etching, solder masking, etc.).

These data can be quantified and analyzed in a variety of ways, and corrective action may then be directed to one or more of the following levels.

39.3.3.1 Faults Specific to the Operation. Fault types may be detected that are not typical of the industry or competition. It can be difficult to assess this type of situation accurately because data commonly available from the customer, alternative vendor, or competitor are likely to be narrow or biased. It may be better to analyze fault types

specific to an operation in terms of cost or profitability. Are certain product types profitable to manufacture? What would be the cost to make them profitable?

39.3.3.2 Faults Specific to the Process. An analysis of fault data may lead to a specific process that regularly induces faults in a wide variety of part numbers, or in a variety of part numbers sharing key characteristics. This may point to requirements for new settings, procedures, materials, training, personnel, equipment, etc.

39.3.3.3 Faults Specific to a Part Number. Fault data on a specific part number are useful in correcting and optimizing processes for future runs of the same part number, and often for similar future part numbers. It may be possible to feed back electrical test data in real time using software systems, depending upon lot size, factory flow, and the type of test and repair analysis equipment available for use. In this situation, results from electrical testing may help drive some adjustments or quick changes in the process that will immediately improve the yield and reduce scrapping, repair, and retesting costs.

39.3.4 Quality System Improvement

Quality control analysis of fault data is only a piece of what needs to be in place already, that is, a quality control system or process. The value of electrical test (or other process) data for process monitoring is only as great as the quality control framework making use of it. It is possible for electrical test results to become a vehicle for improvements to a board manufacturer’s quality system.

39.4 CIRCUIT BOARD FAULTS

For electrical test purposes, faults may be defined as test system measurement results other than those programmed to be representative of a good board. The faults detected may or may not impact the functionality of the circuit board, though in most cases they will. Some guidelines may prove useful when more specific guidance from the original specifier or designer is lacking. Obviously, gross shorts and opens in a circuit are likely to cause problems. Will an electrical test system find all the faults? No. The definition of “all the faults” is too subjective.

The electrical test system will not detect all faults related to aesthetics, annular rings, layer-to-layer registration, etc., unless they present an effect measurable by the test system. Further, the electrical measurement employed, type of test fixture, test program generation method, and end-use requirements vary too widely to state broadly that electrical testing will find all the faults.

For purposes of the following discussion, it is worthwhile to clarify the distinction between a defect and a fault. A fault is a test system designation for an item that does not meet the expected criteria. A defect refers specifically to the board and a defect in its design, fabrication, appearance, etc. Not all defects can be detected by the test system.

39.4.1 Fault Types

Table 39.1 presents common fault types. For those fault types that are commonly detected, it is valuable to distinguish types of tests from types of faults. It may be preferable to refer to isolation testing or continuity testing rather than to shorts or opens testing, as the latter meaning is often confused Shorts and opens are results, not test types. Test methods themselves are discussed in detail elsewhere in this chapter.

TABLE 39.1 Test and Fault Types

Test type	Fault type identified by test
Continuity	Open
Isolation	Short and/or leakage
TDR or network analysis	RF impedance fault
Hi-pot	Voltage breakdown

39.4.1.1 Shorts. Shorts, hard shorts, or short circuits are defined here as erroneous (undesired and unexpected) low-resistance connections between two or more networks or isolated points, typically exhibiting a fairly low electrical resistance value. Shorts are reported as failures of the isolation test of the product. Shorts are produced in a variety of ways, including exposure problems, underetching, contaminated phototools, poor alignment of layers, defective raw material, and improper solder leveling.

39.4.1.2 Opens. Opens represent an absence of expected circuit continuity, or in other words, a missing connection. This divides a circuit network such that the network is split or divided into two or more pieces. Opens are reported as failures of the continuity testing of the product. Opens are produced in a variety of ways, including overetching, underplating, contaminated phototools, contaminated raw material, layer registration errors, and mechanical damage. A common problem during electrical testing is “false open” errors, typically the result of localized contamination on the product or test probe that prevents proper connection to the test system. Of particular concern in testing substrates employing microvias are latent defects

(those which may appear after test during subsequent substrate assembly processing). Examples are improperly formed conductors at stress points where cracks may form during thermal or mechanical stresses of assembly. Small HDI features are less tolerant of such defects. These may be completely undetectable at the time of test, or limited examples may be detected by especially sensitive ohmic measurements able to detect a limited conductor cross section where a future open circuit may occur. Frequent observation of such defects indicates the need for process changes if field failures are to be avoided.

39.4.1.3 Leakage. A leak or “leaking network” is essentially a type of short. Leaks are also referred to as high-resistance shorts, and differ from hard shorts in that they exhibit a higher resistance value. The precise division between the two types of error reports varies according to the type of equipment used, and some equipment does not attempt to distinguish them in fault reports. As in the case of hard shorts, leakage is a failure of the isolation testing of the product.

Common leakage causes are moisture, chemicals, or debris. Contamination can occur during innerlayer fabrication, lamination, plating, solder masking, or any stage due to handling. Chemical contaminants are often deposits of metal salts left as artifacts of the chemical processes used to manufacture the product. With sensitive test methods, even fingerprints can result in detectable leakage between networks. Such contaminants are often spread over an area of the board such that several networks become interconnected. Consideration of the potential for multiple network involvement is useful in selecting the particular isolation test algorithm or test method, as these methods differ in their sensitivity to this situation. Isolation test methods are discussed elsewhere in the chapter. Some circuits are not sensitive to the high-resistance loads

immediately presented by such contaminants. But it is important to note that, in the presence of time, electric fields, and moisture, it is possible for the resistance of a high-impedance short to decrease greatly. Contamination sites may facilitate the growth of metallic crystals that reach out as thin metal threads between networks, forming hard shorts.

Thus an area of the product exhibiting unusual leakage may, at some future time, exhibit hard shorts between networks. This amplifies the need for effective high-impedance testing of high-reliability product types as a means of preventing latent field failures. Note that the nature of board materials is such that they can absorb moisture relatively easily, and they do so over time. Thus even a fairly “dry” contamination providing a very weak electrical path may eventually result in sufficient metal migration during product operation to cause a serious field failure.

39.4.1.4 RF Impedance Fault. Many circuits produced today are required to operate at very wide bandwidths. Examples include fast microprocessors, fast general digital circuits, RF amplifiers in wireless devices, etc. Just as we must use a proper type of cable to connect a television antenna to a TV receiver, it is important for specific RF characteristics to be maintained in interconnections between components of fast electronic circuits on printed wiring boards. One parameter commonly specified and measured is the RF transmission line impedance of the signal traces. This parameter is strongly affected by the materials used in fabricating the board, the trace thickness and width, and the spacing from ground planes and adjacent signals. A common method of measuring RF impedance is to employ TDR.

The TDR measurement provides a statement of RF impedance as a function of distance along the trace.

(Distance and time are related here, as the electric signal flows through the board at velocities approaching the speed of light.) TDR testing is often performed on a test coupon attached to the product during manufacture and subsequently disconnected. TDR testing on actual product traces is also done on selected traces, but is complicated by the need for a trace length of several inches, uninterrupted by branches or other constructions. Common values for RF impedance on circuit boards range from the low tens of ohms to several hundred ohms.

RF impedance should not be confused with ordinary direct current (DC) resistance and cannot be measured with common ohmmeters, even though the same unit of measure—the ohm—is used.

RF parameters of interconnections can also be characterized in the frequency domain using instruments referred to as network analyzers, but this method is not common in bare board testing. Requirements for RF impedance testing are more commonly applied as signal frequencies exceed 100 MHz.

39.4.1.5 Hi-Pot Faults. Hi-pot or high–potential voltage breakdown testing is often confused with isolation testing. The tests are very similar, and, to the extent that high voltage is employed in an isolation test, they might achieve a similar result. But isolation testing of bare boards commonly occurs with 250 volts or less applied between networks, and hi-pot testing is often performed at values from 500 volts to several kilovolts. Hi-pot testing attempts to verify the strength of the insulating material between networks by subjecting it to so high a voltage that a catastrophic or avalanche-type voltage breakdown will occur if the insulator is subpar. In contrast, isolation testing on bare boards attempts to detect the small current flowing through contamination (or, for that matter, a hard short) before voltage breakdown occurs. Of course, if the insulator

is very weak, then avalanche failures can occur at almost any voltage. Hi-pot testers tend to be benchtop devices with a pair of test leads and no switch matrix, and hi-pot test requirements usually specify that the voltage be applied for a sustained period of time.

Hi-pot testing is valuable for inspection of very thin insulating core material, before circuits are etched. This can serve to detect z-axis faults or contamination in the material before value is added in subsequent processes. It can be impractical to perform hi-pot tests between all conductors of finished fine-pitch boards, as the atmospheric environment (air) between conductors will break down before high voltage is reached. The slow speed at very-high-voltage hi-pot testing and the costs of suitable fixtures and electronics present problems. For final product inspection, it is arguable that a very-high-impedance isolation test provides the superior solution.

CHAPTER 40
BARE BOARD TEST METHODS

David J. Wilkie
Everett Charles Technologies, Pomona, California

40.1 INTRODUCTION

Although the main bare board testing technology is electrical, it is important to consider that nonelectrical methods are also important in the acceptance or rejection of bare printed wiring boards (PWBs). This chapter therefore includes detailed descriptions of both electrical and nonelectrical testing methods.

40.2 NONELECTRICAL TESTING METHODS

There are two nonelectrical acceptance/rejection methods, both based on inspection processes:

- Visual inspection

- Automatic optical inspection

40.2.1 Visual Inspection

Visual inspection is a very manual approach in that it makes use of people, good lighting, some type of training defining what is acceptable and what is not, and good operator judgment.

Usually a comparison to a known good product or the artwork is made. If the operator has seen the board often, he or she becomes more skilled at finding faults and looking for faults in likely locations. As product complexity has increased, we find that many modern products are not suited to this method. Many innerlayer defects are completely undetectable, and even the external layer complexity is visually overwhelming. Visual inspection often remains appropriate for detecting cosmetic defects, such as poor solder masking or physical damage. Such defects generally fall outside the realm of electrical testing as they are not detected by electrical means.

40.2.2 Automatic Optical Inspection

There are computer-based visual inspection methods, referred to as automatic optical inspection (AOI). AOI equipment compares the board or its innerlayers to expected data and/or design rules that have been programmed into the controlling computer. These can be generally accepted parameters or design-rule-based parameters, or windows of acceptable dimensions for each specific feature on the board. As with manual visual inspection, faults found with this method can imply that there may be an impact on the board’s functionality, but the board’s functionality and interconnect are not directly tested. Distinctions between the

aesthetics of the board's features and its fitness for use are difficult to differentiate, and may result in false failures. Rather than being used in final testing, AOI is used for inspection of innerlayers prior to lamination, with the goal of increasing final yield by weeding out the majority of defective layers prior to the addition of further value. As such, AOI can achieve significant financial benefit. AOI can detect some defect types not readily detected by electrical means, particularly "mouse bites" (brief narrowing of the conductor cross section). AOI may also be used to inspect the outside layers after lamination, but is not generally accepted as a quality assurance substitute for final electrical testing.

40.3 BASIC ELECTRICAL TESTING METHODS

Electrical testing is the final test method frequently used to determine whether a board should be shipped. Electrical testing emulates the intended function of the board conductor and insulator patterns by passing currents through conductors and applying voltages across insulators. Such direct electrical measurement requires that the board come into physical contact with a measurement system. Two test types are almost universally performed: continuity and isolation testing. Some other tests may be applied selectively, depending upon the product and customer requirements.

Test order is usually such that the continuity test is performed first. This verifies that each network is intact within itself, and that contact is established between any test fixture and the product. The isolation test can then be performed using only a single test point per network. Some test methods attempt indirect inference of continuity and

isolation without making direct current (DC) measurements. These methods are commonly employed in flying probe systems.

40.3.1 DC Continuity Test Method

Continuity testing checks for the expected continuous path within each electrical network. This is done in a series of point-to-point measurements within each network. The resistance found in each measurement is compared to the selected continuity resistance threshold. If the measured value is higher than this threshold, then a fault report is generated. For complex networks, multiple measurements are required in order to ensure that all extremities of the network are interconnected. For example, the network with test points labeled A through D, shown in Fig. 40.1, could be tested in the sequence illustrated in Fig. 40.2. For a network with four test points, the minimum number of tests would be three to determine whether all points are connected. If a board contains a total of N isolated networks, and contains a total of X test points, we may calculate the number of continuity measurements C as $C = X - N$. In assigning test points, the software system often is programmed to delete those that are unnecessary. This is referred to as test point optimization. In Fig. 40.1, a test point located along the path between D and the branch to C would not be useful. Various optimization rules may be applied, but should be applied with care to ensure that adequate test coverage remains in place.

40.3.1.1 Continuity Test: Two-Wire versus Four-Wire Switching. Switch matrixes are constructed using either two-wire or four-wire circuits. A diagram comparing a single continuity measurement being performed on both two-wire and four-wire matrixes is shown in Fig. 40.3.

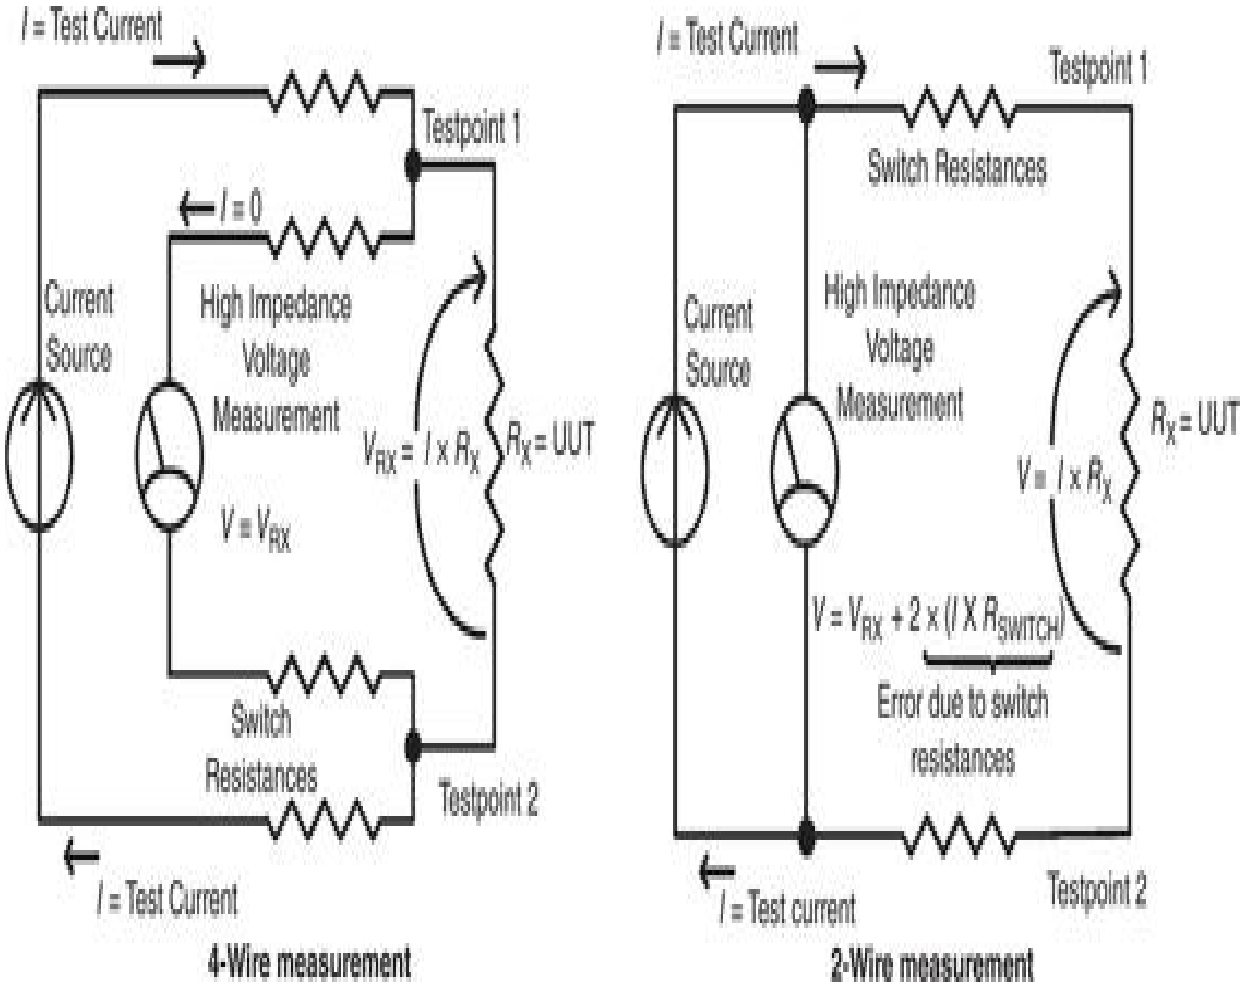

FIGURE 40.3 Continuity measurement circuits.

Grid test systems use solid-state switches to connect appropriate test points to an internal measurement system (which is effectively an ohmmeter). Current *I* is driven from the upper test point through the product network and returned to the measurement system through the lower test

point. The resultant voltage V across the network is measured. The continuity resistance R is then determined using the relationship $R = V/I$.

40.3.1.2 Two-Wire Switch Matrix Construction. The simplest, most affordable, and most common construction of the switch matrix is to have a pair of switches for each test point that can connect the test point to either the high side or low side of the ohmmeter. This technique is illustrated on the right side of Fig. 40.3. However, as the solid-state switches exhibit a certain amount of on-resistance, they contribute error to the measurement. The resistance of the switches is added to the resistance we measure, increasing the likelihood of failing the test. These errors can be reduced in various ways:

- Use switches with low on-state resistance (and thus a small amount of variation in on-resistance). This means using physically larger transistor dies. Such devices are not expensive, but are harder to integrate into integrated circuits. Thus, most two-wire designs rely upon discrete output transistors as switch elements.
- Use software to subtract the estimated typical on-resistance. As switch resistance effects vary from device to device, and change with temperature, some error remains.
- Make multiple measurements for each continuity to be inspected, and mathematically subtract most of the switch resistance. However, this slows the measurement process somewhat by requiring extra measurements and requires high-quality fixture construction such that contact resistances do not vary during the required multimeasurement sequence.
- Attempt to learn the resistance of each switch. Some systems require the operator to install a shorting plate over all test points, and the system then learns the sum of the switch resistances plus contact resistances to this

plate. Note that this technique can actually add error if a high contact resistance value is learned for a particular test point, perhaps due to dirt on a probe. The excessive resistance value learned is subtracted from all subsequent measurements made with that probe, masking some high product resistances. The net result is a slightly increased possibility of passing a board that should be failed.

40.3.1.3 Four-Wire Switch Matrix Construction. The left side of Fig. 40.3 represents a Kelvin or four-wire switch matrix construction. Notice that each test point will require four switches, so that any test point can be connected to the high-side current drive, high-side voltage sensor, low-side voltage sensor, or low-side current return via separate paths. Because the voltage-sensing portion of the measurement system has an extremely high input resistance, almost zero current flows through the extra pair of switches that connect the test points to this circuit. The result is that there is zero voltage drop across these sense switches, and the measurement unit sees exactly the voltage across the unknown load. Because the measurement system knows exactly the current flowing through the load, and exactly the voltage across it, it can calculate the load resistance accurately. The dominant error term in this situation is generally the contact resistances in the fixture and fixture-product interface. Also, the smaller transistors leak less current in the off state, thereby permitting isolation testing at higher thresholds with smaller errors. The continuity accuracy benefit of this technique is realized only if high-quality fixtures with low contact resistance are employed.

40.3.1.4 Continuity Threshold. The continuity resistance threshold parameter is usually specified in the range from a few ohms to 1,000. Several standards useful in suggesting continuity thresholds are summarized in Table 40.1. IPC-9252 has actually weakened the recommendations

of IPC-ET-652, which it replaces. As discussed earlier in the chapter, these must be applied with judgment. Generally, a lower continuity threshold provides a more stringent test of the board. Networks with resistances of 5, 10, or 25, although rare when using copper traces of moderate length, can significantly impact the functionality of precision measurement instruments or high-speed computer products. At the same time, it should be noted that there are practical and economic considerations in determining how low the continuity test threshold should be set. Part of the limitation comes from the test system's measurement and switch matrix capabilities and, to a greater part, from the type of test fixture used. At the time of this publication, a 10- continuity resistance test threshold is a common lower limit for production testing with good-quality systems and fixtures.

TABLE 40.1 Examples of Continuity Resistance Test Threshold Standards

IPC Board Class	IPC-9252	IPC-ET-652 (obsolete)	MIL-55110D (obsolete)
Class 1: General Electronic	< 50–100 Ohms	< 50 Ohms	< 10 Ohms
Class 2: Dedicated Service	< 50 Ohms	< 20 Ohms	< 10 Ohms
Class 3: High Reliability	< 50 Ohms	< 20 Ohms	< 10 Ohms

40.3.1.5 Continuity Test Current. Continuity test current is not addressed in IPC-9252 or in most other publications. Use of high current has been proposed as a means of burning out weak traces or mouse bites. But such currents may also damage good traces. If this occurs after the test system has already determined that there is a good connection, the result is a board that once tested as good but is now bad. It is preferred that the continuity test not be

invasive or destructive. Typical test currents today are in the range of 5 to 50 mA.

40.3.1.6 Continuity Test False Opens. A common problem with continuity testing is a high incidence of false failures due to fixture and product contamination, poor product registration, or fixture damage. Dramatic improvement is often possible with the addition of product and fixture cleaning methods. Separation of the board-testing environment from such dust-producing processes as drilling/routing can be invaluable in increasing throughput. High-voltage pulses are sometimes used to overcome thin-film contaminants or oxides coating the surface of the board and preventing good contact with the test probe. As no current is initially flowing through the oxide, some test systems offer a feature delivering a high-voltage pulse of strictly limited current and duration, and therefore limited total energy. While brief, the energy level is higher than for a normal continuity test and a small risk of damage at defect sites remains. Adding test time for automatic or manual retesting of the product yields additional boards, but this common approach becomes expensive when large numbers of false opens occur. It may be advisable to correct the root cause.

40.3.2 DC Isolation Test Method

Isolation testing verifies the presence of adequate electrical isolation between networks that are not intended to be connected to one another. Typically a resistance measurement is made from a given network to another net (or group of nets). If the measured value exceeds the specified isolation resistance threshold while the specified voltage is applied, then the measurement is considered to have passed. Otherwise, a fault report is generated. So long

as contact with the net has been ensured (during the continuity test), only a single test point per network is required to perform the isolation test. The actual number of isolation measurements required to test a given board can vary substantially with details of the algorithm employed, with subtle impacts upon fault coverage. These issues are discussed in a separate section.

40.3.2.1 Isolation Resistance and Voltage. As isolation testing is a means of evaluating the ability of product insulation to withstand voltage and prevent current flow, it is common for the isolation test specification to include not only a statement of minimum resistance, but also an applied voltage. This is the voltage that the insulator must withstand while exhibiting at least the minimum isolation resistance. Given the relationship $R = E/I$, increasing the applied voltage is also a means of increasing the measurement current level up out of the noise floor internal to the test system. Thus, high-voltage-capable bare board test systems usually are able to verify isolation at higher resistance levels and do so at reasonable speed. Typical values for isolation resistance can range widely, from as little as 1 k. to as much as 1000 M.Values of 2 to 10 M are common, but higher values are useful in detecting trace contamination. Excessive humidity in the test area may preclude the use of very high thresholds and may affect accuracy at lower thresholds. Values below 50 to 55 percent relative humidity are desirable. Common isolation test standards (see Table 40.2) have not always kept pace with the capabilities of new equipment to test at elevated and sensitive thresholds. In any event, assignment of specific test thresholds would ideally be based upon a competent analysis of the intended application of the specific circuits on the product to be tested.

TABLE 40.2 Examples of Isolation Resistance Test Threshold Standards

IPC Board Class	IPC-9252	IPC-ET-652 (obsolete)	MIL-55110D (obsolete)
Class 1: General Electronic	> 500 K Ohms	> 500K Ohms	> 2 M Ohms
Class 2: Dedicated Service	> 2 M Ohms	> 2 M Ohms	> 2 M Ohms
Class 3: High Reliability	> 10 M Ohms	> 2 M Ohms	> 2 M Ohms

There is somewhat less emphasis on test voltage than was true previously, probably as a result of increasingly fine geometry in the product. Older or simpler test systems may be limited to 10 to 40 volts, but most are able to apply 100 to 250 volts during the isolation test. A higher voltage increases the test current, providing a better signal-to-noise ratio and generally improving test speed at higher isolation thresholds. Excessive voltage is inappropriate for very fine-pitch substrates and may result in damage from arcing in normal environments (see Table 40.3). The insulating properties typical of modern board material suggest that it may be of little value in specifying elevated voltages while using low (relaxed) threshold resistances. Raise the resistance threshold first, then use enough voltage to get adequate speed and accuracy.

TABLE 40.3 Examples of Isolation Test Voltage Standards

	IPC-9252	IPC-ET-652 (obsolete)	MIL-55110D (obsolete)
Minimum isolation test voltage	High enough to provide sufficient current, but avoid arcover	High enough to provide sufficient current, but avoid arcover	All least 40 volts, or twice the rated voltage of the board, whichever is greater

40.3.2.2 True Isolation Test Method. Several different algorithms have been developed for sequencing the switching state during the isolation test, and the choice may affect test coverage. In the most rigorous method, each network is individually tested to determine the total parallel leakage resistance to all other networks on the product. This requires one measurement per network, as illustrated in Fig. 40.4 for a board with three networks. Each network is, in turn, given a chance to charge to an elevated voltage. All other networks are connected together and to 0 volts at this same moment. Notice that only one test point is needed per network.

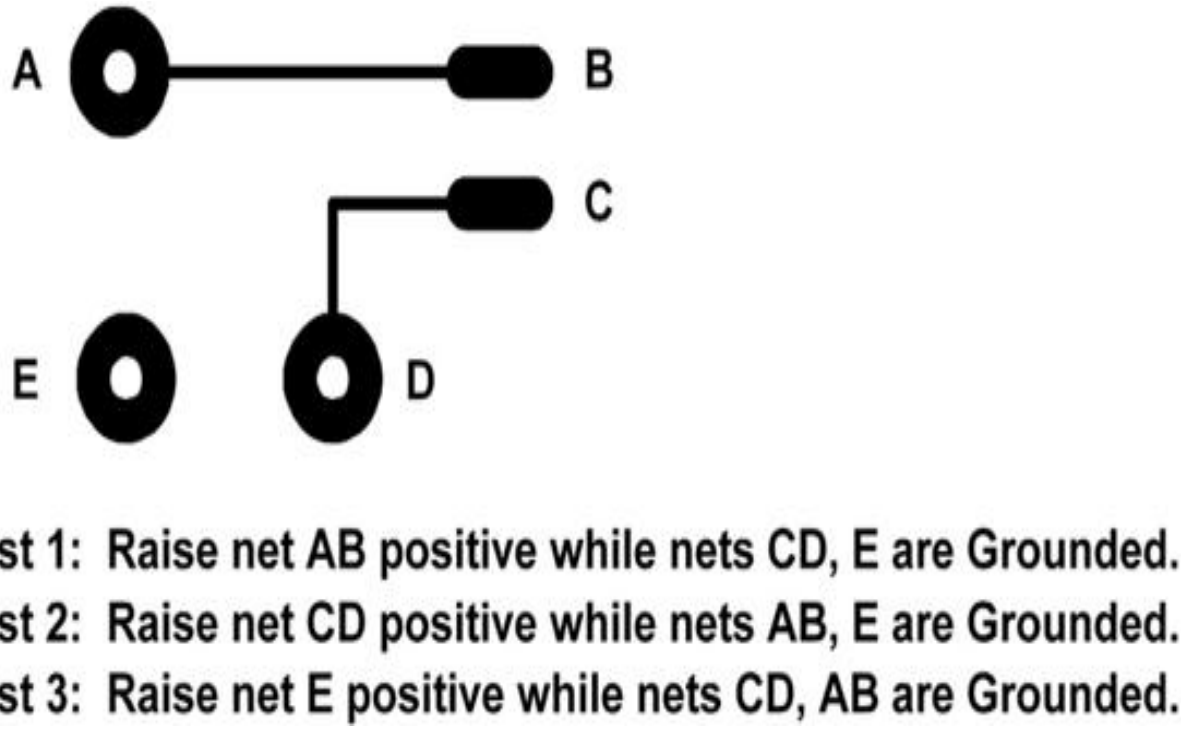

FIGURE 40.4 True isolation test of three-network board.

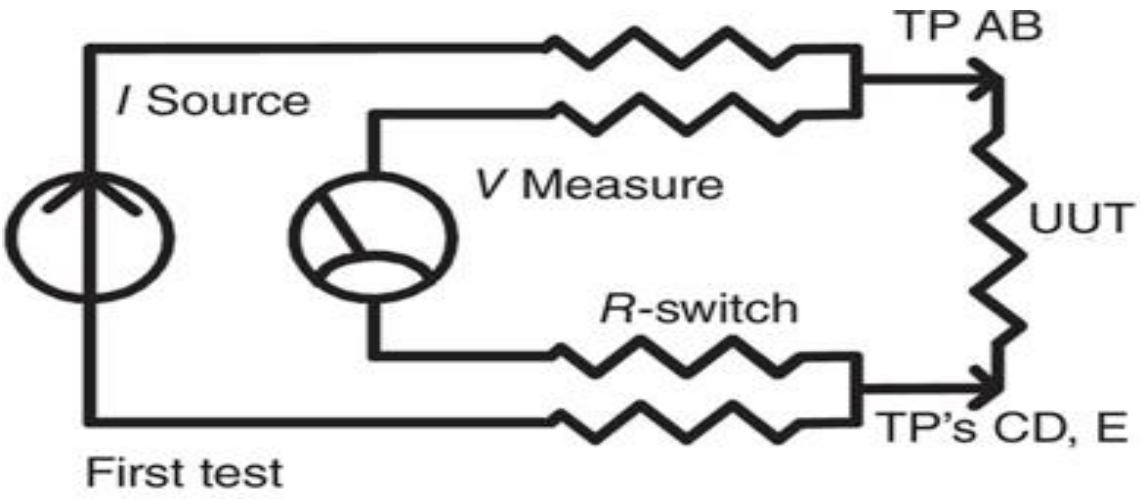
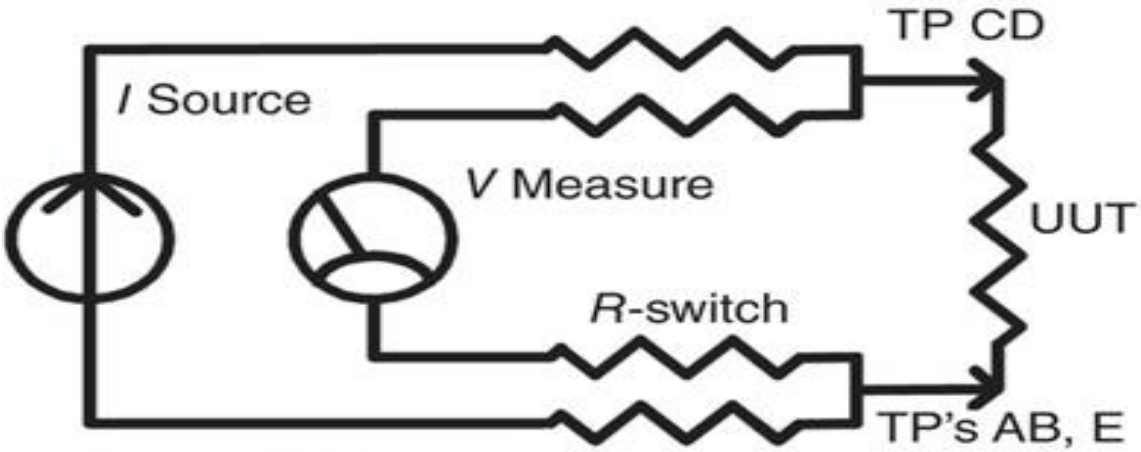
If the network under test is shorted or leaking to any of the other networks, or to any combination of them, it will fail to charge adequately and the test will fail. The pattern continues until each network has been tested.

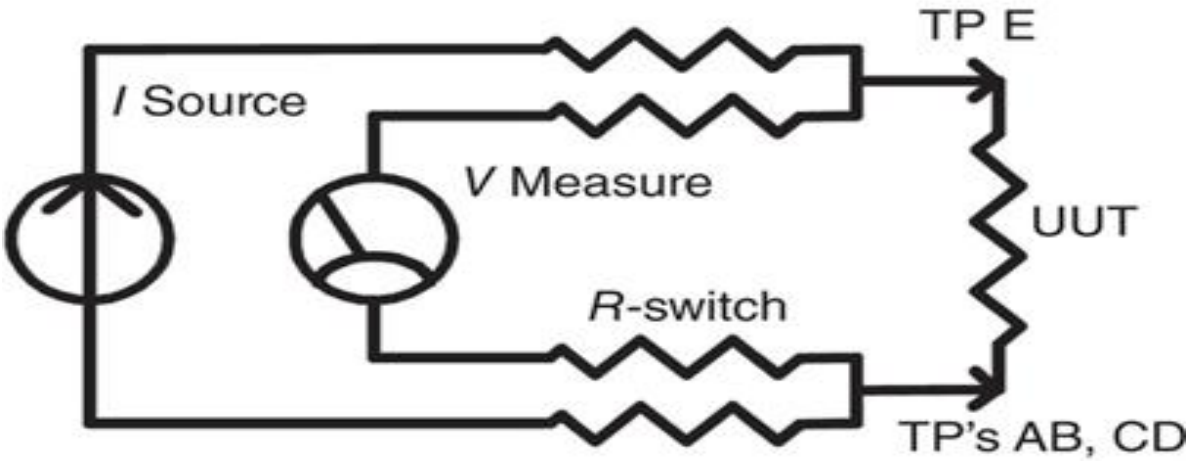
Figure 40.5 illustrates the status of the measurement system during the three tests. Notice that test points A and C are used to access their respective networks, and that test points B and D are not needed for the isolation test. These test point switches remain open through all measurements.



First test



Second test



Third test

FIGURE 40.5 Measurement sequence for three isolations.

A key feature of this method is the ability to answer the rigorous question: “How well isolated is this network from the rest of the board?” Consider the example illustrated in Fig. 40.6.

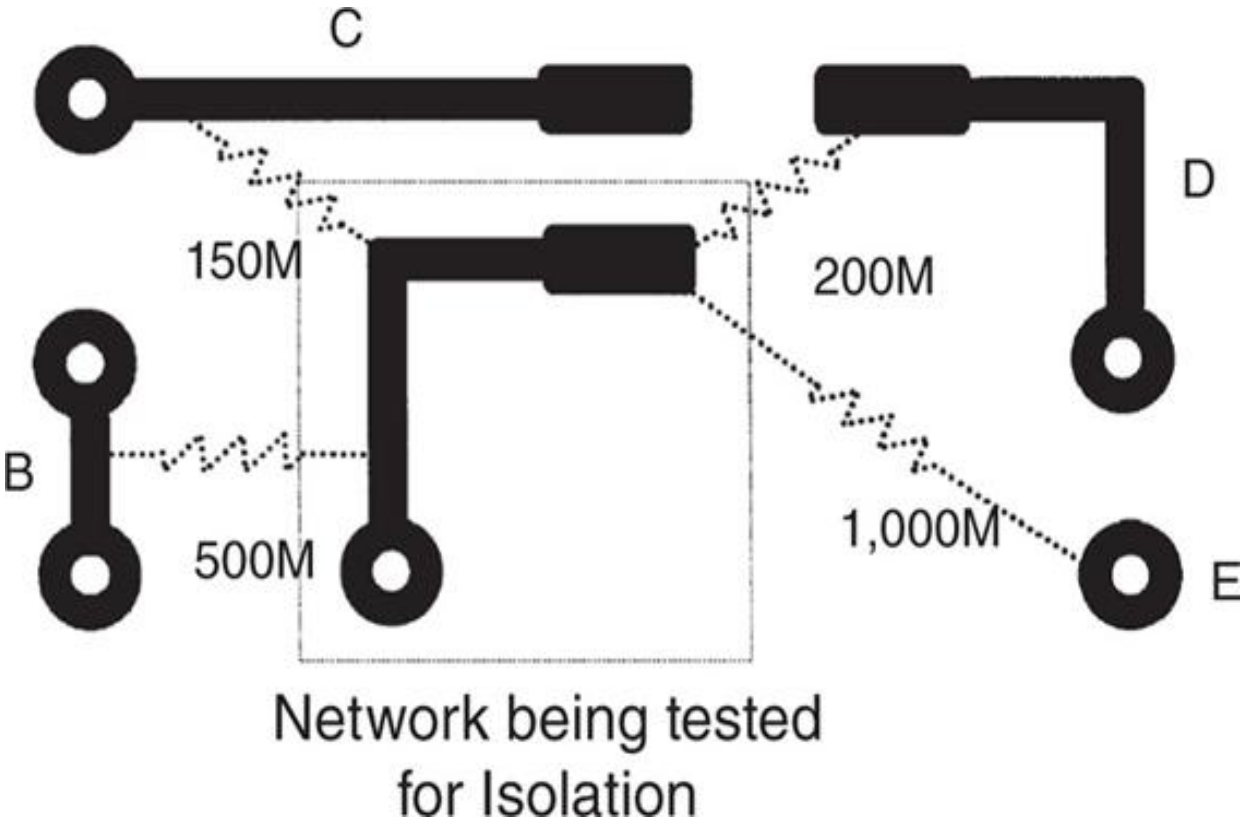


FIGURE 40.6 Parallel leakage detection.

Here the isolation threshold is 100 M. Four leakage paths exit network A, one each to networks B, C, D, and E. Each path, measured separately, is well above the 100-M. pass/fail threshold. But electrically we can only guarantee that network A is isolated by the parallel combination of these four resistances, given by:

$$RA = \frac{1}{(1/R_{AB})+(1/R_{AC})+(1/R_{AD})+(1/R_{AE})} = 68 \text{ Mohms}$$

Thus, the true isolation test method will correctly fail this measurement. A not unlikely real-world situation would be a smear of contamination that touched A, B, and C.

40.3.2.3 Log of (N) Isolation Test Method. Table 40.4 illustrates the log of *N* isolation test method, and compares it to the true isolation method described earlier. The log method offers the powerful advantage that only a small number of measurements are required to test a complex board. That number is given by log2(*N*) rounded up to the next whole number, where *N* is the number of networks.

TABLE 40.4 Isolation Methods Compared

	Network Name							
Measurement Number	A	B	C	D	E	F	G	H
Log method								
1	+	+	+	+	–	–	–	–
2	+	+	–	–	+	+	–	–
3	+	–	+	–	+	–	+	–
True method								
1	+	–	–	–	–	–	–	–
2	–	+	–	–	–	–	–	–
3	–	–	+	–	–	–	–	–
4	–	–	–	+	–	–	–	–
5	–	–	–	–	+	–	–	–
6	–	–	–	–	–	+	–	–
7	–	–	–	–	–	–	+	–
8	–	–	–	–	–	–	–	+

Thus, for a board with eight networks, we need only three measurements. The gain is even greater for large boards. For a realistic board with 4,000 networks, only 12 measurements would be needed.

This method involves a compromise of fault coverage for parallel leakage detection. Consider the example shown in Table 40.4. The top half of the table considers a very simple board with eight networks and illustrates the pattern of measurements required by the log method.

Networks noted with a + in a given measurement are connected to the upper side of the measurement system. Networks with a − are connected to the lower side. Notice that in each measurement, about half the networks are positive and half are negative.

A hard short between any two networks in Table 40.4 will be detected by either method. In at least one measurement, a + will be at one end of the short, and a – at the other. Both methods work well for hard shorts, and parallel resistance effects play no significant role. But consider the effect of two 15–M. leaks, one from network A to network B and the other from network A to network C. If the threshold is 10 M., this fault will not be detected by the log method, but the true method will fail test measurement #1. The log method is ineffective because there is no one measurement that has the + end of the measurement system on network A while the—end is connected to networks B and C simultaneously. (Were the A–B resistor moved to A–D, then we would detect an error on measurement #2 of the log method.)

The log method may fail to detect certain combinations of high parallel leakage. For product types where a low isolation resistance threshold is acceptable, this may not be a significant issue. Note that this risk may be reduced by substantially increasing the test threshold, such that a larger proportion of individual leaks are likely to trigger a fault report.

40.3.2.4 Isolation Failures: Distinguishing Shorts and Leaks.

Earlier discussion made a distinction between hard shorts and leakage failures, although both reports result from the isolation test. Consideration of either the true isolation test method or the log(*N*) method shows us that neither method immediately tells us the opposite end of the short or leak (refer again to Table 40.4). In the true isolation method, we know that the network under test is leaking or shorted to some other network, but we don't know which one. Initially the log(*N*) method tells us slightly less: We know only that the short is between that half of the networks switched positive and the half switched negative (or ground). Upon fault detection, either method must call a subroutine to search all network pairs systematically to localize the fault. Searching all networks in pairs for leakage can be slow as well as ambiguous. Therefore, some test systems allow the user to disable searching for leakage.

In the case of distributed leaks, a clear answer may be impractical because searching pairs of networks never connects all of the leakage paths in parallel. The effort to localize a high-resistance leakage may report the entire problem, part of the problem, or none of the problem. The exact result depends upon the actual leakage resistances present, the pattern of networks involved, and the isolation resistance threshold. Note that a flying probe system seeking to "verify" defects may be unable to detect some or all leakage for the same reason. It may be advisable to return such boards to a grid (or other fixtured tester) for final pass/fail.

40.4 SPECIALIZED ELECTRICAL TESTING METHODS

Certain special testing methods have evolved to provide for detection of defects more subtle than simple shorts, opens, or leaks. Additional methods have evolved as suitable to specific types of test equipment, notably the flying prober. These are discussed in the following text.

40.4.1 Hi-Pot Testing

Hi-pot or high-potential testing is very similar to isolation testing, but is commonly distinguished by the magnitude of the applied voltage and, to some extent, by the expected behavior of the detected failure. In the context of bare printed circuit boards, hi-pot testing usually refers to voltages over 250 volts, often 500 to 3,000 volts. The objective is to locate faults in the dielectric (insulating) layers of the board that may result in subsequent field failures at lower voltages.

When the dielectric is subjected to a voltage substantially in excess of the expected working voltage, certain types of material defects can result in an “avalanche” mode of failure of the insulation. Ionization of the intervening material or atmosphere occurs, resulting in a sudden increase in current flow to some relatively large value. Visible arcing and/or burning may result at the failure site. This contrasts somewhat with the isolation test, where a very subtle leakage current flow is usually detected using a somewhat lower voltage. Most often, the isolation test is less destructive as the total energy delivered is less. However, depending upon product conditions, arcing can occur at many voltages and in such cases an ordinary isolation test is essentially the same as a hi-pot test.

It is often impractical to perform hi-pot tests on finished products, except at limited numbers of test points. Equipment limitations are one factor, it being expensive to construct test equipment and fixtures capable of routing

such high-voltage signals to a large number of test points. However, the product itself is often a poor target for such tests when evaluated in finished form. Modern products are often constructed with relatively fine spaces between conductors.

On the surface layers of the board, the exposed component connection sites are usually too close together to withstand very high voltage stress without surface arcing. Such arcing is destructive to perfectly good product. The voltage at which such arcing will occur is a function of product geometry and atmospheric conditions.

In consideration of this, the most common practical application of hi-pot testing is to inspect raw material for defects before etching. For example, a thin FR-4 core, clad with copper on both sides, might be evaluated by placing a high voltage across the opposing sides. Any crack or other defect in the insulating material may ionize, resulting in a large current flow. Thus the defective material is rejected before substantial value is added in subsequent processing.

40.4.2 Embedded Component Tests

Methods of embedding certain electronic components *within* the board have been developed. The most common example is the embedded or “buried” resistor. Such resistors are constructed by embedding a layer of partially conductive material within the board. By selectively removing (or adding) material, the resistance value is adjusted. Accuracy ranging from a few percent to many tens of percentage points is realized. Typical resistance values range from a few ohms to thousands of ohms. The most common use of this technology is within high-speed digital circuit designs to replace large numbers of termination resistors with a resistance of 200 ohms and lower. Measuring these values accurately is challenging, requiring good fixture construction

and cleanliness. Another difficulty with testing of buried resistors is obtaining usable expected value data for the resistors. At the board shop, most resistors are specified as a shape and a type/thickness of resistance material rather than as a specific resistance value and tolerance.

It may be necessary to analyze the circuit pattern and compute the net resistance of series and parallel combinations, arriving at a measurable final resistance value for the tester.

Embedded capacitors may also be present. All boards exhibit capacitance between various traces, and especially between planes. The amount of capacitance is determined by the parallel surface area of the conductors, the thickness of the insulator between them, and the dielectric constant of the insulating material. Some product designs seek to maximize the desirable noise suppression benefits of capacitance between power and ground planes by making the intervening insulator thin. Some go further and use special insulating cores for these layers.

This is the common form of buried capacitance. Most bare board test systems are not well suited to measuring capacitance values, particularly small ones. In some cases, no measurement is specified and it is only important that the test system tolerate the presence of the capacitance. When measurements are specified, it is usually true that few test points are involved. It may be expedient to use benchtop equipment.

40.4.3 Time Domain Reflectometry

Time domain reflectometry (TDR) is a measurement method often used to verify the radio frequency (RF) impedance of a signal conductor on a circuit board. The RF impedance is important to the proper function of high-speed digital or RF applications. Examples include computer products, cellular

telephones, radios, etc. The RF impedance of a signal path should not be confused with the DC resistance, as verified during the continuity test. It is common for a trace with seriously errant RF impedance to demonstrate a very solid DC connection (i.e., low DC resistance). The RF impedance of the trace is most strongly affected by the trace's width, thickness, z-axis spacing from the ground plane, the location of adjacent traces, and the relative dielectric constant of the type of insulating core used to build the board. These parameters are usually rather constant within a particular panel, justifying use of coupons as a means of monitoring the delivered product. Standard bare board testing systems (other than flying probes) do not incorporate TDR capability, as the signal paths through the fixture will not pass the fast-risetime TDR signal. TDR is commonly conducted on a test bench manually.

TDR test systems inject a very fast-risetime voltage step into one end of the conductor. Discontinuities in the RF impedance level along the conductor result in reflected voltage waves being returned to the driving point, where they are collected by the same probe that injected the signal. The result is usually presented as a graph of RF impedance versus distance from the point of injection. Because of reflections and disturbance occurring at the point of injection, a minimum trace length is needed to get a meaningful measurement. Extremely short networks are not ideal candidates for TDR measurement. A trace 2 in. or more in length is generally required to obtain a useful reading. Longer traces may provide improved accuracy of the result. A branch-off to a second signal path along the measured length will disturb measurement badly; thus an undisturbed signal path provides the best measurement target.

A typical TDR result graph is illustrated in Fig. 40.7. This illustrates a region of approximately 50 ohms RF impedance, rising toward infinity as the trace ends in an open circuit at

the right, but falling between the upper and lower pass/fail bounds in the region of interest.

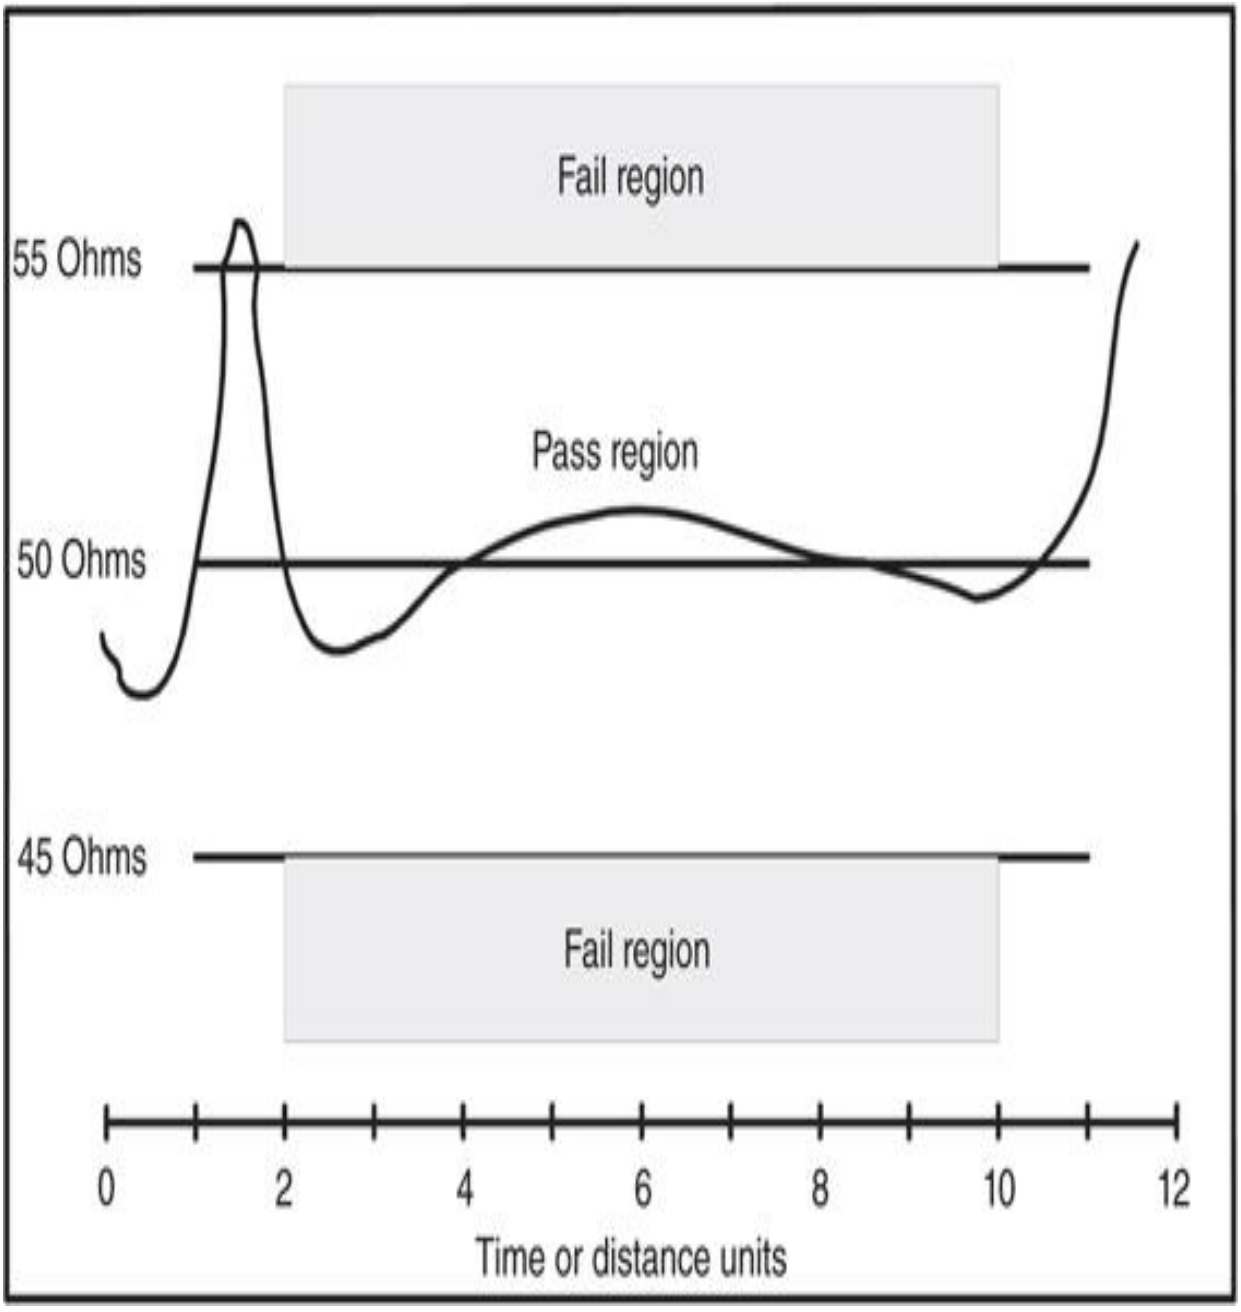

FIGURE 40.7 Typical TDR measurement.

Sample testing using handheld probes is popular and practical, but the influence of hand and body position on the measurement can be significant, reducing the repeatability

of the result. Several vendors offer flying probe solutions dedicated to TDR test. While requiring some additional setup they are faster at higher volumes and greatly improve repeatability.

40.4.4 Test Methods Unique to Flying Probe Systems

Because flying probe systems contact pairs (or other limited numbers) of points at any one time, they cannot directly perform precisely the same isolation measurements as can universal grid (and other fixtured) systems. DC isolation is performed between pairs of networks, with the number of measurements reduced by determining which networks are adjacent to the network being tested and therefore likely to cause isolation problems. Otherwise, flying probers are capable of ordinary DC continuity and isolation measurement, as discussed earlier. In addition, most flying probe vendors have developed alternative measurement methods that reduce the number of measurements and therefore reduce time lost to mechanical motion. These methods are discussed in the following text.

40.4.4.1 Indirect Measurement of Isolation or Continuity. Different vendors have developed various implementations of indirect measurement, but in general these methods share a general assumption that a given product network will display a certain amount of capacitive or other electromagnetic coupling to neighboring planes or traces. The amount of coupling is affected by the geometry of the traces involved. If a trace is broken, the remnant will display reduced coupling. Similarly, if a trace is shorted to another trace, the amount of coupling will increase substantially. If the test system measures the amount of coupling from each trace to a ground plane (or other

electrical environment), a degree of confidence can be obtained that all traces are intact. No direct measurement of isolation or continuity is necessarily made.

Instead, the coupling signature is used to imply the correctness of the configuration. As no direct measurement of isolation or continuity is made, we refer to these methods as indirect measurements.

Typically these methods are highly reliable in detecting hard shorts and opens, but may be less effective in detecting distributed contamination or high-resistance connections of several meg ohms or more. Specific methods include constant-current capacitance measurement (charging or discharging variations), voltage-source measurement of Resistance-Capacitance (RC) time constant, alternating current (AC) capacitance measurement, and measurement of the electromagnetic coupling of an AC signal between adjacent networks.

The capacitive techniques using constant currents are generally based upon the approximation:

$$C = i\frac{dt}{dv} \quad \text{or,} \; C = i\frac{\Delta t}{\Delta v}$$

where C is the network capacitance, i is the charge or discharge current, and v is the change in voltage that occurs during the measurement time t. Related, though more complex, behaviors occur for RC time constant and AC coupling measurements.

Using the preceding example, note that if two networks are shorted, the resulting capacitance is the sum of their individual capacitances. The larger capacitance causes a slower charge rate than is expected for either net individually. The system may note that these two networks are adjacent and displaying suspiciously similar charge time behavior. The system tags the networks as suspicious, and either fails them or verifies the presence of a short with a DC

measurement. Networks containing an open will have reduced capacitance and will charge or discharge too quickly. These conditions are illustrated in Fig. 40.8.

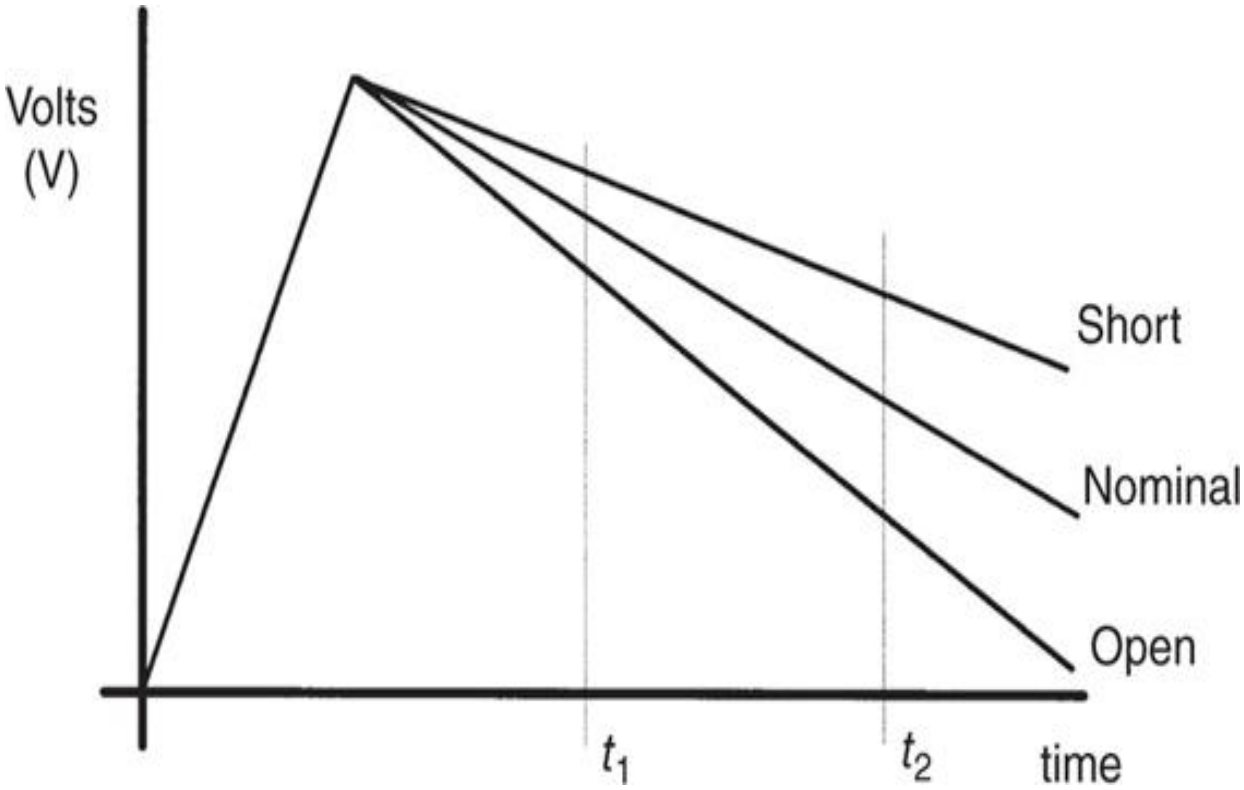

FIGURE 40.8 Indirect measurement: constant-current discharge.

To use these indirect methods, most systems require testing of a first article board using standard direct measurement methods for both continuity and isolation. Once the board is known to be good, the signal-coupling behavior is learned for each network on this board. The learned values are saved and compared to measured results from subsequent boards as described previously. Tremendous speed increases are obtained by eliminating repetitive probing of each network at multiple locations, particularly in the case of isolation testing. Some users combine a traditional DC continuity measurement with the indirect method as a substitute for isolation.

40.4.4.2 Adjacency Analysis: Isolation Testing on Flying Probe Systems. Adjacency analysis simplifies isolation testing on flying probers by reducing the number of measurements, even for direct measurement methods. In adjacency analysis, a database is prepared listing each network and all traces found to be immediately adjacent to that network according to a set of geometric criteria. Such locations are assumed to represent the sole opportunities for shorts and leaks. Isolation testing is then performed only between adjacent pairs, this measurement being well suited to the nature of the flying prober. It is important that attention be paid to whether such analysis is three-dimensional. Networks may cross over a network horizontally, but on a different layer of the board. A hole or defect in the intervening insulating layer may allow a short or leakage to occur.

In the example illustrated in Fig. 40.9, network A would probably be judged adjacent to B, but not to C. B would be considered adjacent to A and D. Assuming that the qualifying dimension was a bit smaller than the distance from E to either B or D, E might not be judged adjacent to either.

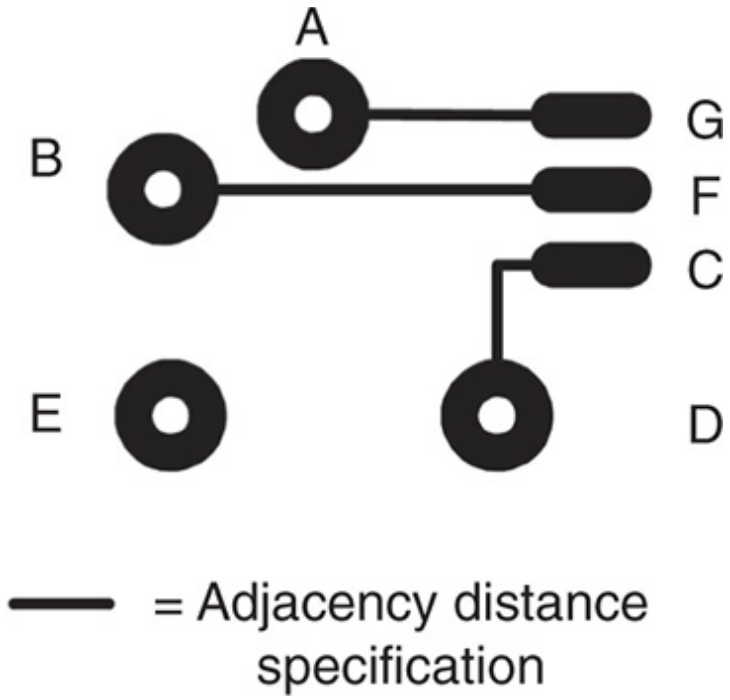

FIGURE 40.9 Network adjacency.

40.5 DATA AND FIXTURE PREPARATION

An essential element in any test operation is the means of generating test programs, and, in the case of fixtured tests, the design of an appropriate test fixture. There are several methods for deriving this program and fixture information.

These methods vary from simple to complex and from escape-prone to very sound. The most common terms used in the language of bare board testing for the test program development are self-learning and netlist testing. *Netlist testing* is a misnomer that confuses computer-aided design (CAD) output with test inputs and implies that there is not much in between. In this discussion, we will use the term *data-driven test program* to indicate the program to be loaded into the test system is derived from the board's design data (which may be provided in any of several

different forms). On the other hand, a self-learned program is derived by placing an assumed good board on the test system and causing the test system's internal computer to create a program automatically that can be used to compare other boards to the detected pattern. It is worth noting that the description "known good" is often used to describe this first board, when in fact our knowledge of its quality is often imperfect.

Flying probe test systems generally require no fixturing, except sometimes a frame to hold thin boards or to load multiple small boards simultaneously. Flying probers still require test program generation and optimization. Instead of a fixture, the product program contains probe position information for planned test. Data preparation processes are therefore similar to those of fixtured tests, but only test program data are output.

Note that the extractions of program and fixture information are quite naturally linked. In fact, the final test program cannot be created until the fixture is defined. The fixture determines how the individual test points of the test system are connected to specific product locations.

Knowledge of how the fixture has taken hold of the product is essential to determining which system test points to employ in performing specific measurements. Thus, the same software system generally outputs both the final test program and the fixture drilling/loading information.

40.5.1 Self-Learning

Self-learning has increasingly limited application and is subject to certain escape risks derived from assuming that the original circuit board is good. The self-learning method requires that a fixture be already available, as well as a known good board (preferably). A shorting plate is placed on the fixture in place of the product, and the test system uses

this to identify which test points are employed in the test fixture. (All test points found shorted to the plate are considered active. This eliminates test points of no interest, shortening the test program and saving considerable execution time during both learning and testing operations. This set of active points is sometimes referred to as a mask.) The known good board is then substituted for the shorting plate, and the pattern of product interconnections is learned and saved as a test program.

A few boards are tested, and, if results appear reasonable, the program is considered valid. The key drawback of the method is that self-learned test programs determine that all the boards are the same, not that they are good. Moreover, for economic fabrication of the test fixture, it is necessary to process product data anyway; thus we may as well have output a data-driven test program. With virtually 100 percent of board designs being CAD-driven, there is little motivation to use self-learning today.

40.5.2 Data-Driven Testing

The preferred method of deriving program and/or fixture data is data-driven programming (DDP), sometimes referred to as netlist testing. The basic idea of data-driven test programming is to test the board using the same database used to specify its manufacture—in other words, the original design database. The fixture and DDP development process can be divided into two stages:

- Input/extraction, the preparation and processing of the various possible input sources into a format usable by the second stage
- Fixture data, test program, and repair file output, and subsequent application of the data.

Factors such as data quality and completeness, the format of data available, and fixture design can significantly reduce or extend software processing and engineering time. Board technology, size, and complexity tend to increase time requirements. While software tools are not always the most immediately visible tools in the testing department, the completeness and automation of software tools can have a large impact upon whether you are able to set up and test boards quickly and efficiently rather than struggling to build fixtures quickly—while testing very few boards.

Ideal fixture software readily accepts the product data, analyzes the data, recommends an optimal fixture design including all fabrication details, and outputs computerized numerical control (CNC) files for fixture fabrication, material requirements, special procedures required, and a test program in the proper format for the selected test system(s).

40.5.2.1 Selecting Fixture Software. A complication arises due to the mechanical incompatibility of many types of test systems. If the available equipment includes something of a grab bag of different equipment types, the test manager's task is made considerably more difficult in several ways. Aside from the obvious problems of manufacturing different fixture types, the manager is also faced with difficult load-leveling tasks. In such circumstances, the test manager may be forced to select general-purpose fixture software packages. By virtue of offering many configuration options, these require additional operator training and present increased opportunity for error. If the testing equipment uses a shared fixture type, it becomes possible to standardize the software process (and raw material). Optimized configurations may be locked into the software, minimizing error opportunities.

40.5.2.2 Test Data Extraction Methods for Fixtures and Programs. The initial stages of processing include the

acceptance and inspection of the input data to ensure that they have been presented in a valid format. These data are then scanned to determine which sites on the board deserve test points, and what measurements are required among these test points in order to ensure proper continuity and isolation of the product. There are a variety of input sources, summarized in subsequent sections.

A usual goal of the extraction process is to eliminate unnecessary test points. According to predefined rules, the software identifies those end points of each network segment where test pins can and should be placed. For example, a T-shaped network probably requires three test points, located at the extreme extensions of each arm of the T. This provides sufficient connectivity to the product to permit a complete continuity test. One point per network is the minimum needed to attempt isolation testing, and two points per network make the isolation test more robust by permitting the tester to ensure that these points are in proper contact with the product.

The following is a generic description of the software process, where CAD or photoplot information is available.

- *Data orientation* The toughest side of the board in terms of test centers is usually oriented face down. It is often easier to manage a heavier, more complex fixture on the bottom side of the test system. This may require flipping or inverting the data.
- *Test site identification and optimization* Depending upon customer preference, it is often true that some test points can be deleted from the program. Figure 40.10 shows a network with a midpoint B that does not need to have a test point on it. The test points at A and C are all that are necessary to determine whether this network is isolated and contains no opens. Test point optimization can reduce the number of points in a fixture by 10 to 50 percent,

thereby reducing the cost of the fixture and the time needed to test the board.

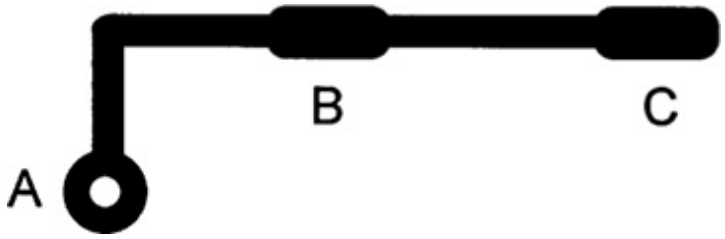

FIGURE 40.10 Optimizing a network.

Although optimization provides some economic and minor throughput benefits, this must be offset by any impact upon the repair process and by any fault coverage risk. Midpoints can provide failure data that help the repair station more easily pinpoint the actual fault site. Where an operator is required, or when flaws appear in the algorithm, the deletion of test points can add to the risk of test escape. Optimization is sometimes not performed, speeding data preparation and reducing escape risk but adding cost to the fixture.

- *Pin type assignment* Once the test sites have been identified, test pins can be assigned to the features to be tested. Different pin types may be required for different features. For example, a through hole might require a large head or larger-diameter pin than a surface-mount technology (SMT) pad on 0.025 in. centers. The software usually includes a table relating feature types to pin types.
- *Test system type identification* Mechanical details of the fixture must suit the target test system. The fixture in a universal grid system requires assignment to a grid of uniform centers. A more detailed description of fixture and system types is included elsewhere in this chapter, but obviously the fixture must be built in the correct size and grid density to match the specific test system to be employed. Figure 40.11 shows three of the most common grid configurations available. Single density (100 points

per sq. in., or a 0.100 in. grid) is the most common, with double-density systems being added as product technology demands.

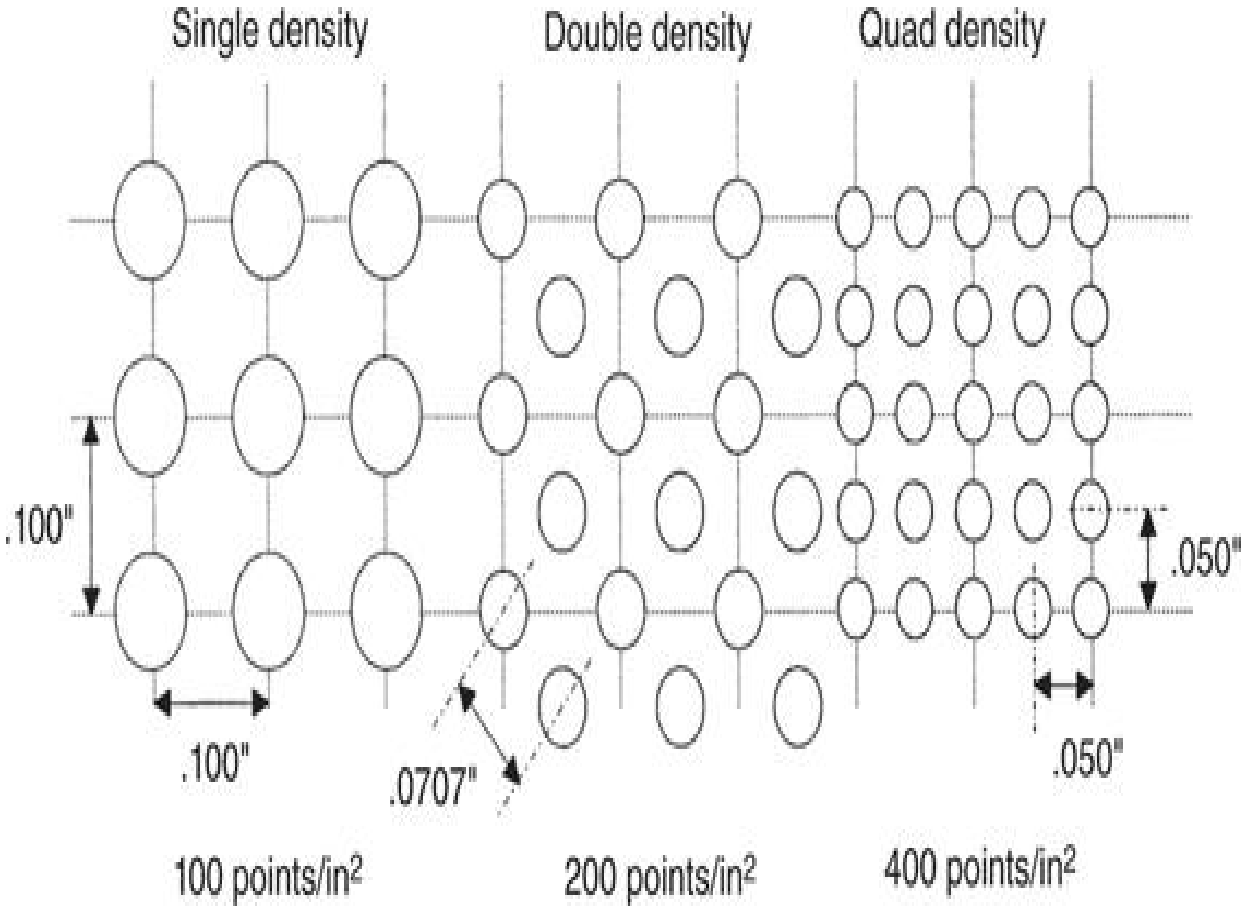

FIGURE 40.11 Single-, double-, and quad-density universal grid patterns.

Of course, a few systems still use wired fixtures, and here the output will be a set of drill files, a wire list, and the test program. The balance of this discussion focuses on tilt pin translator–equipped grid systems:

- *Grid pin mapping* The fixture software determines which system grid location will be mapped to each of the previously determined on-product test targets. Several factors are considered:

- No two targets can be assigned to the same grid location.
- No assignments can allow the pins to touch each other as they tilt through the fixture (cross pins).
- Drilled holes in fixture plates cannot break out into adjacent holes (adequate spacing on all plates).
- No assignment can require a pin to tilt beyond the predetermined deflection limit (determined by the fixture and pin design).
- Test sites that are very close together may require that on-product targets be staggered such that the test pins are more widely separated. (See Fig. 40.12.)

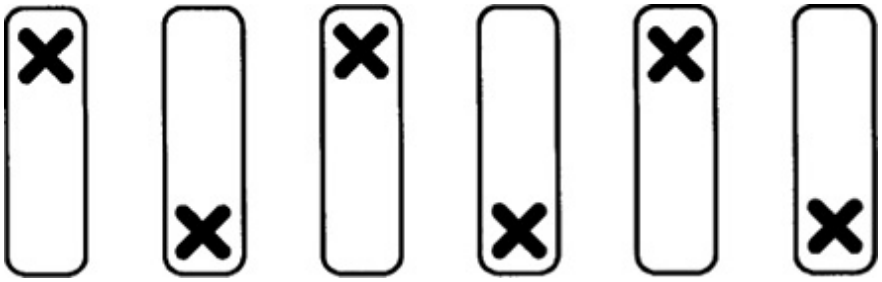

FIGURE 40.12 Test point staggering.

- Hole diameter and placement relative to the pin diameter and pin deflection must be optimized. A nearly vertical pin might be assigned a hole diameter just slightly greater than its shaft diameter. This clearance balances avoidance of friction against pointing accuracy during testing. Other pins of the same diameter that are highly tilted will require a slightly larger hole to avoid binding. The fixture adjusts drill sizes for each hole, depending on the amount the pin is deflected. This maintains pointing accuracy while eliminating pin binding. Hole locations may also be shifted slightly to compensate for the fact that the pin is pointed at an angle and that the point of contact will not be at the

center of the hole. The result is a more reliable test fixture.

- *Test program output* With all pins fully mapped to grid locations, the test program file can now be constructed and saved.
- *Tooling* The last step in data preparation requires the marrying of the job being processed with the tooling. The tooling includes tooling to the test system and tooling for the specific fixture design utilized.
- *Fixture file outputs* The completed CNC files for fixture drilling and fabrication can now be created and the test fixture prepared.

40.5.3 Data Formats

Modern circuit boards are designed using CAD systems. These systems output data files used by the board shop to generate phototools, drill files, routing patterns, and other tools used to fabricate the boards. While several standards have been developed for data outputs from this process that can provide useful data input to the final test process, adoption has not been universal. As a result, test engineers and software providers have developed means of hijacking and converting the photoplot data stream, and can use this to drive the test process with certain compromises and a degree of inconvenience. Both approaches are discussed in the following text.

40.5.3.1 Gerber Format Data Extraction. The primary example of “hijacked” photoplot data arrives in Gerber photoplotter format. Even here a standard was eventually developed. RS-274X is a standard that affords a degree of consistency to the photoplotter files. This data stream is a series of drawing commands that direct the photoplotter in drawing the copper patterns for each layer of the board. The

drawing is made with a selection of “apertures” that define different pen tip shapes and dimensions. Thus a fine line is drawn by choosing a small aperture, issuing a light-on command, and directing a move. These data are contained in a very large set of files, containing a picture of each layer of the board. Combined with a drill file and aperture definitions, the appropriate information for generation of fixture and test program files is present, but a considerable amount of processing is necessary to develop understanding of layer-to-layer connectivity and finally identify test targets.

Although the standardization of Gerber data has been improved with efforts such as RS-274X, it remains a data format originally optimized for the purpose of photoplotting and not for testing. CAD system developers and board designers have a great degree of freedom in how they design board features and in how these features are represented in Gerber. As a child will readily demonstrate, many different sequences can be used to draw even simple shapes. A rectangle might be created by “flashing” a square pattern, or might be created by an elaborate spiral using a much finer aperture, a zigzag pattern, or a sequence of overlapping flashes. This variety leads to occasional errors, because it is difficult for any Gerber extraction routine to be capable of handling all possible permutations. The software system must successfully interpret any of these examples (and many others) as defining the same intact square area of copper conductor pattern on the final product. Some methods result in huge file sizes.

Despite these problems, this method is far superior to self-learning, digitizing, or drill file extraction, and remains in common use in a variety of software packages. The data requirements to start from this format include:

- Photoplot files for each layer, solder mask layers, etc.
- Photoplot files for silk screen legend(s) (required for computer-aided repair)

- Aperture file
- Drill file
- Board outline

40.5.3.2 CAD/CAM Data Extraction Method.

Recognizing the problems inherent in photoplot extraction, system vendors have agreed to add support for test-oriented output formats, in particular IPC-D-356 and 356A. These formats provide data in a much more readily digested format, and eliminate most ambiguities in processing the data. These formats include the following data:

- Signal ID, network name, and/or network number
- Reference designator or PIN number (e.g., U14, 12, R11) for the related component on board
- X-y coordinate of pad center (minimum data set requirement if grouped as connected)
- Pad dimensions relative to the center, and size of the hole (if any)
- Resistor or other component values (if appropriate and not usual)
- Board side (top or bottom)
- Mid-network flag suggesting that test point placement may not be required.

Often this data set is converted to a standard such as IPC-D-356 from the CAD/CAM system's internal data formats by means of an intermediate converter. These software converters, although simple, are usually customized for each individual CAD system. A converter must be updated or modified with any output changes made by a CAD vendor due to a CAD system software update or new product introduction. The number of converters required by an independent PWB manufacturer could be quite high, as data

will likely be received from many different CAD system types. Fortunately, many of the CAD vendors now include direct output of IPC-D-356 data or readily provide converters. Acceptance of these standards is now such that in many cases even Gerber input data are first converted into IPC-D356 format prior to final processing.

40.5.4 Outputs from Data Extraction

Once all the preparation steps and processes have been performed, there are several outputs generated by the fixture software.

- *Test file* A data-driven test program is outputted in a format compatible with the test system type. This file informs the test system of the measurements expected and of pass/fail criteria. Some test system formats permit the data-driven test program to support a graphical representation of the fixture and/or board on the test system monitor, provided that sufficient data are included in the test program file. This graphical presentation is useful in fixture and/or program debugging.
- *Fixture fabrication files* Probably the most significant output—the drill files, one for each plate or pass required by the fixture design—is needed in drilling to start building the fixture. (In the case of wired fixtures, a wiring list is also required.)
- *Repair/verification files* Files can also be outputted that support the repair or verification function. These relate the graphical image of the board to the assigned test point locations in the program. Preparation often relies on inclusion of Gerber data in the input data stream to the software system. Extensions to IPC data formats are planned to better support the repair function without this recourse to photoplot data. Some test systems may carry

trace image information in the test program file as well, for enhanced debugging support on the test system.

40.5.5 Setting Up a Fixture

With the fixture assembled and CAD data–derived program prepared, the next step is to set up the fixture on the test system and validate the fixture and program. Details vary with the fixture and system used, but in general the following steps are taken:

- Program data are loaded into the test machine from the disk or network.
- Test thresholds are set to the desired continuity and isolation values.
- Compression settings on the test system are adjusted to the proper values for the fixture type. In some cases, these values may already be included in the test program file.
- The new (or recalled to duty) fixture is compressed with a nonconductive material of similar thickness to the board being tested.
- An all-isolations version of the test program is executed to verify that the fixture does not contain any internal shorts.
- The fixture is then compressed again with a conductive plate in place of the product, intentionally shorting all fixture test points together. Often this plate is a simple piece of copper-clad G-10. Copper oxidation can prevent reliable contact, and users sometimes wrap the plate in fresh aluminum foil or use a flash-gold-covered plate. In this step, an all-shorts version of the test program verifies that all expected test points are continuous through the fixture, up to the shorting plate. The intent is to verify that the number of test points is correct and that, under multiple compressions or closures, all points are present and remain in contact with the shorting plate.

- Assuming proper alignment and cleanliness, the product can then be tested with the final test program. If certain errors immediately repeat on all boards, then it is reasonable to suspect a pin-loading error or other error in the fixture, and investigation is warranted.

The basic techniques just described are generally applicable to all fixture types, whether tilt pin, wired-dedicated, or other specialized types.

Do not underestimate the value of removing dust and debris from the product and fixture, both during setup and occasionally during operation. Target sizes on modern products are not tolerant of debris, and false open circuit reports are an immediate result. Tacky roller-type cleaning systems may be helpful in periodically removing debris from test fixtures, system grids, and the products themselves. Follow the test equipment manufacturer’s recommendation regarding the use of electrostatic discharge (ESD)-safe cleaning materials near the test system.

Adjustment of fixture compression is also important, especially on press-type systems where the amount of compression stroke is controllable. (In vacuum fixtures, the dimensions of various fixture plates and components usually fix the amount of compression.) Undercompression usually leads to poor contact and false open results. Overcompression can cause excessive marking of the product by probe tips, probe damage, and fixture damage.

Overcompression is a very common problem, and, unfortunately, so is product damage in the form of excess probe marking. It seems intuitive to just press harder when you experience contact problems, and this is often the first step taken. But the actual change in force per spring probe is very small as it travels further, until the spring probe hits bottom—and at that point you begin damaging the product almost immediately. A typical spring probe in a grid system presents about 139 g of force when compressed 0.167 in.

(two-thirds of travel). At zero travel (uncompressed), the spring inside is already preloaded to about 55 g. The force increases at a spring rate of 503 g/in. Just before bottoming, the spring force peaks at about 180 g. Thus, there is only modest force gain possible before serious danger of bottoming the probe occurs. Consult the spring probe manufacturer for details, but most probes function well at about two-thirds of full travel. If contact problems remain at this level of compression, leave further compression adjustment as a last resort and look elsewhere. Generally, you should never cause the probes to hit bottom. (Some older vacuum fixture probes are a notable exception.)

40.6 COMBINED TESTING METHODS

As product density and geometry become more challenging, the cost of fixture construction increases. In a large number of cases, the most challenging test sites occur at only a few areas of the product. It is possible to combine test techniques such that less expensive means are used to test the majority of product features, while more advanced and costly techniques are reserved for the most challenging test sites. Some examples follow.

40.6.1 Split Net Testing

This is perhaps the oldest and most primitive example of a sequential or combinational test. When the product complexity exceeds the capacity of a fixture design to solve the test requirement with a single fixture, it is possible to divide the test responsibility among multiple fixtures. The flip test method of dual-side access described earlier is one example of this. More typically, the test department has

dual-side-access equipment, but the density of test sites exceeds the capability of the fixture and/or test system.

One way to split the responsibilities is to divide continuity and isolation between fixtures. For example, one fixture could be limited to two test points per network. These two would be checked for continuity with each other (to verify that there are no open pins in the fixture) and would then be used to perform a 100 percent isolation test of the product. A second fixture would complete the continuity test. In very difficult cases, multiple fixtures can be used.

Handling boards in this scenario is complicated. Boards that pass the first fixture must be stacked and prepared to run on the second fixture. But boards that fail the first fixture must be tagged with failures, and in many cases must be run through the repair process, retested, and combined with the boards being sent to fixture 2. Such failed boards must not be confused with any failed boards from fixture 2, which have already completed the first phase of testing.

Unless there is a large continuous flow of boards with two different test systems/fixtures set up, it is also likely that the two fixtures will have to be installed/removed from the test system a number of times.

40.6.2 Manual Combination of Methods

It is also possible to divide the test burden by testing the majority of ordinary test sites with a test fixture, followed by a flying probe system to test strictly limited portions of the product. Without special software, one has the same handling problems as in the split net case. But it is possible to automate the data handling between the two test systems using network resources, such that a single error tag results from both tests. All boards then flow through both test systems, and any rejects flow to repair. This flow is very

similar to that of ordinary testing, resulting in less confusion. An interesting additional benefit of this combination is that the flying prober not only can test those sites that you wish to avoid fixturing, but can also retest any of the failures noted by the universal grid. This can eliminate the majority of false open reports caused by stuck pins and contamination, improving the total first-pass yield.

CHAPTER 41
BARE BOARD TEST EQUIPMENT

David J. Wilkie
Everett Charles Technologies, Pomona, California

41.1 INTRODUCTION

The largest volumes of bare boards are tested on fixtured systems. However, for smaller volumes or special purposes, “flying probe” systems may be preferable. This chapter discusses them both to enable the user to make the most effective decision based on testing objectives and volumes.

41.2 SYSTEM ALTERNATIVES

41.2.1 Fixtured Systems

Each dedicated, or hard-wired, test system presents some sort of standardized interface pattern of test points. This may consist of a universal grid’s continuous array of points (bed of nails) or may be a connector pattern of some type. In the most primitive systems, a simple cable connector may be

presented. Each of these types of equipment uses one or more types of customized test fixtures to connect this standard electrical interface pattern to the unique contact pattern of a particular product to be tested.

Each fixtured system includes a measurement unit that can be connected to any of some thousands of test points by a solid-state switching matrix. A central computer controls the measurement unit and switching matrix. This computer also controls the press (or vacuum mechanism), which can compress the product against spring-loaded test points presented to the product by a customized test fixture.

To imagine the system's operation, first consider the measurement unit to be an ohmmeter. The computer commands the switch matrix to connect the red lead of the meter to, say, test point 17. It then connects the black lead of the meter to test point 1027. The measurement system can then be commanded to measure the resistance of the product under test between test points 17 and 1027. The test program dictates a long series of such measurements organized to test the product completely. Because the switching and measuring occur at the high speeds possible with modern electronics, a complex board can be tested in seconds.

41.2.2 Dedicated (Hard-Wired) Fixture Systems

Originally the most popular system type, dedicated systems are generally being displaced by systems employing less expensive and more accurate fixturing methods. The word "dedicated" refers to the fact that it is generally impossible to salvage very much material from these fixtures for reuse in other fixtures. The cost of these fixtures derives from this fact, and from the high labor and material costs involved in the original construction.

41.2.2.1 Advantages of Dedicated Fixture Systems.

A primary advantage of these systems is that, because each test point is routed within the fixture by a flexible wire, it is possible to position any test point at just about any location. If your product requires 8,000 active test points, then you need no more points than this in the test system. One hundred percent utilization of available test points is possible. This contrasts with the universal grid approach discussed later, wherein points can be shifted only a small distance from the original location on the grid. In that case, you must have enough electronic test points to cover the entire surface of the product at some constant density, and any given fixture will generally use only a portion of these points. Thus, the capital equipment cost of a dedicated system may be lower, but the ongoing fixture costs may be much higher. Dedicated systems are generally built with no more than about 10,000 test points, with smaller numbers common.

41.2.2.2 Construction of Dedicated Fixtures.

The test fixture for such systems generally consists of a rigid box structure with one side facing the product to be tested and some other side or surface presented to the interface pattern of the test system. The side facing the product includes the probe plate. This plate of insulating material is drilled to mount an array of spring-loaded pins able to make electrical contact with the product. The reverse side of these pins is connected within the box by physical wires to the system interface connector on the opposite side of the fixture.

Fabrication of the fixture involves the usual data-processing steps, followed by spring probe type selection, drilling of the probe plate, installation of spring probes, drilling of the interface plate, and installation of system mating contacts or connectors. Many spring probe tip styles are available to suit different diameters of target pads and holes (see Fig. 41.1). In most cases, the probe plate actually

carries a socket or receptacle into which a replaceable spring probe is inserted, simplifying service. The underside of the receptacle protrudes into the fixture box and carries a wire-wrap tail. Each of these receptacle tails must be wired to an individual system interface contact on the bottom of the fixture.

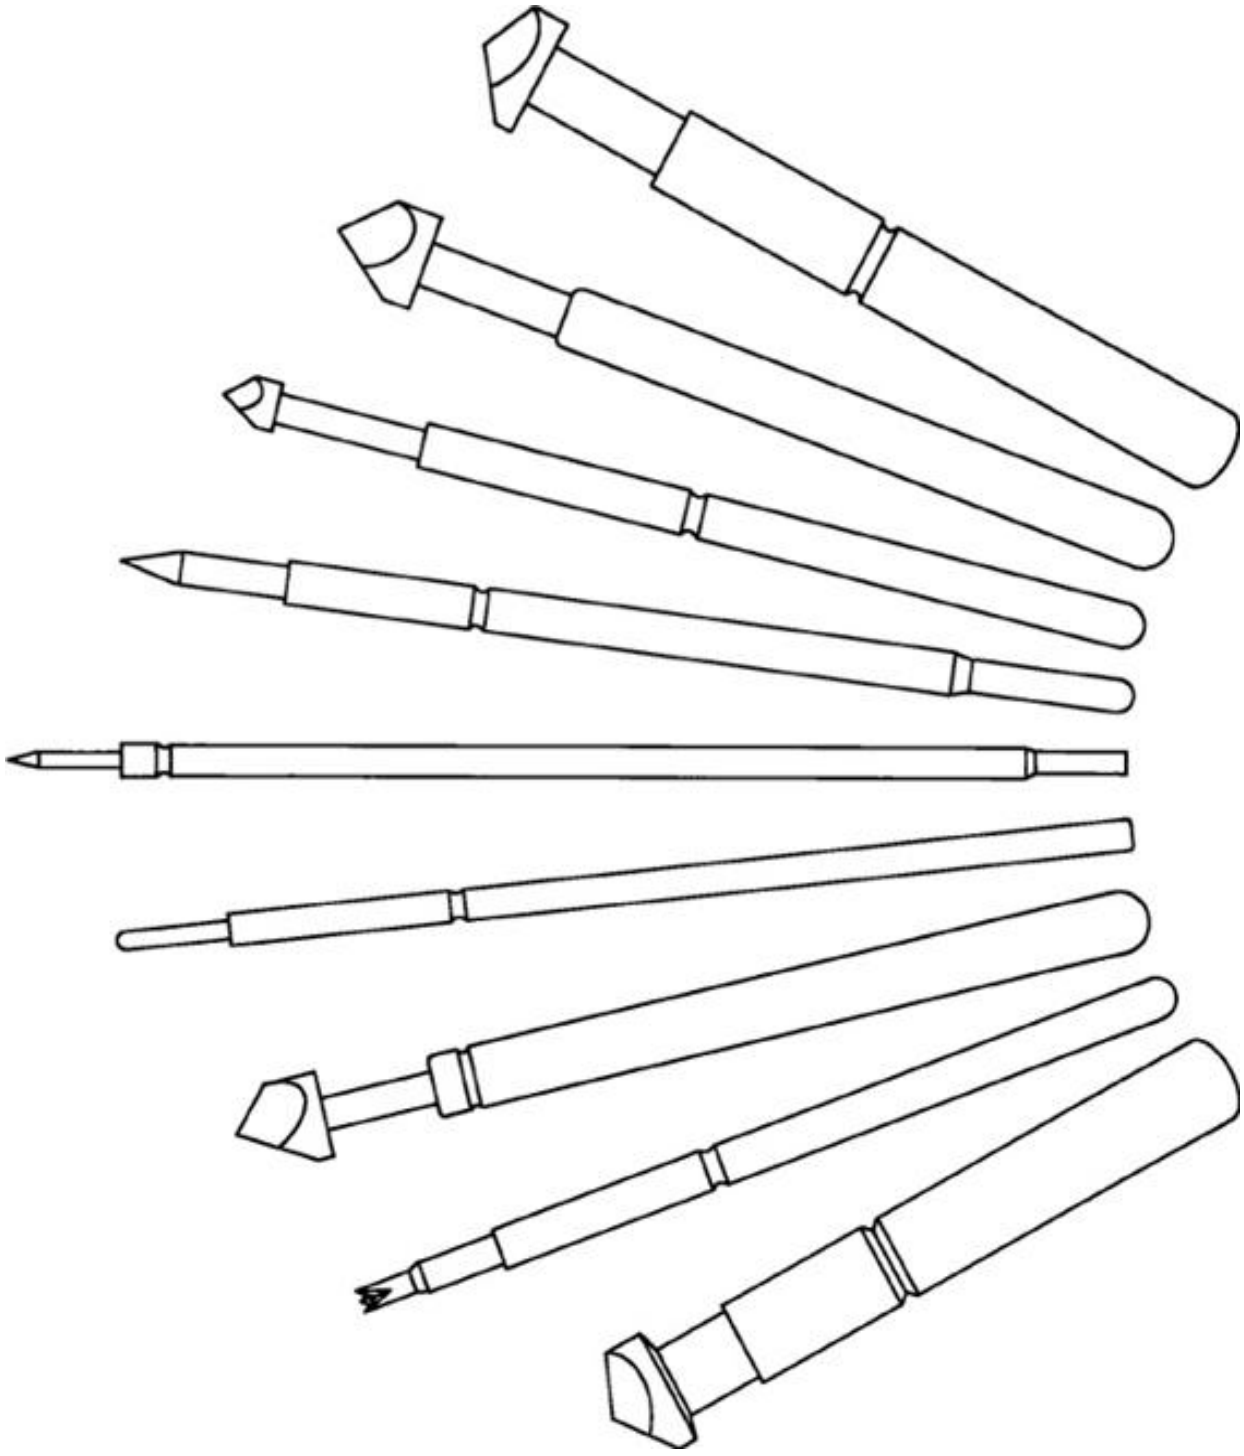

FIGURE 41.1 A variety of spring probes and receptacles. (*Courtesy of Everett Charles Technologies*.)

Compression of the product onto the fixture spring probes may be accomplished with electric drives, pneumatic air

cylinders, or vacuum (see Fig. 41.2). Vacuum compression can result in the lowest system cost, but adds cost to the fixture and limits the total number of probes that can be compressed.

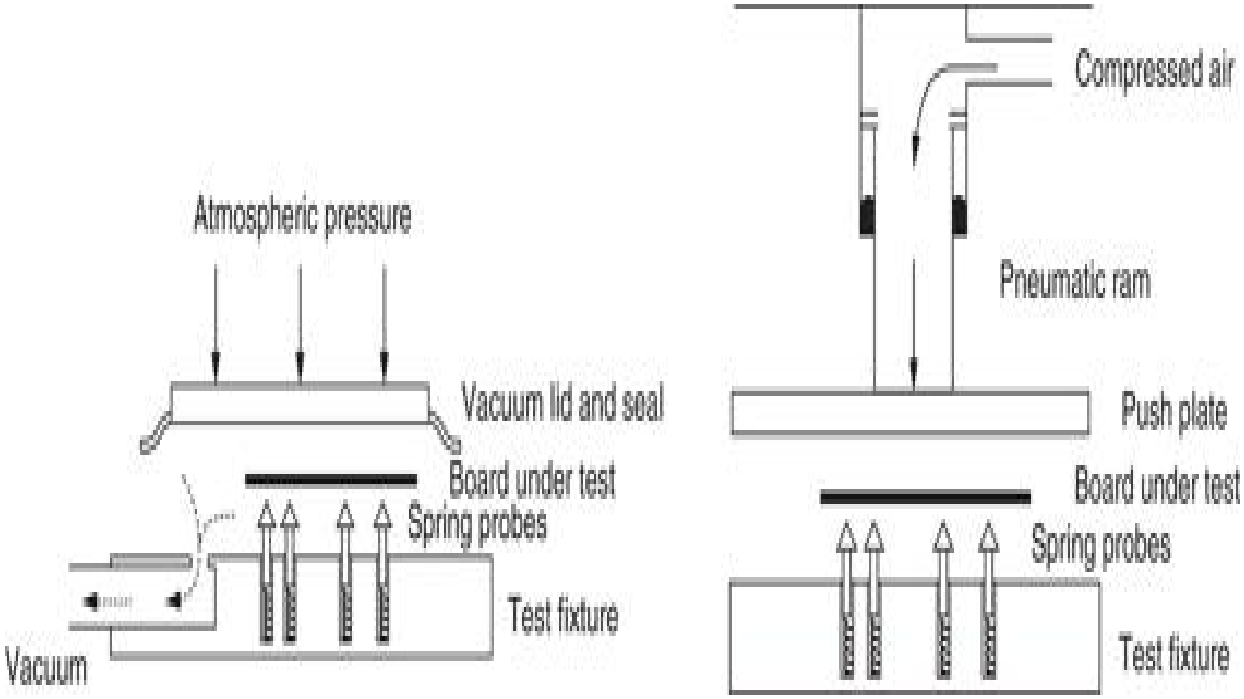

FIGURE 41.2 Vacuum versus pneumatic compression.

Many forms of fixture interfaces have been provided, with many appearing as small universal grid patterns. Some very simple test systems have been constructed with a large number of ribbon (or other) cable connectors presented as the only connection to the fixture. The matching wired fixture may be troublesome to connect (because of the large number of cables), but is left connected for days or weeks at a time to a single fixture type due to the quantities of boards being tested.

41.2.3 Flying Probe–Type Test Systems

Smaller volumes and specialty parts are tested on flying probe–type test systems. These consist of a small number of robotic probes with independent measurement abilities. These are moved among the various product test target locations, and a sequence of measurements is made. Such systems offer the powerful advantage that no fixture preparation is required (although data must still be processed to prepare the test program). The best of these systems are also able to provide extremely high probe placement accuracy, generally exceeding that of fixtured systems. The primary drawback of such systems is low throughput, as a result of the need to reposition the probes mechanically between measurements.

41.3 UNIVERSAL GRID SYSTEMS

The most flexible and widely used electrical test solution is the universal grid test system (see Fig. 41.3). Most systems now include upper and lower grids, permitting simultaneous dual-side access for test of surface-mount technology (SMT)–type products. Grids offer very high test speeds, and moderate the cost of test fixtures by permitting the reuse of many fixture components. Thus, today, the majority of product is tested on universal grid systems and fixtures.

FIGURE 41.3 Universal grid test system. (*Courtesy of Everett Charles Technologies*.)

41.3.1 Universal Grid Test System Design

The universal grid test system presents a rectangular array of equally spaced test points. Generally this is chosen to be large enough to cover the test area of the largest product type to be tested (see Fig. 41.4). It is common to speak of

the density of test points presented. A single-density system presents points spaced at 0.100 in. (10 per in.). Thus, there are 100 points per sq. in. Similarly, a double-density system has test points spaced at 0.0707 in. and provides 200 points per sq. in., and quad-density spacing is 0.050 in. for a density of 400 points per sq. in. As grid cost is largely a function of the number of test points, larger sizes and/or higher-density configurations become expensive. With modern grid designs, the test system grid size can be upgraded in the field by addition of electronic modules. With older designs that use wire between the grid and the electronics, upgrades may be less practical.

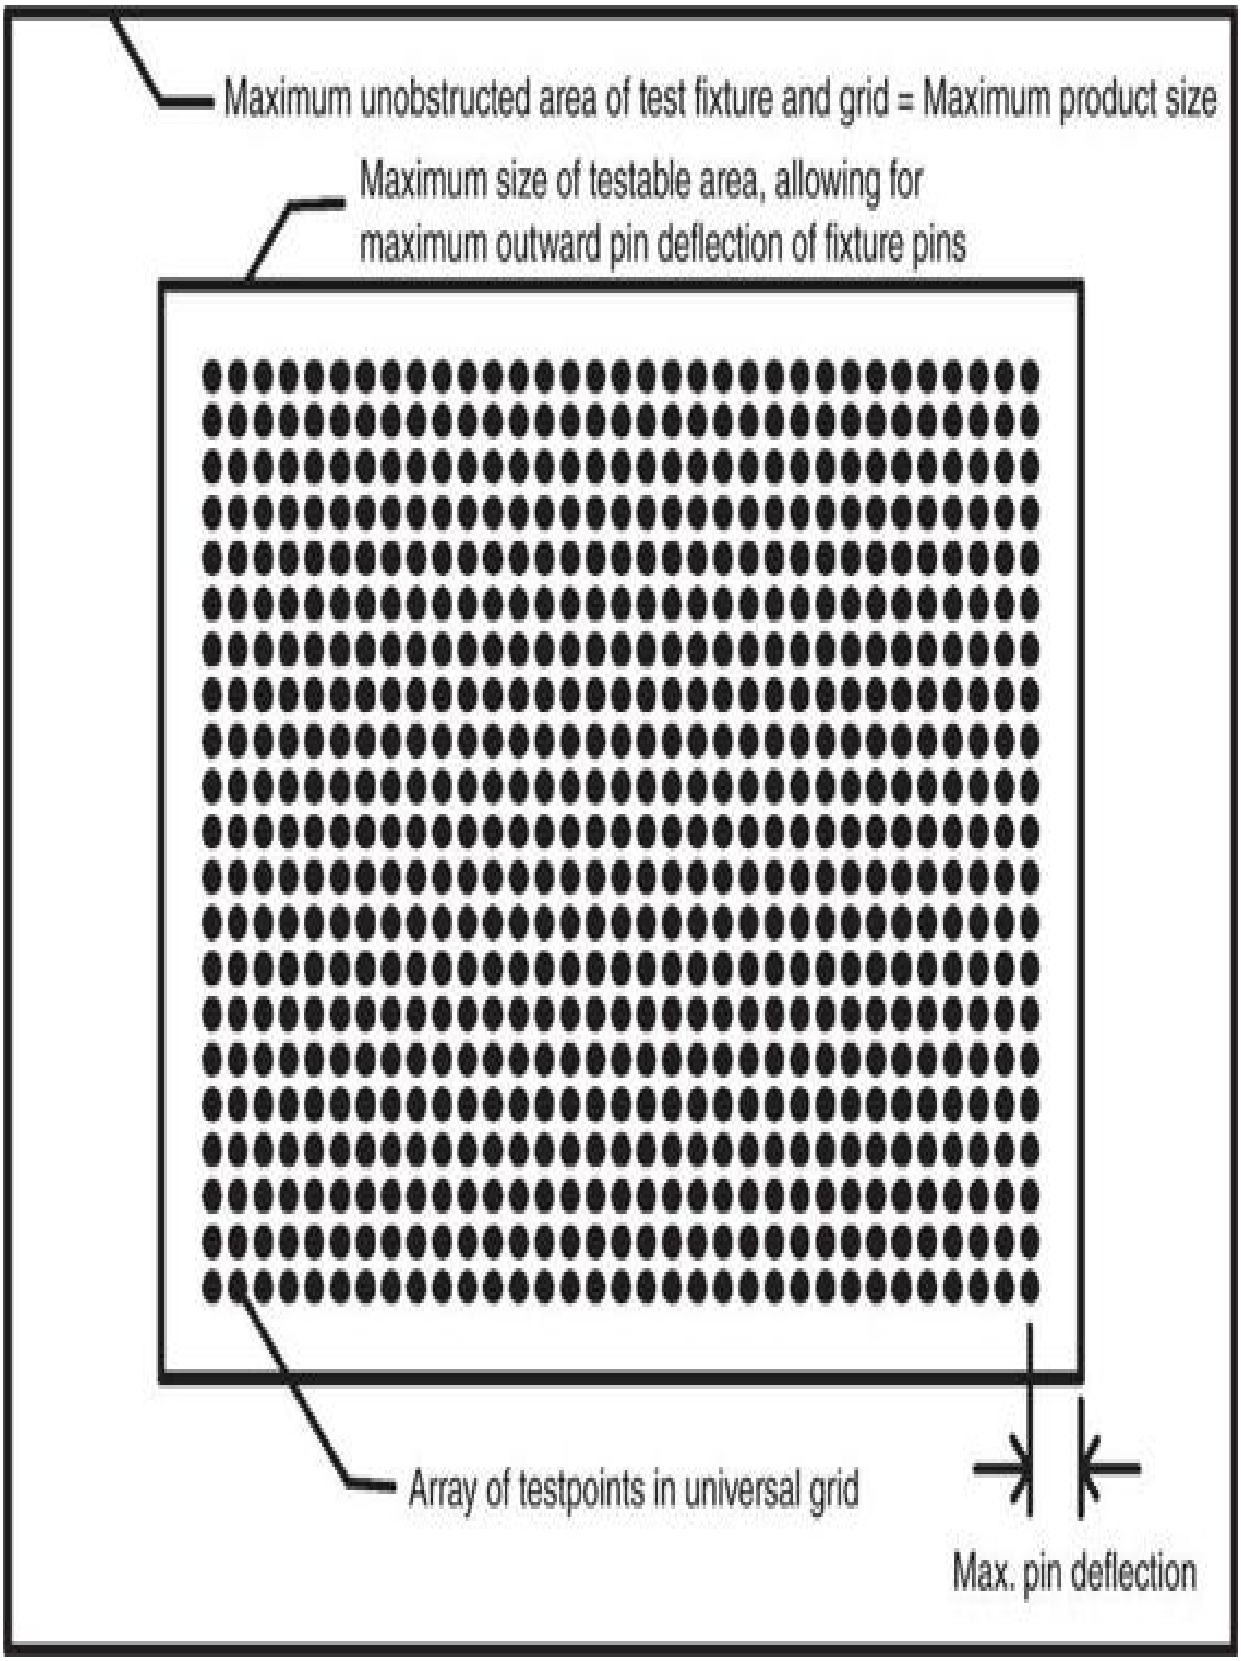

FIGURE 41.4 Universal grid testable area.

41.3.2 Exclusion Mask Fixtures for Universal Grid Systems

Occasionally, some applications involve product whose test-point spacing exactly matches the grid pattern. This situation may permit use of a very simple fixture referred to as an *exclusion mask*. This is composed of a thin glass-epoxy sheet, perhaps 0.030 in. thick, drilled at those locations where test probes are desired to pass through from the grid to make contact with the product. The exclusion mask (see Fig. 41.5) prevents unused grid probes from contacting the product unnecessarily, preventing erratic contacts and marking of the product. To use such a mask, it is necessary that the grid be constructed with a pointed or chisel-tip probe. Unfortunately, few products exist that are so simple to test.

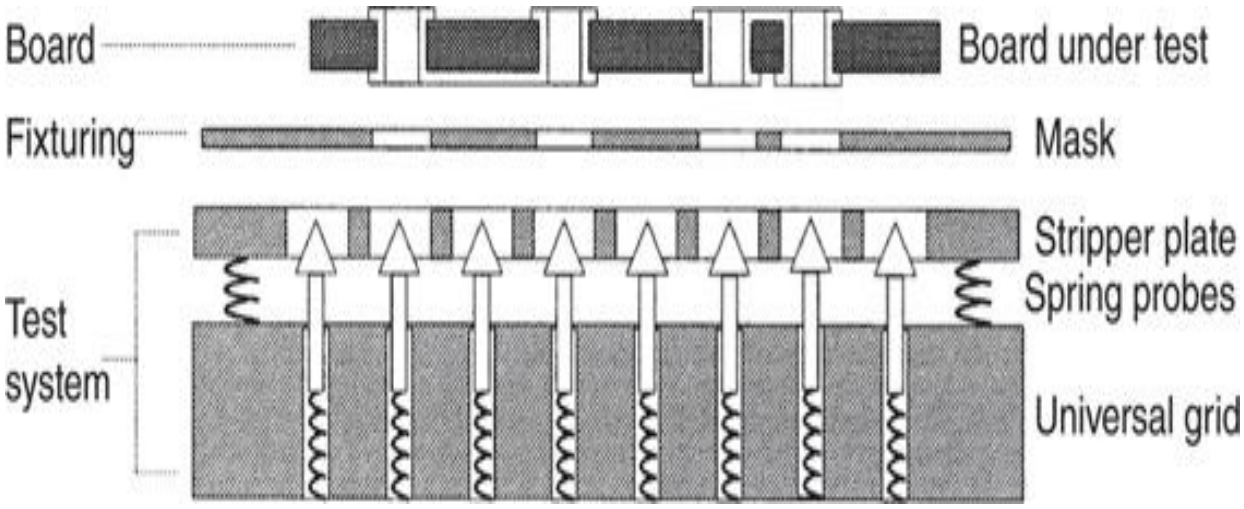

FIGURE 41.5 Exclusion mask fixture.

41.3.3 Pin Translator Fixtures for Universal Grid Systems

Most boards manufactured today are tested on universal grids through the use of pin translator fixtures. These fixtures are rapidly designed and produced using available software systems, and the most expensive material components (the contact pins and plate spacers) are generally reuseable. These fixtures are also referred to as *tilt-pin fixtures* or *grid fixtures*. Grid fixtures and related software remain the fastest-evolving area in electrical testing. Particular fabrication details will not remain current for long. Therefore, this discussion employs current practice only as means of illustrating key issues such as density and registration.

In a tilt-pin fixture, a rigid pin serves the dual roles of providing an electrical contact path from a grid test point to the product and translating the grid test-point location a small distance horizontally (in x- and y-coordinates) such that contact is made to the desired target on the product surface. Because the product targets are unlikely to be perfectly centered above grid test point locations, these pins are usually somewhat tilted from vertical. The amount of tilt or displacement varies according to the amount of x-y shift required. Several lightweight plates of plastic material support these pins. The individual hole locations in each plate are offset the amount required to achieve the desired pin tilt and spaced apart the required distances (see Fig. 41.6). These pins are variously referred to as *tilt pins, translator pins*, or *fixture pins*.

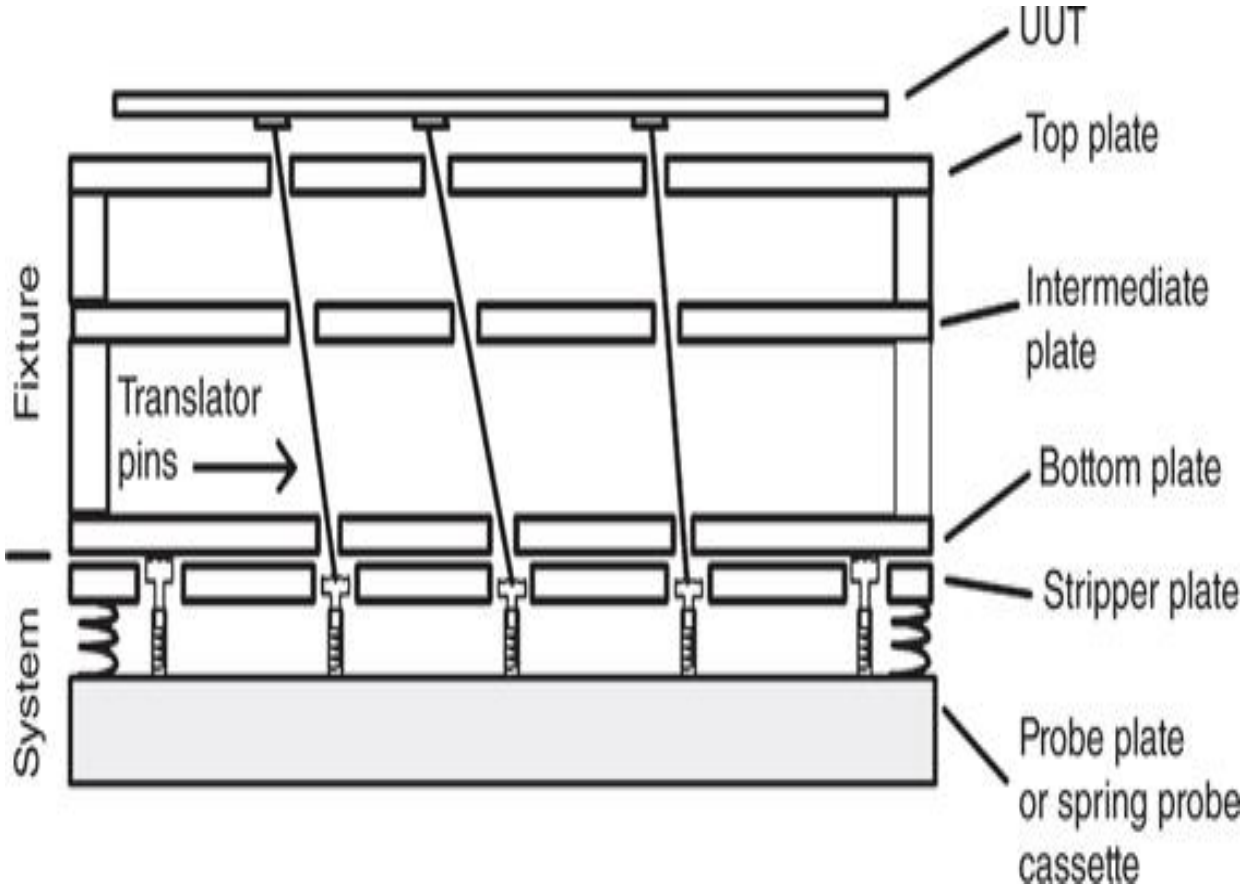

FIGURE 41.6 Single-side multiplate tilt-pin translator fixture.

To enable grid test points to be translated to exactly the correct target location on the product, it is important that each translator pin fall into the correct sequence of holes while the fixture is being assembled. If sufficient intermediate guide plates are employed, then the geometry of drilled holes can be so arranged that a virtual tunnel is created for each translator pin. It becomes impossible for a pin to fall into an incorrect sequence of holes. More plates are required when the maximum degree of pin tilt is increased. Calculation of plate count, position, and drill hole locations is a key function of the data extraction and fixture software, whose process is described elsewhere in this chapter.

41.3.3.1 Test Pins for Pin Translator Fixtures. A wide variety of pins are available for use with different system types and for different applications (see Fig. 41.7). These vary in length, tip style, material, cost, and thickness. For a given angle of tilt, a longer pin is generally able to translate the test point a larger horizontal distance (larger pin displacement). Pins with enlarged heads of various shapes are useful for probing large-diameter holes. Aggressive shapes such as chisels provide the pin with enhanced abilities for cutting through product contaminants, but may be unsuited to closely spaced test applications. At present, the vast majority of pins are headless music wire pins with lengths ranging from 2.5 to 3.75 in. When probing a large-diameter through hole, common practice now is to probe the annular ring around the hole rather than pay the penalty for an odd-headed pin type.

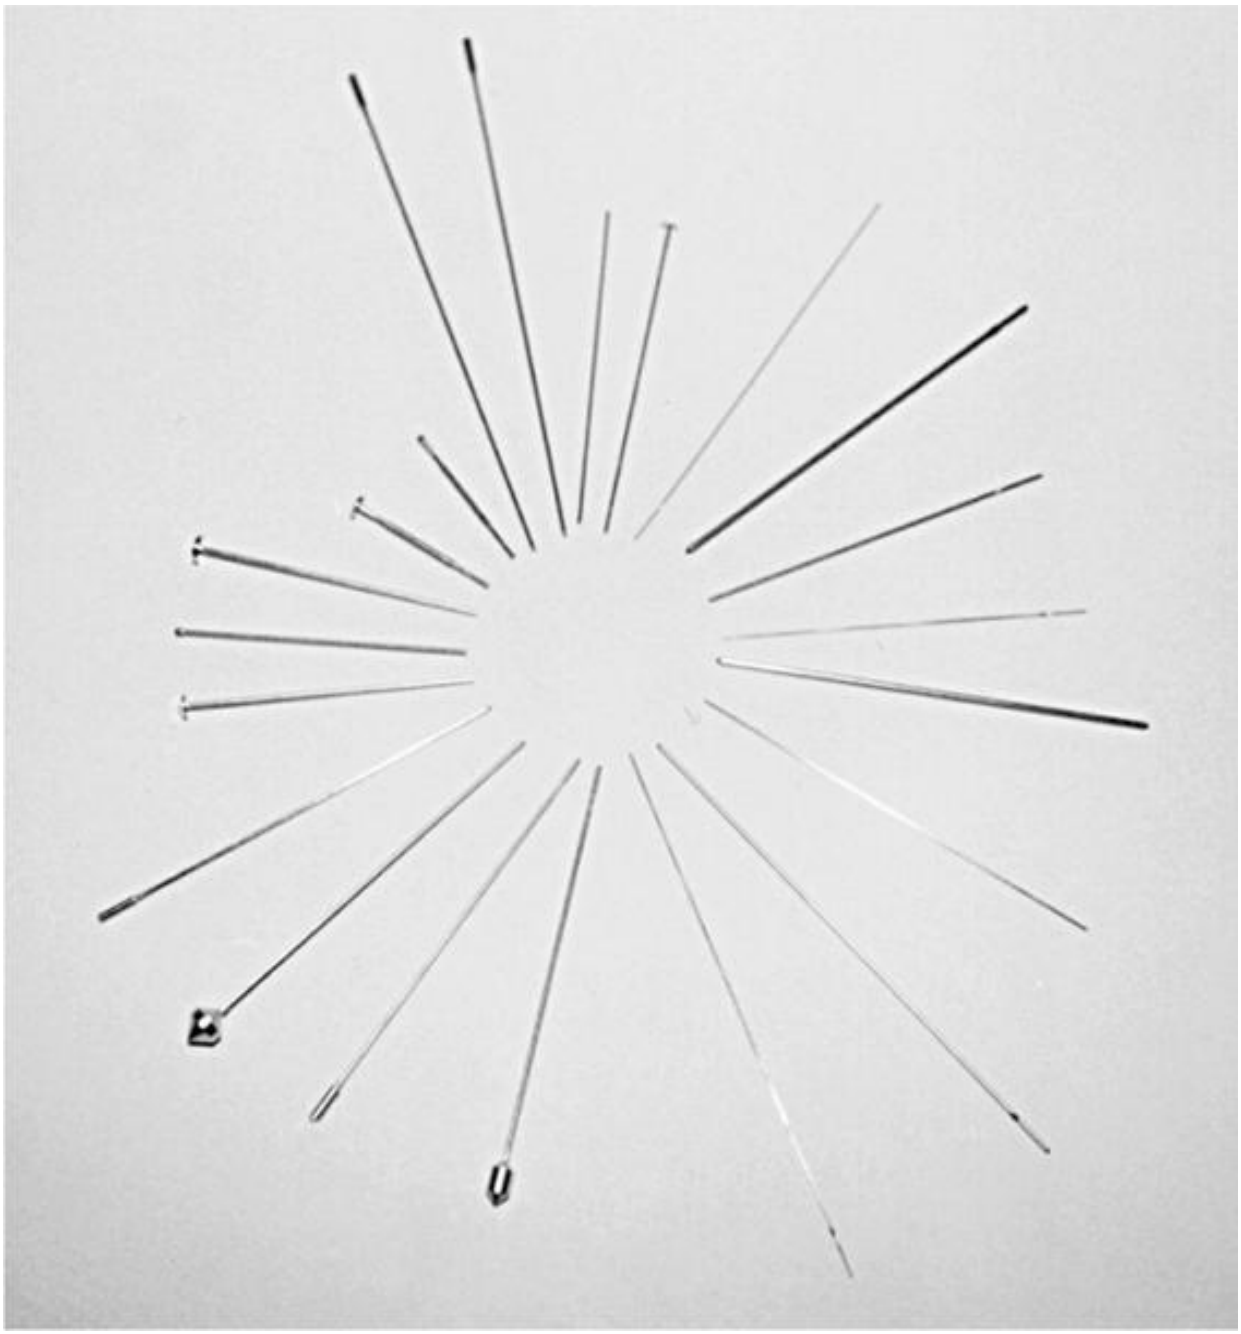

FIGURE 41.7 Examples of translator pins. (*Courtesy of Giese International*.)

41.3.3.2 Pin Displacement in Grid Fixtures. Pin displacement capability is one of the more significant performance measurements of a pin-fixture design combination. A larger displacement ability provides greater freedom in allocating test points, resulting in improved ability to fixture complex products on a test system of given

density. With an arbitrary fixed rule of thumb of 10° maximum tilt, we can see from Fig. 41.8 that the longer the pin, the further the pin can be displaced from its on-grid location to its on-product target location. The maximum pin displacement that can actually be obtained is a function not only of pin length, but also of fixture design and the resultant maximum tilt angle that can be tolerated in the design. The fixture software usually seeks to arrange pins such that the maximum tilt in the fixture is minimized. This decreases the number of guide plates required, minimizes the number of different hole sizes required in the plates, and tends to reduce friction and binding. Nonetheless, a design that permits a maximum tilt capability ultimately provides the greatest flexibility in assigning test points and generally permits the solving of denser products on grids of a given density.

41.3.3.3 Pin Binding and Friction in Grid Fixtures. As noted, the grid fixture pins must lean some distance to connect the grid to the on-product target location. Thus, the relationship between the plate thickness, hole diameter, and angle of displacement is critical. If the plates capture the pin too tightly, binding and friction can result. A pin that is held down below other pins in the fixture by binding will fail to make contact with the product (see Fig. 41.9).

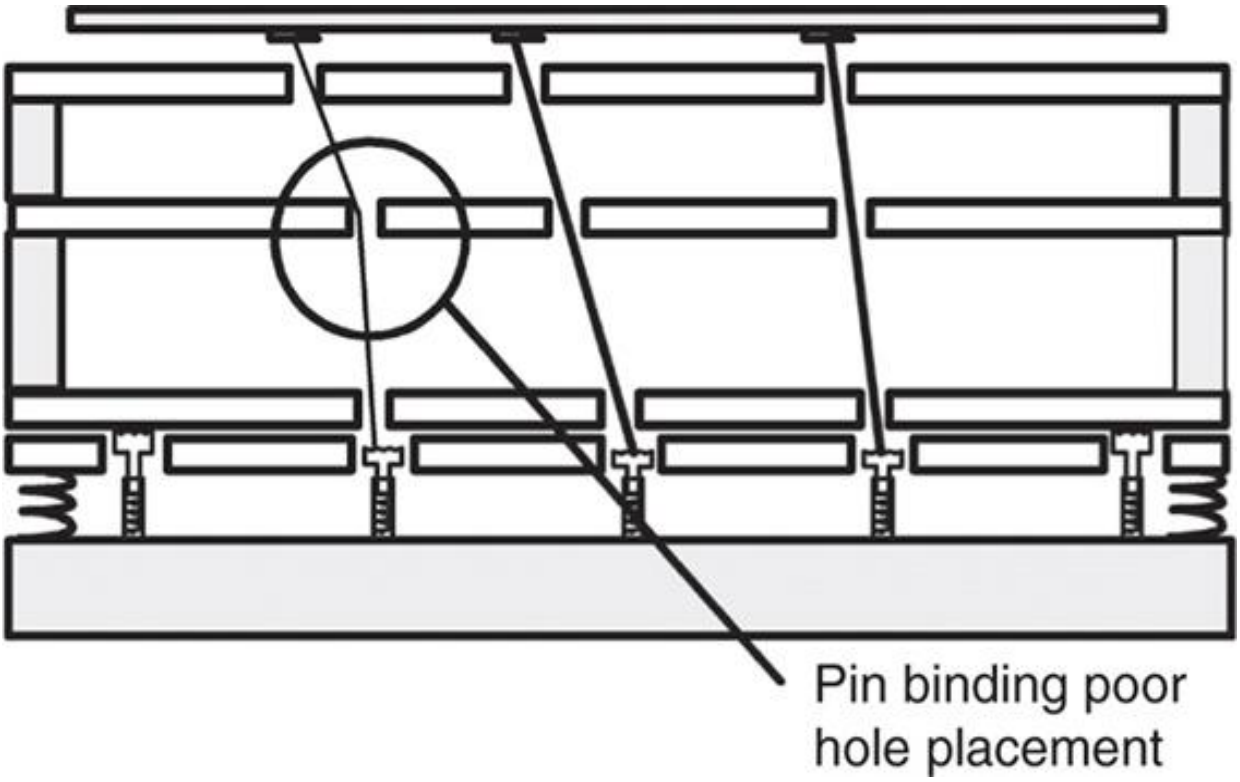

FIGURE 41.9 Pin binding in multiplate tilt-pin fixture.

The spring force of the spring probe in the universal grid is intended to supply the pressure that presses the tilt pin against the product. Every bit of friction in the tilt-pin motion subtracts some of this force. If the friction is great, not only may the pin fail to contact, but if the pin is stuck high (toward the product surface), the product may press on it with undue force in shoving it back into the fixture, resulting

in excess product marking. Binding can be caused within a single plate by hole diameters that are too small for the degree of pin tilt. Binding can result between plates if the plates are offset from one another, forcing the pin to bend as it snakes its way through the various plates. Binding can also result if the plate spacing is incorrect as compared to the design values.

41.3.3.4 Calculations for Tilt-Pin Fixtures. Modern fixture construction software should perform all of the necessary calculations automatically. Yet it is valuable to understand the basic decision processes.

41.3.3.4.1 Minimum Hole Diameter Calculation. The relationships between pin displacement, pin diameter, plate thickness, and drilled hole diameters are trigonometric. We calculate Eq. 41.1:

$$A = \sin^{-1}(PD/PL) \text{ and} \tag{41.1}$$

$$HS_{min} = [SD/\cos(A)] + [PT \times \tan(A)] + HT$$

where HS_{min} = minimum hole size in a particular fixture plate
PT = fixture plate thickness
SD = pin shaft diameter as it passes through the plate
PL = overall pin length
PD = horizontal displacement distance of the pin tail relative to the pin head location
A = angle of pin tilt expressed as degrees from vertical. (i.e., a vertical pin has a tilt of 0°)
HT = minimum acceptable tolerance to ensure that the pin slides freely in the hole

The first term in the equation derives from the effective increase in shaft diameter in the horizontal plane as the pin tilts (see Fig. 41.10). The second term derives from the horizontal distance that the center line of the pin travels as it

passes through the plate thickness. The third term, as mentioned earlier, is to provide a minimal clearance.

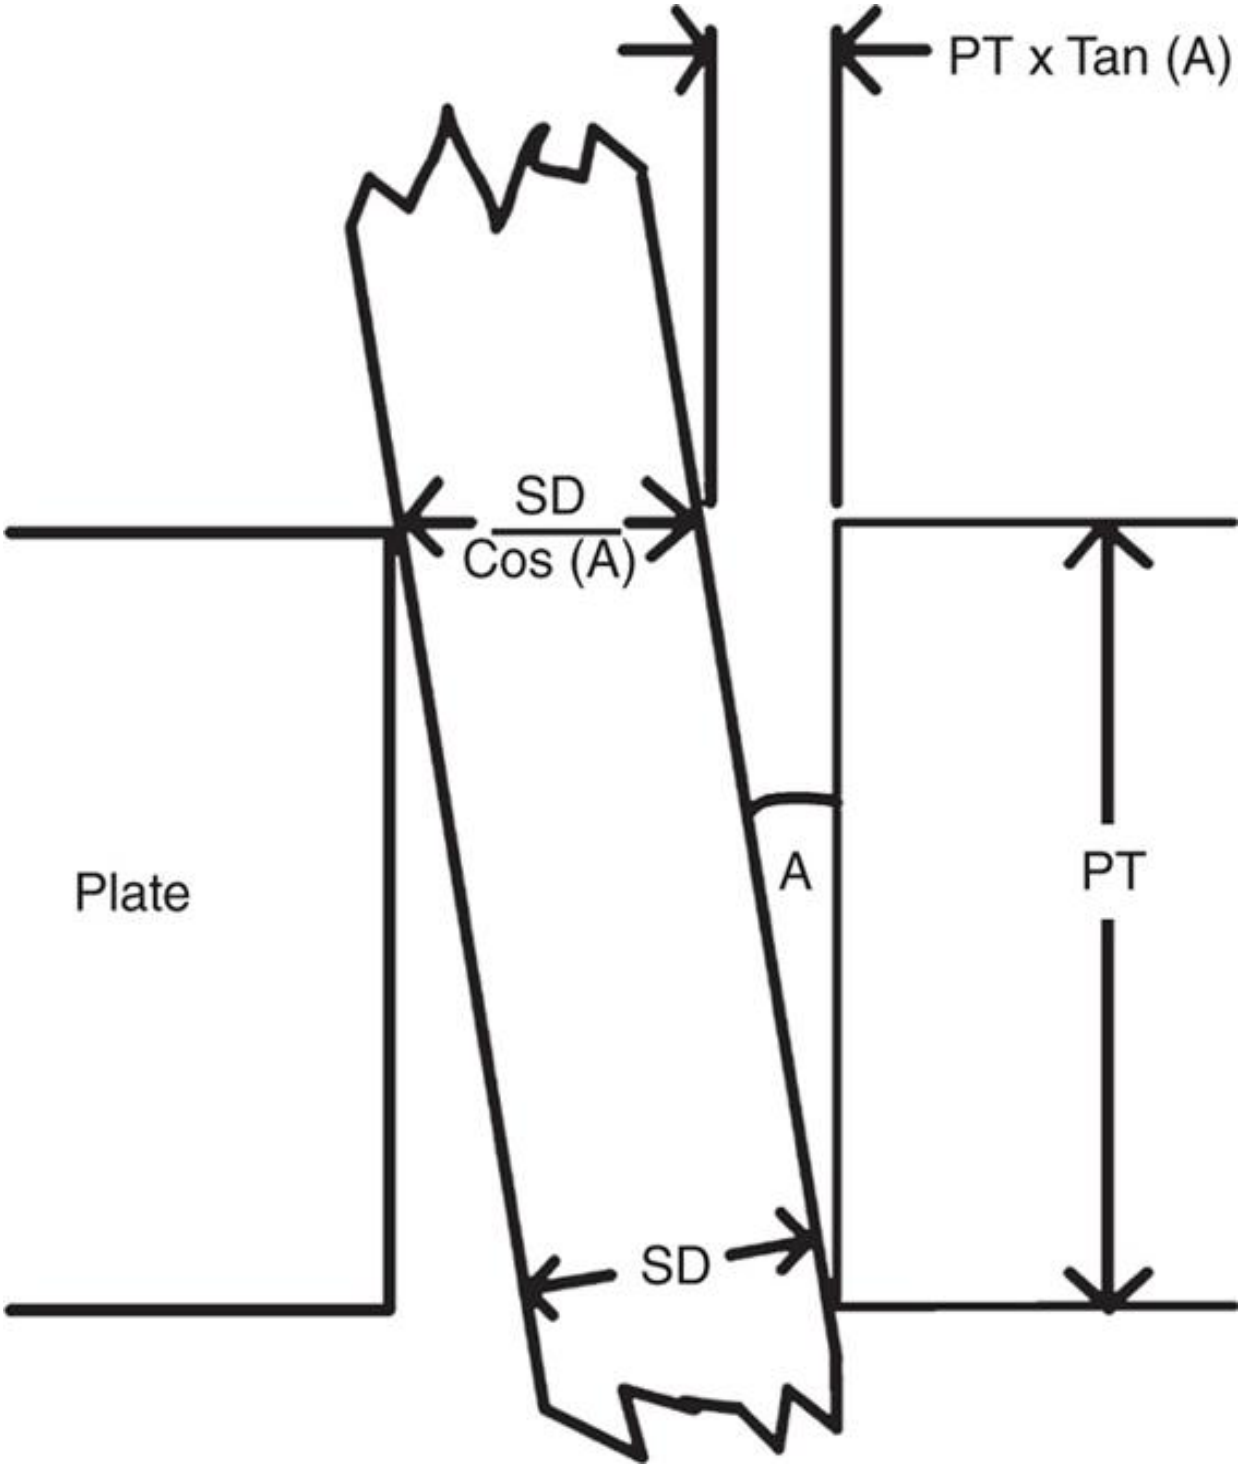

FIGURE 41.10 Illustration of hole diameter calculations for a tilt-pin fixture.

For angles of tilt below 15°, the value of the cosine is close to 1 (over 0.96), and for rough calculations the term may be omitted. (For a 20 mil diameter pin, the contribution of pin tilt to effective shaft diameter is less than 0.7 mil). Similarly, for the same small angles, the calculation of the tangent can be simplified to tan(A) ≈ PD/PL. The error incurred increases as the plate thickness increases. For a 0.1 in. thick plate, the error at 15° will again amount to something less than a 1 mil hole diameter.

With these simplifications, for low tilt angles and thin plates, the formula may be reduced to that shown in Eq. 41.2, with an extra mil or two added to the clearance.

$$HS_{\min} \approx SD + [PT \times (PD/PL)] + HT \qquad (41.2)$$

For the highest-accuracy applications, use the exact calculation.

41.3.3.4.2 Drill Bit Size Selection. Note that the minimum hole size calculated previously is often not the ideal drill size. The most common material used for grid fixtures is polycarbonate.

Polycarbonate tends to have a finished hole size that is about 0.001 in. smaller than the drill size for plate thicknesses typically employed in fixtures. Therefore, 0.001 in. should be included in the tolerance figure HT to permit accurate drill bit selection.

41.3.3.4.3 Pin Lean and Pointing Accuracy. *Pointing accuracy* is defined as the pin's ability to hit an intended target, usually described as a radial dimension (the distance from the intended target to the actual contact location). Because the pin is typically not perfectly vertical, there are several possible sources of error, depending upon the type of pin employed. With the older headed pin types, the head sat above the top plate of the fixture. With modern headless approaches, the pin tip is usually flush with the upper surface of the top plate while in contact with the product. As

the pin tip projects less (nearly zero) above the top plate surface, its tip position in x-y coordinates is better controlled by the hole in the top plate. For this reason, most modern fixture designs operate with the probe tips arriving flush with the top plate surface while the product and fixture are compressed.

It is also preferable that the pins remain approximately flush when compression is released. If they project above the top plate surface, the tip moves out of position in x-y coordinates, as illustrated in Fig. 41.11. When a product is placed on such a pin, the tip initially contacts an incorrect target location. During compression, the pin must drag across the product surface as the pin retracts into the flush position. Thus some spring mechanism, which supports the fixture and pins above the array of grid spring probes, is commonly employed. The fixture may rest on a spring-loaded stripper plate over the grid of spring pins, or the fixture may be designed with spring feet on its underside. In some designs. the fixture kit itself is compressed.

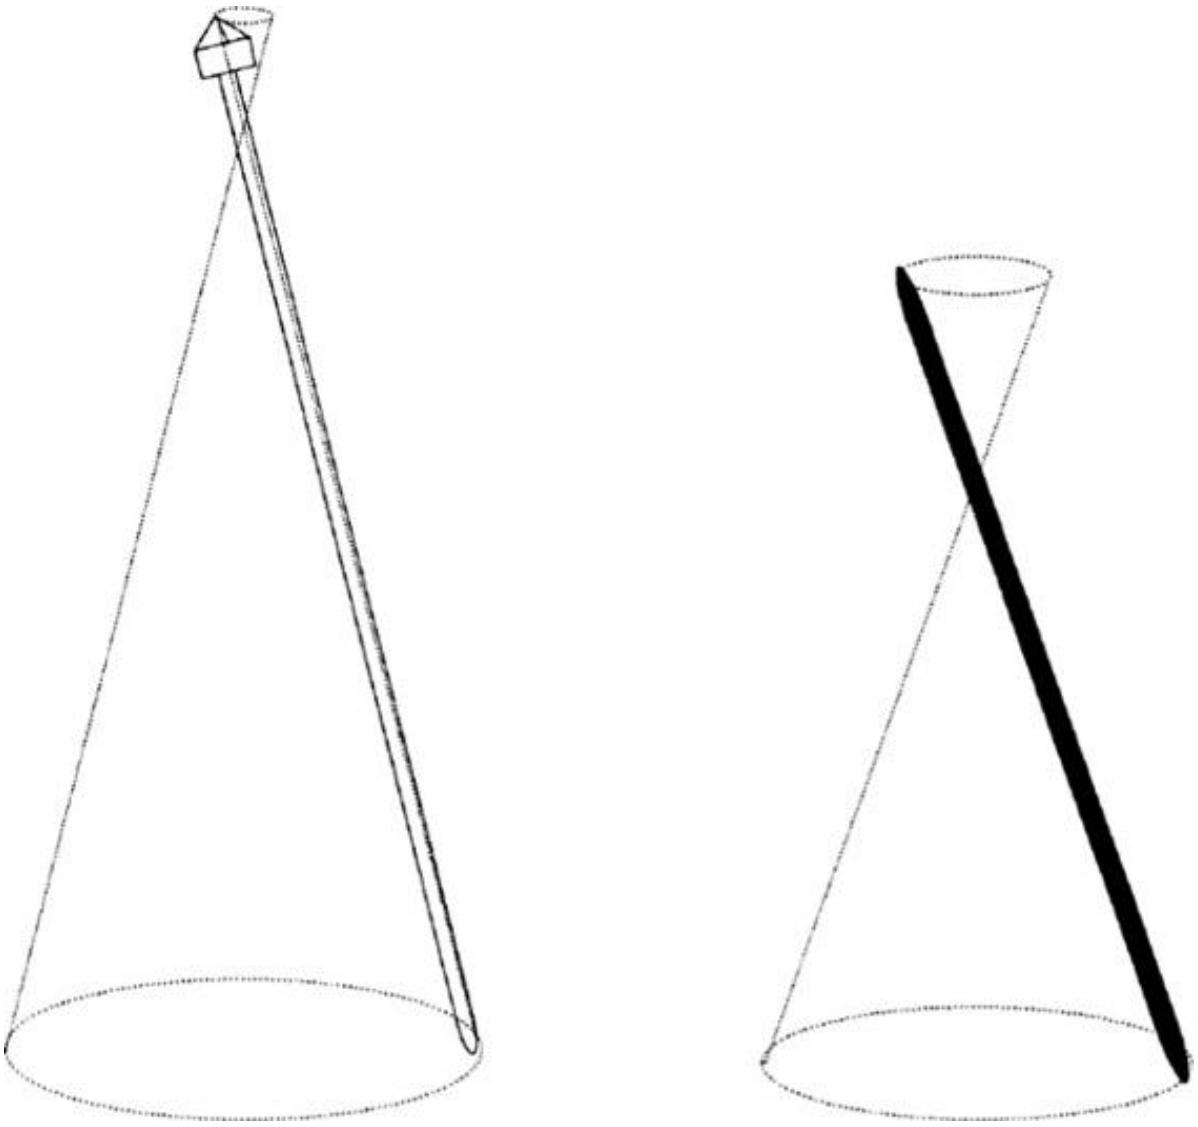

FIGURE 41.11 Pointing accuracy.

Some fixture designs have used bent or curved test pins. In such cases, the pin is bent by including additional fixture plates such that the tip of the pin as it comes through the top plate is perpendicular to the test pad. This allows the top plate holes to remain on the product and mirror the board under test and thus eliminates concerns about the effects of pin contact at an angle. Common examples of such fixtures were built as spring boxes, such that the overall thickness of the fixture decreases during compression. This eliminates the need for spring feet or a stripper plate, but complicates

friction and binding issues as the entire array of test pins must bend and flex during every compression. Contact reliability, product marking, and ease of pin loading all suffer.

41.3.3.4.4 Offset Error Compensation. Figure 41.12 represents the problem associated with the deflection of a pin retained in the top plate and its ability to hit the center of the pad or target. As described earlier, the hole diameter must be sufficiently oversized to allow the pin to pass through the hole at its angle of deflection without binding. Vertical force on the pin from the product above tends to press the pin against one side of the hole, as illustrated. (This has the curious effect that tilted pins can display more consistent targeting performance than do perfectly vertical pins.) As the pin tilts, the center line of the pin becomes substantially shifted from the center line of the hole (note the offset distance *OS* in the illustration). Finally, the conical tip associated with most modern pins has a certain finite radius—the pin is not infinitely sharp. Thus, in the illustration, the product will not contact the pin on its center line. As illustrated, contact will come at the highest point of the tip radius, slightly to the right of the center line. Thus, the theoretical contact point will be at neither the center line of the pin nor the center line of the hole. Probing targets only a few mil wide with probes two or three times as wide requires high-quality probes displaying consistent tip geometry, and software able to calculate the actual point of contact carefully.

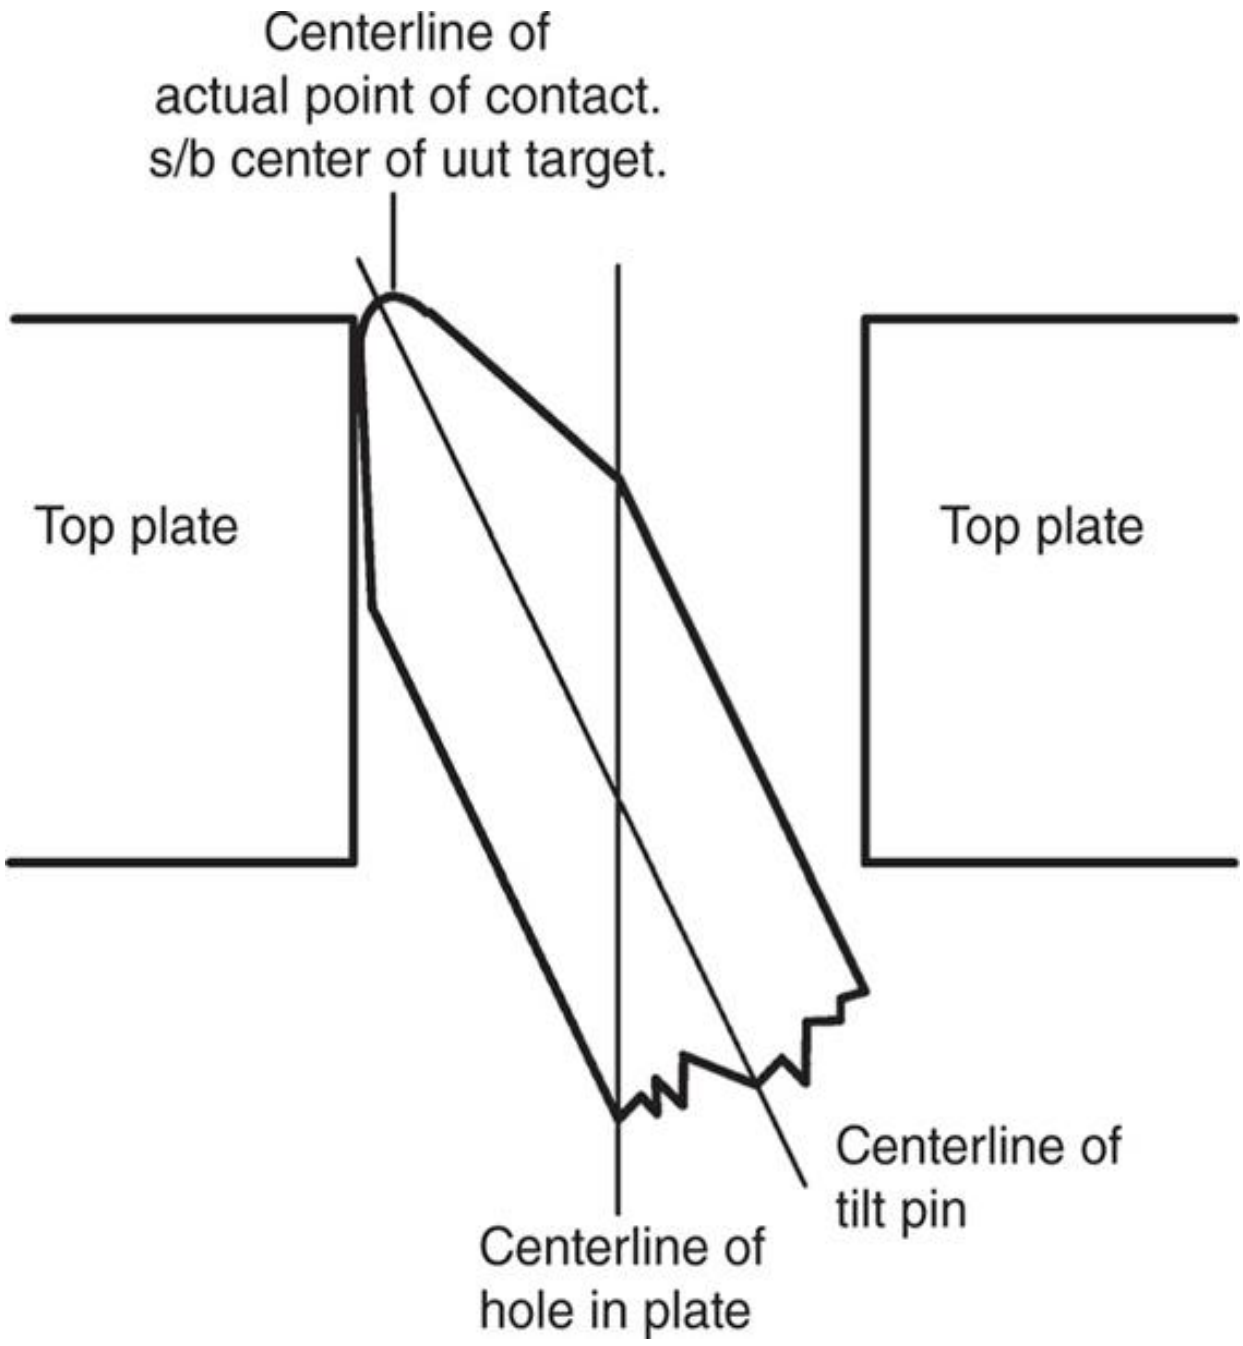

FIGURE 41.12 Pin tip offset error.

41.3.3.4.5 Countersink Drilling of Top Plate. The calculations and considerations just discussed illustrate that thicker plates and higher pin tilt present some interesting problems when combined. A highly tilted pin in a thick plate requires a substantially oversized hole if binding is to be prevented. Looking through the hole at a viewing angle

equivalent to the tilt of the pin, the hole will appear to be oval, with the narrow axis considerably shorter than the drill bit diameter. Of course, the pin is thereby allowed somewhat more freedom of movement along the major axis of the oval. This bit of looseness can be a problem with very fine-pitch products.

A better solution is to use a very thin plate for the upper fixture plate, backed up by a thicker plate drilled oversize. Alternately, a single plate can be countersunk. The effect is the same, as illustrated in Fig. 41.13.

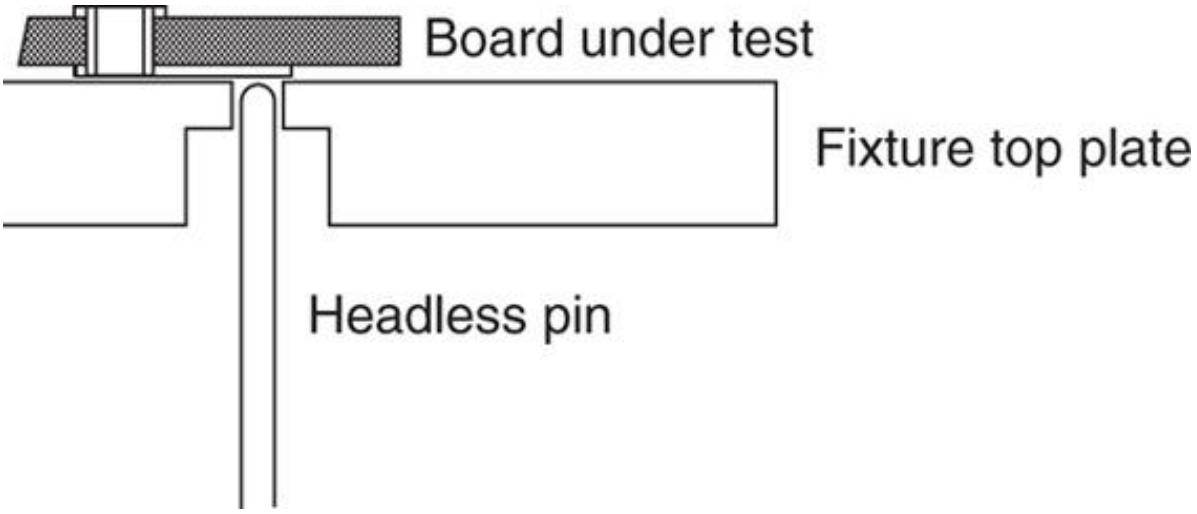

FIGURE 41.13 Countersink drilling of top plate to avoid binding or oversize holes.

41.3.3.5 Retaining Fixture Pins. It is necessary to retain the pins in a translator fixture such that they do not fall out of the fixture during ordinary use and handling. Older headed pin types were often used in single-sided fixtures. The oversized head protruded above the top fixture plate, and therefore the pin was unable to fall out the bottom of the fixture (although they fell out all too easily if one accidentally inverted the fixture). Early top-side fixtures attempted to duplicate this method for the upper fixture by employing a different pin in the upper fixture half, using an oversized "tail" on the fixture. However, the oversized geometry of the

heads is inappropriate for fine-pitch testing, and therefore the use of such pins has fallen out of favor.

The desire to use thin, headless music wire pins necessitated the invention of new means of pin retention (see Fig. 41.14). These have included:

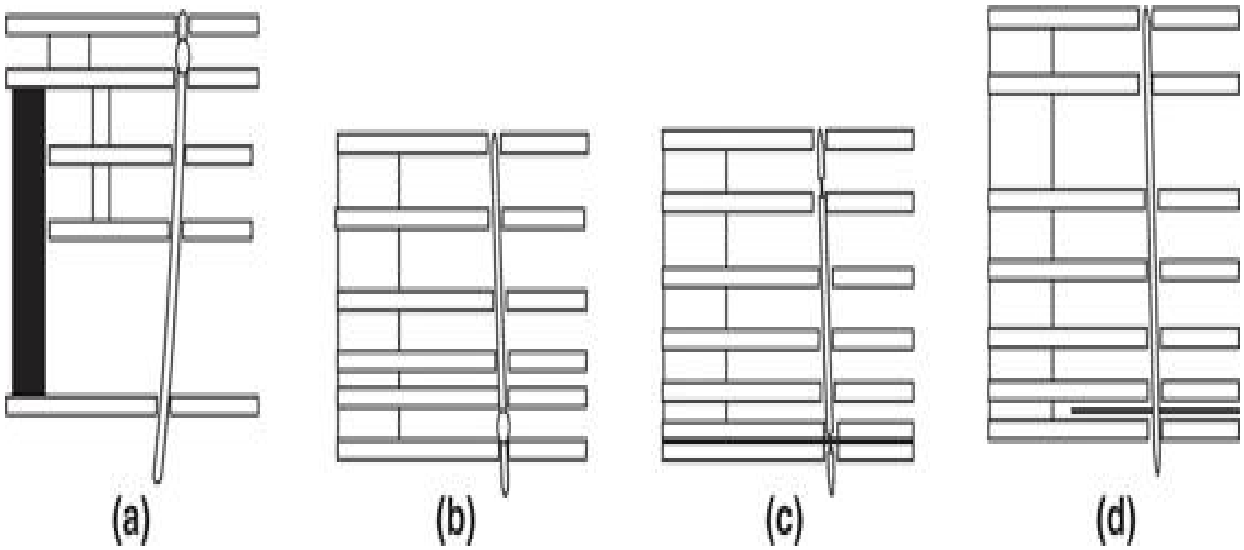

FIGURE 41.14 Alternative pin retention methods. (a) (b) (c) (d)

a. Crimping a wide flat into the pin, and trapping the oversize flat between two plates

b. Trapping the pin in a sheet of foam rubber such that friction retains the pins

c. Passing the pin through a sheet of spandex cloth that grips the pin

d. Passing the pin through a sheet of drilled latex rubber that grips the pin with flexible flaps

41.3.3.6 Examples of Real-World Fixture Designs. While many combinations of fixture techniques have been employed, it is worthwhile to compare several popular examples. No substantial discussion of older headed rigid pin types is included here, as their use is largely disappearing. Most fixtures today are built with headless pins that compress flush into the fixture without bottoming on the

spring probe below, such that the contact force is entirely controlled by the spring (excluding friction or binding effects).

Figure 41.14a represents a common bent or curved pin design using 3.75 in. music wire pins. The upper and lower fixture plates are held apart by a spring mounting, and the entire fixture compresses during actuation. The pins hit the intended target perpendicularly, because they bend toward vertical as they reach the product area. But extra force is required, increasing pad marking. Hole diameter in the top plate can be tightened to improve pointing accuracy because all pins pass through perpendicularly, and a fairly thick top plate is possible. For a given pin length, the maximum possible horizontal displacement is more limited than in straight pin designs, because all displacement must occur in the lower portion of the pin length. The hanging middle plates do not contribute to torsional stability of the fixture design, increasing distortion under compression. This in turn can increase pin binding as the pins try to bend and slide through the compressing fixture envelope. The pins usually used have a flattened crimp trapped between the upper two plates and must be loaded or serviced with the upper plate removed. Pin loading is therefore difficult. The increased diameter in the crimp region limits close spacing of the probe. Finally, the crimp cannot be employed on very fine-diameter pins, as they would weaken excessively.

Figure 41.14b illustrates a significant evolution from Fig. 41.14a. Here the pins are not bent or curved. Shorter pins (3 in.) are sometimes used, providing about the same horizontal translation as in Fig. 41.14a. Deleting the bend significantly reduces pin binding. A retention crimp similar to the previous example is used, relocated toward the bottom of the fixture where the pins are more widely spaced. Pins are loaded from the bottom side, with the lower plate removed. This design still requires disassembly of plates for pin servicing, but the bottom plate is somewhat easier to

reinstall due to the possibility of larger hole sizes. Fixtures are usually rigid as opposed to spring-loaded, reducing friction effects during compression.

Variations of the fixtures illustrated in Figs. 41.14a and 41.14b are produced using a foam-rubber pin retention method. In these versions, the crimp on the pin is deleted and a sheet of foam rubber material is sandwiched between the two lower plates. During loading, pins are forced through this foam, and friction holds them in place. This provides the important advantage that individual pins can be replaced without fixture disassembly. Unfortunately, high-density zones incorporating many pins stretch the foam rubber material. The stretched foam holds adjacent pins so tightly that a group of pins becomes reluctant to move except as an almost solid block. The resulting pin binding effect causes contact reliability and product marking problems. Also, the foam tends to deteriorate with time and/or heavy use. As densities have increased, this fixture has become difficult to use.

Figure 41.14c illustrates a retention technique employing a very thin sheet of drilled Mylar combined with a unique feature on the pin. The Mylar sheet is sandwiched between standard polycarbonate plates. The pins employed begin as straight-sided music wire pins 3 in. long. A grinding operation reduces the pin diameter in a short region (about 0.2 in.) of the pin length. The Mylar retaining sheet is drilled with a hole diameter that is slightly smaller than the original pin diameter. As the pin is inserted, it is forced through this undersized hole until the reduced-diameter zone reaches the Mylar sheet. At that point, the pin can slide freely over the 0.2 in. narrowed length. Only in this region are the pins able to move quite freely up and down. The height of the Mylar plate in the fixture is matched to the reduced-diameter portion of the pin, such that the pin is free to move a short distance up and down from its nominal position without falling out of the fixture. Pins are generally specified with the

grinding operation performed at locations near both ends of the pin, such that the pin is symmetrical and can be loaded without regard to orientation. This pin demonstrates low friction and good contact, but a few problems remain. The Mylar sheet is thin and fairly brittle. It is not uncommon for a particular hole to fracture when extracting or reinserting a pin, such that the damaged hole can no longer retain a pin. Replacing the Mylar sheet requires unloading all pins and removing one or more plates. Pins for this fixture are expensive, as the grinding operation is difficult. The requirement to grind the pin undersize along a portion of its length limits the minimum pin diameter which may be used without causing the pin to become excessively weak at the narrowed section. As product pitch and density demands have increased further, these issues have become significant limiting factors.

Figure 41.14d represents techniques employed in more recently developed fixtures. These fixtures include nonoriented, nonfeatured pin designs, usually 3.75 in. long. A key feature is retention via drilled latex rubber or undrilled spandex cloth. The drilled latex is not sandwiched but rather floats in a gap between two plates, amounting to 0.1 in. or so. Drilling tends to cut or tear a slit in the rubber rather than to cut a round hole. The result upon pin insertion is that the pin is gripped by a pair of tiny rubber flaps, allowing short motions of the pin to occur without actually rubbing the pin against the rubber. (The flaps are able to move short z-axis distances with the pin.) This provides essentially frictionless pin motion over the short range of travel needed to conform to surface irregularities on the product. Properly sized to match pin diameter, the presence of the holes or slits tends to relieve any accumulation of stress in the rubber sheet in high-density areas, providing good contact reliability under such conditions. The lack of motion against the rubber sheet also promotes long life of the fixture. The presence of the hole or slit provides stress relief in the rubber in high-density

situations. Molded one-piece plate spacers speed assembly and disassembly, lower cost, and provide accurate z-axis position control of the plates. Use of the longer 3.75 in. pin provides maximum pin displacement.

The featureless music wire pin is economical and widely available. A countersunk top plate hole or two-ply top plate is generally used for high-performance applications. Notice that no disassembly is required to service a pin.

A variation of this fixture employs a stretchable fabric web in place of the latex, generally referred to as *spandex*. Under close examination, this material appears as a very fine, stretchable net. The stretchable net requires no drilling operation—pins are just pressed through during the pin-loading operation. However, some stress accumulation is observed in very dense areas.

41.3.3.7 Intermediate Guide Plates in Fixtures. Early pin translator fixtures were constructed with only two plates, top and bottom. Modern fixtures add intermediate plates to speed fixture building, produce a more reliable fixture, and make the fixture determined. Determined fixtures ensure that a pin started into a fixture hole during pin loading is able to follow one and only one path through the fixture (without bending). This is required if data-driven test programs are to be used because the test program assumes a specific mapping of grid test points to product targets. The determined pin load must remain constant if the fixture is taken apart and later reloaded; otherwise, the test program will become invalid.

Intermediate plates simplify and shorten the pin-loading process because each pin must fall into the intended track. Assemblers do not have to pick between several possible holes or spend time checking for misloads and/or short circuits. Determined pin loads permit the fixture software to calculate the side loads imposed on fixture plates by the combination of tilted probes in each region of the fixture,

adjusting the pin-loading plan until these side loads are balanced. This prevents the fixture from collapsing sideways under compression. The intermediate plates also support finer-diameter pins, ensuring that they do not buckle under load.

As density increases, holes in the various plates become more closely spaced. At some point, for a given plate stack-up, there is the risk that some pair of holes on the next plate will become close enough that a pin being loaded might fall into the wrong hole. At that density, the fixture software must add an additional intermediate plate to the design. Thus, denser fixtures generally require more plates. Fixture software should analyze the requirements of each fixture and delete unneeded plates.

41.3.3.8 Fixture Plate Spacing Techniques. Errors in the vertical (z-axis) position of fixture plates can result in pin binding. As a tilted pin travels through the plate stack-up, the hole position in each plate shifts slightly in the x and y directions, according to the amount and direction of tilt. If a plate were to be mounted either too high or too low in the plate stack-up, the drilled hole would no longer be at the correct x-y position, forcing the pin to bend in order to pass through the hole. Pins would become difficult or impossible to load; binding and friction would occur during operation. Sensitivity to this problem increases as the amount of tilt increases.

Early multiplate fixtures used a plate-spacing technique referred to as *post and doughnut*, which had mediocre control of z-axis plate position. A long screw passed through a stack consisting of the fixture plates and thick plastic washers. The washers were drilled in the center, and the plates were drilled with corresponding mounting holes. The screw passed through all of these in turn. The thickness of a given washer determined the space between two plates. The problem was that the errors in washer and plate thickness

accumulated through the stack-up. At greater pin tilts, the result was binding. It turned out that the thickness of inexpensive fixture plate material was not terribly precise.

Alternative means of plate spacing have been devised in which a single molded (or machined) part is responsible for the entire fixture stack-up, and which eliminate intermediate plate thickness as an error contribution. One method is illustrated in Fig. 41.15.

FIGURE 41.15 Molded spacer prevents pin binding.

This molded spacer provides a series of flat surfaces upon which individual plates sit. In a top view, the shape of each surface is modified such that plates slip easily over the top of the spacer, but are locked into position when the spacer is rotated 90°. As long as the spacer is accurately molded, no cumulative plate spacing error results. For midfixture plate

supports, a similar part of smaller diameter is used. Short screws at the top and bottom plate secure the support in place. Alternative methods use machined bars around the periphery of the fixture. Either method results in accurate fixtures, reduced parts count, and ease of assembly.

41.3.3.9 Headed Music Wire Pins. For very large through-holes, the preferred probing method is to probe the annular ring of the plated through-hole. If, however, this ring is insufficient, a headed pin may be required. Such pins are manufactured with a machined tip attached to a standard music wire pin. Various head shapes are available. These headed music wire pins work in the fixture design much the same as the headless pin, that is, flush in the top plate (see Fig. 41.16), with the exception that the headed pin must be loaded from the top individually.

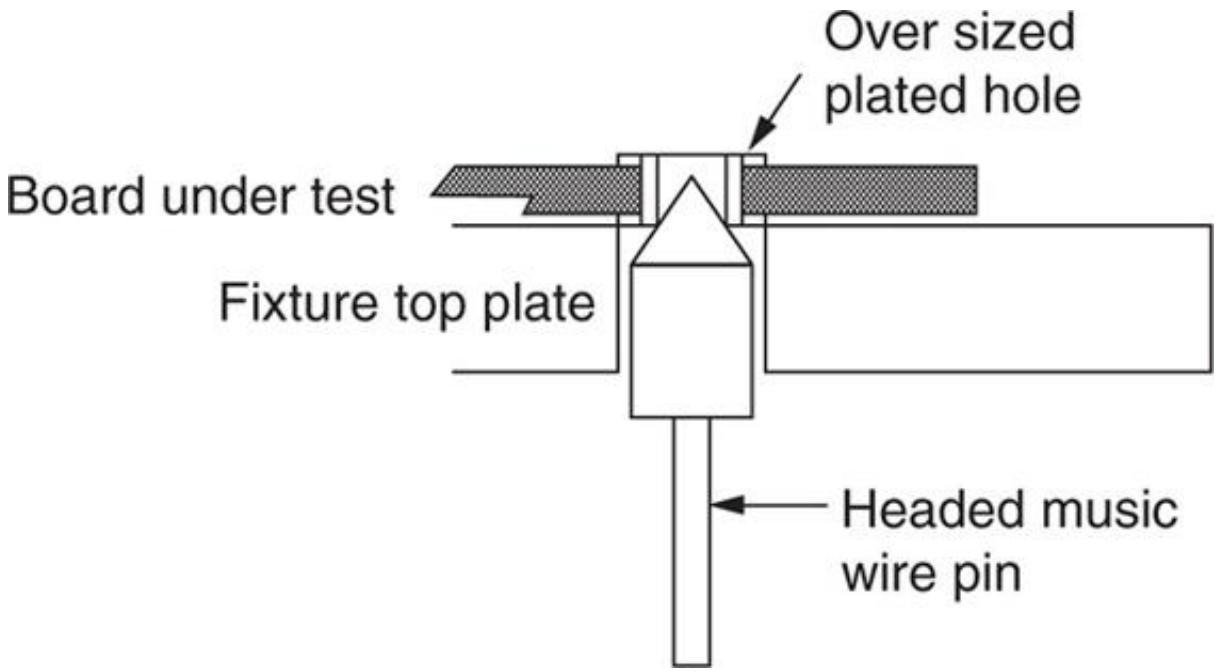

FIGURE 41.16 Headed pin in a tilt-pin fixture.

41.3.4 Dual-Side Testing Considerations

Modern SMT boards often have networks that terminate at component locations on both sides of the board. Continuity testing of such networks requires that the top and bottom terminations of such networks be probed simultaneously. There are three ways to test boards that require dual-side access:

1. Flip test
2. Clamshell upper fixture
3. Dual-side universal grid fixture

These methods vary in terms of test coverage, fixture cost, labor cost, risk of test escape, and required infrastructure. Each method is discussed in the following subsections.

41.3.4.1 Flip Testing. Flip testing is a last-resort method employed where up-to-date dual-side equipment is not available and compromising in test coverage is acceptable. The flip test method requires building either two fixtures, one with the top-side image and one with the bottom-side image, or one fixture with both images on it. The board is then tested one side at a time. Although this does provide partial fault coverage, it does not test those plated holes that link the top-side half of a network to the half on the bottom of the board. This poses a significant risk that bad boards will escape the test process. The problem only becomes worse if these interconnecting vias are tented (that is, if they have solder mask over them), preventing probing. In this case, the traces that run from the tented via to the first pad on the network that can be probed are also untested at both sides of the board.

Flip testing is expensive. Not only are two fixtures built, but also many test points are duplicated between the fixtures.

Much additional board handling and potential for confusion are involved. The cost and risk incurred would likely justify an equipment upgrade to dual-side test capability.

41.3.4.2 Clamshell Upper Fixture. Clamshell testing is another compromise method employed where dual-side equipment is not available. This method provides top-side access through the use of a wired (dedicated) top-side fixture. The method is superior to flip testing in that it can provide complete simultaneous access and full test coverage. However, fixture costs are quite high, especially for top-side test points. In this scenario, a more-or-less normal pin translator grid fixture is built for the bottom side of the board. The board should be oriented such that the busy side of the board faces down, as this minimizes the costly top-side fixture (see Fig. 41.17). Additional test points (called *transfer points*) are added outside the product area on both the top and bottom fixtures, conducting test points from the lower fixture and grid to the upper fixture assembly. Normal wired fixture construction methods are used within the upper fixture to relocate these points to desired top-side product target positions.

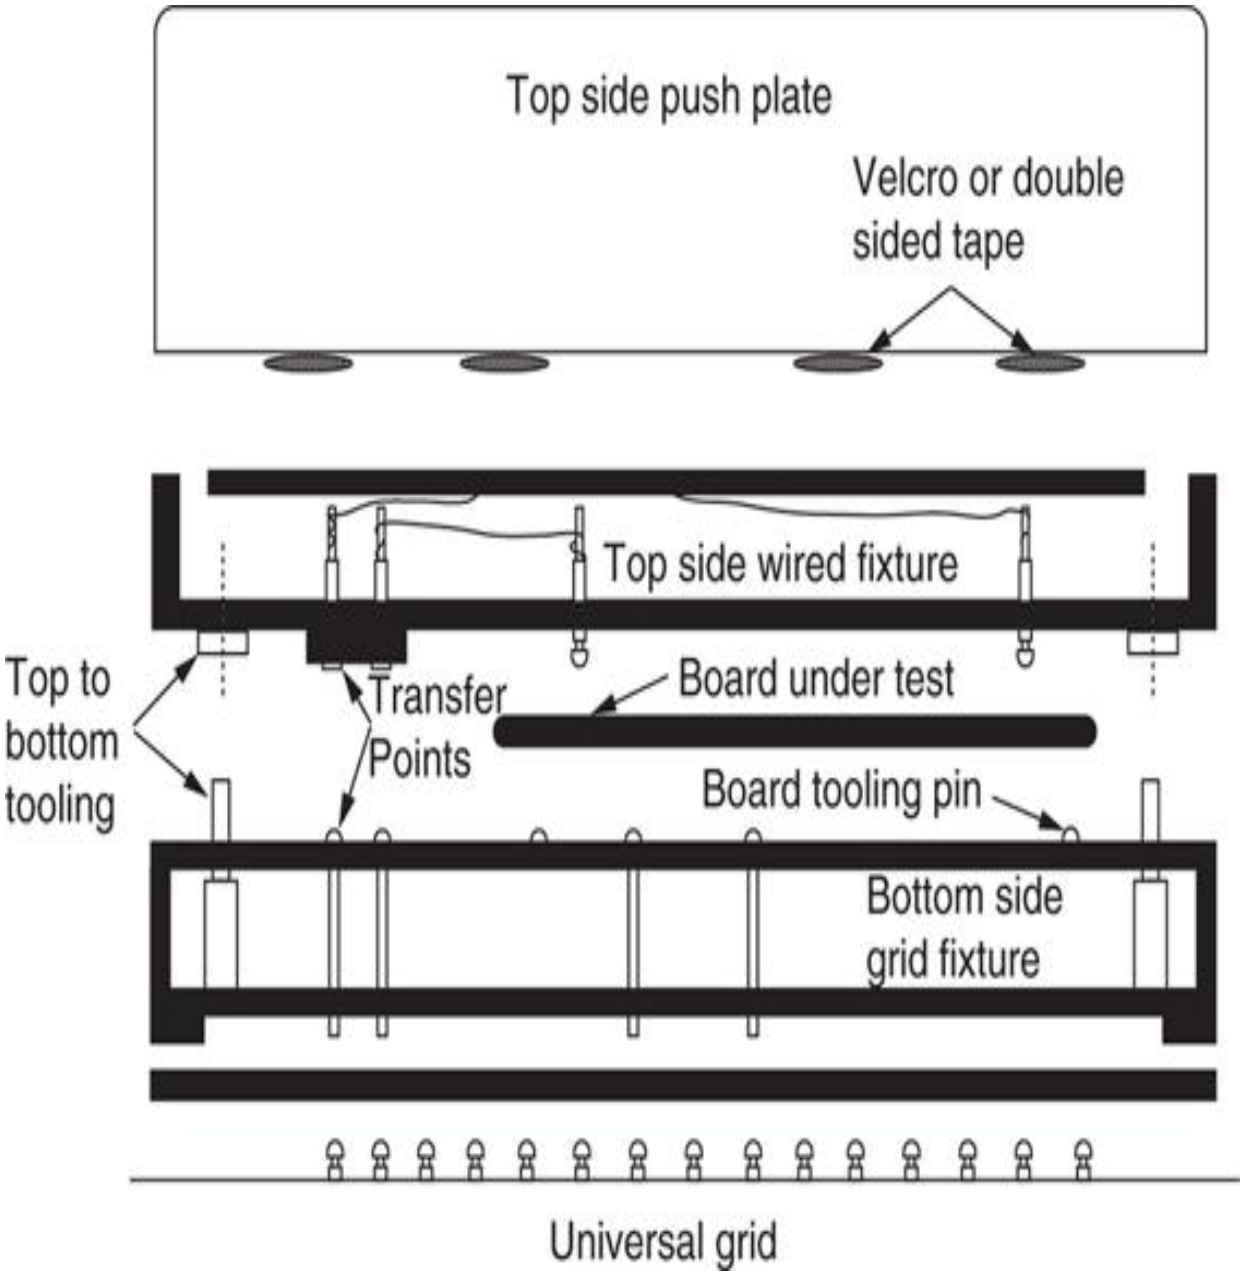

FIGURE 41.17 Transfer point clamshell fixture for dual-side access.

To use this method, it is necessary that the lower grid be larger than the product under test such that a number of transfer test points adequate to provide for the upper fixture can be placed outside the product area. Again, the cost of the extra contact points, spring probes, wiring, and other special material and labor processes associated with the topside fixture may well justify an equipment upgrade.

41.3.4.3 Dual-Side Access Universal Grid. The third and most widely accepted method of providing for volume testing of dual-side product is the double-sided universal grid. Such systems provide electronics and grid probe fields on both the top and bottom sides. Upper and lower translator fixtures are built for dual-side products using the standard techniques discussed earlier, providing economical fixtures, reusable pins and hardware, full fault coverage, excellent throughput, reliable contact, and accurate targeting.

41.3.5 Press Units

The major mechanical component of the grid is a press unit. The three major compression methods used to compress the product onto the fixture are hydraulic, pneumatic, and electric. The total force requirement can be quite large. The spring probes employed in grids usually require a force in the range of 4 to 10 oz. each. A large, complex board may have 20,000 active points per side. This amounts to 5,000 to 12,500 lb. of force, depending upon the probes used.

Hydraulic drive is probably the least used compression method. Although it provides tremendous power, it is difficult to maintain and fluid leakage is a problem. Pneumatic and electric compression are popular and successful. Electric drives are easy to control, but become expensive and/or slow when larger forces are required (as in the case of larger grids). Pneumatic systems are fast and powerful, but require a good supply of clean, dry, compressed air. With any method, accurate compression control is critical to reliable fixture performance.

As noted, universal grids present the test points as an array of spring-loaded contacts. A variety of contact tip shapes have been used, but most contacts used today offer waffle tips.

Waffle tips are nominally flat, but with an *H*-shaped pattern of grooves cut into the surface to provide a somewhat aggressive contact surface. Such a surface is better able to cut through thin contaminants on any surface it contacts.

41.4 FLYING-PROBE/MOVING-PROBE TEST SYSTEMS

Moving probe, flying probe, and x-y prober are all names for test systems that make use of two or more test points that can be accurately positioned anywhere on the board surface by means of a computer-controlled motion system (see Fig. 41.18). Probe tips can be retracted in a z-axis direction away from the board surface, then moved in the x and y directions to a new board location and extended again to make contact. Figure 41.19 shows two probe tips contacting board. Dual-side systems generally provide a minimum of two independently moving probes per side for a minimum total of four heads.

FIGURE 41.18 Flying-probe test system. (*Courtesy of atg Test Systems GmbH*.)

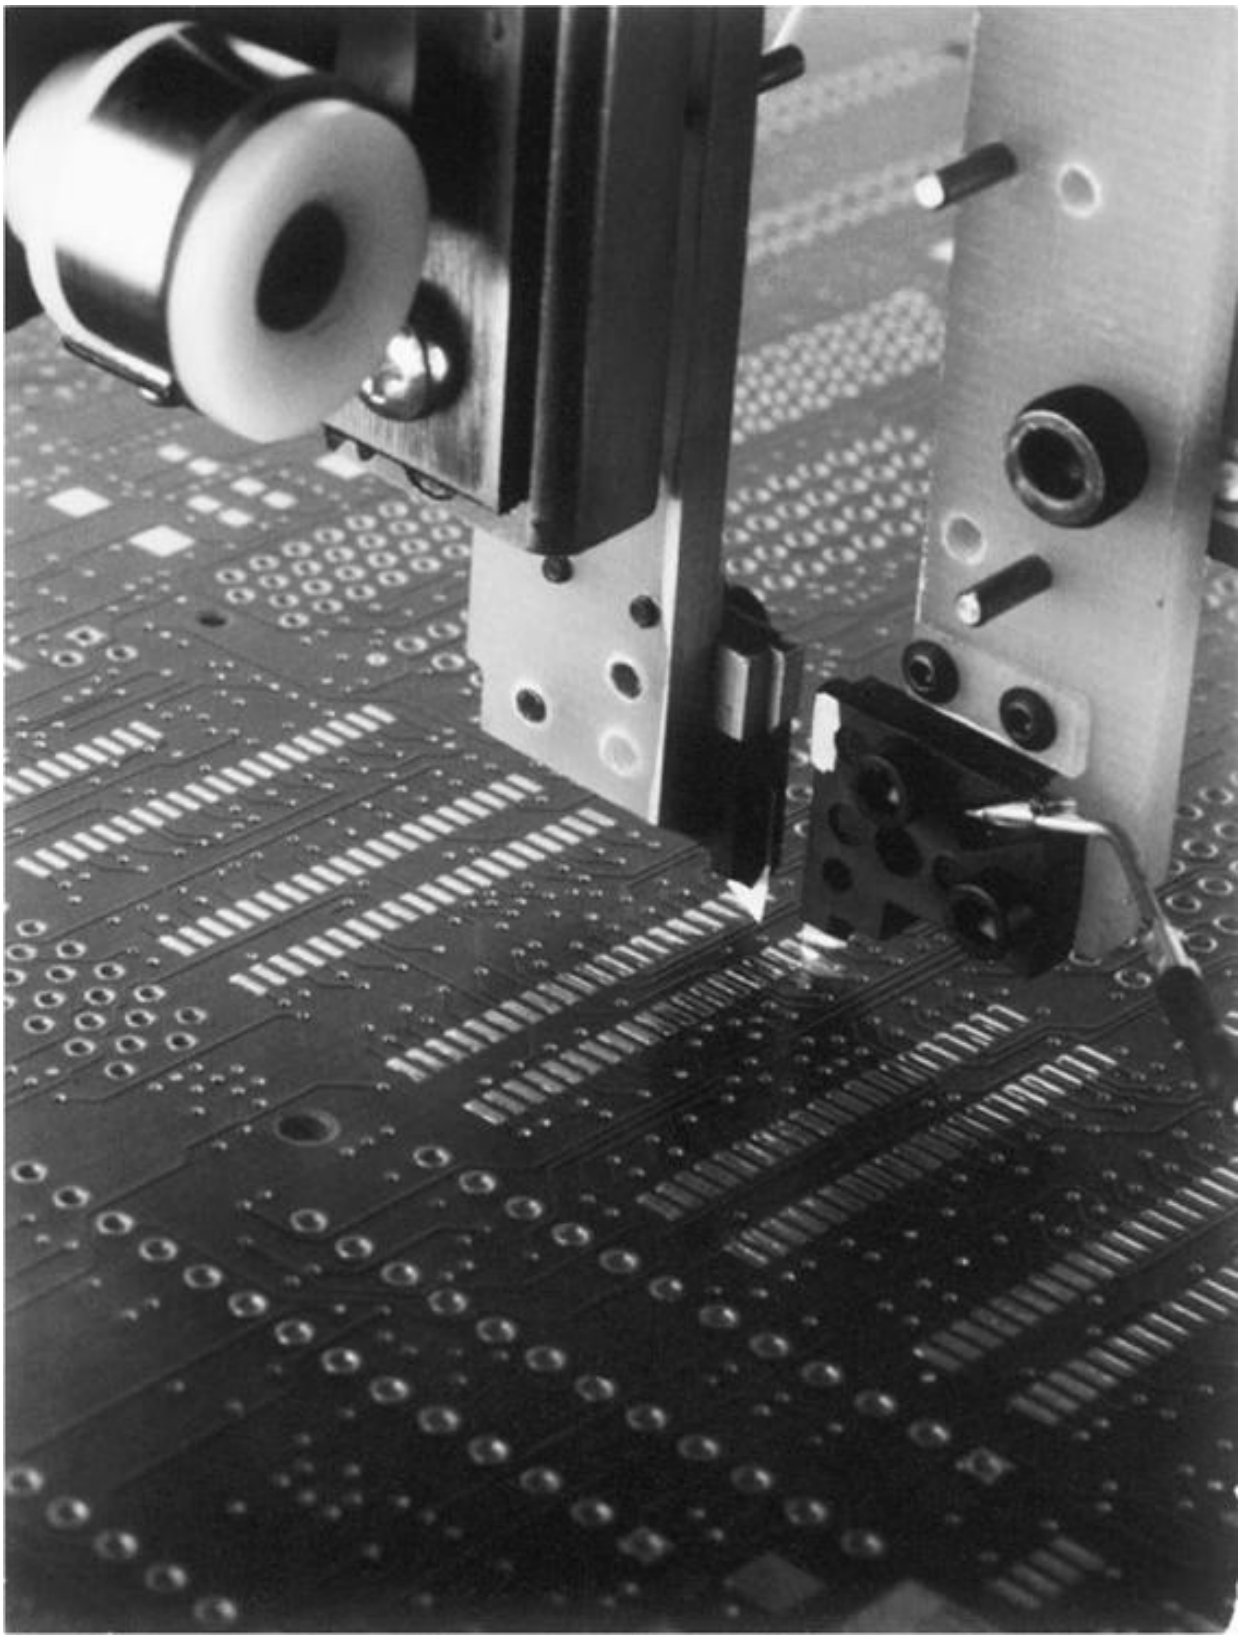

FIGURE 41.19 Two probe tips contacting board. (*Courtesy of Probe Inc*.)

41.4.1 Advantages of Flying-Probe Systems

The major advantage of these systems is elimination test fixtures, making these systems ideal for small-to-moderate volume production. Advanced flying-probe systems provide highly accurate probe placement, and contact the board with minimal force, leaving no discernable witness marks on most surfaces. They are very well suited to testing the finest pad sizes. Although not subject to limitations due to test-point density, these systems do slow down as additional test points are added.

Direct current (DC) continuity test measurements are accomplished by placing one probe tip at each end of the continuity to be verified and performing a measurement. The probes then retract, move to the next measurement site of interest, make contact, and make the next measurement. Similarly, it is possible to perform DC isolation testing of a network by placing one probe (probe A) on the network, while another (probe B) checks all other networks in sequence for the presence of a short or leak. Probe A can then be stepped to the next network to be tested and the process repeated. This continues until each network has been checked against all others.

This requires a huge number of measurements. For a board with N networks, the total number of measurements M required would be:

$$M = (N2 – N)/2$$

For example, a fairly ordinary board with 1,000 networks would require 499,500 measurements. Fortunately, several means of reducing the measurement burden have been developed.

The program preparation software can analyze the conductor pattern on the board and, noting that short

circuits should occur only between physically adjacent conductors, reduce the number of measurements required. This is termed *adjacency analysis*. To achieve further time savings, the testing department might use an indirect measurement method. Please refer to Sec. 41.4.4.

Some indirect methods require only a single probing action of each net, combining continuity and isolation testing with some extra probing to verify any suspect results. Theoretically, our example board with 1,000 networks might have isolation verified with only 1,000 probe placements.

41.4.2 Economics of Flying-Probe Systems

The primary limitation of flying-probe test systems is throughput. Although systems with up to 16 test heads are commonly available, these systems still lose a substantial fraction of the operating time due to mechanical positioning of the heads. Yet the cost savings derived from elimination of direct fixture costs, fixture support infrastructure, fixture debugging, and so on, are substantial.

Accurate comparison of the costs associated with grid and prober methods requires inclusion of all the costs associated with each approach. Common omissions include:

- Labor overhead
- Floor space allocated to fixture storage, materials, and assembly
- Costs outside the test department (such as drilling)
- Stranded investment in completed fixtures, pins, other fixture materials
- Stranded investment in drills and other equipment
- Lost throughput of test systems due to maintenance

- Lost throughput of fixtured systems during fixture setup, debugging, and maintenance
- Peak throughput demand

It is quite possible that, depending upon product mix, a testing department would be made more efficient with a larger investment in capital equipment (in the form of flying probe systems) and a smaller investment in fixtures. With smaller runs and/or smaller lots necessitating frequent fixture teardown/bring-up, this becomes more likely.

41.4.3 Flying-Probe Throughput Enhancement Systems

The tremendous advantages of flying probers for advanced substrates (such as the ability to hit the smallest targets even on large panels, the lack of fixture cost, witness mark reduction or elimination, and fractional ohm measurement) have traditionally been offset by the relatively slow speed of test compared to universal grid methods. As products have included increased amounts of high-density features, test managers find that flying probers are the solution that can reliably contact the smaller features without damaging them. This has provided tremendous motivation for flying-probe manufacturers to find ways to increase throughput.

Recognizing that many of the test targets are easily measured (only a fraction of the sites on most boards presents the majority of the challenge), one new approach uses an extra piece of equipment to prescreen the boards before they are placed on the flying prober, eliminating many of the measurements from the flying prober's task list. This approach is described in this section, with each of the two commercially available models summarized.

In the first case, a row of thousands of regularly spaced sliding contacts moves relative to the board surface,

scanning the surface electrically as a row of scan lines. The contacts are designed to be individually flexible and to apply minimum force, eliminating witness mark concerns for most surfaces. Adjacent to the row of contacts is a planar section of a pliant conductive surface. This surface electrically grounds all exposed conductors on the board that lie beneath any part of the planar area. This conductive plane is fixed in position relative to the row of scanning contacts and extends to within a fraction of an in. of the row of scanning contacts. The relationship is illustrated in Fig. 41.20.

ELIMINATOR
atg
E6

FIGURE 41.20 Flying-probe throughput enhancement system. (*Courtesy of Everett Charles Technologies*.)

As relative motion of the board to the scanning contacts/pliant conductive plane occurs, a high-speed measurement apparatus constantly makes measurements among the scanning contacts and between the scanning contacts and the pliant conductor. For example, if a scanning contact is at one moment making electrical contact at one point end of a network so that another end of the same network is being grounded by the compliant planar surface, then current injected into the scanning contact will fail to increase the voltage of (that is, fail to charge) the network. The pliant planar surface holds the network grounded. Similarly, if two adjacent networks are simultaneously contacted by different scanning contacts, and if at that moment no area of at least one of these networks is grounded by the compliant planar, then it will be observed that at least one of the two networks can be charged to a high voltage and that they must not be shorted together. Software in the prescreening system uses the real-time measurement results to “image” the board and constantly adapt to any shifts in geometry. Thus the system solution is useful for very-fine-pitch substrates appearing in large-panel form.

In a manner similar to the preceding examples, significant portions of most boards may be tested using this apparatus. Some portions of the board usually remain untested, and these measurements are reserved for the subsequent final test by the flying-probe test system. The flying prober also retests and verifies any failures reported by he prescreening system, effectively eliminating most false failures. The resultant speed increase of the combined systems is tremendous, so that true production volumes can be tested. It is important to note that no fixture is required and that both systems provide for true DC measurement of continuity

and isolation. Moreover, because high-density interconnect (HDI) features that are too fine for the scanning contacts of the prescreener are simply passed on to the prober, this solution seems to be appropriate for very advanced substrates.

A second commercially available pre-screening system is very similar, but uses a capacitive measurement made at each time of the finely spaced row of scanning contacts. The overall function is very similar to that just described, except that the alternative of a true DC measurement of continuity and isolation is not provided. For those customers that do not perform such tests with their existing flying probers, this may not prove a significant limitation. For high-reliability applications where DC continuity testing is required the utility of this method may be reduced.

41.5 VERIFICATION AND REPAIR

The test system identifies faults on the board. Assuming that repaired boards are acceptable to the end user and that it makes economic sense to repair boards, a repair process normally follows testing. Because fixture problems, contamination problems, product registration problems, and other issues often result in false error reports, a verification process usually is added between testing and repair. During verification, a technician reads the fault data and makes confirming measurements to determine whether the reported faults are genuine.

If verification of the fault finds that the fault report is valid, the board proceeds through the repair function. If the fault report is not valid, the board may be either retested or directly shipped, depending on customer requirements, in-house policy, etc.

When deciding on a ship-from-verification policy, be mindful of the possibility of multiple defects masking one another (an open hiding a short) or appearing only under the pressure of the fixture. If possible, it may be preferable to perform a complete retest.

In some cases, simple tabletop meter equipment is used for verification, and verification may actually be done at the repair station by the repair technician. More commonly, some form of computer-assisted search-and-display tool is employed. The computer has information concerning the product and test program available, and searches the artwork pattern for areas likely to contain the fault being considered. The resulting risk area is displayed to the operator or superimposed as a visual projection onto the suspect board, simplifying the task of placing meter leads.

Automatic verification may be accomplished by a flying-probe–type system. The flying probe performs a similar analysis, but does the retesting itself and displays a final result. Video camera systems may provide image capture of suspected fault sites, storing the image for subsequent recall at the repair station. Advanced systems may even suggest the repairability of particular fault sites according to user-defined rules.

Figure 41.21 shows an example of a fully automatic verification system and Computer Aided Repair (CAR) station. At the repair station, a display computer similar to that described for verification purposes is used to highlight the proposed repair site to the operator, who performs the appropriate cuts or welds.

FIGURE 41.21 Fully automatic verification system and CAR station. (*Courtesy of Everett Charles Technologies*.)

41.6 TEST DEPARTMENT PLANNING AND MANAGEMENT

In most cases, a new manager inherits a selection of existing equipment, processes, and personnel. Nonetheless, over a period of time, the manager has the same opportunity to shape the test floor operation as does the unlikely individual starting from a clean sheet of paper. To the extent that the past suggests the future, the new manager may expect increased density, finer pitch, higher total test-point counts, decreased tolerance for test escapes, shorter product delivery times, shorter product lifetimes, and larger numbers of smaller batches of boards for just-in-time delivery.

41.6.1 Equipment Selection

Most equipment being purchased for general bare board testing consists of universal grids and flying probers. The increased capabilities of flying probers and increased demand for small lot and prototype testing have increased the number of probers selected. This trend seems likely to continue, but each shop must determine its appropriate solution individually.

A first consideration in selecting equipment lies in recognition of the type of business you anticipate. For very-high-volume production of a variety of part numbers, the universal grid is a likely participant. For medium volumes, considerable savings may result from the elimination of test fixturing costs and delays that can be achieved by combining flying-probe test systems with throughput enhancement systems, as described in Sec. 41.4.3. For prototype or small lot production, a quantity of flying-probe systems may be the best alternative due to the elimination of fixture expense. Dedicated (wired) fixture–type equipment is rarely

demanded due to fixture cost, excepting very simple systems that remain devoted to an extremely high-volume run of a single product type for extended periods of time.

A further important concern is the level of technology that you anticipate. Verify that it does not outrun the capabilities of the fixture or test system types that you plan to use. Plan for change, as the equipment that you purchase must last for several years. Also consider the level of support available from the equipment vendor, including ordinary maintenance service, emergency service, employee training support, and applications support.

For high-volume operations, you can achieve substantial throughput and consistency of operation by adding automatic handling systems to a universal grid system configuration. For prototypes and moderate production volumes, the ability to place a stack of boards on a flying probe system and walk away for an hour or so, rather than wait for a board to come out every three minutes, can result in huge labor savings. Note that some very large, very thin, or very small product types may not be well suited to automatic handling without the use of special carriers or adapters. It may be best to size the automation equipment to handle the major portion of production and leave unusual product configurations on manually loaded equipment.

An often overlooked but practical consideration is maintaining some degree of commonality in equipment and fixtures. It is not uncommon for fixture problems to lead a test engineer to change equipment types several times, resulting in a motley assortment of incompatible (but expensive) test systems but failing to resolve the fundamental underlying issue. With data-driven test processes and automated fault data management in the mainstream, the ability of equipment to share data, fixtures, and operating procedures will decrease cost, increase throughput, simplify training, and enhance opportunities for combinational test solutions. This is harder to achieve with a

random mix of equipment. If this seems to state the obvious, try this experiment: Visit some shops, stopping in drill rooms and in the electrical testing area. Do you see a difference in the assortment of equipment? Department planning should include not only new equipment, but also an exit strategy for old and inefficient equipment that you wish to retire.

41.6.2 Fixtures: Build or Buy, and What Type?

If you plan to use fixtures, the selection of fixtures is probably more important than the choice of equipment on which you choose to run the fixtures. Certainly you must have equipment at least adequate to the fixture, and with sufficient test-point density for the product. This is where a careful evaluation of product technology is crucial.

If the product includes even fairly simple SMT boards, then you should plan immediately for a dual-side capability. If the product includes fine-pitch SMT, dense BGA patterns, and such, then you must consider higher-density universal grids and modern tilt-pin fixtures consistent with the test-site density on these products.

If you plan to build fixtures in-house, recognize that you are creating a complete manufacturing operation. Measurement of complete material, labor, inventory, and overhead costs as well as operating efficiency is critical to effective management of this operation. Don’t just measure how fast you build a fixture, but include measurement of the time it takes to get it running. Consider whether you would be better served by outsourcing fixture fabrication.

Avoid manufacturing multiple styles of fixtures. Ensure that you have an inventory management process that does not run out of pins at midnight, but does not have half a million dollars tied up in obsolete pin inventory. Consider outsourcing at least the more difficult fixtures to specialists.

You may save time, plus gain a partner who provides exposure to alternative techniques and materials.

41.6.3 Selecting Fixture Software

Today’s tilt-pin translator fixture is largely a software product. It should be possible for you to establish a flow of information from your computer-aided manufacturing (CAM) department to the front-end fixture software that automates the design of fixtures and the creation of test programs. (The same goal holds true for processing data to create flying-probe test programs.) A premium tool will pay for itself many times over in reduced fixture scrap, reduced late deliveries, and elimination of test escapes. If you can select a tool that is also used by several fixture outsourcing vendors, you will have a backup supply of fixtures in the event of equipment problems, personnel problems, or workload peaks. If you have special and specific demands for the fixture design, verify that the proposed software package readily supports your requirements. And, as in the case of the test system, evaluate the software vendor’s ability to sustain and support your operations.

CHAPTER 42

HDI BARE BOARD SPECIAL TESTING METHODS

David J. Wilkie
Everett Charles Technologies, Pomona, California

42.1 INTRODUCTION

Printed circuit technology is now being applied to high-density interconnection (HDI) applications that require consideration of new testing techniques. Notable examples include many types of advanced integrated circuit (IC) packaging introduced in recent years, such as area-array devices, ball grid arrays (BGAs), laminate chip carriers (LCCs), and circuit boards employing direct chip attach (DCA) or chip-scale packages (CSPs). In some of these cases, semiconductor dies are being directly attached to a printed circuit surface, and in the case of CSP, the package size is approximately the same as a raw die. Flip-chip die (or CSPs) may be attached to a circuit board by an array of solder balls. Other devices may attach with a peripheral array of wirebond pad sites just outboard of the die area. For

high-pin-count devices, this last example can produce the finest side-to-side test-point pitch as efforts are made to squeeze a large number of contacts onto the limited periphery of the die. The flip-chip or CSP bump array attachment parts generally produce the highest test-point density per unit area. The flip-chip or CSP approaches allow the designer to distribute the solder ball contacts over the full surface area of the die or package. For fixtured test systems, the ability of the tester to provide a sufficient density of test points and the ability of the fixture to achieve the needed pitch and accuracy must be considered.

The general goal of electrical testing for HDI substrates remains about the same—detection of opens, shorts, and leakage, although often with increased concern for latent defects, whose appearance can be made more likely by the fine geometry employed in traces and microvias. The measurement electronics are often the same, and are not further discussed here except for special cases. For some applications, time domain reflectometry (TDR) or other radio frequency (RF) tests are desired, but are complicated by the short signal runs on some of these substrates.

Sensitivity to pad marking is increased as there is not much pad area to mark. Marking that penetrates the metallization layers on the board can affect the chemistry of the solder joint, adversely impacting reliability. It is quite challenging to prepare test fixtures able to test such products on universal grids given the need to minimize witness marks, meet aggressive continuity test threshold expectations, and contact the finest geometries. When HDI parts are tested in panelized form, the very small target sizes combine with potential expansion/contraction issues in the panel construction to place a maximum demand upon test-point positional accuracy within the fixture. The ability of the latest camera-equipped flying-probe systems to locate these targets individually and probe them without

marking combines with the fixture cost savings to make this method of test very attractive, especially as new techniques improve throughput (see Sec. 42.4.3). Because of the high costs associated with HDI fixtures, some fixtured solutions compromise test coverage such that the fixture can be simplified to a practical degree.

42.2 FINE-PITCH TILT-PIN FIXTURES

Many HDI structures can be tested with advanced examples of tilt-pin fixtures. Using such techniques as test pins that taper (see Fig. 42.1) to a very fine diameter at one end, fixtures have been built for devices with pitch down to about 0.010 in., with research and development (R&D) examples at about 0.008 in. These fixtures contain additional plates to support the very thin pins (so they do not buckle under pressure or short to adjacent pins). Those fixture plates very close to the product must be fairly thin, or the closely spaced holes will break out into one another. Such fixtures increase the demand for higher grid densities. These fixtures and pins are moderately more expensive to prepare than standard fixtures, but use similar technologies and processes. Excellent process control is important, as is excellent pin tip symmetry.

FIGURE 42.1 Tapered pin for a fine-geometry fixture.

Areas of the product requiring large numbers of probes are subjected to considerable total force. If no equal and opposing force is applied on the opposite side of the product, bowing or “potato chipping” of the product will occur. Ultimately this can collapse the opposing test fixture, but long before this, the probing accuracy of a fine-pitch fixture will be affected because the product no longer lies in a flat horizontal plane. To avoid this, the fixture software can add support within the opposing fixture, directly opposite the densely probed site. This additional support can be accomplished with a spacer affixed between the top and bottom fixture plates or by using blind pins. Blind pins are ordinary test pins located in the opposing fixture at sites where the top (product side) plate of the probing fixture is not quite drilled all the way through. If a quantity of blind pins equal to the quantity of dense product site probes is employed, then the opposing forces are perfectly balanced in this region.

When dealing with fine-pitch fixtures, the problem of product and fixture registration must be considered. Even if the fixture is manufactured perfectly, the product may not align. Because the tooling features of the product (edge or tooling hole) are added in a process separate from the artwork production, the artwork and tooling features are usually misaligned. With HDI substrates, it doesn’t take much for this error to move pads completely away from the assigned test pins. To overcome this, a variety of test systems are available with optical and/or electrical means of sensing misregistration. Movable plates in the fixture are controlled by servomotors, which reposition the product through motion of the tooling pins. As the product grows in size, or as the manufacturing process deteriorates, the registration errors may not be sufficiently constant over the product area to permit the use of motorized alignment. In

this case, none of the probe-per-pad fixtured approaches may be effective.

42.3 BENDING BEAM FIXTURES

Bending beam fixtures are somewhat similar to tilt-pin fixtures, except that they use extremely thin test pins manufactured from a special alloy. As in the tapered pin fixture, a significant number of thin supports are required near the product, where the pin tends to be held fairly straight to avoid conflict with other nearby pins. These pins are not held rigid, but are expected to buckle under force. This buckling displaces the pin sideways. The buckled portion may be located at some distance from the product plane, where the probes can be more widely separated. Once the pin has buckled, the force applied to move through a substantial travel is constant. This is very different from the case for a spring probe, where the force increases at a constant rate determined by the spring constant. Bending beam fixtures provide good immunity to witness mark damage. The basic technique has been in use in specialty situations for many years.

At the interface side, these pins may mate to spring probes instead contacting a rigid contact surface. In some commercial examples, the pin continues away from the product as a piece of wire routed to widely spaced contacts on the interface portion of the fixture. These in turn interface with traditional spring probes. Within the fixture, the probe wire is bonded in place at some distance from the product, defining the separation between the probe and wiring portions of its overall length. Such fixtures are quite expensive, and replacing damaged probes can be challenging. Thus, this technique is usually restricted to small areas and limited test-point counts.

42.4 FLYING PROBE

The more precise examples of flying-probe systems are very well suited to HDI testing. With on-head optical pattern recognition guiding the probe tips, they can contact extremely small targets—even in the presence of significant product registration problems. They can probe small features without marking or disturbing the surface. These systems can be equipped with true Kelvin contact tips supporting effective single-measurement fractional ohm testing, well suited to the sort of fractional ohm continuity test that may be desirable in efforts to detect precursor phenomena to latent defects caused by cracks or other geometry problems. The principle drawback is, of course, test speed. Used alone, these systems are ideal for prototype or small volume production applications where fixture production would be quite expensive. Used with throughput enhancement systems as described in Sec. 42.4.3, these systems can accommodate moderate production volumes.

42.5 COUPLED PLATE

In a situation where most of the target product is relatively easy to fixture, but a DCA or CSP site is difficult, it may be possible to use coupled plate–type testing. A variety of proprietary products are available, but the basic technique is fairly similar. The primary assumption is that each signal network arriving at the DCA or CSP site is accessible by a traditional probe at some other site on the board. These probe sites are used to perform a normal isolation test of the product. Continuity testing of most of the board is performed in the usual manner also.

To verify the continuity of the signals to the DCA or CSP site, a small metal plate or antenna is suspended just over the site, perhaps insulated from the site only by a thin dielectric. One at a time, the standard probe sites are used to inject some sort of alternating current (AC) signal or pulse into each network in turn. If the network is properly continuous to the DCA or CSP site, then a signal of appropriate amplitude is detected at the antenna. Substantial deviation from the proper amplitude means that something is wrong. The different methods vary in terms of the applied signal, antenna characteristics, and so on.

This method eliminates the need for super-fine-pitch probing at the DCA or CSP site and also avoids marking of the product at this site. However, the test does not perform a true DC test of continuity and may miss high-resistance connections, which would be detected by a low-threshold DC continuity measurement. Signals that loop from one DCA or CSP pin to another and go nowhere else may be untestable as there is no outboard probe site at which to inject the test signal.

42.6 SHORTING PLATE

This method is employed in circumstances similar to the coupling plate method just described. In this case, however, the plate must be movable during the test. Generally, a pencil-sized pneumatic actuator is mounted within the test fixture to accomplish this motion. The plate employed here is a small flat metal plate that is the size of the DCA or CSP site and covered with an electrically conductive rubber (see Fig. 42.2). When pressed against the product, it shorts together all of the pads at the DCA or CSP site. Continuity testing is performed in this condition by using the outboard probe sites to confirm that all of these (otherwise isolated)

networks are shorted together via the path to the DCA or CSP site. All other networks are tested normally for continuity. Then the shorting plate is removed and a normal isolation test is performed. Key advantages of this method are the accomplishment of true DC measurements for both isolation and continuity and the use of standard bare board test systems.

FIGURE 42.2 Pneumatically actuated shorting plate.

In some applications, there is concern about any trace chemicals that may be left behind by the conductive rubber, although outright marking is minimal. Cleanliness of the product is critical, as the rubber or plate must be replaced

when excessive dirt is embedded. As with the coupled plate, certain signal topologies are untestable or difficult to test. Signals that loop from one DCA or CSP pin to another and go nowhere else are untestable, as there is no external probe site with which to verify either continuity (to the DCA or CSP shorting pad) or isolation. Any signal that connects two DCA or CSP pads on the same package may be partially untestable, even if the signal continues to an external probe site. In this case, it is possible to verify that the external signal arrives at the device, and it is possible to verify isolation of this segment. But there is no simple way to discern whether the two device pads are joined to each other. (If they are already shorted together on the board and engaging, the conductive rubber has no effect.) This latter case may sometimes be mitigated by segmenting the shorting pad, such that each of the target device pads is in a separate segment. Then, if the connection on the board is good, the halves will be joined through the board.

42.7 CONDUCTIVE RUBBER FIXTURES

Several designs for fixture systems employing conductive rubber as the basic probe element have been offered commercially. In some cases, the rubber is a specialized material in sheet form and is conductive only in the z-axis (through the thin sheet vertically, but not sideways across its surface). The fixture is itself made from a circuit board, with slightly raised pads to compress the rubber tightly against desired product sites. The fixture board connects to the grid electronics at its reverse side. Other designs have included various types of locally deposited rubber dots, usually of conductive rubber that is not sensitive to orientation. Again, a rubber probe is formed. Problems with

cost, complex manufacturing, complex repair, dirt sensitivity, and suitability to very small pad areas (which limit contact quality to the rubber) seem to have prevented widespread adoption.

42.8 OPTICAL INSPECTION

Optical inspection has been discussed elsewhere (Chap. 30). It is generally applied early in the fabrication process as a yield improvement and data collection tool, not as a means of final product qualification. However, with improvements in resolution, the type of defect that may escape undetected becomes somewhat more limited, and optical inspection is argued as a possible means of final testing.

With complex multilayer product, optical inspection will not be able to identify assembly/contamination-induced defects internal to the board in any case, and may still be limited in cases of contaminants or very fine-geometry shorts and opens on external layers. The equipment is somewhat slower than universal grid test systems, particularly when run at very high resolution. For such reasons, it is still not common practice to employ optical inspection (by itself) as a substitute for electrical testing. This may be a method that develops further in the future or that finds acceptance in special circumstances.

42.9 NONCONTACT TEST METHODS

Quite possibly the greatest daily irritant (and cost) in the operation of a typical test area today revolves around the cost of building test fixtures. Customers still hate to pay for them, and the creation of fixtures burdens the board shop

with an entire manufacturing process that seems to add no value and that distracts from the main productive purpose of the factory. The only fully effective commercially available systems that require no test fixtures are flying-probe test systems and the related throughput enhancement systems. In addition, extensive work has been done by several organizations to attempt to develop alternative noncontact means of fixtureless test. To date, no fully successful noncontact method has yet emerged with a capability for parametric measurement of the normal range of both continuity and isolation, yet some brief description of various techniques seems warranted.

42.9.1 Electron Beam Methods

When a test system contacts a product with an electromechanical contact, it uses this contact to inject or remove electrons. That is, current flows. The sort of electron beam common to the picture tube in a television might be used to do the same thing without contacting the product physically. Experimental systems have been built by several firms to date, but have shared some common problems. First and foremost, the amount of current delivered by the electron beam is so small that only a very poor continuity test is possible. Increased interest in fractional ohm and/or high-current testing to detect latent continuity defects runs counter to this limitation. Lab systems have been limited to continuity thresholds of 100,000 ohms or more, and this only very slowly. As most users wish to test at 10 to 100 ohms, this is a major compromise. (A smear of contaminant across an open circuit would appear to be a perfectly good conductor.)

Test speeds are affected by product capacitance, as a longer time is required for the limited current to achieve significant voltage effect in a highly capacitive environment.

Also, such systems must operate in an extremely high vacuum of laboratory grade. Expensive pumping systems are required. Costly air-lock systems with multiple stages and robotic product handling are probably required to keep any reasonable flow of material through the system. (Staging product in and out through a series of chambers avoids the time delay of constantly pumping down the main chamber when loading new product.) At the present time, flying-probe systems seem to offer superior test and measurement coverage at more practical operating costs.

42.9.2 Photoelectric Methods

Subjecting a metal surface to an intense beam of light, such as that from a laser, can cause electrons to be ejected from the metal. As in the case of the electron beam, a very small current flow can be induced. Again a vacuum is required (so that the ejected electrons can be measured before they collide with air molecules), though the vacuum requirement is less stringent than that for the electron beam technique. The resistance at which continuity measurements can be made is quite limited, as in the case of the electron beam. (See discussion of electron beam method in Sec. 42.9.1.) Again, test speed suffers due to product capacitance. No practical system has resulted from investigative work.

42.9.3 Gas Plasma Methods

Fluorescent light bulbs emit light because a gas is subjected to an electric field, which adds energy to the electrons orbiting the gas molecules until some break free. As they attempt to reattach themselves to the gas molecules, they eject their excess energy as photons (light). The plasma consists of a mixture of gas molecules, ionized gas

molecules (missing electrons), and free electrons. In this state, the gas can conduct an electric current. If a jet of plasma is directed from a small nozzle to the surface of a circuit board, the effect is that of building a “gas probe.” In broad terms, the gas probe can be used just as any other probe or test is completely possible.

Generally a noble gas such as argon is used. The gas residue is nontoxic, only a tiny amount of gas is consumed, and substantial current can flow to the product. Several companies have developed experimental systems in the form of flying-probe systems.

Although gas probes offer the benefit of little or no product marking, it is difficult to achieve one that is as fine as the best mechanical probes. Adjacent jets tend to combine, producing a short circuit just as if two mechanical flying-probe tips shorted while testing. Thus, the commercial system offered to date includes completely traditional mechanical probes as well, using these to probe closely adjacent (i.e., HDI) sites. As a flying-probe mechanism is still used, there is little speed advantage to date. Eventually some benefit may be obtained due to the elimination of any wait time for z-axis travel of the prober head, although this is already the fastest motion axis of most flying-probe systems. The cost of this technique is modestly higher than that of an ordinary flying prober.

42.10 COMBINATIONAL TEST METHODS

One technique that offers immediate practicality in resolving difficult testing situations for high-density product —often using existing equipment—is generally described as combinational testing or sequential testing. As the name

implies, this is testing in one or more stages, using a combination of test techniques. Combining techniques inevitably adds complication. The simplest example is the use of a universal grid to test the majority of a product, followed by a flying probe system to test HDI features and reverify the failures reported by the grid. Software tools have simplified the process of combining test methods.

PART 8

ASSEMBLY, SOLDERING MATERIALS, AND PROCESSES

CHAPTER 43

ASSEMBLY PROCESSES[a]

Happy T. Holden
Co-Editor-in-Chief, Printed Circuits Handbook, *and PCB Technologist, Zeeland, Michigan*

43.1 INTRODUCTION

The electronics “revolution” has been sustained through the development of products having increased miniaturization, enhanced functionality, improved reliability, and reduced costs of manufacturing. In fact, innovations in electronics assembly methodologies have kept manufacturing costs low with each new generation of product.

43.1.1 Feature Density

Product designers have been able to explore new packages, materials, etc., so as to increase functionality further while, at the same time, reducing the size and weight of both consumer as well as high-reliability military and space electronics. The result has been greater challenges for

process engineers. For example, there is a continued trend of decreasing component sizes. Leadless ceramic chip capacitors having sizes of 0804, 0603, and 0402 are commonplace, whereas smaller 0201 devices are being introduced into product lines, particularly handheld products. Manufacturing resources are now developing the means to tool up for 01005-size components. Fine-pitch and area-array packages—ball grid array (BGA), chip-scale packages (CSP), and flip-chip (FC) or direct-chip attach (DCA)—provide the means to increase device functionality significantly. Input/output (I/O) interconnections that are reaching several thousands on BGA packages require stringent solder paste printing, part placement, and reflow processes controls to minimize defects. At the same time, the need for more complex, multilayer substrates has also placed limitations on the process window so as to avoid damage to circuit board microvias and fine traces that are needed to support higher assembly densities. Lastly, these challenges are made more complicated by the use of Pb-free solders. Changing equipment parameters as well as alternative surface finishes impact solderability performance and thus process yields as well.

43.1.2 Printed Circuit Board Assembly Process

There are two basic steps in the assembly of a printed circuit board: (1) placement of the components (resistors, capacitors, etc.) on the substrate and (2) soldering those components into place. Although this is a fairly accurate description of a through-hole, hand-soldering operation, nearly all electronics assembly operations are, in fact, considerably more complex. Multiple-step assembly processes provide the versatility to incorporate different component package types and a wide variety of substrate

configurations and materials as well as to accommodate frequently changing production volumes in order to meet prescribed defect levels and reliability requirements. A more accurate, albeit still relatively general, listing of assembly process steps consists of the following:

- Preparation of the component and substrate surfaces to be soldered
- Application of the flux and solder
- Melting of the solder to complete the joint
- Postprocess cleaning of the soldered assembly
- Inspection and testing

Some of these steps may be either combined together or eliminated, depending on the particular product line.

It is important that the manufacturing engineer and operator understand the critical steps in the printed circuit board assembly process to ensure the manufacture of a cost-competitive, reliable product. That understanding includes both the general function of the equipment as well as the activity taking place *inside* the machines. The following sections of this chapter describe in detail the printed circuit board assembly processes.

43.1.3 Assembly Process Categories

Assembly processes can be placed into the following three categories, which are described by the types of circuit board components:

1. Through-hole technology
2. Surface-mount technology
3. Mixed technology, which is a combination of through-hole and surface-mount components on the same circuit board

Within each of these assembly technologies are different levels of automation that equipment resources offer. The degree of automation will be optimized, depending on the product design, bill of materials, capital equipment expenditures, and actual manufacturing costs.

It is important to remember that through-hole printed circuit boards and their assembly processes remain a critical technology in the electronics industry, albeit clearly not at the same production volumes as experienced before the advent of surface-mount technology (SMT). Through-hole technology may be used because it is the only format available for some components, particularly large devices such as transformers, filters, and high-power components, all of which require additional mechanical support that is offered by through-hole interconnections. A second reason for using through-hole technology is economics. It may simply be more cost-effective to use through-hole components, together with manual assembly (i.e., no automation) to produce an electronics assembly. Of course, through-hole technology is not limited to manual assembly. There are varying degrees of automation that can be used to assemble a through-hole circuit board.

43.1.4 Pb-Free Technology

The introduction of Pb-free technology has not changed, per se, available electronics assembly processes (reflow, wave, hand soldering, etc.). However, it has caused manufacturing engineers to reassess the parameters used in those processes because of two factors: (1) higher process temperatures required by Pb-free solders, and (2) the poorer solderability of these alloys (owing largely to the absence of Pb). With respect to the five general process steps noted previously, the use of Pb-free solders primarily affects steps 3, 4, and 5.

The need for higher processing temperatures limits the assembly “process window” of Pb-free solders. A higher *nominal* temperature is needed to accommodate the temperature variation at components across a circuit board to ensure melting of the solder and adequate wetting and spreading at each interconnection. On the other hand, the maximum temperature must be limited to prevent thermal damage to heat-sensitive devices and the circuit board.

The poorer solderability of the Pb-free solders presents several challenges as well. Although the longer time needed to heat the component lead or termination and circuit board is often cited as the underlying source of poor solderability for Pb-free solders, it is primarily the higher surface tension of the Sn-based alloys (in the absence of Pb) that restricts wetting and spreading behavior. The need for longer heatup times is a particular issue with “faster” assembly processes such as wave soldering and hand soldering. However, the intrinsically poorer solderability impacts all assembly processes because it can degrade the quality of hole fill and fillet development for both short and relatively long (e.g., reflow) assembly processes.

The intrinsic solderability performance of Pb-free solders is being improved by two means. First, new flux formulations are available that more effectively reduce the surface tension of the solder. Second, alternative surface finishes can be specified for the component I/Os and/or circuit boards that improve wetting and spreading activity exhibited by the Pb-free alloys.

Strictly from an assembly process point of view, the mixing of Pb-free and traditional Sn-Pb solder can be beneficial. The Sn-Pb solder can improve the wetting and spreading performance of the Pb-free solder by two phenomena. First, Pb contamination lowers the molten solder surface tension of the solder. Second, the Pb contamination reduces the melting temperature of the Pb-free alloy. However, concerns are raised by the mixing of Sn-Pb and Pb-free solders and its

effect on the long-term reliability of interconnections under thermal-mechanical fatigue environments.

Lastly, the use of Pb-free solders impacts the postassembly cleaning step (step 4) and the inspection step (step 5). The higher process temperatures can produce more tenacious flux residues that require more aggressive cleaning steps to ensure their removal. Also, the more tenacious residues affect the ability of test probes to contact test site pads on the circuit board. Poor contact can be responsible for detecting false opens on the assembly.

43.2 THROUGH-HOLE TECHNOLOGY

Through-hole technology refers to assemblies having components with leads that are inserted into holes in the circuit board and soldered into place. This technology has been used since the early days of electronics (the 1920s). The leap in automation came in the early 1960s with the advent of wave soldering. The particular drawback of through-hole printed circuit boards, which led to the introduction of surface-mount technology (see the next subsection), was low assembly densities. The relatively large devices, and the circuit board real estate required for holes, limited the density of components, which in turn restricted product functionality and further miniaturization. A photograph of a through-hole circuit board is shown in Fig. 43.1 along with an optical micrograph that shows the through-hole solder joint of the component lead extending through the circuit board.

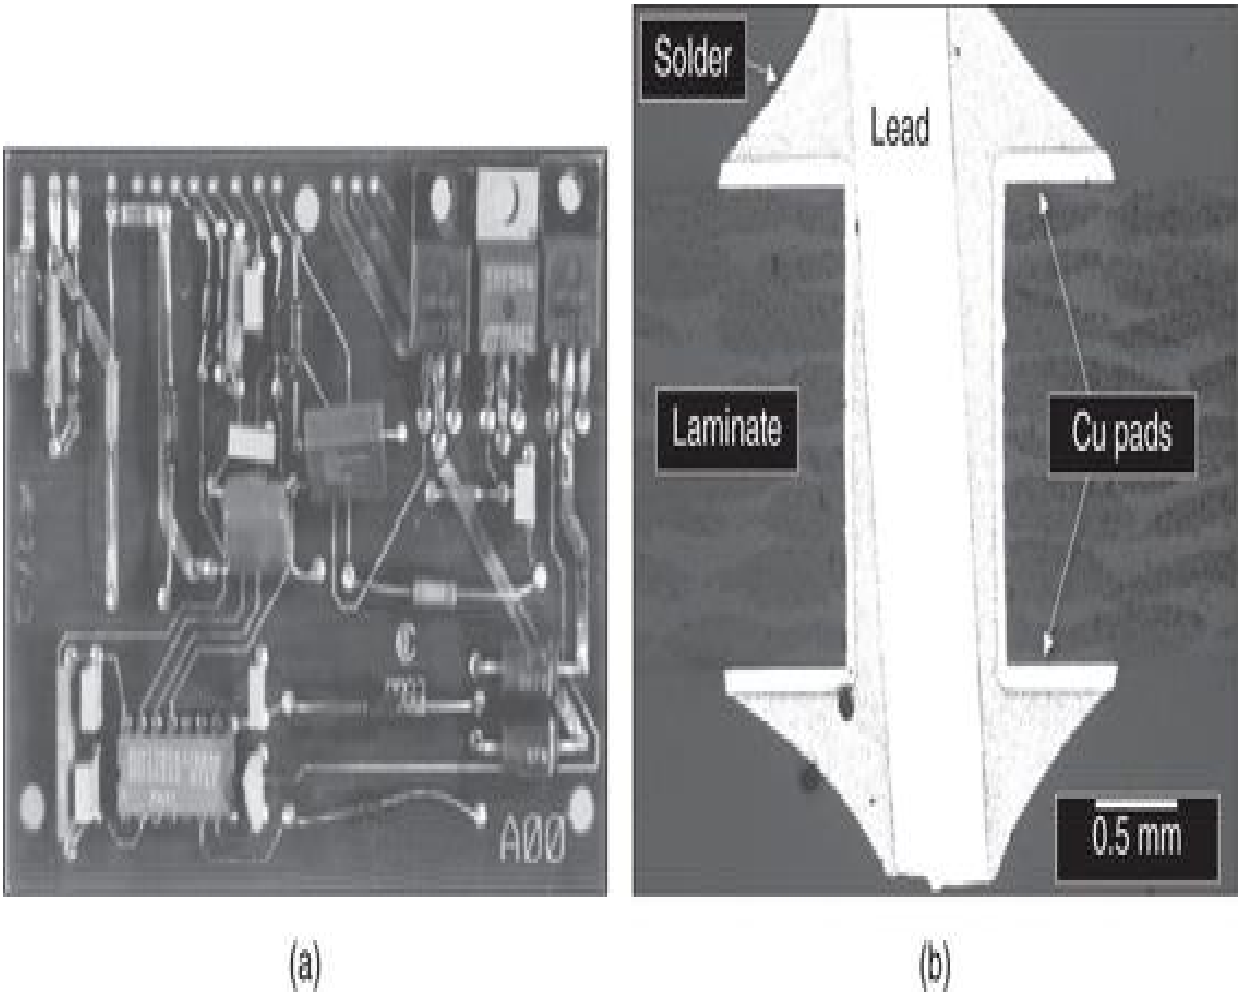

FIGURE 43.1 (*a*) Photograph of a through-hole printed circuit board; (*b*) optical micrograph of the component lead as it is soldered into the circuit board hole. (*Courtesy of Sandia National Laboratories*.)

An advantage of through-hole technology is reduced cost in some applications. That cost benefit may be realized by lower labor costs in some parts of the world that support hand assembly, which is relatively easy with the larger components and products, and lower board densities. Even when fully automated—either by wave soldering, selective soldering, or paste-in-hole/reflow—the capital equipment and manufacturing costs can still be lower than those required for surface-mount assembly.

43.2.1 Impact of Pb-Free Soldering on Through-Hole Technology

The change to Pb-free solders affects through-hole assembly technology. First, there is equipment selection. Manual assembly operations may require purchasing higher-temperature soldering irons. At the other end of the cost spectrum, there are the expenses to replace several hundreds of pounds of Sn-Pb solder with a Pb-free alternative in the pot of a wave-soldering machine. Alternatively, it may be advantageous simply to purchase an entirely new machine to avoid cross-contamination with legacy Sn-Pb operations and/or to have the latest technology that mitigates the higher erosion activity of Pb-free solders on machine components.

The use of Pb-free solders also requires a review of the process parameters. The specific aspects are the higher processing temperature required to use Pb-free alloys and the reduced solderability of these alloys. It has been fortuitous that Pb-free solders, when used in manual (soldering iron) and wave processes, have not required a very significant increase in soldering iron temperature as was first anticipated in the early stages of Pb-free technology development. The added temperature margin was of least concern with manual soldering processes because the localized heating limits thermal degradation to either the component or substrate. Some concern arose in the wave-soldering process because the substrate is exposed to the molten solder bath. On the other hand, paste-in-hole technology that uses a Pb-free reflow process subjects through-hole components and substrates to temperatures higher than those to which they are normally accustomed, thereby possibly degrading them.

The soldering of a through-hole interconnection is also susceptible to the intrinsically poorer solderability of Pb-free

alloys. The higher surface tension of these solders results in a slower flow of molten alloy between the pin and barrel, thereby potentially requiring a longer soldering time. Also, the poorer solderability can result in reduced wetting of the pad and limited fillet formation, particularly on the opposite side of the circuit board to which the joint is being soldered. Some of these solderability issues can be mitigated by changing flux and/or the use of alternative surface finishes (e.g., Au solderable finishes). Both options can reduce the solder surface tension as well as enhance the base material metallurgical reaction, thereby improving solderability.

43.2.2 Design Considerations

The design of a through-hole printed circuit board must necessarily consider currently available equipment and assembly practices as well as the potential for advances in future machines and processes. It is important that circuit board designs comply, as much as possible, with recommendations provided by industry standards, such as those of the IPC Association Connecting Electronics Industries (IPC) and the Joint Electron Device Engineering Council (JEDEC). These recommendations include hole diameters, trace dimensions, and feature spacing. The overriding document is the specific product drawing. Any design deviations from industry standards must be fully considered with regard to how such changes will affect the assembly (process).

The following are important design considerations regarding the assembly process for a through-hole printed circuit board products:

- Tooling requirements (holes, edge clearances, etc.)
- Registration holes (manual alignments or vision systems)
- Component lead-hole sizes

- Circuit board dimensions (length, width, and thickness)
- Size and density of components
- Pb-free solders

Three of these factors are discussed below because of their general role on all assembly processes.

43.2.2.1 Component Lead and Circuit Board Hole Sizes. Designing the correct component lead hole diameters begins by referring to the appropriated industry standard(s) [e.g., IPC, Electronic Industry Association (EIA), etc.]. Hole tolerances must take into account run-out by the drill, etch-back, barrel-plating thicknesses, and the need for a nominal gap of 0.07 to 0.15 mm between the pin and hole to support the capillary flow of the molten solder. In addition, there are added tolerance considerations due to the variation in component lead diameters as well as the positioning accuracy of the equipment.

43.2.2.2 Circuit Board Dimensions (Thickness). The thickness of the circuit board is typically governed by the product design and the number of layers required for signal routing. Thickness has minimal direct impact on the ability of automated machines to accept a circuit board physically. (The same is true of hand soldering.) However, the board thickness affects the soldering process. As thickness increases, it becomes more difficult to supply a sufficient amount of heat to the joint area that allows the molten solder to fill the through-hole completely prior to solidification. Copper layers contained within the laminate, which are used for signal transmission, ground planes, radio frequency (RF) shielding, and power sources as well as layers for thermal management, act as additional heat sinks that can impede the flow of molten solder into the hole.

43.2.2.3 Pb-Free Solders. Design rules and industry standards that have been established are based primarily on experiences with eutectic Sn-Pb solder. Studies are investigating through-hole processes for Pb-free solders. Part insertion, equipment tooling considerations, even paste placement for paste-in-hole technology will be largely unaffected by the change of solder alloy. As noted previously, in spite of the higher liquidus temperature, hand-soldering iron tips and wave-soldering pots will use similar temperatures. The design engineer will have to address the generally poorer solderability of Pb-free alloys, which arises from the higher surface tension of the solder. Flux selection and alternative surface finishes can mitigate this discrepancy to some degree. Other measures may be necessary. For example, the designer may be required to increase the spacing between components in order to avoid solder bridges that cause short circuits during wave and selective soldering. The high Sn content of Pb-free solders results in a greater degree of erosion of the Cu features on the circuit board. This phenomenon is particularly severe at the knee of the through hole when the molten solder is highly agitated such as in a wave-soldering or selective soldering machine. Therefore, it may be necessary to reduce the time that the joint is exposed to the molten solder or to select an alternative Pb-free alloy (Sn-Ag-Ni or Sn-Ag-Ni-Ge) that is less prone to Cu erosion.

43.2.3 Assembly Process

The through-hole printed circuit board can be a cost-effective technology for many applications. One determining factor is the level of automation used to make the product, which can range from hand assembly to fully automated processes (inline or batch). The specific assembly steps include component insertion (also referred to as “board stuffing”),

lead trimming, soldering, and postassembly cleaning. Labor costs, capital expenditures, board design, and production volumes are contributing factors toward determining the details of these steps.

There are two general formats for assembly processes: the cell or batch process and the line process. Both methods are discussed in the following subsections.

43.2.3.1 Cell (Batch) Process. The cell process routes the circuit boards in batches between the different steps. The cells or workstations are not always in immediate proximity to each another and can be entirely manual, semiautomated, or fully automated in terms of the actual process step. For example, component placement may be fully automated, but require several machines for inserting the different component types. Circuit boards are typically loaded and unloaded by hand between machines. Table 43.1 lists the advantages and disadvantages of the cell process. The cell or batch process is best suited for a facility that assembles a high mix of low production volume products (e.g., prototype development or high-reliability circuit boards) where flexibility is necessary on the factory floor.

TABLE 43.1 Advantages and Disadvantages of the Cell Process

Advantages	Disadvantages
• Single machine outage does not immediately stop the entire process line.	• Higher product flow time due to the transfer of parts between cells is unattractive for high volume applications.
• Adds greater flexibility to the process by creating alternative routes.	• Part transfer between cells increases the likelihood of handling damage workflow
• Attractive for high-mix, low volume applications that require frequent equipment change-outs and retooling.	• Difficult to predict product line throughput in a multicell assembly process.

43.2.3.2 Line Process. The second approach is the line process, where the different insertion machines, as well as the soldering process in some cases, are linked together with automatic board-handling equipment. Table 43.2 lists the advantages and disadvantages of the line process line. The line process is best suited for a factory floor where high production volumes (e.g., consumer electronics) and a low mix of product types are typical of the manufacturing operations. Less versatility is required by assembly processes, which justifies the capital equipment expense.

TABLE 43.2 Advantages and Disadvantages of the Line Process Line

Advantages	Disadvantages
• Improved manageability of material inventory, product flow, and operator resources is attractive for high volume, low mix applications.	• Failure or maintenance outage of a singe machine failure can potentially halt an entire assembly line.
• Shorter process times by eliminating the transfer of parts between machines	• Reduced equipment flexibility is unattractive for high mix assembly.
• Reduce the likelihood of handling damage to the assembled product.	• Capital equipment costs and fixed floor space requirements are critical considerations.

The configurations of most through-hole components fall into one of three geometries: axial leaded, radial leaded, and dual inline pin (DIP) packages. These traditional configurations are used for resistors, capacitors, transistors, crystals, and, in the case of active devices, the DIP package. There are also odd-form packages for devices such as transformers, switches, and relays. New package configurations such as the pin grid array (PGA) are being developed to accommodate the increased functionality and further miniaturization of active devices. Besides the actual

component body size, shape, and lead configuration, the other factor that can impact the through-hole assembly process is the lead finish. First of all, the finish can potentially add significantly to the diameter of the lead, which must be taken into account when considering the tolerance budget for the hole in the board design. Secondly, for hot solder dipped leads, the potential accumulation of solder at the end of the lead can interfere with part insertion.

The Pb-free alloys can impact the hand-soldering assembly process. First, the higher melting temperature of these alloys requires a slightly longer soldering time. In the case of hand soldering, tip temperatures designated for Sn-Pb process can be used for the Pb-free soldering of traditional through-hole designs. However, hotter tips and/or irons with a higher power rating may be required for “borderline” designs such as those having bigger component leads or thicker circuit boards. Secondly, the Pb-free solders have a higher surface tension that tends to slow wetting and spreading on surfaces as well as capillary flow into holes. For example, the Pb-free solder may not fully coat pad surfaces on the opposite side of the circuit board. Third, the high Sn content of the Pb-free solder increases the rate of erosion of the soldering iron tip, wave-soldering machine parts, and the Cu features on the circuit board.

43.2.4 Hand-Soldering Process

The sequence of steps used to hand solder a through-hole circuit board varies somewhat between different applications. First, there is part insertion. If the insertion operation is fully manual, the parts will be “kitted” into specific groups: The first group is inserted and then soldered; the second group is inserted and soldered; and so on. The order of the groups is determined so as to maximize throughput as well as to take into account human factors in

order to minimize part error, lead damage, and operator fatigue or inattention. In semiautomated processes, the operator may receive the circuit board for soldering that was partially or fully populated by machine.

Next, there is the soldering step. The location of the joint where soldering is performed depends on the architecture of the circuit board. For single-sided boards without a plated through-hole, soldering must be performed on the component side. On the other hand, in the case of double-sided and multilayer circuit boards with plated-through holes, soldering is typically performed on the bottom side in order to avoid potential heat damage to components by the soldering iron, particularly on densely populated circuit boards.

The hand-soldering process proceeds as follows:

1. The operator applies flux to the joint. The soldering iron tip is contacted to one side of the component lead (see Fig. 43.2). The tip should not contact the circuit board pad, if possible. It may be necessary to contact the pad of thicker circuit boards.

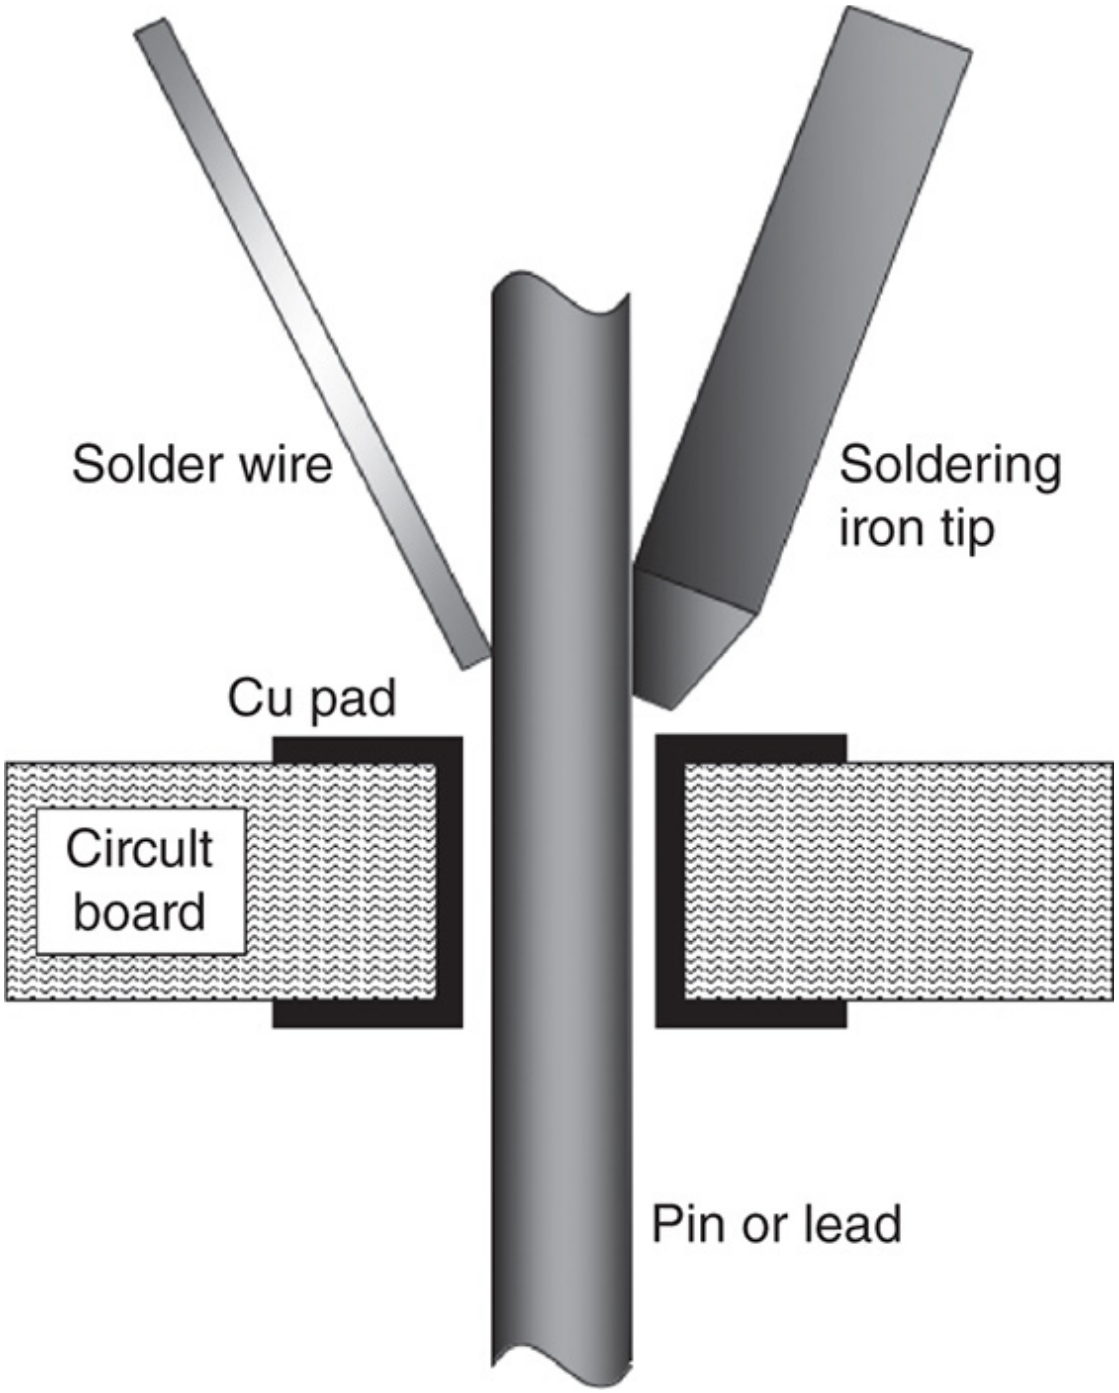

FIGURE 43.2 Diagram showing placement of the soldering iron tip for heating the lead and placement of the solder wire to complete the joint.

2. The solder wire is brought into contact at the side of the lead opposite to the soldering iron tip. The solder wire should not contact the tip in order to melt it. Once melting, the solder is allowed to wet and spread over the

surfaces as well as to flow through the hole. In the case of flux-cored wire, the flux application step is omitted. A properly designed process—that is, one having a soldering iron with adequate power as well as tip temperature and geometry—should complete the joint in approximately 3 to 7 s.

3. Once the soldering process is completed, the circuit board is cleaned of flux residues when required by the flux type or the product's long-term reliability requirements.

Hand soldering may be achieved in an assembly (or "slide") line process for larger volumes. In this case, each one of several operators solders only a few of the total components of the circuit board. In the case of single-person work cells, the operator may solder all of the components to the circuit board. Alternatively, the work cell may be used to add odd-form components as the final assembly step on a nearly complete circuit board.

43.2.5 Automated Soldering and Insertion Technology

In the case of automated assembly processes, the general sequence is part insertion followed by the soldering step. (Slightly different steps are used for the paste-in-hole process; that is, the paste may be applied before or after part insertion.)

43.2.5.1 Components. Part insertion is typically performed in the following order:

1. DIP package
2. Axial leaded components
3. Radial leaded components

4. Odd-form components

The following subsections provide a brief description of each of the component formats and the manner in which the insertion machine addresses those formats.

Choosing the appropriate insertion machine depends on production volume requirements and the mix of products (part density, board sizes, etc.) that must be assembled in the factory. These factors determine the machine's physical dimensions, placement speed, and part-handling (staging) features.

43.2.5.1.1 Dual Inline Pin (DIP) Package. The first autoinsertion process is placement of the DIP packages. The typical DIP package (see Fig. 43.3) is manufactured in one of two widths: 7.6 mm and 15.2 mm. Package lengths vary with the number of pins. For example, a 6-pin DIP package can have the same width and length of 7.6 mm. On the other hand, a 42-pin DIP package has a width of 15.2 mm and a length of 54.6 mm. The DIP packages are typically received in 61-cm-length plastic tubes. The insertion machine carries these tubes vertically in magazines. The part shuttle selects the appropriate package and carries it to the center of the machine for insertion into the circuit board. Tooling on the shuttle head holds the package by the leads during the insertion process. The tooling is simply scaled for different DIP package dimensions.

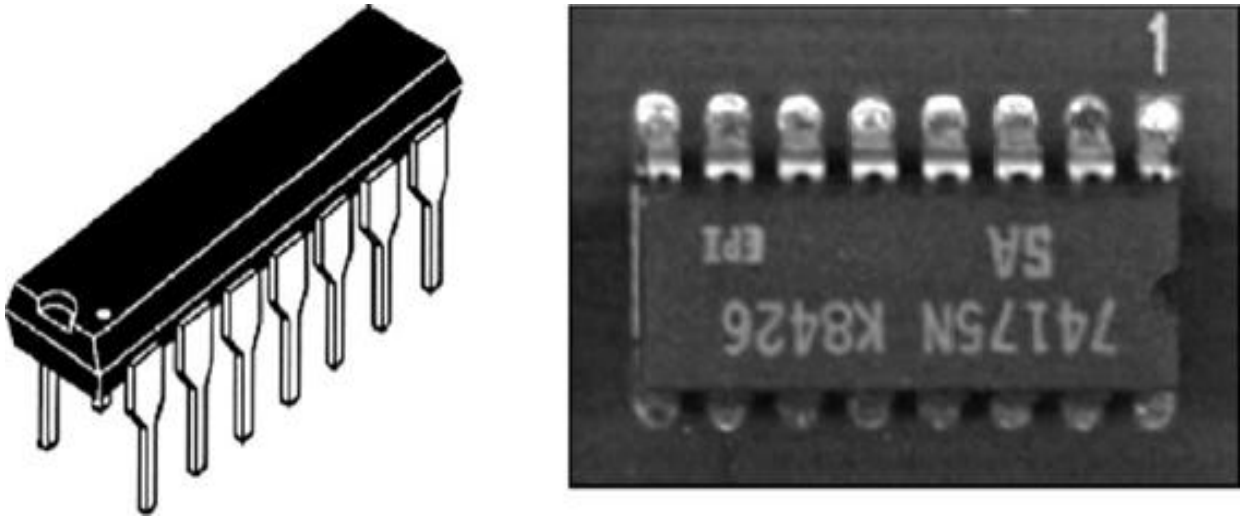

FIGURE 43.3 Dual inline package (DIP). (*Courtesy of Sandia National Laboratories*.)

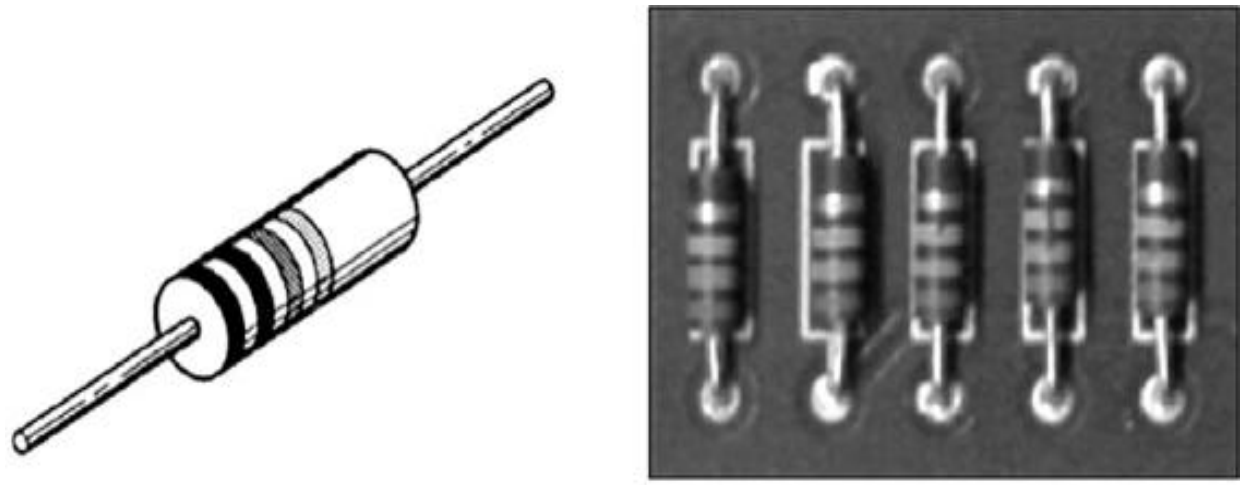
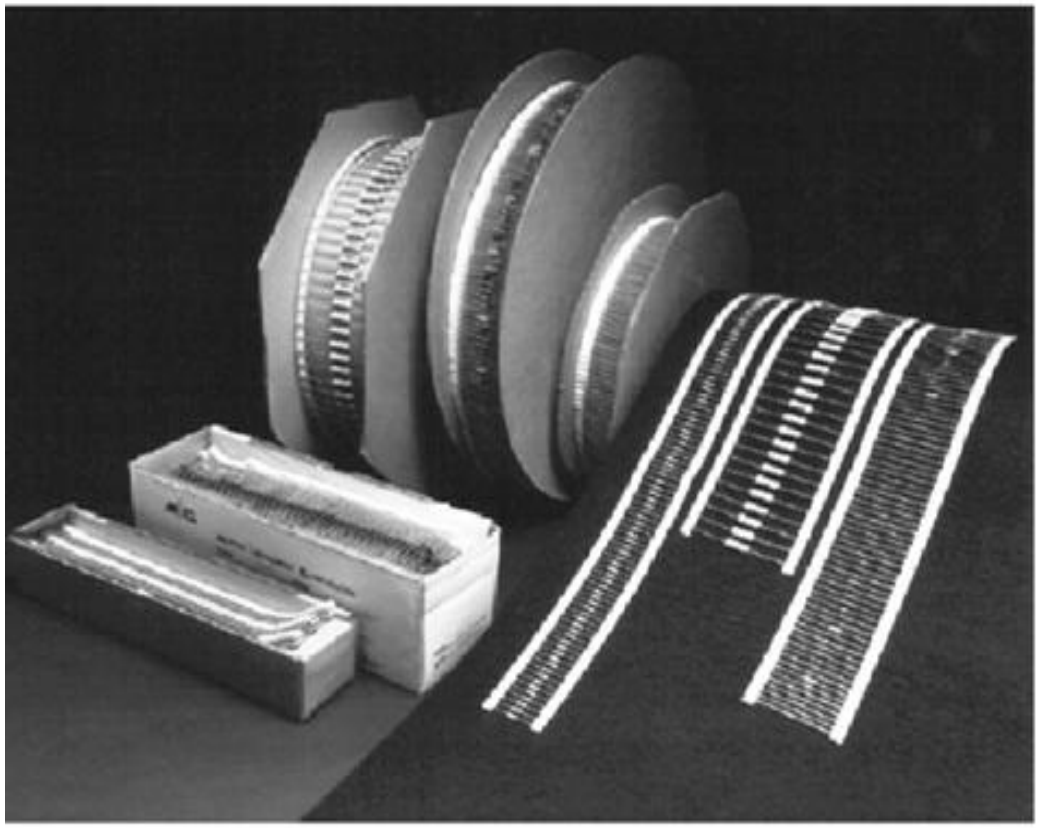
Dual inline packages are either molded plastic (PDIP) or ceramic (CerDIP, or just CDIP). The surface finishes on PDIP packages are typically electroplated layers of Ni (solderable layer) and Sn-Pb (protective finish) over a Cu lead frame. The Sn-Pb finish is being replaced with 100 percent Sn layers to meet environmental requirements. The CDIP package has low-expansion Fe-based alloy leads that are either electroplated with Cu finish for solderability or the alternative lead finish of Ni (the solderable layer) followed by Au (the protective layer). Although the DIP package is rarely received from the manufacturer with a hot-solder-dipped coatings, these coatings may be applied, after-market, to prevent Sn whiskers with 100 percent Sn finishes (PDIP) or Au embrittlement with Au finishes (CDIP). Aside from potential hole interference with a hot-solder-dip coating, there is also the need to unpackage and repackage the components, which can potentially damage the leads as well as add to the overall cost of the assembly process.

43.2.5.1.2 Axial Leaded Components. Following the DIP packages is insertion of the axial leaded components, which are taped together at the leads by the manufacturer to prevent damage. The taping of the leads conforms to EIA

specification number 296-E. Examples of axial leaded devices are shown in Fig. 43.4. During the insertion process, the machine cuts the axial components from their tape to ready them for sequencing into the shuttle head. The leads on axial devices are typically copper or a Cu-clad, Fe-based alloy material. Electroplated Sn-Pb or 100 percent Sn coatings are used to preserve lead solderability. Hot-solder-dipped coatings (Sn-Pb or Pb-free) may be increasingly encountered as a replacement for 100 percent Sn coatings, especially for high-reliability applications. The coating thicknesses must be considered when determining the tolerance stack-up between the hole and pin. Also, hot-solder-dipped coatings often lack uniformity, increasing in thickness near the end of the lead where molten solder accumulated prior to solidification.



(a)



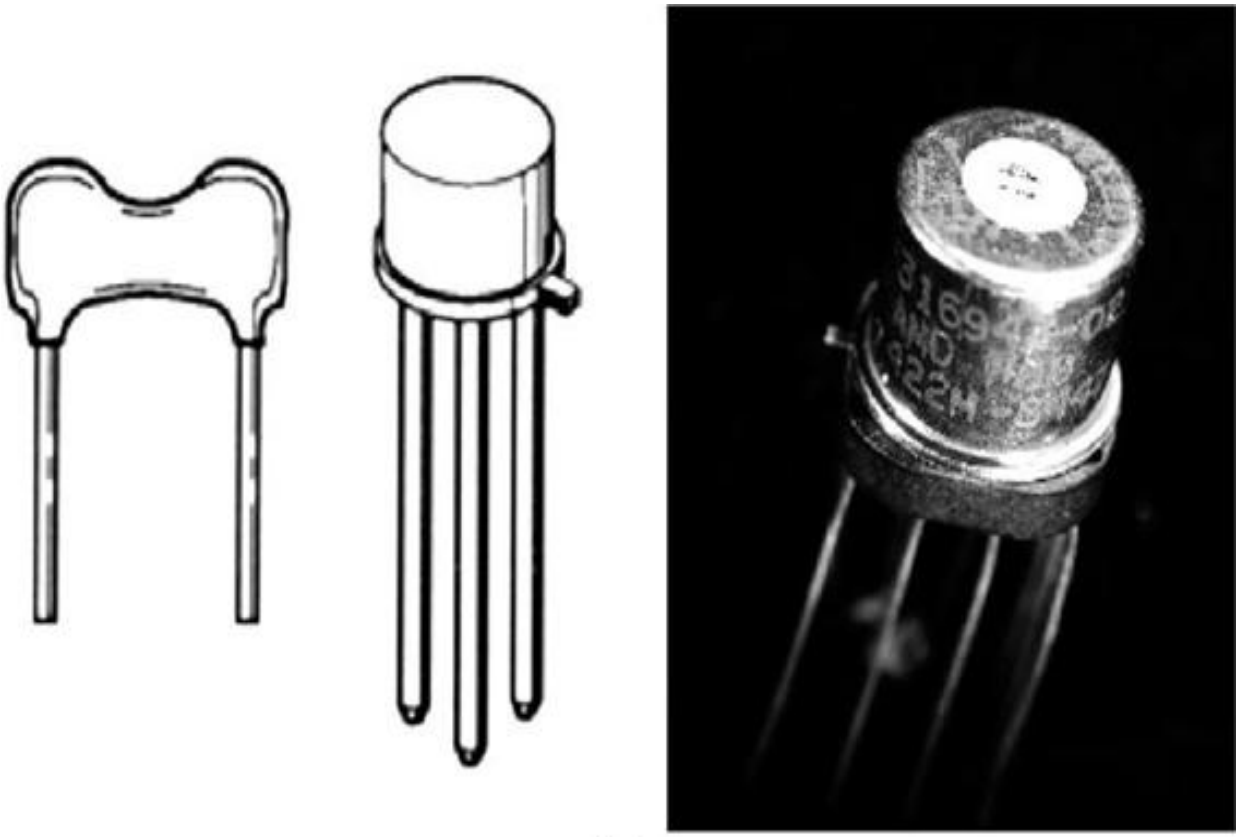
(b)

FIGURE 43.4 Examples of axial leaded devices: (*a*) axial leaded components; (*b*) axial leaded components in reels and boxes. (*Courtesy of Sandia National Laboratories*.)

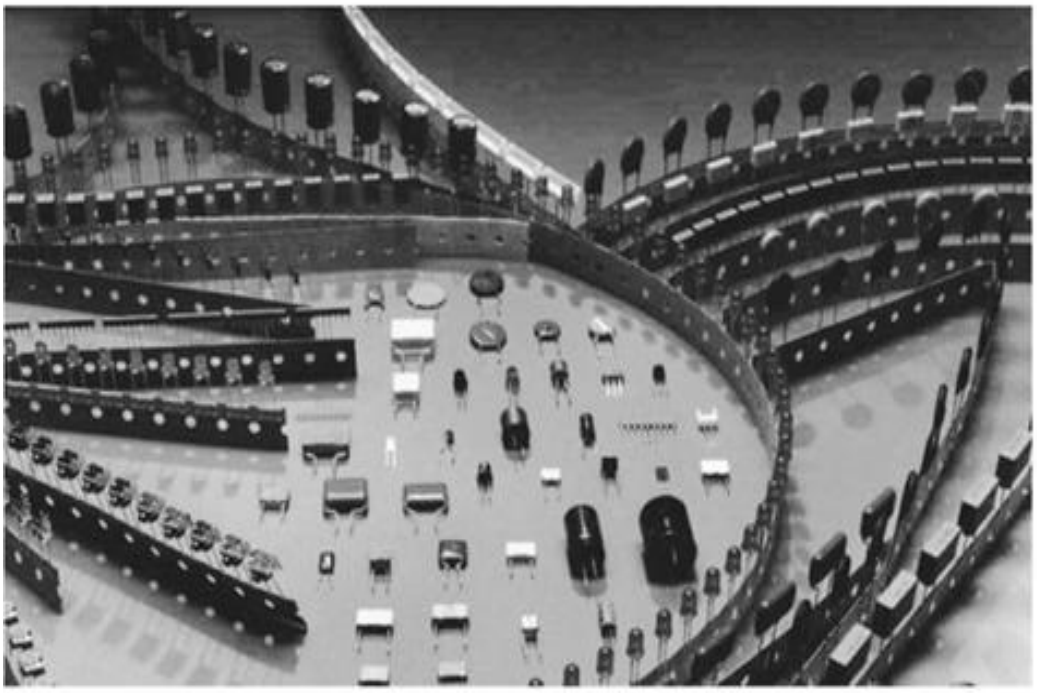
Choosing the appropriate insertion machine depends on production volume requirements and the mix of products (part density, board sizes, etc.) that must be assembled in the factory. These factors determine the machine's physical dimensions, placement speed, and part-handling (staging) features.

Axial leaded components are inserted before radial leaded components because, typically, axial components are smaller overall than radial components. Because the associated tooling size is also smaller, inserting axial components prior to the radial components facilitates the stuffing of higher-density circuit boards.

43.2.5.1.3 Radial Leaded Components. After DIP and axial leaded components, the radial components are inserted into the circuit board. Radial components can vary greatly in size, shape, height, and weight (see Fig. 43.5). The lead finishes—types and thicknesses—are identical to those of axial leaded components. The possible exceptions are hermetically sealed components, such as active Si chip devices in TO-5 cans, optoelectronic packages, and relays. Such devices typically have low-expansion, Fe-based alloy leads that allow for them to be sealed into the header with a glass-to-metal joint. Although some device manufacturers use a Sn-Pb or 100 percent Sn finish over an electroplated Ni (solderable) layer, other suppliers prefer an Au (protective) finish over the Ni (solderable) layer to provide adequate solderability. In such cases, the Au layer is removed by hot solder dipping in order to prevent Au embrittlement of the circuit board interconnection.



(a)



(b)

FIGURE 43.5 Radial leaded components: (*a*) individually; (*b*) in taped reels. (*Courtesy of Sandia National Laboratories and Universal Instruments*.)

Radial leaded components are taped together at the leads. Radial insertion machines remove the components from the tape and insert them in sequence on to the printed circuit board using a shuttle system similar to that used for other components. The insertion machine tooling for radial components is designed to avoid previously inserted DIP and axial components.

43.2.5.1.4 Odd-Form Components. The odd-form components are the last devices to be assembled on the circuit board. Odd-form components, by definition, are those packages that are not readily addressed by automated assembly because (a) they are used at insufficient volumes on the product to justify machine "space" or (b) they are of a geometry (shape or size) that lacks the customer demand to justify the machine manufacturer to provide off-the-shelf tooling for them.

High-power applications often require a variety of odd-form components, including simply oversized DIP, axial leaded packages, or radial leaded packages. Also, odd-form components include transformers, switches, relays, and connectors. Several of these packages are shown in Fig. 43.6. Unusual package sizes and geometries are often accompanied by unusual lead configurations and materials. It is not uncommon to have Cu- and Ni-based alloy leads, or even leads made of refractory materials such as Mo and Ni. The leads may be round, square, or in the form of ribbons. Irrespective of the lead material or nontypical geometry (which must have the hole geometry addressed at the circuit board design step), it is *always* required that the leads have adequate solderability. Leads are typically plated with solderable layers (Cu or Ni) and protective finishes (Au, Sn, Sn-Pb, etc.) very much like those used on traditional components to support the soldering process.

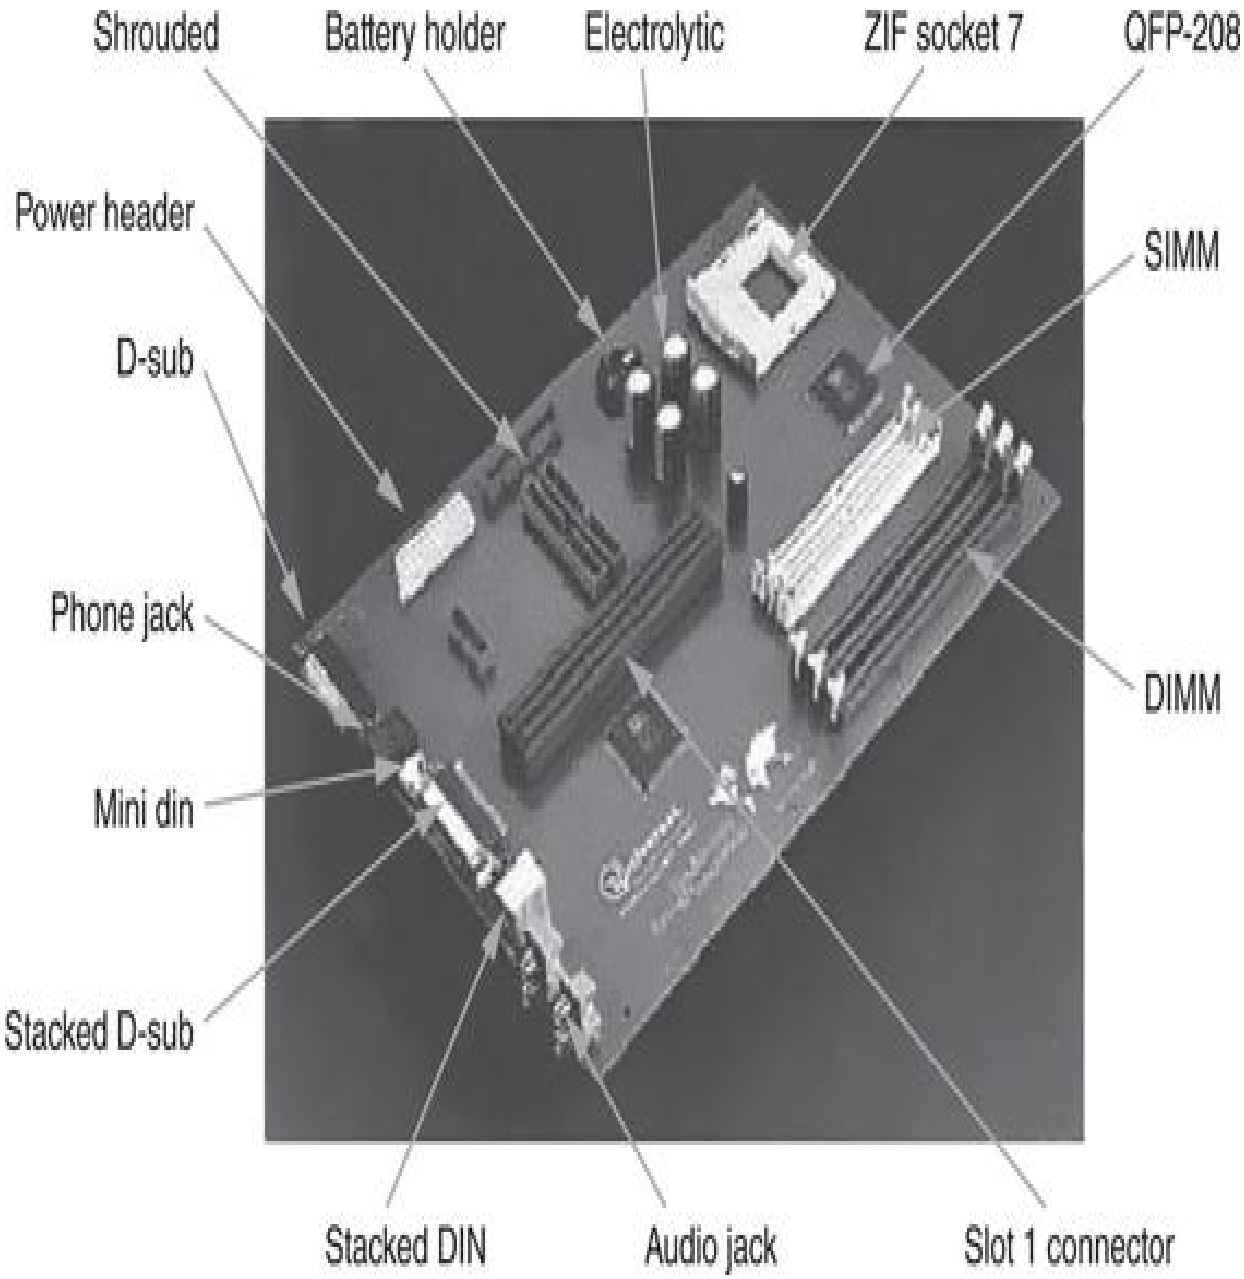


FIGURE 43.6 Examples of odd-form, through-hole components and a circuit board assembly. (*Courtesy of Universal Instruments*.)

43.2.5.2 Insertion Equipment. Because the demand for through-hole circuit boards has remained strong, insertion equipment capabilities have steadily improved. Brushless servo-motors and state-of-the-art motion controllers and sensors have replaced most pneumatic drive assemblies and bulky (and slow) mechanical switches and relays,

respectively. Some equipment options include the capability to test parts electrically prior to insertion. At insertion rates of up to 40,000 components per hour (CPH), defect rates are a couple of hundred parts per million or lower for the common axial and radial leaded packages. Interchangeable tooling has allowed the automated insertion of many odd-form components, as well. The change to Pb-free solders does not have a direct impact on insertion equipment technology.

43.2.6 Automated Soldering and Wave Soldering

The most commonly used process for the soldering of through-hole and mixed (through-hole and surface-mount) circuit boards is *wave soldering*. The wave-soldering process is shown schematically in Fig. 43.7. The populated (or “stuffed”) circuit board is secured to a conveyor belt. The conveyor belt carries the board through the fluxer, then the preheat stage, and lastly on to the molten solder wave.

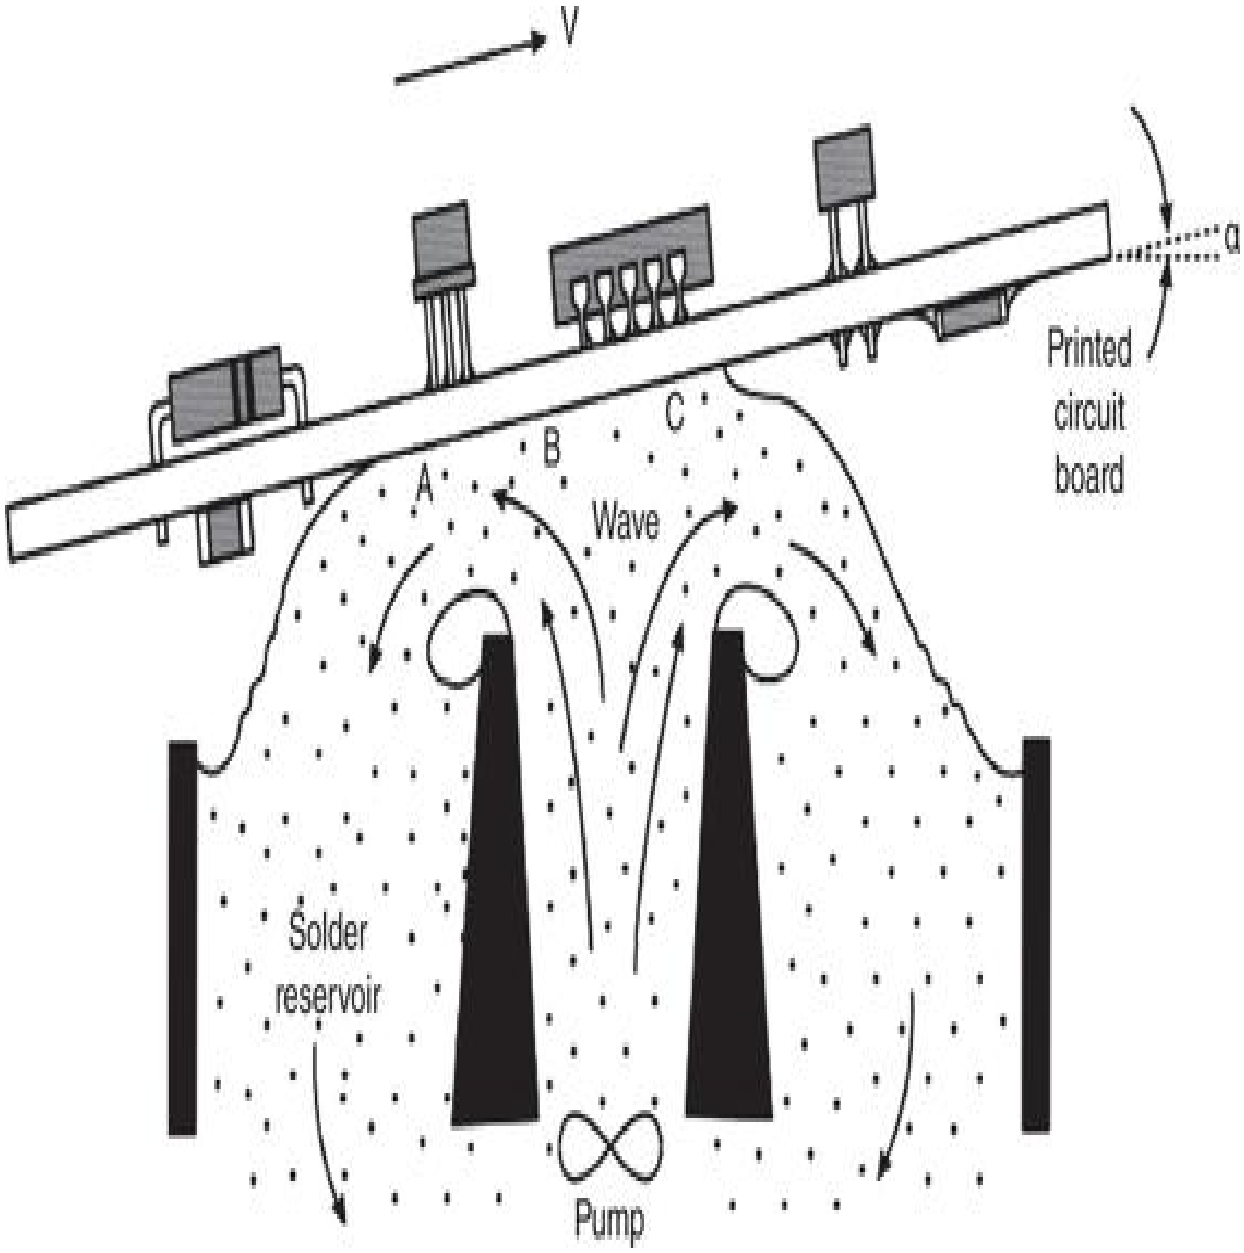

FIGURE 43.7 Schematic diagram showing the wave-soldering process.

Interestingly, one of the most critical steps in the wave-soldering process is the application of the flux. Manual fluxing has given way to more precise, automated equipment in order to improve yields. The advantage is better control of the *quantity* of flux on the circuit board as it enters the wave because the flux controls both the entry and exit geometries of the molten solder wave, which in turn are instrumental toward minimizing skips, bridges, or icicle

defects. Flux can be applied by spraying techniques or by passing the circuit board through the foam or “suds” of the flux. The latter technique is provided by the “foam fluxer.”

After the fluxing step, the circuit board passes through the preheat stage, which is comprised of a set of radiant heaters. As the circuit board is heated, this step evaporates volatiles from the flux coating (which if not adequately removed can lead to voids and blow holes) and activates the chemical reactions between the flux and oxides on the component lead or termination and the circuit board conductor.

The solder wave is created by pumping molten alloy upward through a nozzle, where it exits to a certain height and then falls back into the bath. The solder bath temperature is 260°C for eutectic Sn-Pb solder. The printed circuit board is carried by the conveyor so that is passes over the surface of the wave. The bottom side of the circuit board contacts the wave, allowing the molten solder to wet the exposed pads as well as to flow upward through the holes by capillary action. The speed of the conveyor and the take-off angle—that is, the angle at which the circuit board approaches the wave—are critical parameters for minimizing wave-soldering defects.

Another critical parameter of wave soldering is the wave geometry. The schematic diagram in Fig. 43.8 shows the commonly used dual wave. The first wave is turbulent so as to counteract the surface tension of the molten solder, thereby literally forcing the molten solder into confined geometries in order to initiate the wetting process. The second wave is smooth or laminar. The laminar wave is located at the exit point because its geometry reduces the propensity for bridges and icicle defects to form as the molten solder retracts itself from the circuit board. The photograph in Fig. 43.9 shows a circuit board entering the turbulent wave of a dual-wave soldering system.

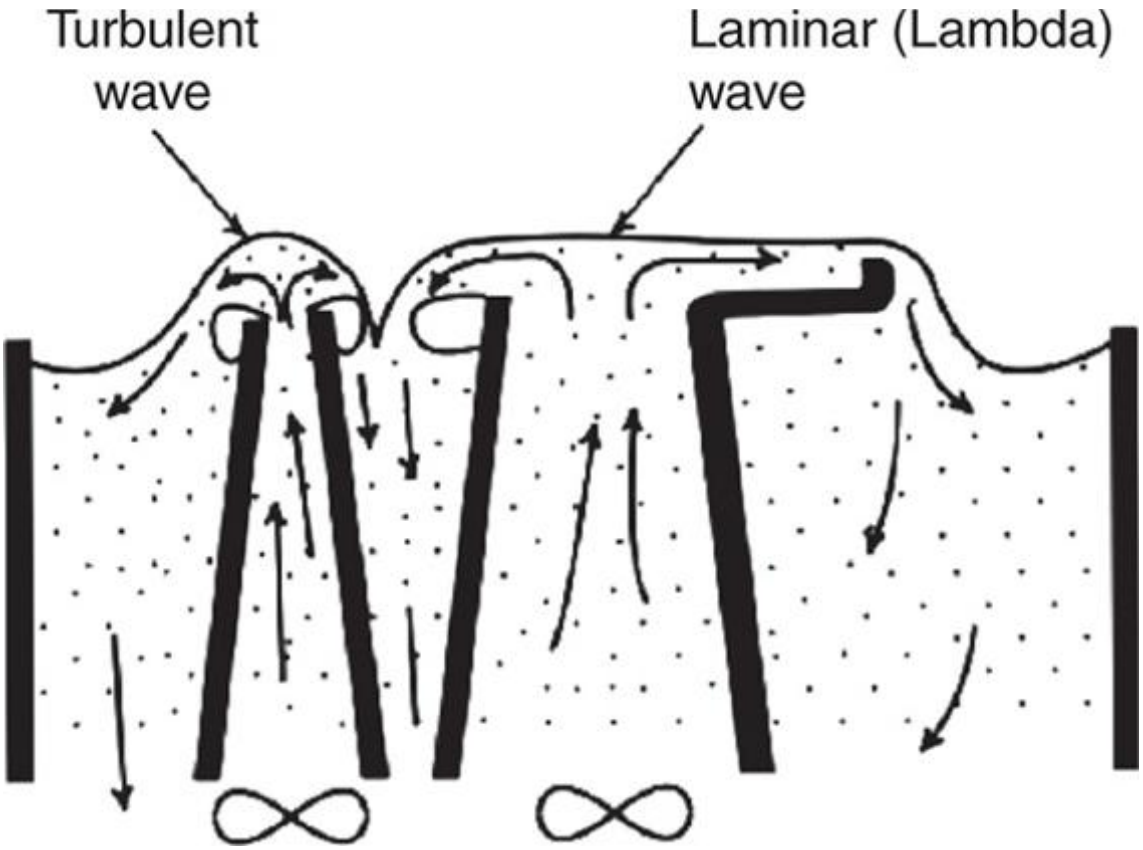

FIGURE 43.8 Schematic diagram of the dual solder wave configuration.

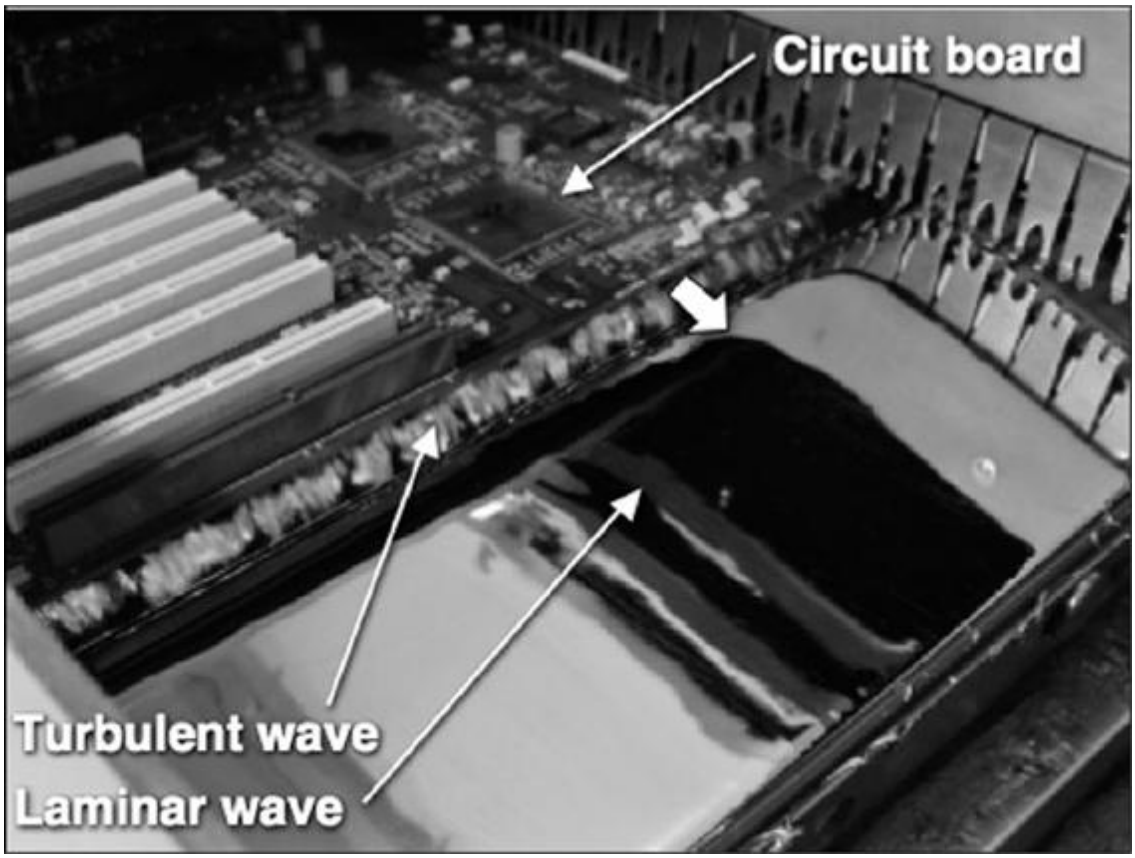

FIGURE 43.9 Photograph of the dual-wave configuration. (*Courtesy of Vitronics-Soltec*.)

A variation of wave soldering is the so-called selective soldering process. Instead of using a long wave to accommodate the dimensions of an entire circuit board, a small fountain is created of molten solder. The reduced geometry allows for the soldering of individual components or several components on only selected areas of the circuit board. A manual operation is used to apply flux and preheat the circuit board prior to the actual soldering process.

The change to Pb-free solders has affected the wave-soldering process. Fortunately, the 260°C bath temperature used with eutectic Sn-Pb solder has proven to be adequate for most applications using the 99.3Sn-0.7Cu (wt. percent) and Sn-Ag-Cu alloys. Some users have preferred to raise the pot temperature to 260 to 270°C. The elements Ni and Ge have been added to the Pb-free solders in order to provide

the shiny fillets that inspectors are accustomed to observing with Sn-Pb solders. The higher surface tension of the Sn-based, Pb-free solders increases the tendency for opens, bridges, and icicles to form as the circuit board exits the wave. A change of flux chemistry as well as adjustments to the take-off angle and conveyor speed have been used to minimize those defects. Lastly, a particular problem with Pb-free wave soldering is erosion of the machine parts by the high-Sn alloy compositions. Special coatings are put on the impeller, nozzles, baffles, and bath walls to mitigate the erosion process.

43.2.7 Paste-in-Hole (Pin-in-Paste) Soldering

Very rapid production volumes are realized with inline surface-mount assembly processes. In general, the surface-mount assembly process consists of three basic steps: (a) screen printing of solder paste, (b) pick and place of components, and (c) reflow of the solder paste. To obtain similar throughputs for through-hole circuit boards, paste-in-hole soldering is being investigated as an alternative to wave soldering. Solder is provided to the joint in the form of a paste, using screen or stencil printing, or dispensed from a needle. The component is then inserted into the hole. In some applications, the parts are inserted into the circuit board and subsequently the solder is dispensed at the hole using a needle and pump. Then the assembly is sent through the reflow furnace. The primary hurdle with paste-in-hole soldering is supplying a quantity of paste that is sufficient not only to develop a fillet on that side of the joint, but also to fill the hole and, optimistically, create a fillet on the bottom side of two-sided and multilayer circuit boards.

A second concern for paste-in-hole soldering is the temperature sensitivity of the through-hole components.

Recall that in wave, selective, or even hand soldering, the temperature rise is confined largely to the leads and circuit board. At worst, the component package materials experience only the preheat temperature environment. However, in paste-in-hole soldering, components must withstand the soldering temperatures within the reflow furnace. Therefore, a conversion to this solder process requires an in-depth review of the allowable temperature range for all of the components.

43.2.8 Cleaning

The final step in the soldering process is the removal of flux residues from the completed circuit board. No-clean fluxes, as the name implies, produce residues that need not be removed from the assembly after soldering. The corrosive activators are locked up in a hard, polymerized residue. However, no-clean flux residues can potentially interfere with in-circuit testing (probes) and inspection, degrade cosmetic appearance, inhibit rework activities, and lessen the adhesion of conformal coatings. In the event that any one of these factors becomes critical, it is best to switch to a cleanable flux than to develop a cleaning process for a no-clean flux.

Low-solids fluxes (which are not to be confused with no-clean fluxes) are simply formulated with reduced solids content so that very little residue is left on the circuit board. Low-solids flux can be successfully used in wave-soldering and paste-in-hole processes, thereby eliminating the need for a cleaning step. However, they are somewhat more difficult to use in hand-soldering processes because the higher temperature of the soldering iron tip can cause premature loss of the activating agent, resulting in poor solderability.

The cleaning step can be performed in either a batch or inline machine. The optimum equipment is determined by production volumes, floor space, and capital expenditure costs. Smaller, batch cleaning (or “dishwasher”) machines are very cost-effective for overall batch-type processes (e.g., hand soldering) as well as for circuit boards assembled in low production volumes. Inline cleaning equipment is placed at the end of the soldering assembly line to accommodate high production volumes. Whether batch or inline equipment is used, an equally important consideration is selecting the type of cleaning solution. Solvent-based, aqueous, and semiaqueous cleaning materials are commercially available that meet environmental regulations and provide adequate efficacy for the removal of flux residues.

The impact of Pb-free soldering on the cleaning step depends on the particular assembly process. By virtue that the same pot temperatures are used in Pb-free wave soldering as are specified for Sn-Pb solder, there is no added thermal degradation to the flux residues that would cause them to be more difficult to remove from the circuit board surfaces. Such degradation may be observed, albeit to a limited extent, with hand assembly due to slightly longer soldering times. Thermal effects are potentially most significant with paste-in-hole soldering because of the increased temperature settings of the reflow furnace required to melt Pb-free alloys.

43.3 SURFACE-MOUNT TECHNOLOGY

Surface-mount technology refers to assemblies that have components soldered to pads on the surfaces of the circuit board. Components may populate only one side (single-sided) or both sides (double-sided) of the circuit board. Surface-mount technology dates back to the 1960s, when it

was developed for hybrid microcircuit (HMC) assemblies for which it was difficult to put holes into the ceramic substrates. The advent of surface-mount technology for laminate substrates, though, is relatively recent (c. 1980). The advantages of surface-mount technology include smaller components and greater board densities. The large holes have been replaced by small vias for signal conduction between sides and internal layers. Finer traces and reduced component heights also contribute to increased circuit board miniaturization and functionality. Surface-mount circuit boards are shown in Fig. 43.10.

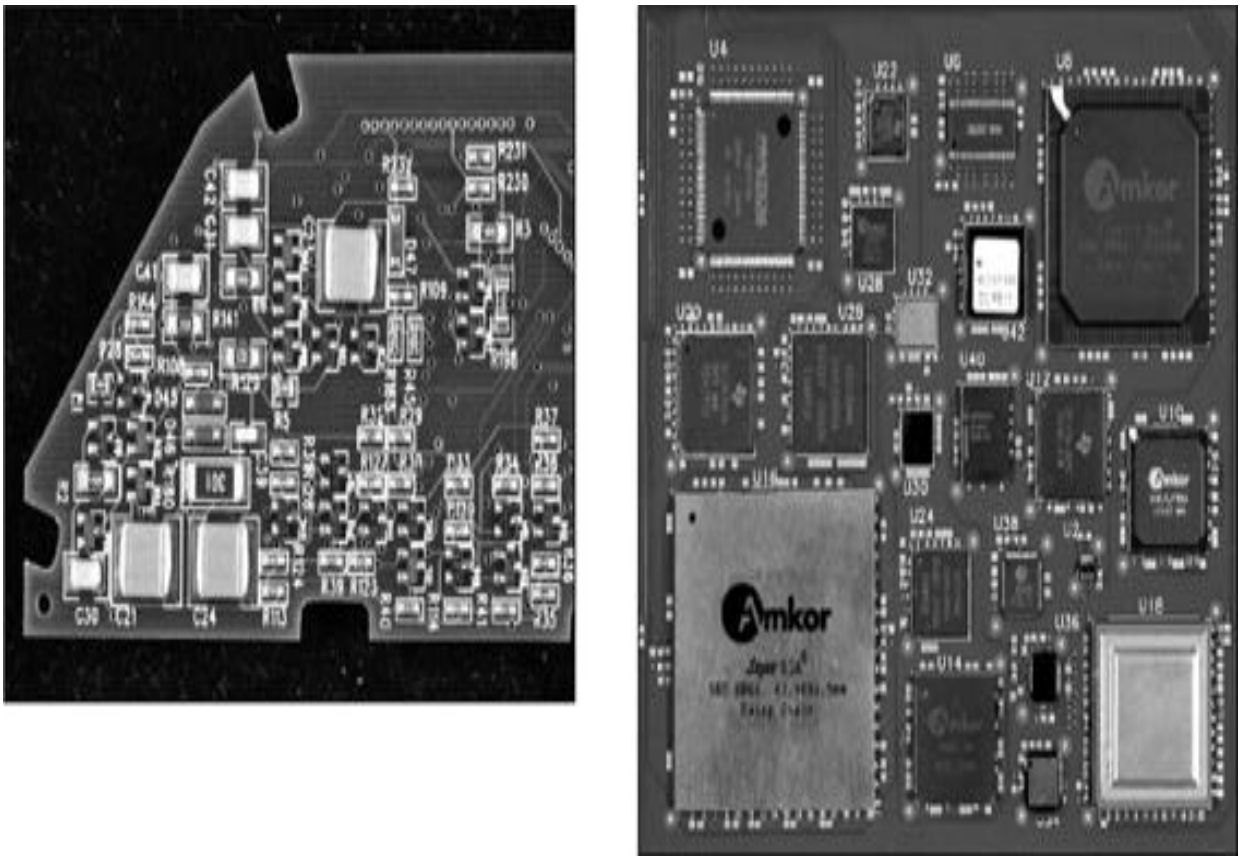

FIGURE 43.10 Surface-mount technology circuit boards showing the range of passive and active device sizes and geometries. (*Courtesy of Sandia National Laboratories and American Competitiveness Institute*.)

The trend in surface-mount technology is to use smaller passive devices such as capacitors, resistors, and inductors.

Also, there is the use of embedded passive devices, that is, resistors and capacitors that are located within the circuit board laminate. Embedded passive devices free up additional surface area for larger, active components.

Active devices are experiencing two opposing trends. On the one hand, memory components (RAM, SDRAM, etc.) are becoming smaller as more transistors are being packed on to the silicon chip. On the other hand, microprocessors and application-specific integrated circuits (ASICs) are becoming larger because of increased functionality on larger chips. Both trends have seen a shift away from peripherally leaded packages to area-array packages. Area-array packages include BGAs and the smaller counterparts, those being CSPs and DCA/FC technology. Examples of peripherally leaded and area-array packages are shown in Fig. 43.11. The advantages of the area-array technology include a reduction of the component footprint by eliminating the leads that extend from the package. Also, fewer assembly defects results from damage to the fragile leads during packaging, transportation, and part placement on the circuit board.

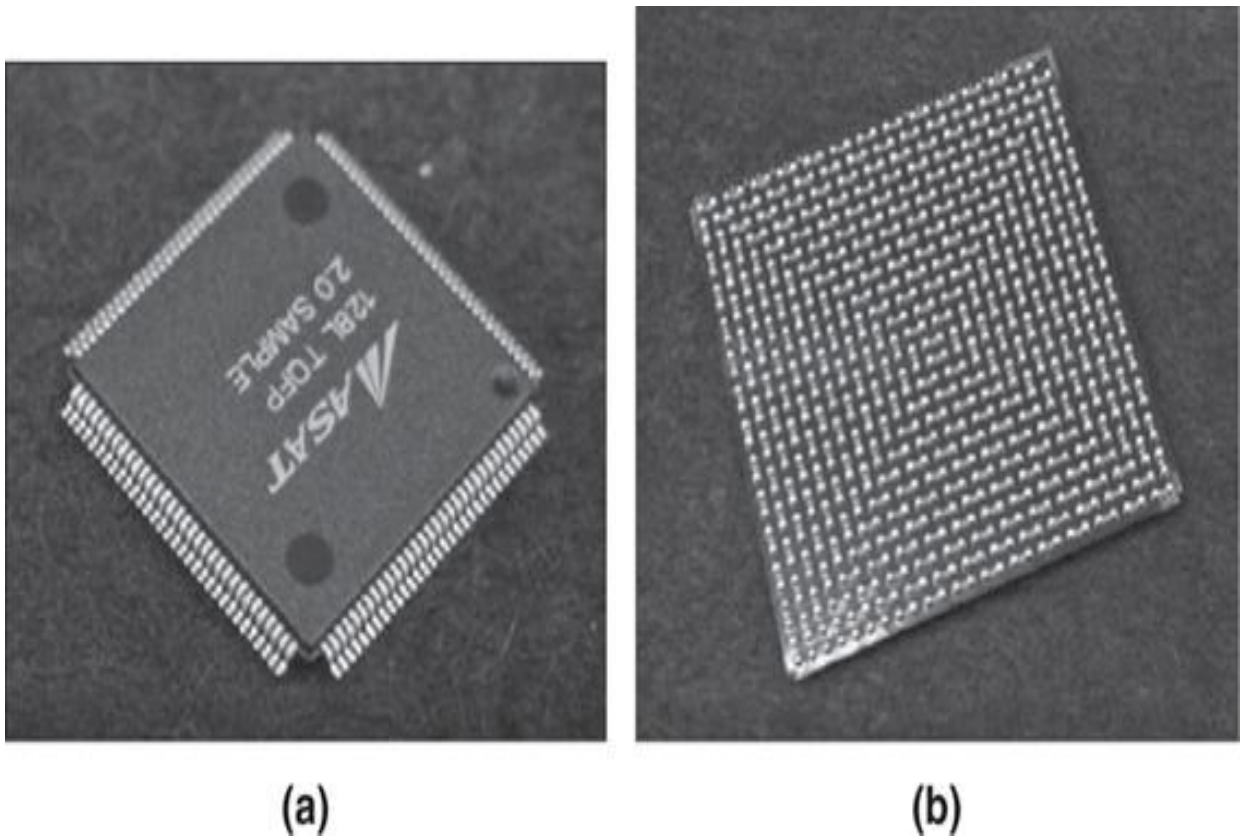

FIGURE 43.11 Photographs of (*a*) peripherally leaded and (*b*) area-array surface-mount packages. (*Courtesy of Sandia National Laboratories*.)

At the inception of area-array technology, the size and pitch of the I/Os were initially higher when compared to what was then 0.4 mm and 0.5 mm fine-pitch, peripherally leaded packages. However, as I/O counts have increased with the functionality of area-array packages, solder ball size and pitch have decreased significantly, particularly when taking into account DCA technology.

Increased device functionality and further miniaturization, which have resulted in higher board densities, are placing stricter requirements on circuit board technology. Increased internal conductor layer counts result in the need for thicker laminates. Whereas once the 1.58 mm board thickness was the norm, now 2.29 mm is commonplace, with many products requiring thicknesses greater than 2.54 mm. The internal conductor layers are being designed to carry not

only the electrical signal, but also contribute to thermal management by removing excess heat from active devices. Similarly, the vias within the laminate are used to transmit signals between layers and the surfaces as well as remove excess heat from large active components (e.g., microprocessors, ASICs, etc.). Vias are reaching aspect ratios (length/diameter) of 8:1 to 10:1, which is nearing the fabrication as well as reliability limits for these structures.

A particular advantage of surface-mount technology is the lower manufacturing cost resulting from automated assembly processes. Solder paste, which is the combination of solder metal powder, flux, and thixotropic agents, is applied in highly controlled amounts (thickness and area) using screen or stencil printing as well as dispensing techniques. Pick-and-place machines handle even the smallest components, locating them precisely on the solder paste deposits (or “bricks”). The tacky nature of the flux component in the paste keeps the components in place. The assembled (or “stuffed”) printed circuit board then passes through the convection/radiation reflow furnace or vapor phase (or condensation) reflow oven to melt the solder. The machines responsible for the steps—paste printing, component placement, and reflow—are connected by conveyor belts to create the inline process. In fact, the final step—cleaning the circuit board—may also be a part of the assembly process sequence.

Of course, various levels of automation may be considered, depending on production volumes and capital expenditure costs. However, with continued miniaturization of surface-mount products as well as the strict requirements for the repeatable placement of specific solder paste volumes and accurate placement of components, it will be a foregone necessity to assemble surface-mount technology with a fully automated assembly process.

Mixed technology refers to the combination of surface-mount and through-hole components on the same printed

circuit board. The lack of components in a surface-mount package is nearly always the reason for using a through-hole counterpart. In general, the surface-mount devices are soldered first to the top side of the circuit board using a convection/radiation reflow furnace or vapor-phase soldering machine process. (Surface-mount is performed first because the through-hole components would interfere with solder paste printing and pick-and-place steps.) The through-hole components are then soldered to the board. The actual soldering process is performed at the bottom side. For larger numbers of through-hole components, the board is wave-soldered. If there are surface-mount components located on the bottom side, they can likewise be wave-soldered; however, those components must first be secured in place by an adhesive. Hand soldering may be preferred if there are relatively few through-hole devices or if bottom-side surface-mount devices cannot be exposed to the solder wave.

43.3.1 Pb-Free Soldering

Pb-free soldering technology has affected surface-mount technology. Fortunately, the fallout has not included the need for new automation equipment. Lead-free solder paste behaves essentially the same as its Sn-Pb counterpart in the printing process. Slight modifications have been suggested for the screen and stencil apertures to accommodate the reduce solderability of Pb-free alloys once the paste enters the reflow furnace. Pick-and-place equipment can remain unchanged by a Pb-free soldering process. Reflow furnaces must be able to accommodate the higher process temperatures required by Pb-free solders. Vapor phase reflow machines are available with fluids that provide the higher process temperatures needed for Pb-free assembly. (As noted earlier, significant equipment costs are associated with altering a wave-soldering machine for the Pb-free

assembly, which would pertain to mixed-technology printed circuit boards. Those costs include the replacement of the solder as well as the replacement of some components that are susceptible to erosion by the high-Sn alloys.)

The most significant impact of Pb-free technology is in reflow process parameters, specifically the time-temperature profile. Longer times at higher reflow temperatures increase the likelihood of thermal damage to components and substrate materials. Also, in seeking to reach higher reflow temperatures, one must also consider the sensitivity of the solder paste to the temperature ramp-up rate. An incompatibility between the paste and time-temperature profile can lead to increased levels of defects such as voids, solder balls, short-circuits due to paste slump, etc. Similarly, excessively fast cooldown rates from the higher reflow temperatures can result in board warpage and cracked passive devices. The greater need to control the Pb-free time-temperature profile favors greater control capabilities for the reflow furnace.

The Pb-free solders have intrinsically poorer solderability performance than their Sn-Pb counterparts. The slower rate of wetting and spreading is not as critical of a factor in reflow surface-mount assembly as it is the faster wave- and hand-soldering processes. However, the higher surface tension of Pb-free alloys may limit the extent of solder spreading on a pad, particularly with bare Cu, leaving the corners uncoated by solder. The choice of flux and use of alternative surface finishes can mitigate this artifact in some cases. A high surface tension also increases the likelihood of *tombstoning* by passive devices particularly for the smaller chip resistors and capacitors. The degree of tombstoning can vary from the device having one termination just lifting from the pad to the component standing up completely on one end.

43.3.2 Design Considerations

The design of a surface-mount circuit board requires the consideration of three factors pertaining to the assembly process. First, there is a wide variety of solder-joint configurations for the different package types. Second, higher board densities can lead to upward of several tens of thousands of solder joints being fabricated at one time. Third, component miniaturization, as well as the unexposed solder joints of area-array packages, further diminishes the viability of performing repair or rework activities to correct solder-joint defects. A number of design rules are printed in documents (e.g., IPC SM-782 and D-330) that govern the size and location of bond pads. Surface-mount circuit boards are at least double-sided and, in most cases, multilayer, so that board design also must consider the interior of the laminate where vias are placed to conduct signals between the layers and surfaces.

Assembly requirements also place constraints on the circuit board layout. A very high part density requires a large number of apertures in the solder paste stencil, which can cause the stencil to become locally too flimsy to control the solder paste deposit. A surface-mount circuit board with a very wide range of component sizes and package configurations may require multi-thickness stencils to properly control the paste deposit. Solder paste printing quality is a determining factor in solder-joint defects observed after the reflow process.

The layout design of the surface-mount circuit board is a factor in the optimizing of the time-temperature profile used in the reflow process. Two important factors are overall thermal mass of the circuit board, determined primarily by the board thickness and number of internal layers as well as the variety package sizes and materials that can lead to temperature gradients as large as 20°C between the smallest passive devices and larger ball grid array packages over the board surface. Also, double-sided circuit boards require two reflow processes. Therefore, larger components

should be placed on the side of the circuit board that is soldered last. If placed on the first side to be soldered, large packages may fall off of the board when the circuit board is upside down for the second side’s soldering step, unless those devices are secured in place with an adhesive or “staking” compound.

The design of a printed circuit board for Pb-free assembly must consider the same points as are considered for Sn-Pb technology, but with a greater emphasis placed on the effects of higher process temperatures—for example, temperature gradients between components across the circuit board. Foremost, there are the enhanced temperature gradients that may be created across a large circuit board having a high mixture of different component sizes and shapes. In the case of a mixed-technology product, there may be limitations placed on the maximum substrate thickness due to the less-solderable Pb-free alloys. It may also be necessary to limit via aspect ratios (typically remaining less than 10:1) to prevent immediate damage (defects) by the reflow process or a loss of long-term reliability.

43.3.3 Assembly Processes

The basic assembly process sequence for surface-mount technology is (1) solder paste printing, (2) pick and place of components, and (3) reflow of the solder. The assembly process is complicated when through-hole components are combined with surface-mount devices on the same circuit board; this is the previously mentioned mixed technology. In general, hand assembly of surface-mount boards is not always practical given the small size of passive devices and hidden solder joints of area-array packages. The use of hand soldering for repair and rework activities is limited by these same factors.

This section lists the sequence of process steps for the different circuit board categories. The term *top side* has typically referred to the side with the greatest density of components and/or where the larger, active device packages are clustered together. As the functionality of printed circuit board products increases, these physical distinctions between the two sides have become less obvious. Therefore, the circuit board sides are simply given a designation: A or B.

Single-sided (top side), surface-mount only:

- Print paste
- Place components
- Reflow solder paste

Double-sided, surface-mount only:

- Bottom side, print paste
- Bottom side, dispense adhesive for larger components, if necessary
- Bottom side, place components
- Bottom side, reflow solder paste and cure adhesive

Flip the board over to the top side:

- Top side, print paste
- Top side, place components
- Top side, reflow solder paste

Double-sided, mixed technology (with bottom-side wave soldering):

- Bottom side, dispense adhesive for surface-mount components
- Bottom side, place surface-mount components
- Bottom side, cure adhesive

Flip the board over to the top side:

- Top side, print paste
- Top side, place components
- Top side, reflow solder paste
- Top side, insert through-hole components

Keep the top side facing up:

- Wave-solder the through-hole and the bottom-side surface-mount components

For mixed-technology products, there is some flexibility regarding the sequence of staking (gluing) of bottom-side components versus the topside soldering step, based largely upon the capabilities of the pick-and-place equipment.

In the case of area-array packaging technology having solder balls (BGA, CSP, and DCA), there is the option of *not* adding solder paste to the pads. Instead, only the flux is deposited on the pads, which serves to tack the package in place during transport of the board to the reflow oven. The solder balls provide the solder to complete the joint; however, the penalty is a reduced gap thickness that may affect self-alignment during soldering (as well as solder-joint reliability later on). Omitting the solder paste is most often considered for the DCA/FC assembly process because the solder balls, and the corresponding pads, are so small that it is not possible to print the acceptable quantity and dimensions of the paste consistently.

There is also the use of step-solder processes for double-sided, surface-mount-only circuit boards. A high-temperature solder, often the 96.5 Sn-3.5 Ag (Sn-Ag) alloy (Teutectic = 221°C), is used to attach the bottom-side components. These solder joints do not remelt when the topside joints are made using the Sn-Pb solder (Teutectic = 183°C). Somewhat tighter process control is required, since the 221°C Sn-Ag eutectic temperature is very near the optimum, peak process temperature for the Sn-Pb process (210 to 220°C). This

approach provides the option of placing larger passive and active components on both sides of the circuit board without the need for an adhesive dispensing and curing step. Unfortunately, the use of the higher melting temperature, Pb-free Sn-Ag-Cu solders all but eliminates this step-soldering approach without identifying a higher melting temperature solder for the first step.

The following sections examine each of the steps in a surface-mount assembly process, beginning with an examination of component types. The different dispensing technologies are reviewed, including those for solder paste and adhesives. Component placement machines are examined, followed by a description of the use of the various heat sources such as convection/radiation reflow ovens, wave-soldering equipment, condensation reflow apparatus, hand soldering, and conduction soldering. Lastly, cleaning processes are described.

43.3.3.1 Components. A wide variety of components are available for surface-mount printed circuit boards. The form, size, and materials used for these components change constantly as new offerings are made by suppliers to meet miniaturization, functionality, and reliability requirements. The most common surface-mount components are the passive or “chip” devices—the resistors, capacitors, and inductors. Chip capacitors and resistors are often referred to by a four-digit number, such as 1825, 1210, or 0804. The first two digits refer to the component body length, which is the distance between the terminations, and are in hundredths-of-inches (0.*xx*). The second two digits refer to the body width in hundreds-of-inches (0.*xx*). [For passive devices, a similar numeric designation is given that is based upon the metric system (mm). The actual values are very close to the English values and can be a source of confusion, especially when partnering with overseas companies.] Thus, an 1825 capacitor has a length of 0.18 in. and a width of

0.25 in. A stereo photograph appears in Fig. 43.12 that shows examples of passive components. Chip resistors tend to be very robust and thus relatively immune to damage during the assembly process. Multilayer chip capacitors are temperature-sensitive and therefore more prone to cracking during assembly, particularly under fast temperature ramp rates.

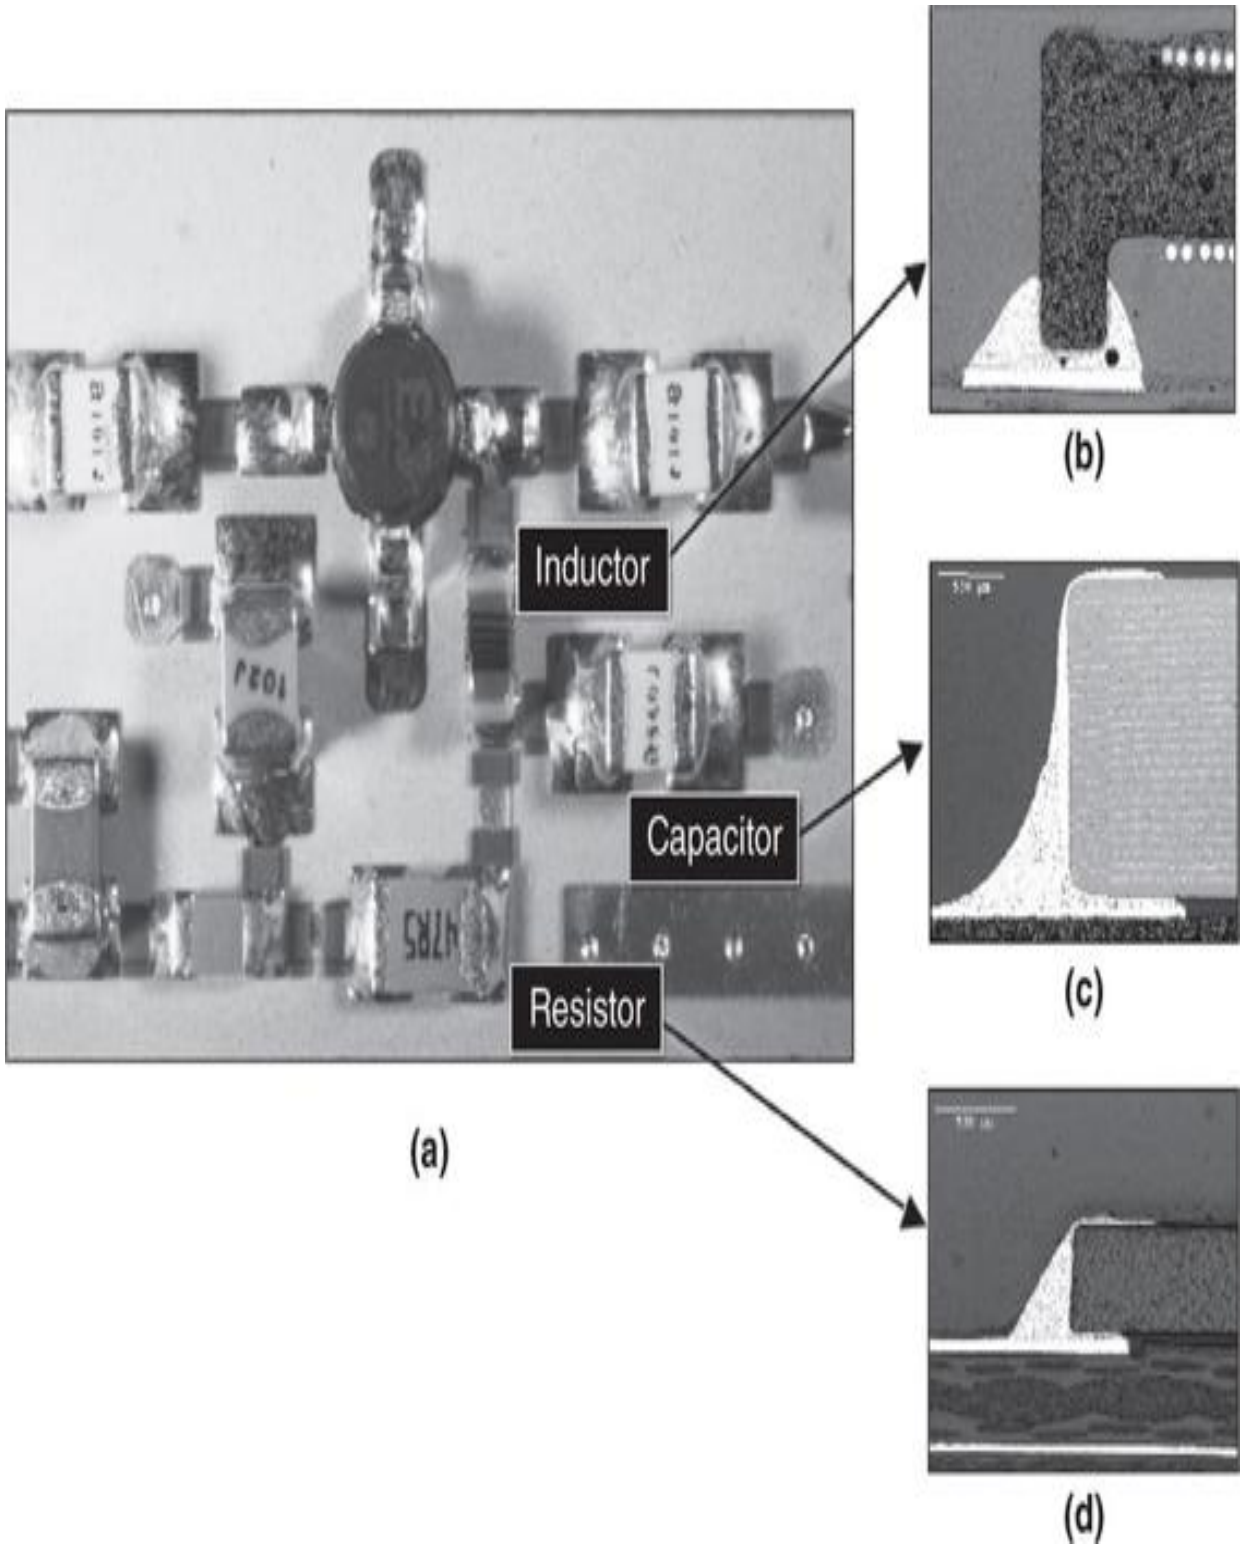

FIGURE 43.12 (*a*) Stereo photograph showing surface-mount passive (chip) devices: inductor, capacitor, and resistor; (*b–d*) cross-sections of their respective solder joints. (*Courtesy of Sandia National Laboratories*.)

The chip resistor is constructed of a piece of alumina ceramic on top of which is deposited a thin film that serves as the resistive element. Attached to the resistive element at the top, on the ends, and partially at the bottom are the termination structures to which the solder joint is made. The termination structures are comprised of a fired, Ag-based thick film; a Ni or Cu barrier layer; and lastly an electroplated finish of Sn, Sn-Pb, or Au.

Chip capacitors are constructed from a special oxide-based ceramic that is built up of alternating layers of ceramics and thin film layers that provide the device capacitance value. This capacitor is the multilayer thin film (MLTF) type. The second capacitor type has electrodes on the top and bottom surfaces of a homogenous “block” of ceramic. The ceramics used to make chip capacitors tend to be more fragile than the alumina body of a chip resistor. The built-up layer structure of MLTF capacitors causes them to be particularly susceptible to both mechanical and thermal shock. Chip capacitors use similar metal layers to build up the terminations that are soldered to the circuit board pad as were described previously for resistors.

Chip inductors are of two types as well. Coil inductors are comprised of a fine Cu wire wound around the alumina body. The body size and number of windings determine the part inductance. The second type is the thin-film inductor. The winding is fabricated from a patterned thin film, which is deposited upon a piece of alumina. (Although the latter are considerably easier to fabricate, they have a limited range of inductance values.)

As much as 40 percent of passive components on a surface-mount product are chip capacitors. The miniaturization of these devices is critical for reducing the size and weight of electronic products. For handheld electronics (such as cell-phones, PDAs, and pagers), common capacitor sizes are from 0603 down to 0402 and 0201.

Some diodes and all active devices come in a wide variety of peripheral lead and area-array packages. The diodes and transistors are typically used in small-outline (SO) packages; they are the small-outline diode (SOD) and small-outline transistor (SOT) packages. The package body is a plastic overmolding compound. There are two leads for the SOD and three for the SOT. The leads are very robust, have a gull-wing shape, and are formed from Cu or an Fe-based alloy. Larger active devices require more I/Os. These devices use the small-outline integrated circuit (SOIC) package with gull-wing leads protruding from the two sides of the long dimension. The gull-wing leads are very robust with a pitch of 1.27 mm (50 mils) or 0.635 mm (20 mils). Pitch is the distance between the centerlines of two neighboring leads.

A further increase in the number of I/Os was realized by placing leads around all four sides of the package; the leads can have the gull-wing geometry or have the J-lead geometry. The J-configuration reduces the bond pad area by bending the lead inward, under the package. Like the gull-wing, the J-lead geometries are robust at 1.27 mm (50 mils) and 0.635 mm (20 mils) pitches.

Pitches below 0.635 mm, beginning with 0.5 mm and 0.4 mm pitches, are called fine-pitch (package) technology. The smaller leads are considerably more fragile, causing them to be more susceptible to damage during handling and pick-and-place activities. Also, the fine-pitch packages have a more stringent coplanarity requirement for the leads. Coplanarity specifies the degree to which the lead bottoms must be at the same level around the periphery of the package. A non-coplanar lead—one that is lifted high—is more likely to generate an open because of the reduced amount of solder used for these smaller I/Os. A lead that is too low will be damaged during package placement and also displace the solder paste deposit, causing a defective joint or short circuit to a neighboring lead after the assembly step.

A second type of peripheral I/O package is the leadless ceramic chip carrier (LCCC). This package is made of ceramic material; the I/Os are castellations on all four sides of the package. Solderability of the castellations is obtained by a Ni finish over which is deposited an Au layer. The Ni and Au layers extend down the castellation and under the frame to form a pad. This package can be used only on so-called matched or low-expansion substrates, that is, circuit board substrates with a thermal expansion coefficient that matches that of the ceramic package. Otherwise, the solder joints are quickly degraded by thermal mechanical fatigue (TMF) when exposed to even modest cyclic temperature environments.

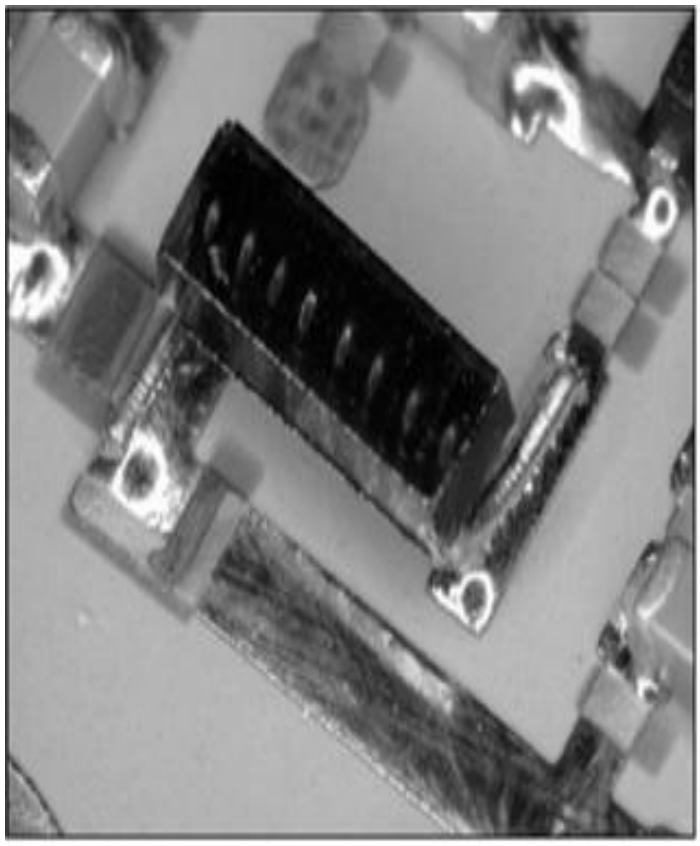
Area-array packages include the BGA, CSP, the land grid array (LGA), DCA/FC, and the ceramic column grid array (CCGA). The common characteristic of these packages is that the solder joint is made to an array of solderable pads on the bottom side of the package rather than to peripheral leads or castellations. The difference between a BGA package and a CSP package is that the latter is stipulated to have molding compound dimensions that are less than 1.2 times the corresponding die dimension. There are no specified limits on a BGA package size.

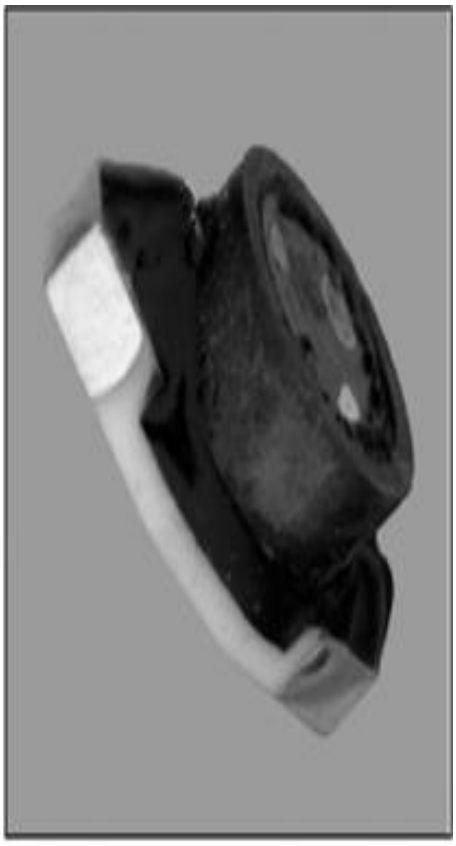
The typical pitch size is 1.27 mm and 1.0 mm for BGA and CSP packages. Here, the pitch is the distance between the center points of any two balls or lands. Therefore, alignment requirements are not very stringent for these area-array packages. Also, there is a sufficient quantity of solder to allow self-alignment between the package and circuit board pads by the surface tension of the molten solder. However, as ball counts reach several thousands, reduced ball sizes and pitches are required, which in turn necessitate closer tolerances on part placement. This is also the case of DCA, where the solder ball size and pitches tend to be as small as 0.10 mm and 0.25 mm, respectively.

The CCGA is a variant of the BGA in which the solder balls have been replaced with solder columns. The columns allow

the ceramic package to be assembled to an organic laminate circuit board of considerably larger thermal expansion coefficient by absorbing the higher strains created by the larger thermal expansion mismatch between the two materials. The columns are created from one of the high-melting-temperature, Pb-based alloys (e.g., 95Pb-5Sn or 90Pb-10Sn) that will not melt during a eutectic Sn-Pb reflow process. The columns may also have a Cu spiral wound around them to enhance durability as those columns are susceptible to damage during handling and part placement.

The accelerated development of surface mount components has generated packages and I/O configurations that have not yet been standardize, resulting in odd-form devices. Examples of odd-form components include surface mount switches and connectors as well as a variety of inductors, (Fig. 43.13) LEDs, and transformers. Typically, so-called surface-mount connectors may actually be mixed technology with through holes providing the mechanical strength needed for cable insertion and removal activities and surface-mount leads establishing the electrical connection. (The through-hole interconnections can be made by paste-in-hole techniques or be soldered manually.)





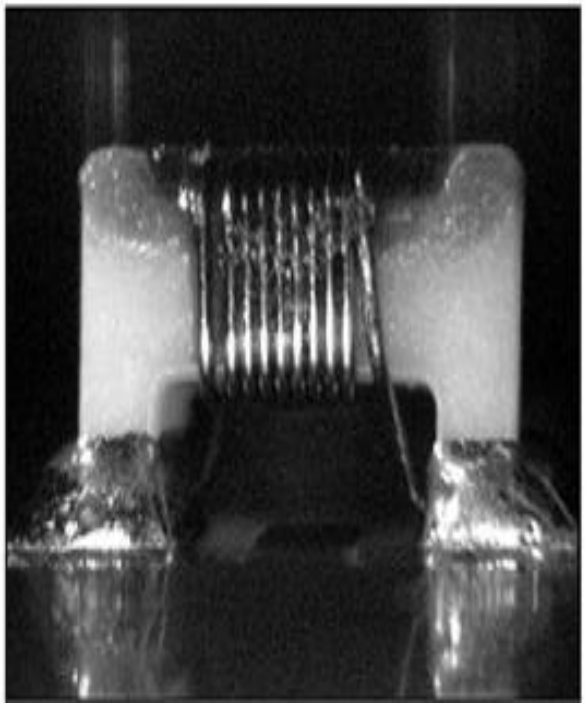


FIGURE 43.13 Odd-form components as exemplified by surface-mount inductors. (*Courtesy of Sandia National Laboratories*.)

A number of assembly-related issues must be addressed with odd-form components. First, it is necessary that correct pad dimensions be designed on the circuit board. Also, the stencil must have the correct aperture size to print an adequate quantity of solder paste. The pick-and-place machine may require custom tooling in order to handle these components. Lastly, odd-form parts are typically larger and heavier. Therefore, it is possible that they will not readily self-align while the solder is molten during the reflow process.

The conversion to Pb-free solders has significantly affected surface-mount components. In the case of leadless passive devices and peripherally leaded packages, the traditional electroplated Sn-Pb finish has been replaced with 100 percent Sn coatings. The Sn coatings have raised concerns regarding the development of Sn whiskers that can potentially short nearby conductors in service. The Sn-Pb solder balls of BGA, CSP, and DCA technologies, having a melting temperature of 183°C, are being replaced with Sn-Ag-Cu alloys with a melting temperature of 217°C. In the case of DCA/FC and CCGA applications, the high-Pb alloys used for the balls and columns, respectively, will not melt during a Sn-Ag-Cu solder process used to create the second-level interconnections.

43.3.3.2 Dispensing. In surface-mount technology, three classes of materials must be dispensed on to the circuit board: adhesives, fluxes, and solder pastes. Each of these three categories, which utilize very similar equipment options for the actual dispensing action, is discussed in the following subsections.

43.3.3.2.1 Adhesives. Adhesives are used to secure surface-mount devices to the circuit board. An adhesive may be required when, for example, exposing surface-mount

components to a wave-soldering process used to assemble a mixed technology circuit board. Also, larger components on double-sided circuit boards may be adhesively bonded in place to prevent them from falling off when the board is turned upside down for the second reflow step. Under these circumstances, the package weight exceeds the surface tension force of the molten solder that keeps smaller components on the board. The adhesive must be able to withstand the temperature conditions of the wave or reflow soldering process as well as the chemical activity of the flux. Adhesives may also be required to anchor larger surface-mount devices to the circuit board. This additional strength is needed for service specifications that include mechanical shock and vibration environments.

(Adhesives are typically not used for through-hole components because clinching the leads provides a sufficient anchor to keep the component on to the board prior to and during the soldering process. After soldering, through-hole solder joints are sufficiently robust to withstand heavy shock and vibration environments. Nevertheless, in very severe environments, adhesives may be used to anchor through-hole components to the substrate.)

It is important to control the quantity of dispensed adhesive since there must be sufficient material to perform the attachment function. On the other hand, too much adhesive can cause run-out onto the solder pad or component I/O, resulting in poor solderability. Some adhesives are prone to run-out or “bleeding” caused by their separation into individual liquid components that together comprise the adhesive material. When bleeding by a component liquid occurs beyond of the adhesive deposit, that bleeding liquid can contaminate nearby solderable surfaces. In the case of very dense circuit boards, excessive migration of the whole adhesive migration, or the bleeding of one of its components, can contaminate the pads of other components, affecting their placement and solderability.

Although the function of the adhesive is to anchor components in place for the soldering process, the adhesive deposit remains as a part of the assembly after soldering, and as such must not interfere with next-assembly steps or negatively impact the long-term reliability of the circuit board. For example, some epoxies readily absorb moisture or other organic compounds. Those absorbed materials may outgas during subsequent temperature excursions that could contaminate critical surfaces (e.g., sensors) when the product is in service. Therefore, it is important to select only adhesive materials that are qualified for a particular application.

Adhesives materials that are used in electronics assembly processes are typically based upon epoxies or silicones. Adhesives can also be described by the following four functional/materials categories: thermosetting adhesives, thermoplastic adhesives, elastomer adhesives, and toughened alloy adhesives. Each group differs in its compositions, the type of curing cycle, and its pre- and postcure material properties. The curing cycle, which typically requires an elevated temperature/time profile, must not degrade the components present on the board or the laminate itself. It is understood that the added step of a curing cycle slows the overall assembly process.

Thermosetting adhesives cure by heat or a catalytic reaction that cross-links the polymer chains. Once cured, these materials remain very strong and will not readily soften at elevated temperatures. Epoxies are one group of thermosetting adhesives, which are used widely in electronics assembly because they do not weaken at the high temperatures of wave and reflow soldering environments. Also, epoxies are resistant to attack by solvents and aqueous-based cleaning solutions. Epoxies can be one-part, in which the curing agent and resin are already mixed together, or two-part, in which the two chemistries are combined prior to application. Although the one-part epoxies

are convenient from the assembly standpoint, their storage and handling must be rigidly controlled to prevent curing prior to use. Both epoxies are cured by exposure to elevated temperatures, which can range from less than 100°C to as high as 125 to 150°C, for time periods of 1 to 4 h, depending on the specific product recommendations. There is very little outgassing associated with the curing of thermosetting adhesives. Higher residual stresses can be generated by these materials due to their rigidity at elevated temperatures when there is a significant thermal expansion mismatch among the package, the epoxy, and the circuit board substrate. The “permanency” of thermosetting adhesives complicates repair or rework functions. The removal of these adhesives usually requires mechanical scraping and abrasion that can damage the component and circuit board.

Thermoplastic adhesives soften when exposed to elevated temperatures. These adhesives are weaker than thermosetting epoxies. However, when tolerances are less restrictive, these materials may be preferred for assembly applications, particularly when excessive residual stresses are of concern during the soldering process temperature cycle. Thermoplastic materials are less resistant to solvents and aqueous-based materials. These adhesives tend to absorb these liquids more readily, resulting in dimensional changes (swelling) and more outgassing than is observed with thermosetting adhesives.

Thermoplastic materials have curing temperatures that are lower and time durations that are shorter than thermosetting materials. Some compositions will cure at room temperature, making them suitable for temperature-sensitive components or when thermal expansion mismatch, residual stresses are of concern. Another advantage of thermoplastic adhesives is that because they readily soften at elevated temperatures, they can be easily removed to allow for the rework of components.

Elastomeric adhesives are a subset of thermoplastic adhesives. These materials tend to be very tough, yet have a higher degree of elasticity. The silicone (rubber) adhesives are examples of this category. The lack of rigidity limits the application of these adhesives in the soldering assembly process. Curing temperatures are relatively low, as some compositions cure at room temperature. However, the curing cycle of some silicone adhesives include considerable outgassing and, moreover, the outgassing of vapors that can be corrosive to metal surfaces (e.g., acetic acid).

Toughened alloy adhesives are blends (or alloys) of elastomeric materials and epoxy resins that together form this special class of thermosetting-like adhesives. These adhesives are engineered to provide both high structural strength and sufficient toughness (ductility) to resist damage due to either thermal or mechanical shock. Examples of this type of material include epoxy-nylon adhesives.

All of these materials have been engineered to have properties that can accommodate one or more of the various dispensing techniques used in printed circuit board assembly (which are discussed later in this chapter). However, these properties do not remain optimal indefinitely. There are two stages of degradation. The first stage is the shelf-life of the material, which is the time frame during which the adhesive keeps its properties while the container remains unopened. Manufacturers date-code specify shelf-life based on changes to the mechanical properties (strength, ductility, etc.) and physical properties (glass transition, density, liquid viscosity, etc.) that occur to the adhesive. Density and viscosity directly impact dispensability.

The second stage of degradation occurs when the adhesive is removed from the container, mixed if required, and is loaded into the dispensing equipment. Exposure to air, even under room temperature conditions, causes the adhesive to begin curing on the assembly floor. The curing can alter density and viscosity and thus the dispensing

properties of the adhesive. Indications of a significantly cured adhesive include a clogged dispensing machine, run-out or bleeding of the deposit, and “stringers” of material created as the dispensing tool moves from one location to another spot.

43.3.3.2.2 Fluxes. The dispensing of fluxes has more limited applications in surface-mount technology (aside from mixed technology that includes a wave-soldering step). Flux dispensing is performed when solder is not simultaneously delivered to the joint—for example, the wave soldering of a mixed technology circuit board or the attachment of an area-array package for which the solder balls provide a sufficient quantity of alloy for the joint. In fact, flux dispensing is most widely used for DCA/FC applications. The DCA joints often require only a very small quantity of solder that would be difficult to control or to place accurately with typical printing equipment and stencils. Thus, the quantity of solder present in the ball forms the joint, and only flux must be added to the assembly.

Soldering fluxes are generally available only as a liquid for electronics applications. The low viscosity prevents the flux from being precisely located on the circuit board using stencil printing. Therefore, flux is usually dispensed by spraying techniques. However, once flux is sprayed on the surface, the circuit board must be soldered very quickly as volatiles and other components begin to evaporate from the flux coating.

In the case of DCA applications, the flux is applied directly to the component. The process is shown schematically in Fig. 43.14. The die is placed into a bath containing a very thin layer of flux. The thickness of the layer controls the quantity of flux taken by the die when it is withdrawn from the bath. The flux must be sufficiently tacky to anchor the die to the substrate for transport to the reflow step. Because of the large exposed surface area of the flux bath, the flux volatiles

readily evaporate so that the bath must be replenished on a regular basis.

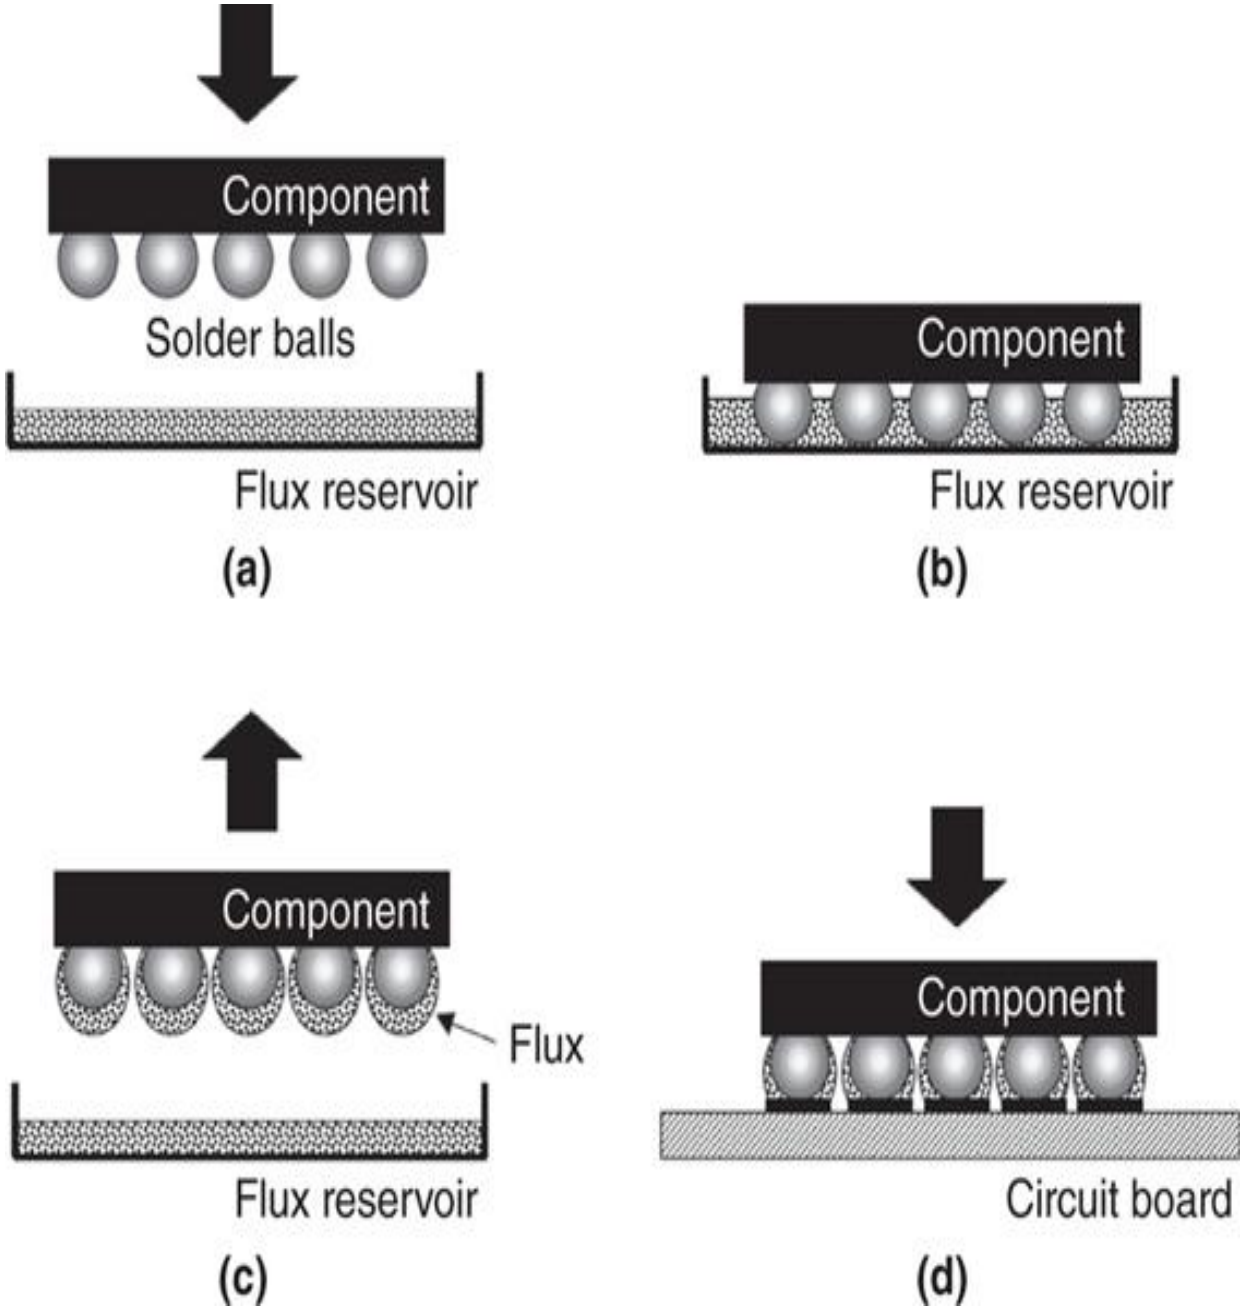

FIGURE 43.14 Flux dispensed on the balls of a flip-chip component: (*a, b*) the solder balls are immersed into the flux reservoir; (*c*) the component is removed from the reservoir with the solder balls coated with flux; (*d*) the component is placed on the circuit board.

43.3.3.2.3 Solder Paste. The dispensing of solder paste is the most widely used means of providing flux and solder metal to the joint for the reflow process. The primary components of the solder paste are the solder metal and the flux. The solder metal is typically 80 to 90 wt. percent of the paste. Aside from the In- and Zn-containing solders, there is very little sensitivity of the paste properties to the solder metal composition for Sn-based alloys. Important properties of the paste with respect to dispensing are the solder powder particle size and weight percent or “metal loading” of the paste.

The flux can be any one of the various compositions—rosin-based, no-clean, low solids, and water-soluble. The flux also provides the tack that keeps the components attached to the board prior to the reflow step. Other ingredients in the paste are the thixotropic agents. It is the thixotropic agents, together with the metal content and flux, that determine the viscosity of the paste.

Viscosity controls the dispensing properties of the paste, irrespective of the particular technique (needle, screen printing, etc.). The viscosity and hence the dispensability of the paste change with time, whether slowly in an unopened jar on the shelf or more quickly when the paste is exposed to air while awaiting the dispensing step. Care should be taken to monitor strictly the manufacturers’ recommendations for shelf-life and lifetime on the assembly floor. Poor solder paste dispensing accounts for the majority of solder-joint defects observed in surface-mount technology.

43.3.3.2.4 Dispensing Methods. There are five primary methods for dispensing adhesives, fluxes, and solder pastes:

1. Pin transfer
2. Screen or stencil printing
3. Time-pressure pump dispensing
4. Archimedes screw pump dispensing

5. Positive displacement pump dispensing

The latter three methods generally produce a single deposit per dispensing step. The first two methods enable the application of the material at multiple sites in a single step. Of course, the five techniques do not perform equally well for the three materials. This section discusses the advantages and disadvantages of each technique.

Pin transfer is the simplest technique for dispensing adhesives and flux. Although a single pin may be used to deposit material one location at a time, a matrix of pins can do so at multiple sites, the pin transfer process is illustrated in Fig. 43.15. This technique is suitable for adhesives and fluxes; it does not work as well with solder paste. A pin is dipped into a reservoir of the adhesive or flux. The length and diameter of the pin determine the quantity of material that is picked up upon its withdrawal from the reservoir. The pin is then lowered to a position just above the surface of the printed circuit board that allows the flux or adhesive to contact the circuit board. Surface tension causes a portion of the adhesive or flux to be deposited on the printed circuit board. It is very important that the pin does not touch the board because this will cause inconsistent dot sizes and shapes. This system requires the substrate to be relatively flat and free from distortion. The nature of the pin array can also allow for adhesive to be applied to the board even after through-hole parts have been put into place.

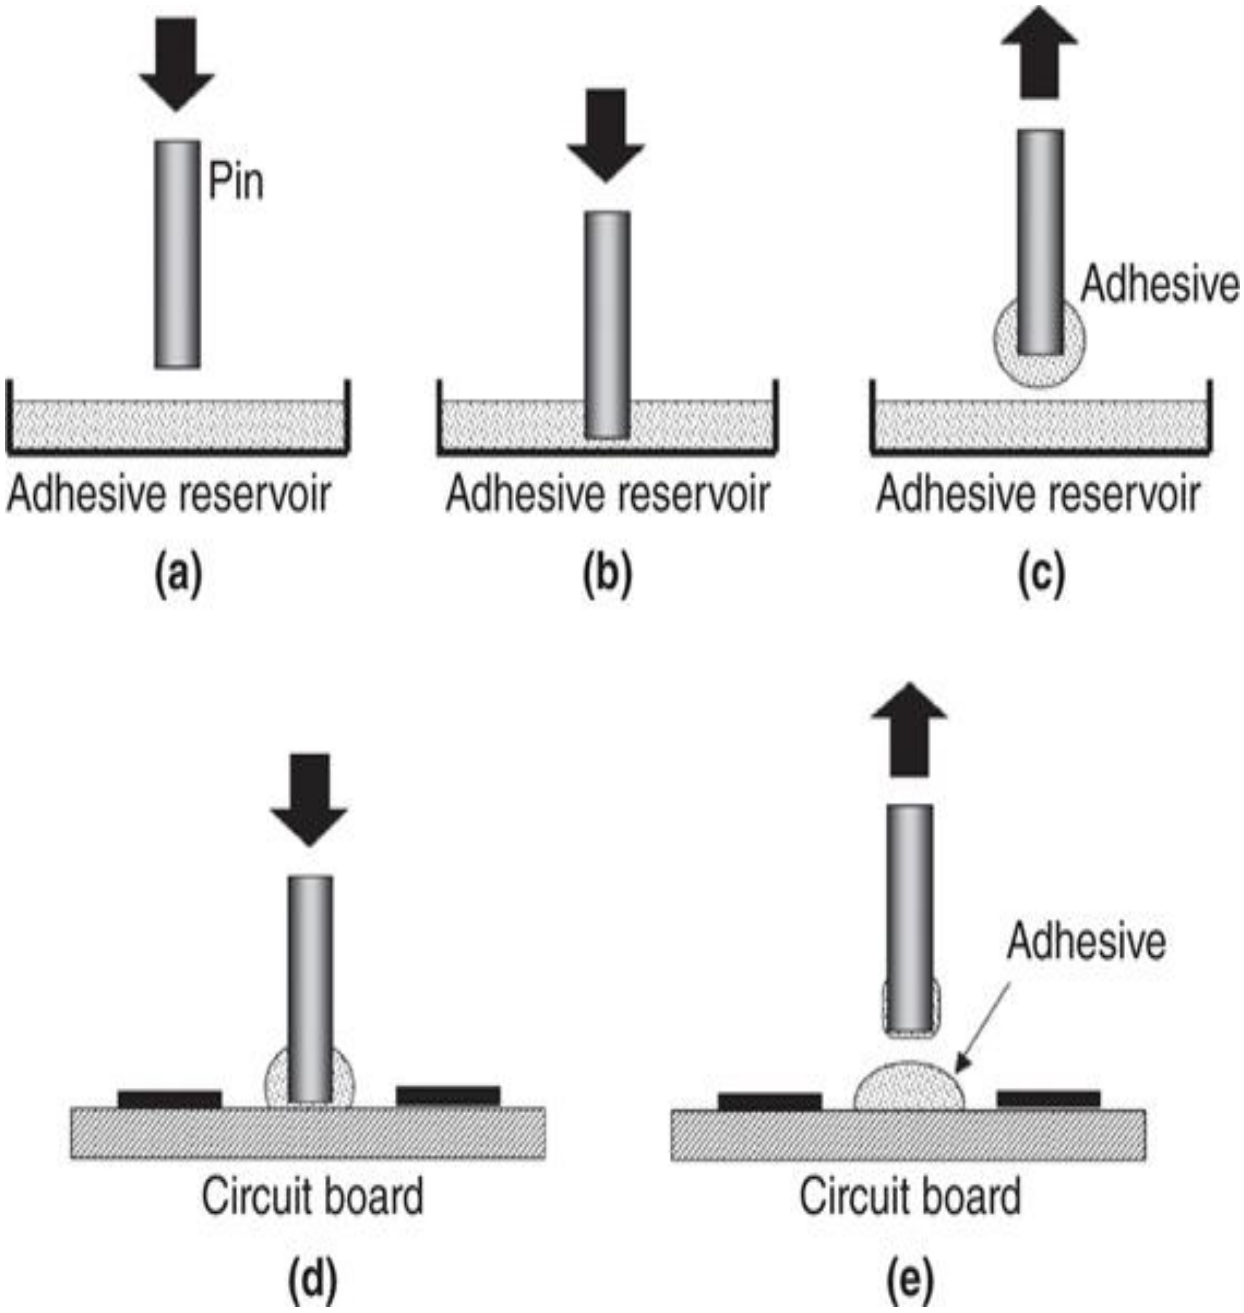

FIGURE 43.15 Pin transfer technique: (*a*) the pin is brought down to the adhesive reservoir; (*b*) the pin is immersed in the adhesive; (*c*) the pin is withdrawn from the reservoir with a repeatable quantity of adhesive; (*d*) the pin is positioned on the circuit board, allowing the adhesive to contact the surface; (*e*) the pin is withdrawn from the surface, leaving behind a well-controlled volume of adhesive.

A similar principle to pin transfer is used for the application of flux on the solder ball of FC components for DCA (see Fig.

43.14). The die is immersed into a thin film bath of flux. The flux depth allows only the balls to be coated so that, in effect, the solder balls become the pin, taking up the flux. The flux on the solder balls is transferred with the die to the circuit board, where it provides the tack function as well as fluxing action for the solder balls during the reflow step.

An important consideration about the pin transfer technique is that it requires an open bath of the adhesive or flux. Adhesives readily absorb water from the air. Fluxes lose vehicle (water or alcohol) and possibly other constituents through evaporation. By either mechanism, the material properties change, which affects the quantity of fluid retained on the pin and deposited at the site (including the flip-chip process previously described). Adhesives must have sufficient “wet strength,” and the fluxes must have enough tack to hold the component in place for the duration of component placement activity as well as subsequent handling of the circuit board on its way to the curing oven or reflow oven.

Screen or stencil printing can be used for adhesives as well as solder paste. The low viscosity of most flux solutions precludes their successful dispensing by this technique. The adhesive or solder paste is deposited through openings in the stencil or screen called *apertures*. The apertures are located over the locations on the circuit board where the adhesive or solder paste is required. The placement of material is performed by a squeegee pushing a quantity of adhesive or paste ahead of it, over the screen or stencil, as illustrated by Fig. 43.16*a*.

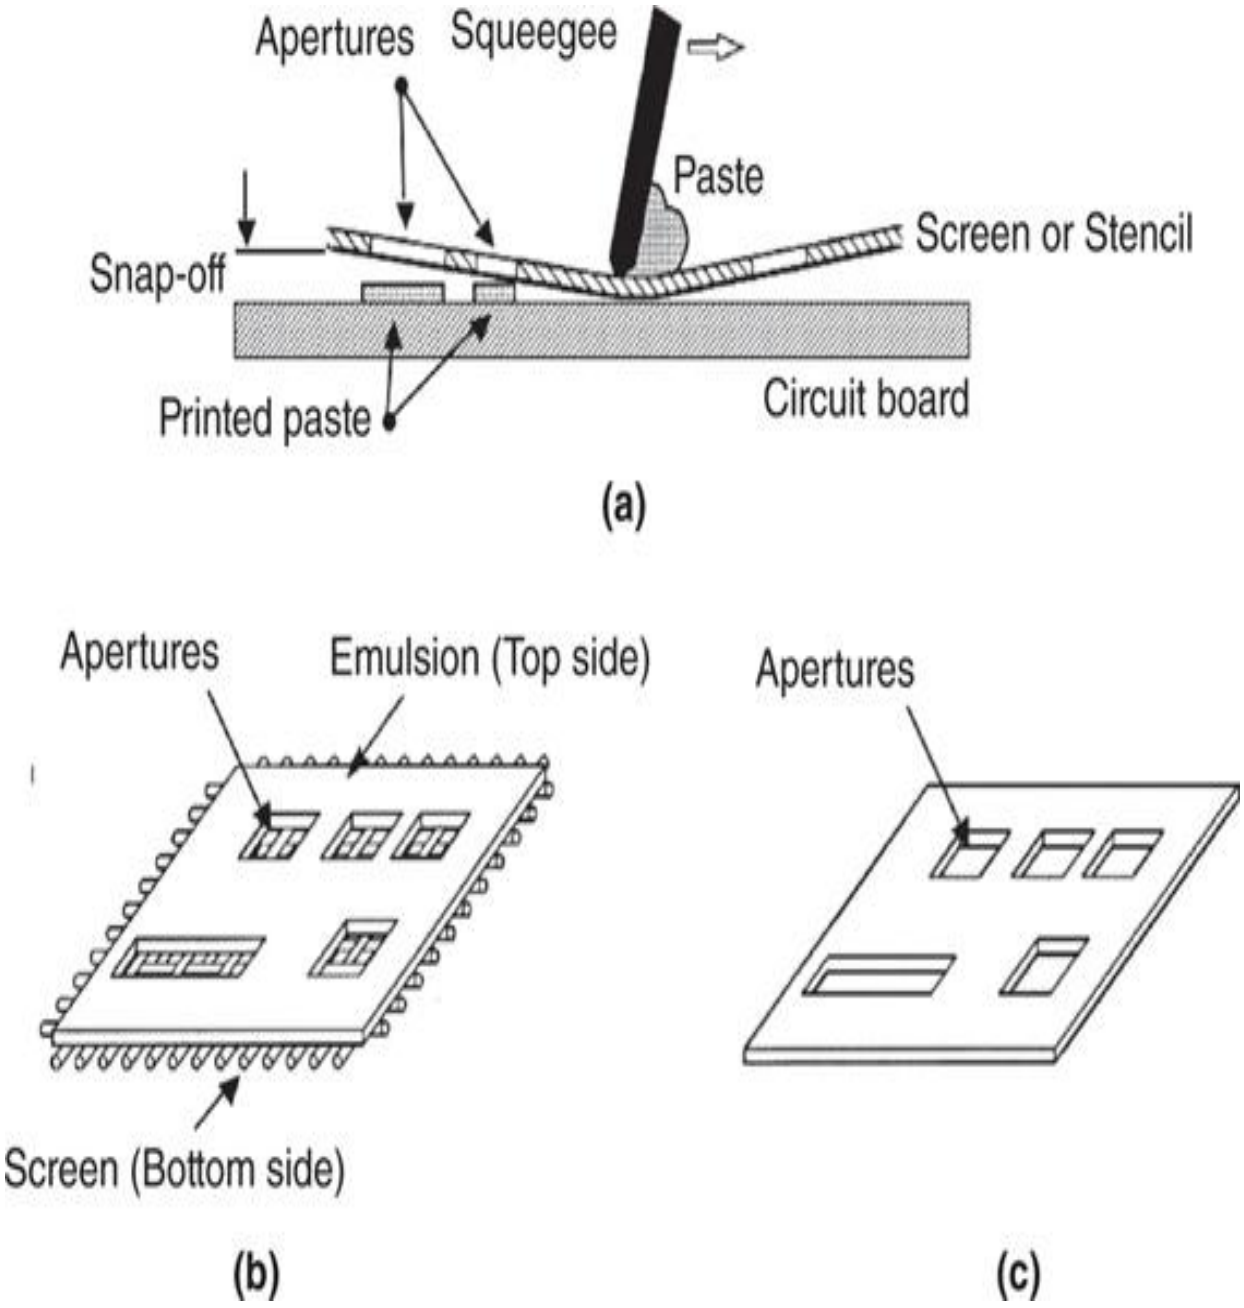

FIGURE 43.16 Screen and stencil printing: (*a*) the squeegee movement used to print adhesive or paste through a screen or stencil; the construction of a screen (*b*) and stencil (*c*) used for printing.

The difference between a screen and a stencil is in their respective structures, as shown in Fig. 43.16*b*, *c*. The screen is comprised of two layers: the emulsion layer and the actual screen that supports the emulsion layer. The apertures through which the adhesive or solder paste is deposited are

created in the emulsion by photoimaging techniques. The adhesive or solder paste simply flows past the screen cross-hatched wires.

The stencil is simply a sheet of metal or alloy (commonly Mo, Ni, brass, or stainless steel) having the apertures formed in them. The apertures can be created by one or a combination of the following techniques:

- Photoimaging (photoresist definition) combined with etching by wet chemistry
- Laser cutting
- Build-up technology by electroplating processes

The choice of fabrication technique depends on the required sizes and densities of the apertures. The stencil has replaced the screen in most surface-mount printing applications, not only because of its simpler construction, but also because it can accommodate finer, denser circuit board features.

The thickness of the screen or stencil and the size of the individual aperture openings are the parameters that control the *quantity* of adhesive or solder paste deposited on the circuit board. Secondary factors are the aperture wall quality, the material viscosity, the hardness of the squeegee, and the speed of the squeegee. In the case of solder paste, the quantity that is actually deposited is usually *less than* the volume of the aperture, which is the product of the width, length, and stencil thickness. The degree of that discrepancy is called the *transfer factor* or *transfer coefficient*. Values can range from 60 percent for very small apertures to nearly 100 percent for larger aperture openings.

Screen or stencil printing is the most widely used means for depositing solder paste on a surface-mount circuit board. The preferred paste viscosity for screen printing is 250 to 550 kcps (kilo-centipoises) for an 80-mesh screen. In the case of stencil printing, the desired viscosity is 400 to 800

kcps. The ability to print consistently upward of tens of thousands of paste deposits per circuit board has been critical to the realization of high-volume electronics production. This process is being developed for through-hole circuit boards and is referred to as *paste-in-hole* or *pin-in-paste* technology.

Solder paste printing technology includes stepped stencils. Stepped stencils are made with two different thicknesses and are used when a circuit board has such a wide range of device pitches and joint configurations that a single stencil cannot yield the optimum paste deposits for all the components. The thinner sections are used for the very-fine-pitch packages, whereas the thicker sections deposit paste for the larger-pitch components. These stencils are more expensive to fabricate than the single-thickness products.

The printing of adhesive or solder paste with a screen or stencil has several limitations. It can only be performed in a single pass; if there is a fault during that pass, the board must be removed and cleaned prior to a second attempt. Second, the circuit board surface must be flat and have no obstructions that will interfere with the stencil or screen surface “sealing” against the board surface as the adhesive or paste is pushed into the apertures by the squeegee. As such, it is important that the screen or stencil be thoroughly cleaned of paste residues prior to use in order to minimize printing defects, which can subsequently become solder joint defects if not caught prior to reflow. Third, stencils and screens wear with time, resulting in an increased number of printing defects. The harder the metal or alloy, the longer is the lifetime. For example, brass stencils, which are relatively inexpensive, have a short service life. Stainless steel stencils have a longer lifetime, but are also considerably more expensive.

Referring to the solder paste printing process with a stencil, Pb-free solder pastes behave very similar to the Sn-Pb pastes for leaded and area-array pitches of greater than

0.5 mm. At the smaller pitches that are characterized by smaller apertures, it has been observed that the Pb-free solders have a slightly reduced transfer coefficient. The likely cause is the reduced density of the Pb-free solder particles, which becomes a significant factor when so few particles are passed through the aperture. Therefore, it may be necessary to slightly open up the apertures to ensure a sufficient quantity of Pb-free solder at the joint.

Time-pressure pump dispensing is a method to deposit adhesive or solder paste by applying a pressure pulse for a specific time duration on a reservoir of material (see Fig. 43.17). A precisely controlled quantity of adhesive or solder paste emerges from the selected orifice size, which is deposited on the circuit board. Often, the material comes prepackaged in a syringe that is inserted into the machine.

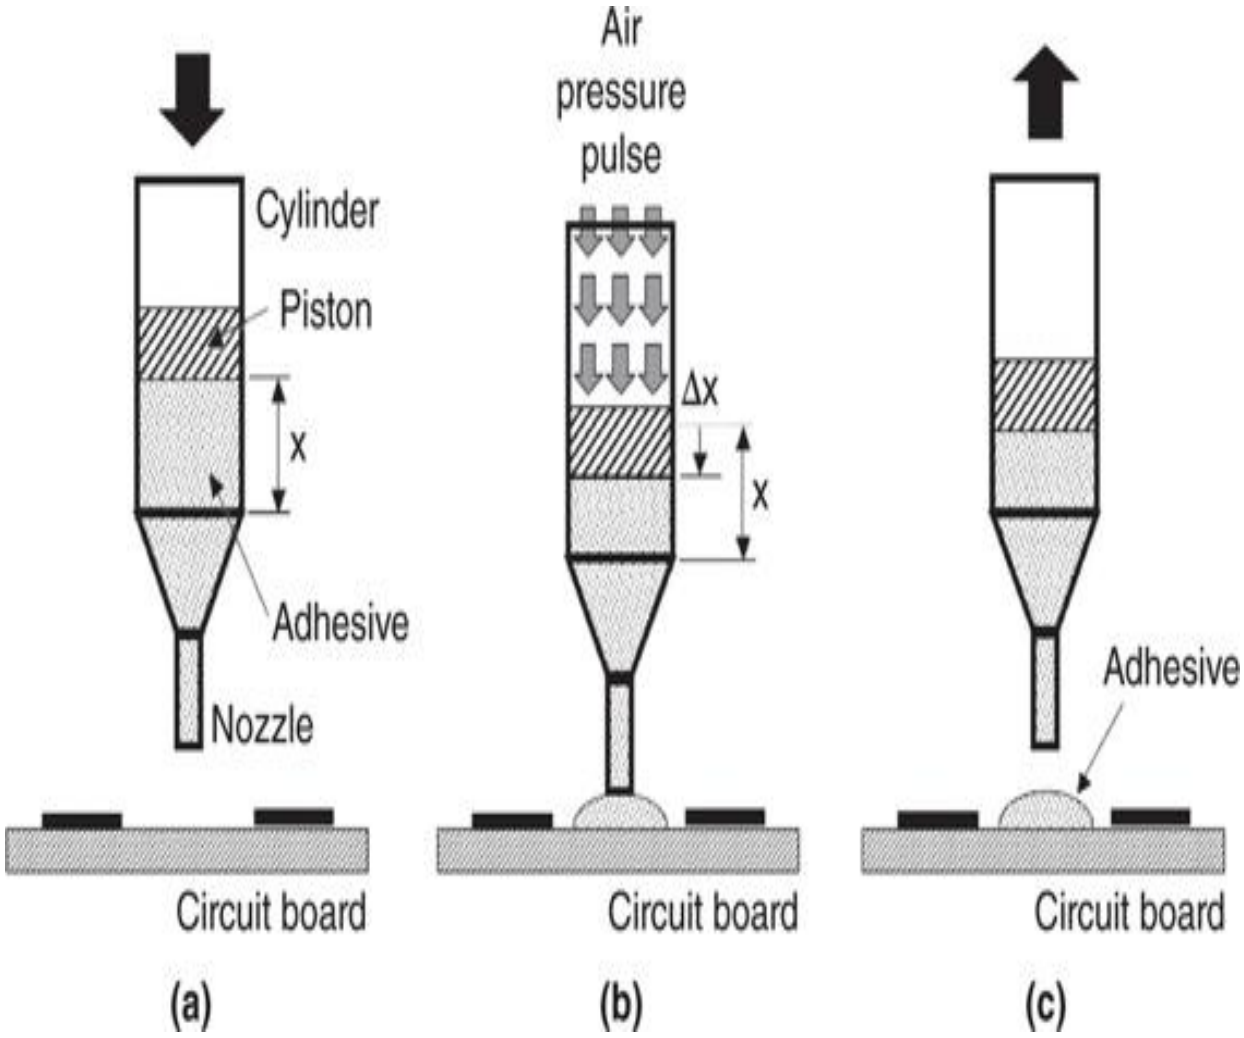

FIGURE 43.17 Time-pressure pump dispensing technique: (*a*) the dispenser is positioned at the circuit board site; (*b*) the dispenser is lowered to near the surface at which time, a pulse of air pushes the piston a distance Δx to dispense a set quantity of adhesive; (*c*) the dispenser is raised from the site, leaving the adhesive deposit.

As with all dispensing techniques, the flow properties of the adhesive or solder paste are important factors that determine the consistency of the deposit between the different sites. Shelf-life requirements should be strictly followed, particularly those pertaining to time allowed for the material to be present in the dispenser due to rapid degradation when open to the factory floor environment. The desired viscosity for pump dispensing through a nozzle is 100 to 400 kcps.

Machines utilizing the time-pressure dispensing technique can dispense different deposit sizes on a single board. One approach is to have multiple nozzles or syringes on a single head, using the same pulse profile. The second approach is to preprogram a different time-pressure pulse that alters the deposit quantity from a single orifice or syringe. This pump-dispensing technique (as well as those described in the following paragraphs) is slower than screen or stencil printing. However, it offers greater flexibility in terms of well-controlled deposit quantities and location.

Archimedes screw pump dispensing utilizes an Archimedes screw to push the adhesive or solder paste out of a nozzle (see Fig. 43.18). The speed and duration of a turn, as well as the size of the opening, determine the quantity of adhesive or paste deposited on the site. As in the case of the time-pressure technique, different deposit quantities can be realized by multiple spindle (heads) or a computer program that alters the screw speed or turn duration to change the amount of material dispensed from the same orifice. All other considerations with respect to the roles of adhesive or solder paste viscosity and shelf-life also apply to this technique.

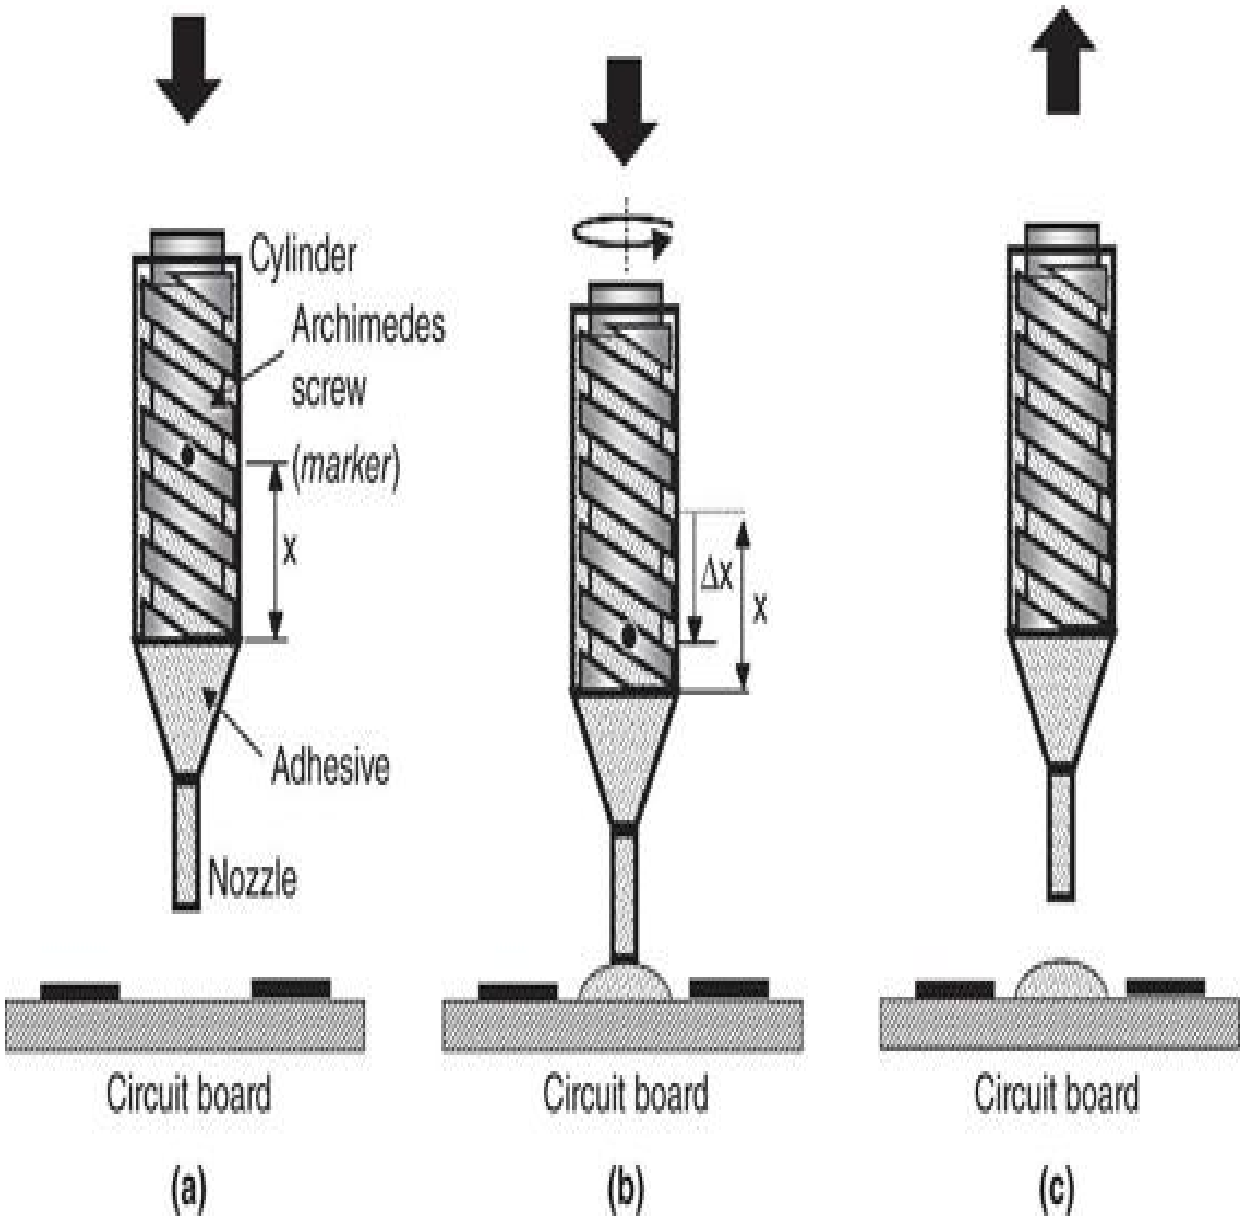

FIGURE 43.18 Archimedes screw pump dispensing technique: (*a*) the dispenser is lowered to above the circuit board surface; (*b*) the Archimedes screw is turned a set rotation (Δx), pushing adhesive out of the nozzle; (*c*) the dispenser is lifted from the circuit board.

Positive displacement pump dispensing uses a piston, rather than an air pressure pulse, to control the deposit quantity. This technique is used primarily to dispense adhesive (see Fig. 43.19). First, the nozzle is placed in a bath of adhesive, in which it retracts to draw a quantity of adhesive that fills the orifice and small cylinder at the top of

the orifice. This suction step works best with low-viscosity fluids. It is difficult to pull up relatively high-viscosity materials such as solder paste and some adhesives. Next, the piston moves downward into the cylinder, forcing an exact amount of adhesive out the nozzle and onto the printed circuit board. This technique consistently produces the same volume of material. Besides the dimensions of the cylinder as well as the speed that the piston displaces, the viscosity of the adhesive also affects the dispensed quantity. Shelf-life specifications should be strictly enforced.

FIGURE 43.19 Positive displacement pump dispensing technique: (*a*) the dispenser is brought to the adhesive reservoir; (*b*) the nozzle is immersed into the adhesive and the piston withdrawn a distance Δx, resulting in a set quantity of material being pulled into the cylinder; (*c*) the dispenser is brought to just above the circuit board surface so that a reverse displacement of the piston pushes out a quantity of adhesive; (*d*) the dispenser is lifted from the circuit board.

The primary objective in each of the five dispensing techniques is to deposit *consistently* a *specific quantity* of adhesive or solder paste at each designated site. Too small of a quantity of adhesive, especially dot height, can fail to attach the part to the board. Too much adhesive causes it to run on to the solder pads, degrading solderability. In the case of solder paste, an insufficient quantity of paste will cause an incomplete joint or, in the worst case, an open circuit. An excess of solder paste results in a fillet that is difficult to inspect for solderability or risks formation of short circuits between neighboring interconnections.

43.3.3.3 Component Placement. The purpose of the component placement machine—also called the "pick-and-place" machine—is to select the proper component, orient it correctly, and then place it on the circuit board, all with degrees of accuracy and precision that minimize defects on the finished product. In addition, the component must be placed on the printed solder paste, the dispensed adhesive, or a combination of the two deposits with a controlled pressure or release distance that does not excessively spread out either material or damages the component package. Moreover, the placement machine must execute these tasks as quickly as possible in order to maximize the production volume. Lastly, the equipment must be sufficiently versatile to address continually changing electronic packages, specifically dimensions and I/O configurations.

The change to Pb-free solders does not have an explicit impact on component placement machine technology.

Indirectly, however, the need for alternative surface finishes on both the components and circuit board fiducials, which have different reflectance characteristics, can affect the performance of the vision systems used to locate accurately both the circuit board and the tooling that delivers the component to the board.

Several machine types are available. The turret-style chip shooter and the gantry-style or flexible fine-pitch (FFP) machines have both been used extensively in the assembly of consumer electronics, telecommunications, mainframe and server computers, as well as for lower volume, high-reliability electronic products. However, the demands for even higher production volumes as well as the flexibility to change product lines rapidly have caused manufacturers to consider alternative machine architectures that include high-speed stepper motors and optical sensors as well as highly parallel methodologies that place multiple components at the same time.

43.3.3.3.1 Turret Systems (Passive Devices). The basic turret or “chip shooter” has been used to place passive components (i.e., capacitors, resistors, etc.) since the early development of surface-mount technology. A photograph of the turret head and schematic diagram of its operation are shown in Fig. 43.20. Multiple heads are positioned around a stationary, horizontally rotating turret. A moving feeder carriage positions tape feeders that deliver a component to each head. After the part is located in the head, the turret rotates it to a vision processing station where a charge coupled device (CCD) camera acquires an image of the part. This image is processed so that the part will be precisely located over the circuit board location. As the turret continues rotating, a moving table positions the printed circuit board so that the target location is in position under the turret head to receive the component. The part is lowered to the circuit board and released. The head rotates to acquire another component, and the cycle repeats itself.

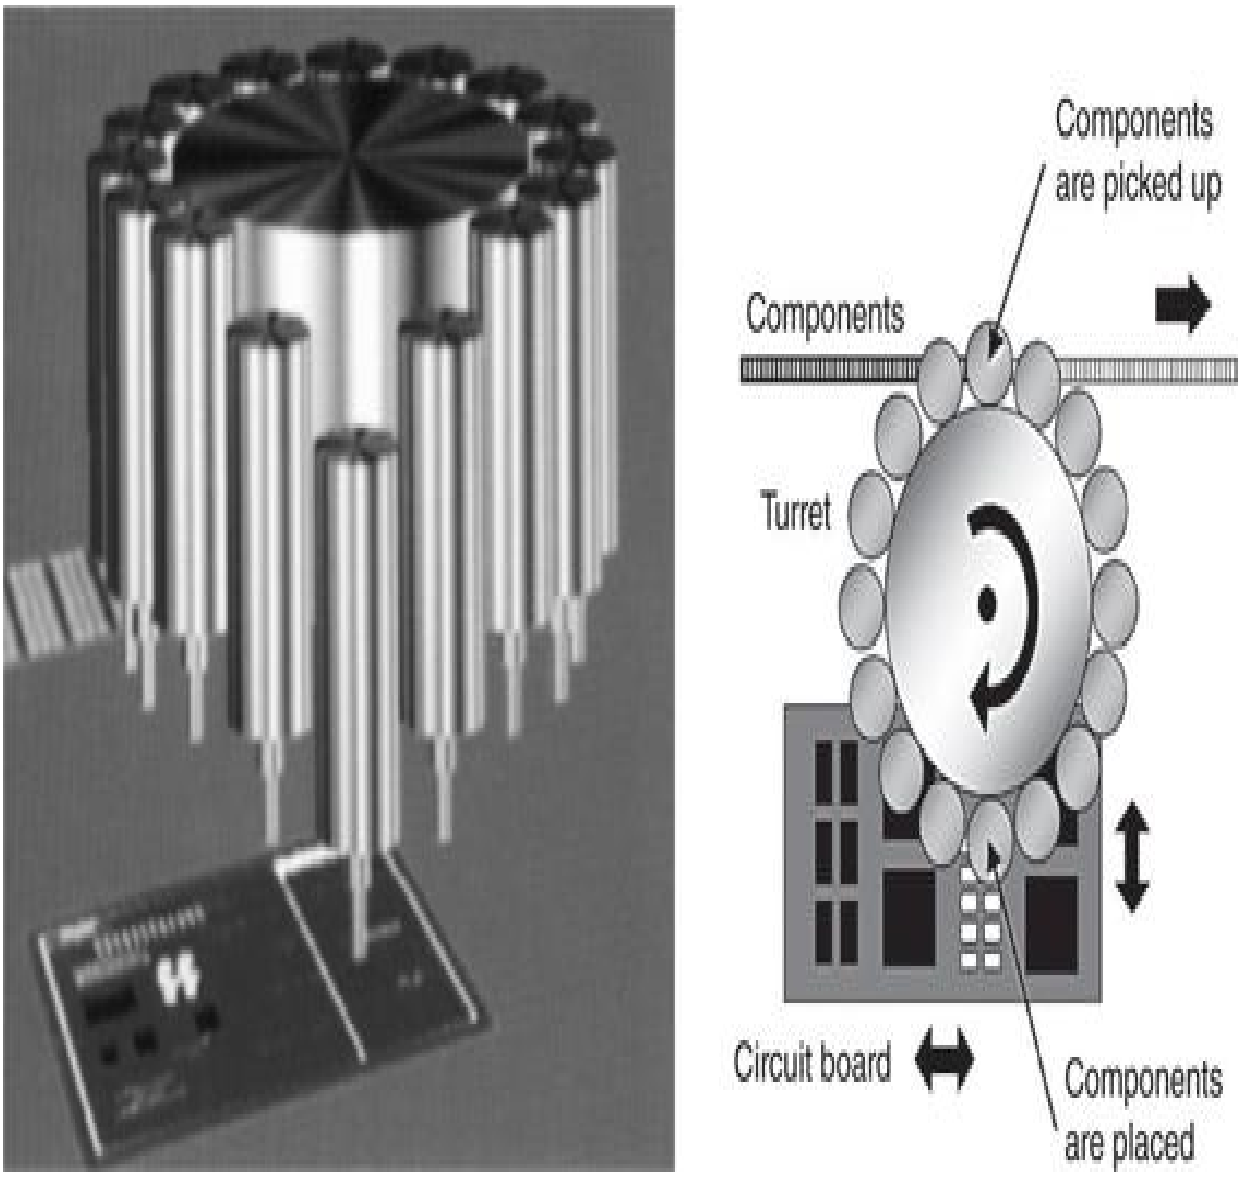

FIGURE 43.20 Turret head used to retrieve chip components from a tape and place them on the circuit board. (*Photo courtesy of Universal Instruments*.)

Listed in Table 43.3 are general performance characteristics for turret chip placement technology. This technology is constantly addressing smaller passive devices (0101 and 01005) as well as an increased demand for placing bare die (flip-chip) components on more densely populated circuit boards. Equipment manufacturers and users must continually address new package configurations with different I/O geometries.

TABLE 43.3 Capabilities of Turret Chip Placement Technology

Property	Range
Part range	0201 (English) passive chip devices to 10 mm area-array packages
Part capacity	Several hundreds
Placement speed	25,000–40,000 CPH*
Capabilities	1. Handle both chips and small area-array packages. 2. Moving turret and PCB to increase placement speed. 3. Flexibility of using either tape or bulk part supply.

*CPH = components per hour

43.3.3.3.2 Gantry Systems (Active Devices). The gantry-style architecture differs from the turret because the printed circuit board is fixed in place and the moving gantry locates the component over the correct position (see Fig. 43.21). The part feeder is stationary. The gantry method is typically used to place larger components (e.g., SOICs, PLCCs, etc.). Several attributes of gantry technology are listed in Table 43.4.

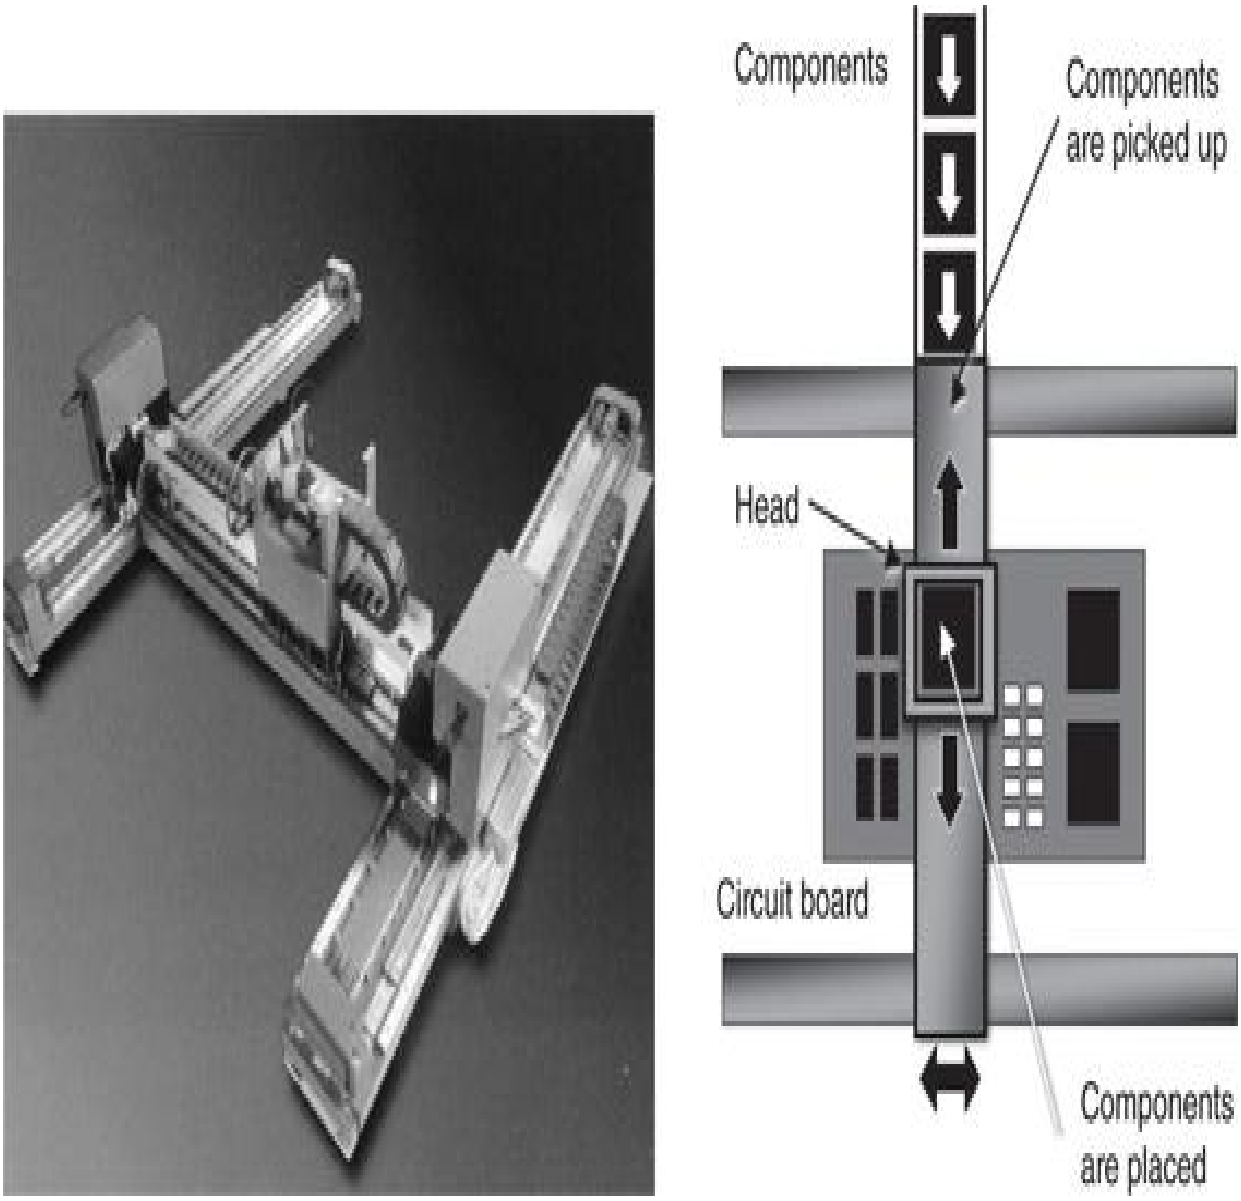

FIGURE 43.21 Gantry architecture used for placing larger components such as SOICs, PLCCs, and area-array packages. (*Photo courtesy of Universal Instruments*.)

Placement speed	5,000–15,000 CPH*
Capabilities	1. Oversized and odd-form parts placed with very high accuracy. 2. Moving gantry, fixed PCB, and feeders. 3. Flexibility of using tape, tube, bulk, and tray part supplies.

*CPH = components per hour

Several equipment variations can be specified to increase the variety of parts placed on the circuit board. Each gantry is made to accommodate different parts when equipped with a multispindle placement head. The placement head is positioned at each feeder location to receive a part. Then, the head moves the component to the upward-looking vision station for inspection followed by its placement on the printed circuit board. A second option is a placement machine made with dual gantries, each placing a single component type or multiple components with the spindle head option.

Several features in gantry-style equipment allow component placement speeds to approach those of turret systems in “high-speed” models. See Table 43.5 for the performance of some dual-beam (gantry) equipment. Machine options that enhance placement speeds include tape splicing for uninterrupted machine operation and simpler bank-changing capability to allow for the rapid changeover of components between different product lines. Also, part inspection can be made using a head-mounted

camera while the gantry(ies) is (are) in motion, which eliminates the time interval required for part inspection with a stationary, upward-looking camera.

Property	Range
Part range	Full SMT (Passives, SOD, SOT, SOIC, PLCC, CCGA, BGA), direct-chip attach (DCA), and odd-form components.
Part capacity	Several hundreds
Placement speed	15,000–21,000 CPH*
Capabilities	1. Oversized and odd-form parts placed with very high accuracy. 2. Oversized board capacity. 3. High volumes of tape, tube, bulk, and tray part supplies.

*CPH = components per hour

Further enhancements in capabilities of component placement equipment can be realized in *massively parallel* architectures. The attributes of this approach are listed in Table 43.6. Multiple placement modules are capable of picking up, inspecting, and placing components at the appropriate location on the circuit board. The circuit board is stepped by an indexing conveyor to locate the placement site precisely under the overhead component.

43.3.3.3.3 Machine Vision Technology. A brief which is description is provided of one of the most critical advancements in component placement *machine vision technology*. The earliest pick-and-place function relied on mechanical stops (*detents*), switches and precision tooling to ensure that components were placed at the correct locations and with the proper alignment of I/Os to pads. As both board densities and component varieties increased, this technology was too slow to meet the requirements for higher production volumes and reduced placement defects. A critical incentive to move away from mechanical registration toward vision-based placement came from smaller I/Os on components. DCA/FC uses die bump pitches as small as 0.1 mm. Passive device sizes are commonly 0402 and 0201. Fine-pitch, quad flat pack (QFP) components have lead pitches as small as 0.3 mm. Each of these cases underscores the need for very high placement precision that can be realized only with machine vision technology.

In addition, there has been a steady increase of odd-shaped devices that include inductors as well as LEDs, surface-mount connectors, etc. The result has been circuit

boards with a greater mix of package types and sizes. Consequently, it is considerably less expensive and time-consuming to reprogram a computer-based, machine vision system to recognize these components than it is to retool a machine based on mechanical relays, detents, and such for component placement.

Machine vision technology uses electronic cameras and optics together with specialized computer software to control the stepper motors responsible for positioning the component and the circuit board (site) relative to each other with the required accuracy and precision. To realize this objective, the placement machine must identify the component in the turret or gantry and establish the position of the turret or gantry. At the same time, the placement machine must know the position of the circuit board. The computer software ties these two requirements together by being programmed with the artwork (drawings) that identify the location of each component on the circuit board. Component recognition and circuit board recognition are discussed next, followed by comments regarding vision system limitations.

Component recognition is typically obtained from the configuration of the I/Os. The I/O configuration includes two attributes: the I/O's shape, whether it is a beam lead, gull-wing lead, or solder bump; and the I/O's layout, which may specify, for example, peripheral leads on two rather than four sides, or solder balls as full area-array packages rather than perimeter, area-array packages. Shown in Fig. 43.22*a* is the machine vision image of a flip-chip die with a perimeter array of solder bumps. The vision system determines the position of the package based upon the coordinates of the I/O locations, for example, two or four of the corner leads or solder bumps. Additional fiducials and/or nonsymmetries in the I/O layout (e.g., missing corner leads or bumps) are used to establish the rotational orientation of the component.

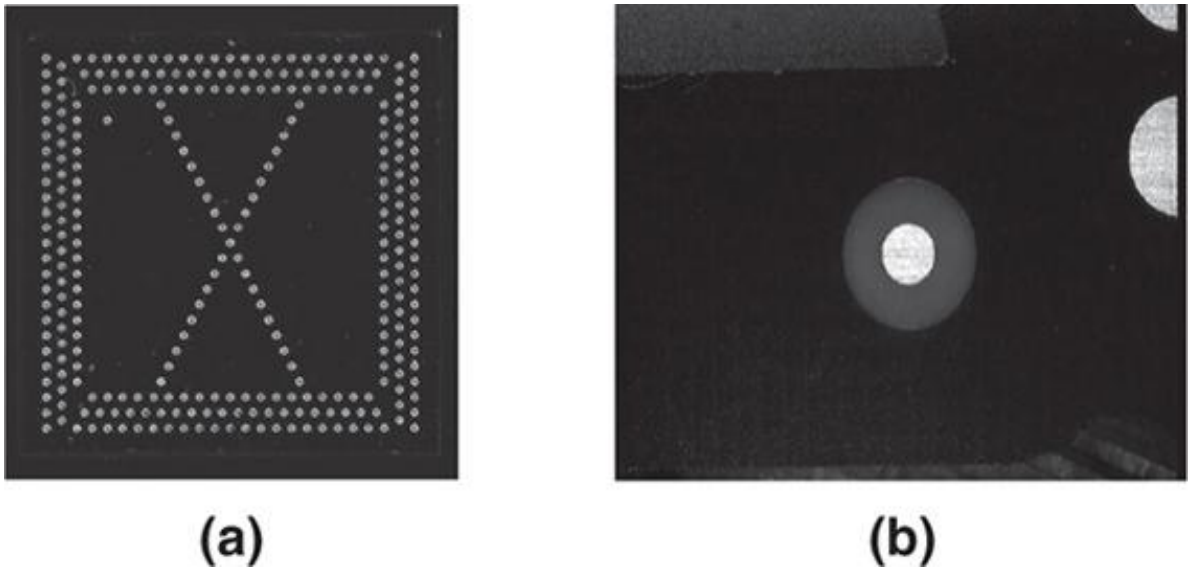

FIGURE 43.22 Vision system images: (*a*) a flip-chip component; (*b*) a printed circuit board fiducial. (*Courtesy of Universal Instruments*.)

Besides determining component type and orientation, vision systems have also been programmed to recognize damage to components. For example, fine-pitch quad flat packages are prone to bending of the very small leads, particularly at package corners, due to worn die sets or improper handling. In the case of area-array packages (BGAs, CSPs, and DCA die), there can be missing balls or solder bumps. The damaged component is rejected into the "scrap bin" and a new unit retrieved for placement. It should be noted that component recognition vision systems are designed primarily for part placement. Although defect recognition can be programmed into the software, increasing the degree of inspection function slows the placement process significantly. Therefore, the optimum approach is to allow the vision system to identify only gross component defects, targeting those defects that would occur between incoming inspection and the component placement step. Otherwise, full, incoming component inspection should be performed *before* the parts are loaded into the placement machine.

Circuit board recognition requires that the machine (computer) be able to locate the circuit board site precisely for the component. First, the circuit board is secured on the conveyor by mechanical clamps, vacuum chuck, or other technique. The circuit board is then positioned under a camera that identifies the registration marks or fiducials on the surface (see Fig. 43.22*b*).

This process is repeated for two to three other fiducials on the circuit board. At this point, the machine "knows" the location and orientation of the circuit board and thus, through the artwork design stored in the software, correlates the fiducial locations with the location of each component site. Subsequently, the software matches the coordinates of the circuit board site to those of the component positioned in the turret or gantry. Then the software instructs the stepper motors to position the component over that site and lower it on to the circuit board.

Some applications, such as those using ceramic substrates that are prone to inconsistent degrees of shrinkage during fabrication (e.g., low-temperature, cofired ceramic, or LTCC), may develop a discrepancy between the software design and the actual circuit board component positions (pads). In this case, the placement site of each component is determined directly using fiducials in close proximity to that component site. Although local fiducials may enhance component placement accuracy to some degree, especially when tolerance stack-up in the product causes it to deviate from the design files, this approach requires added processing time by the machine computer. The result is a decrease in placement speed that can develop into an appreciable process delay, particularly for large production volumes.

Vision system limitations are determined by the speed with which the computer can process information (e.g., circuit board coordinates, component geometries, defects). The more information to be processed, the slower is the component placement step. For products requiring the

placement of thousands of parts per circuit board, even an additional few tenths of a second per component can add up to a significant loss of production throughput.

Similarly, there are operational limitations on vision systems themselves (cameras and optics). The trade-off is between resolution and the range of processable part sizes. The underlying premise is pixel count. The vision system requires a minimum number of pixels to recognize a feature (lead, solder bump, fiducial, etc.). A very small feature (e.g., a flip-chip solder bump) requires both high magnification and high resolution (i.e., pixels/length or pixels/area) in order for the system to recognize the feature. However, using the same system to recognize a large BGA package would require a magnification that may well be outside the capability of those same optics. Moreover, even if the package could be brought into the field of view, using the same high resolution, which is now not necessary, will overload the computer memory and bog down the software processing step, resulting in a slowing of the placement process. And conversely, the same camera that can efficiently process a large, 32 mm QFP (208 I/O) in a single image would generally not have sufficient resolution to process a flip-chip solder bump of 0.1 mm diameter. Therefore, the choice of optics is critical to maximize the efficiency of the pick-and-place function for a particular product. For optimum efficiency, it may be necessary to place the two components on separate machines. Alternatively, multiple cameras and optics may be used on a single piece of equipment. Cost becomes a critical factor.

Once the components have been placed, the circuit board is soldered using one of the techniques briefly described in the following sections. The component placement step is synergistic with the soldering step and, in particular, reflow soldering. That synergism arises from the fact that placement inaccuracies can be compensated by the self-alignment of packages arising from the surface tension

(more accurately, the solder-flux interfacial tension) of the molten solder. This self-alignment phenomenon opens the placement window for passive devices larger than about 0603, smaller LCCCs, and 1.27 mm pitch area-array packages of up to several hundred balls. Unfortunately, for smaller passive devices and larger area-array packages, the self-alignment process becomes less capable of compensating for placement errors. In the case of smaller passive devices, there is the increased likelihood that an imbalance of surface tension forces can result in an asymmetric movement of the part, causing the tombstoning defect. In the case of larger area-array components, poor placement (which is becoming more critical with the finer pitches of smaller balls) cannot always be remedied by self-alignment simply because of the greater weight of the component.

The topic of soldering is described in greater detail in Chaps. 46 and 47. Therefore, this chapter offers only a brief overview of each approach, with the discussion limited to its relevance to the overall assembly process.

43.3.3.4 Reflow Soldering. Reflow soldering is the technique in which a circuit board, which has the components placed on the solder deposit (either as paste or preforms) is passed through a furnace (oven) in order to melt the solder and form the joints. The furnace may be a batch type in which the circuit boards must be loaded and unloaded, one group at a time. The operator inputs the batch furnace time-temperature profile into the controller that alters the power to a set of heating coils as a function of time. The atmosphere can be very well controlled, including the use of vacuum. The batch furnace is advantageous for small production lots, including development work or when the time-temperature profile and environment must be carefully controlled for the application.

The second furnace has an inline configuration. The circuit boards continuously enter one end unsoldered and exit the other end soldered. Therefore, the inline furnace can be part of an overall assembly line, receiving stuffed circuit boards from the component placement machine via a conveyor without operator intervention. The temperature of the different zones along the length of the furnace and the conveyor speed determine the time-temperature profile. More zones (five to seven are typical) provide for better control of the soldering profile. Inert atmospheres, typically nitrogen (N_2) to minimize cost, can be maintained to better than 20 ppm oxygen (O_2). However, control of both the time-temperature profile as well as atmosphere cannot match that of a batch furnace. Also, vacuum conditions are not possible with most inline equipment. Nevertheless, inline furnaces are well suited for high production volumes and are the most widely used furnace type for electronics assembly.

Whether batch or inline, furnace selection is based not only on throughput rates, but is also determined by the type of product being assembled. A greater complexity to the circuit board requires more control of the time-temperature profile to ensure that all of the solder joints are completed at minimum defect levels. In some applications, the extra furnace zones are used to control the cooling rate of the soldered circuit board to prevent thermal shock damage to sensitive components or substrates.

The introduction of Pb-free solders has impacted reflow soldering, less so in terms of actual equipment temperature capabilities than in the development of a suitable time-temperature profile. The heat source technology (infrared, convection, or mixed) can provide the higher reflow temperatures of the Sn-Ag-XCu alloys (T_{melt} = 217°C versus 183°C for the traditional Sn-Pb solder). Of course, higher energy usage and maintenance costs are likely. Two generalized reflow profiles are used for Pb-free soldering.

They are illustrated graphically in Fig. 43.23. The soak-reflow profile in Fig. 43.23*a* derives from the traditional Sn-Pb eutectic solder profile, but with the reflow “spike” increased for the higher melting Sn-Ag-Cu alloys. The soak step provides for activation of the flux as well as heatup of the circuit board and components. The continuous ramp or “hat” profile in Fig. 43.23*b* allows for a more rapid heatup rate, which reduces the time that heat-sensitive components and materials spend at elevated temperatures. On the other hand, the relatively faster heatup rate can increase the chances of thermal shock damage to some components—for example, larger plastic and ceramic devices—or to circuit board structures such as vias.

FIGURE 43.23 Generalized time-temperature profiles for Pb-free reflow soldering: (*a*) the soak-reflow profile; (*b*) the continuous ramp or "hat" profile. Peak temperatures will vary, depending on the particular circuit board product.

In terms of optimizing the time-temperature profile, a balance must be established between achieving sufficiently high temperatures that will reflow the solder of every component (size and shape) and preventing thermal damage to other components or the substrate. Therefore, the higher melting temperatures of Pb-free solders make it more challenging to develop a time-temperature profile that will successfully melt the solder paste of larger components without causing thermal damage to smaller devices or to the circuit board material.

Therefore, in the case of some very-high-mix products, it may be necessary to solder larger packages in a separate operation (e.g., hand soldering or selective soldering). Under this circumstance, the latter packages would be considered as odd-form components.

43.3.3.5 Wave Soldering. Wave soldering is used when surface-mount technology is mixed with through-hole components on the circuit board. (See Figs. 43.7 to 43.9 showing wave soldering as it is used for through-hole circuit boards.) Surface-mount devices that are present on the same side as the wave are soldered as well, being held in place by an adhesive. The surface-mount components must be resistant to thermal shock because of the temperature spike experienced upon entering *and* leaving the molten solder wave. The temperature on the topside surface of the circuit board typically remains well below the solder solidus temperature, thereby preventing the reflow of any solder joints present there.

Wave-soldering equipment can be used either in an inline or in a batch process since the equipment has generally the same construction. The inline approach is used to support high production volumes. Small systems that are used in a

batch-like mode include those used for *selective soldering*. This equipment includes miniwaves or solder fountains and are used to solder only localized areas of the circuit board, such as when attaching through-hole connectors, transformers, or switches. The advantage of selective (wave) soldering is that the entire circuit board need not be exposed to an elevated temperature.

An important consideration in wave soldering is the supporting fixtures that hold the circuit board on of the conveyor. In reflow soldering, the conveyor can support the entire bottom side of the circuit board. However, in wave soldering, the conveyor does not offer such support, as it must allow the wave to contact the circuit board bottom side. Therefore, it may be necessary to provide an additional fixture to prevent warpage and sagging of larger circuit boards.

The impact of Pb-free technology on wave soldering has largely occurred in the equipment performance. It has been determined that the same solder bath temperatures that are used for Sn-Pb processes (250 to 270°C) are suitable for the Sn-Ag-XCu Pb-free alloys. Therefore, excessive dross formation and flux residue removal have not become a significant problem during equipment operation. The lack of shiny fillets with the Sn-Ag-XCu alloys has been addressed by modified alloys having Ni and Ge additions that alter the solidification process, which leads to shinier fillet surfaces.

The Pb-free alloy compositions are more prone to erode the wave machine’s structures, such as the impeller, baffles, and pot walls. New wave-soldering machines address this problem through the use of alternative steel alloys and ceramic coatings.

43.3.3.6 Condensation (Vapor Phase) Soldering.

Condensation soldering, also referred to a vapor phase soldering, uses a working fluid’s heat of condensation to reflow the solder paste or solder preform to

make the joints. Because the condensation reflow process had its origins in the early days of surface-mount technology when production runs were more limited in volume, these machines were primarily batch-type units. Subsequently, inline equipment was developed to “attach” the vapor phase reflow machine to the back end of the placement equipment for higher production volumes. Two particular attributes of condensation soldering are (a) the temperature of the product cannot exceed the vaporization (or condensation) temperature of the working fluid, thereby preventing overheating of temperature-sensitive materials; and (b) the temperature is very uniform over all of the components and the substrate, thereby minimizing temperature gradients that could warp or crack component or laminate materials. This process fell out of favor in the early 1990s, for two reasons. First, the working fluid for Sn-Pb solder, Dupont’s Freon TMF, was categorized as an ozone-depleting substance (ODS). Its use was initially restricted and then prohibited by the Montreal Protocols. Second, the increasingly more complex circuit boards that were being designed with surface-mount technology required more precise control of the time-temperature profile, which lead to the development of multizone reflow furnaces having convective and infrared heating capabilities.

There has been a resurgence in the use of condensation soldering. Alternative working fluids have been developed for both Sn-Pb and Pb-free processing that are compatible with environmental regulations. Preheaters are added to reduce the thermal shock when parts entered the working fluid, thereby providing a more controlled time-temperature profile. Lower capital cost and properties of the condensation heat source previously noted cause condensation or vapor phase reflow to be well suited for prototype development programs and small production volumes.

43.3.3.7 Hand Soldering. As noted earlier, in the highly automated surface-mount assembly line having automated paste printing and component placement capabilities, hand soldering would not be particularly advantageous in terms of maximizing production volumes. However, in some applications, the assembly process includes a hand-soldering operation. For example, often odd-form components cannot be incorporated in a pick-and-place machine, or temperature-sensitive devices cannot be exposed to the reflow furnace environment. Under these circumstances, the hand-soldering step is performed *after* mass soldering (reflow, wave, etc.). The implication is that hand soldering is now being performed on what is potentially a very-high-valued circuit board. Therefore, factors such as handling damage, electrostatic discharge (ESD) damage, and thermal damage to nearby components by the soldering iron tip, as well as flux residue contamination, must be thoroughly addressed at the development stage of the hand-soldering process.

The use of Pb-free solders has not impacted the hand-soldering process itself. There is a slight lengthening of the soldering time, typically from 3 to 4 s to 5 to 7 s, due to the higher melting temperatures of the Pb-free solders. The same soldering iron equipment can provide the necessary tip temperatures. The high-Sn solder compositions, coupled with their higher melting temperatures, can more quickly degrade the tip. Lastly, the operator should not mistake a duller appearance to the fillet surface for a “cold” solder joint.

43.3.3.8 Conduction (Sikama) Soldering. Conduction soldering is the process in which heat arrives to the solder paste by means of conduction through the substrate. The process, which is illustrated in Fig. 43.24, is also termed Sikama soldering, being named after the primary equipment manufacturer. The equipment is set up to accommodate an

inline process, although it can be used in batch mode as well.

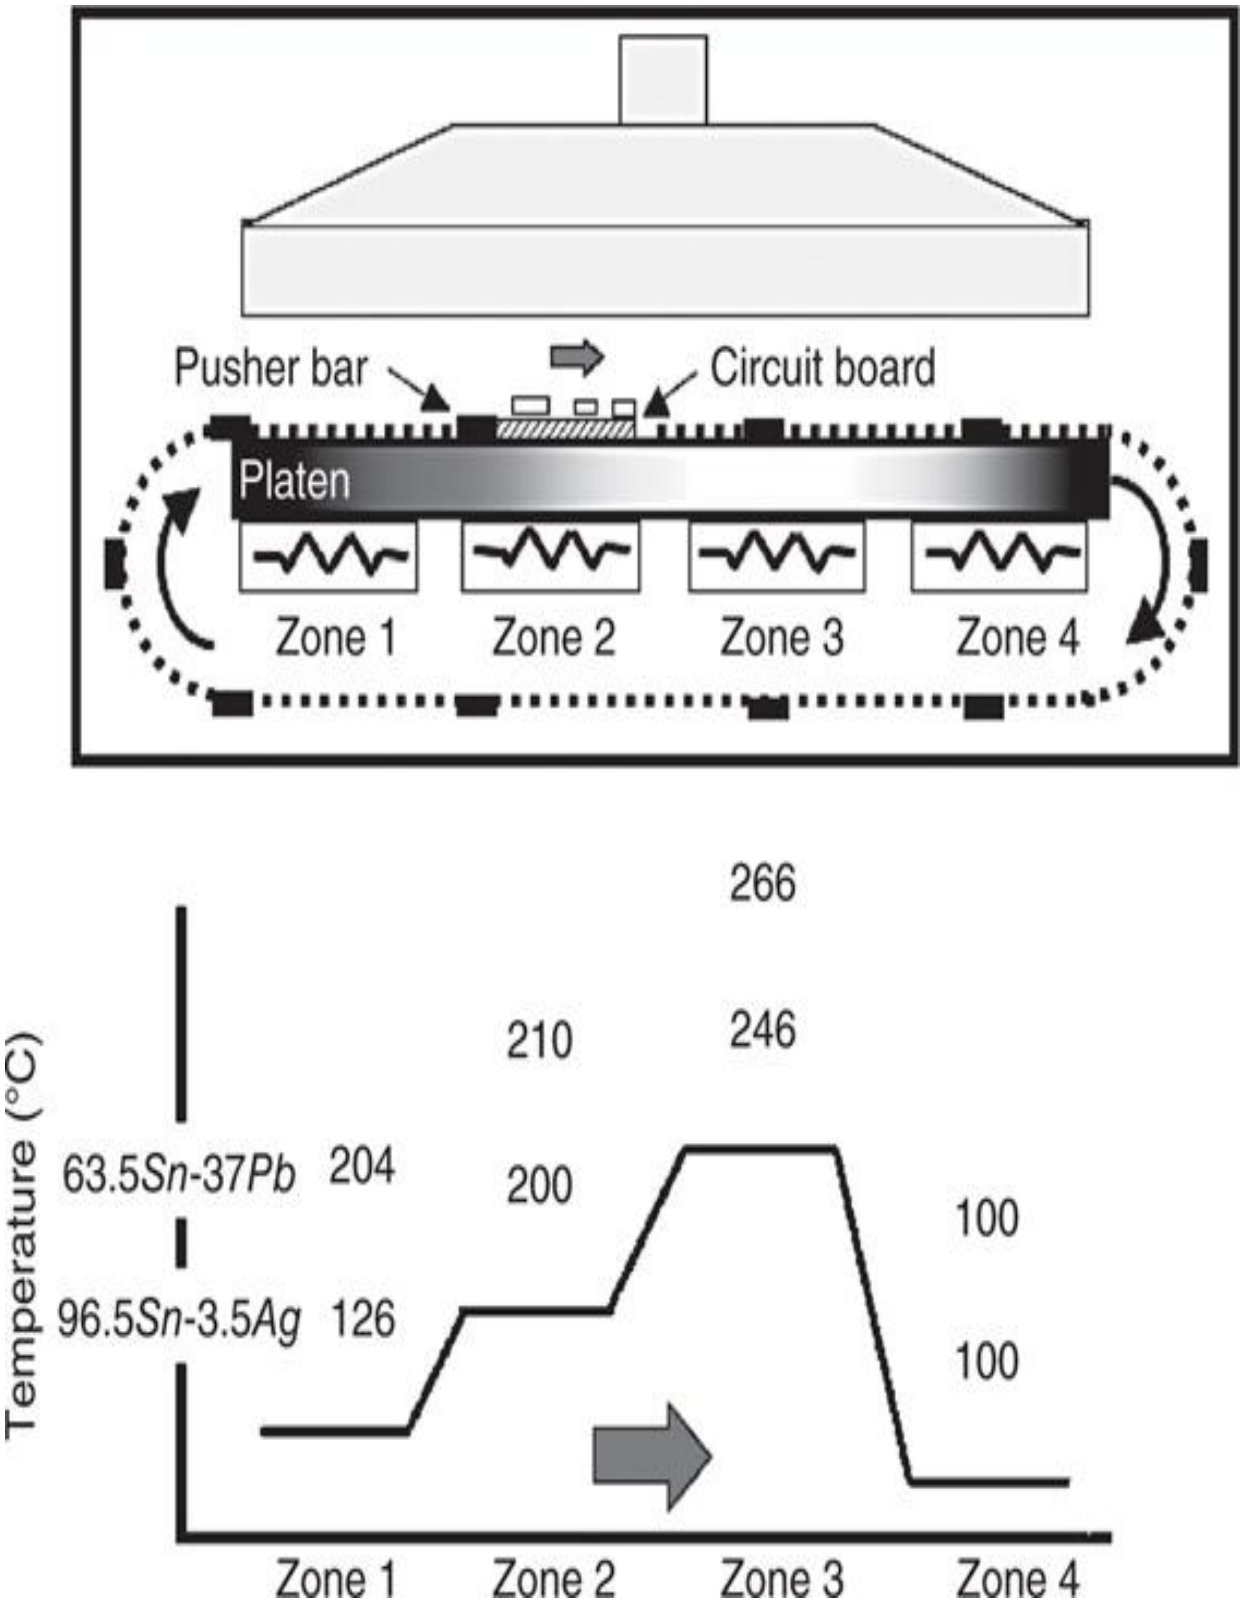

FIGURE 43.24 Schematic diagram depicting conduction soldering. The pusher bar presses the circuit board along the surface of platen. Heaters under the

platen determine the time-temperature profile.

The circuit board is pushed along on top of the heated platen by rods attached to a conveyor. Different sets of heating elements under the platen heat the latter locally to different temperatures along its length, creating heat zones such as those in a reflow furnace. The soldering process can be performed in air or using an inert atmosphere. The fact that the substrate is fully supported along its entire footprint (which is needed to maximize heat input) precludes excessive warpage.

The conduction heating process has been used almost exclusively for ceramic substrate because these materials do not degrade when exposed to the high platen temperatures. Thermal degradation would be more likely for organic laminates. Best results are realized when this process is used with relatively thin substrates (<1.0 mm).

43.3.3.9 Cleaning. Cleaning is typically the final step in the circuit board assembly process. There is a variety of cleaning equipment, from hand-loaded, batch-type "dishwasher" machines for smaller production volumes, up to larger inline units that are integrated into the back end of the assembly line for large production volumes. In response to environmental regulations, cleaning solutions have moved away from the once popular organic solvents to aqueous and semi-aqueous cleaners based on water- and water-alcohol-based compositions. Similarly, the handling of the waste stream is also important. Closed-loop systems are preferable to once-through cleaning process because of regulations governing the disposal of the waste stream. In the case of assemblies requiring multiple soldering steps, the cleaning portion of the prior soldering step does not leave a residue on the surface that degrades the solderability required for the follow-on process.

The use of a Pb-free process does not necessarily have a significant impact on the cleanability of circuit boards. At one time, it was believed that flux residues from Pb-free processes would be more difficult to remove, due to the higher soldering temperatures. Subsequently, it has been determined that thermal degradation of those residues is not as severe, so current cleaning processes appear to perform adequately.

43.3.3.10 Pb-Free Solders. The equipment types described in the preceding sections are often combined to form an electronics assembly line. The term “line” implies that the equipment is physically located end to end, thereby allowing for the movement of circuit boards between the different functions or stations. Although this scenario is, in fact, typically the case, it need not always be so. Under some circumstances, it may be advantageous to locate some stations a distance away others on the shop floor, thus requiring operators to move product between the two sites on wheeled racks. This is usually the case with inspection and repair/rework functions as well as for some cleaning processes due to health or safety concerns. The setup and hence the flow of a product assembly process are referred to as the (assembly) line architecture.

Numerous variables are considered when developing any assembly line architecture. The underlying consideration is optimizing the *level of automation*. Some of these variables include the following:

- Available floor space and facilities (electricity, exhaust, computer networks, etc.)
- Equipment footprint and cost of ownership or lease
- Labor costs
- Production volumes and product changeover flexibility

- Circuit board technology (through-hole, surface-mount, or mixed)
- Soldering technology: Sn-Pb versus Pb-free
- Inspection and quality requirements

It is important for the manufacturing engineer to consider not only each of these points individually, but to also apply the proper weighting factors of their importance when integrating them together to develop a process for the product(s).

The introduction of Pb-free solder technology does not, in and of itself, alter the previously described principles with regard to assembly-line architectures. The equipment is very similar and the factors that determine an optimum line configuration remain unchanged. Instead, consideration must be given to the cost/benefit of having an *entirely separate* assembly line that is dedicated to Pb-free products. In the case of wave soldering, the need for a second line is intuitive; it is simply not practical to empty and refill the solder pot with different alloys from both a process time-management point of view as well as the metallurgical-based concern of mixing the two alloys. An interim approach is to exchange only solder pots in the machine, ensuring that all residues of the previous solder have been removed from all equipment surfaces.

However, even in the case of solder paste printing and reflow soldering, many manufacturers have determined that two separate assembly lines are required, even to the extent of physically locating them at separate locations in the plant. There are simply too many risks associated with potentially mixing the two assembly technologies, particularly in high-volume operations where a significant quantity of product may be built before an error is recognized. The potential mix-ups include

- Use of the incorrect solder paste

- Placement of components with the incorrect surface finish—Pb-Sn (high-reliability electronics) versus 100 percent Sn (consumer electronics)
- Incompatible moisture sensitivity levels (MSLs) of plastic molded components
- Vision system settings for identifying fiducials of alternative surface finish
- Reflow furnace settings for the different time-temperature profiles

43.4 ODD-FORM COMPONENT ASSEMBLY

An accurate definition of an odd-form component is one that cannot be placed and/or soldered with equipment *available in the assembly line*. The likelihood of having to address an odd-form component is actually quite high. Because of the wide range of current component technologies as well as those expected in the future—whether through-hole or surface-mount—there is always the chance that a package cannot be placed or soldered in the assembly line. Certainly, if volumes warrant, new equipment can be purchased, or special tooling made, for adapting the placement and/or reflow equipment for odd-form components. However, there is a significant cost penalty to this approach, especially if it is performed for a variation of sizes and configurations. Each package variation would require separate tooling designs or equipment modifications. However, the advantages of automating odd-form assembly operations include a higher production volume as well as fewer defects resulting from the automated rather than manual operations. Therefore, it is not unusual for odd-form component assembly to be a mix of both manual practices as well as automated techniques.

Generally, the introduction of Pb-free soldering affects odd-form components in a manner not unlike that for other surface-mount and through-hole components. The two primary issues are I/O surface finishes and temperature sensitivity of each component's material set. High-reliability applications have to monitor components for 100 percent Sn finishes. Because odd-form components often fit this category due to a large size, hot Sn-Pb solder dipping is a more viable option to remove the 100 percent Sn finish. Otherwise, the tracking of incoming material and verification of the actual surface finish may be required.

Temperature sensitivity of devices will have to be documented in terms of surviving the Pb-free reflow profile. In fact, some devices that were previously processed on a Sn-Pb assembly line may have to be set aside as odd-form components because they cannot be exposed to the Pb-free process temperatures. Another risk of the higher-processing Pb-free reflow temperatures is the damage to moisture-sensitive components. The typical Pb-free time-temperature profile adds one or two MSLs to a component. Therefore, devices at MSL levels 5 or 6 per a Sn-Pb profile may have to be assembled to the circuit board in a separate operation to avoid damage, thus causing them to be odd-form components.

43.4.1 Components

Connectors comprise approximately 75 to 80 percent of odd-form components. See Fig. 43.6. For example, there are universal serial bus (USB) connectors, dual inline memory module (DIMM) connectors, phone jacks, and zero-insertion-force (ZIF) connectors, as well as a variety of surface-mount connectors. Other odd-form components include sockets, electrolytic capacitors, transformers or large inductors, LEDs, relays, switches, as well as speakers and vibrators for

handheld communications devices. In surface-mount technology, odd-form components are most often through-hole packages, including both passive and active devices as well as connectors. When addressing such odd-form components, the first step is to check the availability of an equivalent surface-mount version since there has been a shift toward surface-mount versions of many of these devices. Of course, the materials used to construct the surface-mount replacement must survive the reflow furnace environment, and especially the Pb-free reflow temperatures, particularly connectors because of their complex internal construction. In some cases, it has been possible to replace the through-hole connector with one of a variety of solderless products.

Also, it is not necessarily size or weight that causes a component to be identified as “odd-form” per the particular assembly line. Temperature-sensitive and moisture-sensitive devices may also be excluded from a reflow step of the assembly process to prevent damage to them. The latter scenario is of particular concern when converting from a Sn-Pb to a Pb-free process. DCA refers to the assembly of an *unpackaged* active semiconductor device directly onto the circuit board. The interconnections are made either by wirebonding or by solder bumps on the front side of the die. The latter application is referred to as FC attachment and can be implemented into a surface-mount assembly process as long as existing equipment can accommodate the placement accuracy required for the very small solder bumps and pads.

Otherwise, a dedicated cell may be required.

The DCA process, which uses wirebond interconnections, is based on the following steps. First, an adhesive is dispensed on the board and the die placed on it. The adhesive, which is often thermally conductive for heat management, is cured. The I/O pads on the die are wire-bonded to the appropriate pads on the circuit board. Then, the die and wire bonds are

encapsulated in an epoxy to prevent damage to them. The encapsulant, or “glob top,” is then cured. Critical to the glob top technology are the following factors: complete coverage of the die and wire bonds with minimal run-out beyond the circuit board pads; adequate adhesion between the die and circuit board; and good adhesion between the encapsulant and the circuit board beyond the perimeter of the die.

43.4.2 Manual Assembly

In the least complicated format, only an operator places the odd-form components on the circuit board. The soldering process is automated in that the operator picks components from bulk bins and repeatedly positions them onto the circuit board as it is carried along the conveyor line. For paste-in-hole assembly, the solder paste and other components (surface-mount or through-hole) may already be on the board, being held in place only by the tackiness of the paste. Therefore, the operator must not inadvertently displace other components off of their sites during handling.

Also, the operator must pay special attention to handling and ESD damage while placing components. Also, those components that incorporate snap-in features (e.g., connectors) can require that the operator exert relatively high forces on the circuit board. Thus, the operator must not damage either that component or other components and the circuit board. Often, special tooling is used to press snap-in components on the circuit board to prevent such damage.

A large number of applications require the operator to place and then manually solder the odd-form component into place, often after the other components have been soldered into place. The operator must be cognizant of handling and ESD damage as well as prevent thermal damage or the inadvertent reflow of solder joints for neighboring components. The impact of Pb-free soldering would be most

significant in this circumstance. It is necessary to verify that a longer hand-soldering time or a higher tip temperature does not cause thermal damage to the component in question or cause the reflow of nearby solder joints.

It should be noted that irrespective of whether manual assembly is performed on only stuffed boards that will be subsequently soldered or on circuit boards that have already been soldered, the units have a higher value to them because of this processing, which is performed beforehand. Therefore, *any* damage (handling, ESD, thermal, etc.) will result in a significantly higher yield loss to production volumes as well as higher costs associated with the repair or scrapping of damaged circuit boards. Therefore, manual assembly steps must be given due consideration during product design and process development activities.

43.4.3 Automated Assembly

The automated assembly of odd-form components uses the same placement equipment as is used for other components, but with special tooling or a dedicated machine (cell), which is already set up with the required tooling and component feeder systems, that can be introduced into the assembly process. The latter equipment typically places more than one type of odd-form component for increased versatility. For example, the close-up photograph in Fig. 43.25 shows the type of gripper tooling that can place different component packages (to within its design limits, of course). After accuracy and component-type requirements are met, speed is the critical performance metric for odd-form placement machines. Odd-form component placement is nearly always a bottleneck or slow point in the line; therefore, minimizing assembly time devoted to odd-form components will speed up the entire process flow.

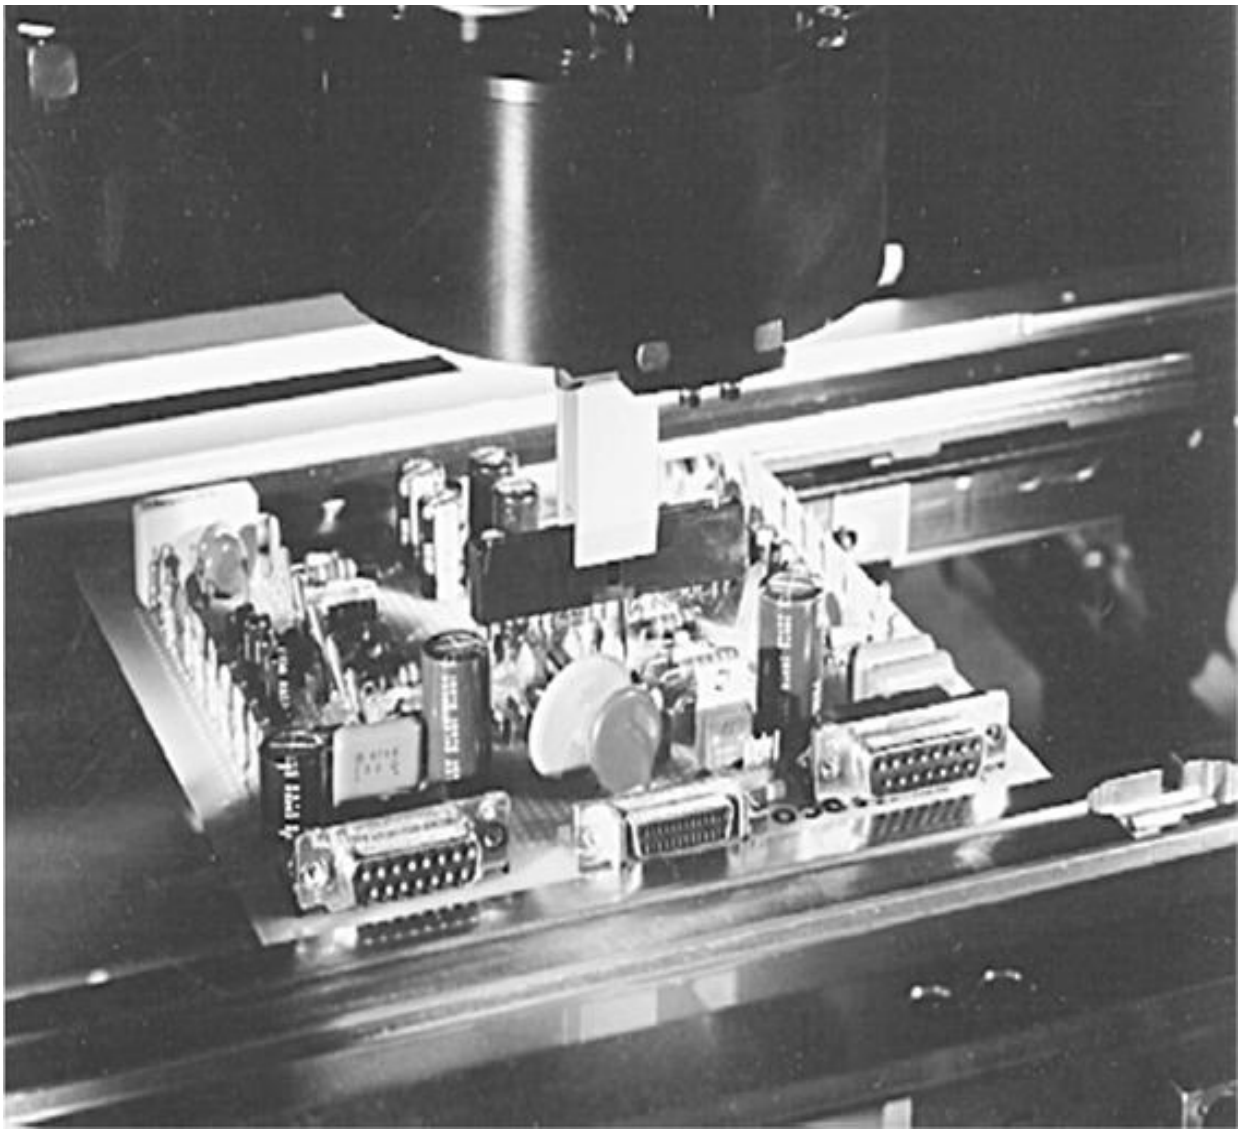

FIGURE 43.25 Odd-form component placement machine having a flexible servo-driven gripper tooling that can place a wide range of different component configurations. (*Courtesy of Universal Instruments*.)

There are both advantages and disadvantages to the automated assembly of odd-form components. Advantages include the following:

- consistent as well as higher quality and faster throughput result from eliminating manual processes.
- Automated assembly saves floor space, as machines typically take up less area than operator work benches.

- Solder dispensing is integrated into the placement process flow, minimizing related defects.
- Automated assembly complements an overall, computer-integrated manufacturing infrastructure already in place with the other assembly steps that, in turn, facilitate process flow, quality control, and product changeover.
- Automation eliminates operator-related health and safety issues (fumes, repetitive tasks, etc.).

The disadvantages of automation include the following:

- Capital equipment costs can be high for machines, dedicated tooling, and plant modifications.
- Prepackaging components are required for automated feeders.
- Equipment changeover for different product lines is somewhat slower due to the need for special component packaging and/or feeders.
- Higher production volumes can generate a greater quantity of defective product before a process problem is identified.

43.4.3.1 Component Packaging Formats. Odd-form components come in a variety of sizes, geometries, and I/O configurations that determine the ease with which the component can be “automated” into the assembly process line. Another important variable is the component placement machine. Typical component packaging formats for the placement machine include tape and reel (radial and axial leaded), extruded tube, tray, continuous strip, and bulk containers. Each of these formats has benefits and drawbacks, as noted in the following subsections. Industry specifications have standardized nearly all of these packaging schemes. For example, there is EIA-468-B for radial devices and EIA-296-E for axial components.

43.4.3.1.1 Tape and Reel. Tape and reel allows for the delivery of parts to the circuit board at very rapid rates. See Fig. 43.26. Tapes are available generally in three formats: flat-carrier tape, deep-pocket tape, and semi-deep-pocket tape. Flat-carrier tape is the traditional method of carrying both odd-form (as well as form-fit) radial and axial components. It is inexpensive and can provide a large quantity of parts for rapid placement rates. Deep-pocket and semi-deep-pocket tapes provide room for the larger component bodies. The packaging of multiple parts having a similar pitch is possible with semi-deep-pocket tape; the particular advantage is to conserve feeder space, particularly when only a few of each type of component are required on the circuit board.

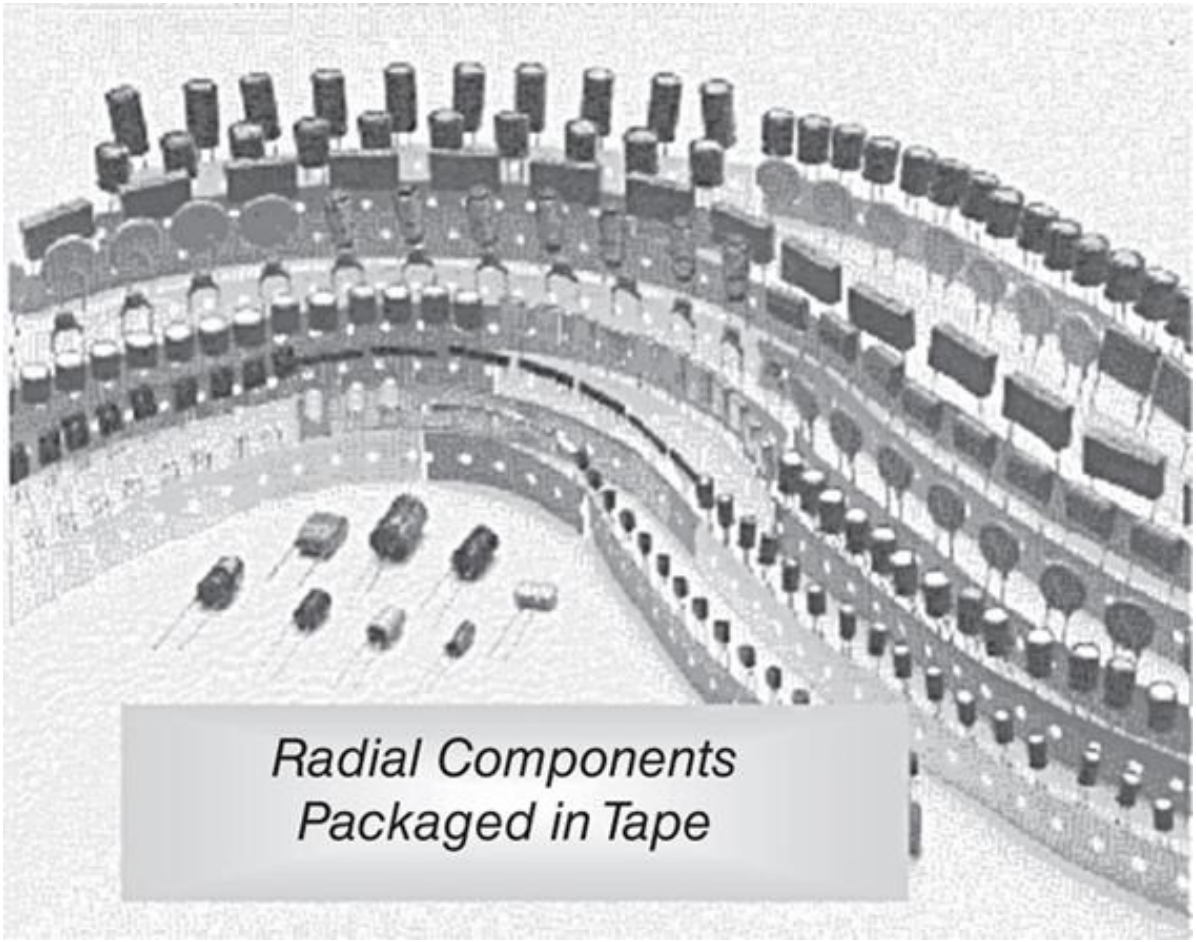

FIGURE 43.26 Radial components packaged in tapes that would come off of reels. (*Courtesy of Universal Instruments*.)

Several drawbacks are associated with tape carriers. For example, tall or heavy parts may change position or break the cover of deep-pocket tape carriers. The potential consequence is that the tape and/or components will jam or damage the feeder mechanism of the placement machine, thereby interrupting the assembly process.

43.4.3.1.2 Extruded Tube. Extruded tube is a commonly used format for odd-form components. See Fig. 43.27. Components such as D-Sub connectors, phone jacks, transformers, relays, and shrouded headers are typically supplied in tube packaging. Recently, component manufacturers have begun to supply long connectors such as single inline memory modules (SIMMs), DIMMs, and other designs of long-aspect ratios in edge-stacked tubes.

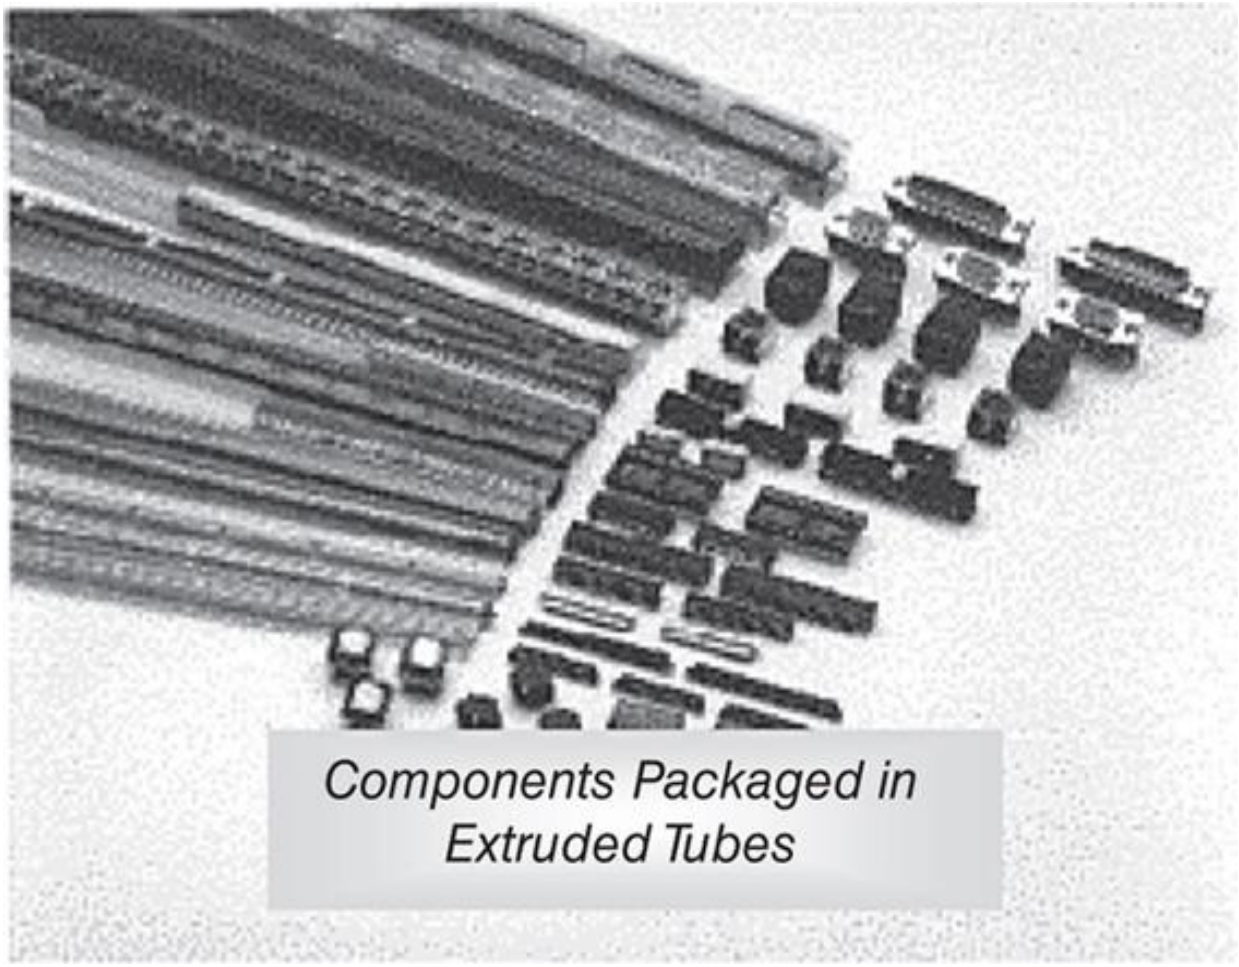

FIGURE 43.27 Components in tube packaging. (*Courtesy of Universal Instruments*.)

Tube packaging is particularly beneficial for protecting the component at a reasonable cost. Also, tubes are less likely than tape to cause problems feeding components into the placement machine. Of course, it is necessary to verify that the tube geometry is compatible with the feeder mechanism on the placement machine. The tube material should be sufficiently thick so as not to bend readily. Bending of tubes is the primary cause for the jamming of devices inside of them during the feeding process. Moreover, heavy components packaged in thin cross-sectional tubes may actually interfere with adjacent tubes when stacked in the automated feeder.

43.4.3.1.3 Matrix Trays. Matrix (or waffle) trays are an inexpensive means to supply components that are generally too large or heavy for tube or tape packaging and must be individually separated from one another. See Fig. 43.28. An important consideration is that the trays themselves may not be a suitable starting point for the automated placement processes especially for very small components. First of all, the components have too much room to move about in each bin to establish coordinates for initiating the pickup and insertion process. Also, component leads are not always oriented correctly in the insertion plane.

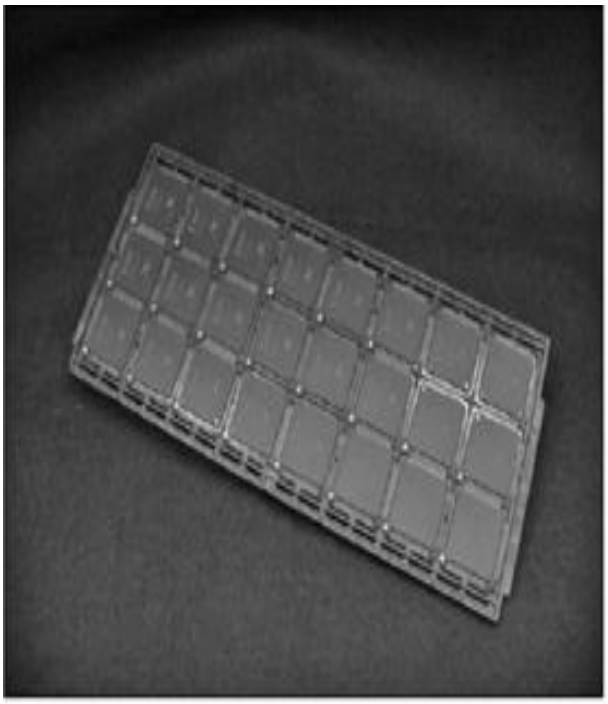

FIGURE 43.28 Components packaged in matrix trays. (*Courtesy of Sandia National Laboratories*.)

Several potential issues may need to be considered when choosing trays. Trays lack the rigidity required by many assembly machines for part pickup. Also, trays hold a more limited quantity of parts to the placement machine, and thus require more operator changeout during assembly. There are no standards for vacuum-formed trays that are used for odd-form components. Lastly, trays simply take up a greater amount of feeder space in a placement machine and on the floor.

43.4.3.1.4 Continuous Strip. Continuous strip packaging is designed for high-volume automation applications of odd-form components. This technique eliminates the need for separate component packaging formats because the individual parts are all attached in sequence to a single metal or plastic strip as part of the assembly process. The parts are located with a specified pitch that can be accommodated by the placement machine. Some components that are packaged in this manner include headers, battery clips, transformers, and motor brushes. Either the metallic part (e.g., brushes) or the leads that are part of the component can be stamped from a continuous strip of metal or thermosetting plastic. This type of packaging provides high levels of online parts inventory. However, such strips are application-specific and may carry a higher cost to automate due to the need for specially designed feed mechanisms.

43.4.3.1.5 Bulk. Bulk packaging eliminates the expense of component packaging altogether by simply placing the devices in a large container. A significant number of odd-form components are shipped in this format. Of course, the component manufacturer has likely established the cost/benefit of the fallout of parts due to handling and shipping damage versus the cost of added packaging by one

of the previously mentioned formats. On the other hand, the degree of part damage may not be acceptable to the circuit board assembly house because of increased downtime due to machine jams and part replacement.

Bulk packaging is the most difficult packaging format to automate for odd-form components. Generally, bulk components require a specially designed bowl feeder to supply parts to the machine with some degree of consistent orientation, which increases cost and process implementation lead times. Also, the unusual configuration of bowl feeders may require a dedicated placement machine (cell) that may have a significant idle time. The feeders usually take up considerable space and are not easily retooled for product changeover. The placement machine must have then the versatility to orient each part consistently from a haphazard “pile” of devices so that the pickup device can obtain each unit and correctly place it on the circuit board. In spite of these numerous drawbacks, bulk packaging is a cost-effective approach for odd-form components in numerous product applications.

43.4.3.2 Equipment. Advances continue to be made in the capabilities of odd-form assembly equipment. Early vintage, single-task robotic systems are giving way to machines that perform all of the alignment and functions of modern placement equipment, and which can be integrated into existing assembly lines. New machines are designed for speed and the flexibility to handle different odd-form component geometries as well as a variety of circuit board configurations.

Typically, automated odd-form component placement machines use an overhead gantry-style positioning system and vision and optics systems underneath the head. The emphasis is on placement accuracy given the high component density of surface-mount boards and, in some applications, the use of solder paste-in-hole printing methods

for a 100 percent reflow soldering process. The component must be placed accurately into the solder paste the first time so that the solder paste is not disturbed, which can result in potential defects. Interchangeable grippers and vacuum pickups as well as improved component feeding mechanisms provide greater flexibility for different product types, faster placement rates, and minimum equipment downtime.

43.4.4 Cleaning

The cleaning of assemblies having odd-form components, like the placement of those devices themselves, can occur at one of several points along the assembly process. If the components are placed prior to the principal soldering step, then they will be cleaned along with the rest of the circuit board. The higher temperatures of a Pb-free solder process can make this cleaning step somewhat more difficult, depending on the tenacity of the flux residues.

On the other hand, when the odd-form devices are soldered to the circuit board after the primary soldering process has taken place, the subsequent cleaning procedure must take into account the other components that are already on the circuit board, particularly potential handling damage. It may be preferred to use a no-clean or low-residue flux to minimize or eliminate the added cleaning step required for the later placement of odd-form components. Because odd-form components are often larger and/or have more complex constructions (geometry and materials), there is an increased likelihood of flux residues becoming trapped in confined areas. Therefore, the cleaning process must be sufficiently thorough to remove residues from those locations on the component. Similarly, it is necessary to verify that the cleaning solution has likewise been removed from those locations as part of the process.

43.4.5 Cleaning

The use of no-clean and low-solids fluxes has reduced the need to clean a greater number of circuit boards. Nevertheless, high-reliability electronics, as well as those used in harsh environments, may still require the removal of flux residues. The primary metric used to control the cleaning process is the quantity of residues that remain on the circuit board or components. Visual inspection (white light or ultraviolet light) and ionic testing are the two most commonly used methods to assess a cleaning step. In addition, in-circuit testing (ICT) provides a secondary means to indicate excessive residus presence. The residues prevent the electrical probe from reaching the conductor, which is registered as an “open” in the data collection routine. Unexpectedly large numbers of “open” defects may indicate excessive flux residues on the circuit boards as well as signify an actual electrical performance defect. Also, in the case of high-frequency circuit boards (radio frequency and microwave), ICT can identify flux residues as indicated by signal leakage and other parasitics when inspecting for electrical performance.

The cleaning step must be carefully considered for a Pb-free soldering process. The higher processing temperatures can increase the tenacity of residues, particularly those of fluxes designed for Sn-Pb processes. This point addresses fluxes used separately, as in manual or wave soldering, as well as the flux in solder pastes. The cleaning step may need to be enhanced to ensure that these residues are removed satisfactorily from the circuit board surface. On the other hand, flux formulations that have been developed specifically for the Pb-free soldering processes may create residues that are not compatible with cleaning processed developed specifically for Sn-Pb technology.

43.4.6 Network Communications

The generation, transmittal, and storage of process information is critical for real-time control of a circuit board assembly process, whether that process is for building consumer electronics in high volume or involves a low-volume assembly line for high-reliability military, space, or satellite electronics. The information that is generated by operators or automated machines on the shop floor typically includes commodity usage (i.e., circuit boards, components, etc.) as well as defects and machine malfunctions. Commodity usage information can then be made available to inventory control in the plant stockroom or even to the bill-of-material (BOM) suppliers across town and around the world, identifying the need for additional components, flux, and such at that particular site.

Process information is also accessed by the manufacturing engineer, who is monitoring the overall assembly flow, as well as by the process engineers or technicians who are directly responsible for equipment operations (e.g., furnace zone temperatures, flux levels, etc.). In addition, information may be shared between the different machines on an assembly line to prevent slowdowns in process flow due to equipment outage. Such slowdowns and stoppages can impact upstream steps. For example, there can be shelf-life issues with solder paste that is left out in a printer too long due to a stoppage created at a subsequent component placement machine or reflow oven.

It is often necessary to archive process-related information. Archived data are used to track defects as a means of process control. These data can assist in quickly determining the root cause of an out-of-control process. Process information can also be used to monitor long-term equipment performance, indicating the need for periodic preventive maintenance or machine replacement. Easy access to historical process information can also facilitate

the reintroduction of a particular product line with a minimum investment in process development efforts.

Finally, archived process data are useful in an investigation of field failures. The traceability of the troubled product to the exact process parameters used on the assembly line at that time, material lots, operators, and so on can be accessed; these data are invaluable for the follow-up root-cause analysis, particularly in the case of high-valued, high-consequence electronics systems (e.g., military equipment, space and satellite hardware, as well as medical and automotive electronics). Understanding the circumstances under which the defective product was made can also provide insight into implications regarding long-term reliability and specifically warranty costs versus liability and the need to implement a product recall.

The need to access information quickly as part of assembly operations extends beyond process and inventory control. Peripheral information such as equipment software and operations manuals must also be quickly accessible. The ready availability of boot-up software and instructions minimizes the downtime required to reestablish a product line or effect repairs on a malfunctioning machine.

Once the need for a network has been determined, the locations of terminals, servers, and information storage equipment must be established. Local area networks (LANs) and the World Wide Web (WWW, or Internet) can link access points located in adjacent rooms or halfway around the world. However, it is critical that the network uses consistent computer and data transmittal protocols in order to provide uninterrupted, information handling in an efficient manner. For example, serial communication via an RS-232 port is relatively common, but too slow for most machine applications. Ethernet communication via transmission control protocol/Internet protocol (TCP/IP) is a preferred method because most equipment suppliers offer this network option. The TCP/IP method allows computers to

share resources, no matter whether the operating system is for an Apple®, a version of the Microsoft® operating system for PCs, or the UNIX operating system. Also, the Semiconductor Equipment Communication Standard (SECS)/Generic Equipment Model (GEM) is widely used as the interface between the host computer and assembly machines.

Lastly, the need for efficient network communications is particularly acute with the advent of Pb-free solders. In the case where OEMs as well as contract manufacturing service (CMS) companies are assembling both Sn-Pb and Pb-free technologies, it is essential to control all aspects of the assembly process with precision. In fact, process control extends beyond simply certifying that the reflow, wave, or soldering iron correctly reflect the higher soldering temperatures. It must also make certain that components and circuit boards have been delivered to the appropriate process line having the correct surface finishes and/or MSLs. Also, process control must establish that other factors, such as flux type and cleaning procedures that may be unique to the Pb-free process, are being used on the appropriate product line.

43.5 PROCESS EQUIPMENT SELECTION

The selection of assembly process equipment is an extensive undertaking for the manufacturing engineer. The three principle variables are equipment utilization, costs, and physical plant requirements. These three areas are listed in order of consideration, not in the order of importance. The analysis behind equipment selection can be very complex, given the wide variety of product designs, potential automation options, and access to worldwide labor markets.

Unfortunately, the failure to consider thoroughly the details underlying any one of these three factors can result in a significant financial burden, lost time to market, and poor product quality/reliability for the OEM or CMS. The following sections provide relatively general discussions of these three areas. The reader is referred to many excellent texts on the topic of manufacturing engineering, as well as source books that specifically address assembly process equipment for electronics manufacturing.

43.5.1 Equipment Utilization

Equipment utilization refers to two aspects of the equipment. The first aspect is the operational time during which the machine is actually performing its intended function. The second aspect is production volume (expressed as parts or assemblies per unit time) provided by the machine while it is in operation. The consequences of operational time can be considered as follows: When the machine is performing its intended function, it is making product and as such is making a profit for the company. On the other hand, when a machine is idle, not only is it not making product (or profit), it may be losing money for the company. Those monetary losses result from wasted electricity and other utilities while the machine is on standby, labor costs for idle operating personnel, continued draw-down on the maintenance interval, and overall loss the equipment lifetime.

Next, equipment utilization is discussed in terms of throughput or product volume. It should be noted that the general approach is nearly the same for both Sn-Pb and Pb-free technologies. Only the specific cost factors may differ slightly between the two cases. A determination of equipment utilization requires that the appropriate metrics be defined that accurately reflect the machine activity. For example, in the case of component placement machines, the

utilization metric may be components placed per unit time or it may be the number of stuffed circuit boards that are completed per unit time. Printed circuit boards or finished assemblies per unit time are the typical metrics for paste printing and reflow furnaces, respectively. For example, component placement rates are expressed as, components per hour (CPH). Some manufacturing engineers prefer to analyze utilization in terms of time per product unit, which is the inverse of production rate. Such an approach would be exemplified by measuring the time required to print the paste on, or to stuff, a single circuit board.

It is important to select a metric that is most appropriate for the machine and the products that are processed in it. Moreover, the metric should allow the process development engineer to monitor the performance of the machine process accurately; it can also be used to compare specifications between different equipment brands for a procurement activity.

Different methodologies can be used to exercise an equipment utilization analysis. The details of these techniques are many and beyond the scope of this text. Nevertheless, it is important to be familiar with several key attributes that are used to make utilization assessments. Descriptive definitions of several attributes are shown below:

- *Theoretical throughput* is the output of a machine based upon its underlying design.
- *Actual throughput* is the output of the machine for the particular product line or application. This value is always less than the theoretical value.
- *Utilization or utilization efficiency* is the ratio of actual throughput to theoretical throughput.
- *Operation time* is the total time during which the equipment may be required to operate. For example, it

may be an 8-h shift or it may be 24 h if three shifts are running in the factory.

- *Equipment uptime* is the time that the machine is available to perform its task; it may not necessarily be performing the task. Therefore, this time period takes into account the various contributions to downtime, such as preventive maintenance, unexpected breakdowns, resupply of commodities, and so on.
- *Productive time* is the time during which the machine is actually performing its task.

These various attributes can be further broken down as the need arises; for example, several factors can account for loss of equipment uptime, including scheduled maintenance versus unexpected machine failures, commodity resupply, etc.

These attributes are reduced to mathematical variables that are used in equations to calculate the performance of a particular machine. However, the assembly process for electronic circuit boards is comprised of several machines or cells that are *in series*. Therefore, once the performance attributes are determined for a given machine, they must be integrated to predict the performance of the entire assembly line. For example, it is preferred that the throughputs of the individual machines be matched for the product application. A mismatch of machine capabilities can generate bottlenecks in the assembly process. The slowest machine or function then controls the production rate of the entire line. The obvious consequence of a bottleneck is an underutilization of the other equipment, which ultimately appears as an increase in manufacturing costs.

But there are also quality control reasons to smooth out the flow of bottlenecked assembly processes. For example, if the component placement machine has a throughput of 100 circuit boards per hour, but the reflow machine can only process 90 circuit boards per hour, then printed and stuffed

boards will spend time in the open factory air awaiting entry into the reflow step. The consequence is a degradation of paste properties, resulting in the increased likelihood of solderability defects and a drop in product yield. Such technical ramifications must also be addressed when considering equipment utilization for an assembly process.

43.5.2 Costs

There are several cost factors to consider when establishing an assembly line: the initial capital investment for the machine(s); depreciation and lifetime (obsolescence) of that equipment; operational costs such as labor rates, electricity, water, or the use of inert atmospheres; and maintenance support costs. Many of these cost factors are determined on a “per product unit” basis so that an estimate of potential production volumes is often required for their calculations. Many OEMs and CMS providers have had to establish their own cost models to take into account labor rates, energy costs, shipping costs, and tax structures that are specific to the assembly plant location—on-shore as well as overseas. Because of the cost variables just mentioned, it is difficult to establish a universal model for these calculations.

When addressing the implementation of Pb-free soldering technology, one must consider two aspects regarding equipment costs. First are the direct costs of purchasing and installing equipment that can provide a Pb-free assembly capability. Second is the cost of simply developing a Pb-free assembly line in the factory.

Regarding the first point, equipment capability vis-à-vis Pb-free solder pertains primarily to the soldering process, including the reflow furnace, wave-soldering machine, soldering irons, etc. Printing and placement equipment is largely unaffected by the Pb-free soldering technology. Most reflow equipment used for Sn-Pb soldering is nominally

capable of also supporting Pb-free soldering for moderately complex circuit boards. Changes are simply made to the time-temperature profile of a reflow furnace. On the other hand, for more highly complex products, a replacement reflow furnace may be required that has more than the typical five to seven zones. A larger number of zones allows more flexibility—and greater control—over the time-temperature profile. In the case of wave soldering, the exchange of Sn-Pb solder for a Pb-free alloy may also require the replacement of the pot, impeller, and baffles to prevent excess erosion by the higher Sn solders. Last, it is expected that erosion of soldering iron tips will be greater with the Pb-free solders. Tip technology has changed little from the Ni-coated or Fe-coated Cu core construction. Therefore, it may simply be a matter of stocking extra tips for those operators using Pb-free solders.

The second cost aspect addresses the manner in which a Pb-free capability is to be implemented on the factory floor. Specifically, the decision must be made whether to have separate Sn-Pb and Pb-free solder assembly lines or to mix the two technologies using the same assembly equipment. Critical factors include capital costs, factory floor space, infrastructure required to prevent inadvertent mixing of technologies, and projected product volumes. It is preferred to separate the two assembly capabilities physically. This separation is not limited to the actual machines, but also includes support functions such as solder material storage and component inventory control in order to prevent the use of the wrong solder or components and circuit boards with incorrect finishes. The extent of this separation of capabilities will determine the need for the capital investment in new machines as well as the cost of duplicating some support functions and personnel that are needed for adequate process control.

43.5.3 Physical Plant

The cost of having a soldering process line extends beyond the capital costs of the equipment or even the labor costs for operators and process engineers. There are also the costs of operating the machines themselves. The factory must have adequate floor space for the assembly line footprint, as well as the access required to move parts and finished assemblies to and from the line. There are also space requirements to perform maintenance functions safely and make repairs to equipment. Finally, there are assembly costs arising from utility usage: electricity, compressed air (pneumatic actuators), and water (cleaning).

If the reflow or wave-soldering machine is to have an inert atmosphere—typically nitrogen is cheaper than argon—then it becomes necessary to select between the options for the gas source. Those alternatives are compressed gas tanks, a liquid nitrogen tank, or an onsite nitrogen generation facility. The compressed gas tanks are usually used only for short production runs. For most moderately sized electronics assembly factories, the most cost-effective option is to use one or more liquid nitrogen tanks, off of which is bled the nitrogen gas. Only for very-large-scale manufacturing facilities is an onsite generation plant the best option. Ancillary costs include the installation of pipe lines that transport the gas to the specific machine sites on the factory floor as well as the provision for adequate ventilation of the used gas from the machine to the external environment.

The physical plant costs are generally similar for both a Pb-free assembly process and a Sn-Pb line. The two possible differences would be electricity usage, which may be greater with the Pb-free line due to the higher soldering temperatures, particularly with respect to a reflow process, and the need for an inert atmosphere capability for the soldering machine.

43.6 CONFORMAL COATING, ENCAPSULATION, AND UNDERFILL MATERIALS

When required, the final steps in the assembly of a printed circuit board are the applications of conformal coatings, encapsulants, and underfill materials. Conformal-coated circuit boards are shown on the bottom of the stereo photograph in Fig. 43.29*a*; the same circuit board, encapsulated, is shown in at the top of the photograph. An example is shown in Fig. 43.29*b* of underfilled flip-chip devices.

(b)

FIGURE 43.29 Stereo photographs showing (*a*) conformal-coated (*bottom*) and encapsulated (*top*) versions of a surface-mount circuit board and (*b*) underfilled flip-chip components. (*Courtesy of Sandia National Laboratories*.)

The role of the conformal coating is to protect the circuit board and components against large-scale contamination from dirt, water, liquid chemicals, corrosive gases in air pollution, mold, and fungus. Because the layers are very thin (<0.25 to 0.50 mm) and relatively soft, they do not offer significant protection against handling damage or mechanical loads in shock-and-vibration environments. Protection against the latter conditions is obtained from encapsulants, also called *potting* materials, and underfill materials. Underfill materials perform a function similar to adhesives by securing the component to the circuit board. The difference is that the underfill material is applied after soldering and must fill the entire gap between the package and the circuit board. In the case DCA/FC, the underfill also improves the thermal mechanical fatigue reliability of the solder joints.

The details of these materials are discussed in other chapters. However, it is important to understand their role in the overall circuit board assembly process. First of all, the functions of these three materials require that they have good adhesion to all surfaces. Therefore, the printed wiring assembly must be cleaned of any flux residues as well as those residues left behind from the cleaning procedure.

Second, the application of conformal, encapsulant, and underfill materials must be tightly controlled in order for them to function properly. The nominal thickness and its uniformity are critical for conformal coatings. A coating that is too thin is a less effective barrier against harsh environments. Thickness and uniform coverage have become even more critical as many designers are relying on conformal coatings to mitigate the consequences of Sn whisker growth on 100 percent Sn coatings. On the other hand, a conformal coating that is too thick can interfere with

rework procedures as well as prevent fit-up of the circuit board into racks and backplane cabinets. In general, visual inspection is used as a nondestructive method to control the application processes.

In the case of encapsulant or potting materials, there must be complete filling of the mold, especially around the components, to prevent stress concentrations that can damage surface-mount solder joints. Potentially damaging stresses can also be generated when the density of the potting material varies excessively about the circuit board. The resulting variation of physical and mechanical properties of the foam encapsulant (thermal expansion coefficient, modulus, etc.) can lead to excessive board bending that damages solder interconnections, particularly those of large components (e.g., BGA devices). Therefore, it is necessary to control the encapsulant material itself as well as the "casting" process to prevent these defects.

Unfortunately, most nondestructive evaluation techniques are not effective at finding encapsulation defects. Voids and density variations are not readily detectable by visual inspection or by x-ray analysis. In the case of x-ray, the inherently low density of encapsulant foams limits the contrast between filled and unfilled (void) regions. Scanning acoustic microscopy (SAM) has had some limited success when the encapsulant layer is relatively thin, which is not often the case. Witness samples taken during the casting process are used to confirm foam density.

A number of studies have been performed that underscore the crucial requirement to control the underfill process used on flip-chip devices. Even small variations in underfill material properties (e.g., viscosity, percentage of filler, etc.) or the method for dispensing the underfill material between the die and substrate can significantly alter the long-term reliability of these interconnections.

The accepted method of nondestructive testing used to control the underfill process is SAM. The thin layer allows this

technique to detect voids in the underfill material, which when located near the solder interconnections can be responsible for a significant loss of thermal mechanical fatigue reliability. X-ray techniques can be used to monitor the density of the underfill material, specifically, the distribution of filler material within the layer under the die. Density variations can indicate a larger distribution of underfill mechanical and physical properties, which may affect long-term reliability performance of the solder joints. Quantitative image analysis can be coupled into SAM and x-ray analysis data to provide valuable process control tools for the factory floor.

43.7 ACKNOWLEDGMENTS

R. Boulanger is acknowledged for contributions to this chapter, which is based on “Assembly Processes,” *Printed Circuits Handbook*, 5th ed., Clyde F. Coombs, Jr. (ed.), 2001, Chap. 43. The author also wishes to thank M. Dvorack of Sandia National Laboratories for his careful review of the chapter.

[a] Paul T. Vianco, Sandia National Laboratories, Albuquerque, New Mexico, is acknowledged for contributions to this chapter, which is based on “Assembly Processes,” Chap. 40 in *Printed Circuits Handbook*, 6th ed. (McGraw-Hill, New York, 2008).

CHAPTER 44
CONFORMAL COATING

Jason Keeping
Celestica, Toronto, Ontario, Canada

44.1 INTRODUCTION

Once a circuit card assembly (CCA) has been fully assembled and tested, it often needs to be protected from the environments in which it will ultimately be used. Moisture, salt, dirt, fungus, and a variety of other contaminants as well as mechanical shock and vibration will cause failure on an unprotected assembly. The CCA's last line of defense against the elements is a thin layer of coating that conforms to the shape of all the part leads, solder joints, and other complex features on the completed CCA. This conformal coating (or flow coating) is applied as liquid, atomized material and/or vapor deposition to the fully assembled CCA, and is cured in place to form a protective layer of insulation for the assembly.

This chapter presents:

- An overview of the five basic conformal coating types

- Preparatory steps necessary to ensure a successful coating process
- Various methods of applying conformal coating
- Aspects for cure, inspection and demasking
- Repair and rework processes
- Design guidance on when and where coating is required, and which physical characteristics and properties are important to consider

44.1.1 Objectives and Applications for Conformal Coatings

Besides protecting the CCA from the elements, conformal coating also provides:

- Mechanical support for components during mild shock and vibration
- Electrical insulation for high-voltage components, especially at altitude
- Chemical resistance for various environment elements, especially harsh conditions
- Prevention of short circuits due to tin whisker growth from pure tin-plated part leads and cases[1]

Because of the extra cost involved with the cleaning, coating, curing, and touchup operations, conformal coating was usually reserved only for equipment that required high reliability, such as military and aerospace electronics, and equipment that needed to operate in severe environments. With the introduction of automated application robots, ultraviolet (UV) curable chemistries[2] and product migration from sterile to outdoor applications, conformal coating has become more common.

44.1.2 Overview of Types of Conformal Coatings

Conformal coating materials are available in five basic chemistries, each with multiple application methods and several drying/curing options. As such, no one material will fit every application, but the wide variety will allow the designer to select a material that meets most technical, budgetary, and manufacturing needs. The various coatings and their characteristics are summarized in Table 44.1.

TABLE 44.1 Conformal Coating Materials and Their Characteristics

	Material type	Urethane			Silicone			Epoxy				Acrylic			XY
	Cure methods	Solvent evap.	Heat cure	UV Cure	RTV	UV Cure	Catalyzed	Solvent evap.	Heat cure	UV Cure	Catalyzed	Solvent evap.	Heat cure	UV Cure	Vapor deposited
Application method	hand paint	x	x	x	x	x	x	x	x	x	x	x	x	x

	batch process														x
	Full masking required														x

The five basic chemistries are

1. *Urethane:* This coating has good moisture and chemical resistance and good electrical insulation.
2. *Silicone:* Being soft and having good adhesion, silicone is useful over a wide temperature range.
3. *Epoxy:* This coating is tough, durable, and very chemically resistant.
4. *Acrylic:* Acrylic is easy to apply and remove.
5. *Para-xylylene:* This very thin, pinhole-free coating is vapor deposited instead of being applied as a liquid.

More information on the less common types of conformal coating may be found in IPC-HDBK-830.[3]

Currently, there is a new coating type (type UT) that is within industry review for final publication and release. These coatings are labeled UT since their application thickness is much less than that of the current para-xylylenes (type XY) coatings. These coatings are within the nano-thickness ranges.

44.1.3 Environmental Issues

The predominant environmental issue with coatings was the use of solvent thinners to aid the application process. Most coatings are available in low-solvent or zero-solvent formulations, so that the emission of solvents can be reduced or eliminated. The change to lead-free solders and plating has produced an increase in the use of conformal coatings, since conformal coating has been shown to prevent tin whiskers (see Chap. 49 on tin plating) from causing short circuits, and is used for that purpose in types of products that have not been coated before. The higher-temperature lead-free soldering processes are irrelevant to the conformal

coating step, since the coating is applied after the soldering process.

44.2 TYPES OF CONFORMAL COATINGS

The most commonly used types of conformal coatings include

- Urethane (type UR)
- Silicone (type SR)
- Epoxy (type ER)
- Acrylics (type AR)
- Para-xylylenes (type XY)

44.2.1 Urethane (Type UR)

Urethanes are relatively easy to apply with dip, spray, or brush. Cure times (other than UV curable) range from a few hours for two-part heat curable, to several days for a single-part room temperature cure. Typical application is 0.001 to 0.005 in thick. They are often used for space applications due to their low outgassing characteristics.

44.2.1.1 Chemistry. Urethanes are based on a diisocyanate and polyol backbone. They are available in solvent evaporative cure, heat cure, and UV cure formulations.

44.2.1.2 Properties. Since urethanes are polymerized and cross-linked in place, they have excellent resistance to chemical, moisture and solvents. They are available in hardnesses ranging from tough, abrasion-resistant varieties

to low-modulus versions suitable for extreme temperature ranges (see Fig. 44.1).

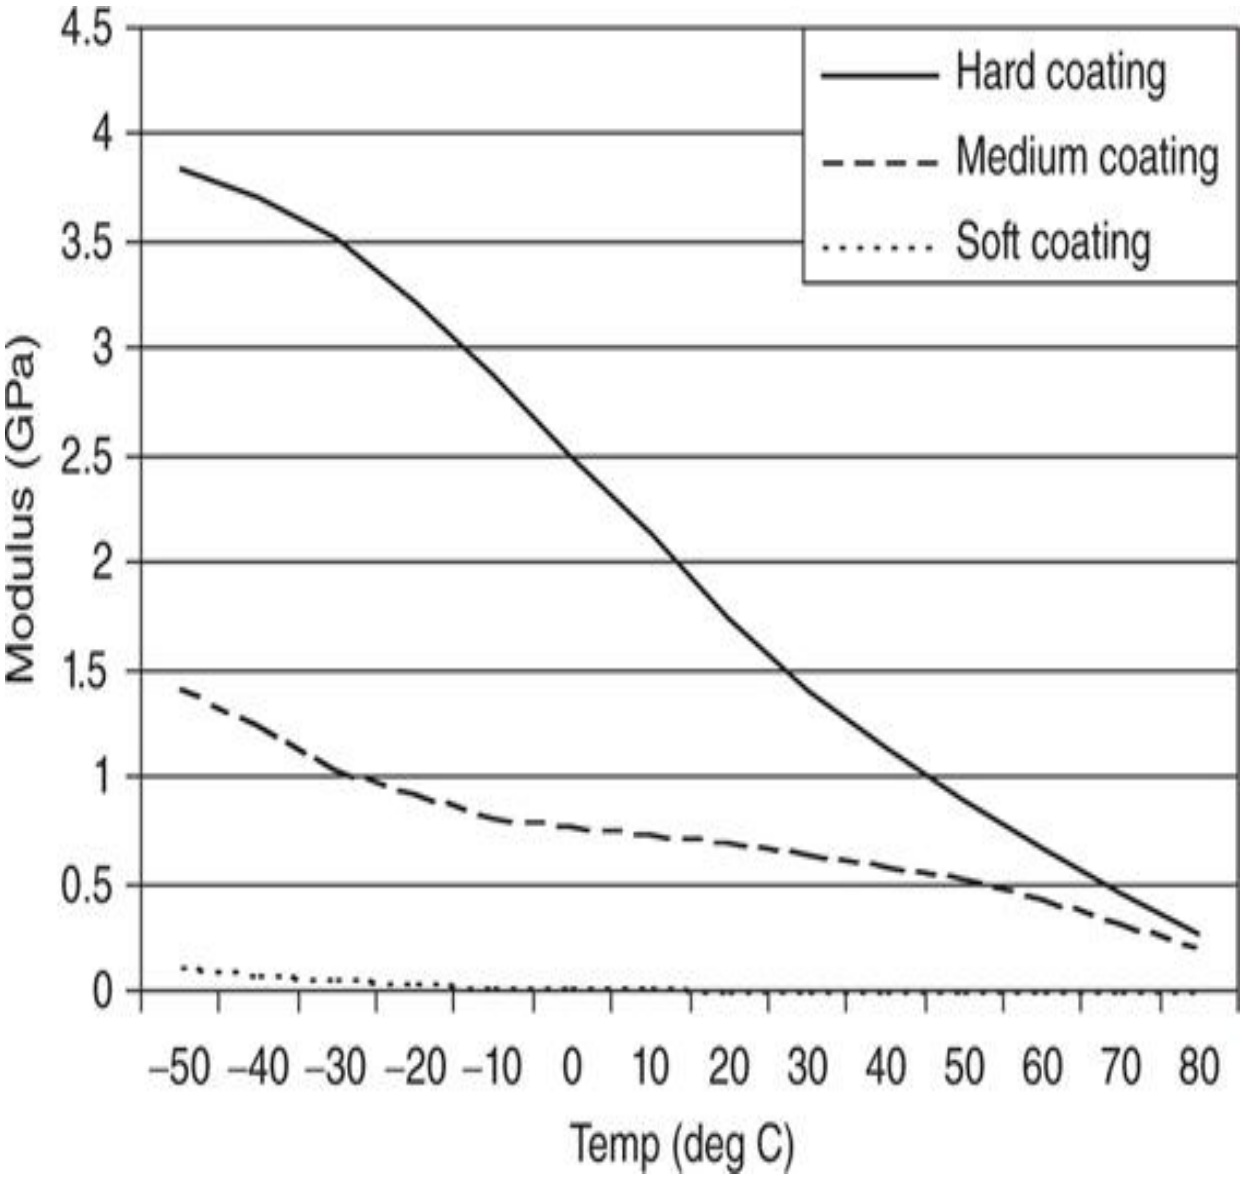

FIGURE 44.1 Elastic modulus versus temperature for three different type UR coatings.

44.2.1.3 Advantages and Disadvantages. Urethanes have good adhesion to most materials, including epoxy part bodies, metals, and ceramics. As such, the coating process is fairly robust. Since urethanes are chemically resistant, they are also difficult to remove except by thermal or mechanical

means. Urethanes can be soldered through, although this often results in a brownish discoloration that must then be removed.

44.2.2 Silicone (Type SR)

Silicones are very flexible, and stay that way over a wide range of temperatures. They have good adhesion to a variety of surfaces, but contaminate the surface and, once applied, prevent other materials from adhering. Typical application is 0.002 to 0.008 in thick. They are often used in automotive applications, where high temperature and moisture-resistance are needed.[4]

44.2.2.1 Chemistry. The silicone polymer chain is based on an alternating silicon-oxygen backbone. SR coatings are available in three types, room temperature vulcanizing (RTV), UV cure, and catalyzing (addition) cure.

44.2.2.2 Properties. Silicones have relatively stable properties from –55 to 200°C. Their coefficient of thermal expansion (CTE) is higher than that of urethanes, but this is mostly offset by their lower modulus, so that the level of stress exerted on parts is still relatively low. They have high resistance to moisture and humidity, as well as polar solvents.

44.2.2.3 Advantages and Disadvantages. Silicones are usable over a wide temperature range and are relatively easy to remove via mechanical or thermal means. If mishandled, silicones may contaminate the work area, causing adhesion problems on other CCAs. Careful process sequencing and process separation is necessary to prevent this.

44.2.3 Epoxy (Type ER)

Epoxies are chemically stable and very resistant to chemical attack. Typical application thicknesses are 0.001 to 0.005 in. Epoxies are useful in extreme environments where chemical vapors or high temperatures are present.

44.2.3.1 Chemistry. Epoxy coatings are based on epoxy resin systems and come in four types: solvent evaporation, heat curing, UV curing, and catalyzed.

44.2.3.2 Properties. Epoxies have a low CTE that matches well with printed wiring board (PWB) epoxy resin, since they share very similar chemistry. They have a higher T_g than most of the other coating materials. They are also very tough and abrasion resistant, so that rework is very difficult; epoxy coating can form the basis of an antitampering coating.

44.2.3.3 Advantages and Disadvantages. Epoxies are useful at moderately high temperatures, up to about 150°C. Because of their strength, they also provide mechanical support for components. The disadvantages of epoxy coatings are their usually pungent odor and the possibility of skin irritation. They are difficult to rework. Some formulations of epoxies are chemically delicate and do not cure properly in the presence of inhibiting compounds. Cure shrinkage is also of concern for fragile components; a softer buffer coating should be applied locally before the epoxy, particularly for assemblies that need to withstand wide swings in temperature.

44.2.4 Acrylics (Type AR)

Acrylic coatings are applied 0.001 to 0.005 in thick and are often used in military and consumer electronics.

44.2.4.1 Chemistry. Acrylic coatings are usually supplied as dissolved prepolymerized acrylic chains. The acrylic chemistry does not cure by polymerization and cross-linking as the other coating materials do, but instead hardens gradually as the solvent evaporates. Acrylics are also available in heat-curable and UV-cured formulations.

44.2.4.2 Properties. Acrylics are easy to apply, and are the easiest coating to remove, since relatively mild solvents soften and dissolve the acrylic coating while leaving the epoxy encapsulated parts and PWB unharmed. They can be cured quickly.

44.2.4.3 Advantages and Disadvantages. The greatest strengths of acrylic coating are the ease of rework and the fast room temperature cure. Acrylics provide good moisture resistance and fluoresce easily, aiding inspecting under UV lamps. Since they are so easy to rework, acrylics are also susceptible to inadvertent chemical attack from solvent splash during hand cleaning of solder joints elsewhere in the assembly. The high emission of solvent inherent in the acrylic process makes them less environmentally friendly than other materials. As the solvent evaporates, the coating shrinks and exerts stress on the components, so acrylics may not be suitable for all low-temperature applications.

44.2.5 Para-Xylylene (Type XY)

Para-xylylene coatings are unique, since they are applied by vapor deposition (see Sec. 44.4.6) rather than as a liquid. They are applied 0.0005 to 0.002 in thick. Para-xylylene coatings are often used in biomedical devices due to the inert character of the coating.

44.2.5.1 Chemistry. XY coating is supplied as a dimer, a polymer chain only two units long. During the vacuum deposition process, the dimer powder is gradually vaporized and is recondensed onto the CCA, polymerizing with the material already deposited. Typical application is 0.0005 to 0.002 in thick.

44.2.5.2 Properties. XY coating is chemically inert and moisture-resistant. Very thin, uniform layers are possible, with no pinholes or voids. XY coating also has very high dielectric strength. Due to the nature of the deposition process, no volatiles are generated.

44.2.5.3 Advantages and Disadvantages. XY coating is the highest performing coating in many regards. It has the highest dielectric strength, and is the lightest weight, lowest outgassing, mostly chemically inert, and most moisture-resistant. It provides the most uniform coating over, under, and inside parts where liquid coatings cannot be applied. The coating process must be performed in batch mode, using specialized coating equipment. It may be impossible to mask adjustable components such as potentiometers adequately. Rework is difficult; since the thin coating cannot be peeled, a microabrasion process is usually required to remove the coating. Additional staking or adhesive bonding of parts is required, since the thin coating provides little mechanical support.

44.3 PRODUCT PREPARATION

Most coating problems can be traced to improper preparation. The four preparation steps are

1. Cleaning to remove flux, oils, and contaminates
2. Masking to ensure coating is applied only where desired

3. Preparing the surface or priming to promote adhesion of the coating
4. Baking out to prevent moisture from being trapped under the coating

44.3.1 Cleaning

Thoroughly cleaning the CCA before conformal coating is the best way to ensure proper adhesion of the coating. The various cleaning chemistries and their effectiveness on different kinds of fluxes are treated in depth in Chap. 45, “Fluxes and Cleaning.” Besides removing flux, the cleaning process removes any contamination such as mold release agents on plastic part bodies, fingerprints, etc. No-clean fluxes reduce the need for waste water and waste solvent treatment. For boards that require conformal coating, the benefits of a no-clean system must be balanced with the risks of poor coating yields. A minor change in flux or coating chemistry could render the coating incompatible with the no-clean flux being used, causing delamination, cure inhibition, or other defects. In general, coating results are not as good with no-clean flux as with standard flux plus cleaning, yet in some cases may still be adequate to do the job.

44.3.2 Masking

To control the areas where coating is applied, some kind of masking is usually needed. Masking tapes or adhesive circles may be used to keep flat areas and holes free of coating. Since the tape needs to be removed completely after the coating operation, the tape adhesive must be capable of withstanding the cure temperature without peeling or becoming permanently bonded to the surface. To mask irregular surfaces, latex masking material is used. This

material is applied with automatic or manual dispensing equipment and is cured in an oven before the coating operation is performed. It then peels off easily after coating. For high-quantity production, boots or covers can be molded to fit over the areas that do not require coating. These are reusable, easy to install, and produce well-defined repeatable results. Rather than being masked, areas may be sealed with a permanent bead of a thixotropic (nonrunny) adhesive. This eliminates the demasking step, and is useful for complicated geometries such as the back of connectors and the perimeter of ball grid arrays (BGAs).

44.3.3 Priming and Other Surface Treatments

The adhesion of some coatings—notably epoxies, silicones, and para-xylylenes—will be improved if the CCA surface is primed before coating. Primers are applied as a very thin coat using dip or spray (generally the thinner the better) and oven-dried to drive any remaining solvent from crevices, vias, and such. If the primer fails to wet all areas of the board, the coating will not wet either but will easily delaminate instead. Such surfaces are not compatible with the primer, and an adjustment in primer chemistry is required. For difficult surfaces, such as large fluoropolymer parts or substrates, a more aggressive measure such as plasma-etch or mechanical abrasion may be needed to promote adhesion. Mechanical abrasion (grit blasting) may be used to roughen troublesome surfaces to promote coating adhesion. It may be easier to do this step as the parts are fabricated (in the case of mechanical parts) or as part of the make-ready process before assembly. Microabrasion can be used with proper care on the finished assembly as long as electrostatic discharge is controlled by the design and use of the abrasion equipment, and is monitored daily to ensure

that it is working properly. Microabrasion is also a viable method for removing coating (see Sec. 44.6.4).

Another aspect that can impact the ability of a coating to adhere to a substrate is the surface energy of the substrate. In general, a rough substrate, having high surface energy, will exhibit better wetting and coating adhesion than a smooth substrate, having low surface energy, all other factors being equal (which of course, seldom happens). A good example is comparing the adhesion of a conformal coating to the surface of a ceramic DIP component vs. a plastic bodied DIP of the same configuration. Smooth plastic surfaces, often compounded by the presence of fluorinated (e.g., Teflon™) or silicone mold release agents from the injection molding process, may show a higher incidence of coating delamination in thermal cycling due to surface energy conditions.

44.3.4 Measuring Surface Energy

There are a number of general methods for measuring or estimating the energy of a surface prior to coating application.

1. *Dyne pens:* These are liquid filled pens, similar to highlighting markers (see Fig. 44.2). Each pen body contains a solution with a calibrated surface tension. The most commonly available commercial sets start with 30 dynes/cm and end with 44 dynes/cm. In use, the marker tip is drawn across the substrate surface. If the solution does not immediately “bead up” or dewet, then the next higher pen is tried in an adjacent area. If a solution of 34 does not dewet and a solution of 36 does dewet, then the surface energy is judged to be 35 dynes/cm. This method is relatively inexpensive, very quick to use, but is variable and requires operator judgment.

FIGURE 44.2 Standard dyne pen samples.

These commercially available pens are very economical and it is often easier to purchase a set than to make your own solutions. However, if solutions are desired for measuring outside the range of 30 to 44 dynes/cm, individual solutions can be formulated using the information found in ASTM-D-2578, titled “Wetting Tension of Polyethylene and Polypropylene Films.” This test method focuses on measuring the surface energy of polyethylene and polypropylene films, but the test method includes the procedures on mixing the necessary solutions.

The methods in D-2578 use combinations of reagent grade formamide (HCONH2) and reagent grade ethyl cellosolve (CH3CH2OCH2CH2OH) to create solutions ranging from 30 to 56 dynes/cm. Be advised that both ethyl cellosolve and formamide are toxic and pose exposure risks.

General rule of thumb: When examining the surface energy of a substrate with dyne pens, the following general guidelines can be used (Table 44.2).

TABLE 44.2 General Guidelines When Using Dyne Pens

Surface Energy, dynes/cm	Expected Result
Above 40	Adhesion expected to be good
35–40	Adhesion generally good, with some intermittent delamination under severe conditions
30–35	Adhesion generally poorer, with increasing incidence of delamination under severe conditions
Below 30	Coating adhesion poor in any climatic testing

A great many factors affect coating adhesion, but all other factors being equal, this scale can be used to determine an overall degree of risk for coating delamination during environmental stress screening tests.

To show how surface energy can have an impact in production and reliability, the following illustrations are provided.

Illustration 1:

Company A used a solder mask coated coupon as part of its process control methodology for the conformal coating process. Each day, operators would coat the coupon using methods similar to those being used on production hardware. Following the standard cure methods, the coupons would be allowed to sit for one hour. The coupons would then have a 1″ × 1″ X scribed into the coating using a sharp razor blade. A standard tape was applied to the surface of the scribed coating and then pulled off. The coating was to have no loss of adhesion in the scribed area. While the company had numerous qualified solder masks, surface energy was never part of the qualification protocol, and the coupons were standardized on the most common solder mask used. Failures in the tape test were seldom encountered, but always passed in a subsequent

retest. All was well and good with the world, the workers were content, and the feudal lords of production smiled.

Then, during the same week, multiple failures began to occur in the process control coupons at multiple manufacturing sites. While processes between sites were similar, it was highly unusual for such failures to occur. The quality assurance policies of company A required that hardware be visually examined after product burn-in testing. No evidence of any coating delamination was found for the hundreds of complex assemblies examined. The loss in productivity and delays in shipment easily ran in the $250,000 to $500,000 range.

After extensive root cause analysis, it was found that the solder mask on the control coupons had been changed. The drawings allowed for any solder mask that was on the approved list, and only tribal knowledge was used in ordering the coupons. The mask was always assumed to be the same. The previous surface energy of the solder mask was in excess of 44 dynes/cm when using the dyne pens. The surface energy of the new solder mask was 30 dynes/cm. The inventory control system for the coupons was done in large lots to keep the per part prices low. The production problems began when the supply of the old coupons was exhausted and the supply of new coupons began.

Fearing that this meant a large scale quality problem, a sampling of unpopulated circuit boards was made for all vendors and all solder masks, again using the dyne pens. All bare boards were found to have surface energies in excess of 40 dynes/cm, which was deemed to be acceptable. Circuit boards go through a much wider range of chemical processes during board fabrication, such as plating and etching, and so have a higher surface energy as the mask surface is etched at the microscopic scale. In contrast, the coupon processing methods were very simple and did not have such exposure, creating the wide

disparity in surface energy between coupon and bare board, even for the same solder mask.

Illustration 2:
As noted, one of the elements which can impact the ability of a coating to adhere to a substrate is the surface energy of the substrate. In general, a rough coating, having high surface energy, will exhibit better coating adhesion than a smooth coating, having low surface energy, all other factors being equal.

To validate this surface energy adhesion, there are a couple methods, such as the IPC-TM-650(2.4.1.6) Adhesion test. This Adhesion test is a destructive test method that is completed by etching a cured conformal coated surface and placing a calibrate tape of adhesion strength and measuring the amount of material loss. Once this test is passed and there is no adhesion loss noticed, the assumption is that you have full adhesion with no potential for conformal coating peeling. However, this is not fully true. If the IPC Adhesion test is passed, however the surface energy below the conformal coating material is below 40 dynes/cm, there can still be a field failure for conformal coating adhesion as noted earlier within the table of surface energies for reference. This potential field failure aspect is only presented as a cured conformal coated material on an assembly is environmentally tested within a cycle consisting of high and low temperatures. In that, as the assembled is cycled the conformal coating material pulls away from the surface area during the heating process and starts to form aspects of a peeling/cracking within the coating area as cooled (see Fig. 44.3).

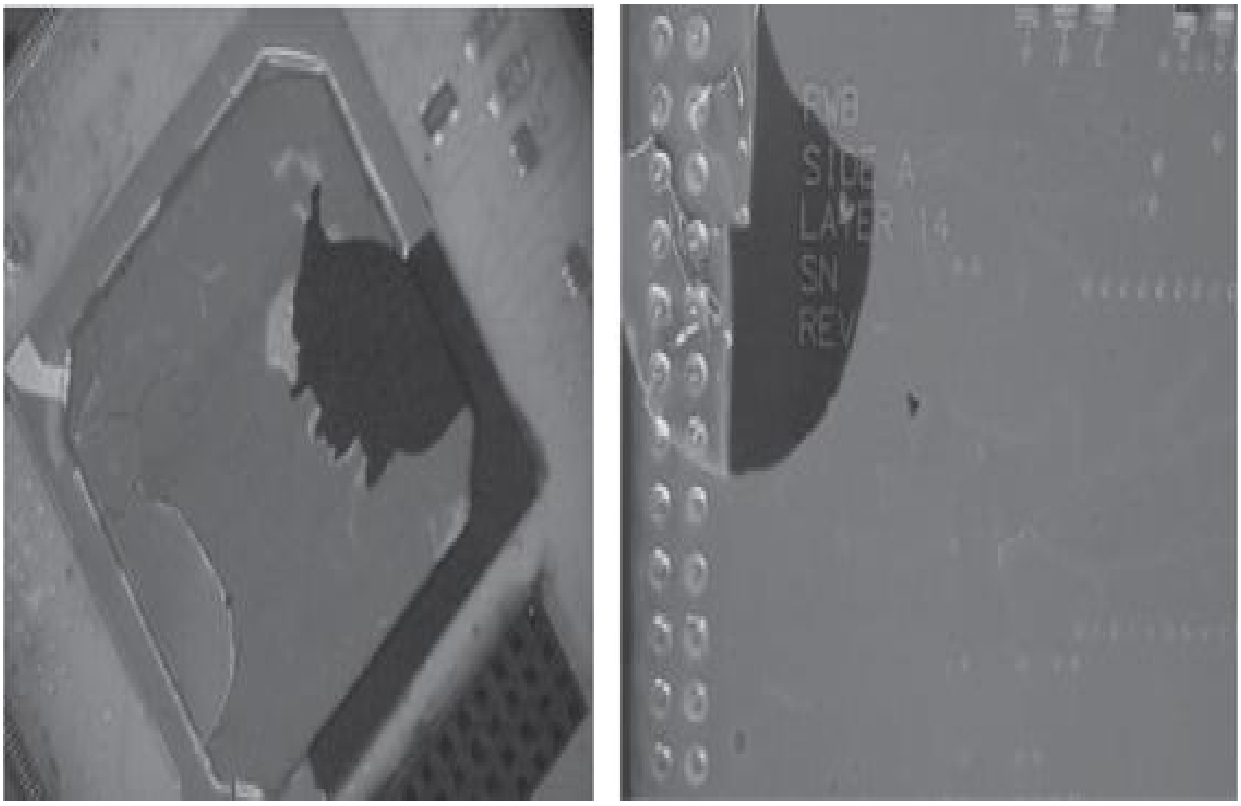

FIGURE 44.3 Cracked and peeling coated areas.

2. *Water break test:* One relatively inexpensive qualitative method for examining the surface energy of a substrate is a test commonly called a “water break” test. This test is common in the printed wiring board fabrication industry to examine the surface energy of a substrate prior to the application of solder mask. The test is also common prior to plating and anodizing operations.

The formal test method can be found in ASTM-F-22, titled “Standard Test Method for Hydrophobic Surface Films by the Water-Break Test.” This test method covers the detection of the presence of hydrophobic (nonwetting) films on surfaces and the presence of hydrophobic organic materials in processing ambients. When properly conducted, the test will enable detection of molecular layers of hydrophobic organic contaminants. On very rough or porous surfaces, the sensitivity of the test may be significantly decreased.

To paraphrase the test methodology:

- Take a cleaned and dried part and set it in a vertical position.
- Use a spray bottle containing distilled water.
- Spray the part two to three times from at least 6″ away.
- If the part is clean and free of oily residue, the water spray should sheet off.
- If some oily residue remains, the water will tend to adhere in droplets or patchy, nonuniform slicks.

Alternatively, apply several drops of distilled water to the cleaned surfaces. If the surface is inadequately cleaned, the spherical form of the drop is largely retained, and the surface must be cleaned once more. If the water runs on the treated surface, then wetting has been satisfactory and the part is ready for subsequent operations.

Caution: This test can be “fooled” by certain wetting agents, which will cause a continuous liquid film to spread over the metal surface even though the surface still has grease or oil on it.

This difficulty can be overcome in certain cases by dipping the parts in a dilute sulfuric or hydrochloric acid solution (the acid inhibits or destroys the “spreading power” of the wetting agent so a more truthful test result is obtained) and then rinsing again. Keep in mind that even with a good water-break test the surface still may contain soils.

3. Solder Mask Handbook—in Handbook can cut paste from existing document.

IPC-HDBK-840, titled “The Solder Mask Handbook,” discusses solder masks and surface energy.

A practical method for surface direct surface energy measurement and A to B comparison revolves around the simple concept of placing a known volume of a liquid on a surface and then just measuring the resulting drop

diameter. With a micro-liter pipette, it is fairly easy to place many small drops on a substrate and then measure the resulting drop diameter by any number of methods such as optically with a microscope, or mechanically with a caliper. If one desires to go through a very long geometric proof, the drop diameter can be directly related to the contact angle, which in turn can be related to the surface energy. Figure 44.4 shows this relationship for a 5 µL DI water droplet at 50 percent RH. So, it is fairly quick and low cost to place a number of 5 µL drops on a surface, measure the diameter and the relative humidity, convert drop diameter to surface energy and come up with a fairly accurate estimation of the substrate surface energy. The application of this test method isn’t limited to just DI water. Correlations for other fluids and/or curing materials can be obtained.

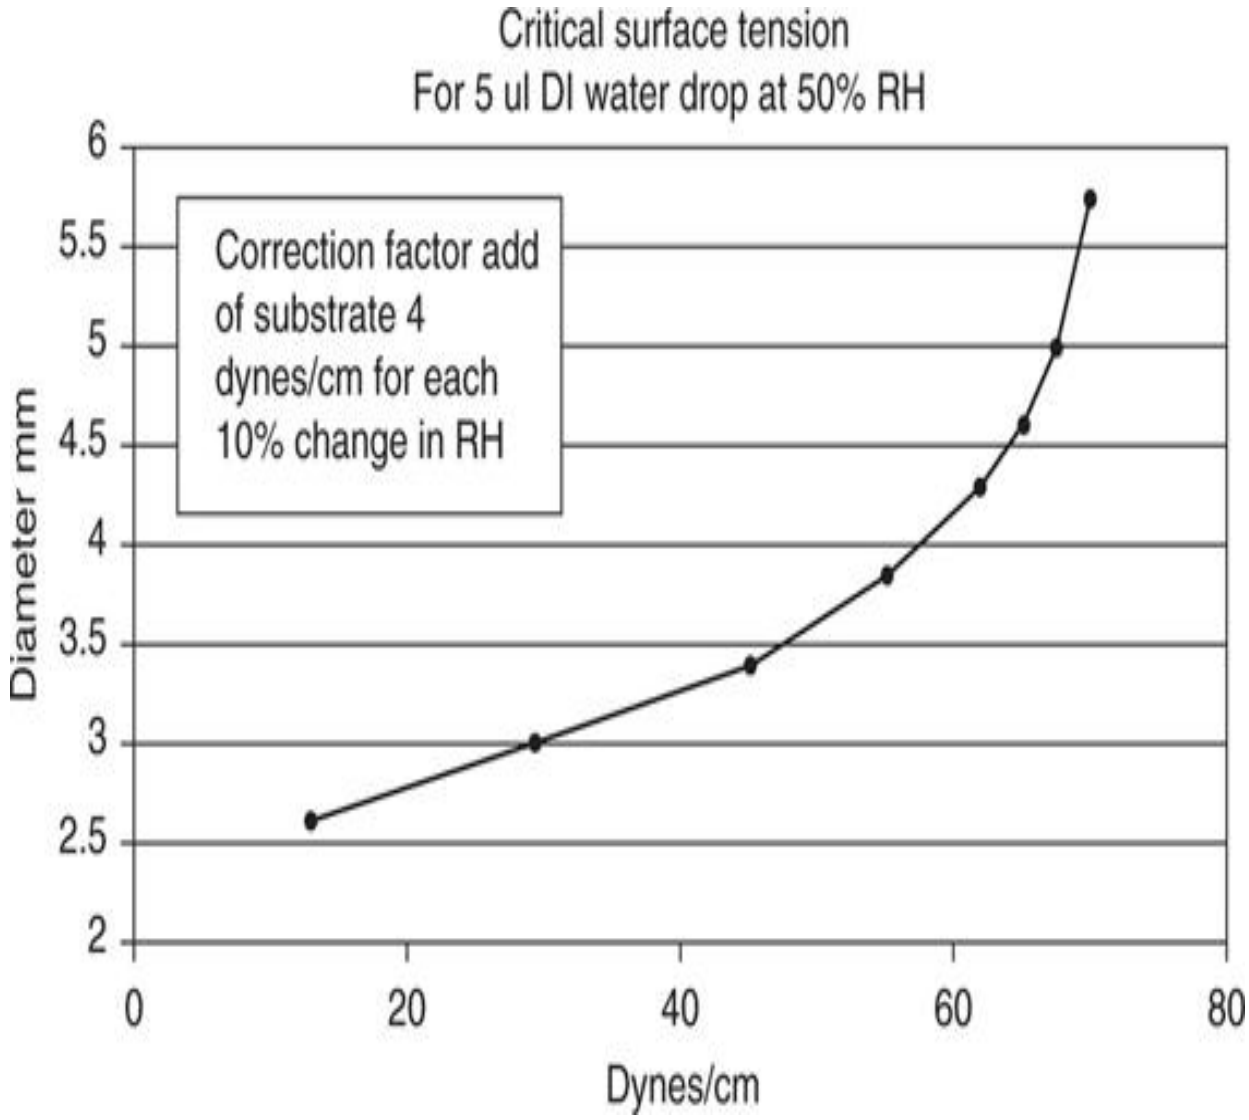

FIGURE 44.4 Critical surface tension for 5 uL of DI water drop at 50% RH.

Illustration 1:

The following example of applied surface energy shows how this test method may be applied to a silicone conformal coating. This example shows the interaction between materials (flux, solder mask)[5] and process (the wave soldering process). Just like the previous DI water example this example applies a known and controlled volume of a conformal coating and then measures the resulting drop diameter after the conformal coating cures.

A 5-µL drop of a conformal coating was applied to various substrates which were previously exposed to different fluxes (same basic flux formulation with different surfactants). This example shows that a no-clean flux formulation with a fluoro-surfactant had a major impact on the conformal coating wetting. The fluoro-surfactant significantly reduced wetting when compared to another potential flux ester based surfactant. Again, the amount of wetting directly corresponds to the relative drop diameters (i.e., a large drop diameter indicates improved wetting). In this example, to solve the coating wetting issue, the production wave soldering flux formulation was changed (see Fig. 44.5).

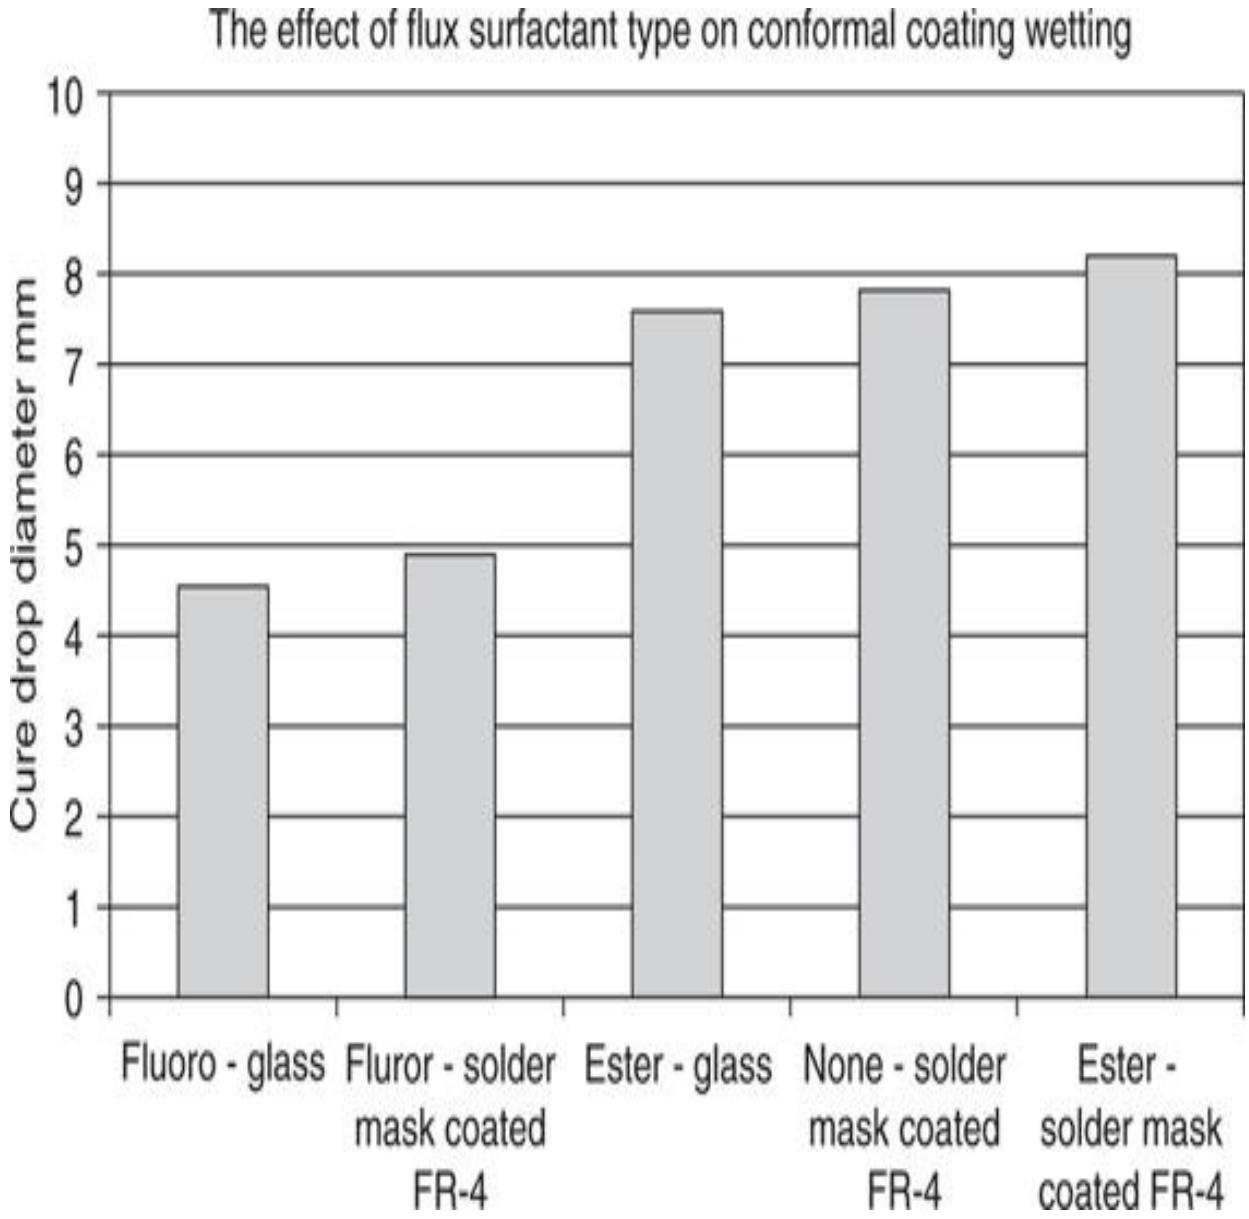

FIGURE 44.5 The effect of flux surfactant type on conformal coating wetting.

44.3.5 Water Drop Contact Angle

One quantitative test method for the determination of surface energy is to measure the contact angle of a droplet of distilled or deionized water on the substrate surface. A substrate with a high surface energy will have a large contact angle (water will bead up). A substrate with a low surface energy will have a low contact angel (water wets

out). This method is more quantitative and repeatable than the dyne pen method, but requires a greater capital investment.

ASTM-D-7334, titled “Standard Test Method for Measurement of the Surface Tension of Solid Coatings, Substrates and Pigments using Contact Angle Measurements,” outlines one method used to determine contact angle and a calculation of resulting surface energy.

ASTM-D-5725 titled “Standard Test Method for Surface Wettability and Absorbency of Sheeted Materials Using an Automated Contact Angle Tester,” shows an automated (though capital intensive) method of determining contact angle.

Figure 44.6 shows a diagram of the pertinent measurements for contact angle.

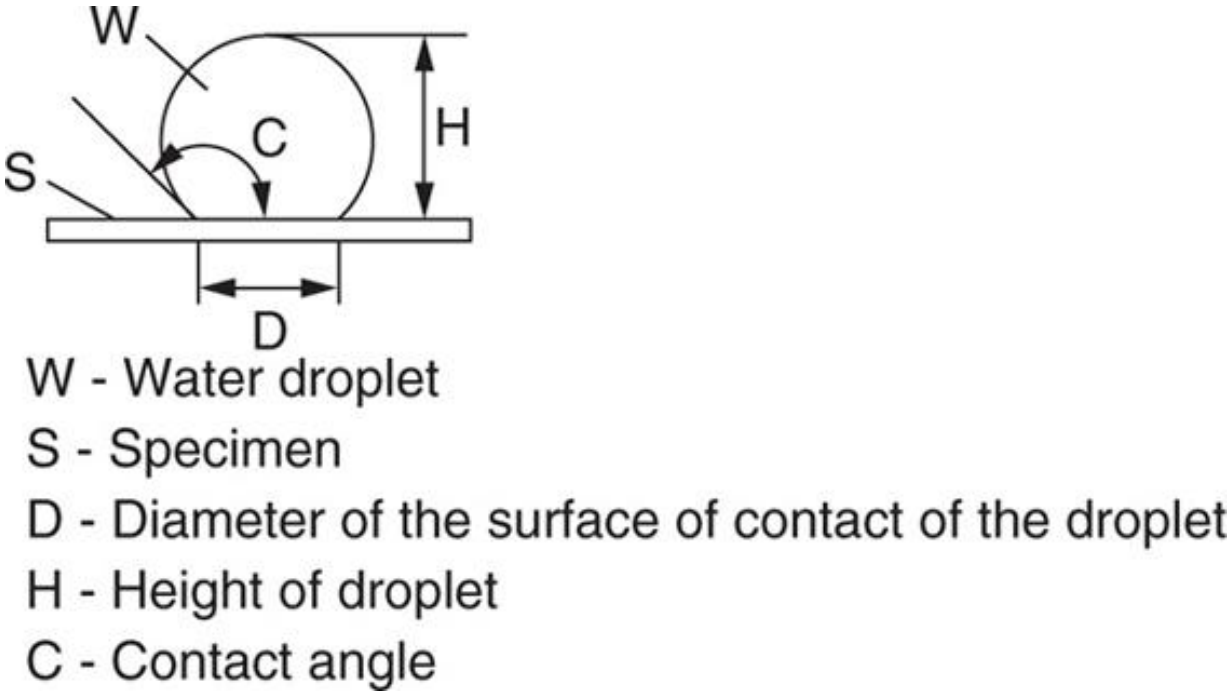

FIGURE 44.6 Measurements for contact angle.

A manual method of measurement makes use of a device called a goniometer. An example of such an instrument is shown in Fig. 44.7. A substrate is placed on the center

pedestal. A calibrated syringe is used to dispense a droplet of distilled/deionized water on the surface of the substrate. A light source behind the water droplet illuminates the water droplet. A front viewer is set level with the surface of the substrate. Reticules in the eyepiece are adjusted to measure the contact angle of the drop. A hydrophobic surface will have a high bulbous shape. A hydrophilic surface will have a flat and wide droplet shape.

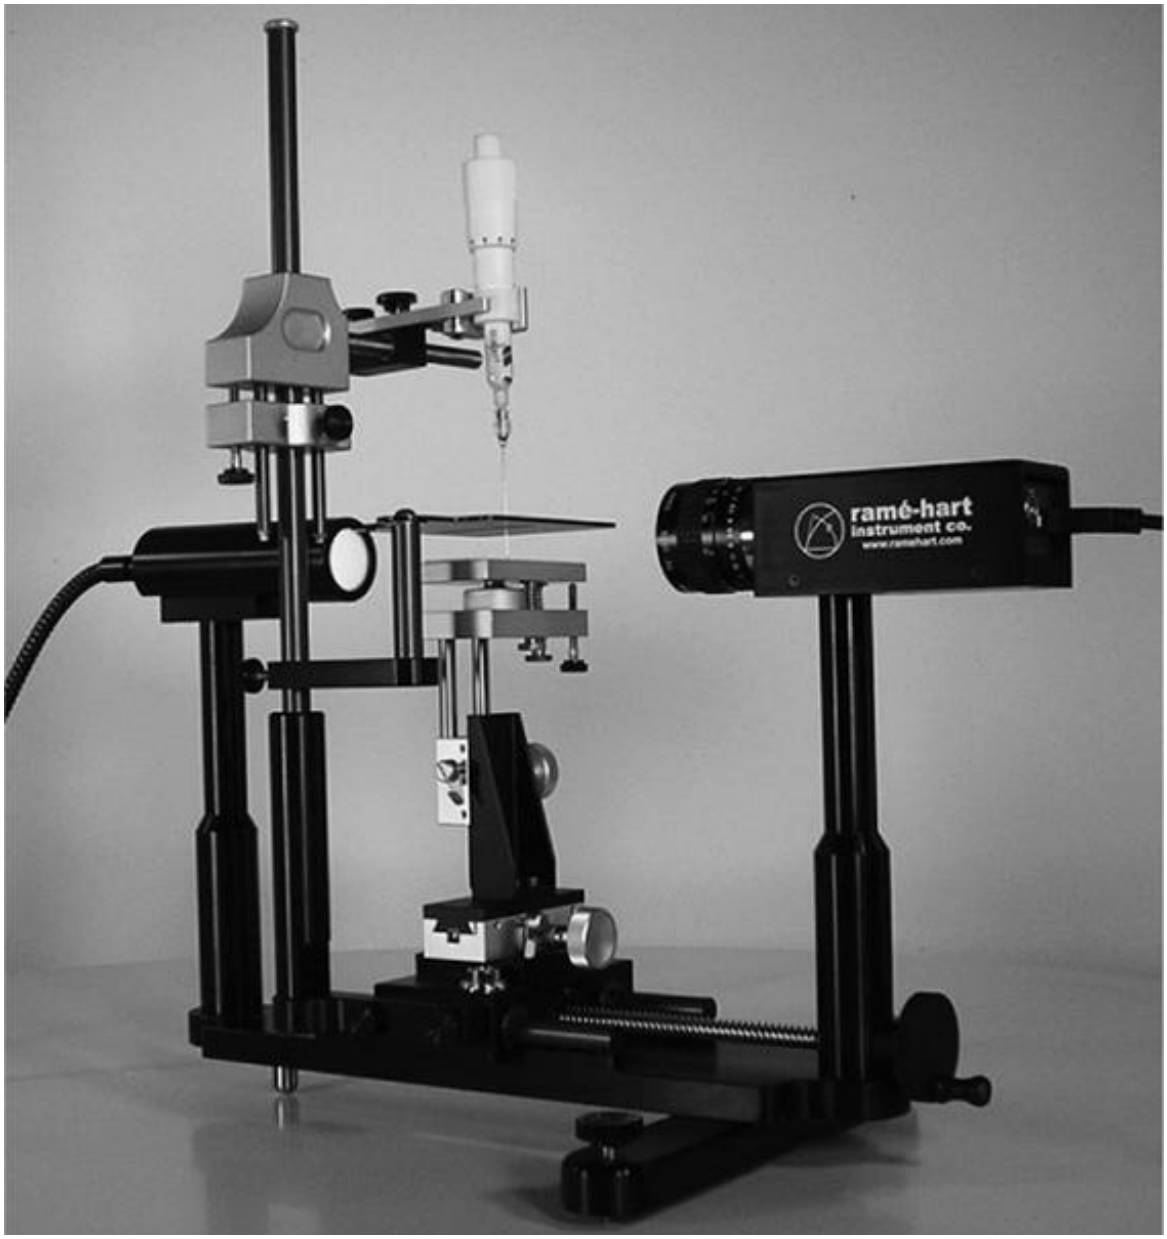

FIGURE 44.7 Goniometer (*Courtesy Rame' Hart Instrument Company*.)

44.3.6 Bake-Out

Since the coating is intended to be waterproof, it is imperative that all moisture be baked out before the coating is applied, especially for hydroscopic substrates such as GI polyimide. If moisture is left in place, it can cause corrosion of traces and/or parts and will promote dendritic growth between conductors, as well as enabling the growth of conductive anodic filaments (CAF) along the glass fibers in the weave of the PWB (see Chap. 59). A bake of 93°C for 4 h will be sufficient to drive out moisture from the CCA. With certain component designs, a lower temperature and different qualification time may be required.

44.4 APPLICATION PROCESSES

Conformal coatings can be applied by a variety of methods, including

- Hand painting the coating with a brush
- Dipping the board into the coating
- Hand spraying with an aerosol can or handheld spray gun
- Automatically spraying the board with coating as it passes by on a conveyor
- Selectively applying coating to certain areas of the board with a robotic nozzle
- Vapor depositing para-xylylene onto the board with specialized equipment

44.4.1 Hand Paint

Hand painting allows coating to be applied wherever desired with no setup time and low equipment cost. It is still the preferred method for touching up thin spots in a bulk applied coating and for coating replaced components. It can be used to reach areas where spray or automatic nozzles cannot reach, and works well for smaller, one-of-a-kind items. Hand painting is the most variable of all methods.

44.4.2 Dip

Dip coating works best for coatings that have a long pot life at room temperature, such as solvent evaporation cured coatings and one part materials. Since the unused coating remains in the dip tank, a long (or infinite) pot life keeps the waste down to a minimum. The viscosity of the material in the bath should be checked daily, using a flow cup viscosimeter or other method, and solvent added to keep the viscosity of the material within the acceptable range. For a given dip speed, a lower viscosity will produce a thinner coating. The dip machine (see Fig. 44.8) will have bars or hangars on which to hang the board to be coated. Insertion speed should be slow enough to prevent the formation of bubbles as the coating flows around and under surface mounted parts, etc. Withdrawal speed should range between 1 and 6 in/min and will dictate the finished coating thickness; a slower withdrawal will produce a thinner coating. Dip coating cannot be used multiple times to build up thicker layers of acrylic coating, since solvent in the bath will loosen or dissolve previously applied layers of acrylic. Any areas that are not to be coated must be completely masked before dipping. Assemblies can be partially dipped to leave the top edge of the board uncoated if the board is designed so that all components that need coating are below the level of the bath.

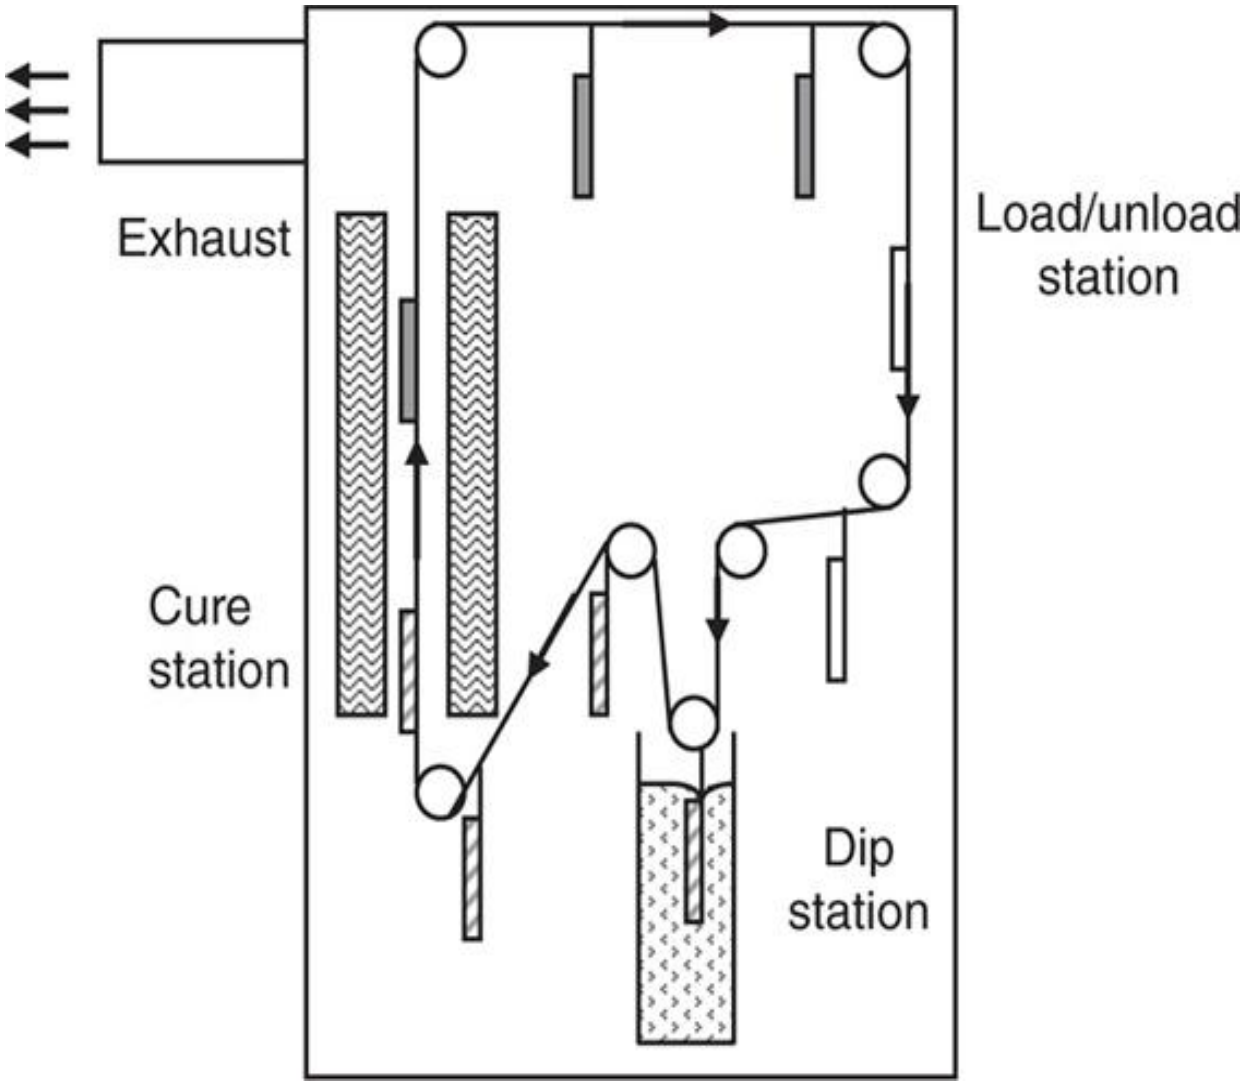

FIGURE 44.8 Dip coating machine.

44.4.3 Hand Spray

Hand spraying is used for all types of liquid coatings. The boards to be coated are sprayed several times; the angle is changed 90° each time so that complete coverage is achieved. Tall components may shadow or block the spray from lower profile components behind them, so care must be taken to ensure all areas of the board are fully coated. A witness strip is often sprayed at the same time for use in measuring the coating thickness. As with the dip method,

viscosity control is a key factor to reducing bubbles, cobwebs, and improper coating thickness. Two part materials are mixed immediately prior to filling the spray gun container, or are mixed in line if a continuously fed mixing gun is used. Solvents may also be used to modify the viscosity of the coating being applied. Single-part materials (particularly acrylics) are also available in aerosol cans, eliminating mixing altogether.

44.4.4 Automatic Spray

For high-volume coating application, a semiautomatic spray machine is used to eliminate the dependency on the operator and allow in-line coating. The boards enter the machine on a paper-covered conveyer and are sprayed by a rotating or reciprocating spray head. The motion of the spray head(s) is designed to cover a given width of the belt completely from all angles. Shadowing is of greater concern with semiautomatic spray equipment, since special treatment cannot be given to any one area of the board. Full masking is required to keep the coating out of areas that should not be coated. Once the board is coated on one side, it is partially cured (or fully cured), turned over, and coated on the other side.

44.4.5 Selective Coating

The selective coating process utilizes a robot similar to the automated pick-and-place machine to dispense coating only where it is needed. Four- or five-axis machines can be used to coat the sides of tall parts and around corners. The greatest benefit to selective coating is that it drastically reduces the amount of labor needed for masking and mask removal; areas that need to be free of coating simply have no coating applied there. Coating utilization is highest of all

methods, since almost no coating is lost in continuous production. Spray patterns may be either atomized, spraying droplets onto the board and providing a thinner coating (see Fig. 44.9), or continuous, applying a stream or sheet of liquid to the board (Fig. 44.10), producing a well-defined boundary between the coated and uncoated areas and eliminating the need for masking. In the same way as the semiautomatic sprayer, the board is tack-cured and then turned over and coated on the other side. An automated board flipper may be used to accomplish this to automate the entire coating process.

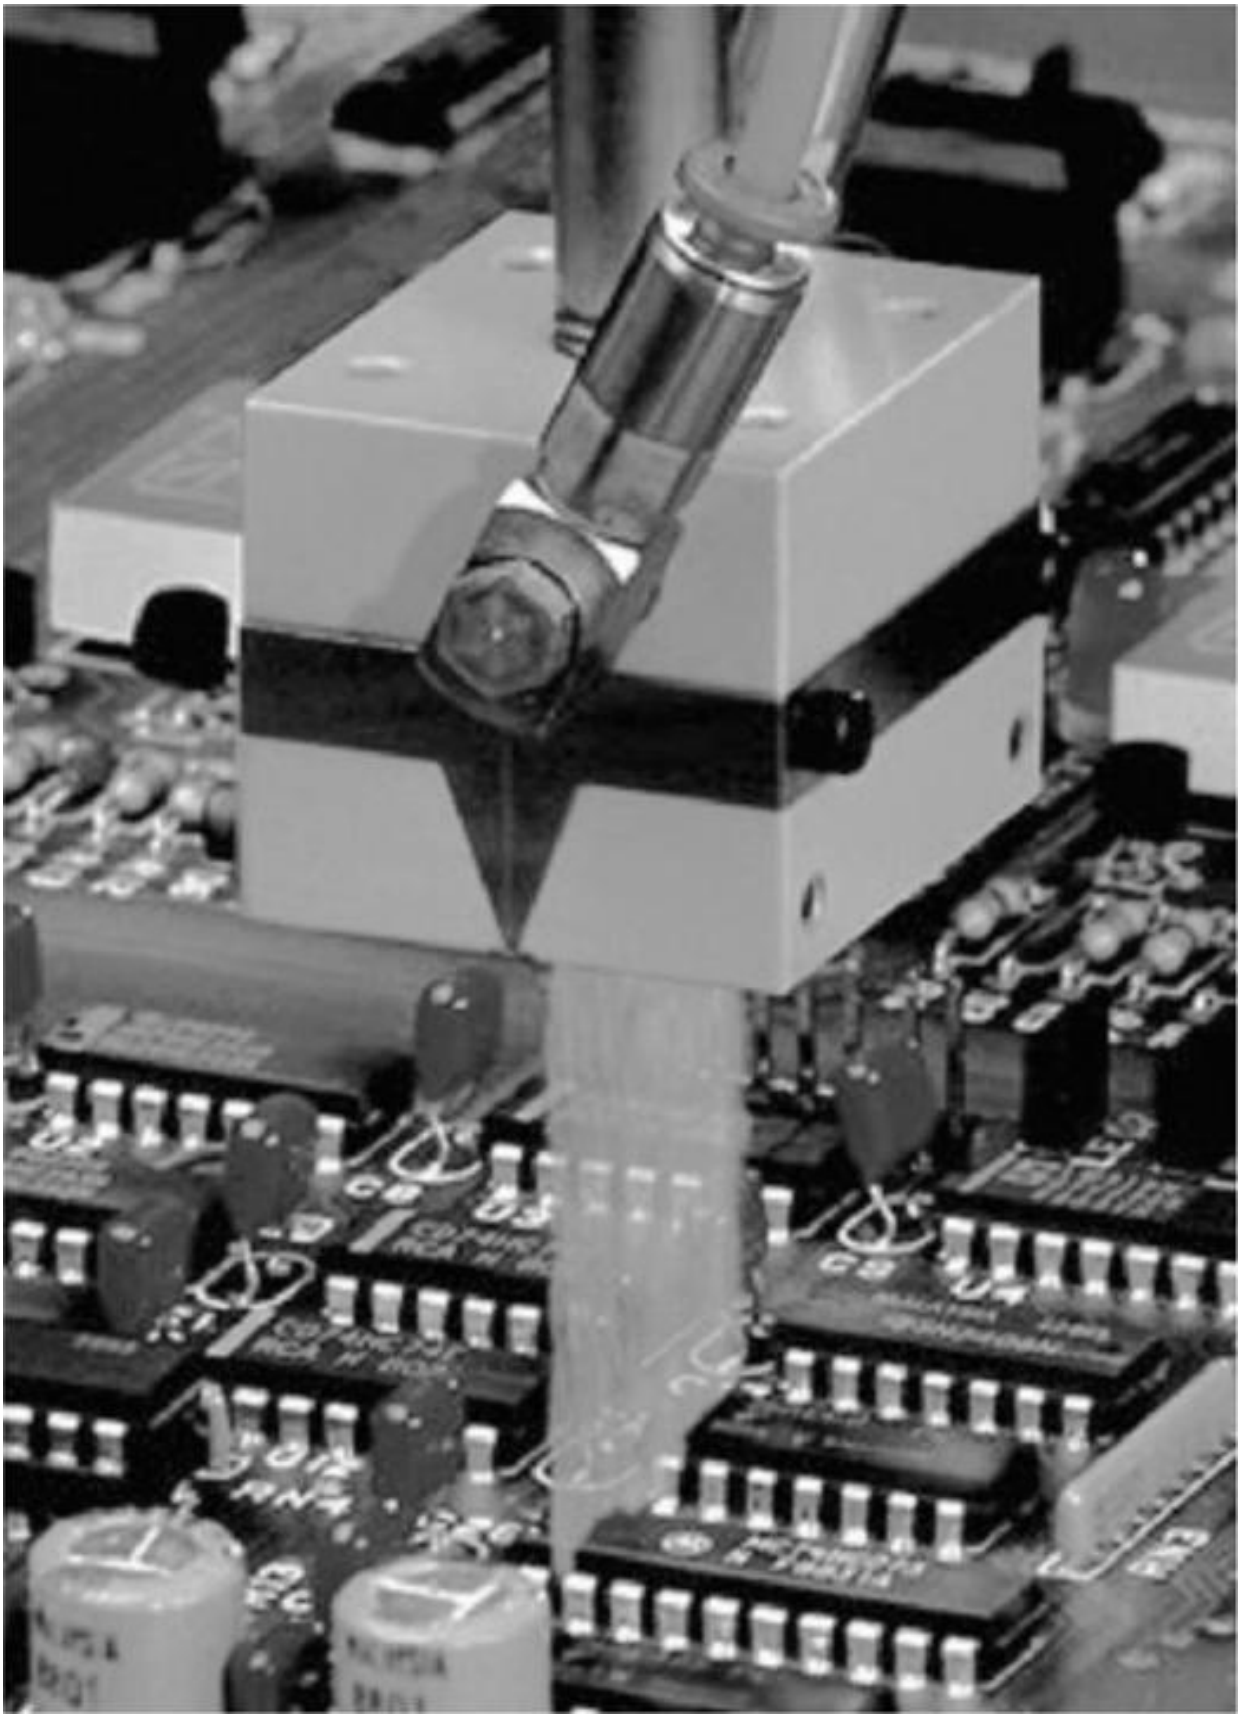

FIGURE 44.9 Selective coating using an atomizing nozzle. (*Courtesy of Asymtek*.)

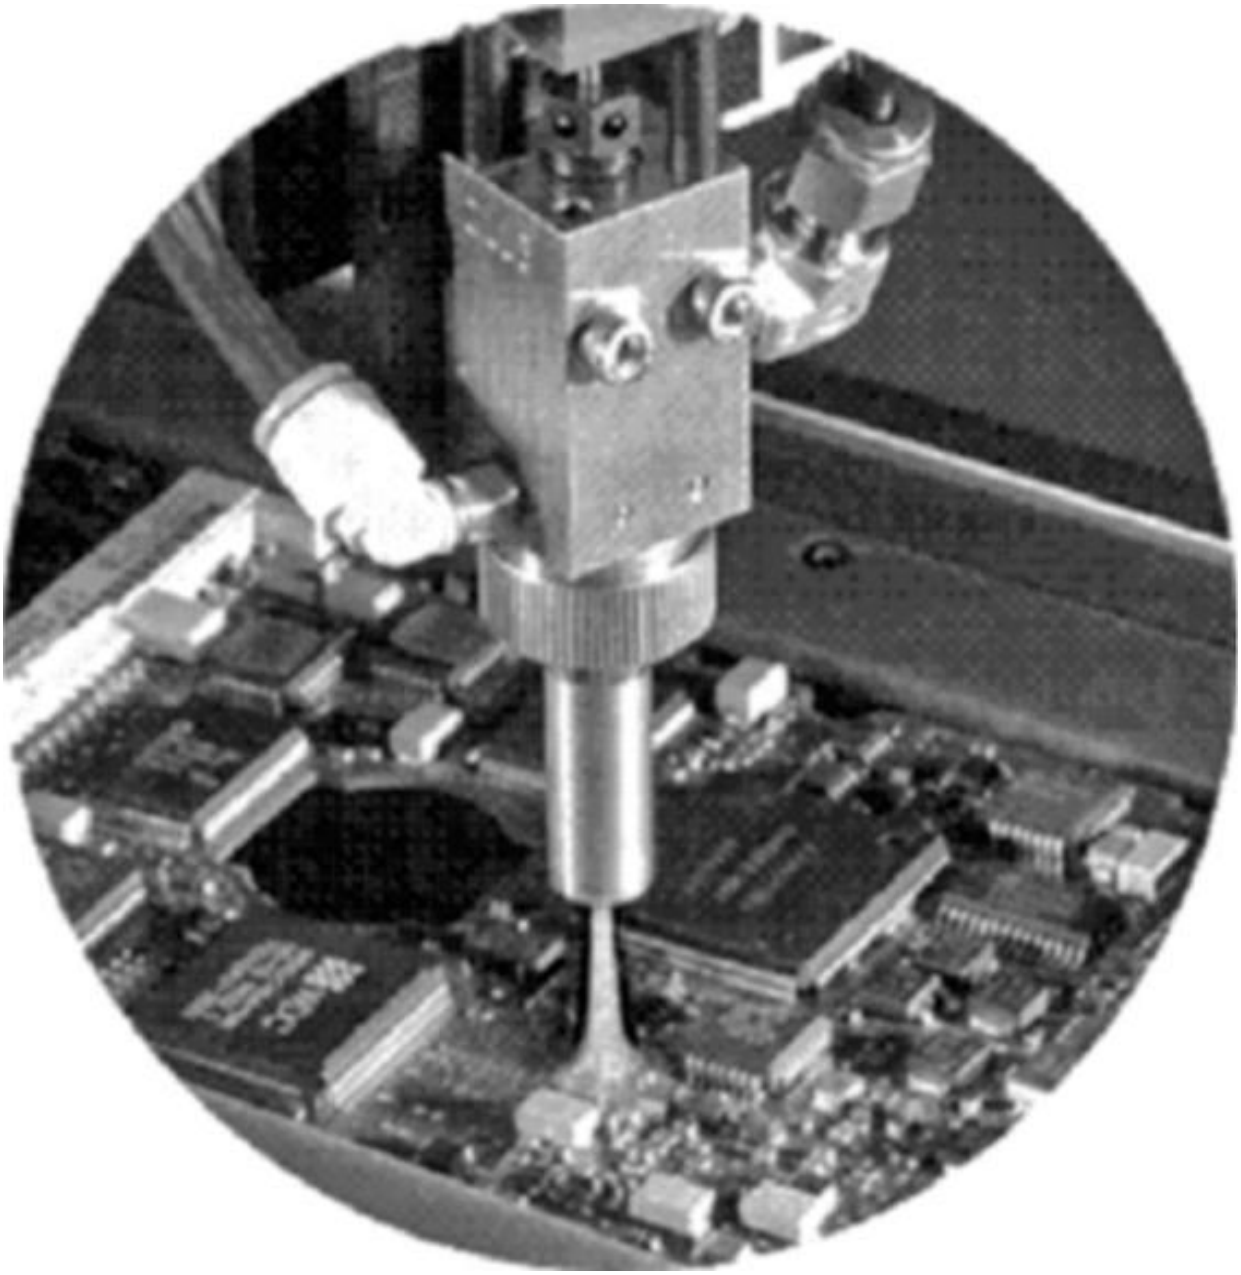

FIGURE 44.10 Selective coating using a continuous flow nozzle. (*Courtesy of Chipco, Inc*.)

44.4.6 Vapor Deposition

Vapor deposition is only used with XY coatings, and requires specialized coating equipment. In the evaporator, a measured amount of dimer is placed in a crucible. The coating cycle is then started, and the chamber is pumped down to an almost complete vacuum (see Fig. 44.11). During the deposition process, the dimer powder is vaporized and recondenses onto the batch of CCAs, forming a uniform coating covering all corners and edges evenly. The vapor deposition process drives the vapor into any crevices and openings. Vapor deposition has the most stringent masking requirements, since leaks in the maskant will still admit vapor that will contaminate the surface behind, and air pockets inside masking boots or tape may dislodge the boot in the vacuum and create leaks as the air escapes.

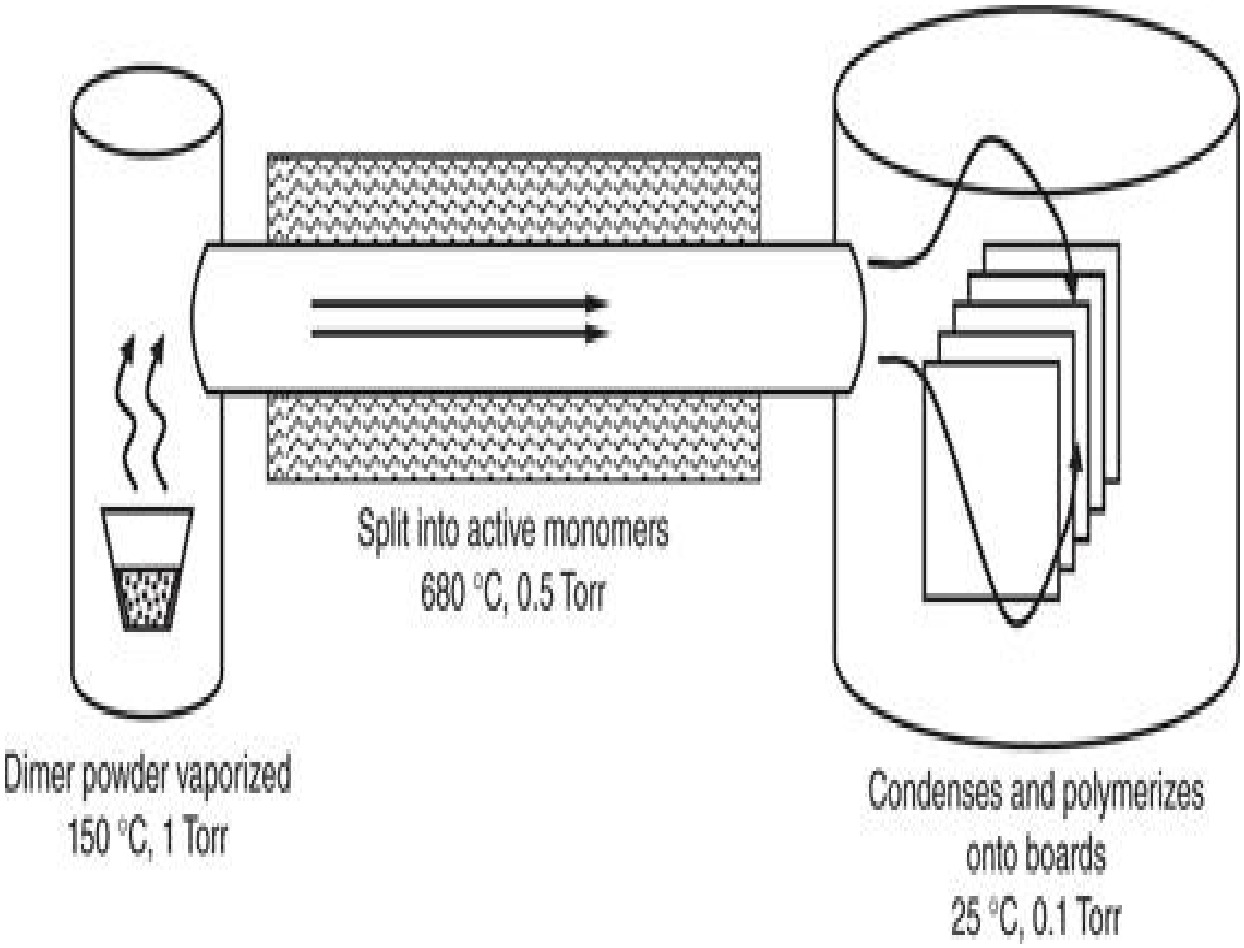

FIGURE 44.11 Para-xylylene vapor deposition process.

44.5 CURE, INSPECTION, AND DEMASKING

The finishing steps require most of the labor involved in conformal coating process. Three finishing operations are

- Curing the coating
- Inspecting under UV light to verify complete coverage and touch-up
- Removing mask materials

44.5.1 Cure

Each of the four liquid chemistries is available in a formulation offering different cure mechanisms, as shown in Table 44.1.

44.5.1.1 Solvent Evaporation. Systems that are cured by solvent evaporation can be air dried, or slightly heated to drive the solvent out faster. Care must be taken not to overheat the freshly coated assemblies; the coating will skin over and cause bubbles. Long-term exposure to the unevaporated solvents trapped in the coating may also be deleterious to the materials in the parts and PWB. Drying of solvent cure assemblies must be done under a ventilation hood or other properly ventilated area.

44.5.1.2 Room Temperature Vulcanization. Some silicone-based coatings use the room temperature vulcanization (RTV) cure process, which consumes moisture from the surrounding environment as part of the cure process. Some means of humidity control is required; if cure is attempted in a dry oven, the material will not cure properly, if at all.

44.5.1.3 Heat Cure. Oven-curable systems use an extended bake, ranging from 15 min to several hours or longer, for the material to cure fully. Thermally activated systems require the increased temperature to start the curing process, whereas thermally accelerated systems will cure eventually at room temperature but are baked to speed up the process and improve material properties. Generally, the hotter the oven, the quicker the cure, and the harder the finished material. However, care must be considered to ensure there are no thermally sensitive components that are added prior to the coating process when higher temperatures are used to expedite the cure.

44.5.1.4 UV Cure. For high-volume production, UV-curable materials are used. Immediately after the coating machine is a booth with high-intensity ultraviolet lamps to illuminate the assembly. After several seconds, the assembly has cured enough to be able to be handled at the next stage of assembly, such as coating the opposite side. UV-curable materials do not cure fully under components, where the coating is not illuminated. Therefore, most UV-curable materials also contain a secondary curing mechanism, such as heat or moisture cure, so that at the end of the line the CCA can be fully cured in a single baking or moisture step or naturally come to full cure in ambient conditions inside the finished product. Since different coatings are sensitive to different wavelengths of UV light, it is important to coordinate the purchase of the light source with the supplier of the coating.

44.5.1.5 Catalyzed. The catalyzed process involves mixing two parts together just before application, to initiate polymerization and cross-linking. This process occurs slowly at room temperature but may be accelerated by elevating the temperature in an oven. Catalyzed coatings may be affected by contaminates present in the PWB or parts being

coated, resulting in uncured areas or peeling coatings. Since the pot life of catalyzed materials tends to be short, it is imperative that the mixed material be cleaned from sprayers, tubing, and so on, before it thickens and hardens.

44.5.2 UV Inspection

Coatings contain a fluorescent dye that will glow under UV light and show where the coating has (or has not) been applied. Areas without coating can be touched up at this time. The areas most susceptible to insufficient coating are corners of parts, where the coating can flow away and leave little behind; the protruding ends of through-hole part leads; and shadowed areas under or behind larger components. If large flat areas are uncoated and show beads of coating, there is a wetting problem due to improper surface preparation or a material incompatibility. The coating should also be inspected for improper thickness, bubbles, trapped material or debris, and incomplete curing (see Fig. 44.12).

FIGURE 44.12 Various conformal coating defects.

Recently, with the migration of conformal coating into new market segments, new suppliers have developed camera-based AOI systems that can measure the presence of the coating, detect defects such as insufficient coverage and voids and calculate the coating thickness of flat, unencumbered cured surface. Completely transparent coatings yield a low optical signature, the signal the AOI system detects under ambient lighting. The resolution of the AOI is frequently not high enough to see the clear film.

Fluorescent coatings provide an enhanced optical signature when illuminated, making AOI inspection easier. AOI systems utilize filters to eliminate background light not emanating from the fluorescent coating. This can be a fast solution for in-line verification of coverage.

44.5.3 Demasking

Mask materials should be removed carefully; to prevent peeling, it may be desirable to score or cut the coating at the edge of the mask so that the coating tears along the correct line. Ensure that the mask is removed entirely and that no residue has been left behind on the board. Latex mask that has been overheated will be sticky and difficult to remove completely, as will overheated masking tapes.

44.6 REPAIR METHODS

Since the different varieties of available coatings vary widely in their properties, removal methods must be evaluated and developed on practice boards first before being used on deliverable CCAs. The coating can then be removed as easily

as possible, with the least risk to the CCA. Several methods to remove conformal coating are

- Using a solvent to loosen or dissolve the coating
- Using a hot soldering iron or hot-air nozzle to solder through the coating while simultaneously removing the offending electrical part
- Mechanically cutting, abrading, or picking away the coating
- Etching the coating away using rarefied gas plasma (typically for XY coating only)

44.6.1 Solvent

The easiest coatings to remove are acrylics, since they do not react when they are applied. For local coating removal, the area to be repaired can be cotton swabbed several times with the proper solvent. Care must be taken to keep the solvent only in areas that are to have the coating removed. The entire board may be stripped of coating with a solvent soak. This is most useful on acrylic coatings, but is also possible for some urethanes and silicones, which swell and loosen when soaked. Note that this process may damage the components or solder joints on the board, which will be stressed as the expanding coating pushes up the components. The solvent may attack the components and PWB itself; epoxy coatings cannot be removed with solvent or chemical strippers, since many parts and the PWB are also made of epoxy.

44.6.2 Thermal

Thin coatings may be loosened from solder joints with a soldering iron or a hot-air reflow tool, while the faulty part is being desoldered. The area is then cleaned of charred and or

damaged coating, and the repair completed. Although this method is simple, it usually produces toxic gases, and must be performed with adequate ventilation. The decomposed coating is also difficult to clean off of the board and soldering iron.

44.6.3 Mechanical

Mechanical means such as scraping and picking are necessary to remove all coatings, even if the bulk has been removed via one of the preceding methods. Softer coatings such as UR or SR can be scraped away with a wood implement, so as not to cause damage. A soft rotary tool may be used for larger areas. The board may be heated slightly to make the job easier. For harder coatings, a hot knife is used to cut through the material.

44.6.4 Abrasion (Microabrasion)

The principle of micro abrasive blasting is based on projecting a small particle onto the coating surface with enough force to mechanically abrade the surface and eventually remove the coating. Balance must be achieved between the abrasion of the coating surface and abrasion of the printed wiring board surface beneath the coating.

This coating removal method uses a micro abrasive blasting system and a very fine soft abrasive powder. The powder is propelled through a small nozzle toward the area where the coating needs to be removed. The nozzle is positioned around the base of component leads to selectively remove the coating. This technique requires practice in order to not damage the substrate beneath the coating along with contamination by the abrasion media to the surrounding board areas.

Micro abrasive blasting will generate substantial static charges. Proper ESD measures need to be used in order to ensure that static charges are handled appropriately.

44.6.5 Plasma Etch

An extended plasma etch will remove XY coatings from large areas, since the plasma erodes the surface evenly. Since the plasma will chemically change the surface (leaving behind oxides, reduction products, and ash), compatibility of the plasma-stripped surface with the new coating must be verified.

44.7 DESIGN FOR CONFORMAL COATING

When designing a conformal coating system into the product, the designer needs to consider a number of questions:

- Is coating required for this product, or should it be omitted for cost savings or other reasons?
- What material properties are most important for this application, and which materials will provide the best balance?
- What areas should not be coated?

44.7.1 Is Conformal Coating Required?

One of the basic questions to consider is whether or not to coat the particular assembly. Generally this will be a trade-off

between reliability and cost.

44.7.1.1 Why Use It? Customers may flow down requirements for conformal coating for industries where it is commonly used such as military or aerospace electronics. The following are some of the reasons to consider the use of conformal coating:

- The end products are used in humid or condensing atmospheres, such as electronics boxes for military and shipboard applications. It should be noted that although conformal coatings are moisture resistant, they are not waterproof, and should not be used for items that will see extended or continuously wet conditions. For those applications, use a watertight enclosure and conformal coat the boards inside. Conformal coating will protect against condensation, such as when the product is brought from a cold environment into a warm humid one.
- Clean conformal coating does not support mold and fungus growth.
- The end products can become contaminated by dirt and debris. Conformal coating is especially useful in space applications, since loose debris will float readily from place to place inside the electronics box.
- Conformal coating greatly improves the board’s capability to withstand high voltage, especially at altitude or low pressure, since an electrical arc now has to travel through two layers of insulation rather than just jumping from one trace to its neighbor.
- Conformal coating protects against tin whiskers. Pure tin plating has the tendency to recrystallize and extrude long (>1 mm) whiskers of pure tin, which can short to neighboring part leads and cause short circuits. Conformal coating provides protection against short circuits caused by tin whiskers. Even if a tin whisker can force its way through a layer of coating on the way out, it cannot force

its way back through the coating on the neighboring lead without bending and buckling

- Conformal coating provides mechanical support for components during shock and vibration. Components weighing more than ¼ oz per lead should be supported by other means as well, such as staking with a bead of adhesive along the side.
- Lastly, conformal coating may be made opaque, and thus provide a level of security. A thick opaque epoxy coating will prevent the casual observer from determining what is under the coating.

44.7.1.2 Why Not Use Coating? Most of the reasons for not coating on an assembly stem from the recurring cost of cleaning, masking, demasking, touch-up, etc. The target cost of the product may not support the extra cost incurred by the coating, and if reduced reliability of the uncoated assembly is still acceptable, the rational decision is not to coat the assembly. Since the coating is a dielectric material, it changes the impedance of high-speed traces on the surface of the PWB. Boards with microstrip are usually not coated for this reason. Radio frequency (RF) PWBs for severe environments can still be coated if the traces are buried microstrip or stripline, which are unaffected by the additional coating on the board surface.

44.7.2 Desirable Material Properties

When selecting a coating, the entire suite of material properties must be considered in order to choose the best coating for the application. Unfortunately there is no “one size fits all” solution, but many different coatings, each suited to different applications, as shown in Table 44.1.

The following are some of the properties to consider:

- *Ease of application and producibility:* The intended production environment may determine the cure process and application process that is best for the job, and will narrow the field of alternatives.
- *Compatibility:* The coating must not be inhibited from curing by any material on the completed assembly. Often the best way to address this is to ask the manufacturer and try out the coating in question on a sample of the materials that you are going to use.
- *Moisture resistance: S*ometimes called moisture and insulation resistance (M&IR), is a measure of how well the insulation characteristics are maintained when exposed to elevated conditions of temperature and humidity. A material with a low M&IR value would be a poor choice to protect a circuit in a high humidity end-use environment.
- *Dielectric constant:* For RF and high-speed circuits, a material with a low dielectric constant will change circuit performance less than a material with a higher one.
- *Dielectric strength:* For high-voltage application, materials with a high dielectric strength should be used. For a valid comparison, tests must be performed on samples of equivalent thickness, since thin samples will break down at a higher volt/mil than thick samples of the same material.
- *Insulation resistance:* Also known as resistivity, insulation resistance is of concern in high-voltage or high-impedance circuits, where the resistance in the circuit is very high (>10 MΩ) and is significant compared to the resistance of the coating and PWB laminate. For these applications, choose a coating with high (>10^15 Ω-cm) resistivity and excellent moisture resistance.
- *Hardness:* For products that need to withstand cold temperatures <−10°C, a soft coating is recommended so that at cold temperatures the coating will not exert excessive force on fragile or beneath components (see Fig. 44.13). For products that need good abrasion resistance

and protection from external handling damage, a harder coating must be used.

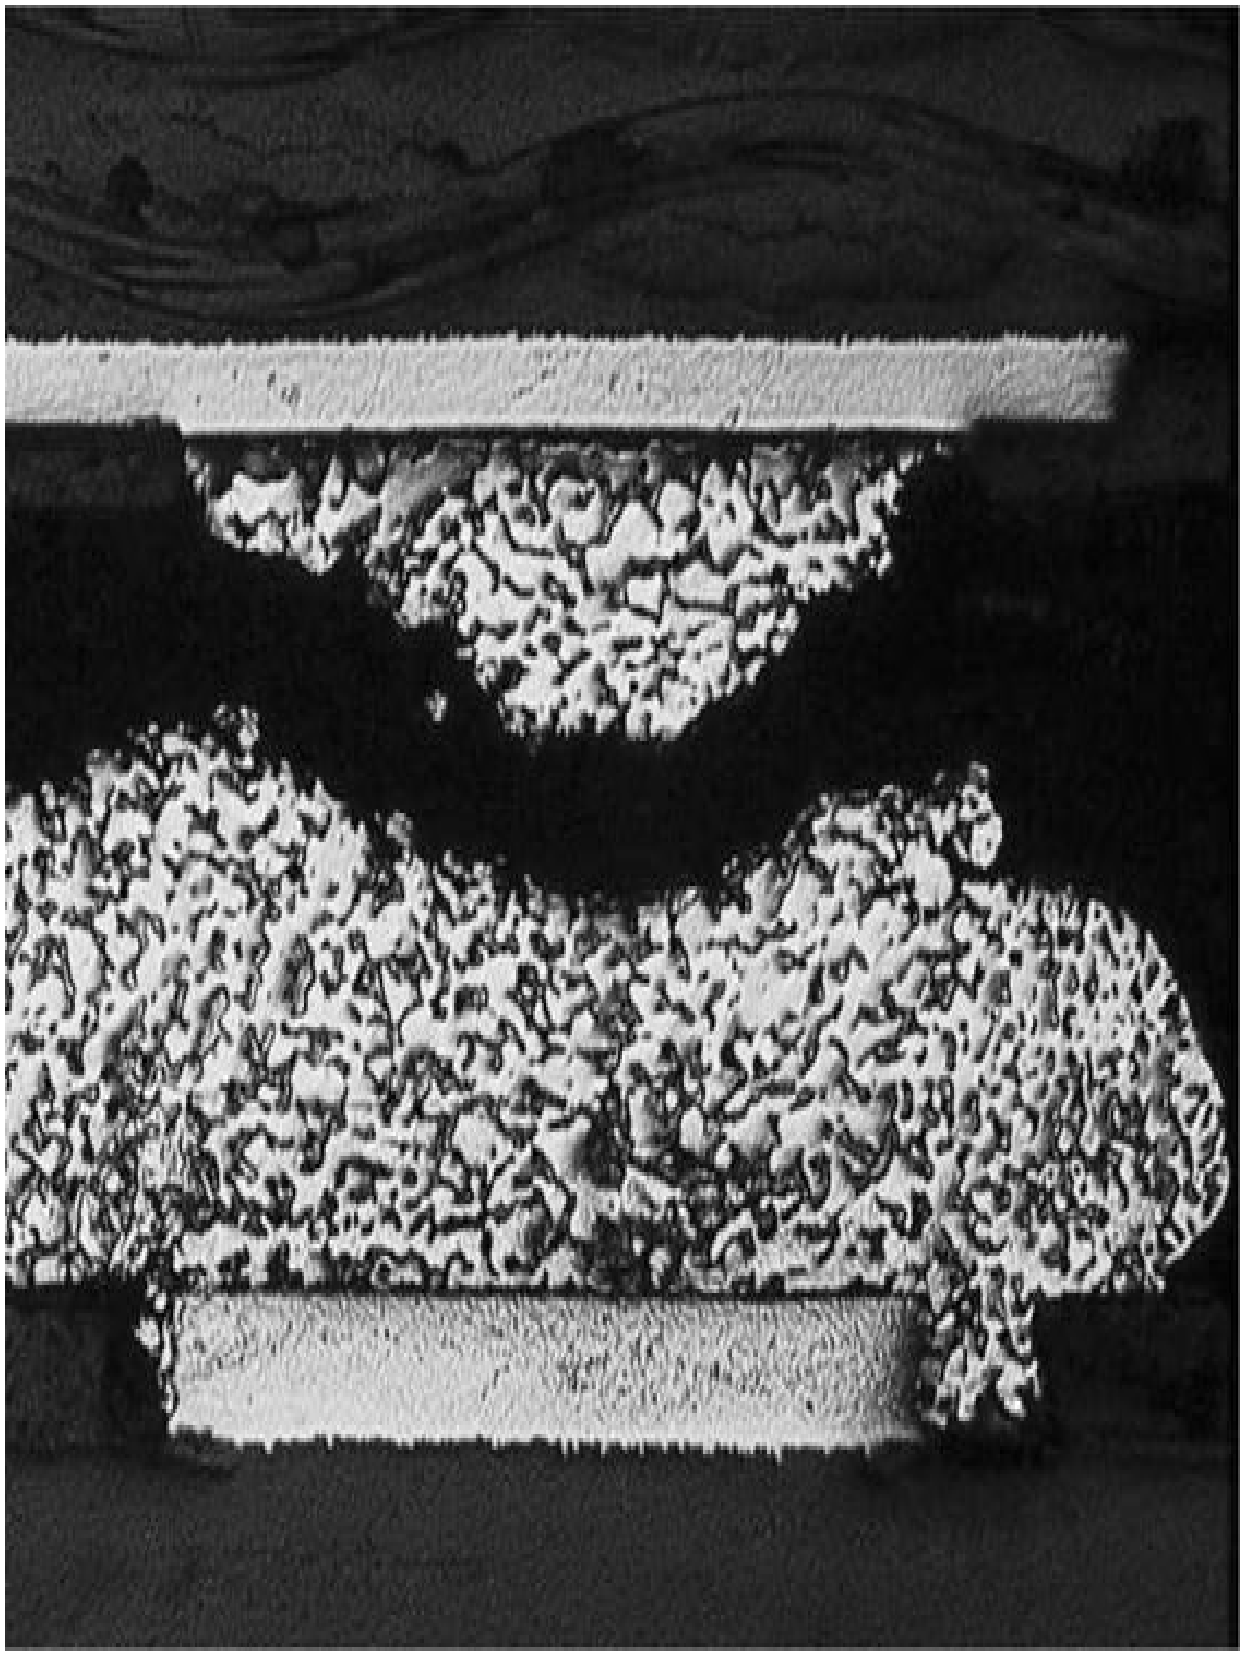

FIGURE 44.13 BGA ball cracked by high-modulus coating.

- *Glass transition temperature (T_g):* For assemblies that need to withstand cold environments, select a coating that either has a T_g below the coldest temperature required or a T_g of 25°C and above. Coatings that have a low T_g in the range of operation will suddenly get hard at cold temperatures and impose great stress on the surrounding components.
- *Elongation:* Materials with high elongation are resistant to cracking and abrasion.
- *Reworkability:* AR coatings are the easiest to rework, whereas XY and ER are the hardest.
- *Abrasion resistance:* This is ability of the coating to withstand damage from handling and later assembly operations, as well as in the field.
- *Flammability:* For assemblies that need to withstand prolonged exposure to sources of heat, select a coating that has the correct flammability standards that are published by Underwriters Laboratories may be a requirement. Coatings that do not have this certification, if used within this condition could fail and in danger the public.

44.7.3 Areas to Mask

During the design, the designer needs to consider all the areas and parts on the board that need to be uncoated and identify them on the assembly drawing, shop instructions, or other paperwork that the coating technician will use. Although it is obvious to the design engineer that an expensive infrared (IR) sensor element should not be coated, it may not be so obvious to the technician holding a drawing that says, “Coat entire board,” and nothing else. Being specific on the drawing clarifies what should be coated and how.

Consider the following areas:

- Coating on connector pins can cause open circuits, and may interfere with the full mating of the connector. It is necessary to mask the back of the open back connectors as well as the front, to keep the coating from flowing along the back of the pin into the active area. Also, pin alignment depends on a certain amount of looseness on the pins, and filling the connector shell with coating will defeat this feature.
- Coating should be kept from the edges of plug-in CCAs where the card guides travel. The coating will interfere with proper operation of the card guide and may prevent proper grounding of the card.
- Mounting holes for screws should be masked to keep the coating from filling or reducing the size of the hole and to ensure that the PWB is properly grounded.
- Test points should be masked so that they can be reliably accessed during testing.
- The adjustment screws of adjustable components. If the adjustable components have openings in them, the openings should be masked also.
- If the product contains sensors for air temperature, pressure, humidity, etc., the coating should not block the air from entering the sensor.
- Optical devices, light-emitting diodes (LEDs), infrared sensors, and light sensors may have their operation affected by the coating. This is especially true for UV and IR devices since the coating may be opaque to UV and IR wavelengths of light. The coating may also darken, cloud, or turn brown as it ages, eventually affecting the operation of the circuit. Connectors for fiber-optic cable should also remain clear of coating for the same reason.
- Components mounted in sockets should have the sockets masked and the components inserted after coating.

- Areas under BGA packages should not be underfilled with conformal coating but with an underfill adhesive particularly suited for that purpose. If no underfill is used, the edges of the BGA should be masked, or dammed with a permanent adhesive barrier to prevent the coating from entering under the BGA. Due to the shrinkage of conformal coating, during thermal cycling the balls will be crushed and the reliability of the BGA will be adversely affected.

CHAPTER 45
FLUXES AND CLEANING

Gregory C. Munie

IPC—Association Connecting Electronics Industries, Bannockburn, Illinois

Laura J. Turbini

International Reliability Consultant, Waltham, Massachusetts

45.1 INTRODUCTION

Cell-phones, iPods, digitial cameras, laptops and desktop computers, DVDs, and indeed all electronic equipment in our world have one thing in common: They each contain an electronic assembly composed of integrated circuits and discrete components soldered to a printed wiring board (PWB) to create an electrically functional circuit.

In years gone by, printed circuit assemblies were made exclusively with through-hole components. Today's assemblies contain components that are both through-hole and surface-mount, and some contain unpackaged integrated circuits (ICs) attached directly to the PWB. Except

in the case of direct chip attachment by wirebonding or conductive adhesive, the use of a soldering flux to ensure good joining is almost universally practiced. Thus, soldering flux choice has become an important consideration in the manufacturing of electronic assemblies. As electronic product designs have moved to more densely packed PWBs with fine lines and spacing, double-sided surface-mount technology, fine-pitch components, ball grid arrays (BGAs), chip-scale packages (CSPs), stacked packages, etc., the role of the soldering flux has become a critical link in the chain of events required for a successful manufacturing process.

In the past, the soldering process was usually followed by a cleaning step to remove flux residues and to ensure the reliability of the assembly. This practice was challenged in the early 1990s by the elimination of a major class of cleaning materials, which had been used for flux residue removal. The targeted cleaning agents include chlorofluorocarbons (CFCs) and methyl chloroform (1,1,1—trichloroethane) that have been shown to destroy stratospheric ozone.[1] These were replaced by aqueous detergent cleaners and saponifying agents, and in some cases cleaning was eliminated by the use of low solids or no-clean fluxes.

Up to the mid-1970s, the predominant flux chemistry was rosin-based. Today, although rosin fluxes are still in use, great advances have been made in flux chemistries and a large variety of formulations with very different chemistries are being used.

The implementation by the European Parliament of Directive 2002/95/EC on the restriction of the use of certain hazardous substances (Restriction of Hazardous Substances [RoHS]) in electrical and electronic equipment, including lead in solder, has had significant impact upon the manufacturing process. Traditional tin-lead solder melts at 183°C, whereas the most common lead-free alternatives have a much higher melting temperature, including tin-copper (227°C), tin-silver

(221°C), and tin-silver-copper (217°C). This affects the substrate materials, the flux formulations, the cleaning materials and processes, among other things.

This chapter will review the assembly, soldering, and cleaning processes, briefly touch on choice of surface finishes for both printed boards and components, discuss the soldering flux in terms of its role in soldering, review the variety of flux chemistries available along with their advantages and disadvantages, and comment on the challenges for flux formulation and cleaning due to lead-free soldering temperatures.

45.2 ASSEMBLY PROCESS

The basic elements of an electronic assembly are the PWB, the components and the interconnecting metallization. The majority of PWBs are made of epoxy-glass substrate with copper or solder-coated copper metallization. In many cases, a solder mask covers most of the circuit traces, leaving exposed only those patterns where soldering will occur during assembly. Boards designed for through-hole components usually contain copper-plated through holes that may be solder-coated; those designed for surface-mount components will have metallized pads for interconnecting the surface-mount parts to form the assembly.

45.2.1 Assembly Process Issues

The assembly process for electronics includes wave soldering, reflow soldering, and vapor phase soldering as well as selective soldering. Components range from through-hole and surface-mount—BGA, μ-BGA, CSP, and stacked packages—to chip-on-board (COB). The high density and reduced size of today's electronics has led to system-in-a-

package (SIP), where the integrated circuit (IC) package contains several active devices, and system-on-a-chip (SOC), where all the functions of an electronic system are integrated on a single chip. These package types increase the complexity of the electronic assembly process, requiring adhesive attachment for bottom-side discretes, underfill for CSP, wirebonding and encapsulation for COB, and solder paste, paste flux, and liquid flux for various applications.

When manufacturing complex printed wiring assemblies (PWAs), the thermal process chosen must take into account the thermal mass of the assembly, the component density, the solder flux and solder paste characteristics, and the maximum temperature limitation of the components. Most of the components assembled to the board in the soldering process have a maximum temperature of 240°C for traditional Sn/Pb soldering. Some electronic components, such as electrolytic capacitors and plastic-encapsulated components, are not rated to experience the high temperatures required to process with lead-free solders. The resulting heat-induced degradation can result in early field failures. Also, the higher temperatures required for lead-free solders are not compatible with many optoelectronic components. The increased heat can cause a variety of conditions with these components, among them electrical variances, changes in silver-epoxy die attach properties, delamination between plastic and lead-frame parts, deformation of plastic encapsulants and plastic lenses, damage to lens coatings, and changes in the light transmission properties.

45.2.2 Assembly Temperature Profiles

IPC/JEDEC[2] has developed a recommended reflow profile for nonhermetic packaged semiconductor components. These

recommendations are based on the temperature taken at the top side of the packaged device, and also based on package volume, excluding external leads, or solder balls in the case of BGAs, and nonintegrated heat sinks. Table 45.1 lists the recommended range for Sn/Pb and Pb-free assemblies.

TABLE 45.1 Reflow Profiles Recommended for Sn/Pb and Pb-free Assemblies Based on Temperatures Taken on the Package Body

Profile Feature	Sn/Pb Assemblies	Pb-Free Assemblies
Average ramp-up rate	3°C/sec. max.	3°C/sec. max.
Preheat		
Temperature min.	100°C	150°C
Temperature max.	150°C	200°C
Time	60–120 sec.	60–180 sec.
Time maintained above melting Temperature	60–150 sec.	60–150 sec.
Time within 5°C of peak temperature (T_p)	10–30 sec.	20–40 sec.
Ramp-down rate	6°C/sec. max.	6°C/sec. max.
Time 25°C to T_p	6 min. max.	8 min. max.

The maximum recommended temperature for the package depends on the package thickness and volume. Table 45.2 lists the recommended reflow temperatures for Sn/Pb processing, whereas Table 45.3 lists the recommendations for Pb-free processing.

TABLE 45.2 Recommended Maximum Package Reflow Temperatures for Sn/Pb Process

Package Thickness	Volume <350 mm^3	Volume ≥ 350 mm^3
<2.5 mm	240 +0/−5°C	225 +0/−5°C
≥2.5 mm	225 +0/−5°C	225 +0/−5°C

TABLE 45.3 Recommended Maximum Package Reflow Temperatures for Pb-Free Process

Package Thickness	Volume <350 mm^3	Volume 350–2,000 mm^3	Volume >2,000 mm^3
<1.6 mm	260 +0°C	260 +0°C	260 +0°C
1.6–2.5 mm	260 +0°C	250 +0°C	245 +0°C
≥2.5 mm	250 +0°C	245 +0°C	245 +0°C

45.3 SURFACE FINISHES

Surface finish is defined as the outerlayer metallization on a component or substrate being soldered. Both the type and quality of the surface finish have a major impact on surface solderability and on process soldering ability. Here, *solderability* is defined as the ability of the surface to be wetted by a solder, and the forming of an intermetallic layer between the solder and the base metal. *Soldering ability* is defined as control of the soldering process parameters, such as a heating profile that produces that wetting action. The preference is always to have a surface that exhibits good solderability—that is, ease of wetting and formation of high-quality solder interconnections—for all soldering processes and materials to which it might be exposed. Soldering ability is best described as the quality of a solder process such that

the operating window is wide, that is, the process is not overly sensitive to minor shifts in process parameters such as time and temperature. Thus a process with good soldering ability would be easy to control and would produce high-quality interconnections given that the incoming materials have good solderability.

45.3.1 Substrate Finishes

The substrate surfaces of choice are usually one of the following: electroless nickel/immersion gold (ENIG), immersion silver (ImAg), and organic solderability preservative (OSP). Two other finishes, hot air solder leveling (HASL) and immersion tin, are also in use, but HASL has declined in volume and immersion tin has not reached significant volumes due to concerns over reliability.

- *ENIG* This finish is widely used because it provides a very flat surface for surface-mount component placement. It has good solderability and a long storage life but is somewhat expensive compared to other finishes. Careful control of the gold plating process during board fabrication is required to prevent a defect known as black-pad. Black-pad is caused by galvanic corrosion of the nickel layer, creating corrosion products that affect the ability of the surface to be wet with solder. If severe enough, black-pad will impact reliability of the final solder joint.
- *ImAg* Immersion silver provides a flat surface with good solderability and storage life. It is also less expensive than ENIG. However, the ImAg finish is prone to tarnish under certain atmospheric conditions; in the presence of sulfur, it forms sulfides that darken the surface and reduce solderability.
- *OSP* Organic solder preservatives are inexpensive and also provide a flat surface for surface-mount technology

(SMT) placement. Storage life for OSP is less than for the metallized finishes, and multiple thermal cycles cause it to degrade.

- *HASL* One of the oldest surface finishes, HASL is based on exposing the PWB to molten solder and then removing excess solder using hot-air knives. In the lead-free world, the processing temperature is higher than for tin-lead. HASL is inexpensive, has good solderability if the solder is sufficiently thick, but has the disadvantage of not being a flat surface.
- *ImSn* This finish is similar to immersion silver in most characteristics. However, because tin tends to form metallic whiskers that can cause electrical shorts, it is not widely used.

45.3.2 Component Surface Finishes

Component surface finishes, like those of substrate finishes, are intended to provide good solderability. In the past, the majority of component leads had a tin-lead solder finish. This finish was either plated on the base metal of the component or was applied by dipping the leads in liquid metal. Given the push for lead-free assembly, most of these finishes containing lead are being replaced by alternatives. The main contenders in replacement of lead containing finishes are based on noble metals (e.g., palladium or gold) or some form of tin plating. Palladium finishes have been in use for many years and are a known commodity. However, as noted previously, the tendency of tin to form metallic whiskers as a result of stresses in the plated layer is a matter of serious concern for the electronics industry.

45.4 SOLDERING FLUX

Soldering[3] is defined as the process of joining metallic surfaces with solder without melting the basis metal. For this joining to take place, the metal surfaces must be clean of contamination and oxidation. This cleaning action is performed by the flux,[2] a chemically active compound that, when heated, removes minor surface oxidation, minimizes oxidation of the basis metal, and promotes the formation of an intermetallic layer between solder and basis metal. The soldering flux has several functions to perform. It must:

- React with or remove oxide and other contamination on the surface to be soldered
- Dissolve the metal salts formed during the reaction with the metal oxides
- Protect the surface from reoxidation before soldering occurs
- Provide a thermal blanket to spread the heat evenly during soldering
- Reduce the interfacial surface tension between the solder and the substrate in order to enhance wetting

To perform these functions, soldering flux formulations contain the following types of ingredients: vehicle, solvent, activators, and other additives.

45.4.1 Vehicle

The vehicle is a solid or nonvolatile liquid that coats the surface to be soldered, dissolves the metal salts formed in the reaction of the activators with the surface metal oxides, and, ideally, provides a heat transfer medium between the solder and the components or PWB substrate. Rosin, resins, glycols, polyglycols, polyglycol surfactants, polyethers, and glycerine are among the major chemicals used. Rosin or resins are selected when more benign chemicals are required

since their residues are less apt to cause reliability failures. Glycols, polyglycols, polyglycol surfactants, polyethers, and glycerine are used in water-soluble flux formulations because they provide excellent wetting of the board surface and dissolve the more active materials used in these formulation.

45.4.2 Solvent

The solvent serves to dissolve the vehicle, activators, and other additives. It evaporates during the preheat and soldering process. The solvent chosen depends upon its ability to dissolve the flux constituents for a given formulation. Alcohols, glycols, glycol esters, glycol ethers, and water are common solvents used.

45.4.3 Activators

Activators are present in the flux formulation to enhance the removal of metal oxide from the surfaces to be soldered. They may be reactive at room temperature, but their activity is enhanced as the temperature is raised during the preheat step of the soldering process. Among the common activators found in flux formulations for traditional soldering fluxes are amine hydrochlorides; dicarboxylic acids, such as adipic or succinic; and organic acids such as citric, malic, or abietic. Higher molecular weight activators are needed for lead-free soldering. Activators containing halide and amine give excellent soldering yields but may cause reliability problems if not properly removed in a well-controlled cleaning step. The halides may be present in either ionic or non-ionic form depending on the level of activation desired. Ionic activators provide, in general, a higher level of activation for a given halide content.

45.4.4 Other Additives

Soldering fluxes often contain small amounts of other ingredients that serve a specialized function. For example, a surfactant may be added to enhance the wetting properties. This constituent can also assist in the foaming characteristics required for foam flux application. Other additives may be included to lower the interfacial surface tension between the molten solder and the PWB as it exits the solder wave, decreasing the chance for solder bridges to form. Solder paste formulations require the presence of additives to provide good viscosity or flow characteristics, low slump during the preheat step, and good tack characteristics for holding the component in place until reflow occurs. Finally, cored-wire flux used for hand-soldering contains a plasticizer to harden the flux ingredients that are present in the core of the wire.

45.4.5 Flux and Temperature Issues

The flux becomes active as it is heated. In traditional flux chemistry for Sn/Pb solder, the assembly is preheated to around 100 to 125°C to remove the solvent and begin to activate the chemicals used to remove the metal oxide. After this plateau, the temperature is increased above the melting point of the solder (183°C) to 240°C for sufficient time to reflow the solder paste, and then the assembly is cooled, solidifying the solder and creating a metallurgical bond between the board metallization and the components. For lead-free soldering, the preheat plateau temperature is higher—150 to 200°C—and the peak temperature is 245 to 260°C. This requires solvents that evaporate at a higher temperature and activators that become chemically active at a higher temperature. In addition, new activators are needed to address the new metallurgy on board surfaces and new

lead-free solders containing Ag, Cu, and much higher levels of Sn. The decrease in pitch for area-array packages has resulted in a need for finer solder powders. This is driving a change in paste flux chemistry since the higher surface area of these fine powders results in increased oxide formation and decreased paste stability.

45.5 FLUX FORM VERSUS SOLDERING PROCESS

Although one usually thinks of soldering flux as a liquid, in fact the soldering flux can exist in several different forms. *Liquid flux* is commonly used for wave-soldering or hand-soldering applications. *Paste flux*, a thick, viscous flux, is used to hold components to the board prior to reflow of the already present solder. Direct attachment of a solder-bumped chip or BGA packages to solder pads on a PWB is an example of paste flux's usefulness. Also known as *tacky soldering fluxes*, these materials are useful in repair of area-array devices. Solder paste contains *solder paste flux*, which is the solder paste without the solder particles. Solder paste is used in surface-mount attachment of components such as chip carriers, quad flat packs (QFPs), BGAs, μ-BGAs, CSPs, leaded packages, and discrete resistors and capacitors. *Flux-cored solder wire* is used for hand-soldering, and *flux-coated or flux-cored solder preforms* are used as the solder/flux source in some applications such as backplane connector pin reflow soldering.

Fluxing underfills can also be considered as a new type of flux material. Many fine-pitch, low-profile array packages suffer from poor reliability due to their low standoff from the substrate, small area of solder interconnection and CTE mismatch with the substrate. Often, a reinforcing material is dispensed around the solder joints after assembly to improve

attachment reliability. Fluxing underfills provide fluxing action for the solder process and cure into a hard supporting material during the soldering process, eliminating the need for a post-solder dispensing step.

45.6 ROSIN FLUX

Early flux formulations for electronics used rosin, which is a naturally occurring resin, obtained from the sap of a pine tree. Its exact composition varies depending on the part of the world from it originates as well as the time of the year. Rosin contains a mixture of resin acids, the two most common ones being abietic acid and pimeric acid (see Fig. 45.1). Rosin has been a favorite material for soldering because it liquefies during the soldering process, dissolves the metal salts, and then solidifies when cooled, entrapping and for the most part immobilizing the contaminants. In addition, rosin has some innate fluxing activity since its molecular structure contains a weak organic acid. Finally, rosin-based fluxes work well in hand-soldering and repair operations because rosin provides good heat transfer characteristics.

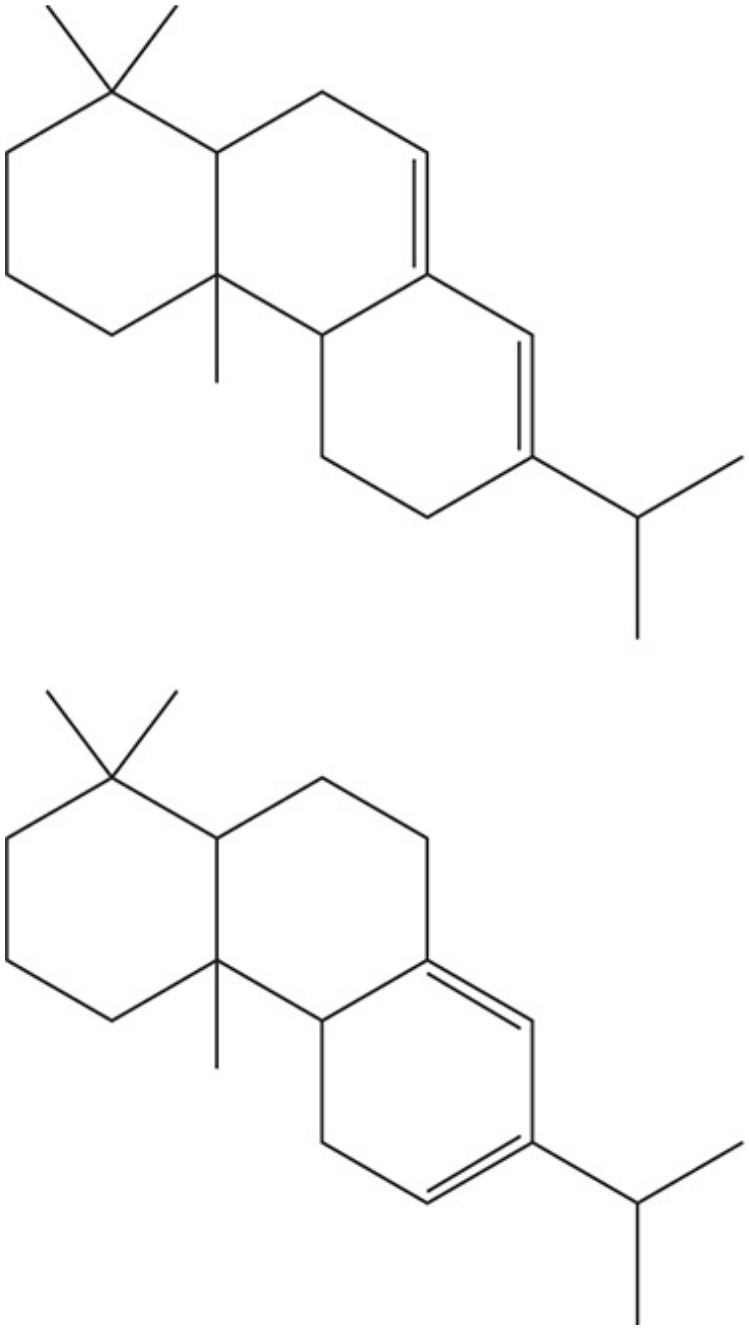

FIGURE 45.1 The two most common rosin isomers are abietic acid and pimaric acid.

The activity of a rosin-based flux will be determined by the activators and surfactants, which are part of the formulation. Some activators help to remove metal oxide but also leave residues that are essentially noncorrosive. Halide-containing

activators leave residues that could be corrosive if too much is left on the board.

Military specifications[4] in the past have required the use of rosin-based fluxes. These were defined as pure rosin (R), rosin mildly activated (RMA), rosin activated (RA), and rosin super-activated (RSA), based upon the level of halide activators they contained. Typically only R or RMA fluxes were approved for high-reliability military applications.

In the 1970s, telecommunication companies in the United States and Europe predominantly used rosin fluxes for their wave-soldering requirements. These companies had their own internal set of test methods for selecting noncorrosive rosin flux formulations. Using their selection criteria, they believed the fluxes to be sufficiently safe. For their applications, they cleaned only the bottom side of the assembly, where rosin residues needed to be removed to ensure good electrical contact during bed-of-nails testing.

In the early 1980s, the IPC developed a flux characterization criteria based on the flux and flux residue activity. Thus, fluxes were classified as:

L = low or no flux/flux residue activity
M = moderate flux/flux residue activity
H = high flux/flux residue activity

These designators were determined by a series of tests, including the copper mirror test, a qualitative silver chromate paper test for chlorides and bromides, a qualitative spot test for fluorides, a quantitative test for halides (chloride, bromide, and fluoride), a corrosion test for flux residue activity, and a surface insulation resistance test at accelerated temperature and humidity conditions.

The industry standard “Requirements for Soldering Fluxes” (J-STD-004A) includes a test for electrochemical migration and updates the earlier IPC-SF-818 solder flux specification to include some international elements from the

International Standards Organization (ISO-9454). In addition to defining the flux categories L, M, and H, it notes the absence or presence of halides by a 0 or 1 that is added to the descriptor. In parallel the international standards, industry standards list the basic chemical constituents as RO (rosin), RE (resin), OR (organic), or IN (inorganic) (see Table 45.4).[5] The test methods for this specification are contained in the Test Methods Document (IPC-TM-650).[6]

TABLE 45.4 Flux Constituents and Activity Levels

Flux Materials of Composition	Symbol	Flux Activity Level (% Halide)	Flux Type
Rosin	RO	Low (0%)	L0
		Low (<0.5%)	L1
		Moderate (0%)	M0
		Moderate (0.5–2.0%)	M1
		High (0%)	H0
		High (>2.0%)	H1
Resin	RE	Low (0%)	L0
		Low (<0.5%)	L1
		Moderate (0%)	M0
		Moderate (0.5–2.0%)	M1
		High (0%)	H0
		High (>2.0%)	H1
Organic	OR	Low (0%)	L0
		Low (<0.5%)	L1
		Moderate (0%)	M0
		Moderate (0.5–2.0%)	M1
		High (0%)	H0
		High (>2.0%)	H1
Inorganic	IN	Low (0%)	L0
		Low (<0.5%)	L1
		Moderate (0%)	M0
		Moderate (0.5–2.0%)	M1
		High (0%)	H0
		High (>2.0%)	H1

45.7 WATER-SOLUBLE FLUX

Water-soluble fluxes have also been called “organic acid fluxes.” This name is misleading since all fluxes used for electronic soldering contain organic ingredients and many contain organic acid activators. The term “organic acid flux” probably originated from the designation of water-soluble fluxes as “organic” and those activated with organic acid activators as “organic acid.” Other activators for these fluxes include halide-containing salts and amines. Although the correct name for this category of fluxes is *water-soluble*, it should also be noted that the flux solvent is normally not water, but alcohols or glycols.

As the name implies, water-soluble fluxes are soluble in water and their soldering residues are also expected to be water-soluble. These fluxes are much more active than rosin fluxes, have a wider process window, and give a higher soldering yield with reduced defects. This means that the final assembly will require less touchup or repair. On the down side, water-soluble fluxes contain corrosive residues that, if not properly removed, will cause corrosion in the field and long-term reliability problems.

As indicated earlier, water-soluble fluxes usually contain glycols, polyglycols, polyglycol surfactants, polyethylene oxide, glycerine, or other water-soluble organic compounds as the primary vehicle. These provide good solubility for the activators, which are usually the more corrosive amines and halide activators. With the onset of highly efficient cleaning equipment, this type of flux became popular for computer and telecommunication applications.

F. M. Zado[7] raised concern in the late 1970s that water-soluble fluxes affect the electrical characteristics of the epoxy-glass laminate by reducing the insulation resistance. This reduction was due to the dissolution of the polyglycols of the flux formulation into the epoxy substrate during the

soldering process. Later work by J. Brous[8] indicated that some polyglycols were much more deleterious than others. In general, polyglycol containing fluxes (and fusing fluids used by board manufacturers to fuse tin-lead plating) can cause an increase in moisture absorbance of the epoxy-glass substrate.

The user must consider several factors when determining whether to use water-soluble fluxes in a given application. One important factor is the operating environment. If the assembly will experience extremes of temperature while under power, it is possible that localized condensation will occur and dendrites will form, shorting out some of the circuit elements. Assemblies of this nature should be conformally coated. A second critical factor is the use of a board design and cleaning process, which ensures that corrosive residues are removed. A third consideration is the voltage gradient in the electrical design of the circuit. Within reduced lines and spacings, a failure mechanism called conductive anodic filament (CAF)[9] formation has been associated with high humidity and high voltage gradients. This will be described in detail in a later chapter.

45.8 LOW SOLIDS FLUX

Until the mid-1980s, liquid soldering fluxes were formulated in 25 to 35 percent (weight percent) solids or nonvolatile liquid. Then flux chemistries changed and new formulations that were lower in total solids content came on the scene. These fluxes are composed principally of weak organic acids, often with a small amount of resin or rosin. Early formulations had 5 to 8 percent solids, but today’s low solids fluxes are 1 to 2 percent solids composition. For lead-free soldering, weak organic acids with higher molecular weight are being used.

Nomenclature of these fluxes moved from “low solids flux” to “low residue flux” to “no-clean flux.” The thinking was that the amount of residue left by these fluxes after soldering was so minimal that it did not need to be removed. This is only true if the residues are noncorrosive.

One challenge of low solids fluxes is the processing window. Unlike water-soluble fluxes that give very low defect levels and have a wide processing window, the soldering process for low solids fluxes must be carefully designed. To begin with, the recommended preheat temperatures are different from those for rosin flux and the preferred solder wave temperature is lower than that for rosin. Additionally, the solderability of incoming boards and components must be ensured. Although water-soluble flux can cut through heavy metal oxide layers, the amount of fluxing ingredients in low solids fluxes is not sufficient to accomplish the task.

Lower cost manufacturing can be achieved with low residue fluxes if the cleaning step can be eliminated. This assumes that the incoming components and boards are clean, and that operators handling the boards are careful not to introduce contamination. This requires a flux with noncorrosive residues that will not impede or contaminate the electrical bed-of-nails test probes.

A new category of low solids fluxes was introduced in the early 1990s to meet the needs of localities where volatile organic compounds (VOCs) are regulated. These fluxes are marketed as VOC-free or low-VOC fluxes. The solvent in this case is 100 percent water or at least greater than 50 percent water. Use of these fluxes requires special care in the preheat step where the water (solvent) must evaporate before the assembly reaches the solder wave. Failure to do this will result in excessive solder ball formation.

Solder fluxes and pastes have gone through significant evolution since the early 1980s. As of 2006, in North America about 70 percent of the fluxes were not cleaned, 25 percent were water-soluble, and 5 percent were rosin-based for

military applications.[10] However, in the lead-free soldering world, more cleaning is required.

45.9 CLEANING ISSUES

Flux removal is motivated by several factors, and the importance of these factors varies with the end use of the product. In general, the purpose of cleaning is (1) to remove corrosive residues from the soldering process or handling operations (some fluxes have high levels of halide activators that would cause corrosion were they not removed); (2) to remove rosin, resin, or other insulating residues that would interfere with bed-of-nails electrical testing; (3) to remove rosin, resin, or other residues that attract dust, dirt, and other airborne contaminants; (4) to ensure that the board is free of residues and contamination prior to conformal coating.

In the early days of soldering, cleaning was either not done, because the flux was mostly rosin and noncorrosive (e.g., the telecom fluxes), or cleaning of rosin flux residue was done with solvents. Typically the solvent was a halogenated material, as such solvents were considered relatively nontoxic and were nonflammable. However, in the late 1970s, the Environment Protection Agency (EPA) listed some of these solvents, such as perchloroethylene and trichloroethylene, as suspected carcinogens and lowered the allowed level of these in the operator-breathing zone. This led to the application of CFC azeotropes with methyl alcohol, ethyl alcohol, and methylene chloride as replacements.

However, the CFCs were not without their own environmental problems. In September 1987 at the United Nations Environment Program Conference in Montreal, 24 countries signed the Montreal Protocol on Substances that Deplete the Ozone Layer. The protocol was the beginning of

an international agreement on the reduction of CFCs that were shown to have a deleterious effect on the stratospheric ozone layer that protects us from harmful ultraviolet radiation. The initial protocol targeted CFCs and halons (bromine-containing CFCs) and proposed a 50 percent reduction in production by 1998 based on 1986 levels. Revisions to the protocol led to a ban on the manufacture of CFCs and other ozone-depleting chemicals effective by the end of 1995.

45.9.1 Solvent Cleaning

With the general elimination of the halogenated solvents, manufacturers have changed their flux and cleaning choices. The new cleaning materials must be capable of dissolving the particular chemical residues from a given flux formulation. Several detailed cleaning references are available.[11,12,13,14,15,16]

Solvent cleaning options[17] have focused on semiaqueous cleaning, solvent defluxing using a blend of solvents, and vapor degreasing using a single or co-solvent mix. Semiaqueous cleaning usually involves a two-step process where the assembly is first cleaned in the organic solvent, then rinsed in a separate step. Terpenes have been widely used as the solvent with dibasic esters and non-ionic surfactants added to improve cleaning and rinsing. An alternative semiaqueous cleaning solvent is composed of high molecular alcohols. The solvent is usually sprayed under immersion onto the assemblies in its pure form. This step is followed by a rinse step that emulsifies the semiaqueous solvent and dissolves the ionic residues. Innovations[18] have shown that an aqueous emulsified solution of the solvent can also provide good cleaning.

Solvent cleaners may be inline or batch. Inline cleaning usually involves spray under immersion. The temperature of

the solvent wash tank is set below its flash point, and several rinse tanks follow the wash tank to ensure good cleaning before the final drying step. Solvents such as glycol-ether blends are used for this process. Batch degreasers may use n-propyl bromide in specialized applications.

Traditional batch cleaning was performed in a vapor degreaser that has a wash sump of boiling nonflammable azeotropic solvent and a rinse sump. A vapor blanket forms above the sump and is contained using cooling coils at the mouth of the machine. The assembly is first placed into the wash sump, and then is transferred to a rinse sump that contains clean solvent from the condensation at the cooling coils. As the assembly is removed, it is held for a period in the vapor blanket for a final rinse and drying of the remaining solvent.

Co-solvent cleaning involves the use of a rinsing agent that is volatile and a solvating agent that is not volatile. The assembly is placed into the wash tank of boiling solvent where the solvating agent enhances the cleaning process. The vapor blanket above the wash sump contains only the rinsing agent. The assembly is moved from the wash sump into the rinse sump, which contains only the condensed rinsing agent. Finally, the assembly is removed from the rinse sump and held in the vapor blanket for a final rinse and drying step.

45.9.2 Aqueous Cleaning

Aqueous defluxing is performed using a high pH saponifying solution that is diluted to a 10 to 25 percent aqueous solution. The saponifier may be organic or inorganic, with additives such as solvents and surfactants to improve wetting and cleaning. The organic cleaning agent usually contains an amine, such as monoethanol amine, whereas the inorganic cleaners use buffered metal salts such as

NaOH/sodium carbonate/sodium bicarbonate. The wash step is usually done in an inline spray machine, followed by a de-ionized (DI) water rinse with several spray sections to remove the more contaminated material, then by a final rinse and a final blow-dry step. The cleaning agents in the saponifier react with the rosin or resin from the flux to form a "soap" in the same manner that the detergent used to wash greasy dishes reacts with the grease and helps it dissolve, or at least be emulsified and removed in the rinse water. Once the rosin or resin is removed, the rinse water solubilizes the ionic residues that were on the surface of the board as well as those trapped within the solid rosin matrix.

Table 45.5 summarizes the possible cleaning agents for the various flux types.

TABLE 45.5 Soldering Flux/Paste Cleaning Options

Flux/Paste Type	Possible Cleaning Agents	Comments
1. Rosin/resin	a. Detergent cleaning	
	b. Semiaqueous cleaning	
	c. Solvent cleaning	
2. Low-residue flux	a. No-cleaning step	If flux is rated L0 or L1 in ANSI-J-Std-004
	b. Aqueous cleaning	If flux does not contain rosin or resin
	c. Detergent	If flux contains rosin or resin
	d. Solvent	
3. Water-soluble	a. Water	
	b. Detergent cleaning	

45.9.3 Flux and Cleaning Issues Related to Lead-Free Soldering

Solder flux residues are much more difficult to clean after lead-free soldering.[19,20,21] Fluxes formulated to remove oxidized metals (SnPb, Cu) for traditional tin-lead soldering must be modified to address the needs of different metallization for the solder, the board finish, and component terminations. Soldering flux formulations for lead-free soldering use higher molecular weight resins and activators for the more aggressive flux chemistry needed to achieve wetting. Also, the higher tin content of the alternative solders (SnAgCu, SnCu) requires more aggressive flux chemistries for good wetting.

The process window for lead-free soldering requires higher peak reflow temperatures and longer times above liquidus. Soldering in a nitrogen environment improves wetting and reduces oxidation of the flux residues and the solder. Due to the higher reflow temperature, greater polymerization of the flux constituents can occur—producing residues that are more difficult to remove.

The cleaning challenge represented by lead-free soldering must be addressed by modifying the cleaning process to increase the wash time, wash concentration, and wash temperature.

Cleaning for fine-pitch components soldered under lead-free conditions requires an increase in cleaning time, the use of increased solution agitation (e.g., ultrasonic), and the modification of spray nozzles and impingement angle. Flux residues are more difficult to remove when they set. Thus, it is important to minimize the time between reflow and cleaning. Aqueous cleaning chemistries should include wetting agents, solvating agents, and reactive agents. Water-soluble fluxes that can be cleaned with water after lead-based soldering conditions may require the addition of

some cleaning agent to remove the higher molecular weight organic acids and the tin salts created when the flux decomposes during lead-free reflow.

45.10 SUMMARY

This chapter has reviewed the processing issues and materials used for the soldering and cleaning processes. In the lead-free era, thermal profiles and component maximum temperatures require different reflow profiles. The various types of soldering fluxes, their constituents, and their role in the soldering process have been discussed and the formulation changes required for the higher temperature soldering examined. Cleaning materials and processes have been identified and the challenges with higher temperature soldering discussed.

CHAPTER 46
SOLDERING FUNDAMENTALS

Gary M. Freedman
Colab Engineering LLC, Stow, Massachusetts

46.1 INTRODUCTION

The complexity of printed circuit assemblies continues to increase in every sector of the electronics industry. The number of solderable contacts of IC components is on the rise. In the portable electronics segment, smartphones dominate the consumer market. They have ever-increasing computer functionality with integrated optics for video and still photography, accelerometers for phone position sensing, audio systems including miniature speakers, GPS, storage for addresses, calendars, music and video players, Wi-Fi, Bluetooth, and more. They are rugged, shock-resistant and some are even waterproof, all packaged in a form that fits in the pocket.

Smartphones, smart TVs, gaming appliances, cloud storage and other smart devices, online banking, buying, stock transactions and myriad of other applications has spurred a new Internet boom. This has driven increased

reliance on and need for more powerful computer servers, routers and storage, which in turn has driven the need for more complex computer room equipment and a miniaturization of sorts as more computational power needs to fit into the same space for economic reasons. Today, blade servers are quite common and these powerful, modular, swappable units are small, energy efficient and run cooler all adding to the value proposition for computational service and cloud storage providers. The form factor for a blade is described as “1U,” meaning 1 unit that can fit into a 19-in rack, where 1U is 480 mm (19 in) wide and 44 mm (1.75 in) tall. Each blade may be composed of one to over hundred servers. In order to achieve this compactness, device input/output (I/O) has had to increase, electronic device package size has had to decrease and printed circuit board (PCB) layer-count has increased to aid in routing traces in the confines of the 1U form-factor.

Higher density boards and higher layer counts result in more thermally massive assemblies, which are difficult to solder during surface-mounting and doubly difficult to assemble by the wave solder process. Through-hole technology, although on the wane, is still prevalent. When both surface-mounting and wave soldering are used on the same assembly, it is referred to as mixed-mount technology. The proliferation of press-fit connections [force fitting compliant electrical contacts into a circuit board’s plated through-holes (PTH)] has alleviated some of the problems of mixed-mount assembly driven largely by the difficulties faced in wave soldering large and thick circuit boards. See Chap. 51 for an introduction to press-fit technology. Land grid arrays (LGAs) with separable pressure interconnect have become more prevalent especially for high-end motherboards for computing and telecommunications. LGA incorporation on a board has influence on layout and implications for soldering. This will be discussed in Chap. 52.

Soldering is a technology that has been used extensively for utilitarian and decorative purposes for thousands of years. The Romans and especially the Celts were masters of this art. In the last 100 years or so, soldering has been raised from art to science mainly driven by the need for joining electrical assemblies. By the late twentieth century, the tin-lead solder joint and properties of its constituent materials had been studied well enough that it could be modeled for purposes of predicting wetting, solder shape and reliability.

Circuit board soldering has traditionally been accomplished with eutectic or near eutectic tin-lead (Sn-Pb) alloy. The eutectic alloy is approximately 63 percent Sn and 37 percent Pb by weight (alloy Sn63) and was the mainstay of printed circuit board assembly until recently. A binary alloy (composed of two constituent metals), its melting, wetting, solidification and reliability are well understood and predictable. Being a eutectic alloy, it has a distinct melting point and for eutectic Sn-Pb that point is 183°C. This temperature is low enough that it is compatible with a significant set of materials such as circuit board laminates, integrated circuit (IC) package molding compounds and encapsulants, ceramics used for packaging, silicon IC devices, molded connector bodies, etc. Materials for these components were in part codeveloped to be compatible with Sn-Pb soldering processes. Now the electronics industry has made the move largely to lead-free (Pb-free) solders. This massive industry change was driven by the European Union's (EU's) environmental initiatives to limit electronics waste and restrict toxic materials used in electronics manufacturing.[1,2]

The main thrust of the EU directives was to limit or ban a short list of materials that the EU deemed harmful to the environment. Lead (Pb) is most prominent on the list of restricted materials, and limitations on its use have had the most dramatic impact on electronics manufacturing, since Sn-Pb solder was the preferred alloy for electronics assembly

worldwide. Now the industry has largely transitioned to Pb-free solder alloys. Most viable Pb-free alloys have a higher melting temperature than Sn-Pb and most Pb-free alloys are composed of three or more metals.

46.2 ELEMENTS OF A SOLDER JOINT

There are four important constituents of a solder joint: the two materials or surfaces to be joined, the solder itself and the process by which the materials are joined. Each has its own set of attributes and variables that contribute to the ease and quality of soldering. A delicate balance of material conditions and process parameters determine the solder joint appearance, resultant strength, and reliability of the finished assembly. The composition of the solder, the surface finish on lead, pad or PTH, environmental factors, chemical implications, and thermal conditions all impact the soldering process. Each will be discussed.

46.2.1 Common Metal-Joining Methods

Welding, brazing, and soldering are the three most widely used metal-joining techniques. Although this section does not provide a rigorous review of welding and brazing, a cursory comparison of these metal-joining processes is useful in setting the stage for a discussion of circuit board soldering. All three depend on metallurgical alloying; mixing and wetting of two or more molten metals.

Welding involves heating of two similar or dissimilar abutting metals to the point that they fuse into one another. Unlike brazing and soldering, there is considerable depth to the metallurgical changes in welding. Sometimes another

metal or filler metal is applied to lower the melting temperature of the weldment metals, to promote wetting or for desired mechanical properties of the finished bond. As in brazing and soldering, sometimes chemical treatment is required to help dissolve surface oxides and also a cover gas may be applied to retard oxidation during the high temperatures of the welding process. Typically welding is a very high temperature process; hot enough to melt the surfaces of the metals to be joined.

Brazing and soldering always involve the use of a filler metal (brazing compound or solder), which has a significantly lower melting point than the basis metals associated with the two bonding surfaces. The filler material must be able to alloy with the surfaces to be joined. As the filler is heated to liquidus, there is near-surface metallurgical dissolution and mixing (alloy formation) with the contacted bonding surfaces. Continued heating above the liquidus temperature of the filler metal results in its further spreading and alloying via molten metal surface tension effects. As the bonding surfaces are cooled, the filler metal returns to solidus and a bonded assembly results.

There are only subtle differences between soldering and brazing, the primary distinction being the temperature required for joint formation. Brazing is generally accomplished at a relatively high temperature (>450°C) as compared to soldering. (There is no consensus in the literature, but values between 400 and 500°C are commonly cited.) Brazing temperatures would be detrimental to most electronic components and PCBs. Since circuit board assembly is done almost exclusively by means of soldering at temperatures generally below 270°C, this chapter is devoted to that traditional joining method.

46.3 SOLDER OVERVIEW

Solder is the cement that joins lead to pad, imparts the mechanical robustness required for a reliable assembly, and also possesses the electrical conduction needed for circuitry. The metallic alloy choice, the solder, is chosen for a melting temperature compatible with other materials associated with the soldered assembly. It must be metallurgically compatible with the metals to be joined. Once molten, the solder must wet to the component lead and circuit board bond pad. Upon solidification, the resultant solder joint must provide sufficient electrical conductivity, bond strength and reliability for the intended application. It must resist corrosion, vibration, shock, thermal expansion and contraction cycles over a range of temperatures and environments commensurate with the assemblies use. All the factor are dependent on the materials used in and associated with the soldering process including the solder itself.

With the onset of RoHS and the wide adoption of Pb-free solders, tin (Sn)-silver (Ag)-copper (Cu) solder alloys, called “SAC,” have become the most prevalent alloy family. There is no clear consensus on which solder alloy is the best, but SAC305 is widely used. The “305” designation indicates that the composition is 3 percent Ag by weight, 0.5 percent Cu and the balance Sn. Although the industry has moved to Pb-free, a quick overview of the Sn-Pb system is provided for grounding in solder technology. It is a simple binary system (two-metal alloy) and much easier to understand and demonstrate than SAC solders (ternary systems … composed of a three-metal alloy). It is the best understood metallurgical system in terms of soldering, with very predictable bonding attributes.

Since the start of electronics, Sn-Pb eutectic alloy has been the dominant solder alloy choice. A eutectic alloy goes molten at one distinct melting point as opposed to a noneutectic alloy, such as SAC, which has a melting range but not a distinct melting point. Sn-Pb eutectic alloy possesses a relatively modest liquidus temperature (183°C)

and a molten working range typically about 205 to 230°C. This overage in temperature by about 20 to 50°C is the temperature range applied during the soldering process to ensure that all parts have achieved a temperature commensurate with good soldering and all solder joints are wetted sufficiently. It also may be necessary to reach such temperatures on thermally massive boards where the lightest parts may heat quickly while the most thermally massive parts may just barely achieve a temperature adequate for soldering. Everything in the electronics industry was tailored to working in that temperature regime. ICs and passive components, laminates, and process equipment associated with soldering have been qualified for use at those temperatures. Over the last several years, the electronics manufacturing industry has been adjusting materials and strategies to accommodate Pb-free soldering, since Pb-free alloys typically have liquidus onset of approximately 215 to 227°C depending on alloy choice. Adding a thermal overage as described for Sn63, then solder process temperatures for Pb-free alloys may be in the range of 260°C; a challenge to many of the conventional materials used in circuit board assembly.

46.4 SOLDERING BASICS

The case presented below is based upon eutectic Sn-Pb solder (Sn63) in contact with solderable and nonsolderable coatings on a basis metal.

Primary soldering steps include

- Intimate contact of the solder to materials being joined
- Slow application of heat to warm the parts to be soldered
- Oxide removal from the surfaces to be joined and from the solder itself

- Application of heat sufficient to melt the solder
- Solder wetting to joining surfaces and intermetallic formation
- Quenching of the solder liquidus

There are a few other materials that need to be covered for this discussion. The first is solder paste. This is a mixture of minute solder beads, flux, and other materials to give the paste specific rheological properties for dispensing, most notably stencil printing, and chemical agents for metal surface preparation. For surface-mount applications, it is typically stenciled onto PCB bonding pads. The paste is also formulated to hold its printed shape, even at elevated temperatures, otherwise, it would slump and cause solder bridging from bond pad to bond pad. Once printed, the electronic component is placed upon the solder paste deposit. The paste holds the component in place during the reflow process prior to the onset of solder liquidus. The second term is flux, which, as mentioned previously, is a key component of solder paste. Oxides, tarnishes and other contaminants inhibit soldering. Flux is a heat-activated chemical agent used to clean and strip oxides and tarnishes from otherwise solderable metal surfaces. Flux will be covered in subsequent sections of this chapter.

46.4.1 Intimate Contact of Solder to Surfaces to Be Joined

The most basic requirement is for the solder to contact the materials to be joined. The contact area of the solder is not wholly important as long as the solder is in point contact with the surface to be soldered when it reaches liquidus. Surface tension effects and metallurgical wetting will complete the spreading of solder between component lead and PCB pad.

46.4.2 Slow Heating of Boards and Parts to Be Soldered

This is important for three reasons: (1) Overly rapid heating can cause certain electronic devices to experience thermal shock and subsequent failure as in cracking or may cause degradation of device electrical characteristics. (2) Solder paste may spatter if heated too rapidly. (3) appropriate heating rate is crucial to good surface preparation through fluxing. A balance between time and temperature has to be determined so that the flux has enough time to accomplish its cleaning step and does not dry out prematurely or spatter. Conversely, an inappropriately long heating cycle may cause re-oxidation of flux-cleaned parts. If the process temperature is too high, the flux can denature and bake onto otherwise solderable surfaces and inhibit soldering.

46.4.3 Oxide Removal from Bonding Surfaces and from Solder

Most materials, when in equilibrium with Earth’s oxygen-rich environment, develop an oxide coating. Upon heating, solder surfaces as well as the bonding surfaces will more thoroughly oxidize in a normal air environment. If a silver-bearing surface is exposed to a sulfur-containing ambient (sulfur-tainted air, pollution), sulfidation occurs and that tarnish also inhibits soldering. Generally, the higher the storage temperature, the more oxidation is present unless oxide growth is self-limiting, as it is in some materials. The same holds true for soldering process temperature or process time. Higher temperature and/or the longer process time, results in thicker oxidation or tarnish on most metal surfaces and also may render the flux ineffective also.

An oxide or tarnish coating acts as a physical barrier preventing the molten solder from contacting metals to be joined. In the case of gold (Au), known to remain largely oxide-free, there is insufficient oxidation to degrade soldering. But unless oxidation is removed from the solder itself, soldering Au may not be possible or will be incomplete. Note that in most soldering processes, the ambient can be altered to mitigate the detrimental effects of oxygen or other airborne contaminants. This will be discussed later.

The most generally applied remedy for the effects of oxidation and tarnish as relates to the soldering process is the application of a chemical agent, flux. It is formulated to react with specific metallurgies for removal of tarnish and oxidation. It also acts as a barrier preventing fluxed metal surfaces from reoxidizing prior to and during the joining process. The word *flux* comes from the Latin *fluxus*, which means flow or flowing. Flux ensures that the solder, once molten, will flow over the surfaces to be bonded, unconstrained by oxide skins on the solder or the metals to be joined. Certain materials form oxides very rapidly, and some oxides are rather chemical-resistant. Nickel is one such element. Copper, like nickel, can also form resistant oxides and may necessitate the use of strong fluxing agents to achieve a bondable surface. Tin and silver oxides are easily attacked by even weak organic acids. Gold, which is known to remain oxide-free, can be applied as a thin, nonporous barrier over less noble, oxide-stripped metals such as nickel. During reflow, the gold dissolves quickly into the solder and the solder bonds to the underlying oxide-free nickel. Figure 46.1 shows the difference between a solder wettable surface and a flux-resistant oxide-coated surface.

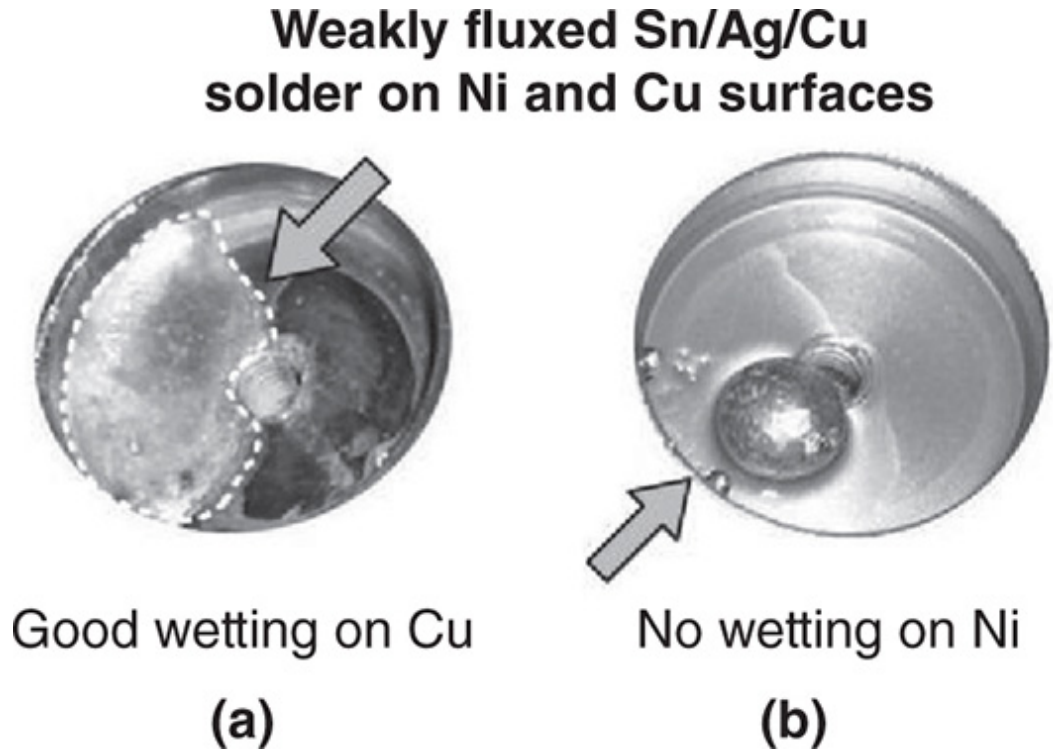

FIGURE 46.1 Comparison of soldering to copper (*a*) and nickel (*b*). In both cases, surfaces were treated with a weak organic solder flux and equal amounts of Sn-Ag-Cu solder were added prior to heating. Both were heated simultaneously to 235°C for 2 min. Note that in the case of the copper surface (*a*), the solder has wet and spread, characterized by a low wetting angle (the extent of wetting is indicated by the dashed outline). In the case of the nickel surface (*b*), the flux was ineffective in penetrating the surface oxide and the solder beaded up on the surface of the nickel; an indication of non-wetting. (*Courtesy of Hewlett-Packard*.)

Several types of fluxes are available for soldering, but only two broad categories are in widespread use. The first is aqueous-clean, also known as water-clean flux. This is generally composed of relatively strong organic acids and may be fortified with halogens to increase its chemical activity. Aqueous-clean formulations are meant to be thoroughly washed from the surface of the printed circuit assembly after soldering to prevent metal corrosion and ensuing electrical failure.

There are several electrical components that make aqueous-clean chemistry less attractive. These include dual inline package (DIP) switches (sealed switches, which are known to leak), high-density connectors, large area-array

packages, micro-BGAs, and any other components with low headroom between the underside of the package and the surface of the PCB. It is for this reason, plus the opportunity to eliminate an expensive and vagarious process step (aqueous-cleaning) and associated equipment, that the vast majority of electronics manufacturers have widely embraced soldering fluxes that require no cleaning.

The second broad category is termed “no-clean” flux. No-cleans are composed of resins or rosins with additives to make them chemically active to varying degrees. They are formulated so that the post-soldering residue is inert and can remain on the board obviating the need for cleaning.

46.4.4 Heating to Liquidus

Once heated to melting and oxide-free, solder begins to wet to oxide-free, solderable surfaces. It forms a metallurgical bond with contacted metals by dissolution of the surface, alloying with it. Of course, this process is dependent on having a largely oxide-free surface on the solder and the metal to be soldered. Once the wetting is initiated, alloying proceeds slowly, causing the solder to spread on solderable surfaces. The molten solder is drawn by surface tension to fill fine capillaries as between component lead and PCB bonding pad, and surface tension draws the solder up and around wettable surfaces forming *fillets*. Once solidified, the solder fillet acts as a mechanical gusset imparting strength to the resultant solder joint.

46.4.5 Solder Fillet Formation

The solder fillet is an overt manifestation of surface tension and wetting. Fillets are readily apparent in Fig. 46.2*a*, which

shows the fillet as a web of solder extending from the PCB bonding pad to the lead of this surface-mount component.

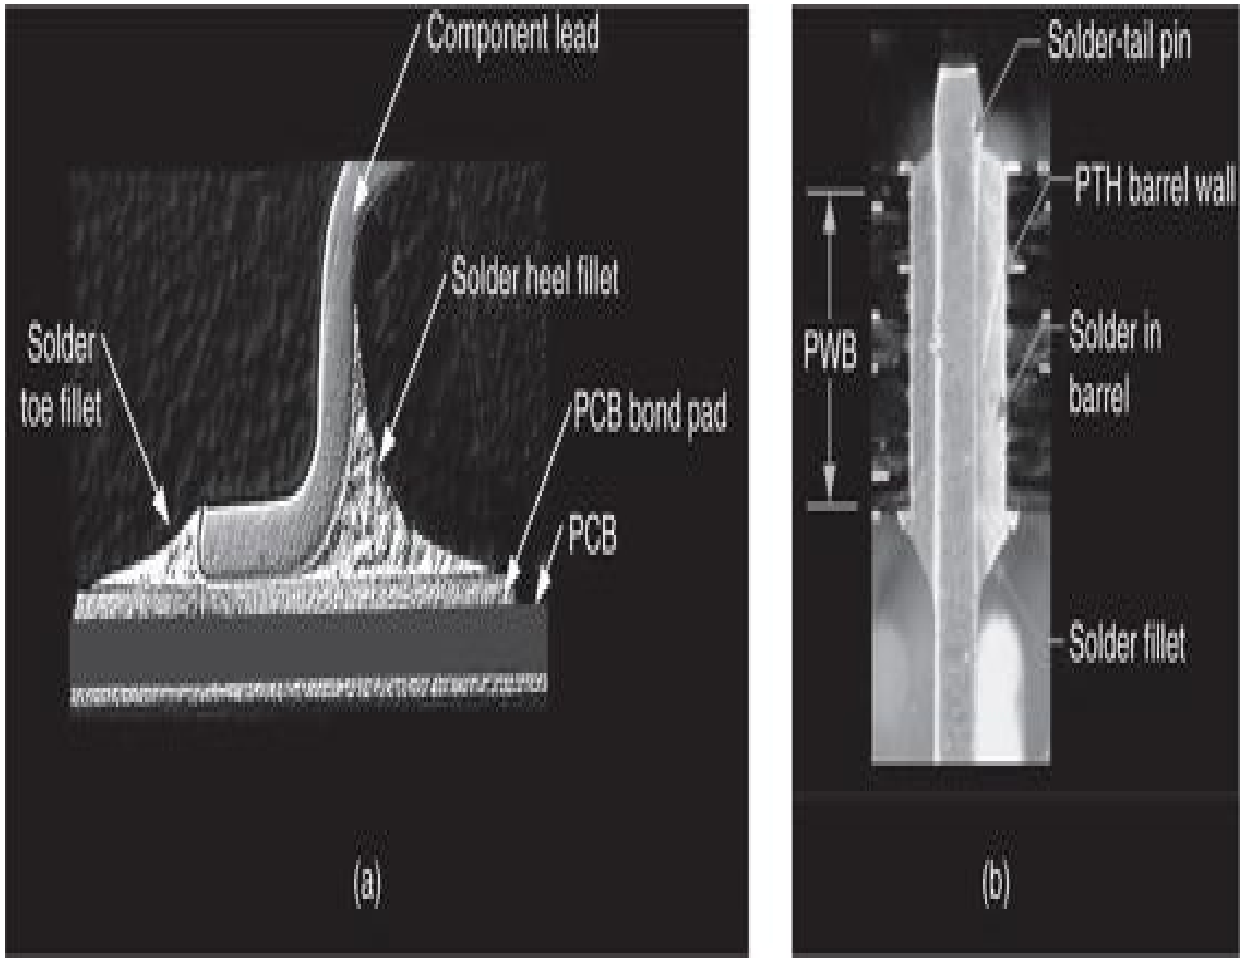

FIGURE 46.2 Solder fillet formation: (*a*) cross-section of an SMT solder joint, (*b*) a PTH solder joint. In the case of the SMT joint, solder has wet to pad and lead. Low wetting angles and good fillet formations are indicative of good solder wetting. The PTH solder joint shows good fillet formation on the secondary side of the PCB. At the top, the primary side, the fillets are not as well formed, probably due to lower temperature at the top-side of the board and onset of solidus before the wetting was complete or from a lack of solder. (*Courtesy of Hewlett-Packard*.)

Such gull-wing leads rely on good heel fillets for solder joint strength. Toe fillets may be present or absent depending whether there is exposed copper or other oxidized or unsolderable, exposed metal at the lead tip, where the lead-frame was excised from its tooling strip. Conventional no-clean fluxes as used for PCB assembly are

not strong enough to remove oxides from bare copper. Toe fillets are of little importance, adding no appreciable strength to the soldered assembly. The bulk of the strength comes from the heel fillet and the solder wetted to the capillary between the top of the bond pad and the bottom of the component lead. Similarly, side fillets may be present, but if the component lead width is on the order of the bond pad width, there may not be enough room to develop good side fillets. The wetting angle is also known as the *dihedral angle*. A low dihedral angle is an indicator of good wetting.

For an example of a PTH solder fillet, see Fig. 46.2*b*. The fillet is a reasonable indicator of the degree of solder wetting and, therefore, of process goodness. It is generally believed that the higher solder fillet, the better the solder joint, but high fillets can be indicative of three problems: (1) excessive heating, which can result in brittle solder joints; (2) excessive solder volume, and in the case of the gull-wing lead-form, and (3) loss of component lead flexibility which may affect solder joint reliability. If too much solder wicks up the lead, it may cause solder shorting, particularly near the package body, where the lead spacing may be finer than at the distil end of the lead. Therefore, fillet examination alone is not sufficient to accurately assess soldering process performance. But, for a fixed set of process parameters, fillet appearance may provide a good means of first-pass comparative assessment of solderability and soldering results.

46.4.6 Intermetallic Compound Formation

Intermetallic compound (IMC) formation is the key to soldering. IMC is the local alloying created at the boundary of the solder liquidus and the surfaces of the metal with which it is in contact. It is the essence of solder bond. There is

much misinformation about IMCs. One thing is certain: without intermetallic formation, there is no solder joint. This is stressed because some erroneously claim lack of IMC in such processes as laser soldering. In the case of that technology, the IMC can be exceptionally thin immediately after soldering due to the short time of liquidus, but it is and must be present for soldering to occur. High temperature, time, and intimate contact of the liquid solder enhance the rate and volume of intermetallic compound formation. The IMC is a crystalline intermediate alloy phase composed of some or all of the contacting metal constituents. This high-alloy concentration region generally has properties that are vastly different from those of either the solder or the contacted metals. Solder is thought of as a soft, forgiving material of low melting-point and good electrical conductivity. IMC, the essence of soldering, is the greatest irony of soldering technology. Although it is the basis for the actual bond, it is in fact, a brittle, high melting-point composition of generally poor electrical conductivity.

The IMC layer will grow over time even at room temperature. There are compositional mechanisms that slow its growth as in the case of Sn63 where Pb crystals line up and retard IMC advancement. Initial IMC thickness is largely predicated on the temperature and the time above liquidus. The thicker the IMC, the more brittle the solder joint; this is but one important reason that precise process control in soldering is required.

46.4.7 Cooling and Phase Change to Solidus

As the solder approaches solidus, the rate of IMC formation decreases. When it does reach solidus, the solder joint is formed. It is critical that the solder freezes prior to circuit board handling for two important reasons. First, accidental

movement of the PCB may cause the components to move in the molten solder. This could result in defects such as solder joint opens (dis-bonds) or solder shorts (unwanted bridging of solder from one bond pad or from one lead to the next). Second, a solder joint disturbance at the critical transition from liquid to solid may result in a bond of degraded reliability. This type of bond has an inherently grainy look and can even have microfractures within caused by motion-induced interruption of orderly crystal growth during solidification.

The cooling rate at the tail end of the process is as important as at the onset of heating. Extreme cooling rates may result in electrical device cracking or electrical performance degradation induced by differential contraction of materials.

More in depth discussions of soldering is included in subsequent chapters on soldering materials, fluxes, and process.

CHAPTER 47

SOLDERING MATERIALS AND METALLURGY

Gary M. Freedman
Colab Engineering LLC, Stow, Massachusetts

47.1 INTRODUCTION

Design, materials, assembly, and usage are the parameters that dictate reliability of a printed circuit assembly (PCA). They all have profound impact on the individual solder joint, electronic device reliability or the reliability of the whole assembly. Design engineers must consider all of these factors when laying out a printed circuit board (PCB) and choosing components for same. Temperature extremes, thermal excursion ramps, mechanical shock and vibration, the number of power (on-off) cycles expected over its lifetime, exposure to airborne particulates, gaseous pollutants, humidity, and handling during shipment and use must be considered for the design. It also behooves the design engineer to consider the rigors of PCB assembly. Subtle changes in design can have dramatic impacts on the assembly process.

The process engineer needs to be cognizant of the influence of the process on every electronic component on a circuit board and the whole PCA. Each exposure to reflow or rework will influence the ultimate reliability of the product as will the choice of solder alloy, solder flux, or PCA handling during the process. It is important to use materials and equipment as intended. For example, overheating a flux or solder paste may dramatically alter the quality of a solder joint. Too hot a reflow process may cause brittle solder joints. A poor soldering profile may result in excessive entrapped voids in solder joints. Improperly stored ICs may suffer subtle damage during soldering. Components designed for wave soldering may not be appropriate for oven reflow soldering. Uncontrollable hand soldering methods may lift solder pads. Mechanical flexure or interference with storage racks on the factory floor may impact a PCA. These are but a few of the many process or materials shortcomings that influence the reliability of the final product.

The process engineer must possess excellent interdisciplinary skills to foresee and avoid process issues associated with mechanical forces, chemical influences and thermal consequences on a solder joint, electrical device, or PCA. The choice of process materials (solder, flux, adhesives, etc.) has bearing on the reliability of the finished product. If a PCA is assembled according to a strict, well-understood process with known and constant materials, it will have a reproducible reliability profile.

In some cases, the cost to repair a PCA or an entire product may exceed the value of the combined material and labor content of the first-pass assembled product. It is also well understood that the reliability of a repaired assembly is not as good as a properly soldered first-pass printed circuit assembly due to additional board handling and solder joint degradation as a result of resoldering. The repair solder flux chemistry and how it is applied and heated may also impact product reliability. These points reinforce the need to

understand PCA processes thoroughly and to solder properly the first time. The materials and requisite solder joint reliability properties for a desktop computer are markedly different from those for an automotive ignition system which are unlike those for a smart phone. As such, this chapter will strictly avoid offering up generalized rules for all soldering process applications. Instead what is presented are the fundamentals of metallurgies as relates to the assembly of the PCB.

47.2 SOLDERS

47.2.1 Alloy Systems

Nearly all solders are alloys. An alloy is formed by combining two or more metals in a molten state. When cooled, alloy properties are dependent on constituent metals and the ratio of the number of atoms of one constituent to the atoms of the other(s). Variations in these atomic ratios result in alloys of vastly different properties that are exploited to suit a particular application. Melting points or melting ranges can be adjusted, as can hardness, tensile strength, shock resistance, etc. In alloy formulation, adjustment of one constituent to achieve a suitable melting point will likely cause an impact to other material properties. Mechanical properties, for example, may degrade to the point that the alloy may not be suitable for its end-use application even though its melting point or melting range is ideal. Such is the case in the search for lead-free (Pb-free) alloy substitutes. Although the electronics industry made its dramatic move to Pb-free soldering several years ago predicated on the European Unions WEEE[1] and RoHS[2] directives, to date, no direct replacements approximate the properties of the well-understood standard of eutectic Sn-Pb (SN63 alloy) solder. In most cases, liquidus temperatures (the temperatures at

which a material goes from solid to liquid) of the Pb-free solder alloys are higher than that of eutectic Sn-Pb. As a result, the adoption of Pb-free alloys has imparted changes to process, process equipment, PCB laminates, electronic components and finished assembly reliability.

Families of alloys that are created from two or more metals in different ratios are called alloy systems. Tin-lead (Sn-Pb) is one such system, available in any number of compositions (50Sn-50Pb, 60Sn-40Pb, 10Sn-90Pb, etc.). Some solder alloys are composed of two elements. These are binary alloys such as Sn-Pb or tin-bismuth (Sn-Bi). Others are ternary systems such as tin-silver-copper (Sn-Ag-Cu), which is also commonly referred to as *SAC* [for the “S” in Sn (tin), the “A” from Ag (silver), and the “C” from Cu (copper)]. SAC305 is the alloy designation for 3.0 weight-percent Ag, 0.5 weight-percent Cu, and the balance Sn. Similarly SAC3807 is the designation for 3.8 weight-percent Ag, 0.7 weight-percent Cu, and the balance being Sn.

Quaternary alloys are composed of four elements (e.g., Sn-Ag-Bi-Cu) and pentanary alloys, five (e.g., Sn-Ag-Cu-In-Sb). Quaternary alloys are least understood, binary systems are best understood and easiest to formulate. Small differences in compositions (0.5 weight-percent) as seen in ternary, quaternary, and pentanary systems are difficult for solder vendors to control accurately during formulation. Also, in wave soldering, where the solder pot contents are in constant contact with metals from component leads and circuit board surface finishes, materials will be dissolved into the molten charge in the solder pot and will effect solder composition over the long term. Naturally, the minor constituents of a solder will be altered or depleted more quickly in such a situation.

47.2.2 Tin-Lead Solders

These alloys were the staple of PCB assembly until recently and still are used in some RoHS-exempted applications, with SN63 being the most prevalent. Knowledge of the simple Sn-Pb binary, the de facto standard of soldering, will set the stage for understanding and choosing Pb-free alloys.

47.2.2.1 The Sn-Pb Eutectic Alloy. Sn and Pb can be formulated into many alloys but its eutectic alloy is the most familiar to the electronics assembler. A eutectic alloy is characterized by having a distinct melting point rather than a melting range and its melting point below its constituent metals (Table 47.1).

TABLE 47.1 Sn-Pb Constituent Melting Points Compared to Its Eutectic Melting Point

Material	Melting Point, °C
Sn	232
Pb	327.4
Sn63wt% Sn:37wt% Pb*	183*

*Eutectic alloy composition.

The eutectic composition has the lowest melting point of any other members of its alloy family. At the eutectic temperature, the eutectic metals coexist in a liquefied alloyed state as opposed to a state where there are some solids of one metal and liquid of the other as often is the case in ternary alloys and above.

SN63 is a ductile metal exhibiting a melting point of 183°C, a temperature benign for most materials associated with or attached to a printed circuit board. Its fatigue resistance is sufficient for most commercial applications. Sn-Pb is easily fluxed by very weak organic acids and its shelf-life in terms

of solderability is long lasting and generally not an issue. There are many solder alloys to choose from, but few as compatible as eutectic tin-lead when it comes to production assembly soldering of PCBs. There are also several metallurgical properties that make this alloy attractive as a solder, which explains why it was so widely embraced and the paradigm by which all solders are gauged. That is not to say that other metal alloys cannot be substituted, but this composition has endured the test of time and countless investigations for alternatives.

When noneutectic Sn-Pb alloys melt, phases of Sn or Pb precipitate out of the liquid solution and give rise to a solid-liquid mixture with broad melting range rather than a discrete melting point. The further from the eutectic point, the greater the band of the melting range for the alloy. This region of broad melting temperature is known as the “pasty” or “plastic” range. Noneutectic compositions do not solidify as quickly as eutectic alloys. Because eutectic solders nucleate and crystallize very rapidly at the solidus point, fine grain growth and high mechanical strength in the solidified solder joint result. Upon solidification, noneutectic compositions result in internal stresses and coarse, dull solder joints with perturbed surfaces. These are all points in favor of using eutectic or near-eutectic solders for circuit board assembly.

47.2.2.2 High Pb-Content Solders. High Pb content Sn-Pb solders are known for producing compliant solder joints owing to elemental lead’s high ductility. Due to high melting temperatures, these alloys are generally used to solder nonorganic circuit board substrates like ceramic. An organic laminate such as glass-epoxy is likely to incur degradation through a reflow cycle at such temperature extremes as required by alloys as 5Sn-95Pb (melting range 301 to 314°C) and 10Sn-90Pb (melting range 268 to 302°C). For these solders, the assembly process temperature is generally

chosen to be about 20 to 40°C higher than the melting point or the upper bound of the melting range for reflow and even higher for wave soldering. High-temperature solders are difficult to work with and are relegated to niche applications such as ceramic hybrid circuits or as a contact material for ceramic ball grid array (CBGA) and ceramic column grid array (CCGA) packages and hand-soldering operations. Even in these applications, the solder ball or column is often soldered to the package using a lower melting-point formulation.

47.2.2.3 Tin-Lead Additives

47.2.2.3.1 Antiscavengers. Occasionally a small fraction of silver (Ag) is added (up to 2 weight-percent) to retard Ag scavenging. Scavenging occurs when there is the propensity of one metal to dissolve rapidly and thoroughly into another upon reaching liquidus. A good example would be silver traces on a thin-film ceramic device and the use of Sn-Pb solder to bond to it. During soldering, the Ag would readily dissolve into the Sn-Pb. If too much Ag is dissolved, then the bonding pad on the thin-film ceramic device may be rendered unsolderable due to the lack of a wettable surface finish. The addition of Ag to Sn-Pb solder slows the dissolution rate of Ag from the thin-film ceramic bond pad and retards scavenging.

47.2.2.3.2 Brighteners. Sometimes Ag is added to solder to improve wetting, making the solder joint smooth and shiny. When not used as a scavenger, the addition of Ag should be avoided as it is not usually needed for most electronic joining applications with Sn-Pb.

47.2.2.4 Sn-Pb Intermetallic Compound.

Intermetallic compound (IMC) is the localized alloy created at the interface between the solder and the surface to which it is wetted. Without IMC creation, there is no solder bond. IMCs are thin, brittle bonds composed of the constituents of both

the solder and the metal to which the solder is wetted. In the case of Sn-Pb solder wetted to Cu, the intermetallics present would be Cu_6Sn_5 and Cu_3Sn. Note the Pb is not part of the bond interface. Instead it has been alloyed with Sn (m.p. 232°C) to depress its melting point and for the metallurgical properties it imparts to the solder joint. Pb retards Sn-Cu intermetallic formation by piling up at the intermetallic boundary, frustrating further tin-copper intermixing. Sn-Cu intermetallic compound, while crucial for solder joint formation, imparts brittleness to the interface and the thicker the IMC, the more brittle the interfacial boundary. Solder joints with overly thick IMCs are more prone to failure during thermal cycling or mechanical shock. Thickened IMC layers come from overheating a solder joint either during initial assembly or during subsequent assembly processes.

Although Sn-Pb solder is known for its ability to wet well to a number of component lead platings and circuit board finishes, Pb actually inhibits wetting and keeps the solder localized to the targeted solder joint area. Excessive solder spreading can be detrimental in three ways. First, if solder wicks away from the intended solder joint area, the resultant joint will be solder starved, weaker than intended. Second, if the solder were too mobile, it would wick up connector leads and into the connector, decreasing inner contact flexibility, decreasing contact gap, and changing connector contact physics. This may result in a less reliable interconnect. Finally, if the solder wicks up too high on a gull-wing component lead, it would inhibit the flexibility of the component lead making it more susceptible to mechanical failure.

47.3 SOLDER ALLOYS AND CORROSION

Just as some metals are more corrosion resistant than others, the same is true of solder alloys. When a solder corrodes on a circuit board, it is more than an aesthetic issue. Contaminants on the surface of the PCB between adjacent, oppositely charged conductors can result in corrosion dendrites. These are tiny conductive crystalline filaments or filamentary networks that may extend from one conductor to the next. They may cause hard shorts that prevent an electrical system from operating or soft electrical shorting imparting an electrical leakage path that interferes with proper circuit functionality. Additionally, dendrites may short intermittently. In this case they carry enough current to heat and fuse. Once melted, it may return the circuit to normal proper operation. This can be a cyclical event with the dendrites growing, fusing, and regrowing, making diagnosis difficult. Finer-pitch surface-mount geometries and fine PCB conductor traces are particularly susceptible to this phenomenon if there are corrosives on the PCB surface. Sometimes, with repeated shorting and fusing, carbon tracks from arcing will occur resulting in permanent hard or soft short circuiting.

M. Abtew et al. published a chart of the electromagnetic force (EMF) of various metal couples present in some lead-free solder alloys.[3] As a rule, the lower the EMF, the more corrosion-resistant the alloy. Eutectic Sn-Pb, the basis of comparison, was by far the lowest value on the list at 0.010 V. The next nearest, Sn-51In, was 0.201 V or 20 times the voltage as that of Sn-Pb solder. Other values reported were Sn-57Bi at 0.323 V, Sn-9Zn at 0.624 volts, Sn-3.5Ag at 0.937 V, and Sn-80Au at 1.636 V. So tin-lead solder is significantly more resistant to corrosion and dendritic growth than the other seven alloys studied.

47.4 PB-FREE SOLDERS: ALTERNATIVES AND IMPLICATIONS

47.4.1 Elemental Alloy Candidates for Pb-Free Solder

Of the 90 naturally occurring elements, only 13 can be practically combined with each other to form a practical solder (Fig. 47.1).

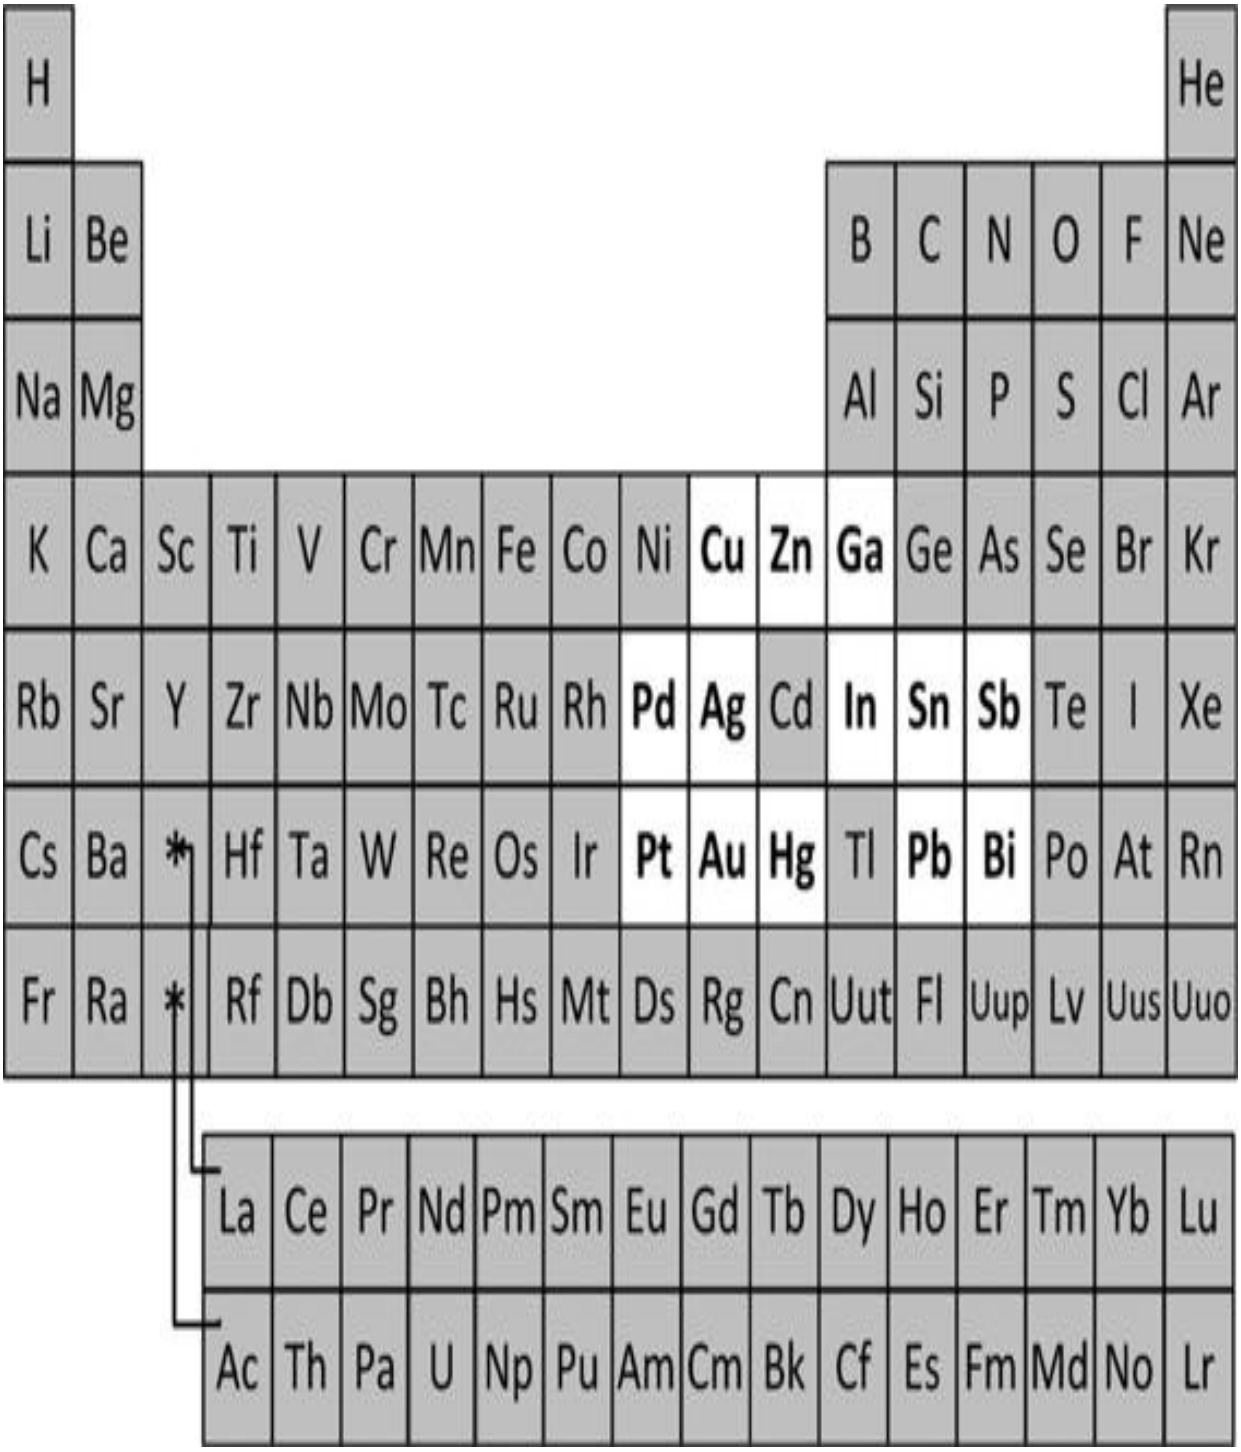

FIGURE 47.1 Highlighted elements can be combined to form solders useful for circuit board assembly. Grayed out elements are not useful for solder formulation for PCB assembly.

Of those elements that can combine to form solders, several have limitations that restrict their practical

implementation for solder use (Table 47.2).

TABLE 47.2 Elemental Candidates for Solders

Element	Symbol	Melting Point, °C	Comments
Antimony	Sb	630.5	Toxic. Currently in use as a minor constituent in some solders
Bismuth	Bi	217.5	In current use
Copper	Cu	1084.5	In current use
Gallium	Ga	29.75	Too expensive
Gold	Au	1063	Too expensive
Lead	Pb	327.5	Use restricted by EU RoHS Directive
Mercury	Hg	−38.83	Toxic. Use restricted by EU RoHS Directive
Palladium	Pd	1550	Too expensive
Platinum	Pt	1768.3	Too expensive
Silver	Ag	960.15	Expensive but in current use in some solders in small quantities
Tin	Sn	231.89	In current use
Zinc	Zn	419.6	In current use

Gallium (Ga), gold (Au), indium (In), platinum (Pt), and palladium (Pd) cannot be mined or refined in sufficient quantity to satisfy the needs of the electronics industry and are prohibitively expensive, blocking their consideration as a major constituent of a worldwide solder supply. The Bismuth

(Bi) supply, a by-product of lead (Pb) refining, would be marginally sufficient. Mercury (Hg) and antimony (Sb) are too toxic. Both Hg and Pb are already on the EU's RoHS list of restricted materials. Ga and Hg possess too low a melting point to be used on their own. This leaves five metals for practical solder alloy consideration: Bi, Cu, Ag, Sn, and Zn. Due to its value, silver, too, can only be used as a minor constituent of solder and is already in wide use that way today. Given the four remaining metals (Bi, Cu, Sn, and Zn), there are many possible metallurgical permutations available for solder alloying, but there are few that either possess low enough liquidus to be useful for circuit board assembly or have attractive physical properties as a solder. Although Pb-free solders have been in use for many years (jewelry making, plumbing, brazing, etc.), there is no one clear alloy choice for electronics assembly. Most have too high a melting point to be useful, and none come with the well-documented properties database as is the case for Sn-Pb solder.

47.4.2 Candidate Pb-Free Solders

Although many manufacturers completed the conversion to Pb-free soldering in time for the July 1, 2006, implementation of the RoHS directive in Europe, there was still no consensus across the industry for a single tin-lead solder replacement at the time. Pb-free alloy systems receiving the most attention include those listed in the Table 47.3.

TABLE 47.3 List of Lead-Free Solders and Their Temperature Ranges

Alloy Family	Most Common Compositions[a], Wt.%	Solidus Temperature[b], °C)	Liquidus Temperature[b], °C
Sn-Cu	Sn-0.7Cu	227	227[c]
Sn-Ag	Sn-3.5Ag	221	221[c]
	Sn-5.0Ag	221	240
Sn-Ag-Cu	Sn-3.0Ag-0.5Cu	217	221
	Sn-3.5Ag-0.9Cu	217[c]	217[c]
	Sn-3.5Ag-0.7Cu	217	220
	Sn-3.8Ag-0.7Cu	217	220
	Sn-3.9Ag-0.6Cu	217	223
	Sn-4.0Ag-0.5Cu	217	225
Sn-Ag-Bi	Sn-1.0Ag-57Bi	137	139
	Sn-3.4Ag-4.8Bi	200	216
	Sn-3.5Ag-5.0Bi	208	215
	Sn-3.5Ag-1.0Bi	219	220
	Sn-2.0Ag-7.5Bi	191	216
Sn-Ag-Bi-Cu	Sn-2.5Ag-1.0Bi-0.5Cu	214	221
	Sn-2.0Ag-3.0Bi-0.75Cu	207	218
Sn-Bi	Sn-58Bi	138[c]	138[c]
Sn-Zn-Bi	Sn-8.0Zn-3.0Bi	191	198
Sn-Zn	Sn-9.0Zn	199[c]	199[c]

Notes:

[a]There are too many noneutectic formulations composed of the same elements in varying ratios to list comprehensively here. Each variation in composition will have its own melting range. The ones listed in this table are examples only to show approximate temperature range and composition.

[b]Discrepancies in the literature exist as to the exact melting point or melting range of alloys listed, but the table will be useful for approximating phase-change characteristics of the alloys listed.

[c]Eutectic alloys have a distinct melting point; onset of solidus and liquidus is the same. Noneutectic alloy melting is characterized by a melting range, where the alloy is present as both solid phase and liquid phase(s), its pasty range. At the upper temperature of the melting range, only the liquid phase exists.

47.4.2.1 Characteristics of Pb-Free Solders. Pb-free solders generally exhibit poorer wetting and spreading characteristics than Sn-Pb alloys, but may offer an advantage in tensile strength and creep resistance. Each alloy will have its own properties in terms of the soldering process such as: propensity for solder void formation; oxide chemical resistance; solder paste shelf-life; fatigue characteristics; alloy interactions with board and component surface finishes; corrosion resistance; mechanical shock resistance and numerous other properties. Many of the lower melting point Pb-free solders have precious elements added to them, whereas some of the inexpensive alternatives wet poorly, are prone to oxidation during soldering, and tend to corrode. A few of the most favored alloy systems will be briefly discussed.

47.4.2.1.1 Bismuth Alloys. Bismuth (Bi), an element closely associated with Pb is, in fact, chiefly a by-product of Pb smelting. It is generally used for lower melting point solder alloys. Bi is in short supply and Bi solders cost about twice that of Sn-Pb alloys. Bi is compliant like Pb and shares several of its properties, such as high specific gravity and ductility.[4–6] Pure Bi melts at 271.3°C, about 50°C lower than that of Pb. Very easily oxidized, bismuth alloys are best soldered with the aid of highly activated fluxes or in a nitrogen environment.

Bi forms a binary eutectic with Sn in the proportions 58Bi:42Sn (m.p. 138°C). There are numerous bismuth alloys in use, many composed of two or more metals in addition to bismuth. The Sn-Bi eutectic, if contaminated with Pb, can be problematic as it is known to form a ternary alloy with a melting point of 96°C adversely affecting solder joint fatigue characteristics. In some applications, solder joints will fall apart if the service temperature is high and the low melting point Sn-Bi-Pb alloy is formed. This becomes all the more critical with smaller Sn-Bi solder joints. The Pb can come from solder predeposited on component leads,

noncollapsible Pb BGA balls, non-collapsible Pb CCGA columns or Sn-Pb hot-air solder leveled pads.

Bismuth expands upon freezing, whereas tin contracts. A phenomenon called fillet lifting has been reported[7,8] (Fig. 47.2). It is mostly associated with bismuth ternary alloys such as Sn-Cu-Bi and Sn-Ag-Bi used in plated through-hole (PTH) wave soldering, but has also been observed with the Sn-Bi binary. As the board cools, it contracts at a different rate than the solder, and the fillets may lift, especially if cooled slowly or contaminated with Pb. Rapid cooling (≥ ~3°C/s) has been advised but may not completely eliminate this phenomenon, but this cooling ramp may exceed manufacturer's specified thermal ramp rate for some components. Too high a cooling rate may result in component cracking or degraded component performance or reliability. Fillet lifting may also result in lifted or damaged PTH annular ring (bonding pad) if solder joint strength is high and bond strength of the ring to the board is also high.

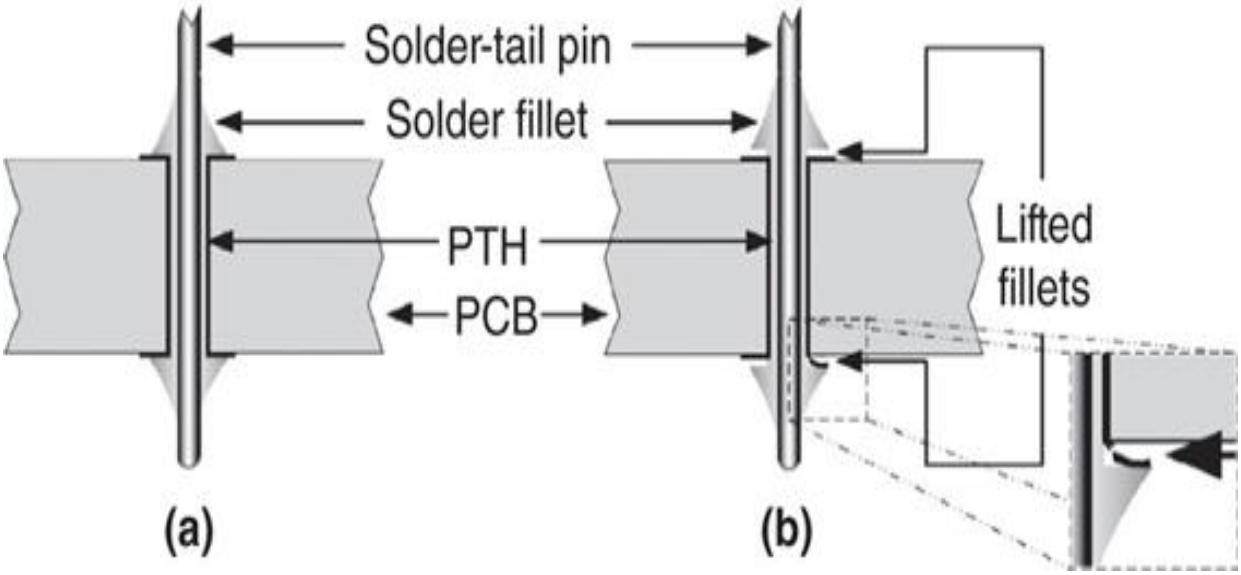

FIGURE 47.2 Bismuth alloy solder joints with fillet lifting: (*a*) normal wave soldered PTH joint, (*b*) expansion upon solidification in a bismuth-containing solder alloy may cause solder fillets to fracture and lift from the plated through-hole annular pads (see inset).

Some Bi alloys have too low a melting point for many applications. Despite its excellent tensile strength and thermal cycling endurance (better than Sn-Pb), Sn-Bi eutectic (m.p. 138°C) would not be practical for use in most automotive applications, where the service temperatures are exceptionally high. Bi also oxidizes rapidly, making Bi alloys difficult to maintain during wave soldering due to copious oxide (dross) production.

Bismuth soldering alloys are noted for their brittleness[9,10]; nonetheless, several bismuth solders are used commercially, the most popular alloys containing Bi in the 2 to 14 percent range. Aside from bismuth alloy's inappropriateness for high-temperature applications and potential for Pb contamination, hygiene is an issue. According to C. White and G. Evans,[11] safety is a concern when using alloys with high concentrations of bismuth as Cadmium (Cd), a poisonous metal, is a common bismuth contaminant. Care is recommended in handling this solder, and special venting requirements may also be mandated for its use. On the other hand, the RoHS legislation has reinforced prior EU restrictions on cadmium, limiting it as a constituent or contaminant to less than 100 ppm by weight.

Bismuth and indium alloys are suitable for *step soldering*, which refers to the use of two different solder alloys with two different melting temperatures used on the same circuit board. The higher temperature alloy (e.g., Sn-3%Ag-0.5%Cu, melting onset 217°C) is used to solder surface-mount components and an alloy of lower melting temperature (e.g., 58%Bi:42%Sn, m.p., 138°C) is used for wave-soldered components. The temperature experienced at wave solder will not cause the Sn-Ag-Cu to re-reflow, thus preserving the integrity of surface-mount technology (SMT) solder joints through wave soldering and avoiding re-reflow of same.

In the case of repair or replacement of top-side components, the use of low melting temperature solder will

have less adverse thermal effect on adjacent or bottom-side solder joints. In fact, use of low melting point solder reduces the possibility of pad delamination or through-hole barrel cracking; failure mechanisms associated with localized overheating, especially at repair. It should be noted that if there is a significant amount of the original solder on the bonding pad, it will alloy with the Bi-containing solder to create a new alloy of unknown properties.

47.4.2.1.2 Tin-Silver-Copper (Sn-Ag-Cu). As previously stated, the Sn-Ag-Cu (SAC) family is the most widely used Pb-free alloy for PCB assembly. Its tensile strength is superior to that of Sn-Pb, but its shear strength is worse. It is moderate in melting temperature; roughly 35°C higher than eutectic Sn-Pb solder. It is easily fluxed, but care must be taken to prevent premature flux activation or flux dry-out due to the elevated working temperature regime of SAC solders. Fluxing formulations for wave and reflow soldering have generally been formulated to accommodate the higher melting range of this alloy family by use of higher molecular weight resin fluxes and volatile organic compound (VOC)-free flux formulations. The eco-friendly VOC-free fluxes are devoid of alcohols or other low boiling organics which would enhance flux dry-out.

The SAC family has good compatibility with most Pb-free board surface finishes and Pb-free component platings. Its process window is narrower than that of Sn-Pb. It has been demonstrated that SAC can be used with parts containing Pb or vice versa, but the reliability of resulting solder joints is less than if soldering leaded to tin-lead or lead-free to lead-free. SAC solders sell at about two to three times the price of Sn-Pb solder alloys. A comparison of Sn-Pb solder to SAC solder is offered in Table 47.4.

TABLE 47.4 Comparison of Sn-Pb Solder with Pb-Free SAC Solder

	Solder Alloy	
	Tin/Lead Sn-37%Pb	Tin-Silver-Copper Sn-3.0 → 4.0% Ag-0.5 →0.7% Cu
Melting temp.	183°C	~215°C → ~223°C
SMT peak temp.	~215±10°C	~240±10°C
Wave solder temp.	245°C → 260°C	260°C → 270°C {with higher preheats and longer soldering dwells}
Solder reliability	Adequate	Still subject to investigation {Ag content related to mechanical shock resistance (increasing Ag decreases shock resistance)}
Process compatibility	Adequate	Adequate but still some development work underway

Figure 47.3 demonstrates the process temperature differences for SAC soldering as compared to Sn-Pb.

FIGURE 47.3 Comparison of SAC solder to Sn-Pb solder in terms of upper and lower reflow process temperature ranges and onset of liquidus.

It should be noted that mechanical shock resistance of an assembly generally decreases with increasing silver content in the SAC formulation. SAC305 will be less shock resistant than SAC105 (1% Ag, 0.5%Cu).[12]

To improve the reliability of SAC solders, small amounts of impurity metals can be added. Zinc, cobalt, cerium, nickel and iron are but a few that have been investigated. Such formulations are called “SACX” solders. The intent of the additions is to impact the way the SAC solder constituents segregate or precipitate upon solder solidification, or to affect solder joint void content or grain size. There is no still no clear consensus as to which formulation is advantageous.[13]

47.4.2.1.3 Sn-0.7Cu Alloy. Eutectic Sn-Cu (m.p. 227°C) is being used as a wave solder charge material. It is compatible with most board surface finishes and component lead-frame finishes. Its relatively low cost (about 50 percent more than Sn-Pb solder) making it an attractive Pb-free alternative. It also has been demonstrated to be an effective alloy for Pb-free hot-air solder-leveled (HASL) surfaces on PCBs.

This alloy is in widespread use especially for wave soldering and to a lesser degree for oven reflow soldering of surface-mount PCBs. As mentioned previously, soldering is done at a temperature well above the onset of liquidus to add margin to the process, to ensure the whole board and components thereon are heated sufficiently for soldering and to provide conditions for good and efficient solder wetting. With a melting point of 227°C, this alloy must be boosted to about 265±10°C for wave soldering. Wave soldering is a dynamic process with the molten wave in constant motion and in contact with the bottom of the PCB during soldering. The action of the wave dissolves copper and other metals

from the PCB lands and component leads and because the soldering temperature is high and the copper content of this binary alloy is only 0.7 percent copper by weight therefore, only small changes in the copper content will upset the balance and change it from a eutectic composition with a distinct melting point, to a noneutectic, higher melting range alloy. The rise in melting point can be dramatic and if not identified and corrected will prevent proper soldering to occur. The eutectic composition of an alloy system has the lowest possible melting point for that system and noneutectic alloys have melting ranges rather than one distinct melting point. The high melting temperature of this alloy and the fact that it is 99.3 percent tin enhances rapid material dissolution from PCB surfaces and component lead platings. Care must be taken to top off the wave solder pot with an appropriate amount of Sn or Sn-Cu to maintain proper Sn-Cu alloy proportions. Sn-0.7Cu is also doped with small amounts of nickel, bismuth or other elements to affect its resulting grain structure and solder joint characteristics as for SACX.

47.4.2.1.4 Indium Alloys. This metal and its effect on the solder joint is very much the same as for bismuth. Indium (In) is very soft and ductile in its elemental form and melts at about 157°C. Indium-based soldering alloys are much more expensive—about 25 times that of Sn-Pb—due to indium's scarcity, thus it is not suited as a dominant alloy metal in solder. Price and supply make it unattractive even as a trace agent or a minor solder alloy constituent. B. Allenby et al.[14] concluded that the world's indium supply would be depleted in about 1 year if indium were consumed at the same rate as was Pb for Sn-Pb solders.

An In-Sn eutectic occurs at 58 weight-percent In with a eutectic temperature of 120°C. Copper is highly soluble in indium and it forms intermetallic compounds with copper from the circuit board's bonding pad or copper-based component leads. Indium has been demonstrated to be of

value in reducing the leaching of gold into solder as reported by Yost,[15] with a lower gold dissolution rate for indium-based solders as compared to tin solders. The use of indium allows soldering to gold films without thoroughly consuming the gold. The resulting solder joints are not brittle, as is the case of Sn-based solder joints exposed to too much gold.

Indium and some of its alloys can wet to glass, quartz, and other normally unsolderable inorganic substrates with the aid of an ultrasonic soldering tool. Ultrasonic soldering is discussed in the chapter on soldering techniques.

47.4.2.1.5 Zinc Solders. Zinc (Zn) alloys, once favored by some Japanese companies, oxidize rapidly. Solder paste shelf-life has been an issue even when these alloy pastes are refrigerated at very low temperatures. Dross formation in wave soldering has also been problematic. Zn alloys are prone to corrosion. The Cu-Sn-Zn alloy system can form ternary phases which may cause the solder spall.[16] None of the Zn alloys are in widespread use for PCB soldering.

47.5 BOARD SURFACE FINISHES

Most circuit boards consist of a stack-up of insulator material such as glass-reinforced epoxy and conductive layers (traces and planes) composed of copper. Copper oxidizes quickly and its oxides are chemically resistant necessitating the use of harsh fluxes to enable soldering. Copper also corrodes in the long term from left-over process residues, fingerprints (body salts), or airborne contaminants. It is for these reasons that copper traces on circuit boards are protected by solder mask and solder lands (bonding pads) are plating, or otherwise treated to enhance soldering. The following section covers the most common board finishes. The process engineer needs to bear in mind that in addition to

solderability, other surface finish-related issues that may affect manufacturing including the following:

- *Probe ability:* The ease with which conventional in-circuit test probes are able to make contact with a particular surface finish.
- *Cost:* Some surface finishes are significantly more expensive than others.
- *Shelf life:* Bears on the ability of a surface finish to resist oxidation, tarnish or other surface conversion or corrosion, and remain solderable.
- *Reliability:* Refers to the influence surface finish may have on resultant solder joint strength as it relates to long-term use, thermal cycling, resistance to mechanical shock or vibration, and other environmental factors.
- *Corrosion resistance:* Some surface finishes are more prone to corrosion than others. Immersion silver, tin and copper are three such finishes that are frequently associated with corrosion.
- *Tribology:* The frictional properties of a material become important for press-fit connections.
- *Other surface finish-related defects:* Immersion silver (Imm-Ag) surface finish has been known to exhibit linear arrays of microvoids at the intermetallic interface which detracts from solder joint strength. Electroless nickel/immersion gold (ENIG) sometimes results in brittle fracture if the plating chemistries are not maintained properly.

47.5.1 Hot-Air Solder-Leveled Surfaces

Hot-air solder-leveled (HASL) coated boards are manufactured by dipping, wave soldering or otherwise

coating a raw PCB with molten solder and using a stream of hot gas to blow off excess solder, thus leveling the solder which has wetted to PCB bonding pads. It was a common board finish for Sn-Pb.

There is the old industry adage that “nothing solders like solder,” which has made HASL a safe and preferred finish for many years. There are never solderability issues with this coating. If the coating is present then it is solderable. It is inexpensive, easy to apply, and has excellent shelf-life/aging properties. There have been fears about the flatness of the HASL finished pads and potential effect on surface-mount component placement and soldering. Pads need not be perfectly flat for component placement. Since 0.1 to 0.2 mm of solder paste are applied over the pads for reflow soldering, the notion of original PCB bond pad flatness is not a significant concern unless the HASL finish is grossly out of specification and escaped board shop final quality control. During reflow, the solder paste and HASL solder on the pad starts to reflow, it domes up as a liquid and will self-level. Once it wets to component lead, surface tension of solder to wetted pad and wetted lead will hold things to together until solidification. It is a well-proven surface finish for component lead pitches down to at least 0.5 mm. Reputable board shops no longer consider HASL difficult to apply and some board shops are finding new use for their expensive HASL application equipment by extending it to Pb-free solders. Sn-Cu has been demonstrated to be one such HASL coating material.

Since HASL constitutes a soldering reflow cycle there an intermetallic compound (IMC) layer present prior to PCB assembly and the thicker the IMC the less reliable the solder joint. But HASL was used for many years for Pb-bearing solders with complete success and the same should be true for Pb-free solders even though the soldering temperature is slightly higher. Since HASL usually has thin, probe-friendly oxides, it is a favored surface finish for in-circuit testing.

47.5.2 Organic Solder-Preservative Copper

Known as OSP-Cu,[17,18] organic solder-preservative copper is an organic coating applied to the copper lands on the PCB at the board shop to retard oxidation. The lands are first given a microetch to remove oxides and to increase surface area for OSP coating adhesion. The protective coating is an organometallic compound such as benzotriazole or imidazole, that chemically bonds with the freshly etched copper pads and plated through-holes of the PCB. It is formulated to retain copper solderability through multiple reflow cycles. OSP-Cu is widely used and best for “just-in-time” board assembly strategies since its effectiveness diminishes with time, temperature and humidity.

During the soldering process, the OSP coating degrades with each reflow cycle resulting in increasing levels of copper oxidation. Chemical-resistant copper oxide inhibits solder wetting, requiring ever stronger solder fluxes. This may be particularly evident with thick [≥2.36 mm (≥0.093 in)], thermally aggressive PCBs with mixed-mount technology since PCB heating regimes are necessarily high. Reflow results on the secondary side and primary side of such boards are generally satisfactory. But by the time such a board reaches the solder wave, the OSP coating may have lost enough of its effectiveness that remaining copper oxidizes and compromising PTH barrel fill. Today’s OSPs are formulated for the high temperature rigors of Pb-free soldering, and if PCBs are properly coated, stored in a cool dry environment as recommended by the PCB supplier and not abused during reflow and wave soldering, then the OSP coating should be effective for the two reflow soldering cycles and one wave soldering operation as is required for mixed-mount assembly.

When solder paste printing goes awry and the PCB needs to be cleaned of the misprinted or smeared solder paste, most organic solvents used for removing the paste may thin, or remove the OSP coating reducing its effectiveness in preventing copper oxidation. Care must be taken to ensure paste misprint solvent compatibility with the OSP coating.

Another deficiency of OSP-Cu is found at in-circuit test (ICT). As the board is passed through top- and bottom-side reflow cycles and wave soldering, the unsoldered and un-fluxed test points oxidize. The insulating oxide layer is difficult to pierce even with sharp, pin-type or blade-type ICT probes. Multiple fixture re-seatings may be necessary to attain probe penetration and electrical contact. This reduces the probe working life as probe sharpness is dependent on the number of contact activations. It is good practice to coat test points with solder; however, some no-clean flux residues are difficult for ICT probe contact. The best strategy goes against modern PCA practices: reverting to the use of water-clean paste and flux formulations and coating test points with solder. The postsoldering, aqueous cleaning cycle removes any flux residues, enhancing ICT probe contact on solder-coated test points on the finished PCA. But most large electronic manufacturers have worked diligently to remove aqueous cleaning from their factories—a move for improved process economics and significant environmental impact.

47.5.3 Electrolytic Nickel/Electrolytic Gold

This plating combination has been in use for many years and is considered a high-end surface finish but a highly reliable one in terms of solderability and product life. The amount of gold (Au) is small, but the plating process uses toxic and expensive materials that further increase the price of the plating. This plating system should not be confused with

electroless nickel/immersion gold (ENIG). That surface finish will be discussed separately and does not have the reliable history of electrolytic nickel/electrolytic gold.

The electroplated nickel (Ni) serves as a barrier between the copper and the gold. Ni on its own is a poor candidate for a solder pad coating as it oxidizes rapidly and its native oxide is very durable and stable; chemically tough to dissolve or react away. Un-oxidized Ni can alloy with tin, which means that it can be soldered. Were the gold deposited over the copper directly, the gold layer would begin to inter-diffuse with the copper even at room temperature forming a brittle intermetallic compound. The reaction rate is temperature-dependent. This intermetallic, like most intermetallic compounds, is difficult to solder, requiring a higher process temperature, a more active fluxing agent, or both. The Au-Cu system has poor solderability and the brittleness of this intermetallic results in diminished solder joint strength.

Ni/Au coatings are in widespread use. Ni coating thickness is generally on the order of ≥2.54 µm (≥100 µin). Au is a more difficult metal to plate. It tends to coalesce into islets, resulting in a porous coating. Any pores in the gold overcoat allow oxidation of the underlying Ni, rendering it locally unsolderable. To preclude this, the gold is liberally plated with a targeted minimum thickness greater than about 0.127 µm (5 µin) to ensure complete coverage of the Ni.

There are problems with the Ni/Au metallurgical system. First and foremost, it is well known that gold can cause solder joint embrittlement. When gold is alloyed with tin as in tin-lead solder, it forms alloys with both the Pb and Sn. The Au-Pb alloy has two predominant intermetallic compounds: Au_2Pb and $AuPb_2$. Of the two, the latter is of greatest concern. It begins to form at the Au-Pb eutectic (85 weight-percent Pb, m.p., 215°C), a temperature that encroaches into the normal reflow solder processing regime.

$AuPb_2$ is stable below 254°C and is characterized by brittle, plate-like structures. Regardless of the composition, size, and concentration of the intermetallic grains in the solder joint, they can either strengthen it (forming miniature reinforcing bars in a solder "cement") or embrittle it, detracting from the solder's inherent ductility.

Gold is nonoxidizing, like platinum and palladium, its noble metal neighbors in the periodic table. It readily alloys with most common solder alloy compositions, especially Sn-Pb and Sn-Ag-Cu. A. Korbelak and R. Duva[19] consider gold the most readily solderable material, but Sn-Au intermetallics are of even more serious concern than those of Au-Pb. The former is a characteristically brittle intermetallic that has been widely linked to solder joint failure. Too much gold in a tin-lead solder imparts a dull, grainy look to the resultant joint; the only possible visual clue, although there are other conditions that can lead to a similar appearance. It should be noted that most Pb-free solder joints have a grainy look even if inherently pure. There are marked differences in solder joint integrity when it is loaded with Au. The embrittlement causes a reduction in the joint strength and fatigue life. There is universal agreement that Au can be detrimental to the final assembly if its fractional weight-percent is not strictly controlled. There is wide disagreement on the exact amount of gold permissible. Reported values generally fall between 2 weight-percent and 10 weight-percent, with most experts agreeing that less than 2 weight-percent is a safe value.[20,21] Ebneter[22] determined that Au as a thin, protective coating 0.762 to 5.84 µm (30 to 230 µin) does not pose an embrittlement problem and that Au thickness required was a function of the plated grain size and porosity. Further, grain size is dependent on the type of plating bath (cyanide or acid) used. Hedrig[23] also concluded that >5 percent Au in Sn-40Pb solder was problematic. Foster[24] reported a small net increase in solder joint strength with a 2.5 percent Au

addition to the same alloy, but when the addition was as high as 10 percent, there was a marked degradation in solder joint strength. C. J. Thwaites[25] reported that 4 percent gold in a Sn-Pb solder joint is the threshold value above which there is a marked embrittlement and reduction in fatigue resistance.

There are three important Au-Sn intermetallics: AuSn, $AuSn_2$, and $AuSn_4$. Eutectic points are at about 85 weight-percent Sn (215°C) and 20 percent Sn (280°C). Gold can also form a ternary compound when joined with Sn-Pb solder, exhibiting a eutectic at about 175°C.[26] This can radically alter reflow characteristics and solder joint performance. Au, like Pb, is poorly soluble in Sn, which means that it dissolves in hot Sn, Pb, or Sn-Pb solder and precipitates out of solution during the liquid-to-solid phase. When it does, it forms brittle, plate-like crystals that are readily apparent, needle-like in cross-section.[27]

When an intermetallic forms a distinct interfacial layer or is in otherwise high localized concentration, it is a rigid structural element, prone to crack formation along its solder interface upon flexure. Therefore, in the case of Sn-Pb, even though the solder joint is composed of a ductile composition, its overall strength and endurance is dominated by the brittle intermetallic composition and its thickness and structure within the solder joint.

As component lead pitch decreases, so does the requisite solder volume. Au concentration becomes increasingly difficult to control because its plated thickness cannot be easily regulated to accommodate the reduced surface area and lower solder volumes that accompany finer-pitch component requirements. After all, Au deposit thickness is dependent on its deposition grain size and plated porosity.

Another pitfall of Cu-Au or Cu-Au-Sn systems is that of Kirkendall voiding. Voids in the solder joint or at copper-gold interfaces occur with time through solid-state diffusion.

Copper, which has a relatively high solubility and solid-state mobility in gold, diffuses into the gold. Transported by grain boundary diffusion at temperatures below 150°C and by bulk diffusion above that temperature, Au-Sn regions result along with atomic vacancies. When lattice vacancies are in profusion, microscopic voids can be observed, and this material depletion weakens the solder joint. Several references are available on this phenomenon.[28–31] Kirkendall voids should in no way be confused with voiding that results from entrapped gases or residues from solder paste in the surface-mount process or from fluxes or PCB laminate materials in wave soldering.

Although there is still much controversy on the subject of Au concentrations and effects on the solder joint, there is no doubt that this metal system is being widely exploited successfully in electronics manufacturing. It is, however, prudent to ensure that the Au levels are kept to a minimum via adequate vendor management and implementation of good process control methods for solder deposition. Note that because gold is a non-oxidizing material and therefore does not deplete the flux, more flux is available to work on the other components of the metallurgical system—namely, the underlying nickel (which must be kept from oxidizing), the solder, and the component lead. The Ni-Sn intermetallic is more brittle than that of Cu-Sn, and this surface finish is generally not recommended for applications where the product may experience high mechanical stresses such as shock or vibration.

It has been stated that in the Ni/Au system, the soldering actually occurs on the Ni surface and the Au serves as a protective coating. Another intermetallic of this system, $NiSn_3$, has been cited as a problem in long-term solderability degradation.[32] This IMC rapidly develops a platelet structure at low temperatures, with the greatest growth rate in the vicinity of 100 to 140°C. When intermetallic platelets grow

large enough, they may penetrate the surface of the overlying tin, oxidize, and become a material difficult to flux and solder. The presence of elemental Pb was determined to retard $NiSn_3$ IMC formation. Ni/Au surface finish is in use with Pb-free soldering, but there is currently a watch in the industry as sporadic brittle fracture has been observed on occasion. The exact nature of this fracture mechanism is yet to be understood and it is not certain that Ni/Au surface finish is at fault or just coincidental with some other failure mechanism.

47.5.4 Electroless Nickel/Immersion Gold

As the name implies, Electroless Nickel/Immersion Gold (ENIG) is not an electroplated surface finish. Still comprised of Ni over the PCB's copper, it has an overcoat of Au. ENIG is a lower-cost alternative than electrolytic Ni/Au and is in widespread use today. When the plating process is kept in control, it provides an excellent, solderable, and reliable surface finish. On the other hand, it is a finish that has caused many well-known reliability problems. Terms such as "black-pad," "black line nickel," and "mud cracks" describe some of the evidence of failed ENIG-related problems. These phenomena have been commonly observed on BGA packages plated with ENIG for package-to-ball attachment[33] and also at board level with solder joints built upon ENIG surface finish.

The main defect is brittle failure of the solder joint; a clean break beneath the intermetallic layer formed on the PCB bonding pad. Were the package completely pried loose from the board, a high surface area, dull finish bonding pad would be evident; the well-known "black-pad." Often the pad has an array of cracks visible on its surface reminiscent of mud

cracks. Once the failed component is removed, the black-pad afflicted bonding pads are unsolderable or unreliable for further use and the board must be scrapped. Although the exact cause of ENIG failure is not well understood, it seems to be linked to phosphorus concentration in the electroless nickel plating bath.

ENIG's appeal is its modest cost, flat topography consistent with all plated surface finishes**,** excellent solderability, excellent testability, and reasonable shelf-life if plated well. Unfortunately, the risk associated with this surface finish must be weighed alongside its benefits. In general, the assembler will find good results with ENIG. Unfortunately, there are no quick screening methods to weed out failure-prone ENIG plating lots.

47.5.5 Electroless Nickel/Electroless Palladium/Immersion Gold

A relatively new surface finish, it is immersion gold (Au) over electroless palladium (Pd) over electroless nickel (Ni) plated on the PCB's exposed copper (Cu) lands and traces. Pd serves as a diffusion barrier preventing Ni from intermingling with the Au in order to eliminate Au/Ni embrittlement. In many ways it is has qualities like ENIG but less chance of the "black pad" defect seen with ENIG. It is more costly than ENIG and highly dependent on the market price for palladium; a very expensive metal.[34] It has been shown that the interfacial strength of electroless nickel/electroless palladium/immersion gold (ENEPIG) is more robust than that of ENIG.[35]

It is also useful for press-fit as the Pd and Au offer some lubricity to the system which results in a slightly lower force needed during the press-fit process.

47.5.6 Immersion Silver (Imm-Ag)

This electroless silver-plated surface finish is in common use for Sn-Pb assembly and is also compatible with the most common Pb-free solders. Although it is has excellent solderability and good electrical test probe-ability, it has some negative attributes. Its solderable shelf-life is reasonable if stored properly (air-tight bags), but it readily combines with sulfur contaminants in the atmosphere and tarnishes (sulfidizes). Silver sulfide is somewhat resistant to weak organic fluxes as used for no-clean soldering. This makes it a poor choice for manufacturing locations where air pollution is prevalent and heat and humidity are not controlled within acceptable standards of practice.

A failure mechanism called “Planar micro-voids” or “champagne voids” associated with this surface finish has been reported.[36–38] These are small voids aligned atop the intermetallic layer of a solder joint bond line that impart diminished bond strength and resultant solder joint fracture (Fig. 47.4).

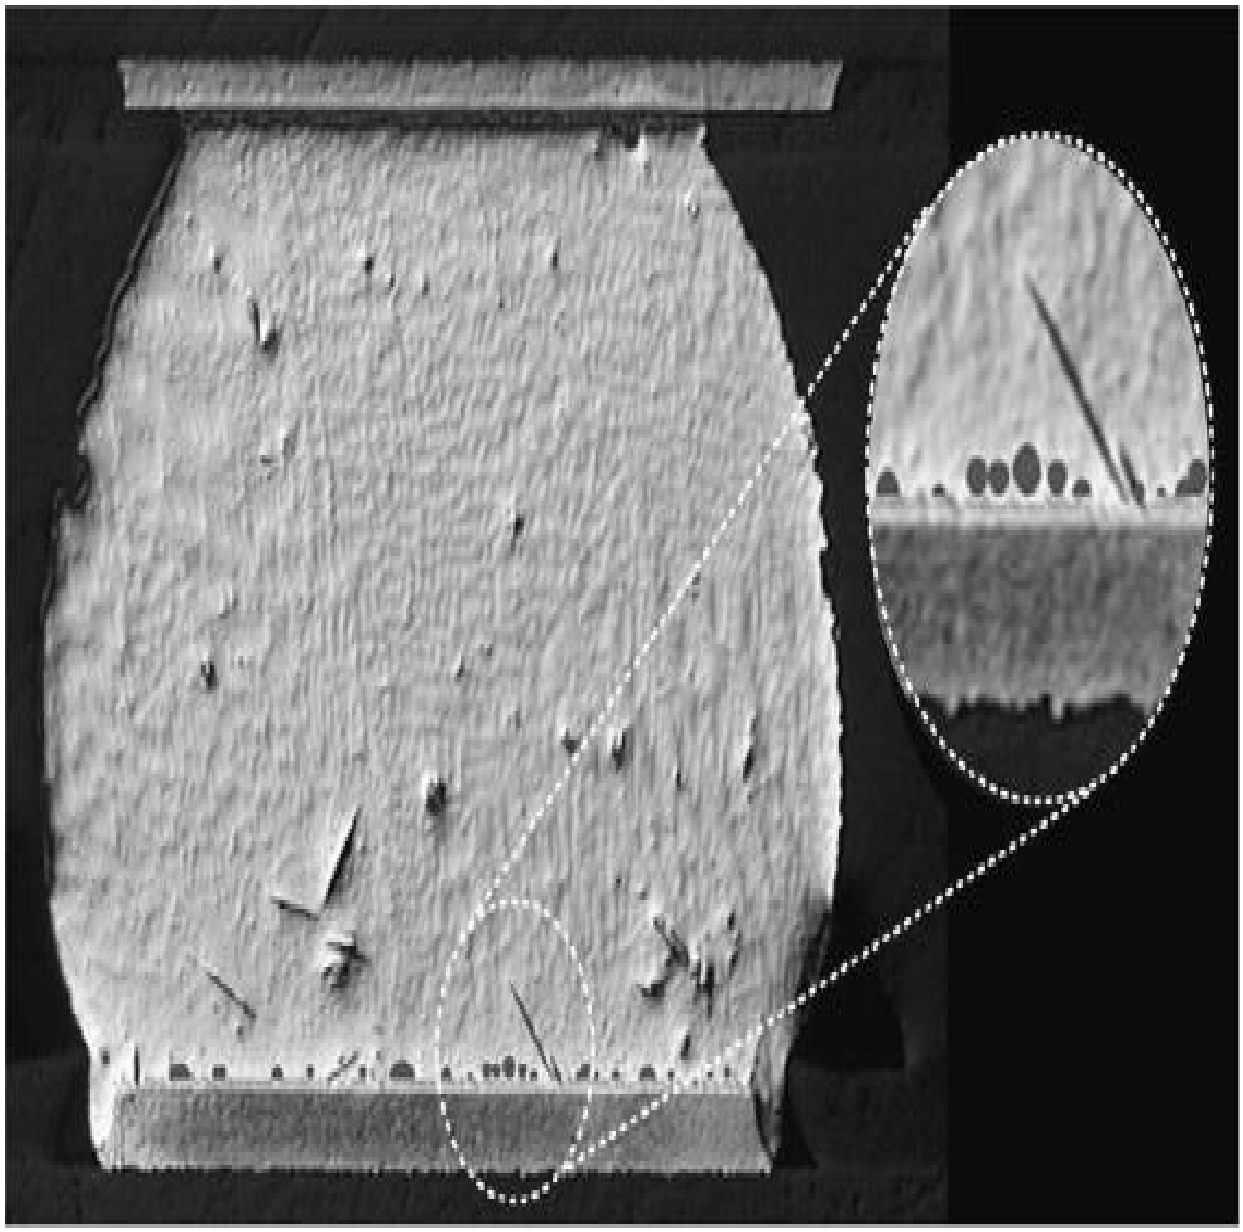

FIGURE 47.4 Cross-sectional micrograph of SAC BGA solder ball bonded to a silver surface finished PCB bond pad. Planar voids are clearly evident in the section and in the magnified inset. Voids in close adjacency above the intermetallic layer and the BGA ball can significantly detract from the solder joint strength. Note the Ag_3Sn platelets evident in the cross-section. These can occur from the immersion Ag or from Sn-Ag-Cu itself. They too can contribute to weakened solder joints. (*Courtesy of Hewlett-Packard*.)

This defect has been responsible for some noted product failures and recalls. The root cause of the microvoids is

generally believed to be the result of volatile organics incorporated during Ag plating at the board shop.

Silver ions are known for their mobility especially in the presence of an electrical field. Ionic residues on a board with silver-coated surface finish together with adsorbed moisture from the atmosphere can result in electrochemical migration and corrosion dendrites originating from any exposed, unalloyed silver plating (Fig. 47.5).

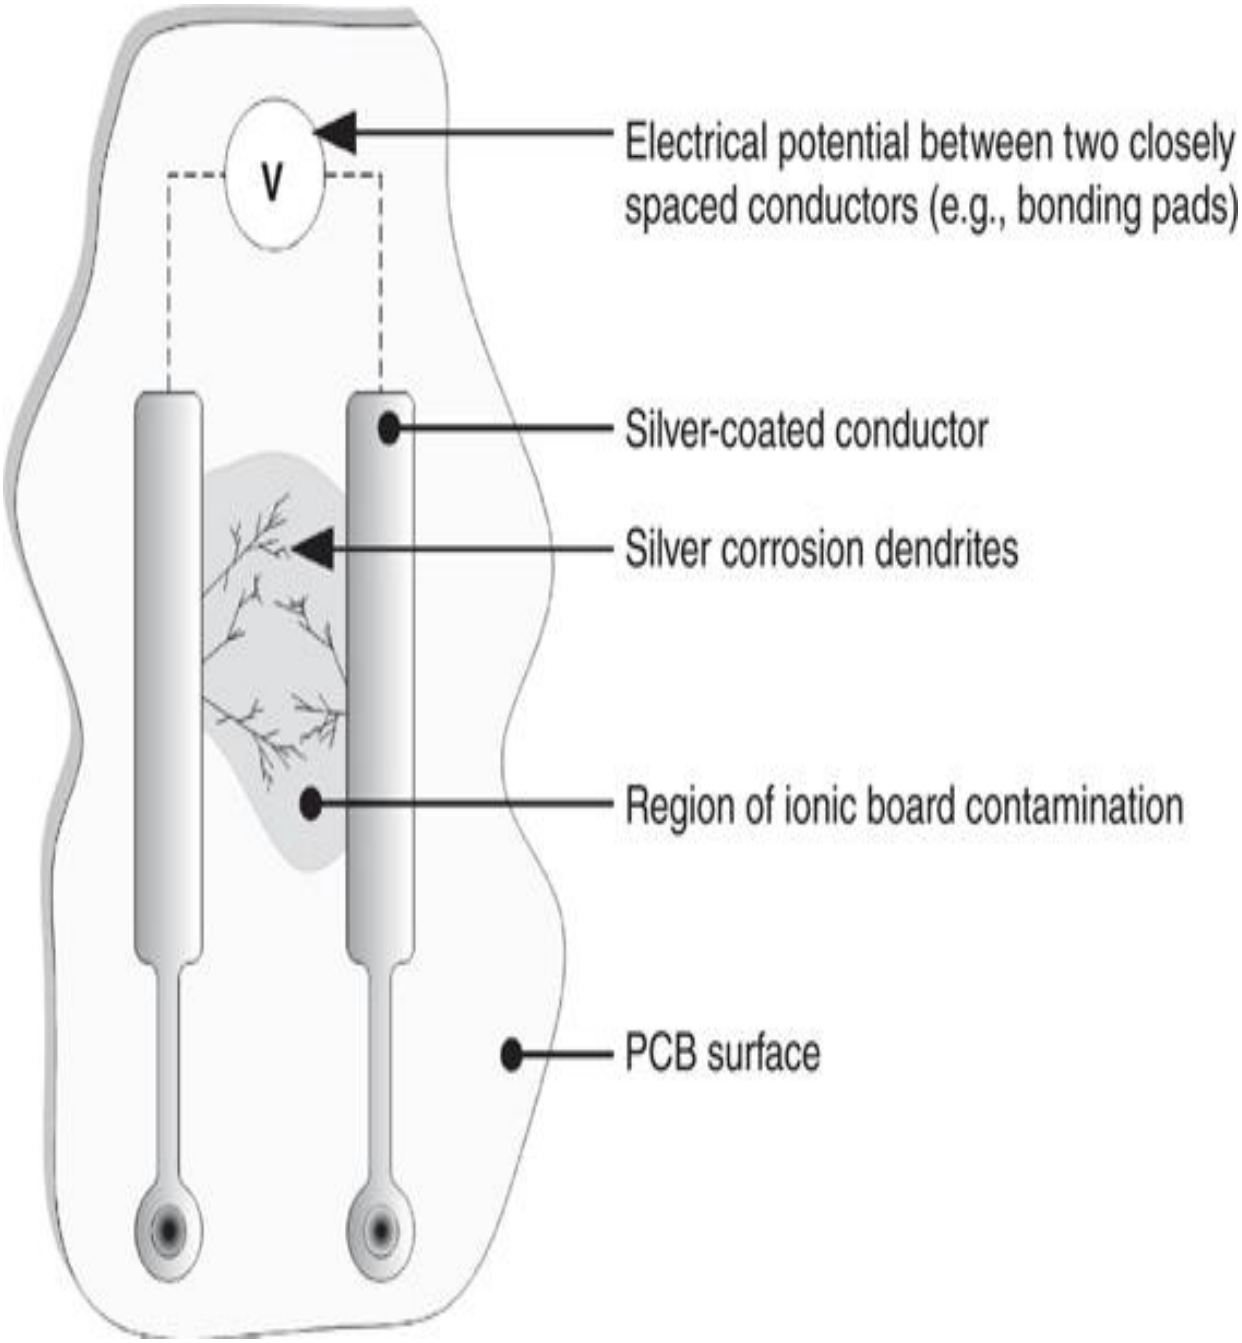

FIGURE 47.5 Ionic contamination on a board surface can adsorb moisture from the atmosphere. If an electrical charge is present, silver from bond pads may corrode and electrochemically migrate, resulting in a short circuit between bond pads.

Such dendrites not only occur on the board surface but can also develop under solder mask. If the dendrites are long enough, they cause electrical shorting to one another or to

adjacent traces. Since corrosion dendrites are exceptionally small in cross-section, they are poor electrical conductors and if enough current is passed, dendrites heat and fuse. Once melted back, the once-shorted circuit will become open again. If moisture and contaminant conditions are favorable, corrosion dendrites may re-form again once again resulting in an electrical short. This cyclical growth-and-fuse phenomenon can complicate locating and diagnosing the source of the shorting. Additionally, the shorting may cause surface carbonization around the dendrite; the carbon tracks acting as another source of electrical shorting.

Silver is an expensive metal. With its increased demand for solders (e.g., Sn-Ag-Cu), it is expected to rise in price, making it economically less attractive.

47.5.7 Tin (Sn)

Tin deposited directly over copper, whether by electrolytic or electroless methods, should be avoided except for low-end/low-cost, short-field-life products. Sn alloys with copper, even at room temperature, forming a brittle intermetallic compound, albeit slowly. It has limited solderable shelf-life at room temperature and the Sn-Cu intermetallic inhibits soldering and may result in incomplete solder wetting or solder joints of inferior strength. For tin to be used effectively, an appropriate nonporous barrier metal, such as Ni, should be deposited between oxide-free Cu and Sn. Immersion Sn can be plated only as a very thin layer since its deposition is by a self-limiting replacement reaction. When there is no more exposed Cu on the surface of the PCB during the surface-plating operation, Sn deposition ceases. Therefore, it is impossible to plate enough Sn by this method to extend the solderable shelf-life of the bond pad. When fresh, tin has good solderability, but tends to oxidize quickly.

There are two important phenomena that are associated with Sn platings: tin whiskers and tin pest.

47.4.7.1 Sn Whiskers. Not to be confused with corrosion dendrites, whiskers are crystallites (Fig. 47.6) that grow from pure tin surfaces into free space whereas corrosion dendrites grow on ionic contaminated, hydrated surfaces between two charged conductors. Corrosion dendrites are metals which plate out of areas of salt contamination whereas whiskers are born out of solid-state crystal mechanics. Although whiskers have been studied since the 1940s, their root cause is yet to be fully understood.

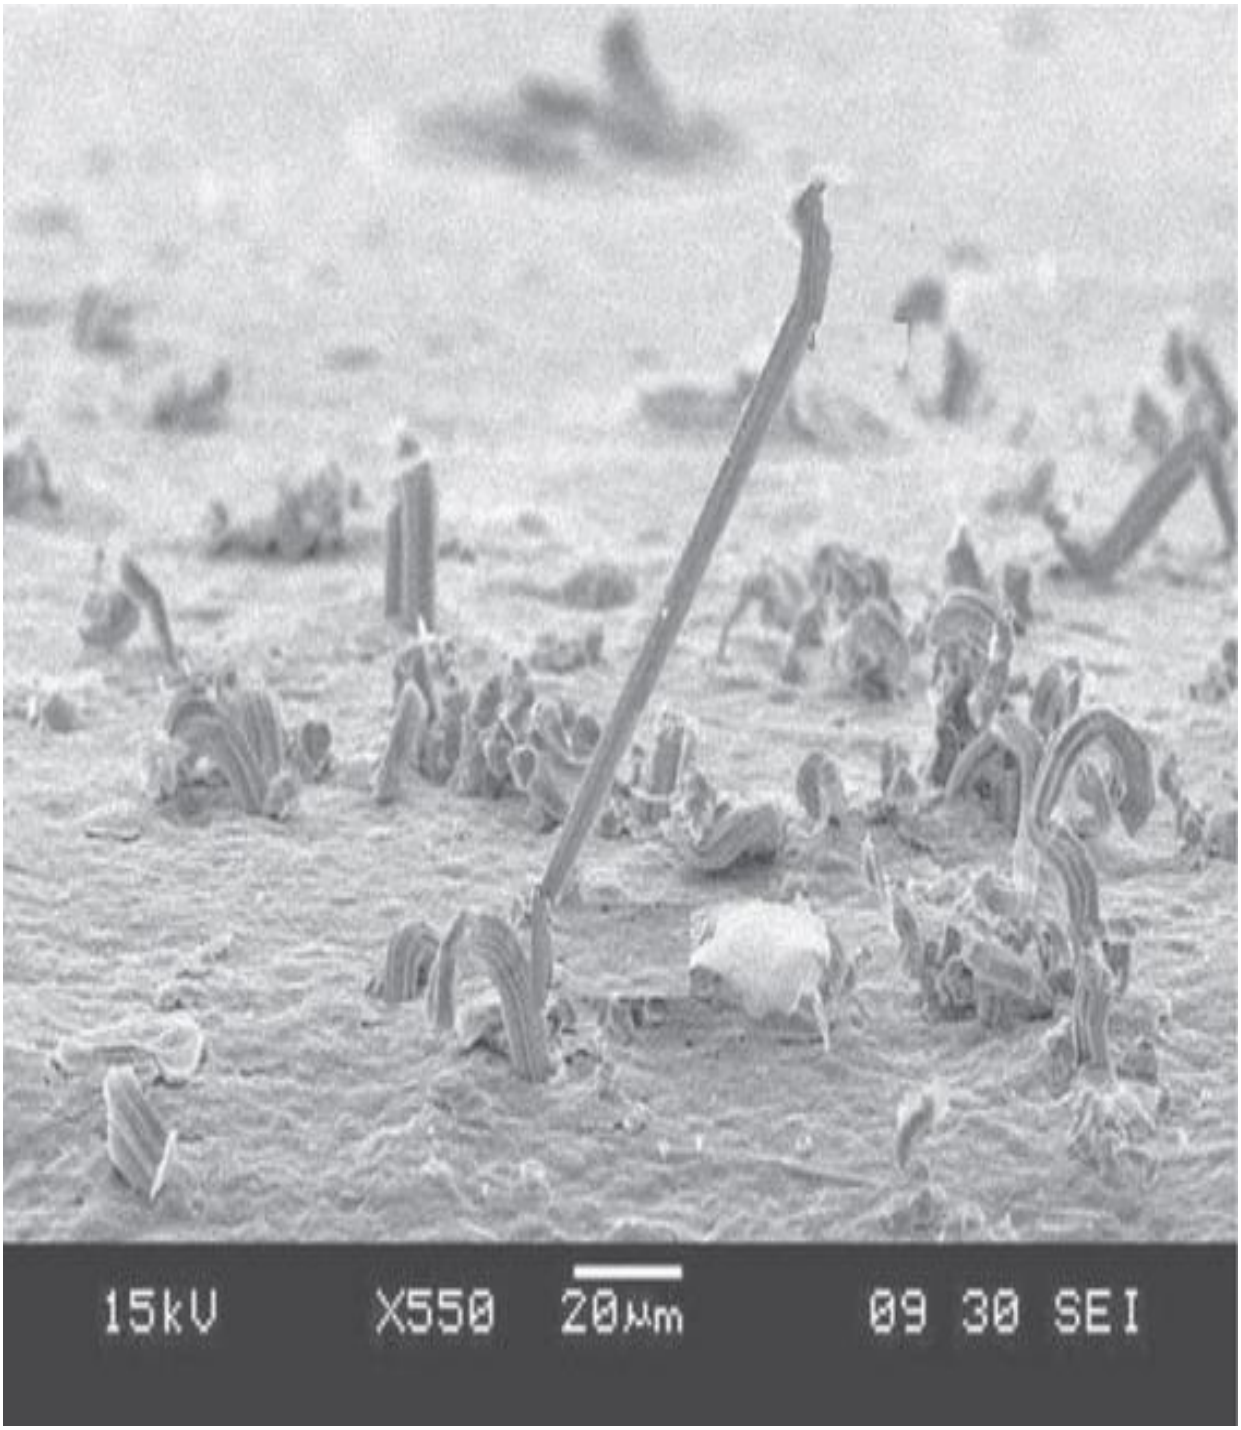

FIGURE 47.6 Scanning electron microscope (SEM) micrograph of Sn whiskers growing from a pure Sn surface. When whiskers break, they pose danger of shorting between fine-pitch conductors. Whiskers can also grow long enough to bridge to a nearby conductor. (*Courtesy of H. Hsu, Mitac Corporation, ShunDe, China*.)

The concern over whisker growth is twofold, both related to electrical short circuits. If a tin whisker is long enough, it may break due to mechanical shock, vibration or other perturbation. The broken whisker may bridge two closely spaced contacts or traces on a component or PCB. Whiskers need not break to cause a short circuit, as they can grow long enough to bridge two adjacent, closely spaced conductors. In 1998, the in-orbit Galaxy IV communications satellite failure was traced to tin whiskers.[39] Spare boards for that satellite stored on Earth clearly showed whisker growth in sufficient length and quantity to have caused the problem. It is ironic that the first known electrical-related whisker issue occurred in 1946 on Bell telephone equipment, which caused another telecommunications disruption.

Although tin whiskers have been studied since at least the 1940s, there is no definitive known mechanism for their formation, although theories abound. There are lattice dislocation theories and grain boundary diffusion theories. But the most prevalent theory for whisker generation relates their origin to compressive stresses within the tin lattice and perhaps weak spots in the overlying natural oxide on the tin surface. Where tin and copper are in contact with one another, copper is found to diffuse into tin faster than tin into copper. This causes a disruption of the tin lattice and resultant compressive strains. When tin grains are compressed against each other, and particularly when there are large compressive forces against a small, near-surface grain, the small grain may start to recrystallize or extrude in the least stressful direction, outward through a weak spot in the native oxide layer (Fig. 47.7). Growth continues until the lattice energy reaches equilibrium. Tin whiskers can grow to a diameter of approximately 1 μm and their length can reach tens of micrometers.

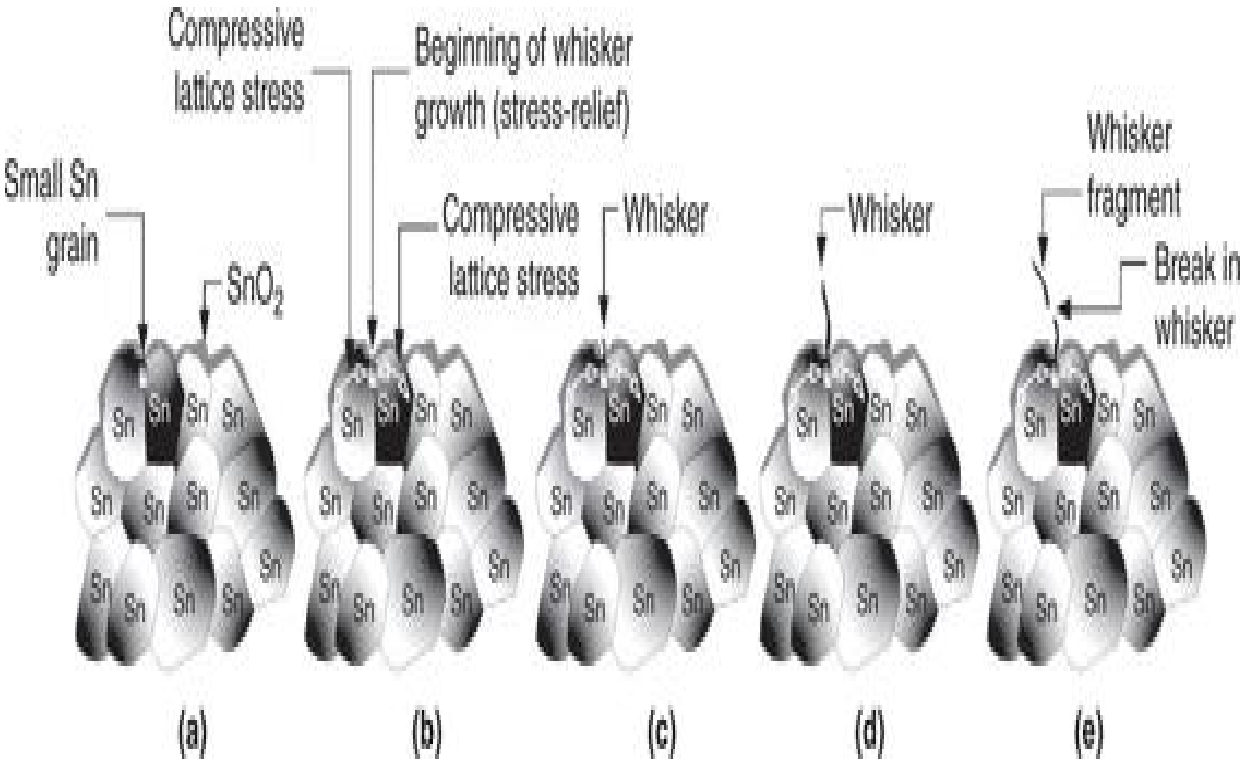

FIGURE 47.7 Compressive stress within the tin lattice may cause whisker formation. The picture sequence depicts a likely mechanism for tin whisker growth and risk to printed circuit assembly: (*a*) tin lattice with small, near-surface grain between two large grains; (*b*) compressive stresses cause recrystallization of grain and stress relief by extrusion; a thin spot in the oxide layer allows the rudimentary whisker to penetrate the surface, (*c*) continued whisker growth/stress-relief; (*d*) continued growth; if long enough it may pose a shorting hazard; (*e*) whisker breaks due to mechanical shock, vibration or handling. Whisker fragment poses a shorting risk to circuitry.

When Pb is even a minor constituent in Sn alloy the likelihood of whiskers diminishes. The resulting lead-doped tin lattice imparted some compliance, reducing Sn grain compressive forces to the structure and reduced the risk of tin whisker formation. The same has been noted for Bi or Sb. Now that Europe's RoHS legislation restricts Pb to a level of less than or equal to 1000 parts per million by weight in electrical and electronic assemblies, the addition of Pb is no longer considered an option for whisker prevention or reduction. The increased use of Sn-coated component terminals and Sn as a PCB surface finish has renewed the interest in Sn whiskers. Additionally there has been an

upsurge in the number of observed whiskers now that Pb has been removed from the assembly equation.

Matte Sn plating over a thick, nonporous nickel barrier layer over the copper reduces, but may not eliminate Sn whiskers. The relatively thick nickel deposit is generally under tension and the tin diffuses into the nickel faster than nickel into the tin. Since the nickel exerts no compressive influence on the tin lattice, tin whiskers are less likely to form. Besides metallic dopants, there are other ways to mitigate the growth of tin whiskers. Brighteners in tin-plating baths should be avoided. Annealing tin coatings is known to reduce whisker growth as recrystallization minimizes lattice stress. Ensuring that the reflow temperature during PCA soldering is above the melting point of tin (232°C) reduces whisker risk also.

47.5.7.2 Tin Pest (Tin Disease). In addition to risk from whiskers, tin also poses another, though rare, problem in some applications involving low temperatures. At about 13°C, tin undergoes a crystalline structure transformation. The ductile, tetragonal crystal of white (β) tin converts to the brittle, diamond-structured allotrope, gray (α) tin. Since gray tin has less density than white tin, there is an expansion of the tin lattice upon transformation and the tin starts to fall apart, turning to a gray dust.

Use of pure tin coatings should be avoided as a surface finish for low-temperature duty. The transformation is most profound at −40°C but will occur, albeit more slowly, at temperatures below the allotropic transition threshold. As in the case of tin whiskers, tin pest has been combated with the addition of a dopant metal such as bismuth, antimony, or lead. Lead addition, however, is no longer an option due to the RoHS directive and similar mandates.

It has been conjectured that on Napoleon’s army was victimized by tin pest.[40] Tin-soldered, brass uniform buttons may have fallen apart during the harsh winter of the Russian

campaign, hastening the defeat of an already beleaguered and hypothermic army. Tin pest has also been reported in the context of Pb-free soldering.[41]

CHAPTER 48
SOLDER FLUXES

Gary M. Freedman
Colab Engineering LLC, Stow, Massachusetts

48.1 INTRODUCTION TO FLUXES

In a simplistic sense, the soldering process model is generally treated as solid and liquid metals interfacing with a gas (the soldering ambient). However, realities dictate a modified view. Nearly all metals oxidize when exposed to air and these oxides, whether on the solder itself or on the metals to be joined, always impede soldering. To keep the solder and surfaces to be joined bondable, metal oxides, tarnishes or other contaminants must be removed and bonding surfaces must be kept clean, tarnish-free and oxide-free until soldering is complete. To this end, a chemical fluxing agent has been used from ancient times to now and is essential to the process of joining. Fluxes are tailored to both the metals to be joined and soldering process temperature. Some metal oxides such as aluminum and nickel are notably thick and chemically unreactive, which make soldering difficult. Even copper oxides can be tough to

dissolve. Most fluxes used in printed circuit assembly are acid-based, formulated to be strong or weak depending on the metal systems to be joined, post-soldering treatments, and reliability needs.

Fluxes are typically composed of high molecular weight organic materials that are slow to dry, slow to evaporate, and slow to decompose as they approach soldering temperatures as well as acids. The acids are tailored to etch, dissolve, or disrupt oxides and tarnishes on solder and surfaces to be joined. Both the absence and presence of liquid flux have an effect on the extent of solder wetting. Some fluxes can transition from a runny liquid during preheat to a viscous liquid or gel and ultimately to a gummy solid as it dries out, polymerizes, and decomposes during the soldering cycle.

48.2 FLUX FUNCTIONS

Selection of the flux type depends on the soldering method, solder alloy, metal finishes on the board and on components, condition of the surfaces to be joined, requisite solder joint attributes, reliability requirements and the intended final use of the assembly. Some fluxes leave benign residues formulated to remain on the board. Flux residues may be difficult to clean, interfere with in-circuit test (ICT) probing or may hinder subsequent processes such as conformal coating or under-fill adhesive application. Postprocess flux deposits can cause corrosion, especially in the electric field between closely adjacent conductors on the surface of the PCB. Fluxes may impart gas bubbles, or voids, which may be “frozen” into the solidifying solder (Fig. 48.1).

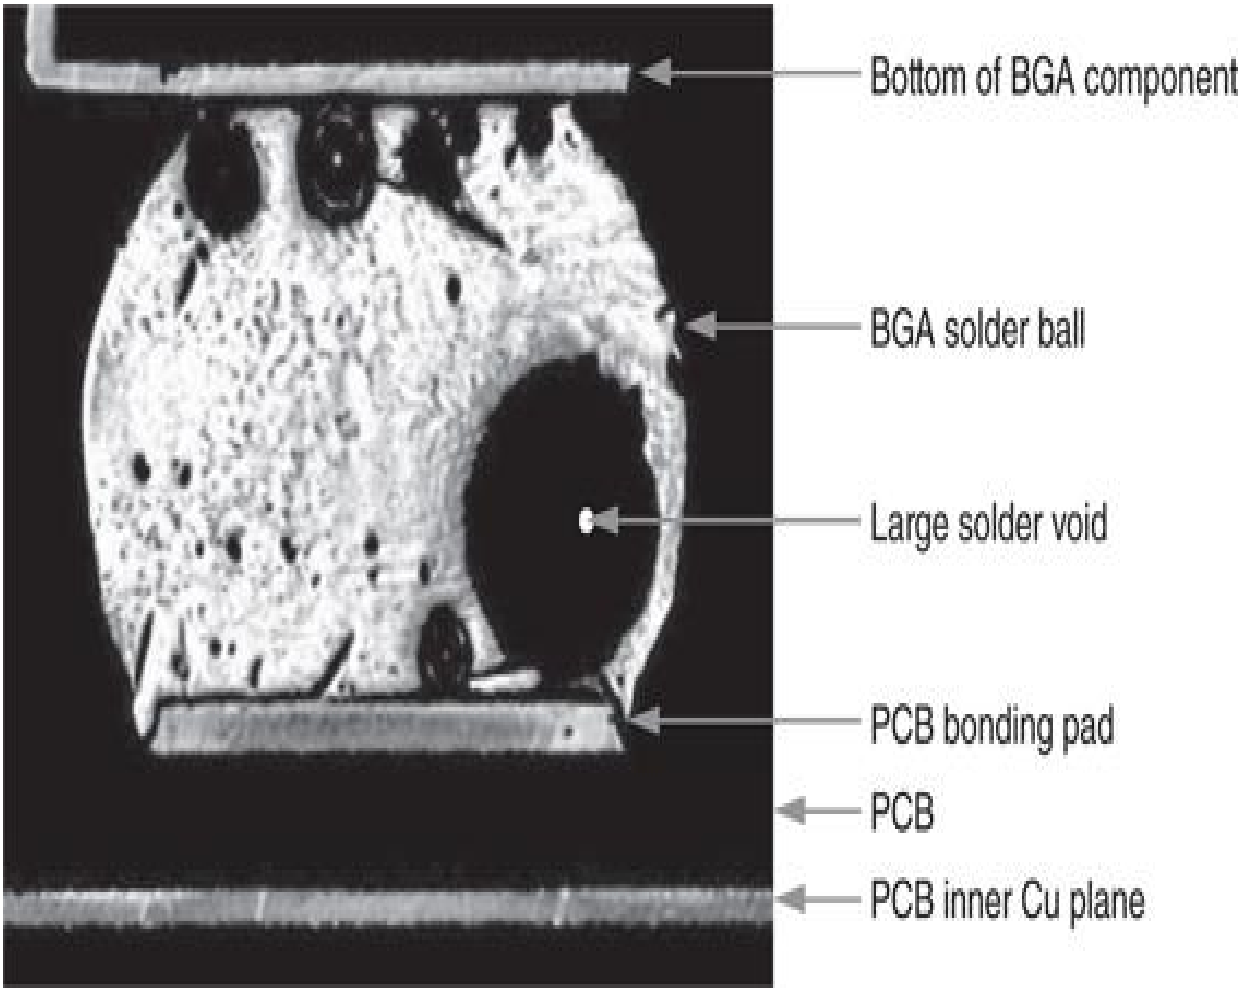

FIGURE 48.1 Metallographic cross-section of BGA component ball soldered to a PCB. Dark areas are solder voids; gas pockets frozen into the solder. Solder voids, if large enough or in abundance, may detract from solder joint reliability. (*Courtesy of Hewlett-Packard*.)

Resultant voids may detract from the mechanical strength if they are large enough, are in abundance, intersect bonding surfaces, or are in close proximity to one another.

48.2.1 Oxide Removal

The primary role for flux is oxide or tarnish removal from the metal surfaces to be joined. This includes oxides from the surface of the solder. In order for metals to alloy, the essence of soldering, each metal to be alloyed must be in contact

with one another. The metals must be free of any nonmetallic coatings including oxides, other coatings or contaminants. Flux is formulated primarily for dissolving oxides and tarnishes.

48.2.2 Reoxidation Inhibitor

Once the metal surfaces are denuded of oxide, they must remain that way until the soldering process is complete. Fluxed metal surfaces are chemically unstable, vulnerable to reoxidation if in an air environment, therefore the organic chemical constituents of fluxes are formulated to coat, protect and retard metals from reoxidizing until the soldering process is complete. If the solder flux is exhausted or overheated before or even after oxide stripping and prior to the onset of solder reflow, reoxidation would occur and solder joint formation would be impeded.

Solder fluxes are formulated for the high temperatures encountered during soldering. Were the flux to denature (polymerize or char), the byproducts would inhibit solder wetting. It is of utmost importance to follow the flux manufacturer’s guidelines for time and temperature during soldering for each flux or solder paste. Process optimization should be confined to the working limits (time-temperature) of the flux or solder paste.

48.2.3 Contamination Removal

Another role for flux is to disrupt and dissolve any organic contaminants on the surfaces of the metals to be joined. The organic solvent composition of the flux is appropriate for this. Fluxes are either alcohol-based or water-based, in either case they are composed of organic chemicals suited, not only to eliminate metal oxides, but to dissolve oils (e.g., body

oils) and other common contaminants that may be on the surfaces of metals to be joined.

48.2.4 Thermal Spreader

In some forms of laser soldering, the flow of hot flux may help to preheat leads and pads, readying them for solder joint formation. In the case of hot-bar soldering, a pool of liquid flux may help to even out thermal disparities over the length of the heated bar.

48.3 FLUX DELIVERY METHODS

Fluxes can be delivered in many different ways. For surface mounting, solder paste is used. The paste is a mixture of pure solder spheres, a fluxing agent and other materials to adjust rheology for efficient stencil deposition of the solder paste on printed circuit board (PCB) solder lands and also to endure the rigors of surface-mount oven reflow process. In wave soldering, a liquid flux is sprayed or otherwise applied to the secondary side of the board before preheat and soldering steps. In hand-soldering, the flux can be an integral part of the solder wire, which has flux-filled lumens within it (Fig. 48.2).

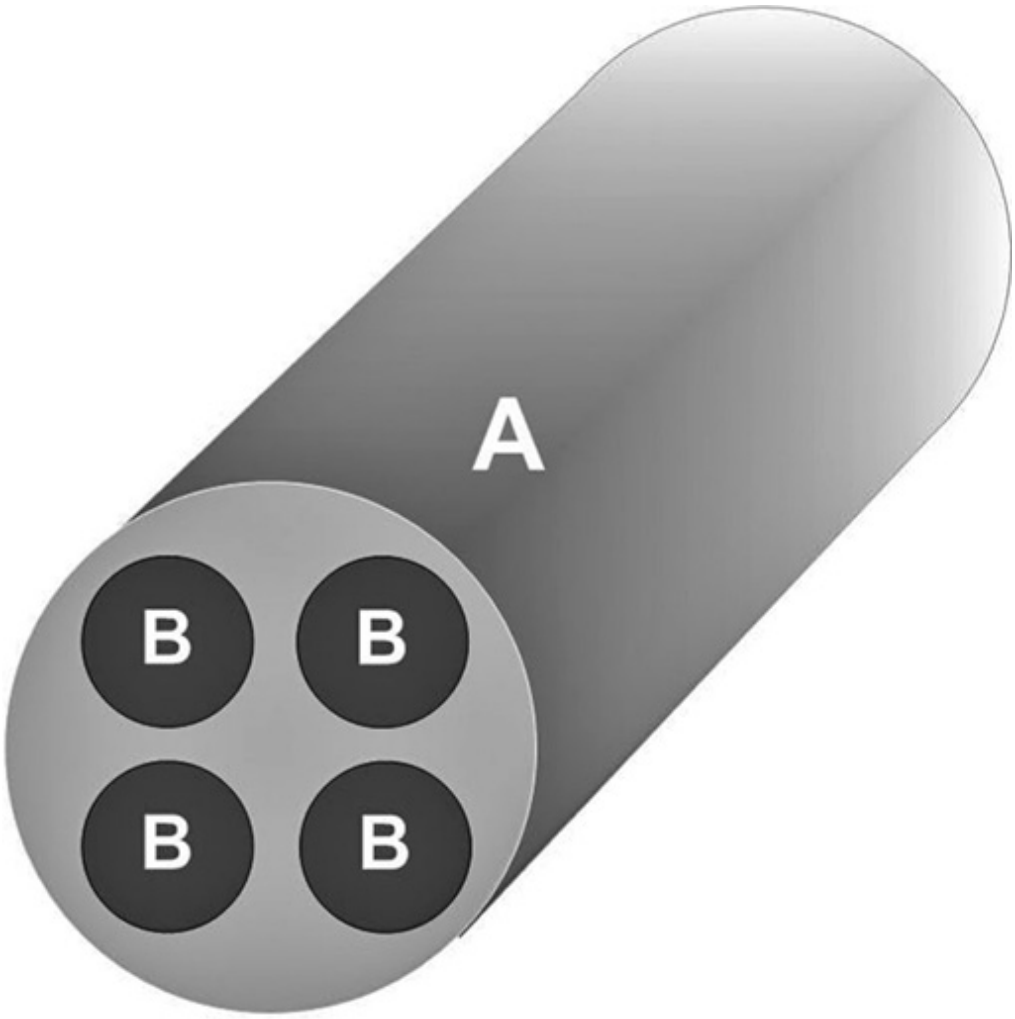

FIGURE 48.2 Schematic of a section of solder wire: (A) solder wire, (B) flux-filled lumens within the wire. The lumens extend the full length of the solder wire.

As the solder wire is heated and melts, the flux is released to do its job. For touch-up applications, a minute quantity of paste flux (a thickened gel) can be applied with a pick. Liquid flux for repair can be delivered through the use of a fine-tipped felt pen meant for flux application. Use of a dropper is discouraged as it generally dispenses too much flux and that can be a problem as discussed later in this chapter.

Not only can flux be dispensed as a liquid or paste, but it can even be delivered as a gas. Gaseous fluxing is rarely used but is gaining popularity especially in IC device manufacture because of its effectiveness and lack of residue.

This technology will be discussed briefly as it has been demonstrated to be applicable to PCB assembly.

48.4 FLUX ACTIVITY AND ATTRIBUTES

A flux's ability to prepare a surface for soldering is dependent on its chemical strength or *activity*. Just like reagents on the chemistry lab bench, there are various concentrations available. A flux may be naturally strong or it may have additives to enhance its reactive power. These additives are referred to as *activators*.[1] Activators accelerate the fluxing action either by direct chemical contribution or by catalysis. The activator can be an inorganic or organic material and combines with other ingredients in the flux, or decomposes with temperature to form an acid that is effective for oxide removal. Halogens, amino-halides, organic acids, and other materials are common activators. As the flux is heated, the activator begins its work. Flux heating for the soldering process has to be tempered for the particular type of flux formulation and solder system. Some activators may decompose if heated too quickly. Others may not be effective for a long enough time for the soldering process. Weaker fluxes (flux + activator) may require a longer preheat time and higher temperature in order to have sufficient chemical activity to remove oxidation and tarnish from parts to be joined as well as from the solder. Flux selection must be appropriate for the materials to be joined, the solder alloy melting temperature as well as for the type of soldering process. The solder chemistry chosen will greatly influence the process time-temperature profile required for the soldering process.

Like most chemical reagents, a flux's reactivity is in part a function of the exposure time and the temperature; many

exhibiting Arrhenius-like behavior, where time-dependent chemical performance increases sharply with temperature. Some fluxes are weakly active at room temperature, but most require a significant thermal assist to enable them to be useful. Ultimately the only valid test of flux performance is whether the system works for the types and conditions of printed circuit boards and components and process equipment for the soldering process. A more active flux may be needed for low melting point solder, especially if manufacturing demands high throughput for this process step. In this case, the flux will not have the benefit of longer exposure times and higher process temperatures to assist in its job of oxide or tarnish removal. Higher-temperature solder alloys require fluxes that can withstand the rigors of the required thermal process. The flux must not volatilize or decompose too rapidly nor polymerize or char at temperatures commensurate with bonding. Some metals are more prone to oxidation than others. Bismuth and zinc used in solder, and copper on circuit boards are notable examples that may require a more active flux. An inert environment is helpful in augmenting flux performance.

48.5 FLUX: IDEAL VERSUS REALITY

The ideal flux would be one that is potent, requires only a small quantity and leaves little or no residue. If it does leave a postprocess residue, the deposit would be thin, transparent, nonreflective, easily penetrated by in-circuit test probes, electrically insulating and chemically inert. If the residue is not inert, it should be easily and completely removable in an inexpensive solvent. However, this is far from reality of actual materials and process.

Flux must be applied in sufficient quantity for thorough oxide removal and to avoid both metal reoxidation and flux

exhaustion prior to solder wetting. Some post-soldering flux residues may have deleterious effects on the final circuit assembly since they may be chemically reactive and result in corrosion of exposed metals over the long term. The corrosive agents can be electrically conductive causing electrical leakage (soft shorts) between closely spaced, oppositely charged conductors on the circuit board surface. In reality, these residues are hygroscopic adsorbing moisture from the atmosphere further enhancing residue mobility and corrosiveness. Corrosion may be augmented either by natural electromagnetic force (EMF) couples between two different metals or driven by an imposed charge between two closely adjacent conductors. In either case, electrochemically driven metallic ions can plate out as metal dendrites on the once insulating, now contaminated surface of the board and produce intermittent or even persistent hard short circuiting (Fig. 48.3).

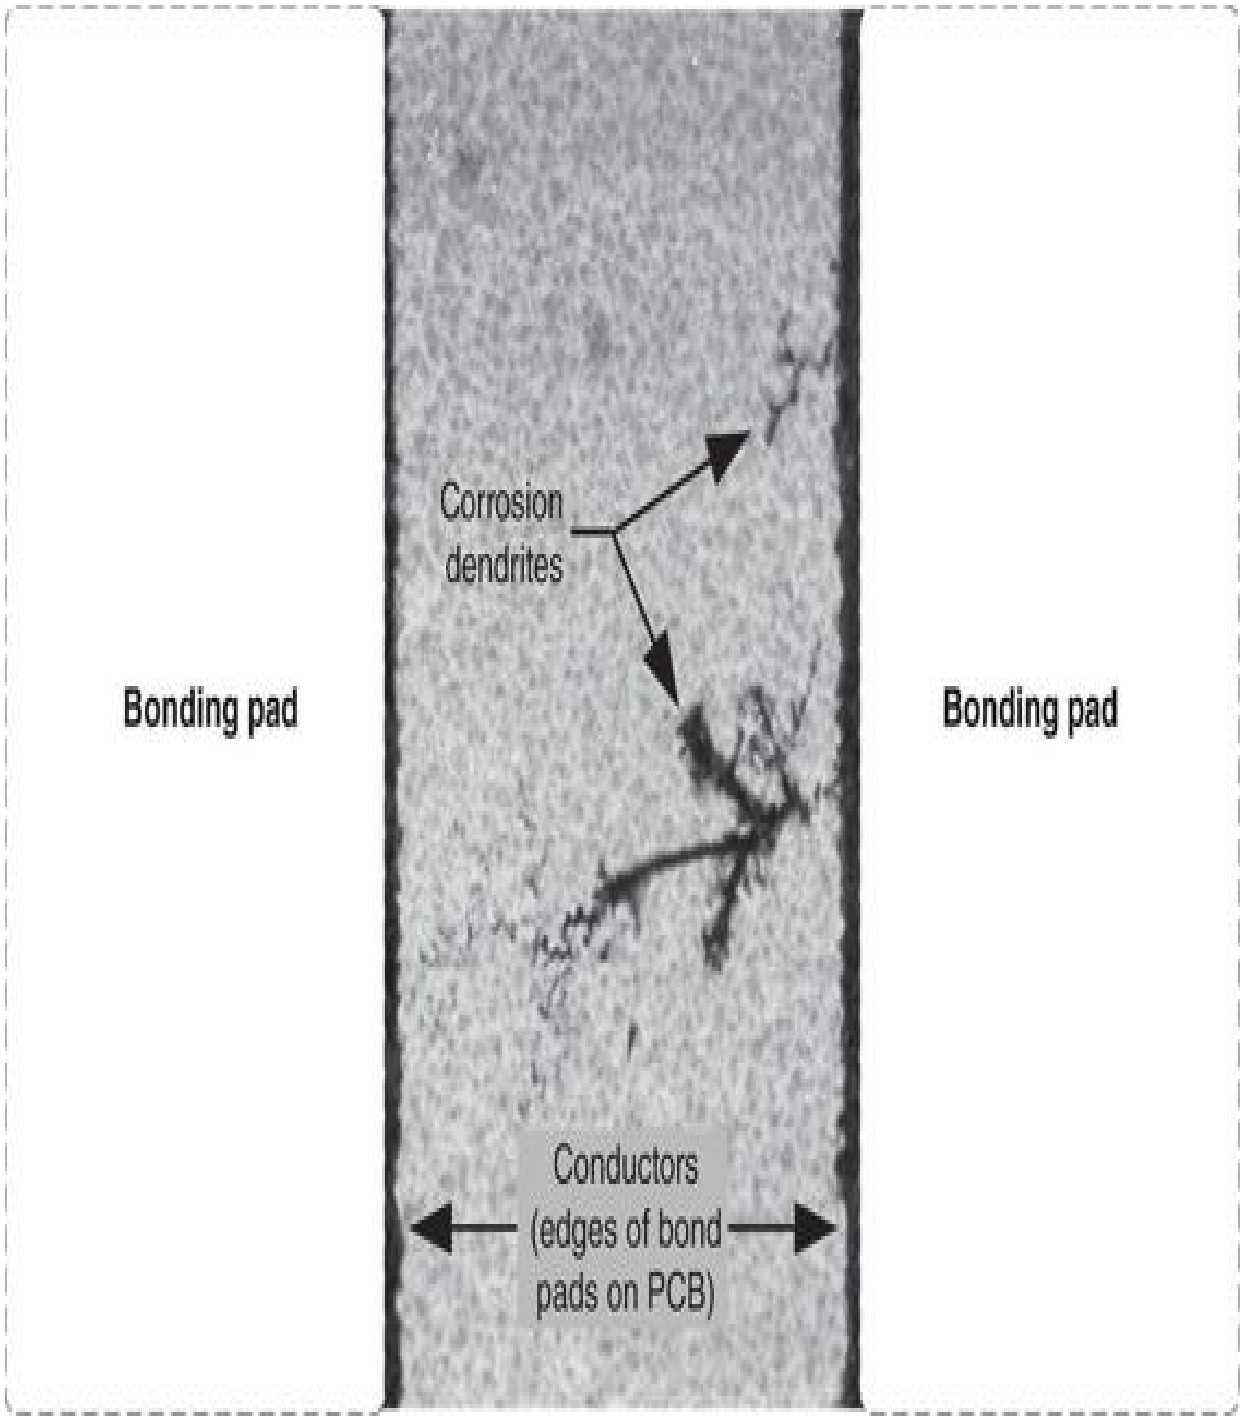

FIGURE 48.3 Corrosion dendrites caused by corrosive, hygroscopic flux residues. The dashed lines delineate the bonding pads. The corrosion dendrites are growing from the bonding pads across the PCB surface. (*Courtesy of Hewlett-Packard*.)

Flux must be heated to a temperature which allows the best reactive conditions while avoiding dry-out or

denaturation. For the sake of economy and cleaning, a thin application is necessary and should be confined to the bonding site(s) of interest.

48.6 FLUX TYPES

The 1989 adoption of the Montreal Protocol[2] imparted far-reaching changes to electronics manufacturing. In the circuit board assembly arena, it drove the elimination of chlorofluorocarbons (CFCs) and the reduction of volatile organic compounds (VOCs) for earth's ozone layer preservation. Many fluxes that used volatile organics such as alcohols were reformulated to use water as their solvent. Solvent-clean fluxes, which required nonaqueous cleaning chemicals [alcohols, CFCs and, hydrochlorofluorocarbons (HCFCs), etc.], were practically eliminated from the marketplace.

Today only two flux categories are in widespread use for PCB assembly: water-clean (aqueous-clean) and no-clean. The former leaves a residue that must be removed from the printed circuit assembly (PCA), otherwise, corrosion will occur. The latter, as the name implies, leaves a benign residue that is meant to remain on the circuit board. In fact, some no-clean residues perform as a conformal coating shielding the board from moisture and atmospheric contaminants. The choice between water-clean and no-clean has a profound effect on the process and may also affect subsequent process steps and long-term reliability. Both can be effective oxide strippers for soldering, but there are several considerations for choosing and using the proper flux.

48.6.1 Water-Clean (Aqueous-Clean) Fluxes

Also referred to as aqueous-clean flux or organic acid (OA) flux (a misleading term, because most fluxes are organic acid-based), this category contains the most aggressive fluxing agents used for large-scale commercial circuit board assembly. They are formulated with strong organic acids, inorganic acids, amines, amino salts, or often a weak organic acid fortified with reactive materials such as halogen salts (Br^-, F^-, I^-, Cl^-) that further acidify the flux. For this reason, as the name implies, this type of flux requires an aqueous wash step to remove any trace of reactive residue in order to avoid corrosion on the PCA.

Many of the water-soluble solder pastes are hygroscopic as are their residues. This property impacts solder paste or flux shelf life and the solder paste's physical attributes during printing. Of course any residue left on the PCA will affect the assembly's reliability. Most solder pastes are thixotropic; that is, they shear-thin as they are being squeegeed onto the board, becoming thinner with use. Generally, pastes are formulated to limit the degree of thixotropy. In addition to thixotropic thinning, water-clean solder pastes, when exposed to a humid atmosphere, pick up moisture, which further thins paste rheology. As a paste becomes runnier, solder paste stencil deposition becomes more difficult to control and tack (flux's stickiness as required for holding components in place), and slump characteristics (ability of paste to hold its printed shape) can be adversely affected. Ironically, some of these same organic acid solder pastes are prone to dry out in a low-humidity environment; a condition which also frustrates solder paste stencil deposition. Always check paste manufacturer recommendations for optimal temperature and humidity regimes for storage and use. Localized control of air temperature and humidity within the

printer enclosure or factory-floor air conditioning (temperature and humidity) control are necessary to preserve solder paste rheological characteristics for ease an reproducibility of printing.

48.6.1.1 Cleaning Process. PCB cleaning of unwanted flux residue consists of more than a dip in a tank of water. Generally commercially available conveyorized wash tunnels are used for effective removal of the reactive residue from the soldered PCA. Such equipment can be many meters long and may have numerous zones consisting of cold-water spray nozzles, hot-water spray nozzles, and hot-air drying. Some systems may incorporate sumps where the board is briefly submerged for a short time to enhance residue dissolution. High-purity (deionized) water is recommended to enhance washing and eliminate or minimize corrosion. Saponifiers are sometimes injected into the water stream to target organic residues and convert them to water-soluble entities. Following the saponification step, thorough rinsing with pure water is required to remove traces of the saponifying agent, which may be corrosive.

48.6.1.2 Component Compatibility. Not all components are compatible with the water-wash process. Circuit board mounted switches are notable in this regard. Even some switches sold as “environmentally sealed” or “water-wash compatible” have been found to leak during the high-pressure wash spray or submersion steps of aqueous cleaning. High pressure water jets may force water past the seals of the so-called “sealed” switches. This can result in failure of the switch to work properly (the water causes an electrical short within the switch) or, if there is enough ionic content in the wash water or in the switch itself, switch contact corrosion may occur in the long term.

Many circuit assemblies are very dense with parts. The higher the part density, the less effective aqueous cleaners

are. Like stones in a stream, the water swirls around them and eddy currents of relatively stagnant water form behind the stones. Components on a circuit board act in the same way, as they block the free flow of water and impede proper rinsing even in the most turbulent water spray systems. Many components have low clearance beneath them, inhibiting rinsing effectiveness. In the case of pin-grid arrays (PGAs), ball grid arrays (BGAs), ceramic column grid arrays (CCGAs), ceramic ball grid arrays (CBGAs), etc., the water's path is further frustrated by the presence of solder joints beneath the component. Increasing I/O count, increased package size, and decreasing space between the PCB and component underside make water washing all the more difficult. The same issues hold true for chip-scale packages (CSPs) where the headroom is little more than a capillary and good wash-water exchange is difficult to achieve. High-density, multi-row connectors are also difficult to rinse. To counteract this, aqueous wash machines have multiple spray nozzles directed at board surfaces in several directions and angles. All of the preceding are equally difficult to dry. Water beneath components or within components may interfere with in-circuit test or functional test results immediately following aqueous cleaning; the water causing shorts between adjacent circuit elements. Water from aqueous wash has been known to enter unsealed integrated circuit (IC) encapsulant fill/vent holes and cause electrical failure of the IC by shorting (Fig. 48.4).

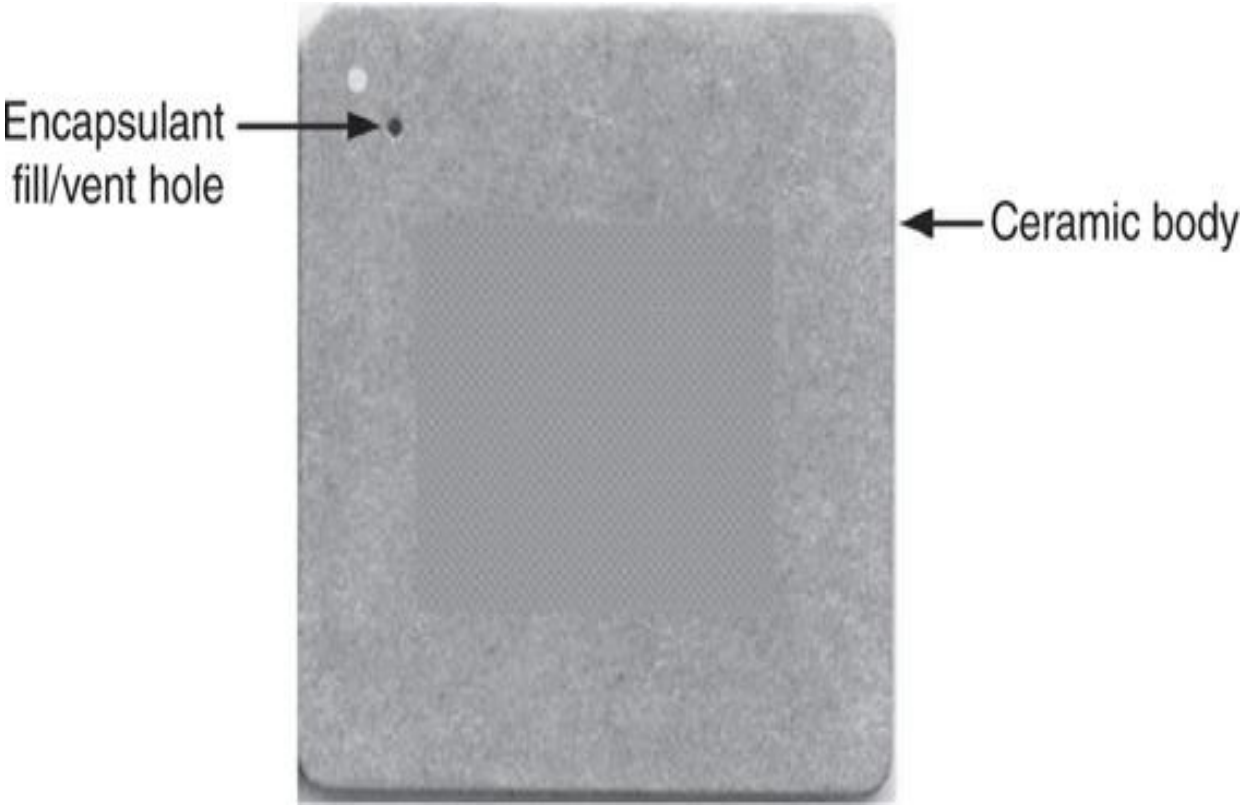

FIGURE 48.4 Top view of Ceramic PGA. If water enters an improperly sealed encapsulant fill/vent hole on an IC package, shorting or corrosion can occur within the IC package. (*Courtesy of Hewlett-Packard*.)

***48.6.1.3 Manufacturing Impact of Water-clean Process*.** There are several significant issues to consider when using water-clean fluxes and decisions are dependent on the specific parts and final product:

- *Expense:* Key financial costs include: capital equipment (washer, water treatment system); factory floor space; installation; utilities (water, compressed air, electricity); staff (operational, maintenance, training); maintenance (repair, routine). Aqueous washers are expensive and require a large footprint on the manufacturing floor. Depending on product throughput, multiple washers may be needed. Generally, high-purity, deionized water is used instead of tap water to enhance rinsing effectiveness and to minimize corrosion or shorts caused by tap water particulates or ionic species such as chlorine or fluorine as

found in treated public water supplies or even leachate from metal piping (e.g., copper, iron, lead, tin). Most aqueous systems are installed with closed-loop water systems where the water is purified onsite and reused. Regardless of reuse, some water has to be replaced due to evaporation (heating and atomization) and for rinsing of the ion exchange beds.

- *Additional process steps as compared to no-clean processing*. Washing represents several additional handling steps, and with each handling step comes risk to the board. Due to the force of the water jets in the cleaning machine, boards (especially smaller ones), are put in baskets or carriers to go through the water-wash process. This involves additional materials (baskets/carriers) and handling. There is ample opportunity to knock parts off the board during loading or unloading of these baskets. Occasionally tall parts (such as surface-mount capacitors) or miniature parts with fragile solder joints are blown off the board by the force of the water blast or solder joints can be cracked for the same reason impacting reliability. Boards that somehow escape the water-wash process or were not washed sufficiently will develop corrosion in short order.
- *Additional labor:* Besides the need for additional operators to load and unload the conveyorized wash machine, increased maintenance is required for the aqueous cleaning machine, deionized water system, and waste-water treatment.
- *Environmental impact:* The deionized water system requires frequent monitoring and filter replacement. Solder fines washed off the PCA must be filtered from the waste-water stream, and dissolved metals and other species harmful to the environment should be monitored and removed when the concentration reaches a critically high concentration before releasing spent water to the drain.

This process is not suited to geographies with water shortages, water restrictions, or poor-quality water, or where the cost of water is high.

- *Component compatibility:* As mentioned previously, some circuit board components may not be compatible with aqueous cleaning.

48.6.1.4 Benefits of Water Washing. There are significant benefits to using water-clean fluxes, but the decision involves trade-offs and must be made based on the specific needs of the parts and the product:

- *Unimpeded inspection:* PCAs that have gone through a proper aqueous cleaning process are easy to inspect because there is no flux residue on the surface to interfere with solder joint inspection by eye or automated optical inspection devices.
- *Best adhesion for conformal coating:* Some boards that are intended for harsh environments rely upon a coating of silicone, epoxy, or other material to enhance their resistance to moisture and airborne contaminants. Such treatment when applied thinly is called conformal coating (as opposed to encapsulation). Aqueous cleaned boards provide the best surfaces for adhesion of these coatings and for encapsulants (thick polymer coatings) also.
- *Recommended for use with under-fill compounds:* For added solder joint reliability, epoxies or other adhesives are sometimes dispensed under certain critical components to anchor them to the PCB surface. Aqueous cleaned PCBs will provide the best surfaces for adhesion of under-fill compounds.
- *Possible electrical implications for RF circuitry:* Flux residues can interfere with high-speed circuit conduction by changing top surface dielectric properties and increasing parasitic capacitance.[3] It is for this reason that

radio-frequency (RF) circuitry is often specified to be assembled using water-soluble fluxes.

48.6.2 No-Clean Flux

Boosted largely by cost, floor space, and environmental concerns, no-clean fluxes now dominate printed circuit assembly. This class of flux is generally composed of rosins (e.g., natural acidic plant residues such as pine pitch) and/or resins. Often, but not exclusively, the term *resin* is used to denote a manmade rosin analog.

Historically, pine sap (*colophony*, as it is referred to in older publications) is the most notable natural product used as a flux. Once extracted from the tree, the pine rosin is purified and neutralized to remove excess acidity imparted by the extraction process and dissolved in alcohol. Termed *water-white rosin*, the key fluxing agents are a mixture of abietic and pimaric acids. Water-white used to be the basis for many commercial flux offerings.

Rosin is a solid at room temperature, is water insoluble and can be dissolved or partially dissolved in alcohols. During the soldering process, the alcohol or other volatiles in the flux begin to evaporate and the rosin-based solids precipitate. The solids soften at low temperatures (50 to 70°C) and begin to flow, covering the surfaces to be fluxed. With higher temperatures comes higher reactivity and oxides and other tarnishes are stripped from metal surfaces, including from the solder, readying surfaces for solder wetting. The most widely used fluxes today are resins but act in the same fashion. Generally weak organic acid activators such as succinic, malonic, and adipic acids are added to increase the reactivity of the flux. These, too, volatilize or decompose during the reflow cycle and only a clear polymerized, noncorrosive residue is left on the board. If the process is conducted properly, the remaining deposit is relatively inert

and can remain on the PCB; hence the term *no-clean*. The best additives are ones that will not evaporate or decompose too early in the heating cycle but will completely volatilize or decompose at or near the peak temperature of the soldering process.

Halogenated activators should be avoided with No-clean chemistries. Some high-temperature organic acids may not completely volatilize or decompose, so reliability testing of the flux residues should be conducted to ensure that corrosion will not negatively impact product reliability. Besides adding activators, one can boost a flux's chemical reactivity by increasing the rosin or resin content, but the higher the rosin/resin content, the heavier the post-soldering flux residue. Pure rosinic residues, especially from high-rosin content formulations, are benign, hydrophobic, and electrically insulating, but they tend to be thick and sticky.

48.6.2.1 Benefits of No-Clean. No-clean advantages include lower manufacturing costs through fewer process steps, less board handling, less maintenance, and reduced floor space than is required for PCB assembly via water-soluble fluxing. There are also environmental benefits of no-clean, as there is almost no significant waste effluent other than from the solvent within the paste or flux that evaporates during the process and from solvents used to clean the stencil, squeegee blades, and any misprinted boards; the same stencil-related cleaning steps as needed for the water-clean process. This represents an extreme reduction in waste stream to the environment as compared to the use of water-soluble paste and flux equivalents. Most no-clean formulations are now VOC-free making this class of chemistries even more attractive from an environmental perspective. Such pastes and fluxes are generally compounded with a water-soluble solvent instead of an alcohol.

48.6.2.2 The Negatives of No-Clean. Before talking about the negatives of no-clean, it should be understood that the no-clean approach to circuit board assembly is widely embraced and is the mainstay of the industry. Any negatives of this technology are counterbalanced by major process, reliability, cost and environmental benefits. No-clean is impractical for only a small number of niche soldering applications.

48.6.2.2.1 Difficulty of Inspection. No-clean residues, especially from surface-mount technology (SMT) soldering, are generally hard, transparent polymerized deposits that interfere to some degree with solder-joint inspection. The flux deposit may crack upon cooling and sometimes operators will mistake the cracked flux residue deposit for solder joint cracking. The residue is also reflective, which can interfere with visual inspection or automatic optical inspection (AOI) methods.

48.6.2.2.2 Decrease in Barrel Fill at Wave Soldering. Since no-clean fluxes are weaker than water-soluble flux formulations, wave soldering is a somewhat less robust process. Poorer barrel fill is generally found with no-clean fluxes, although in most cases subtle changes to the wave solder machine configuration and wave solder time-temperature profile are sufficient to gain excellent or acceptable plated through-hole (PTH) barrel fill with No-clean flux at wave soldering.

48.6.2.2.3 In-Circuit Test (ICT) Probe Noncontact. Much of the no-clean flux residue associated with wave soldering of the secondary side of the board is washed off by the molten solder during the wave soldering operation. Generally, ICT is accomplished by bed-of-nails testing where sharp spring probes contact dedicated test pads located on the secondary side of the board. Although test points are masked during wave soldering through use of a selective wave soldering pallet (shield), sometimes the liquid flux,

when dispensed to the secondary side for the wave solder operation, wicks between the pallet and the PCB (Fig. 48.5).

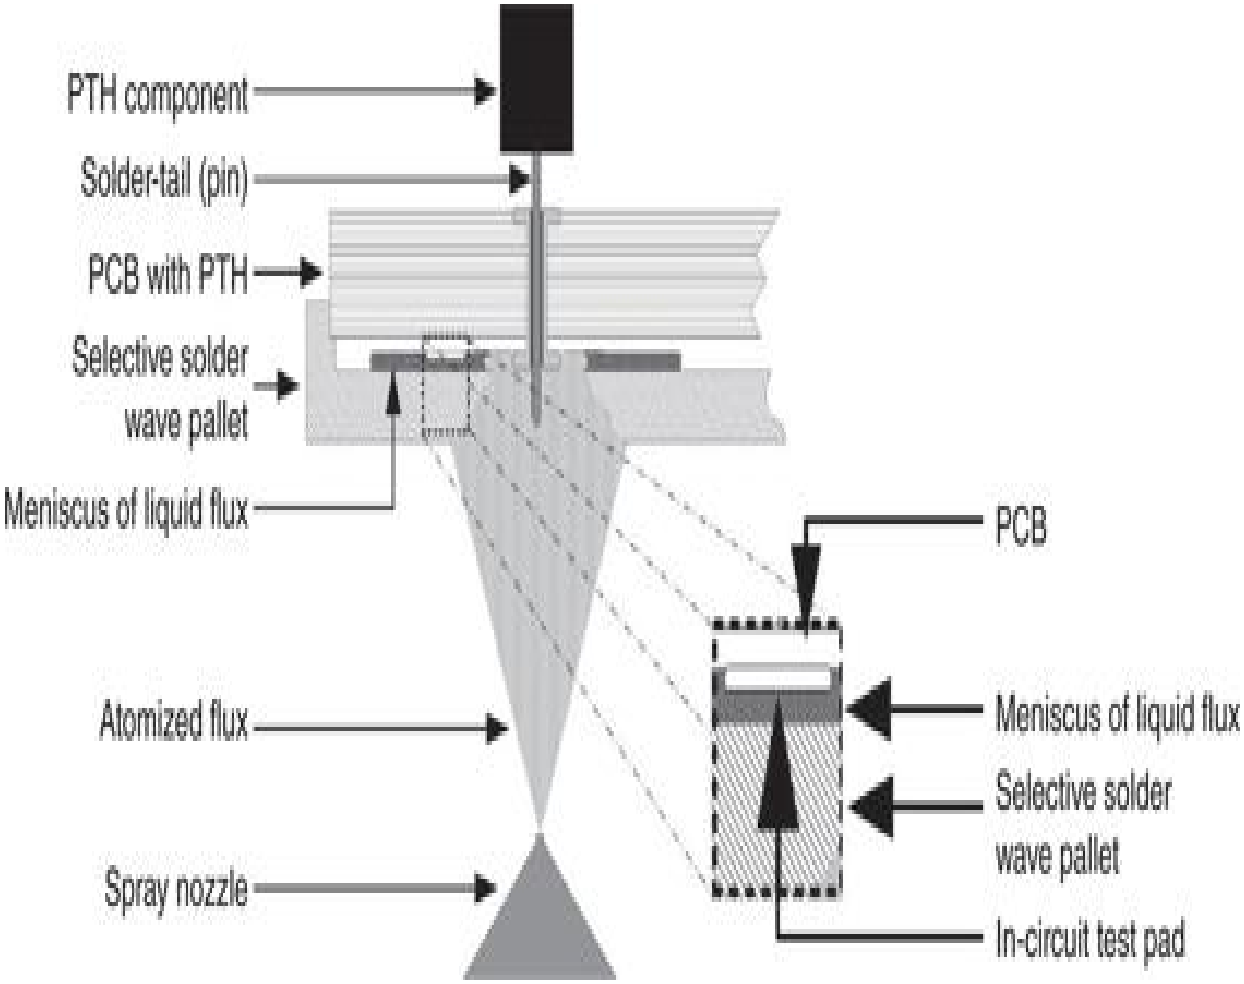

FIGURE 48.5 Spray flux wicked between the PCB and wave solder pallet forming a liquid meniscus covering an in-circuit test pad (see inset). Once run through the wave soldering process the flux will harden on the pad and interfere with ICT probe contact.

As the PCB is heated during the wave solder process, the flux hardens over the test pad and impedes post-soldering ICT probe contact (Fig. 48.6).

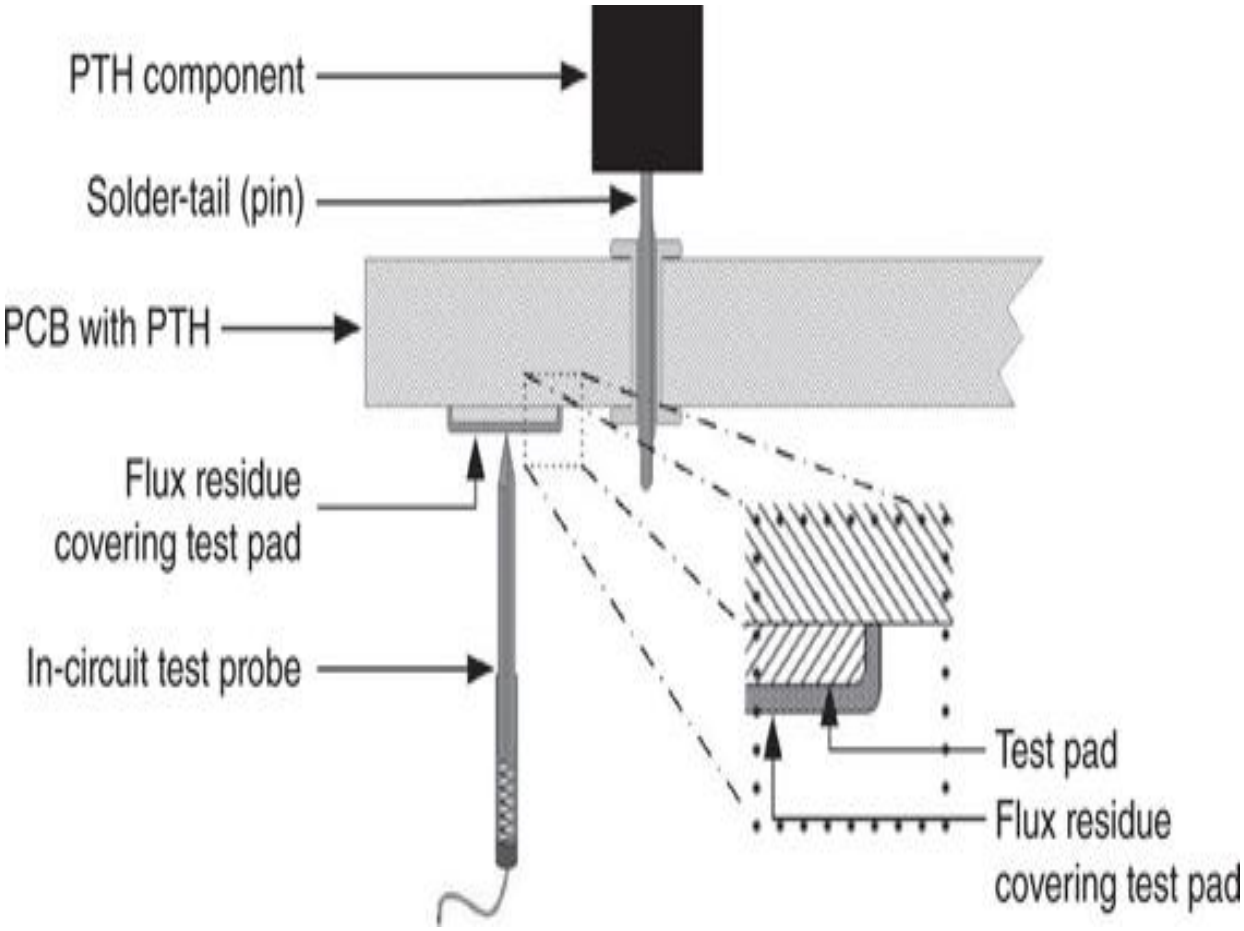

FIGURE 48.6 Hardened flux residue on test pad impeding ICT probe contact (see inset for detail). Even though the pad was shielded by the wave solder pallet, flux wicked in and hardened during wave soldering making probe contact difficult.

Without cleaning, these residues will persist. Adjustments to probe tip style and spring force may be necessary to overcome the noncontact issue. There are various types of test probes and different spring forces available. Generally, single-point probes rather than crown probes will have the best chance to penetrate hardened flux residue. With a single-point contact, point force is maximized rather than spread out over multiple points as would be the case with a crown-type probe. Using probes with high spring rates may cause the board to flex and damage solder joints or pierce through pads. Adjustment to the fluxing process, the wave

soldering process parameters or use of a different flux may help to eliminate this problem.

48.6.2.2.4 Not Recommended for Conformal Coating or Under-Fills. No-clean residue may inhibit adhesion of under-fills or conformal coatings. In fact, the flux residue may wick under a component and completely block an under-fill from entering the space between the board and the IC package to be under-filled. There are some new developments in this area and there are no-clean under-fill/flux combinations that may be effective.

48.6.2.2.5 Corrosion from Repair. Very often, even water-clean boards are repaired with no-clean formulations to avoid another aqueous cleaning step. Sometimes after a board is totally assembled, some hand-assembled mechanical components may not be suited for exposure to water. Although post-soldering no-clean residues are generally benign, care must be taken to minimize the flux dispensed during board repair. There is a chance that the pooled flux will not be fully heated (fully activated) and organic acids (activators) may not be driven off from the perimeter of the pooled flux (Fig. 48.7). If this happens, the flux will remain acidic and promote corrosion.

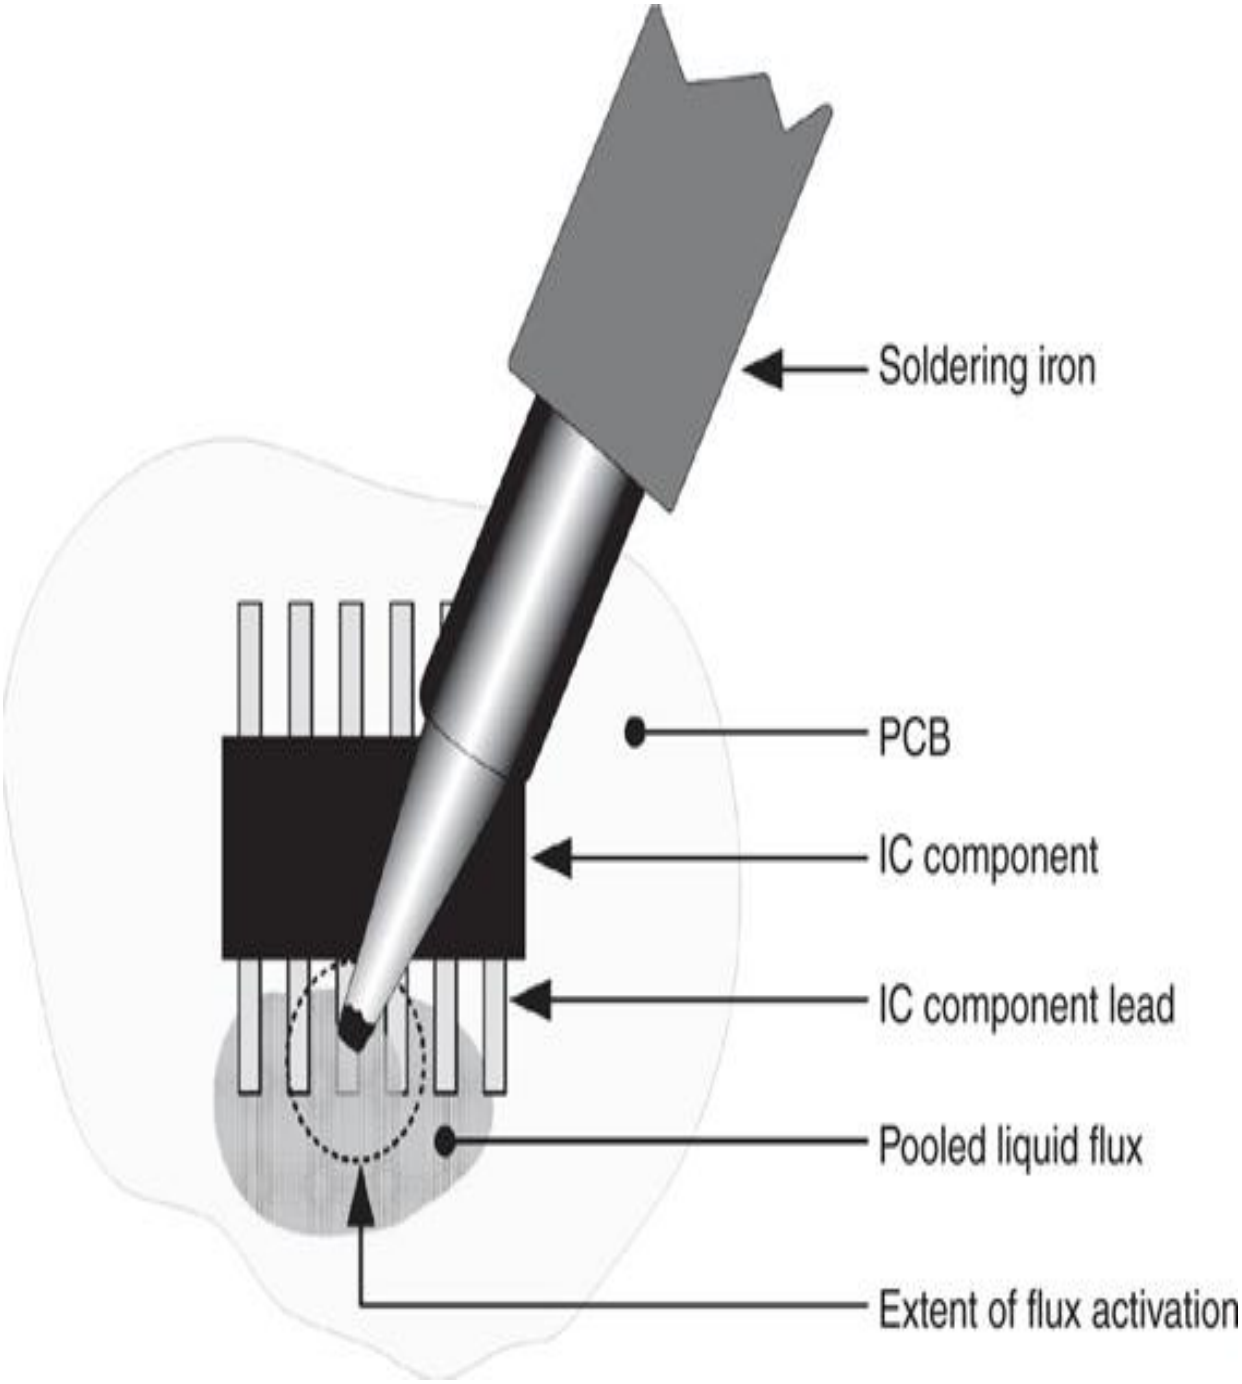

FIGURE 48.7 During repair a no-clean liquid or paste flux was dispensed and spread upon heating. Only the flux in close proximity to the soldering iron will reach sufficient temperature to be fully activated (within the dashed circle). If not fully activated, no-clean flux residue will be corrosive.

Follow these guidelines for use of no-clean solder flux:

- The use of flux-core wire guarantees that any flux for repair is fully activated.
- Use the smallest diameter flux-core solder wire for repair to minimize residue.
- If the use of flux-core wire is not practical, use the smallest amount of flux possible for each repair.
- Flux should be strictly confined to the area that is to be heated for repair.
- Dropper-dispensed liquid flux should be avoided. Liquid fluxes are prone to spreading and if not heated sufficiently any flux residue poses a corrosion hazard. Small amounts of liquid flux can be applied with an ultrafine, electrostatic discharge (ESD)-safe, felt-tip flux pen or artist brush.
- Use the smallest amount of paste flux as it too will spread upon heating and outer limits of pooled flux may not be fully heated (fully activated) and corrosion will occur. Minute amounts of paste flux can be applied with a fine pick or pin. Paste flux does not spread as much as a liquid flux. Once the heating begins, the paste will liquefy and spread but not to the extent of a liquid flux.
- Ensure that all the flux dispensed has reached a near-soldering temperature to drive off or denature any corrosives and render its residue less prone to corrosion.
- Use the same flux or flux from the same family for repair as was used for primary assembly of the PCB to avoid corrosion. Reputable solder flux manufacturers should be able to provide test data to show which fluxes are compatible with each other and which repair chemistries are compatible with which solder paste residues.
- Do not clean no-clean residues. Do the repair correctly the first time. Cleaning tends to spread flux residue. Often cleaning results in unsightly residues; much worse than was the original repair.

- Heating a repaired PCA in a box oven will activate any stray flux. Consult flux manufacturer for proper temperature-time range for activation. Ensure that all hand-assembled parts on the PCA will be compatible with the activation cycle.

48.6.3 Other Fluxing Caveats

Several general issues regarding fluxes must be considered before selecting one for a process and product.

48.6.3.1 Solder Paste Misprint Cleaning. When solder paste is printed in a manufacturing setting, occasionally the paste deposit is misprinted or smeared, requiring that it be thoroughly removed from the PCB before reprinting. Although this is not truly a fluxing issue, it does have ramifications to the process and reliability and is an important flux chemistry-related topic. The cleaning solvent may also diminish the effectiveness of OSP-copper coatings.

If the PCB has components mounted on one side while the other side is being printed, this too has implications for the misprint cleaning process. Here are some guidelines for accomplishing this:

48.6.3.1.1 Aqueous-Clean Solder Paste Misprint Cleaning

- A standard aqueous board cleaner or an aqueous stencil washer can be used for solder paste removal. DO NOT WIPE OR SMEAR THE PASTE. Allow the paste to wash off during the aqueous cleaning process.
- Ensure that all parts on the board are compatible with aqueous cleaning. Some surface-mount switches may not be compatible and may need to be removed from the board or masked to prevent damage from water leakage.

- If SMD placement has begun, remove any high-value components from the paste on the side that is misprinted or smudged.
- Do not wipe solder paste off the board, as this will force paste into vias, plated through-holes, and solder mask clearance areas. Once reflowed, any solid solder residues may interfere with PTH component insertion or press-fit operations (Fig. 48.8).

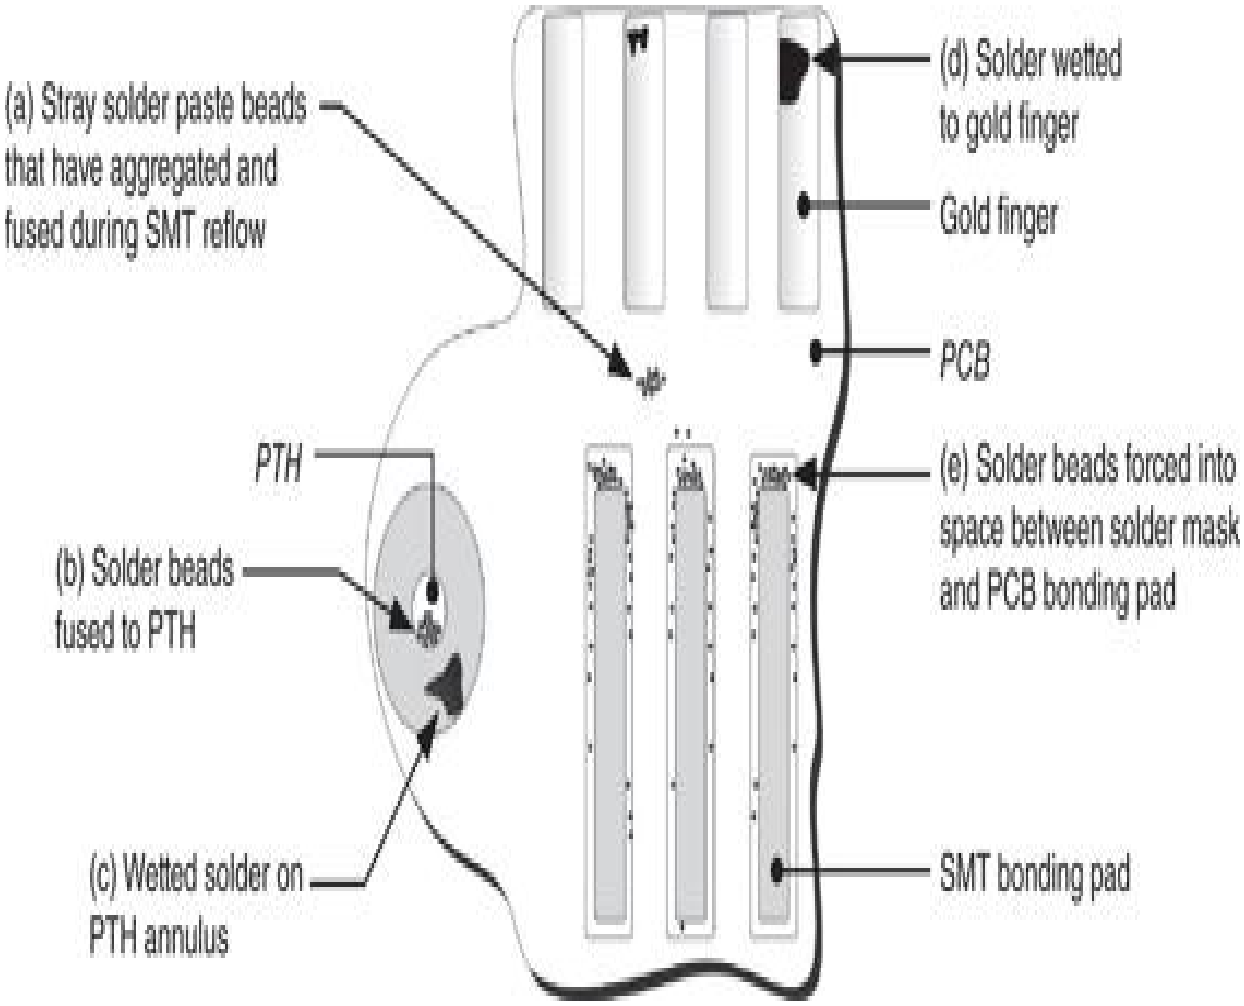

FIGURE 48.8 Common problems associated with wiping paste off of a solder paste misprinted PCB. Stray solder beads on the surface of the PCB (*a*) may weakly solder together and pose a shorting hazard. Solder beads fused to PTH (*b*) may prevent proper insertion of solder-tail. Stray solder on PTH annulus (*c*) may interfere with proper seating of PTH or press-fit component. Unwanted solder on gold fingers (*d*) may damage the mating edge connector. It may also result in an

unreliable contact in the long term. Solder beads swiped into the space between solder mask and bonding pad (*e*) may fuse and become a shorting hazard.

- If tape is used to mask gold fingers or other features, remove it before the commencing misprint cleaning to avoid entrapping solder beads or paste residue beneath the tape.
- Do not use a saponifier or solvents other than water unless the flux chemistry has been tested and qualified for compatibility and unless saponification or other solvent is in use with standard post-solder board cleaning.
- Do not use ultrasonic cleaners. Even random-frequency/random-amplitude ultrasonic cleaners may impact certain devices already mounted on the board (e.g., on the secondary side). Crystal oscillators are notoriously sensitive to ultrasonic cleaning. Other components have been known to degrade or fail as a result of ultrasonic agitation-induced damage to internal bonds or die attach.
- After cleaning, use a microscope with as high a magnification as is needed to see individual solder spheres from the paste. Ensure that stray solder spheres are not present, or, if they are, ensure compliance with the workmanship standard in use. Also confirm that paste beads are not agglomerated in plated through holes. Generally a ≥30× stereo-zoom microscope with good lighting is recommended for this inspection.
- If excess solder beads are still apparent, the board should be re-cleaned. Reposition the PCB in the cleaner rotating it 90° or 180° for the repeat cleaning cycle.

48.6.3.1.2 No-Clean Solder Paste Misprint Cleaning. Cleaning boards printed with no-clean paste requires a little more care, but most of the same rules apply as for removing paste from a PCB printed with water-clean solder paste. Generally misprinted boards are cleaned in the

same machine for cleaning stencils, using the same paste cleaning solvent as used for the stencil. In addition to the rules in the previous section, observe these for treating misprinted no-clean solder paste:

- If one side of the PCB has been soldered already do not use water to clean a no-clean soldered board unless the solder paste manufacturer recommends it especially. Mixing water with some no-clean flux residues may result in a sticky, white residue. Besides being unsightly, the hydrated deposit may impact electrical surface insulation resistance (SIR) and result in corrosion.
- Do not use saponified water with No-clean unless the process has been tested for materials compatibility and corrosion. SIR testing and electrochemical migration (ECM) testing should be performed to ensure that there are no destructive interactions.
- If using solder-preservative coated copper (OSP-copper), determine if the cleaning solvent has any adverse effect on the coating. Some solvents have been known to reduce the solder-preservative coating’s effectiveness.
- Direct immersion should be avoided. Immersion can cause cleaning solvents and diluted flux residues to enter previously mounted switches and other components. This, in turn, can result in an electrical short internal to the switch (from cleaning solvent conductivity), an open (from insulating flux residue), or corrosion (also from flux residue).

48.6.3.2 Mixed Repair Strategies. If a PCB has been soldered using a water-clean flux formulation, complete all solder repairs prior to a final cleaning using a solder flux chemistry compatible with the flux used for the original assembly. If the board requires repair after final cleaning it is common practice to complete the repair with a no-clean flux. This strategy precludes the need for another wash cycle. In

another situation, there may be parts that are added to the PCA after mass reflow such as electromagnetic interference (EMI) shields, enclosure pieces, heat-sinks and other mechanical or hand-assembled parts. These may not be compatible with an additional wash cycle as may be required for repair are accomplished with an aqueous-clean solder flux. This, too, necessitates the use of a no-clean repair strategy.

Once a board is repaired with a no-clean flux, it is imperative not to subject the board to an aqueous cleaning process for the reasons previously described (white residues, degraded reliability). Conversely, aqueous cleaning must be used if a water-wash flux chemistry is chosen for repair.

48.6.4 Test for Flux Compatibility

Certain no-clean fluxes are not compatible with each other. Their chemical interaction could result in corrosion on the PCA. To avoid corrosion issues, solder paste flux, wave solder flux, and repair flux should be tested separately and in combination for SIR and ECM for compatibility with each other and for compatibility with the board surface finish and solder mask.

48.6.5 Ensure Full Flux Activation of No-Clean Fluxes during Repair

As mentioned previously, it is important to heat no-clean flux sufficiently to activate it (make it chemically reactive) and to burn off the activators by the end of the soldering process. If an unactivated, insufficiently heated no-clean solder flux is left on a board, the weak organic acids in the flux residue often result in corrosion over the long term. Usually temperatures between 80°C and 150°C (depending on the

flux composition) are sufficient to activate a flux fully. To minimize the possibility of corrosion:

- Avoid pooling flux by banning the use of liquid fluxes or large quantities of paste flux for soldering iron-based repair.
- Dispense liquid flux sparingly by using an ultrafine artist paint brush, ESD-safe, fine-tipped felt fluxing pens or a bit of paste flux on a fine pick.
- Use finest diameter no-clean flux core solder wire to minimize flux deposition and for the best chance of reaching flux activation temperature. This is the only convenient strategy that guarantees full flux activation during repair. Flux-core solder wire is available in diameters less than 1 mm. Of course, flux-core solder wire cannot be used for area array device repair, but in that process flux is certainly fully activated by the soldering process.

48.6.6 Localized Solvent Cleaning of No-Clean Flux Residue

The need to remove no-clean flux residue from a PCB after repair is the sign of a failed repair strategy resulting in too much flux and reflective of poor workmanship. Often cleaning solvents are applied locally in an effort to move excessive flux deposits. Sometimes these solvents are formulated specifically for flux cleaning. Sometimes pure chemical solvents, such as alcohols, are used. Very often solvents and flux cleaners leave gummy residues on the board. They can also dissolve the no-clean flux residue and redistribute it, exacerbating the mess. There is danger that dissolved residues can find their way into board-mounted connectors via capillarity or dripping or onto board-edge gold fingers. This can result in electrically insulating flux residues

that interfere with proper electrical interconnect. In general, the use of flux removal solvents for localized cleaning should be avoided. Instead, either eliminate the need for repair or define repair methods that result in good workmanship and do not necessitate the use of a cleaning solvent.

When cleaning is mandated, as would be the case where flux or flux residue contaminates a board-edge gold finger, care should be taken in choosing a cleaning solvent. Some solvents have been known to result in corrosion. Others may interact with solder-mask or other materials on the PCB. Some have health and safety implications.

Some solvents are more effective than others depending on the quality of the flux residues. In general, methanol (methyl alcohol) is a better cleaner than isopropyl alcohol (IPA). It has lower water content and it dries much quicker and more thoroughly than the latter. Care must be taken with methanol as it is flammable and its fumes are toxic. This is often true of other commercially available flux cleaners.

Any cleaning solvent, if applied liberally, may remain trapped in connectors or under low-headroom devices such as chip-scale packages (CSPs) and micro BGAs, mounted on the PCA. Any flux cleaner, especially the slower drying ones such as IPA, may cause electrical shorting if not thoroughly dry before powering up an electrical circuit on a recently cleaned PCA.

Although sometimes flux cleaning is necessary or useful, it is best to avoid the need for cleaning by minimizing the flux dispensed and dispensing the flux only to the lead or leads to be repaired. Training, skill, patience, and practice are required for accurate flux dispensing and soldering. Best practice is to apply a dab of the flux cleaner to a lint-free wipe or lint-free swab and clean very locally taking care not to mar the PCB surface or damage any solder joints. Dry thoroughly after cleaning. Even a short drying cycle in a box oven at a low temperature (e.g., 45°C for 15 min) would be useful to ensure full evaporation of any entrapped solvent

before electrical power-up. But the very best practice is no cleaning whatsoever.

48.7 SOLDERING ATMOSPHERES

The natural heat of the soldering process, combined with the oxygen from the air, can inhibit soldering by creating oxides that compete with the action of a flux. To avoid this problem, inert or reactive gas atmospheres can be used during soldering.

48.7.1 Nitrogen Soldering

Nitrogen (N_2) as a cover gas for soldering has been in use for many years and is considered commonplace in today's electronic assembly.[4–14] Its role in reducing oxidation during the joining process ensures best solder wetting. Soldering in a nitrogen atmosphere has become increasingly important in recent years, driven by the rise of weaker no-clean fluxes and no-clean solder pastes and the upsurge in the use of area-array devices such as BGAs, CCGAs, CBGAs, CSPs, QFNs in reflow, and PGAs, along with complex, finer-pitch connectors in wave soldering.

Area-array devices have one thing in common: their solder joints are hidden by the package body and it is impossible to repair an isolated open solder joint beneath the package. Nitrogen provides added insurance that best solder wetting will result if soldering conditions and materials are process-appropriate.

The most recent increase in N_2-assisted soldering comes with the onset of large-scale lead-free soldering implementation around the world. Higher process temperatures, as necessitated by the most popular lead-free

solder alloys, translates to higher oxidation rates during soldering. Also, certain solder alloys (e.g., those containing Zn, Bi) are more prone to oxidation than conventional Sn-Pb or Sn-Ag-Cu solders.

48.7.1.1 Use of N_2 for Increased Fluxing Effectiveness.

The soldering environment is an important variable. Obviously the most common and least expensive soldering ambient is air, but many board assemblers choose to introduce nitrogen to their reflow ovens, wave soldering machines, or repair stations for the soldering advantage it offers. N_2 is particularly effective when working with no-clean solder pastes or fluxes and has gained increased importance with the conversion to Pb-free soldering. Most all of the Pb-free solders that are in widespread use for the electronics industry are slower to wet and require higher reflow temperatures than the old Sn/Pb standard. The higher the temperature of a metal in an oxidizing atmosphere, the more prone it is to oxidation. The introduction of nitrogen limits oxidation of the metals to be joined, the solder, and even the flux itself. Replacement of air with N_2 results in more effective removal of oxides and tarnishes and enhances solder wetting. At wave soldering, when N_2 is used there is a substantial reduction in dross production rates. Dross is composed of metal oxides from the solder that forms a dense, floating mat on top of the molten solder. It is known to cause wave solder defects (shorts and opens) and since it is oxidized solder, it represents a loss of solder mass therefore it has direct economic implications for the wave soldering or solder fountain processes. In order to cope with the dross, it has to be manually skimmed or ladled from the molten solder to keep the process in control; another time consuming and dangerous maintenance step.

48.7.1.2 Use of N_2 for Lighter, More Transparent No-Clean Residue. When circuit boards are soldered in air, some no-clean residues turn yellow or brown. This is more apparent after multiple reflow cycles as for mixed-mount assembly. Residue coloration is absent when soldering in a nitrogen environment. Clearer no-clean residues make for easier visual or machine inspection of solder joints on finished PCAs. It should be noted that the use of nitrogen even keeps the PCB laminate from darkening especially at the higher temperatures required for Pb-free soldering.

48.7.1.3 Nitrogen Negatives. There are some negative points that must be considered when working with N_2.

48.7.1.3.1 Cost. Nitrogen is an added expense for manufacturing, not only for the cost of the gas itself, but the infrastructure that is required for bulk N_2 delivery, storage and process use. In a factory environment it is impractical and dangerous to store large numbers of gaseous cylinders or portable liquid N_2 dewars onsite and manually change them out on a regular and frequent basis; for this reason, onsite, outdoor bulk gaseous storage is needed. This comes with facility capital costs including: cement pad for outside storage tank and vaporizers to convert stored liquid N_2 into usable room temperature gas. Pressure regulation is required for delivery into the factory as well as piping and further pressure regulation at point of use.

48.7.1.3.2 Tombstoning. It has been found that even modest flows of N_2 are beneficial. However, too much nitrogen during reflow leads to passive component tombstoning (Fig. 48.9).

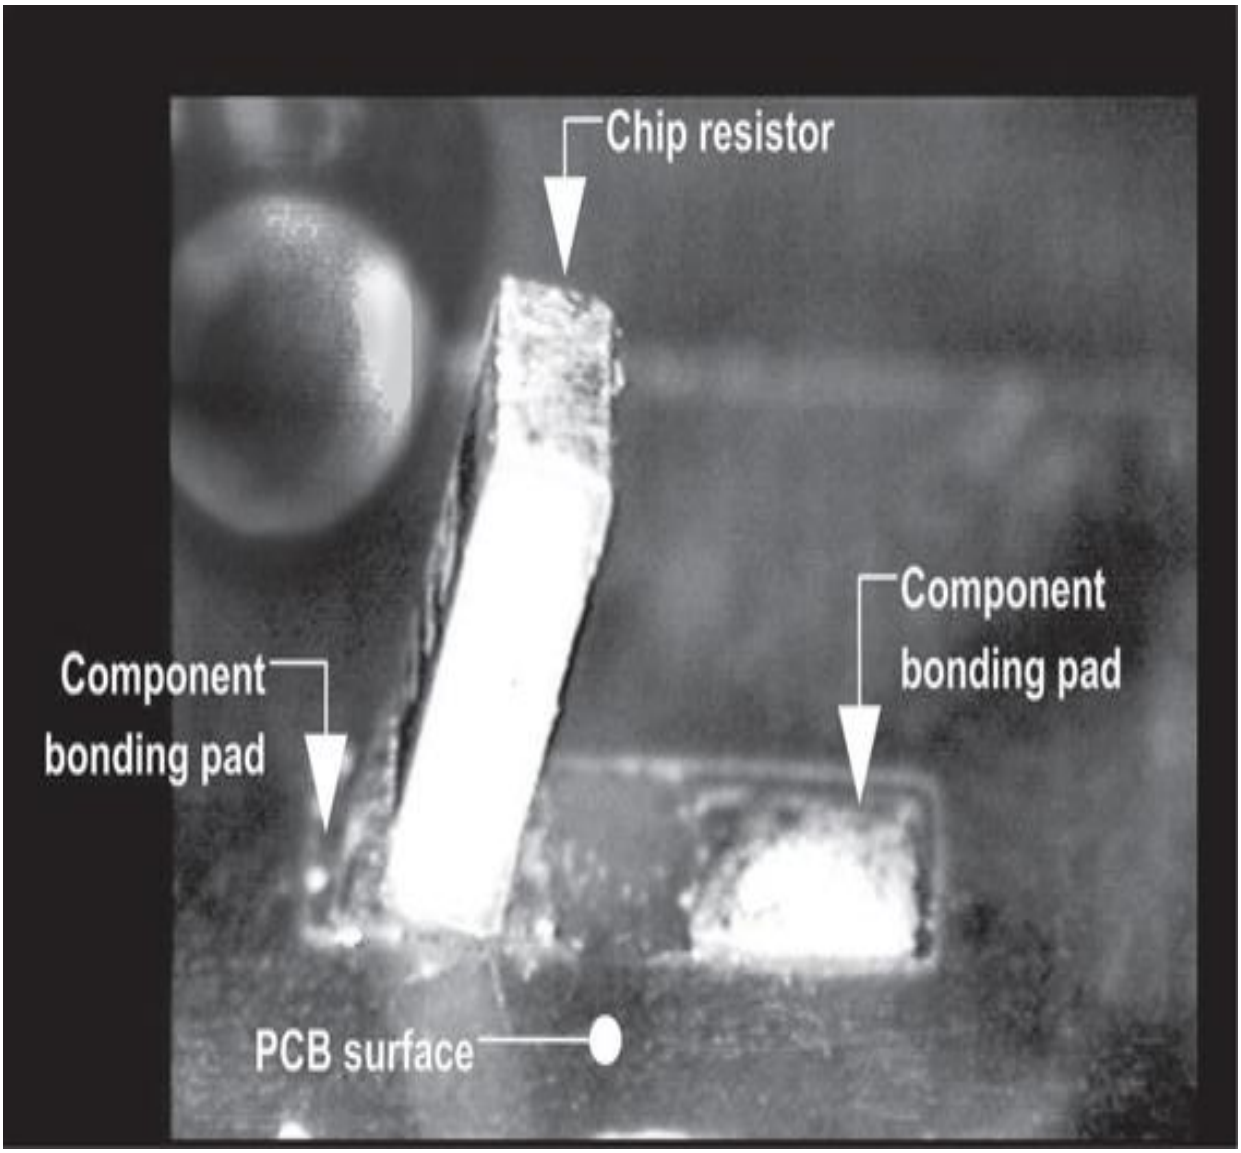

FIGURE 48.9 Passive component exhibiting tombstoning. Differential heating and surface tension effects have drawn the lightweight chip away from the surface of the PCB during reflow. On solidification, the component is frozen in the raised position and an open circuit results.

Often tombstoning is the direct result of a thermally imbalanced PCB design. One bonding pad is connected to a thick, slow to heat subsurface copper conduction plane or even multiple planes. The opposite bond pad is connected to a low thermal mass surface copper trace. During reflow, solder paste on the fine trace goes molten first. As the solder continues to wet around the one end of the passive device,

surface tension of the molten solder on that wetted end lifts the chip off the board before the solder paste on the opposite end goes fully molten and wets. An open solder joint results. This defect, sometimes referred to as the “Manhattan Effect,” “standing proud,” or “drawbridging,” is most often seen on the smallest passive devices.

The defect is exacerbated by an excessively low O_2 content (high N_2) of the reflow oven atmosphere. Low oxygen results in better fluxing which results in increased surface tension of available molten solder, since it is devoid of oxide platelets on its surface. Wetting to one end, the molten solder seeks its lowest energy state, a dome. As the solder continues to wet around one end of the passive component, it draws its one wetted end more fully into the dome lifting the other end clear of the PCB. Care should be taken in design for a thermally balance PCB design. Oxygen monitors can be used to sense the amount of nitrogen in an oven. Maintaining a reflow oven oxygen concentration level of about 1000 to 1500 ppm O_2 will benefit reflow and minimize tombstoning. Inerting to this level is also significantly more economical since nitrogen consumption is less than when running at lower O_2 concentrations. It is easier to maintain a constant O_2 level in this regime as opposed to ultralow O_2 concentrations since subtle drafts at reflow tunnel ends can result dramatic variations in O_2 concentration.

48.7.2 Fluxless Soldering

There have been many discussions and investigations into fluxless soldering, but often this term is incorrectly applied. Disruption of the integrity of oxides on the parts to be soldered and on the solder itself is a requirement for solder wetting. If a thermal or thermal-mechanical method is solely

employed (e.g., as by ultrasonic soldering), then it is truly a fluxless method. If a chemical agent is applied for oxide removal, whether it is in solid, liquid, or gaseous phase, it is still a flux-based process. Using cover gases alone does nothing to clean oxidized leads, bonding pads, or solder, but will limit further oxidation.

Work by G. Disbon and S. M. Bobbio[15] and K. Pickering, et al.[16] have demonstrated that a plasma can be used to strip oxides from circuit boards and components, and, if they are maintained in an inert environment, they can be soldered without the use of additional liquid fluxing agents. In these schemes, the plasma serves as the oxide-stripping flux. Such processes would not be appropriate for mass production of today's PCAs.

48.7.3 Gaseous Fluxing

It has already been discussed that flux can exist as a liquid, paste or solid (solidified rosin), but it can also be dispensed as a gas. There have been several investigations into the realm of fluxing with various gaseous species, including hydrogen, carbon monoxide, carboxylic acids, and others. Some have been demonstrated to be effective fluxing agents, but none of these methods have found their way to large-scale manufacturing. Instead, they are used in niche applications. Investigations continue in this area.

48.7.3.1 Hydrogen. There has been talk in the industry of hydrogen as a fluxing agent, but at soldering temperatures, hydrogen is predominantly an unreactive, diatomic, gas; in fact, even at 1730°C, it is only 0.33 percent dissociated at atmospheric pressure.[17] Therefore, it is relatively stable chemically, serving ostensibly as an expensive cover gas; an inerting blanket rather than a reactive fluxing agent. H_2 explosively combines with O_2 in

the presence of an energy source such as a spark, so it is typically mixed with N_2 or another inert gas when used for processing. This mixture, called *forming gas*, is susceptible to separation. Since hydrogen is lighter than air, it rises and may pocket in the upper recesses of the soldering machine or in the room. Its lower explosive limit in air is only 4.65 percent[18] so precautions have to be taken either to keep below this value or to preclude exposure to an ignition source (difficult to do in a reflow oven or today's PCA factory environment). Its upper explosive limit is 93.9 percent, above which hydrogen is once again considered safe, but this is impractical economically and a gas containment vessel would rule out a reasonable continuous process and affordable equipment and for use as a cover gas only.

48.7.3.2 Carbon Monoxide. Carbon monoxide is an interesting choice. Very dense, it readily displaces air from the soldering environment and is inexpensive. Since it is a heavier-than-air toxin with considerable public notoriety, it is unlikely that it will ever be considered an attractive assistive agent for reflow. Also, carbon monoxide does not dissociate sufficiently well at soldering temperatures to be useful for effective fluxing, but does make an excellent, weakly reducing cover gas much as hydrogen does.

48.7.3.3 Methyl Bromide. This material has been shown to be an effective fluxing agent but is toxic. In fact, it is now a banned pesticide in the United States.

48.7.3.4 Carboxylic Acids. The idea of a gaseous fluxing agent has much merit. It could be inexpensive, eliminate post-solder cleaning, and leave no residue to impede inspection or test. Without residues, the prospect of corrosion would be minimized.

Carboxylic acids in gaseous phase have been demonstrated to be useful in this regard, but it has yet to

undergo large-scale testing in a manufacturing environment. Of the carboxylic acids, formic and acetic have received some attention as fluxing agents. They are very simple materials, weak organic acids that decompose to water and carbon dioxide at temperatures above 160°C.[19] Acetic, in its dilute form, is vinegar. Carried as a vapor and introduced to the soldering environment, it is truly a gaseous flux. Both formic and acetic are widely used industrially and are inexpensive reagents. H. J. Hartmann[20,21] has shown that as formic decomposes, it is a good reducing agent for oxides of solder. The process produces metastable tin formate, which further decomposes, yielding elemental tin, water, and carbon dioxide. Acetic acid follows a similar reaction and decomposition cycle, forming metastable tin acetate and ultimately elemental tin. Especially attractive is the fact that there is no flux residue on the circuit board after the gaseous carboxylic acid reactive soldering process.

R. Iman et al.[22] have demonstrated formic and acetic acids to be especially effective for fluxing in the wave-soldering process in conjunction with a light application of adipic acid, a common food preservative and also a known fluxing agent. However, a water rinse was required to remove the adipic residue lessening its value as a fluxing agent.

CHAPTER 49
SOLDERING TECHNIQUES

Gary M. Freedman
Colab Engineering LLC, Stow, Massachusetts

49.1 INTRODUCTION

Soldering has changed significantly over the millennia progressing from melting heated materials in an open fire to the fire-heated soldering iron to the blow-torch and to present electrical resistance-heated techniques. Although the materials and scientific knowledge have evolved drastically, the fundamentals of this joining process remain the same. The advent of the printed circuit board (PCB) drove the need for soldering and repairing finer geometries. Mass marketing of the finished printed circuit assemblies (PCAs) spurred the invention of a handful of soldering technologies to cope with demands of intricate assembly, timely manufacturing and machines for repair.

There are two categories of soldering methods: (1) mass soldering and (2) directed-energy bonding. Mass soldering techniques target the entire circuit board, soldering all components simultaneously. Directed-energy methodologies

are useful for localized soldering of a single component lead, whole component comprising two or more leads or for soldering a small section of a circuit board.

49.2 MASS SOLDERING METHODS

Mass flow or reflow methods are suited for high-volume manufacturing. The entire board is heated and the entire complement of components on the board are soldered simultaneously. The two most common of these methods are oven reflow soldering and wave soldering. A third technique, vapor-phase reflow soldering, has dwindled in popularity due to environmental concerns regarding the use of the chlorofluorocarbon-based solvents that were key to this process. Now, however, perfluorocarbons are substituted and the technique is still in use. Regardless, it is a slow technique as compared to oven reflow or wave soldering. Its benefits will be discussed in a subsequent section. The choice of soldering method is dictated by the types of components and boards being soldered, the required throughput rate, and requisite solder joint properties.

49.3 OVEN REFLOW SOLDERING

Oven reflow is used primarily for surface-mount component soldering. To prepare a board for this process, a mixture of minute solder spheres and paste flux (solder paste) is stenciled onto the circuit board. Stencil openings are cut to roughly match the size of the soldering lands on the PCB. Stencil thickness is tailored for the amount of solder paste needed and somewhat by the geometry of the solder lands. The paste flux, a constituent of the solder paste, prepares the metal surfaces for solder attachment while the solder

spheres provide the alloy for solder joint formation. Electronic components are precisely machine-placed onto the stenciled solder paste and the entire assembly is placed in an oven and heated through a controlled ramp and dwell cycle. The heating regime is dictated by the thermal mass of the assembly, thermal exposure rating of the electronic components to be soldered and the time and temperature requirements as specified by the solder paste manufacturer. After the solder reaches reflow temperature and slightly beyond, the PCB is cooled and the surface-mount process for that side of the board is complete.

The equipment used to accomplish the PCB heating and reflow is a conveyorized reflow oven and the board is moved past stationary heaters in an insulated tunnel. The oven is set to raise the circuit board and component temperatures gradually. Flux in the solder paste becomes active with increased temperature and strips oxides and other contaminants from metal surfaces on the components, on the solder lands (pads) on the board, and from the solder spheres that would inhibit solder joint formation. Finally, enough heat is imparted for the solder to flow (meaning to liquefy, also known as reflow). When implemented properly, the oven reflow process should result in a controlled and predictable heating and cooling cycle and reproducible solder joint formation.

Rapid heating of the solder paste is widely known to cause excessive gasification of solder paste volatiles resulting in bursting bubbles in the solder paste and in the molten solder. The spewed solder debris is one source of solder ball formation. Solder balls (isolated spheres of solder not necessarily connected to the solder mass of the joint) may induce electrical shorts, especially with finer-pitch components where solder ball diameters may be on the order of component lead or PCB pad spacing. Such solder fines also make for a messy assembly (Fig. 49.1).

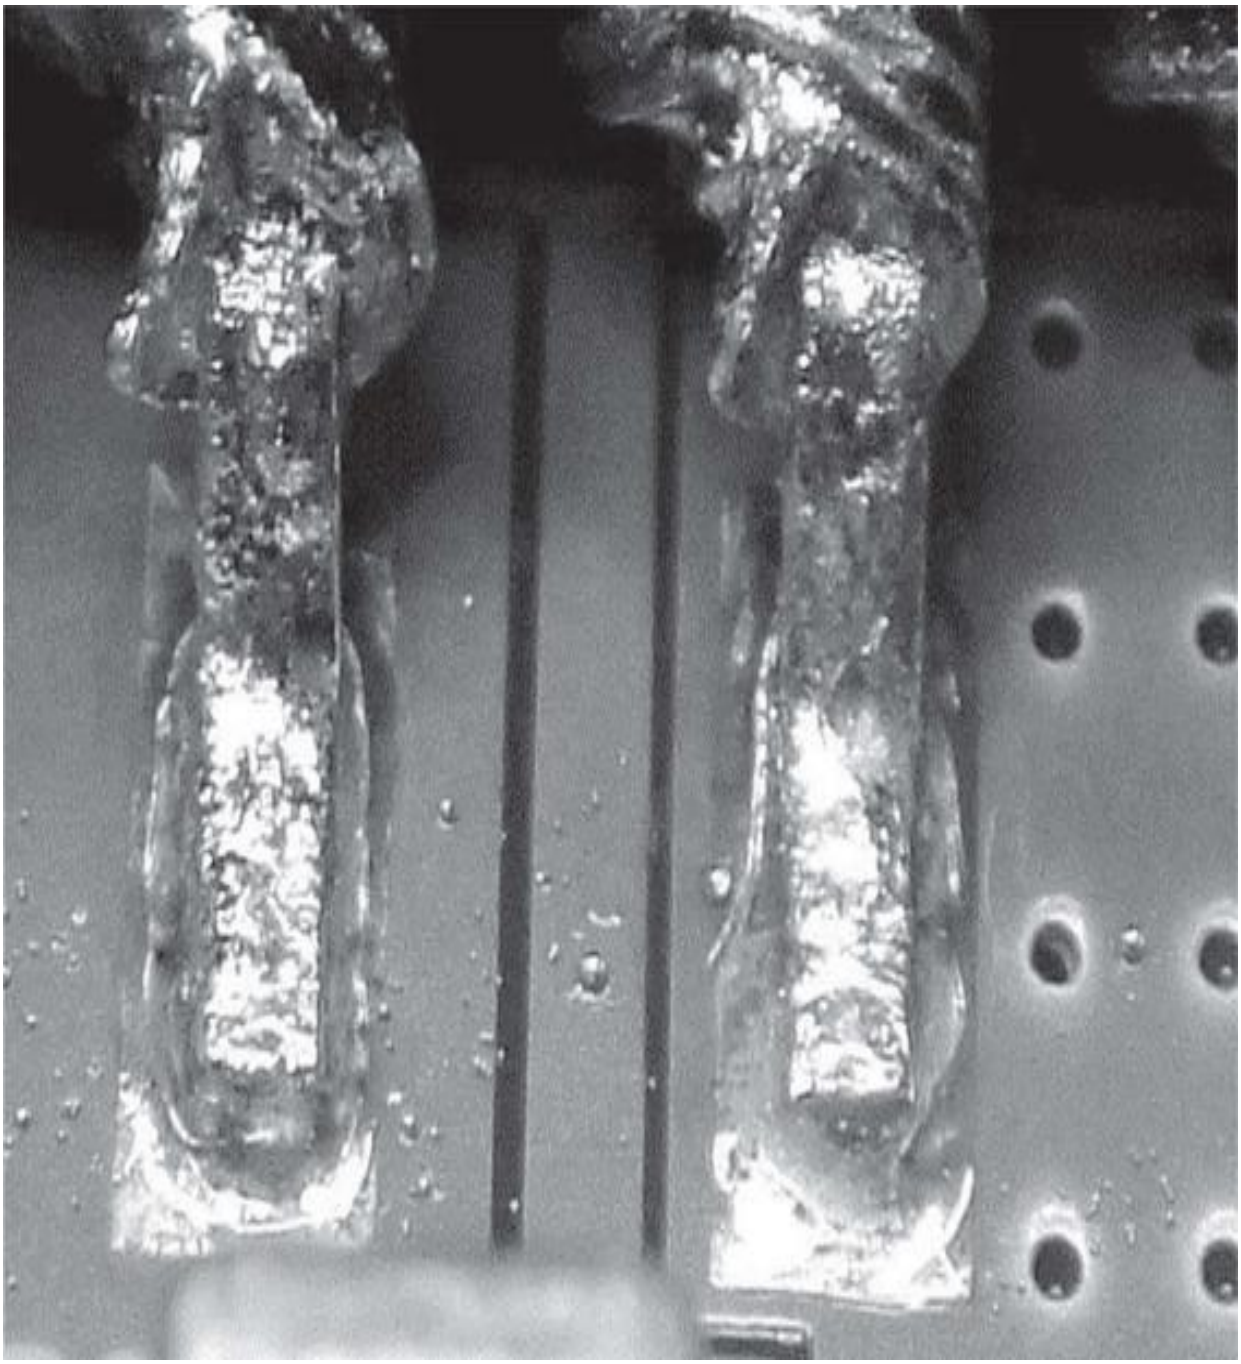

FIGURE 49.1 Solder balls on surface of PCB. Rapidly volatized solder paste constituents can result in explosive solder ball formation. (*Courtesy of K. Selig, AIM Solder*.)

The soldering time-temperature profile must be carefully adjusted to prevent excessive heating which can cause flux charring or “caramelizing,” reoxidation of fluxed soldering surfaces and solder joint degradation. Deterioration of the

circuit board (delamination, charring, etc.) or damage to thermally sensitive components may also result from overheating. Conversely, too low a temperature may result in solder opens or “graping”; a defect where the solder spheres have not fully melted and coalesced into a uniform solder mass. The spheres are either poorly soldered or sintered and look like clusters of grapes rather than a smooth, reflowed solder joint (Fig. 49.2).

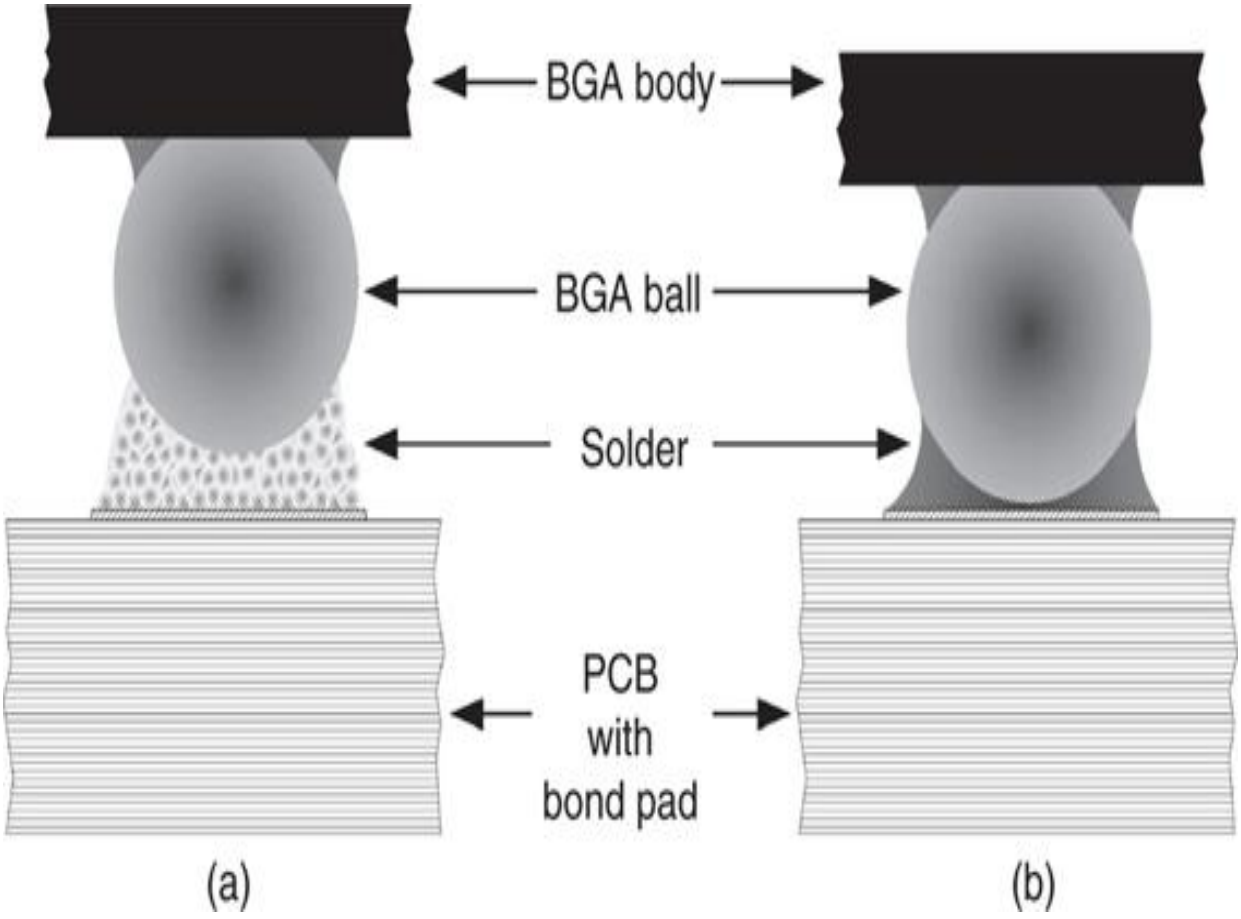

FIGURE 49.2 Illustration of the “graping” phenomenon. (a) shows “graping” where the solder balls of the solder paste have not coalesced in to a smooth and uniform solder mass. (b) is a normal solder joint properly reflowed. Smooth fillets bond the BGA ball to the PCB bond pad. “Graping” will result in a poor reliability solder joint.

Today’s reflow ovens are highly complex, precise and repeatable in performance. Accurate temperature and

precise control of the process temperature on all components is required for solder joint goodness.

49.3.1 Reflow Oven Subsystems

Even the simplest reflow ovens consist of several basic subsystems: insulated tunnel, board conveyor, heater assemblies, cooling, and venting (Fig. 49.3).

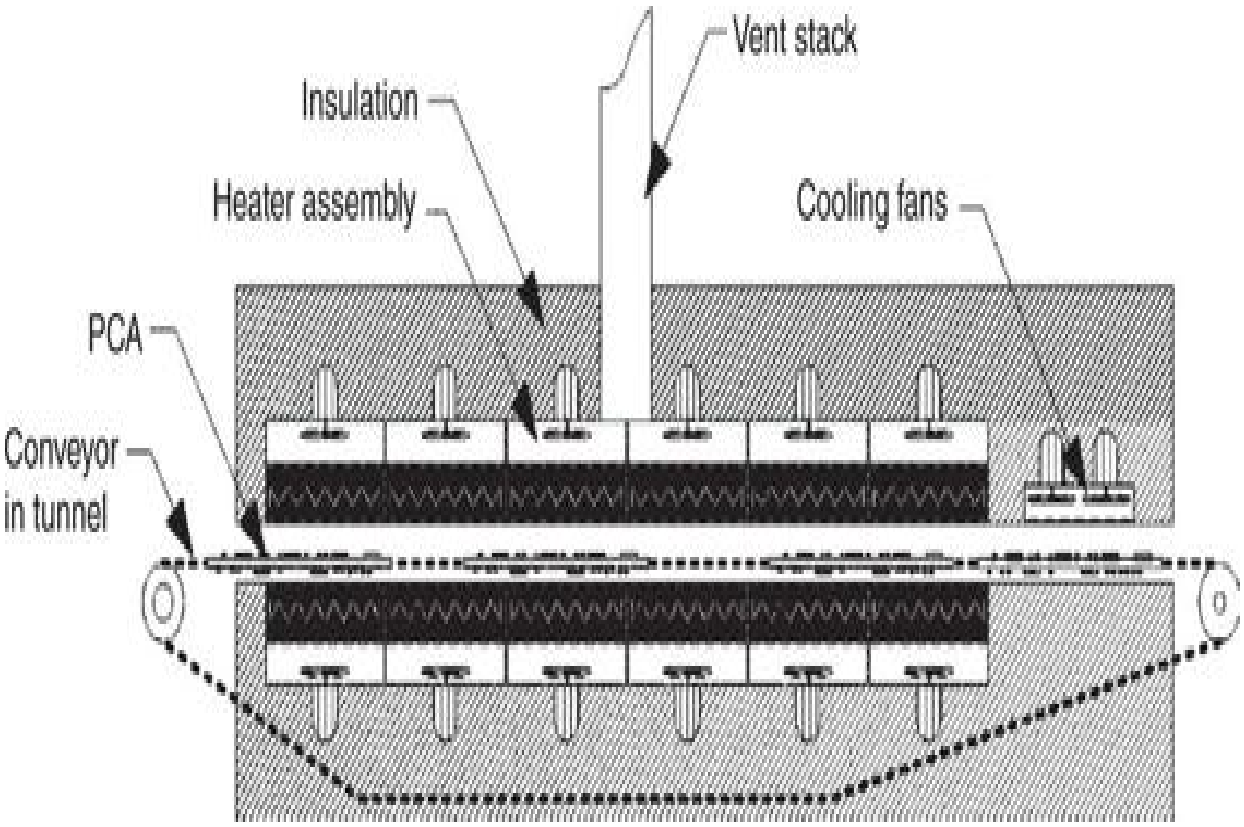

FIGURE 49.3 Cross-sectional view of reflow oven with top and bottom heater assemblies, cooling module, vent stack, insulated tunnel, and motorized conveyor.

Reflow ovens have reached a high level of sophistication, and there are many other items that enhance oven suitability for the manufacturing floor. Those items, beyond the basic reflow oven subsystems, are niceties, accessories, and gimmicks offered by oven manufacturers, not discussed

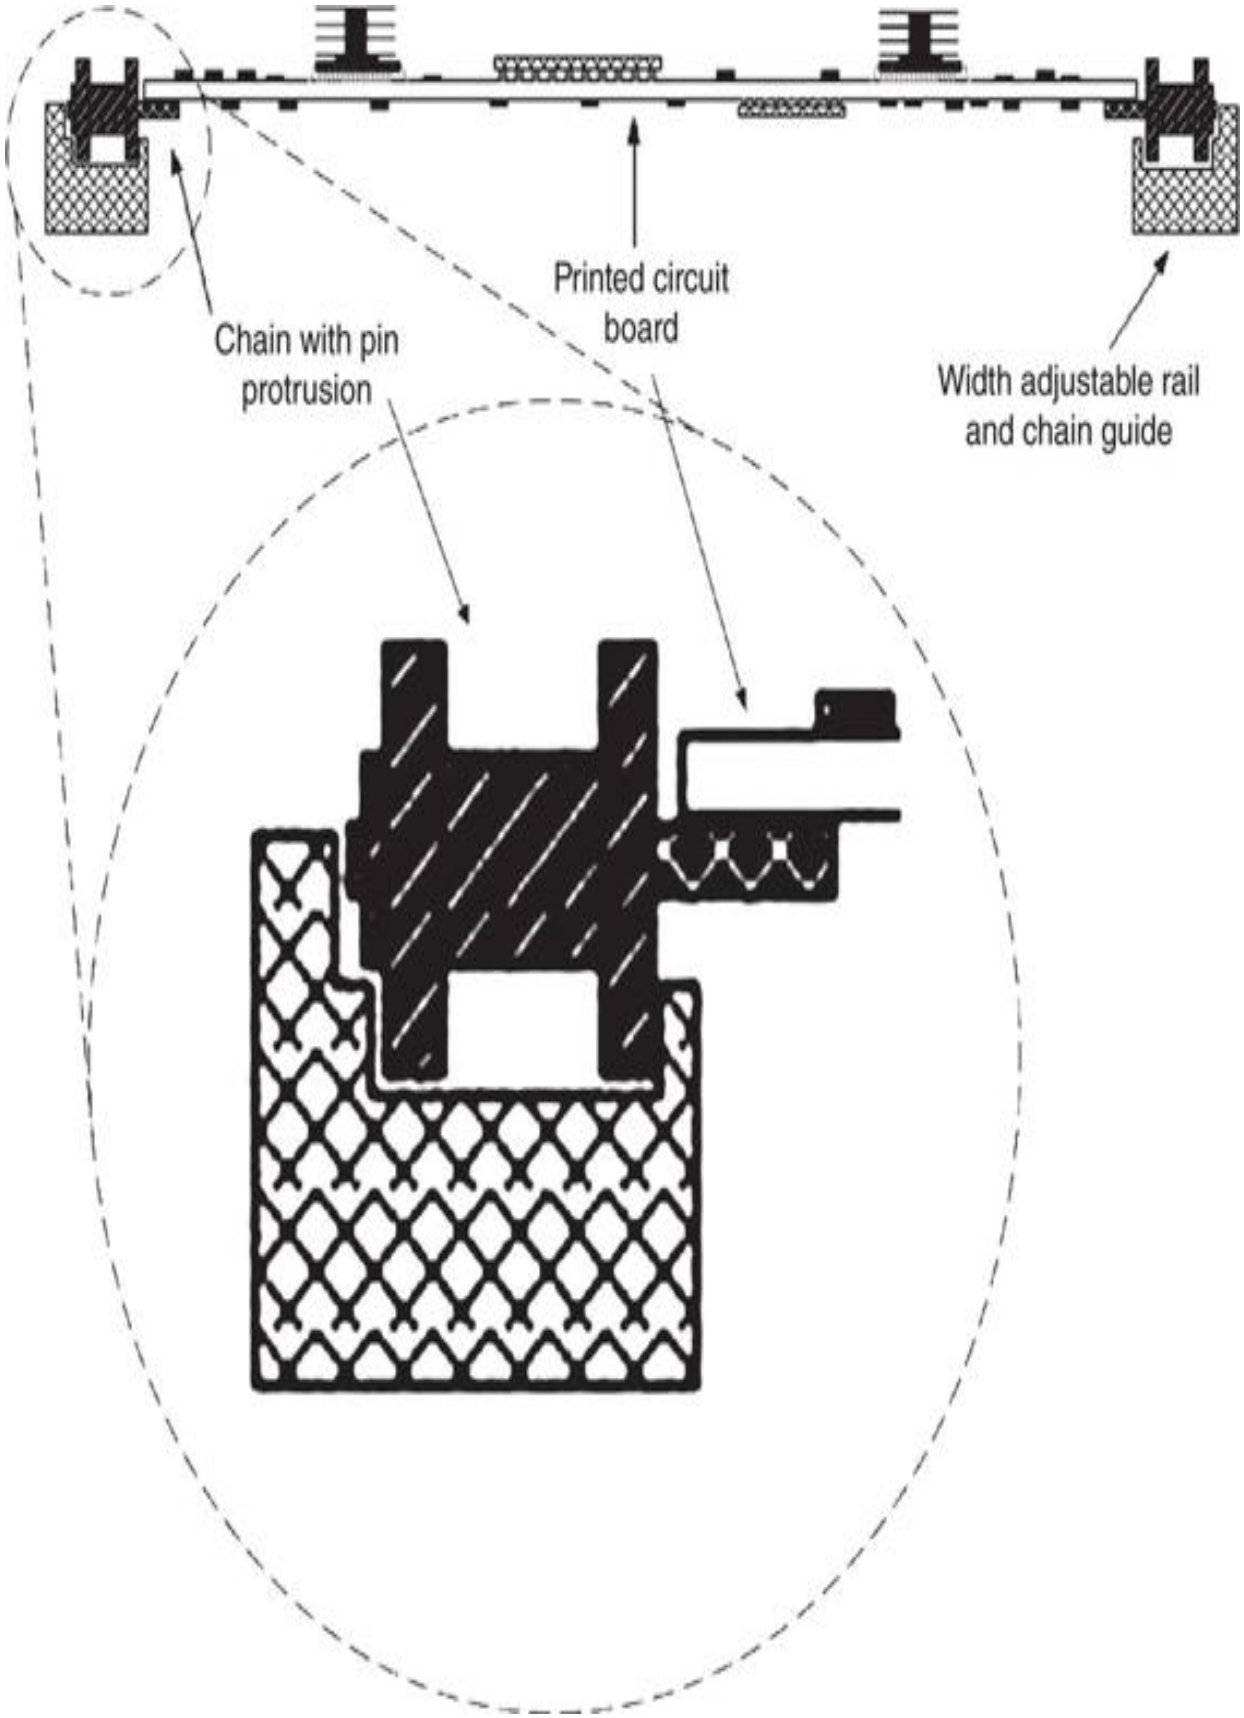
in this section; however, those subsystems previously listed are reviewed to impart an understanding of the basics of oven construction, operation and most advantageous configurations.

49.3.1.1 Tunnel. The tunnel is a thermally insulated passage through the length of the oven where the board is heated and cooled for a continuous reflow process. It serves to insulate the heaters and boards from the external (room) environment just as much as it is designed to preserve thermal conditions as prescribed by the process and demanded by the heaters.

Consideration of tunnel dimensions is critical for the reflow application. Short tunnel ovens may not permit an adequate profile for attaining requisite reflow temperature-versus-time profiles for larger, thermally massive PCB assemblies. Tunnel height dimensions must also be sufficient to accommodate the tallest components or component heat sinks. Tunnel width will limit the size of the board that can be introduced to it.

49.3.1.2 Conveyors. Boards are moved through the tunnel and past multiple heaters by a width-adjustable constant-speed conveyor permitting controlled and gradual pre-heating, reflow, and post-reflow cooling of the circuit board. There are two main conveyor systems used in reflow ovens: pin-chain and mesh belt. One is required and both are recommended for any reflow machine.

49.3.1.2.1 Pin-Chain Conveyor. The pin-chain conveyor, also known as an edge-hold conveyor, looks like a bicycle chain with a pin protruding inward from evenly spaced links, as shown in Fig. 49.4.



Printed circuit board
Chain with pin protrusion
Width adjustable rail and chain guide

FIGURE 49.4 Cross-sectional view of circuit board carried on oven pin-chain conveyor. Chain runs in guide slot to keep it positioned. PCB rests on pin-chain protrusion as illustrated.

There is one such chain on each side of the reflow oven. The circuit board rests on these pins on the inner aspect of the chains and is transported through the oven during the soldering process. The two chains are driven from a common motor, appropriately geared to ensure that the circuit board is conveyed through the oven evenly and to preclude angling and jamming of the board in the oven. Conveyor speed is adjustable and is one of the major variables of the reflow soldering recipe (time-versus-temperature) profile development.

Pin-chain conveyors are best for circuit boards with components on both sides since the circuit board is conveyed by its edges. This edge-hold method prevents misregistration of parts to be reflowed and also eliminates movement of or mechanical interference with previously reflowed components on the bottom-side of the board during transport through the oven. An edge keep-out area must be designed into the board such that there will be no pin-chain or component interference.

Thin, large circuit boards, may sag during reflow when held by the edges on a pin-chain conveyor. The sagging is due to thermal excursion above the glass transition temperature (T_g) of the PCB epoxy during the reflow process. T_g is the temperature at which a partially crystalline polymer will change from a hard structure to a rubbery, viscous state, as in the case of FR-4 and similar laminate materials used for PCB construction. The T_g of most circuit board laminates is generally below the peak reflow process temperatures of most solders. Sagging will be pronounced due to the fact that the board is unsupported at its middle as it surpassed its T_g during transport on the pin-chain conveyor. Copper ground and power planes within the board provide significant

support, but may not impart enough stiffness to counter this problem. Sagging alone or together with rail-to-rail non-parallelisms at process temperature can even lead to boards falling off the conveyor. Most of the major vendors in the reflow oven market have conquered the rail twist problem, but hot testing an oven with precisely toleranced test vehicles or even precisely milled aluminum plates should be performed prior to final acceptance of an oven. Board sagging can be mitigated, to some extent, by means of mechanical stiffeners affixed permanently or temporarily to the circuit board or by reflowing the board on a pallet. It should be noted that stiffeners and pallets affect the thermal mass of the board, making reflow more of a challenge. Care should be taken to ensure that the attachment of stiffeners or use of reflow pallets neither interfere mechanically nor thermally with components on the board.

Some ovens are sold with an accessory steel cable strung the oven length that is meant to serve as an antisag support or even a third pin-chain in the middle of the oven to contact the bottom of the PCB. A clearance (“keep-out” area) must be designed into the board or panel for the support cable or chain. The chain and its supporting rail may influence the reflow profile. The board will be cooler in the shadow of this additional thermal mass. In a properly designed oven, the pin-chain inflicts little thermal influence on the conveyor.

Some edge-hold systems have been known to impart a heat-sinking effect at board edges. To counteract this, some oven manufacturers have incorporated rail-heaters. It is best to avoid such systems because it adds further complexity to the oven and makes the job of process control all the more difficult. This should not be a problem with the conventional pin-chain conveyor because the pin-chain is only in point-contact with the circuit board. Thermal transfer through these contact points is very poor. Further, most of the newest reflow oven manufacturers have replaced carbon steel chains with stainless steel chains. Stainless steel has

better wear characteristics and is a poorer thermal conductor than other commonly available chain materials.

49.3.1.2.2 Mesh Belt Conveyor. Mesh belts used in reflow ovens are generally fabricated of stainless steel links. Some are wide open with large spaces, many centimeters from link to link. Others are more like chain-mail mesh (Fig. 49.5). Widely spaced links allow more air flow to the bottom-side of the board.

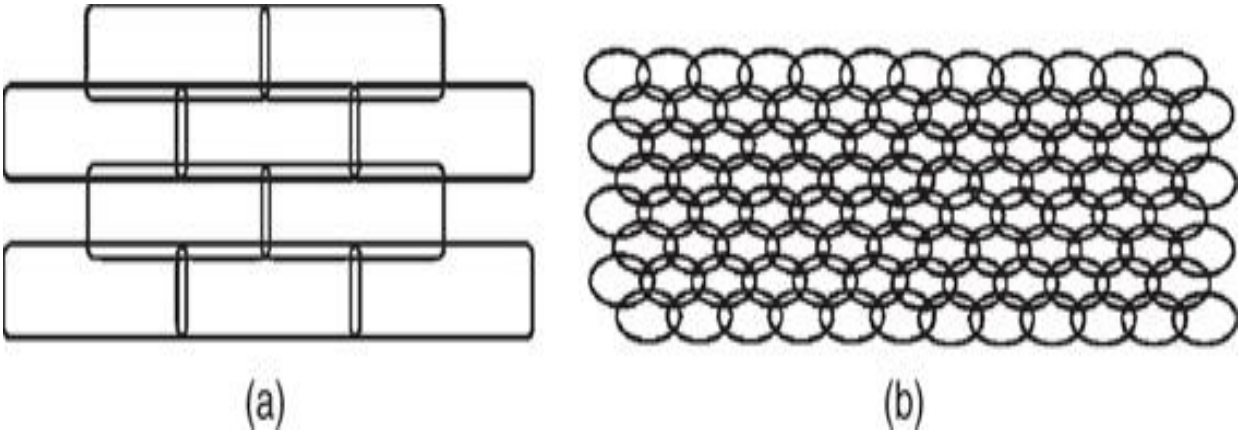


FIGURE 49.5 Mesh conveyor. A large space mesh belt (*a*) allows more air flow than the "chain-mail" mesh (*b*).

The mesh belt is close to the full width of the tunnel and traverses its entire length. Mesh belts offer exceptional versatility, as there is no need to adjust for various board widths and never a concern for board sagging or dropping, but they are best suited to single-sided circuit assemblies.

Preferred is a combination of conveyors with the pin-chain running above a mesh belt. In this case, redundancy can save boards, reduce maintenance time, and enhance personal safety. The mesh belt serves as either an optional means of conveyance for boards populated on a single side or as a safety net to catch a board that may fall off the pin-chain conveyor. Dropped boards are a rare occurrence if the pin-chain conveyor is set properly and the equipment, process, and materials are properly specified and controlled. If the mesh belt were not used with the pin-chain, any

dropped boards would smolder on the heater assemblies, resulting in the release of noxious fumes. Additionally, the heater or heaters affected could become encrusted with the decomposed board laminate, which may impact their thermal performance. If a thermocouple (sensing instrument for oven temperature control) is blocked by a fallen PCB, damaged or insulated by the laminate decomposition products, zone overheating may occur, causing oven damage, circuit board loss and manufacturing downtime.

If mesh conveyor is the only means of transport, any PCB with components on both sides of the board (double-sided assembly) would require a carrier (pallet) to prevent previously mounted components from contacting the mesh belt. The carrier adds thermal mass, so it is wise to minimize its thermal mass by removing unneeded material by perforating it to allow good air flow during the soldering process. Time-temperature profile development must include such a carrier.

49.3.1.3 Oven Heaters. Each heater's thermal output is sensed via a thermocouple, which is used to close the loop to the heater controller. In larger, production-worthy systems, heaters are located both above and below the plane of the circuit board and are at least as wide as the conveyor. Thermal uniformity across a 60 cm tunnel width can be better than ±2°C on top-of-the-line ovens. This is a function of tunnel insulation, heater performance, heater control, and convective mixing of the heated air or gas within the tunnel.

There are several heating schemes used in reflow ovens, the result of years of technological evolution. Focused infrared (IR) lamps have given way to secondary emission panel heaters and, finally, to forced hot-air convective ovens that are today's de facto industry standard.

49.3.1.3.1 Infrared Heater Types. Alternative IR heater types are shown in Fig. 49.6.

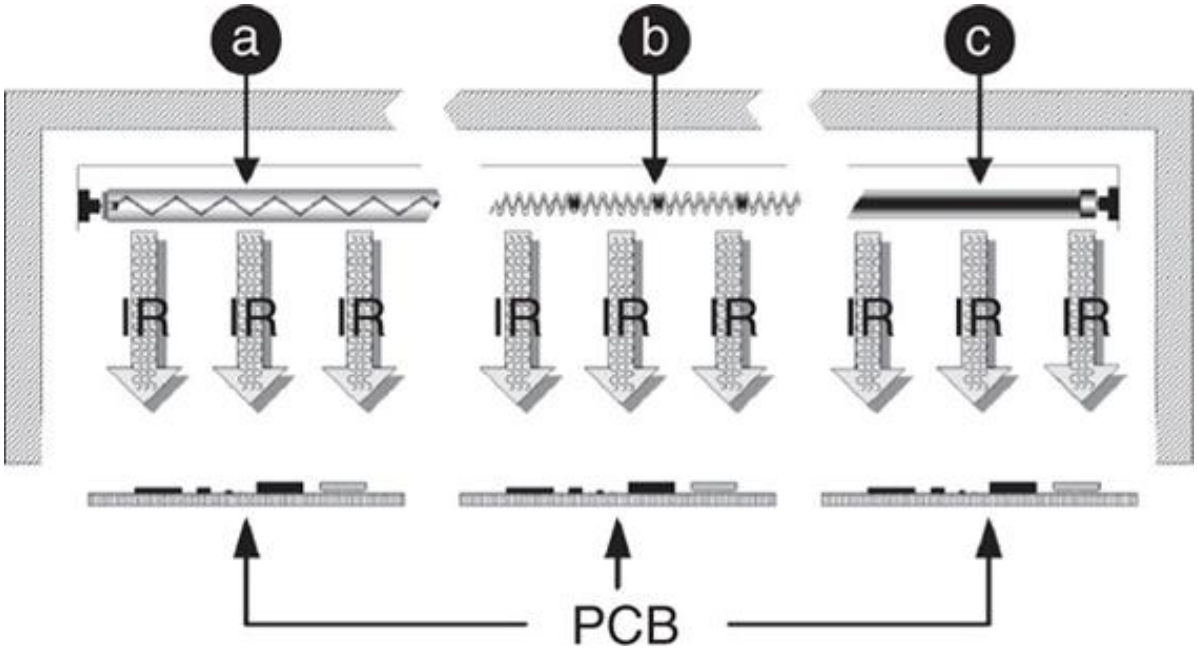

FIGURE 49.6 Three infrared heating schemes for reflow ovens: (*a*) IR lamp, (*b*) open resistance wire heater, and (*c*) resistance rod (calrod-type or cartridge heater). Note that each directly radiates the PCB.

Early SMT reflow ovens utilized focused and unfocused IR lamps, mounted in the reflow oven tunnel. These bathed the solder paste-coated circuit boards and associated components with a broad spectrum of photonic energy heavily weighted to the infrared (IR) end of the electromagnetic spectrum. The intensity of the IR and exposure time as regulated by the conveyor speed results in solder reflow. As the board travels beyond the last IR heaters at the exit end of the oven, the absorbed heat is lost to the environment and the solder solidifies. Alternatively, the molten solder may be actively cooled by fans to complete the solder joint.

Material such as plastic and ceramic component bodies, component lead and pad metallurgies, solder type, solder paste volume, PCB laminate and its lay-up, solder paste flux, and adhesives all absorb infrared radiation at different rates. Therefore, the direct radiative approach is known to cause overheating of some components and under-heating of

others. For this reason, direct IR heating is no longer the preferred method for reflow.

49.3.1.3.2 IR Panel Heaters. Better than direct IR heating is the secondary IR emitter panel (Fig. 49.7). Emitter panels are constructed of metal or ceramic platens heated either conductively via attached resistance heaters or by direct IR irradiation on the back side of the panel. They rely on longer IR wavelength radiation and natural air convection for heating the PCB, solder paste and associated electrical devices on the board.

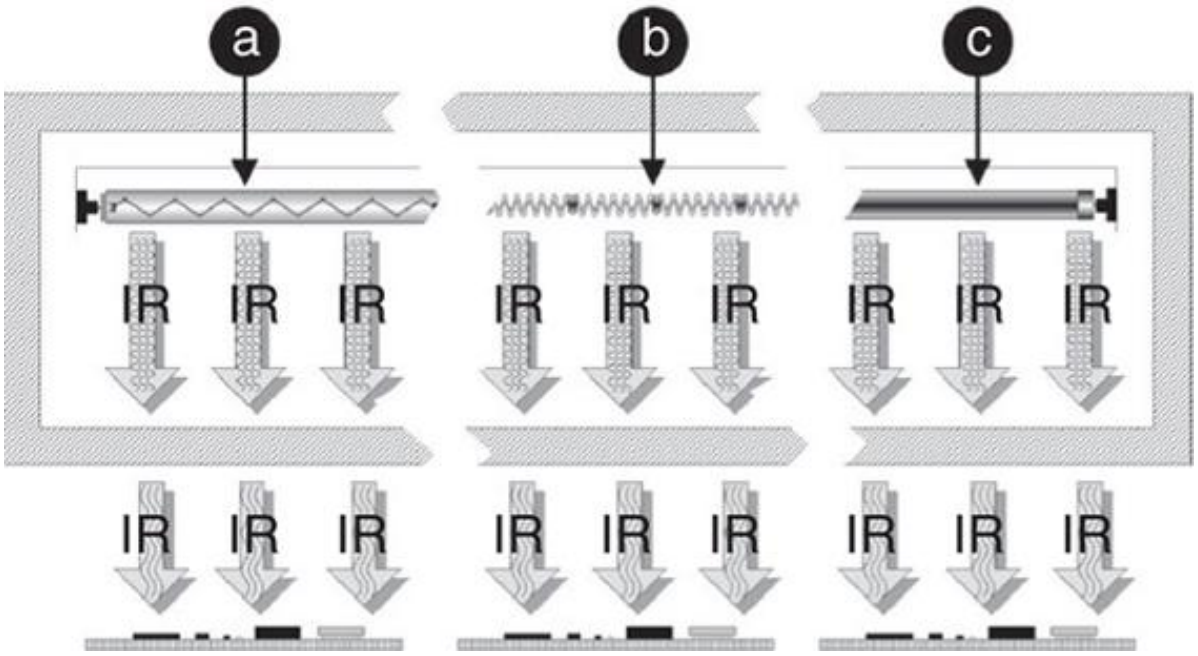

FIGURE 49.7 Secondary IR panels rely on radiant IR sources such as (*a*) lamps, (*b*) wire resistance heaters, or (*c*) heating rods/cartridge heaters. The primary IR impinges on a baffle and the absorbed short-wave radiation is converted to longer wavelength radiation which heats the circuit board. This imparts more even heating of the PCB and components during soldering.

During reflow, the circuit board is shielded from direct short-wavelength IR impingement. Instead, it is heated by blackbody emission of the heated platen, resulting in much longer IR wavelengths, slower heating rates, and more even heating—a significant improvement over the direct IR lamp oven reflow soldering method.

There are two variants of this method: convection IR oven and forced-air convection oven. The former relies on radiant or panel IR heating, but the air in the oven is stirred by fans to enhance uniformity of heating. However, techniques such as IR lamp, IR emitter, and combination convective units have been largely supplanted by forced-air convection ovens. In that technique the air is forced through the panel heaters at high velocity resulting in even oven temperatures and rapid heating response and control. Forced-air convection ovens are the mainstay of oven reflow and will be dealt with in a subsequent section.

49.3.1.4 Venting. Oven venting is required to remove harmful fumes from the oven tunnel. Too little venting and fumes will not be removed effectively. Too much exhaust will pull in too much room air through the tunnel entrance, tunnel exit, or both and may interfere with the oven's thermal performance. If nitrogen is being introduced to lower oxygen levels, too strong an exhaust draw will negate the effect of the nitrogen or make it difficult to control the oxygen level within the oven. A more detailed look at venting will be covered in a subsequent section.

49.3.1.5 Cooling. Just as important as heating the solder, the solder must be cooled to solid state before the board is handled. Otherwise, components sitting in liquid solder could move causing open- or short-circuits. Also, as a molten material such as solder solidifies and crystallizes, mechanical motion may perturb the solder's lattice structure. The resultant solder joints may be of poorer quality and lesser reliability. Some ovens rely upon passive cooling, whereas others have active cooling elements such as fans or chillers (fans blowing over actively cooled radiators).

49.3.2 Forced-Air Convection Reflow Oven

This is the preferred method for controlled, reliable reflow soldering. Dependent on heated air recirculated at high velocity in the oven tunnel, the only direct irradiation of the PCBs is by the longest IR wavelengths emitted by the hot surfaces within the tunnel and the bulk of the heating from the forced hot air.

49.3.2.1 Forced-Air Convection Reflow Module. Heating is accomplished primarily through heated air streams directed at the PCB's top and bottom surfaces. This method imparts greater thermal uniformity and controllability of the reflow process than any other reflow oven heating method. It precludes preferential absorption common to direct IR heating methods and resultant overheating of some parts and under-heating of others during the reflow process. Although the combination IR-convective method has helped in this regard, it is no substitute for the forced-air convection technology.

Top-of-the-line forced-air convection ovens have heating modules mounted above and below the board conveyor. Heating is accomplished by passing a high-velocity air stream drawn from the tunnel ambient over resistance heaters and through hot perforated platens. The stream of hot air is directed at board surfaces raising the temperature of the board, solder paste and placed components. The high-velocity air flows are baffled and regulated to impart a uniform temperature across the tunnel width. Each module is quickly heated and highly controllable. Several heating modules are set one after another along the length of the oven. It is typical to duplicate the top-side forced-convection module configuration on the bottom of the oven tunnel for even heating and controllability of the reflow time-temperature profile. Figure 49.8 depicts this arrangement.

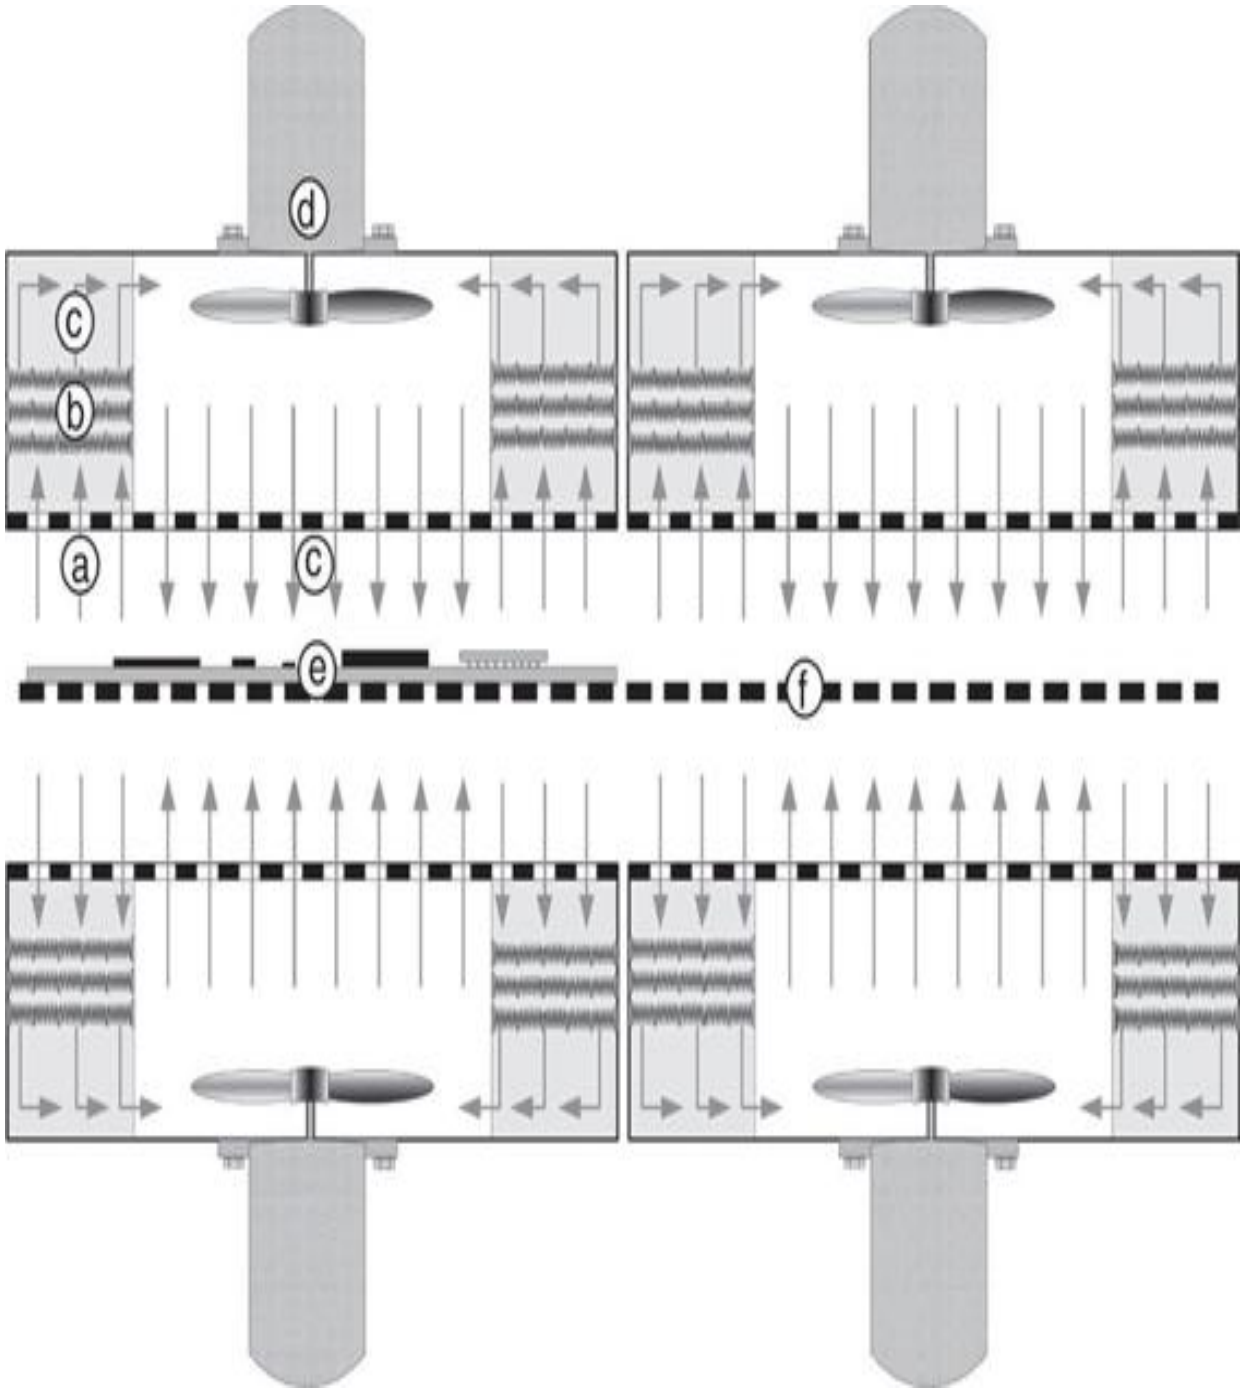

FIGURE 49.8 Forced-convection heating modules. Cooler air (*a*) is drawn across the resistance heater (*b*) by a fan (*d*). The heated air (*c*) is forced through a perforated plenum or multiple plenums tuned for even heat distribution to the PCB (*e*), which is riding on the conveyor (*f*). A second set of forced-convection heating modules is directed at the underside of the PCB. Several such modules are arrayed the length of the oven for precise thermal profile control.

49.3.2.2 Cooling. Some ovens rely upon passive cooling to bring the temperature of the PCB assembly below the solder liquidus point. In this case, the board traverses a region of the oven devoid of heaters. This is generally adequate for thin, low thermal mass boards. But multi-layer, densely packed PCBs necessitate active cooling to ensure that solder joints are solid prior to exiting the oven and before board handling. To this end, many ovens incorporate an area of active cooling after the last heating zone within the oven (Fig. 49.9).

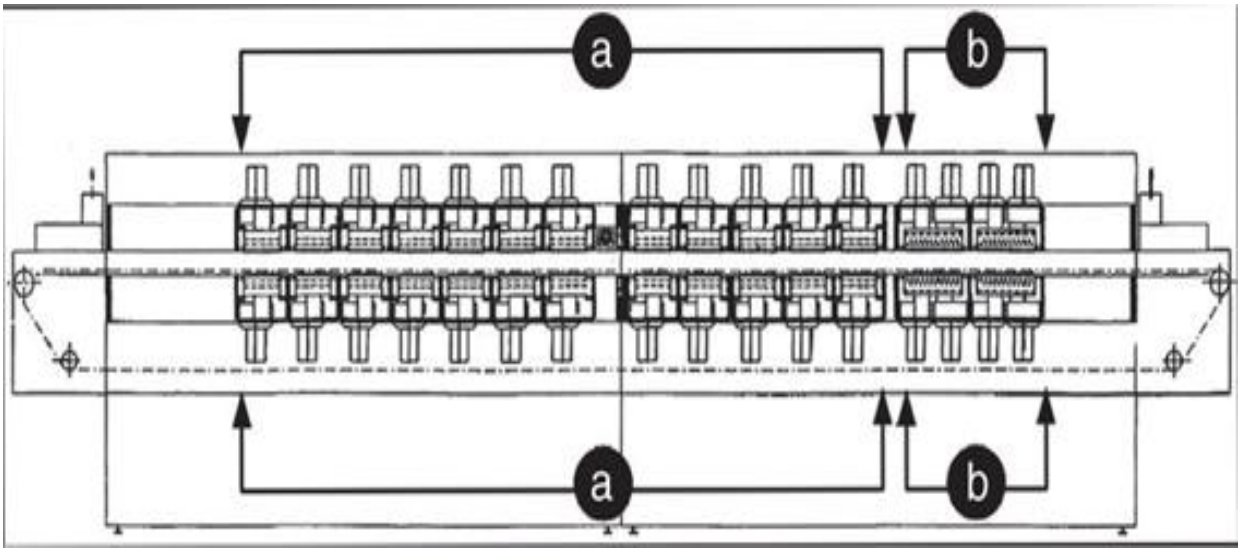

FIGURE 49.9 Forced-convection oven with 12 top and 12 bottom heating modules (*a*). Each module is independently heated and controlled. The last two top and bottom modules (*b*) are for active cooling of the soldered circuit board to ensure that solder has reached solidus before exiting the oven. In this machine, cooling zones are aided by fans blowing over water-cooled radiators. (*Courtesy of Heller Industries*.)

Active cooling comes in many forms. Some ovens use plastic “muffin” fans close to the oven exit. These must be kept on at all times to prevent overheating of the fan blades and the motor’s plastic fan support structures.

Forced-air cooling by fans is the most common. Fans can be deployed on top, on the bottom, or in combination for board cooling. Among the most exotic but the most efficient

is the water-to-gas heat exchanger found inside some ovens. This provides a stream of temperature-controlled cool air at the exit end of the oven for board cool-down and has distinct advantages for reflow systems using nitrogen atmosphere. It uses whatever process gas is in the oven, cooling it and redirecting it onto the circuit board mitigating the need for additional nitrogen for cooling. Also, it does not draw any additional air into the oven that might degrade the nitrogen atmosphere, and precludes the need for cooling fans outside of the oven adjacent to the tunnel exit. External fans create turbulence at the tunnel exit and may have a profound influence on the oxygen concentration in the oven's nitrogen-purged environment. Water-to-gas cooling is efficient, but it must be included in the reflow profile to ensure that thermal ramp rate is correct.

Some ovens use air rakes or air amplifiers to direct a flow of cooling compressed air or nitrogen at the board. In-oven cooling schemes often result in condensation of flux volatiles and flux decomposition products. As deposits build up on the coolest surfaces within the oven, they change the thermal transfer characteristics of the cooling system. This alters the thermal profile of the oven over a long period of time. Flux condensates may also drip onto circuit boards as they pass through the oven.

Nitrogen atmosphere ovens running no-clean solder pastes face the biggest challenge in trying to control these condensates. No-clean pastes give off abundant volatiles during reflow. Ambient air introduction or entrainment is kept necessarily low for precise control of the nitrogen ambient within the oven. Nitrogen volume is minimized to keep board processing costs reasonable. The result is low gas exchange within the oven's tunnel and little dilution of condensable vapors. Condensates build up rapidly on the cooler surfaces and are baked on over time and difficult to remove. Oven manufacturers have devised many elaborate schemes for flux condensate management. Gas stream filtration in and

around cooling zones, replaceable filters, cold traps, and cold fingers with self-cleaning burn-off cycles (kitchen oven-style) have been incorporated into some of the newest ovens. Several ovens have quick-change finned radiators that are swapped out, cleaned, and readied for the next change-out.

Many integrated circuit packages (ICs) and ceramic passive components have specifications for maximum thermal ramp rate. Exceeding this heating or cooling rate may damage die attach materials, crack packages, or otherwise alter electrical performance of the device. This is especially true of ceramic devices. Often the ramp is recommended in the range of 1 to 4°C/s. Additionally, some solders like Sn-Ag-Cu (SAC) require cooling rates in this range to allow for quick solidification and to discourage solder alloy segregation. Cooling too slowly encourages redistribution of alloy constituents and silver platelets, or needles can form that may detract from solder joint strength.

49.3.2.3 Venting. An often overlooked reflow oven subsystem is exhaust venting. This is most important from an industrial hygiene point of view, but it can also have a significant effect on the soldering process itself. During soldering, minute quantities of metal oxides accumulate in the oven atmosphere or coat oven tunnel surfaces. The dangers of prolonged exposure to micro-quantities of lead (Pb) or lead compounds are well documented. With the change to Pb-free materials, the risks are likely lower, but there should still be concern for inhalation of any metal or metallic compound particulates. As previously discussed, during reflow, solder paste volatilizes and releases flux reaction products. Since most solder pastes and fluxes are highly guarded proprietary formulations, the paste and flux vendors may neither accurately disclose the composition reagents nor report the decomposition products in the mandated Material Safety Data Sheet (MSDS). Additionally, if a PCB should fall off the pin-chain conveyor or a component

should fall through the mesh belt, it may land on a high-temperature surface—either the heater itself, or, in the case of forced-air convection reflow machines, the perforated baffles above the heater assembly. Either the PCB or plastic components mounted on it will overheat, decompose, and release unpleasant or even dangerous fumes. A properly designed and implemented exhaust system will mitigate these hazards.

A high-velocity exhaust may influence oven performance. Too much exhaust will cause a significant net flow of atmosphere through the oven. This may result in unwanted turbulence within the oven, upset intentional forced-convection patterns and make temperature regulation more difficult. If the exhaust is not constant and not damped for changes in outside wind speed or gusts, it may influence the soldering profile and induce process variability.

Some ovens are designed with one central exhaust flue; whereas others may be have an exhaust port near both the tunnel entrance and exit. A dedicated manometer or other vent sensor should be installed in each exhaust line to monitor setup and routine exhaust performance. Blast gates in the exhaust line permit flow adjustment. It is customary to mount vent sensors after the flow damping device. Follow oven manufacturer’s guidelines for exhaust requirements. Since the exhaust gases are laden with volatile materials, mostly from the solder paste, active exhaust systems should be checked routinely for performance. Impeller blades can foul because of the condensates from these cooling volatiles. Exhaust stack monitors should help pinpoint such problems. The smoke from a piece of smoldering cotton twine can be used to sense whether there is a net flow into or out of the oven. When venting is correct, there should be a lazy net flow into the oven at both the entrance and exit. Of course, the oven should be hot and fully operational for proper exhaust assessment. Similarly, it would be instructive to perform this test using hottest and coolest reflow profiles to

ensure that heater module settings do not affect the exhaust conditions for minimal net flow into the oven at entrance and exit. Once the exhaust properties are set, repeat the measurements with dummy boards in the oven and observe whether they have an influence on net flow. Fine-tune the exhaust flows and repeat testing as needed. Proper exhaust setting will help achieve consistency in oven reflow soldering and protect plant personnel from exposure to noxious chemical or particulates generated from the reflow soldering process.

49.3.3 Reflow Oven Requirements

49.3.3.1 Multiple Heating Zones. Reflow ovens are designed with multiple heating zones at the top and bottom along the tunnel length. Each heater or zone is independently settable and controlled to a different temperature for stable temperature control. Note that a zone here is the top and opposing bottom heater pair, as shown in Fig. 49.9. Multiple heater zones allow the required adjustment and shaping of the time-temperature soldering profile necessary for successful heating, activating of flux, reflow of solder paste, and cooling of the soldered assembly. The number of heating zones required depends on the thermal mass of the product being assembled and the necessary throughput; the more heating zones, the more controllable the reflow process.

49.3.3.2 Heater Independence. Zone separation—the influence of one thermal zone upon another—is also essential for controllable and repeatable reflow soldering. One heating zone set to 250°C should have minimal effect on an adjacent zone set to 200°C. There are no set rules for zone separation requirements; however, the greater the zone separation, the more controllable the process. Testing

this parameter prior to buying or deploying a reflow oven is necessary for proper process setup. To test, set one heater zone high and adjacent zones lower. Allow the oven to stabilize. Determine conditions that cause the higher temperature zone to influence the lower set-point zones. The lower set zones may rise in temperature above their set point; an indication that the hotter zone is causing an uncontrollable temperature influence on adjacent zone(s). In setting the oven for circuit board assembly, avoid the large differential zone-to-zone thermal conditions and stay within the range of safe zone separation as previously characterized. Overly aggressive oven venting may also influence zone separation, drawing too much room air into the oven's tunnel.

49.3.3.3 Temperature Distribution. Temperature distribution across the width of the tunnel determines the quality and uniformity of heating. Top-quality ovens have rail-to-rail thermal uniformity of about ±2°C, even for largest board widths. Such tight thermal distributions are necessary for controllable and consistent soldering.

49.3.3.4 Heater Responsiveness. Rapid response of the oven's heaters and accompanying thermal control circuitry are critical to oven performance. As a board or multiple boards pass through the oven, the oven's heat is absorbed by those cooler boards on their way to reflow. The oven has to respond to the net heat loss absorbed by the train of PCBs with their solder paste and components. The thermocouples built into the oven should sense the thermal impact on the tunnel's ambient and the net loss in temperature from the flow of product in the tunnel. Note: Boards should never be spaced too closely together, as doing so will fully segregate the top from the bottom heaters and alter oven performance. Testing should be accomplished to establish proper board-to-board spacing. The spacing is

dependent on line throughput requirements, thermal mass of the product design and effectiveness of forced-air convection and temperature control within the oven.

Board separation may be as small as a few inches, but the effects of board loading and spacing need to be determined empirically and checked to detect any impact on the process time-temperature profile. Assessment of new equipment ought to include load testing to ensure that the oven can handle anticipated process throughput and capacity. The oven's profile needs to be examined before, during, and after loading of the train of boards and compared to the performance with the same oven settings for a single board.

49.3.4 Elements of Reflow

The relationship of temperature with respect to time is of utmost importance in the oven soldering process. The settings for this relationship on the oven is referred to as the "reflow recipe" or "reflow profile." The profile will bring the PCB assembly to solder liquidus and back to solidus before exiting the oven. But it must be accomplished in a controlled manner and in accordance with the thermal requirements (maximum temperature and thermal ramp rate for heating as well as cooling) of solder paste, components on the PCB and the PCB laminate itself.

49.3.4.1 Profile Dependencies. The solder paste composition, circuit board lay-up (number of layers, thickness and quantity of copper traces and planes, PCB material), component types, component count, and the number of components per unit area on the PCB and PCB spacing within the oven will dictate or influence reflow profile characteristics. Oven performance such as heating characteristics (number of heater zones and responsiveness of each module) and repeatability of oven settings will

influence the reflow process and profile. Of course, of paramount importance is the attention to process detail of a well-maintained reflow oven by the process engineer.

49.3.4.2 Solder. The solder alloy chosen dictates the peak temperature and time required for reflow and wetting. It may also influence the post-reflow cooling rate chosen, as some solders, especially Pb-free compositions, have preferred cooling ramps.

49.3.4.3 Flux and Other Solder Paste Constituents. As discussed previously, solder paste is typically composed of three main ingredients: solder alloy, flux, and other materials added to help with rheological properties critical for solder paste printing on the PCB. The solder alloy dictates the peak temperature regime, whereas the flux and other paste components dictate the pre-reflow heating ramp rate. Heating too rapidly may prematurely dry out solder paste components. Overly rapid heating may cause the solder paste to spatter. Too little heat may not allow proper activation of the flux. There is no universal profile recipe for reflow for a given solder alloy. The solder paste manufacturer will provide guidance for the time-temperature profile for each solder paste formulation. The reflow characteristics should be consistent from batch to batch for a given paste formulation.

49.3.5 The Reflow Profile

There are four distinct steps in the reflow profile that must be accommodated by the reflow oven for successful soldering. Each step is tailored for the solder paste composition and accomplished in proper, controllable, and repeatable reflow equipment. A misstep at any of the four stages of reflow may result in product loss. Refer to Fig. 49.10 for this discussion on thermal profile.

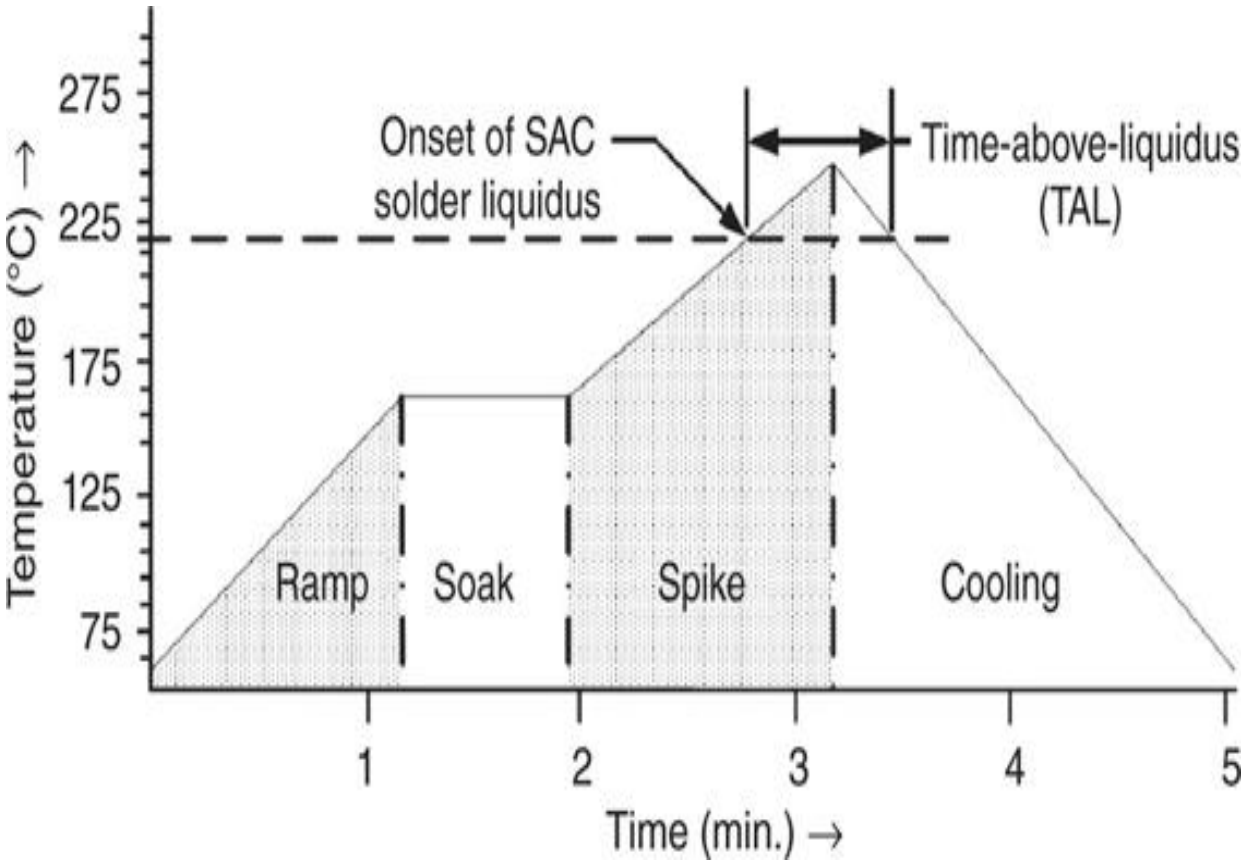

FIGURE 49.10 Schematic of a generic reflow profile for Sn-Ag-Cu (SAC) solder paste. Time-temperature values are not precise and are shown for illustrative purposes for a discussion of reflow soldering.

49.3.5.1 Initial Ramp. In this step of the reflow time-temperature profile, preheating of the boards, components, and solder paste is initialized. The solder paste begins to lose some of its volatile components and the flux becomes chemically active (activates). If the ramp gradient is too steep, volatiles will be given up too rapidly, boiling will result, and the solder paste will erupt spattering solder balls on to the PCB surface. This will result in decreased solder volume at eruption sites. The subsequent reduced solder volume may impair bond reliability. Unattached solder balls may bridge two closely spaced conductors and impart an electrical short circuit.

Overly rapid heating is known to cause component cracking. This is particularly true of ceramic components. To

be safe, restrict the ramp rate to between 2 to 4°C/s, but investigate component manufacturers' specifications as well as the solder paste vendor's recommendations for the maximum allowable heating ramp.

49.3.5.2 Thermal Soak. During this step, the solder, board, and components are further heated. The flux from the solder paste flows onto all metal surfaces in which it is in contact, continues to react away surface oxides, and also acts as a barrier to prevent reoxidation in the critical moments before the onset of solder liquidus and solder wetting (alloying). The soak is designed to provide the requisite time and thermal energy for the flux's prolonged chemical reaction with oxides and tarnishes on metal surfaces including on the solder itself.

49.3.5.3 Spike

49.3.5.3.1 Onset of Solder Liquidus. In this step, the solder undergoes a phase change from solid to liquid. The liquid metal solder wets onto fluxed metallic surfaces and flows along the component lead/PCB pad interface drawn by surface tension, capillary forces, and convective flows within the liquid metal. This is the essence of soldering and effective solder joint formation. Characterized by a rapid thermal rise, the spike's peak temperature is chosen to be well above the solder's melting point to ensure that all parts of the board, all components, and all solder paste deposits have surpassed solder liquidus onset.

49.3.5.3.2 Surface Tension Effects. While the solder is molten, surface tension effects draw component leads into best registration with circuit board pads if the component is light enough to float upon the molten solder. Passive devices (resistors, capacitors, inductors, etc.), most components with formed leads, and plastic or laminate ball-grid array packages (BGAs) self-align during this step. Solder surface tension is typically not strong enough to effect self-alignment

of heavy ceramic components such as ceramic ball grid arrays (CBGAs) and ceramic column grid array (CCGAs). Surface tension effects may also cause solder opens such as when small passive components “tombstone” (also known as “drawbridge”) because one end of the component reaches soldering temperature before the other.

49.3.5.3.3 Intermetallic Compound Formation. As previously discussed, intermetallic compound (IMC) formation occurs when the molten solder wets to metal surfaces of component leads and PCB pads. IMC thickness is dependent on the temperature and time especially when the solder is at or above liquidus. The longer the solder is heated, the thicker the intermetallic layer, and thick IMCs result in brittle bond lines and therefore degraded solder joint reliability. For this reason, overheating the circuit board during the spike should be avoided. Time-above-liquidus (TAL) should be roughly in accordance with the solder-paste manufacturer’s recommendation, which is typically 30 to 60 s, although there are no hard and fast rules for TAL. A longer TAL for some components may be evidenced on large thermal mass boards that are slow to heat and heat unevenly. In this case, some devices may overheat while others barely reach soldering temperature. Similarly, some component or board metallurgies may be slow wetting and a longer TAL may be necessary.

Some PCB finishes, such as hot air solder leveling (HASL) or reflowed tin on copper bond pads, possess a thin intermetallic layer between the applied surface finish and the PCB bond pads from the process at the PCB fabrication shop. During surface-mount technology (SMT) reflow, the additional reflow cycle will further its growth. Therefore, the TAL should be limited to minimize IMC but must be sufficient for good solder wetting.

49.3.5.3.4 Materials Degradation. During spike, board laminates, component bodies, etc., can degrade, so trials should be performed to ensure that all materials are

compatible with chosen reflow parameters. If plastic-bodied connectors are being applied during SMT reflow, make sure that the connector's normal contact force has not been jeopardized by distortion or softening of the connector body during the spike. Inspection of connector contact gaps before and after reflow and comparison to the connector manufacturer's specifications will provide clues as to whether the connector is truly compatible with the reflow process.

49.3.5.3.5 Cooling. The fourth and final stage of the reflow cycle is cooling. It is here that the board's temperature is lowered beyond that of solder liquidus prior to exiting the oven. Once again, recommendations for device heating- and cooling-ramp rates should be heeded. Most electronic packaging and board materials are reluctant to shed heat quickly. If the board is thick, the laminate, a relatively poor thermal conductor, will remain hot. It must be cooled to below solder liquidus prior to exiting the oven to preclude dislodging of any solder-wetted components or disturbing the solder joint solidification process. On the other hand, with the trends toward thinner circuit boards, slimmer components, and hot, fast-soldering profiles (to keep up with high-volume product demand), it is wise to ensure that the negative thermal ramp requirements are considered for this step also.

As mentioned previously, the solder paste manufacturer will provide recommended profile guidelines, but those are only a starting point. The process engineer must optimize the reflow oven profile with product profile boards and analysis based on actual product runs. Board profiling will be covered in a subsequent section.

Older textbooks and industrial references cite completeness of fillet formation and solder reflectivity as typical hallmarks of a good reflow process, but these are subjective measures that may not be true indicators of solder joint quality. As mentioned previously, overheated

joints will be brittle although they may appear to be well wetted. SAC and other Pb-free solder alloys have a naturally grainy-looking solid structure as compared to that of Sn-Pb, so a dull solder joint is not necessarily indicative of a poor solder joint. Tests such as tensile pull- peel, shock and vibration, thermal cycling, x-ray for solder void content, and metallographic cross-sectioning are much better means of assessing solder joint quality. There is yet another implication with the move to SAC solders. If not quenched quickly, this alloy is known to result in some constituent separation. Silver may precipitate out as platelets or needles. This can be minimized by using a fast cooling ramp. Check with component manufacturer's specifications so as not to jeopardize component integrity.

49.3.6 Successful Oven Reflow

Successful soldering is dependent on several factors including suitable, well-maintained and properly controlled reflow equipment; good-quality solderable parts; a thermally balanced board designed for the reflow process; a well-tested and reliable solder paste; a proven time-temperature profile; and good thermometry techniques.

49.3.6.1 Adequately Maintained and Controlled Reflow Equipment. The oven should have small thermal differentials across the width of the tunnel and should be capable of adequate heating and cooling ramps as well as appropriate zone separation characteristics. It should be stable for a given zone setting, not varying by more than a couple of degrees centigrade. Similarly, the conveyor speed should be stable, not varying by more than 1 to 2 cm/min.

49.3.6.2 Good-Quality Solderable Parts. The best reflow equipment, profiles, and solder paste will not make up

for inadequacies in part quality or restore solderability. Good solderable parts and boards are a must for successful reflow.

49.3.6.3 Coplanarity of Component Leads. Coplanarity of component leads, BGA balls, or CCGA columns is a must. All leads on a component should share a common seating plane within the specified tolerances associated with the component vendor's specification. The coplanarity requirement also depends on the stenciled solder paste height and paste deposit uniformity, as the solder paste accommodates some small differences in lead-to-lead coplanarity both as a paste and also as the solder assumes the characteristic dome shape upon melting.

49.3.6.4 Component Storage. Extended storage should be avoided and parts should be kept cool and dry prior to use. Sufficient quality control methods should be established to ensure that the solder and components leads are solderable. Plastic molded parts such as plastic quad flat packs (PQFPs) and plastic ball grid arrays (PBGAs) can absorb moisture from the atmosphere over time. When moisture-laden plastic packages are subjected to reflow soldering, the entrapped vapor may expand to the point where the package fractures, often damaging the silicon die and associated wires internal to the package. This phenomenon is commonly known as "popcorning" throughout the industry. Ensure that plastic packaged components are stored in unopened bags as supplied by the component vendor until time of use. Once the components are removed from the manufacturer's packaging, follow IPC/JEDEC guidelines[1] for useful shelf-life in the unbaked state and any bake-out requirements prior to soldering.

49.3.6.5 Board Design for Oven Reflow Soldering. Thermal balance of the board design is important for reliable and adequate reflow. Ensure that a

design for manufacturing (DFM) review of the board has been done and that thermally massive components are distributed over the board and not relegated to one portion of the PCB. Also, it is desirable to distribute smaller components rather than to create component fields to permit uniform thermal balance across the board. Components should be spaced adequately to prevent shadowing of smaller devices on the board by larger, neighboring components. This is particularly important in IR ovens without the forced-convection option. If the oven is characterized by poor uniformity across the tunnel width, the board should be oriented, if possible, to take advantage of the imbalance; that is, the board edge with greatest thermal mass should be aligned to the oven edge with the highest recorded process temperatures. Component placements should be designed far enough away from board edges to preclude mechanical interference with the pin-chain conveyor. Design in enough edge clearance tolerance to accommodate board movement on the pin-chain or variations in pin-chain length from machine to machine.

49.3.6.6 Paste and Profile. The profile provided by the solder paste manufacturer is only a recommended starting point that needs to be optimized for the reflow conditions and process time requirements. Solder paste with finer solder particles are more troublesome to flux owing to their greater total surface area and corresponding greater surface oxide volume per unit volume of solder. It is important to limit exposure to high temperatures and particularly time above liquidus, as it is in this regime that the intermetallic layer growth is most vigorous. The thicker the intermetallic layer, the more brittle and less reliable the solder joint will be.

49.3.7 Good Thermometry Techniques

Understanding the thermal impact of the oven on the board and the board on the oven is critical for a controlled and reproducible reflow process. Thermometry is the only practical method for validating these influences by means of oven profiling. Oven-and-board interactions are explored in this pre-soldering step and the oven is adjusted for proper time-temperature profile of the PCB with the parts to be soldered. Some of the most important process points determined through board and oven profiling are

- Ensuring heating-cooling ramp rates are within the recommended bounds prescribed in surface-mount device (SMD) component and solder paste specifications
- Peak process temperature and duration
- Dependency on the heater types, quantities, cooling methods on board, and component materials
- Conveyor speed
- Heat distribution along the oven's width
- Heating characteristics of the PCB and the SMD components upon it
- Rate at which the oven reacts to the board's presence

49.3.8 Product Profile Board

The only way to assess the impact of reflow variables as listed above is to accurately gauge the thermal environment in the oven in the presence and absence of the board or boards. Most process engineers trust their favorite profiling board to determine the health of their reflow oven or assess the performance of a new oven prior to purchase. The profiling board is simply a thermocouple-instrumented

product board or test vehicle that is run through the oven for the purpose of determining the oven’s effect on the board for given heater and conveyor speed set points. The thermocouples trace the temperature profile of the oven as seen by the component lead or package as the board is conveyed through the oven for reflow. However, reliance on a product board to determine oven performance may mask some inherent problems with the reflow oven. If the board is not thermally balanced in terms of component placements, component mass or board inner layers, it may not be able to detect a strong transverse (rail-to-rail) thermal differential. Also, when the same board is sent through the reflow process many times, the laminate starts to degrade. If layers separate or if thermocouples start to lift, false readings may result. It is for these reasons that a balanced oven diagnostic profiling device should be made and run to assess oven performance independent of a product board. The oven diagnostic board is not a direct replacement for the product profiling board. The product profile board is used to verify that the critical sectors of the board and device leads are heating per set profile. Thermocouples for this board should be deployed at the leading edge, trailing edge, center, and sides, with the thermocouple beads ideally embedded within the solder joints of disparate component types. Additional thermocouples can be placed on unusually massive components as well as on adjacent smaller components to determine whether a large component is thermally shadowing its diminutive neighbor. The number of thermocouples deployed depends on the package types, known oven characteristics, board thickness, board layout complexity, etc. The following sections describe good thermometry practices and the oven diagnostic board, as well as some of the thermocouple measuring innovations that are now routine for large-scale mass reflow manufacturing operations.

49.3.8.1 Oven Diagnostic Board. The oven diagnostic board can be a very simple or a rather complex device. Its job is to probe the normal operating conditions of the oven and determine variations in the oven and whether all the heaters and forced-convection fans are working properly. It is useful in assessing not only the oven's time-temperature profile parallel to the tunnel's long axis, but also perpendicular to it at the rail edges. The data recorded from this board are not necessarily translatable to the establishment of a product time-temperature profile, but are more suited to determining oven performance. The diagnostic board, whether a product board or a separate test board or other device, should be thermally symmetrical, made from a low thermal conductivity material, or best, a rigid thermal insulator. It should also be of low thermal mass. Attached to this are thermocouples mounted top-side and bottom in an evenly spaced array across the width of the material. They should be mounted close enough to the conveyor rails to gauge their influence on the thermal profile. Thermocouples should be identical in wire gauge, bead size, length and spacing from the insulating material. Furthermore, they should also be mounted slightly off the insulating material such that the heated oven environment can freely swirl around them. Measuring with such a device provides a true picture of the oven's thermal environment. Figure 49.11 shows a schematic of one such device developed for oven diagnostics.

FIGURE 49.11 Schematic plan view and detailed side view of an adjustable oven characterization fixture (oven diagnostic tool) composed of pairs of thermocouples, shielded from one another by a rigid, heat-resistant insulator. The thermocouple positions are adjustable in width and length for investigating temperature distribution along the tunnel width.

49.3.8.2 PCB Thermometry. Knowledge of good thermometric practices and thermocouple use is critical to acquiring accurate and useful board time-temperature profiles and oven thermal performance information.

49.3.8.2.1 Good Thermocouple Practices. A thermocouple is composed of two atomically disparate metals or alloys in contact with one another. The wires are joined by twisting them tightly together or preferably by welding (Fig. 49.12*a*, *b*).

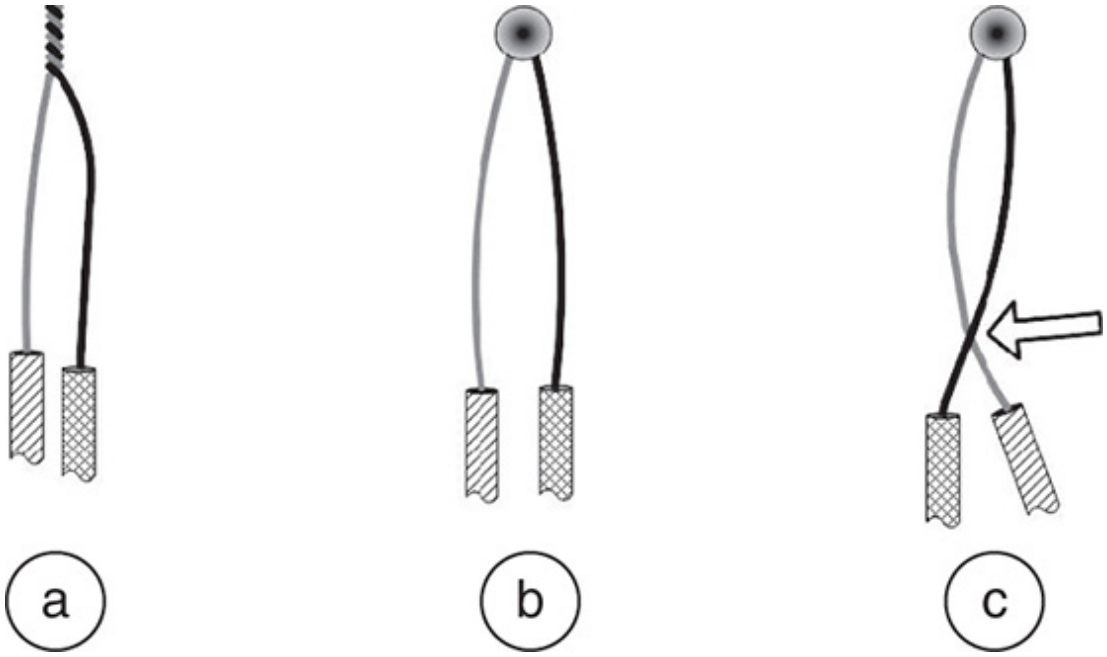

FIGURE 49.12 Thermocouples: (*a*) twisted couple; (*b*) welded couple; (*c*) welded couple with an inadvertent couple (see arrow).

Once joined together, the atomic difference between the two metals results in an electron flow and a measurable voltage which is temperature dependent. It can be calibrated and used for accurate temperature measurement.

Thermocouples are simple to make. The two different wires need only touch one another at a single, discreet point to form the couple. This simplicity in construction can also be problematic. If the two wires inadvertently contact (Fig. 49.12*c*), thermocouple output will be related to the temperature at that accidental juncture rather than at its termination. In the case of a thermocouple sandwiched between a component lead and PCB pad (Fig. 49.13) and an accidental junction formation nearby, the thermocouple will register the temperature of the oven air plus any thermal conduction along the thermocouple rather than the true temperature of the combination of component lead, solder and the PCB at that intended sensing location. Since the oven air temperature is generally much hotter than the PCB traveling through it, the resultant soldering time-temperature profile (based on the false thermocouple reading) may be cooler than desired and cold (under-reflowed) solder joints may result.

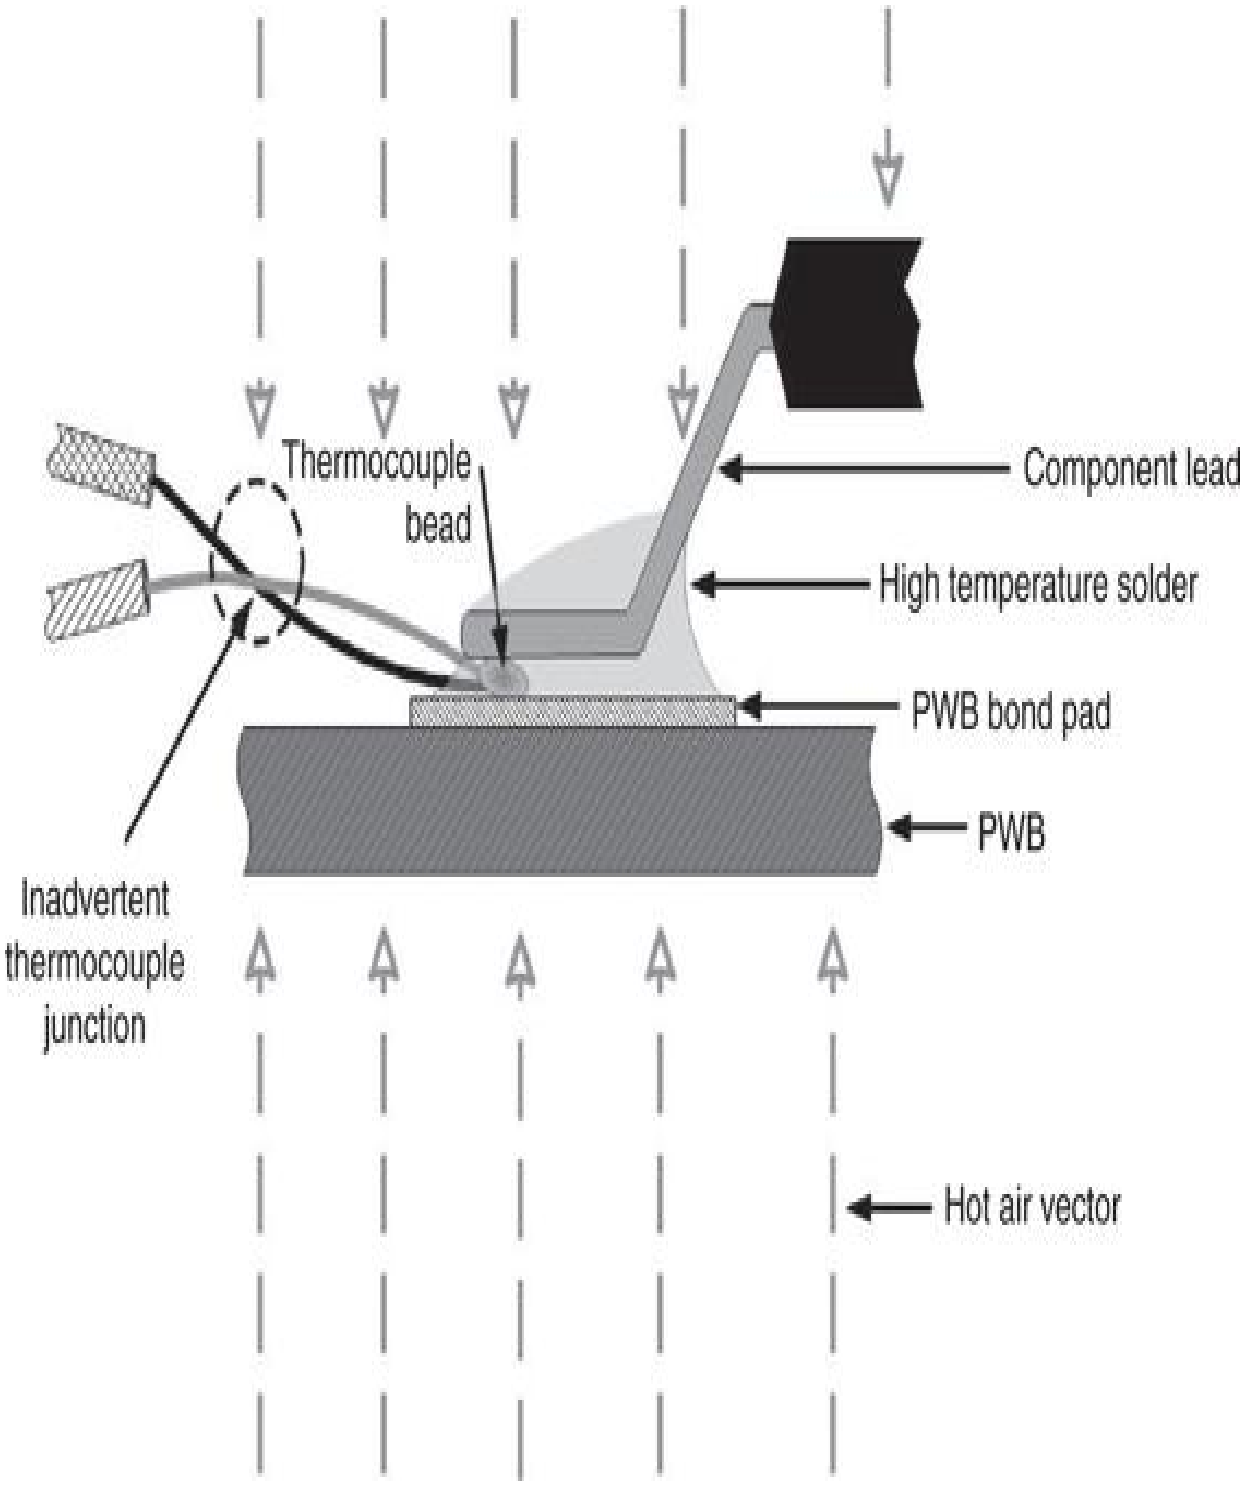

FIGURE 49.13 Arrows indicate impinging forced-convection flows from oven blowers. The inadvertent thermocouple junction (crossed wires) will record oven local air temperature rather than the intended measurement target—the solder joint area. The component lead is covered in high-temperature solder so it will not melt during reflow profiling.

49.3.8.2.2 Welded versus Twisted. A thermocouple wire pair should welded at its end to preclude noise-induced measuring errors from intermittent wire pair contact. Small, inexpensive bench-top welders are available for this purpose. Ideally, the two halves of the thermocouple pair should touch at only one point—that closest to the area desired for temperature measurement. The welded pair has a significant advantage in that the resulting weld bead can be made small and uniform in shape. As a rule of thumb, the weld bead diameter can be made as small as about 1.5 times the diameter of the individual wires that compose the couple. If constructed properly, the temperature will be sensed only at the weld bead. Regardless of whether the couple is made or bought, always check with a magnifier or microscope to ensure the integrity of the bead and that couple wires are only touching at the bead and not at any point below it. During manufacture of a thermocouple assembly, the usual practice is to twist the thermocouple wires together prior to welding. Upon welding, the twisted material will fuse and melt back to form the bead. After welding, it may be necessary to untwist the pair just behind the bead. While doing this, inspect the integrity of the bead to make sure it is a good metallurgical joint. Note that many thermocouple materials are brittle before welding and are even more so afterward.

49.3.8.2.3 The Most Common Couple. The most common thermocouple used for PCB profiling application is the “K” type, Ni-Cr/Ni-Al (chromel-alumel) couple, as it possesses a thermal measurement range best suited for soldering of circuit boards regardless of solder alloy type.

49.3.8.2.4 Measurement Instrumentation. There are two main devices in use for measuring the output of the thermocouple: the reflow tracker and digital (electronic) thermometer. The latter is a primitive device which uses a long thermocouple attached to a single point on the PCB and does not provide the wealth of information afforded by the

reflow tracker. Digital thermometers have an output that must be recorded by hand or connected to a time-based chart recorder.

Preferred is the electronic reflow profiler or tracker, an electronic package that can not only output the time-temperature plot of multiple thermocouples but can also make certain assessments of the data, such as heating ramp rate, preheat time, time above liquidus, cooling ramp rate, and other attributes. Tracker systems are computer-based and battery-powered and can generate detailed reports and graphs of a reflow cycle. They are made to travel through the oven with a profile board. As such they are designed with a thermal protective cover that protects their battery-powered electronics to survive the rigors of the high-temperature environment of the reflow oven. The reflow tracker eliminates the need for excessively long thermocouple wires as necessitated by the digital thermometer. Long thermocouples can result in resistive losses and thermal heat-sinking effects both of which detract from the accuracy of temperature measurement.

Tracker sampling rate can be selected to record the circuit board’s attached thermocouples at short time intervals (several times per second) for the entire trip through the oven’s tunnel. When the tracker emerges from tunnel, it is removed from its protective thermal barrier and docked to a computer. The data stored in the electronic tracker are uploaded to the computer, conditioned, displayed and or printed for analysis. The user defines the reporting format, including the type of data sought, thermocouple plots, and other relevant, run-related data. Some systems are capable of making predictive corrections to the profile based on tracker measurements and oven settings. This can further enhance the ease of adjusting a complex multizoned reflow oven to meet the requirements of a particular job. Whether a simple or complex model is selected, the reflow tracker is invaluable for setting up the oven and checking process

repeatability. Some reflow trackers even output temperature by a wireless transmitter so that measurement data can be observed in real time.

When an electronic tracker is used, its presence in the oven may have an impact on the resulting profile data by affecting the local aerodynamics within the oven. The trackers also have thermal mass, but all trackers are sold with an insulating cover to protect their electronics. It is best to check the influence of the tracker's presence as it traverses through the oven tunnel. To do this, ensure the oven has warmed to a steady-state operating condition, run the profile tracker with the tracker a fixed distance behind the profile board. Note that the tracker is usually placed to follow the board in reflow. Were the tracker to precede the thermocoupled profile board, it might cause the heaters to ramp up as the oven attempts to compensate for the thermal mass of the tracker or compensate from the disrupted or deflected air flow. Although that is what happens during a reflow cycle as a cooler board enters a heated zone of the oven, the oven would attempt to adjust for the board's thermal mass. The added thermal mass or disruption of the air flows from the profile tracker would not be a factor in the normal reflow process. Rather than assessing the reflow tracker effect on the profile, keep the tracker approximately one board length or slightly more away from the instrumented profile board, to eliminate tracker influence on the measured profile.

49.3.8.3 The Profile Board. The profile board is the keystone for any soldering process. It is a board loaded with its complement of appropriate components. Thermocouples are attached to critical locations to ensure that proper soldering temperatures are reached during the bonding cycle. Typically thermocouples are embedded under BGAs (innermost joint and outermost joint) and on fine-pitch device leads and even on some passive components to

ensure that that all parts are receiving enough heat without significantly overheating or under-heating other parts. Sometimes it is impossible to achieve the perfect balance, and in such cases the thermal advantage is given to the area array components (BGAs, CCGAs, etc.) to ensure good soldering beneath while slightly overheating the lighter components.

It is good practice to attach thermocouples to components on the leading edge of the board, the trailing edge of the board, the sides, and the middle. It may take more than one trip through the oven to collect all the data for all these locations and to get a good picture of the thermal effects of the profile on the various components on the PCB.

There is no substitute for a profile board. Some have tried weighing the board for an estimate of thermal mass. Generic profiles with overly hot peak temperatures have been applied and other supposed shortcuts have been attempted. None of these approaches have been proven to be reliable or successful over a range of board types. There is no replacement for preparation and proper thermal assessment with a profile board.

Typically for oven reflow soldering, one profile board is prepared for the secondary-side reflow profile (on which only secondary-side components are mounted), then another for primary-side reflow profile (in which both secondary- and primary-side components are mounted). Another board is prepared for wave soldering (all SMDs loaded plus PTH parts). These boards also double as rework profile boards.

It is wise to attach thermocouples to power and ground pins if that information is readily available. These connection points are the most thermally challenging points for a particular device. This is especially true on thick motherboards where there may be multiply interconnected, thick ground, or power planes embedded within the board. Thick copper planes are thermally massive, slow to heat and

slow to cool because they are somewhat insulated by the PCB's epoxy/glass lay-up.

Always allow the profile board and the reflow profile tracking instrument to cool to room temperature before attempting another profile check. Cooling with a fan greatly decreases the wait time.

49.3.8.3.1 Thermocouple Deployment. The size and position of the thermocouples is critical for accurate and reliable thermometry. There are many methods for securing the thermocouple bead to the PCB and some simple rules for proper thermocouple use:

- The thermocouple junction (the bead) must be in contact with the object to be measured.
- Each of the thermocouple legs must be kept at the same temperature.
- There should be only one junction (the bead) between the two legs of the thermocouple as mentioned previously.
- The measuring technique must not interfere with the outcome of the measurement.
- The thermocouple bead must be in intimate contact with the lead and pad combination of the solder joint to be measured. Therefore, the thermocouple bead should be inserted between the device lead and the circuit board bonding pad or as close to it as possible. Flattening the thermocouple bead also helps in positioning it between lead and pad. Flattening can be accomplished with smooth-jaw pliers, a smooth-jaw vise or a hammer.
- After flattening the bead, check to ensure that it is neither cracked nor broken.
- It is good practice to tailor the size of the thermocouple wire and, thus, the bead, for the scale of the solder joint to be measured.

49.3.8.3.2 Preparing the PCB for Thermocouple Placement. For BGAs and other area-array devices, it is necessary to drill a small diameter hole through the board and into the BGA ball or column. This procedure is done with a fine drill bit slightly larger (~0.25 mm) than the BGA ball. The drill bit should be kept short (slightly longer than the board plus ball thickness) to avoid breaking the bit and also to gauge the drill depth. Drilling on a drill press rather than with a hand drill will also serve to minimize breakage and improve positional precision.

It is helpful and easiest to drill the thermocouple hole locations for BGAs or other area array devices before populating the profile board with any components. Doing so allows the board to sit flat on the drill press table since there are no mounted components on either side of the board. After drilling, the board can be assembled (printed, SMD components placed and reflowed) using an overly hot thermal profile as this is only a mechanical assembly. It is critical that there are solder joints for each and every component on the board but solder joint quality is not important here.

Once assembled, the pre-drilled holes can be cleared of any solder by using a hand-held twist drill bit the same size as used for the original hole. The hole is deepened to extend into the BGA ball in preparation for thermocouple insertion. As long as the hole diameter is kept small, there is no need to add solder to retain the thermocouple within the BGA. If the hole is kept slightly larger than the thermocouple bead, the radiated air temperature within the hole and around the thermocouple bead should be the same as the ball temperature. Of course a very fine thermocouple is needed for this application (Fig. 49.14).

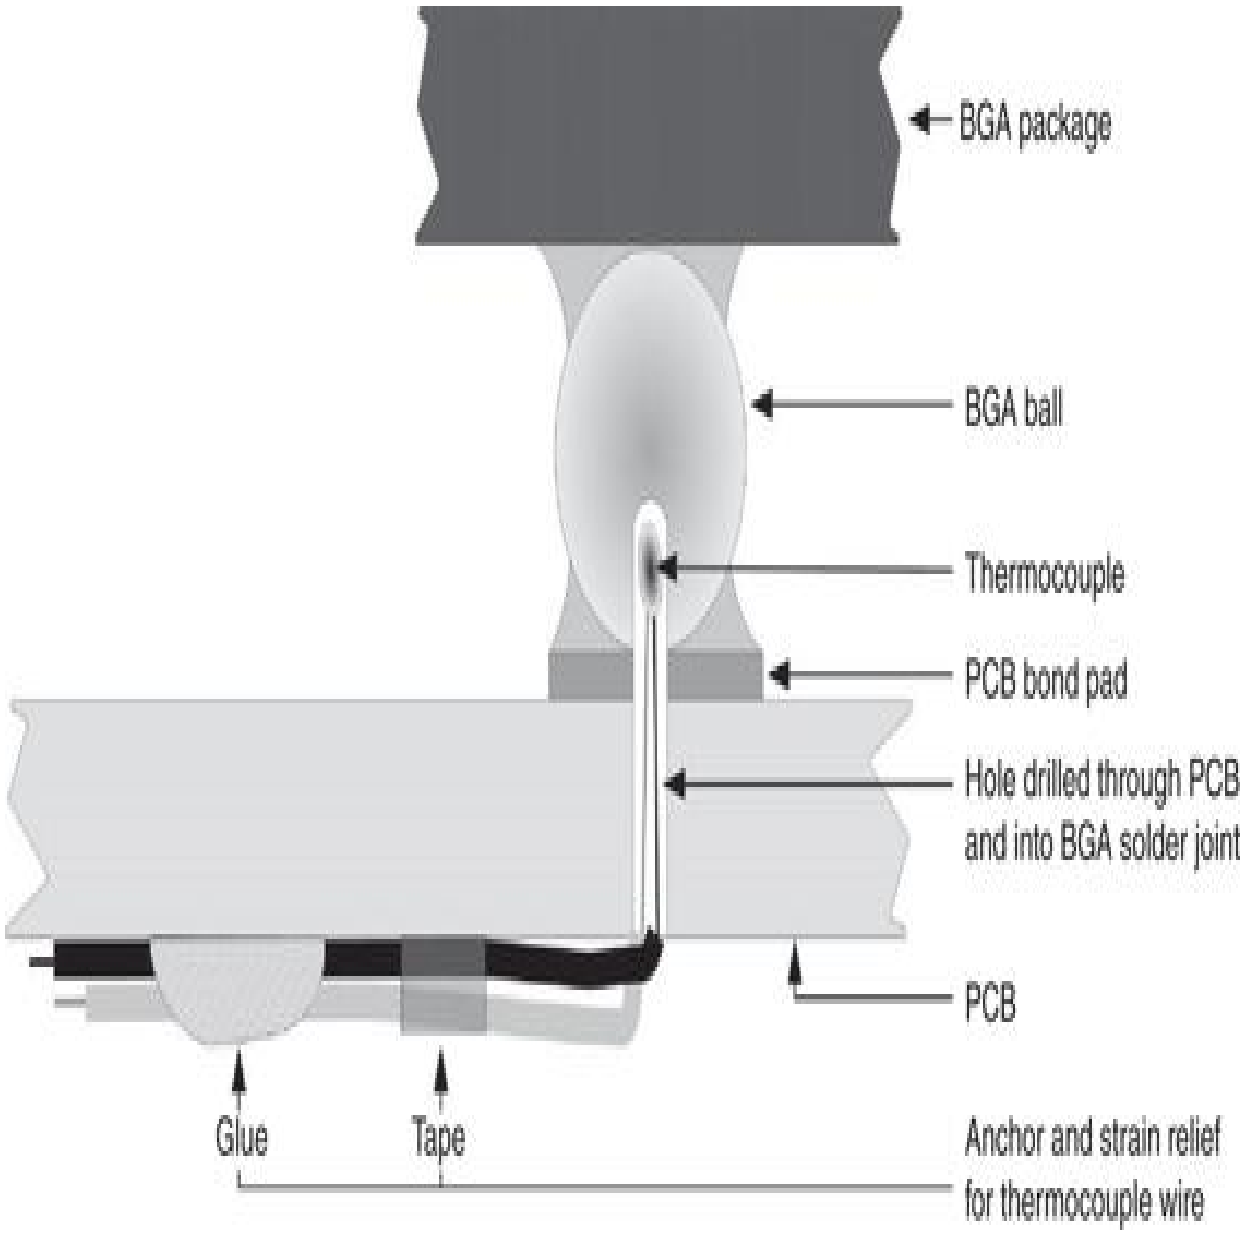

FIGURE 49.14 Thermocouple embedded into BGA ball. Thermocouple leads are anchored to the board with a small dot of high-temperature adhesive or high-temperature adhesive tape.

It is good practice to anchor thermocouple leads to the board to keep them in place and to prevent dislodging of the bead from its intended measurement target. The anchor also serves as a strain-relief for the thermocouple wire. A high-temperature adhesive or heat-resistant adhesive tape should be used. Tapes and glues are insulators, so care must be

taken to keep the anchoring glue or tape small in size and away from areas of thermal interest. Note that there is no need to seal the drilled hole into which thermocouples are inserted. These are miniature blind holes largely filled with thermocouple wires. Air transfer within this hole will be negligible. The air temperature in the hole will be fractionally close to the surrounding PCB and BGA materials. Use care so as not to cross thermocouple legs within the drilled hole as explained previously (Figs. 49.12*c* and 49.13).

49.3.8.3.3 Thermocouple Size. Many factors can confound the solder joint temperature measurement process, regardless of whether the thermocouple bead is properly deployed between lead and pad. Among these are the size of the bead and the thermal mass of the thermocouple assembly. In general, the use of finer-gauge thermocouples such as 30 to 36 American Wire Gauge (AWG) (Table 49.1) is recommended. Small size permits insertion between lead and pad even at very fine lead and pad pitches. It also facilitates inserting the bead into or near a solder ball of a BGA as discussed. Ideally the thermocouple bead will be completely embedded within the solder joint to be measured. If pitch is so fine that it is not practical to measure just one lead-pad combination, then it is reasonable to measure two sets of leads and pads.

TABLE 49.1 AWG versus Wire Diameter and Anticipated Thermocouple Bead Diameter

AWG	Wire Diameter, in	Wire Diameter, mm	Bead Diameter, in	Bead Diameter, mm
20	0.032	0.81	0.048	1.22
24	0.020	0.51	0.030	0.76
30	0.010	0.25	0.015	0.38
36	0.005	0.127	0.0075	0.19

Strive for the shortest possible length of thermocouple wire pair that is practical for the application. Long, large diameter wire may conduct heat away from the solder joint to be measured, altering its true heating nature and actual temperature.

49.3.8.3.4 Securing Thermocouple Beads

THERMALLY CONDUCTIVE ADHESIVE If an adhesive is to be used to hold a thermocouple bead to PCB pad or lead/pad combination, the adhesive's thermal conductivity must be taken into account. Most thermally conductive adhesives are not nearly as conductive as metal or solder. The best are filled with materials such as aluminum, boron nitride, or other thermally conductive materials. If the thermal conductivity is not high enough, a false thermocouple reading may result. Thermally conductive adhesives are meant to be applied thinly since conductivity depends on bond-line thickness. It is wise to baseline a filled adhesive against a soldered thermocouple to ensure that its insulating properties are not affecting measurement results. Also confirm that the adhesive will survive multiple reflow cycles and still maintain its thermal conductivity as reflow profile boards are used many times to establish the original soldering profile and to verify the profile from time to time.

Were the adhesive to release the thermocouple bead during the process, then measurement data would be useless. Many adhesives will not tolerate the high-temperature environment of soldering or the continuous thermal cycling encountered in trying to attain a proper soldering profile. This is especially true with the onset of lead-free soldering and the higher soldering temperatures associated with the move away from lead-bearing alloys.

ADHESIVE TAPE. Tape should be avoided for holding the thermocouple bead to the board. As tape heats, it stretches, expands, or even releases from the PCB allowing the thermocouple bead to float off its measurement target. If the thermocouple lifts, it will be gauging the environment rather than the lead/pad combination. Tape may also shield the thermocouple and the solder joint from the oven ambient, which is contrary to the task at hand. Some polyimide-based tapes can be used sparingly to anchor thermocouple wires (not beads) to the board to keep the wires in position and for strain-relief; but never for holding down the thermocouple beads.

HIGH-TEMPERATURE SOLDER. Best practice is to use a high-temperature solder to secure the thermocouple bead to its measurement site. The bead is not really soldered, as the K-type thermocouple wire is not easily wetted by most solders and fluxes useful for the surface-mount process. Instead, the solder bead is positioned under a component lead, and the lead/thermocouple/pad is covered over with the high-temperature solder alloy to anchor it in place (Fig. 49.15).

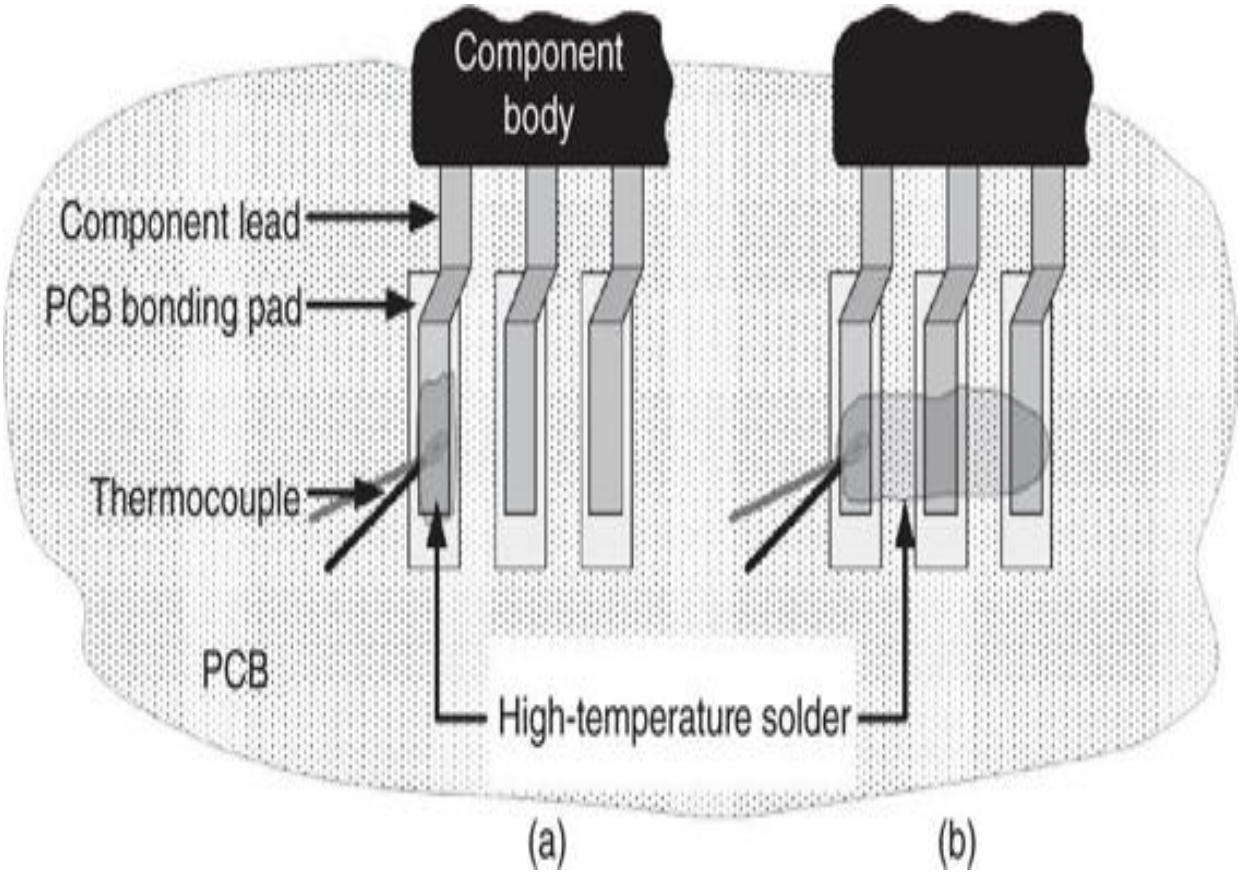

FIGURE 49.15 Check the quality of the thermocouple attachment: (*a*) a good thermocouple deployment. The bead is secured beneath a single lead and held in place with high-temperature solder. (*b*) The thermocouple is held in place by high-temperature solder but the solder has bridged to multiple leads and the bridged solder and extra leads has added significant additional thermal mass to the measurement. Temperature indicated will be that of the entire thermal mass of leads and solder rather than a single lead as in “a.”

The chosen high-temperature solder should have melting range or melting point well above the intended peak reflow temperature needed for PCA production. An alloy such as 10Sn/Pb (melting range near 300°C) is appropriate as most Pb-free solders melt in the vicinity of 220°C and the peak soldering temperature is generally less than 255°C. Before applying the high-temperature solder, it is advisable to use a fluxed copper wicking braid to remove any solder associated with normal manufacturing assembly of the board. The alloying of the high-temperature solder with the solder used for SMT may depress the melting range of the high-

temperature solder and increase the potential for reflow and release of the thermocouple bead during profiling.

For leaded components such as SOICs, QFPs and other externally leaded devices, a piece of polyimide tape can be used on the solder paste stencil to block the aperture associated with the thermocouple location. That will preclude the need to unsolder and remove solder from the component lead/pad for thermocouple insertion.

49.3.8.4 Profile Board Components. The profile board can be populated with dummy, electrically failed or reject components. It is not important that all leads be soldered, just a majority of them.

The board should last many profile cycles. Save the profile board after profiling is completed as it should be used to verify oven performance and profile prior to a manufacturing run.

49.3.8.5 Profile Board Spacing. In ovens with pin-chain conveyors, it is common practice to place the profile logging device (reflow tracker) on a dummy board that is trailed behind the profile board or on an expandable carrier made for holding the data tracker. The distance between the profile board and the dummy board or data tracker carrier should be at least one board length. Thermocouple wire length beyond the thermal profile board should be slightly longer than one board length (Fig. 49.16).

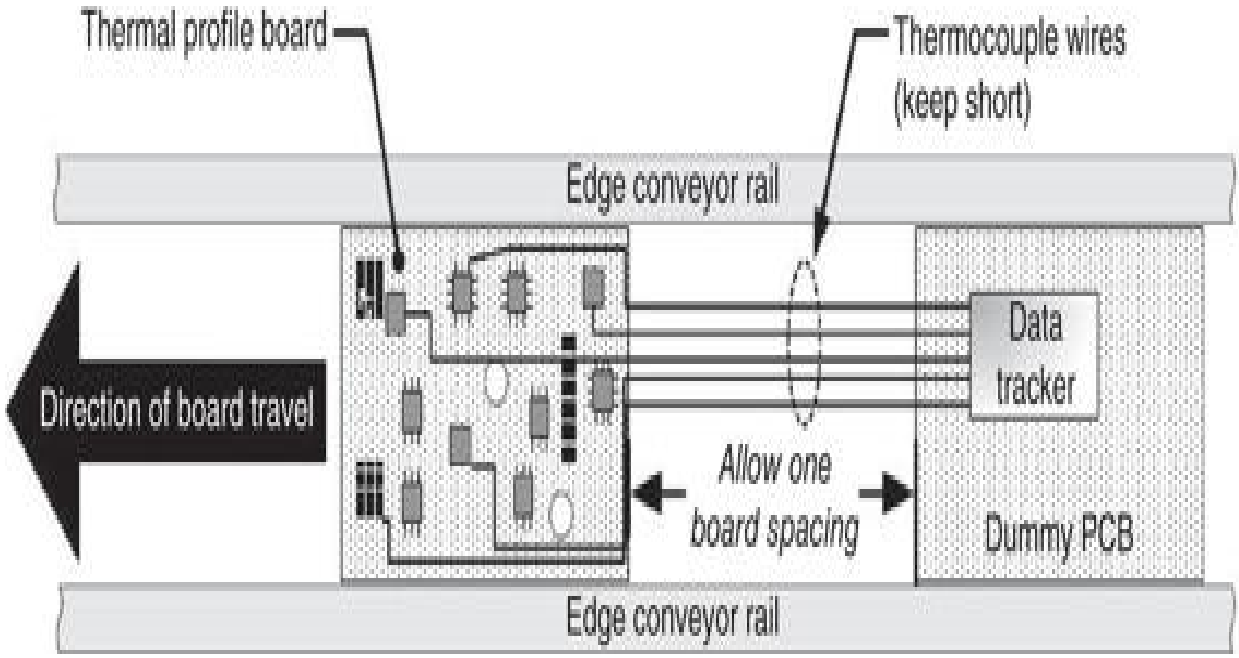

FIGURE 49.16 The thermal profile board should be kept a distance of about one board length from any dummy board or carrier for the data tracker. This enables the oven heaters and air-flow in the oven to function properly.

Were the two boards abutting, the heaters would try to compensate for a much larger thermal mass and tend to overheat; a situation different than during steady-state manufacturing. This rule also applies to thermal profiling at wave soldering.

49.3.9 Pin-in-Paste Soldering (Intrusive Reflow Process)

An adjunct to the surface-mount process, pin-in-paste (PiP) soldering, sometimes referred to as intrusive reflow, allows the soldering of some through-hole (solder-tail) parts into plated-through holes (PTHs) on the circuit board during SMT oven reflow. This process can eliminate or reduce the need for wave soldering—a step prone to defects.

To accomplish PiP soldering, solder paste is printed over PIP PTH locations during the SMT solder paste printing

process. Next, the through-hole components (axially leaded parts, pin-grid arrays, solder-tail connectors, etc.) are inserted into their respective PTHs before or after surface-mount component placement. Once the surface-mount components and the solder-tail parts are placed, the paste-bearing PCB is passed through the SMT reflow oven heated with an appropriate time-temperature profile. During the reflow process, the molten solder coalesces around the through-hole pins wetting between the pin and the PTH barrel. Surface tension and capillary action draw the solder paste down between the pin and the PTH barrel. As the solder alloy melts, it wets to the fluxed pin and barrel and upon cooling a solder joint results.

49.3.9.1 Solder Paste Deposition for Pin-in-Paste Soldering. To prepare a board for pin-in-paste soldering, generous amounts of solder paste are deposited over or adjacent to the circuit board's targeted PTH sites. This is done during solder-paste stenciling in preparation for SMD component placement and reflow (Fig. 49.17).

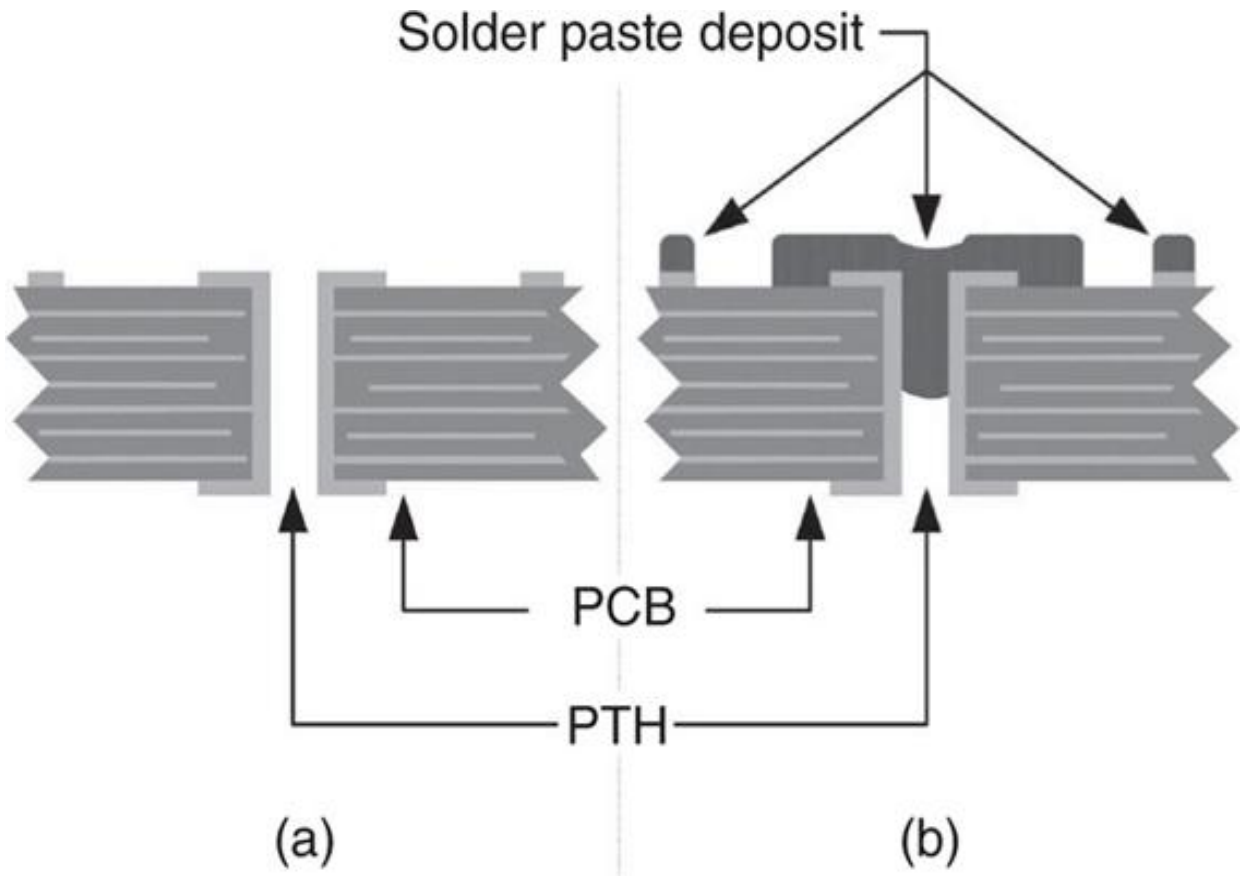

FIGURE 49.17 Solder paste stenciling in preparation for SMD and pin-in-paste component placement: (*a*) a PCB cross-section prior to solder paste deposition; (*b*) the same PCB after solder paste deposition. Note that SMD pads and plated through-hole (PTH) have received solder paste deposits. In the case of (*b*), paste has been forced into the PTH by the squeegee during solder paste printing (stenciling) process.

Of course, stencil apertures have to be created in the surface-mount stencil to accommodate paste deposition on PTH sites for pin-in-paste soldering.

49.3.9.2 Solder Volume. The inability to apply enough solder paste to meet standard through-hole solder joint acceptability criteria is one of the major shortcomings of pin-in-paste reflow. That is why this technique is usually relegated to thinner boards [≤1.6 mm (0.063 in) thick]. Requisite solder volume is dictated by: component pin pitch; available printing space between component leads; stencil thickness (generally limited by the smallest or finest pitch

surface-mount components on the PCB); PTH volume and associated component lead displacement volume.

Since necessary solder volume for pin-in-paste reflow is a function of the ratio of PTH volume to component lead displacement, it follows that reducing PTH barrel size is advantageous, especially in the case of thick PCBs. But if the annulus between lead and barrel is reduced by too much, there is a tendency for excessive void formation. Solder pastes formulated for surface-mount applications consist of solder spheres in a creamy matrix of organic chemicals composed of soldering flux and other materials to help with printing and component placement requirements for SMT processing. PTH voids during pin-in-paste soldering are generally caused by vaporization of solder paste organic components and entrapment of the gas in the molten solder or gaseous ejection of solder during the reflow process. Paradoxically, enlarging a plated-through hole in a thicker board may also benefit the pin-in-paste technique. The paste printing process drives solder paste into the PTH, effectively increasing the solder volume available for joint formation. A double-print cycle forces more paste into through-holes. If solder paste is in the PTH, some quantity of it will be displaced as the component's lead is inserted (Fig. 49.18*a*). Upon reflow, the solder generally wets back up the pin (Fig. 49.18*b*). Sometimes, though, the displaced solder will form a bead on the pin tip, as seen in Fig. 49.18*c*). Although electrically it is of no consequence and well adhered since it is soldered, it can interfere with critical clearances (such as aboard to chassis) or impede proper board seating at in-circuit test or in other fixtures.

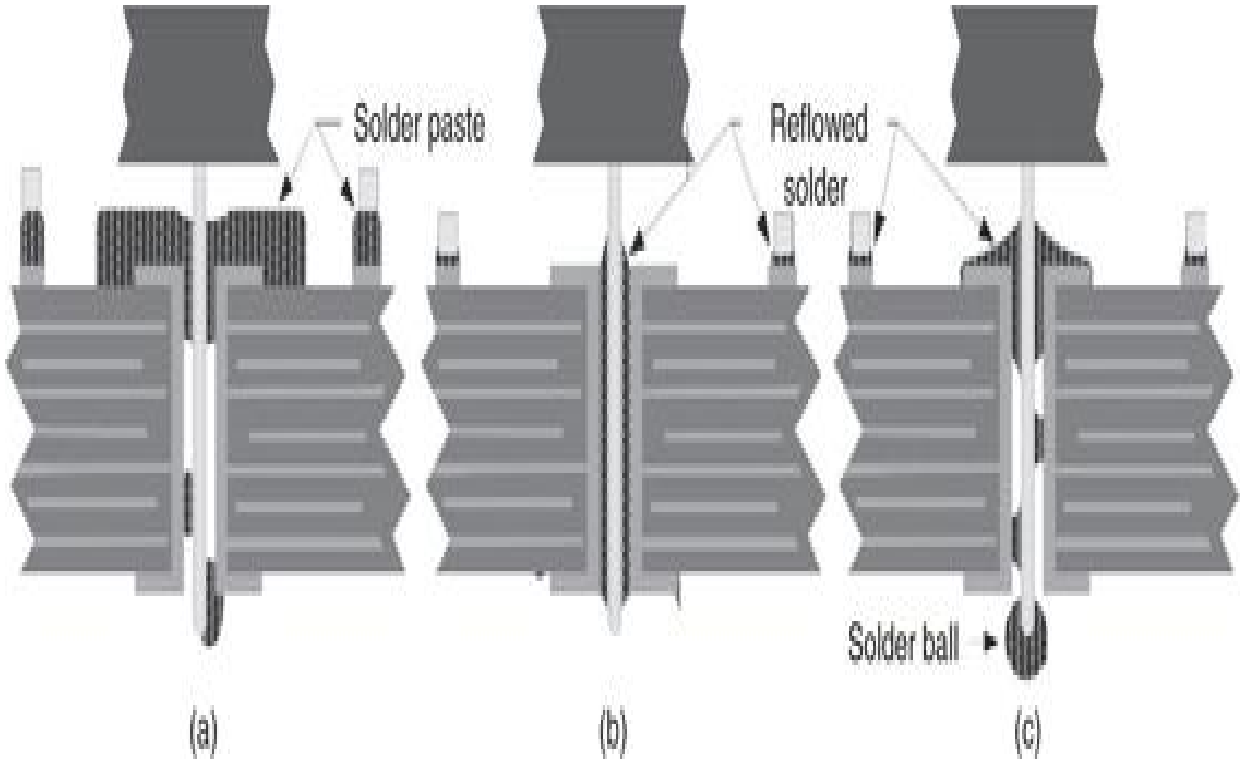

FIGURE 49.18 Board sections illustrating pin-in-paste process: (*a*) A PTH component pin inserted through solder paste squeegeed in and around a PTH. (*b*) At reflow, the solder has melted and wet to pin and component leads. If solder volume is correct, surface tension effects will draw the solder between pin and barrel and a good solder joint will form. (*c*) The solder paste displaced by the pin insertion has melted into a ball around the pin tip. So much solder was displaced that voids are apparent between the pin and the PTH barrel.

A solder paste stencil can be designed to occlude solder deposition on top of or in the board's PTH, as can be seen in Fig. 49.19.

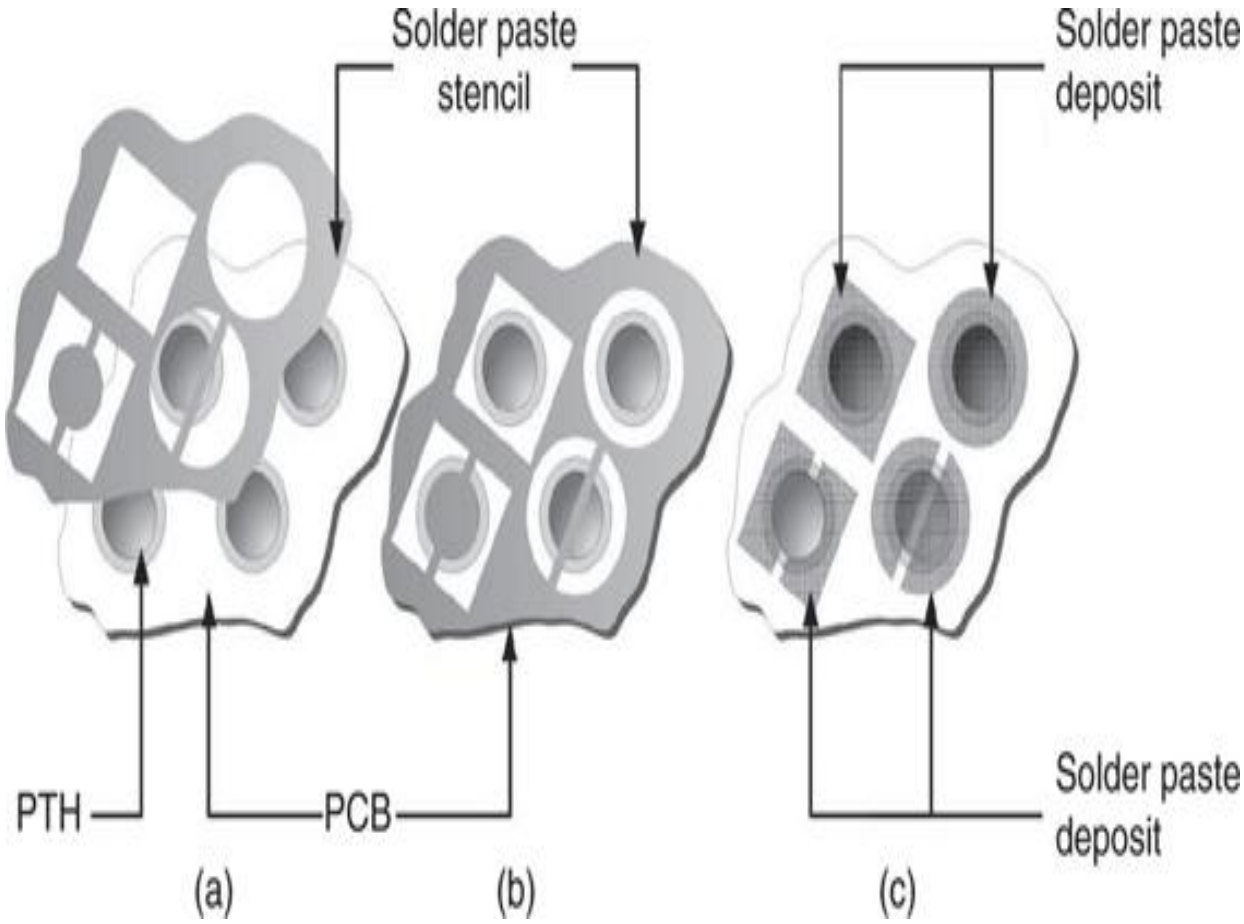

FIGURE 49.19 Solder paste deposition on PTH for pin-in-paste soldering: (*a*) stainless steel stencil being applied to a PCB in preparation for solder paste printing for a pin-in-paste component. The stencil has four typical pin-in-paste aperture types. Starting from the upper left are: square or diamond; circle, "half-moons," square aperture with a feature to prevent paste from printing in to the PTH. (*b*) shows the stencil aligned to the PCB and c) illustrates the resultant solder paste deposits. Note that in each case the solder paste has been over-printed onto the laminate of the PCB to increase the solder volume and hopefully result in fully wetted solder joints.

Stencil designs that preclude solder paste from entering the PTH also result in a significant reduction of solder paste on the top surface and in the PTH. These reductions may make the pin-in-paste technique impractical for some boards. If the solder volume is too low, the available solder distributes unevenly around the PTH pin and the PTH barrel, resulting in voids and inferior solder joints (Fig. 49.20).

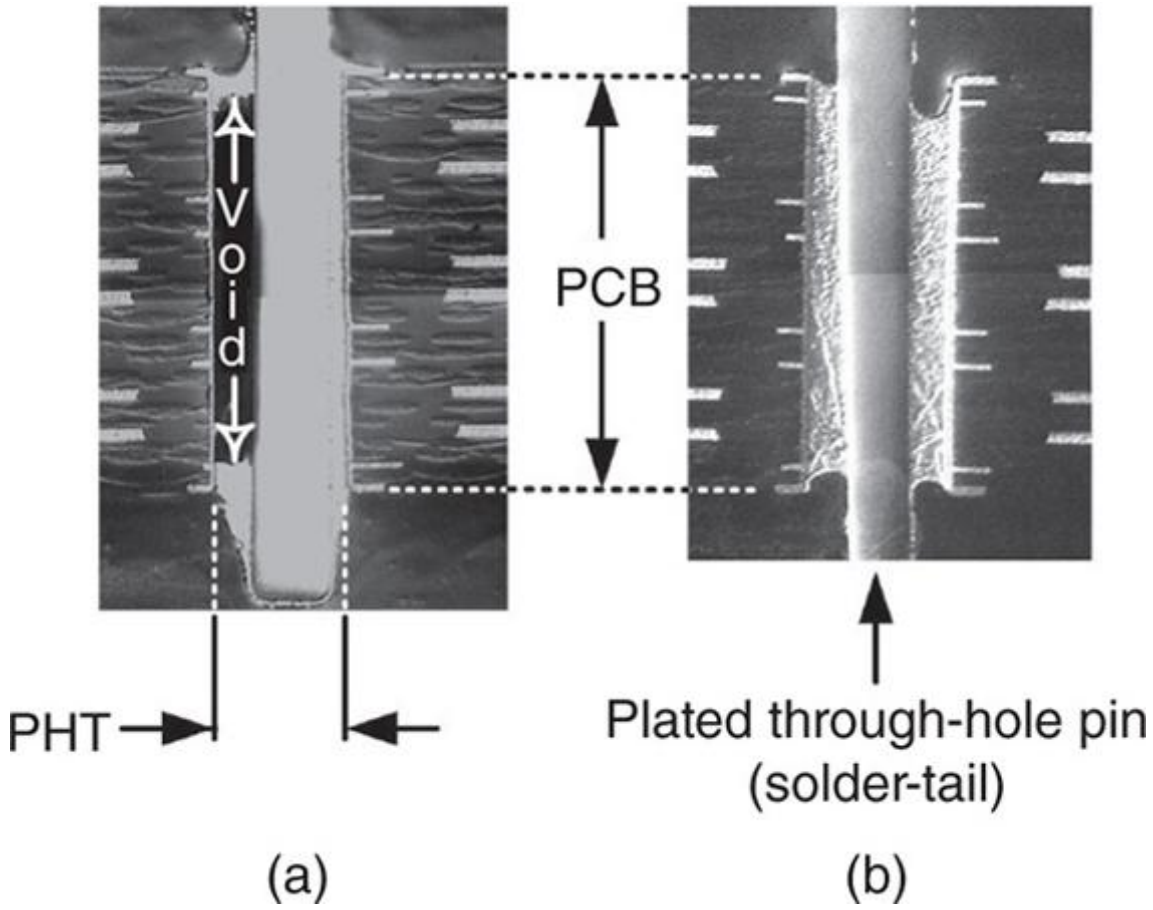

FIGURE 49.20 Solder joint defects can result from uneven solder distribution: (*a*) solder-starved pin-in-paste solder joint showing large void; (*b*) good pin-in-paste solder joint showing nearly 100 percent barrel fill, no voids and good wetting. (*Courtesy of Hewlett-Packard*.)

A normal-incident x-ray (x-rays perpendicular to PCB surfaces) will highlight circumferential voids in plated-through joints as evidenced in Fig. 49.21.

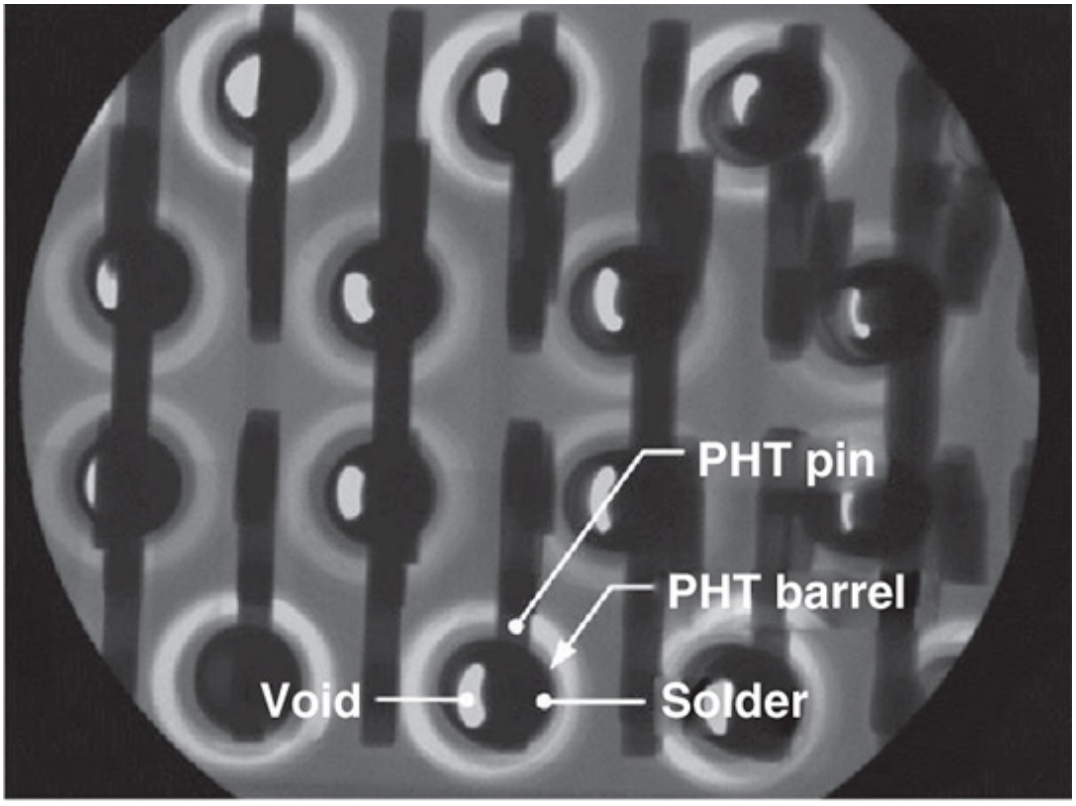

FIGURE 49.21 A normal incident x-ray photo of a connector soldered in SMT reflow with pin-in-paste technique. The light spots around the pins are solder voids (no solder) indicative of insufficient solder resulting from pin-in-paste soldering method. The dark area is solder wetted to PTH barrel and connector pin. (*Courtesy of Colab Engineering, LLC*.)

49.3.9.3 Pin-in-Paste on Thick Boards. Since the solder volume requirement increases proportionately with increasing board thickness, pin-in-paste soldering is best suited for thin PCBs (≤1.6 mm). The technique is limited by available solder and required solder volume for proper barrel fill. Adding additional solder by overprinting may result in nonwetted solder balls that separate from the solder paste mass during the reflow process and loose solder balls with an inherent short-circuiting hazard. There are three ways to augment solder volume for an effective pin-in-paste process:

49.3.9.3.1 Thicker Solder Paste Stencil. A thicker stencil will deposit more solder paste, but ultimately the solder paste stencil thickness must be tailored to suit the finest device lead-to-lead pitch on the board. Step stencils with

selectively thick areas can be used but care must be taken to ensure that there is sufficient transition in the step-up area to allow for proper squeegee action and solder paste deposition.

49.3.9.3.2 Addition of Solder with Foil Pre-Forms. Solder foil pre-forms (stamped solder foil) can be added to through-hole parts to augment intrusive reflow solder volume (Fig. 49.22). This approach is expensive and application of the pre-forms is tedious and time consuming.

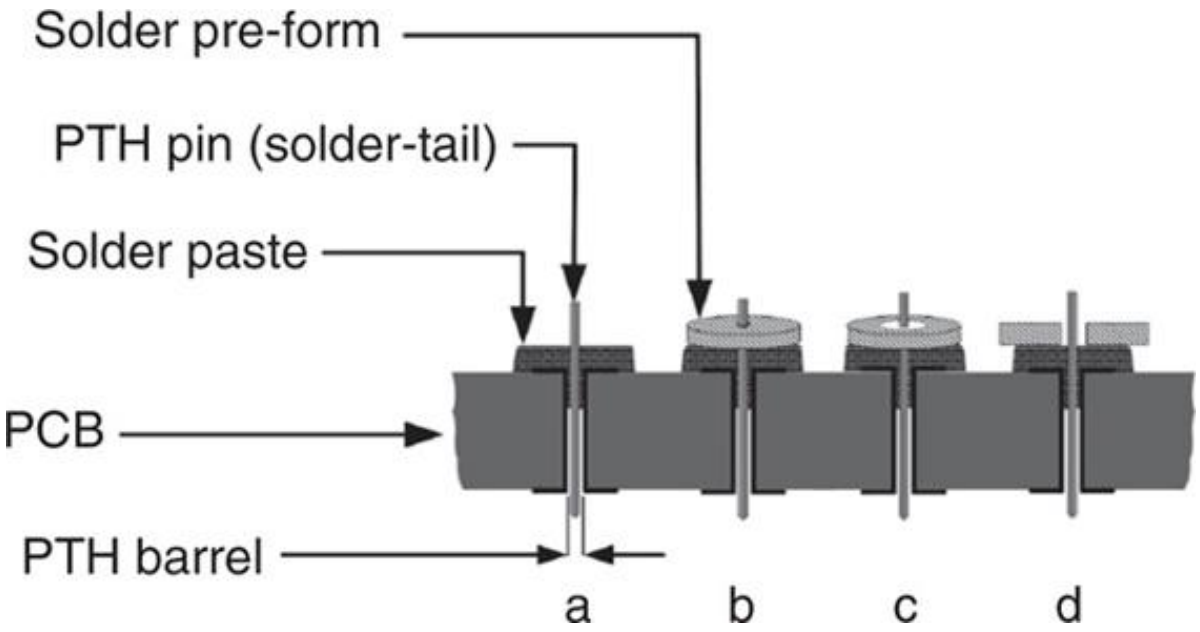

FIGURE 49.22 Various approaches to pin-in-paste (intrusive) soldering. Solder volumes in "b," "c," and "d" are augmented with solder foil pre-forms. (*a*) Stenciled solder paste only, (*b*) tight fitting solder washer applied to the solder-tail prior to placing the device into the PTH on the PCB. (*c*) Pre-form washer with a generous inner diameter hole such that the washer can be picked up with a special suction head at the SMT pick-and-place step and placed on paste deposit. (*d*) Orthogonal pieces of solder pre-form foil, also inserted at the pick-and place step. In each case, the flux for joint formation comes from the application of solder paste as required for the SMT process.

Large solder pre-forms can be deposited on the solder paste with the SMT placement machine. The flux from the solder paste will clean the pre-form during the reflow process to allow it to wet to the paste and solderable surfaces. Some

pre-forms come with a coating of flux, too. Ensure that the flux on the pre-form is compatible with the flux in the solder paste otherwise corrosion could result in the long term with ensuing circuit reliability issues.

49.3.9.3 Buried Intrusive Method. There is another method for formation of a somewhat nonstandard solder joint in thick PCBs. A foreshortened pin, on the order of that used for a board 1.6 mm in thickness, is used in the thick board. So, too, solder volume is treated as if for a board 1.6 mm thick. When the solder melts, it coalesces and wets to the pin and barrel as in any through-hole soldering process. Nearly all the solder is retained by surface tension forces around pin and barrel. If the solder volume is calculated properly and appropriately delivered, there is 100 percent pin wetting both longitudinally and circumferentially (Fig. 49.23). Accelerated thermal cycling followed by tensile testing has shown that resultant solder joint reliability is sufficient and equivalent to conventionally formed pin-in-paste or wave-soldered joints of twice the pin-wetted length.[2]

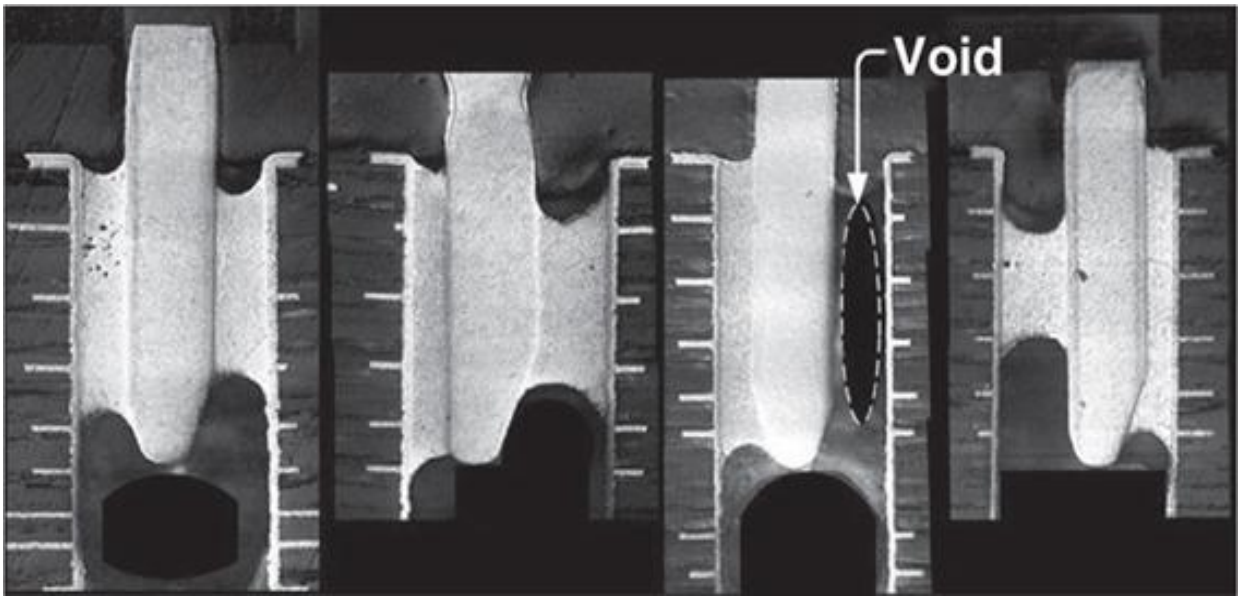

FIGURE 49.23 Cross-sectional micrograph showing pin-in-paste buried intrusive soldering. Note that in each case very little solder has drained down the PTH. Instead, it is held by capillarity between the solder-tail and the PTH barrel wall. All solder joints pictured are somewhat starved for solder. The left-most is the most robust solder joint and such joints are approximately equivalent to standard full-barrel wave soldered PTH joints in terms of resistance to thermal cycling and shock/vibration reliability.

49.3.9.4 Temperature Compatibility.

If pin-in-paste soldering is to be used, ensure that components are temperature-compatible with the oven reflow process. The high temperatures and long exposures associated with oven reflow soldering may cause unsuited, plastic molded component bodies to melt or warp. Connector contact normal force may be impugned if the molded body softens or distorts. Solder joints or wire bonds internal to some devices may become dis-bonded, and some devices, such as electrolytic capacitors, may leak or even explode as a result of an oven reflow cycle. Check component manufacturer specifications for thermal limits and compatibility with reflow oven soldering.

49.4 WAVE SOLDERING

Once the predominant method for mass assembly of circuit boards, wave soldering has taken a back seat to oven-based reflow soldering with surface-mount technology (SMT). The ease and speed of assembly with SMT led to its rapid dominance and the decline of wave soldering. Nonetheless, the need for through-hole componentry persists and mixed-mount (surface-mount plus through-hole) technology still may be the only alternative for some assemblies, and it is unlikely that wave soldering will disappear from PCB manufacturing in the short term. Since wave soldering, compared to reflow soldering, is fraught with defects, it

behooves the designer and assembler to minimize the number of PTH components on a board.

Wave soldering is an automated method for joining the pin of a component into a drilled through-hole on a PCB. The drilled holes are plated on the inside and a pad, also plated, is connected to the plated through-hole barrel (Fig. 49.24).

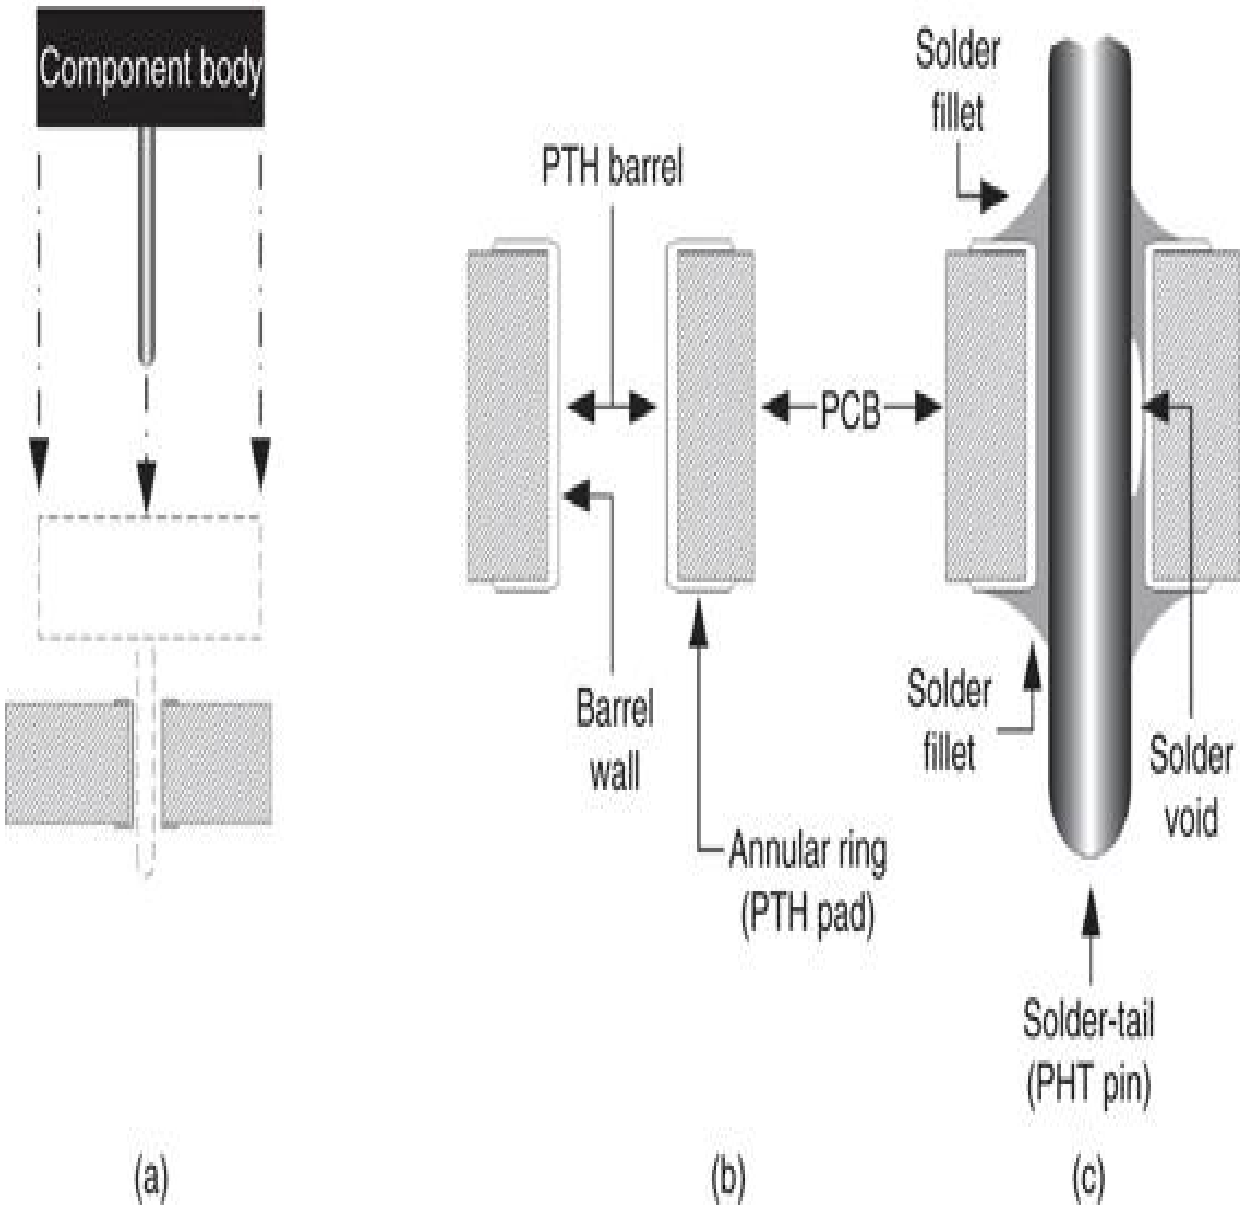

FIGURE 49.24 Schematic of a PCB section with a plated through-hole (PTH). (*a*) Solder-tail component is inserted into the PTH. (*b*) The PTH is composed of a plated barrel and annular rings on the top and bottom surfaces of the PCB. The annular rings are connected to the barrel. Surfaces of the rings and barrel are

solder-wettable. (*c*) During wave soldering, solder wets to the PTH and the pin and solder joints are formed. Gaseous inclusions in the solder are called voids.

The barrel may be connected to copper power planes or ground planes within the printed circuit board (PCB) or to surface traces for electrical connection to other components on the PCB. The PTH has three parts to it: a drilled, plated hole, a top-side plated annular ring and a bottom-side plated annular ring. During wave soldering, the PTH and component pin are first coated with a soldering flux to clean the parts of any oxides, tarnishes or contaminants. Next, the bottom of the PCB is exposed to a standing wave of molten solder. The solder wets to the solder-tail and also to the annular ring. As the board continues to heat, the solder wets to the PTH barrel and is drawn into the space between the solder-tail pin and the PTH barrel by capillary action. If conditions are right, the solder will wet to the pin and barrel and travel all the way up to the top-side annular ring. When the solder cools, it solidifies and solder fillets (wetting between the barrel, annular ring and the pin) will be present. Sometimes, entrapped air or volatiles from the fluxing agent will create bubbles in the molten solder. These are called solder voids. If a void is large enough it may detract from the mechanical integrity and reliability of a solder joint. Voids can be examined by mechanically cross-sectioning the finished printed circuit assembly (PCA). More practically, voids can be imaged non-destructively by transmission x-ray analysis.

49.4.1 Wave-Solder Process Basics

Wave soldering utilizes a reservoir of molten solder pumped and circulated to form a standing wave. The circuit board is prepared with devices for wave soldering in one of three ways:

1. Coarse-pitch surface-mount components, especially passive devices, are affixed to the bottom-side of the PCB using surface-mount adhesive. The adhesive is in contact with the body of the component, which is aligned with its respective pads on the circuit board in preparation for wave soldering. The adhesive is cured or partially cured prior to wave soldering.
2. Solder-tailed components, such as connectors, PGAs, or other through-hole devices, are inserted into PTHs from the top-side of the board.
3. Solder-tailed components such as axially leaded devices are inserted from the top-side of the circuit board and their leads are clinched on the bottom-side of the board to hold the components in place.

The circuit board is placed on a motorized, edge-hold conveyor where it is fluxed. Next, the loaded PCB is preheated, both to activate the flux and give the PCB a thermal boost in preparation for soldering. The board is next skimmed over the crest of the molten solder wave. Only the bottom of the circuit board is exposed to the molten solder (Fig. 49.25).

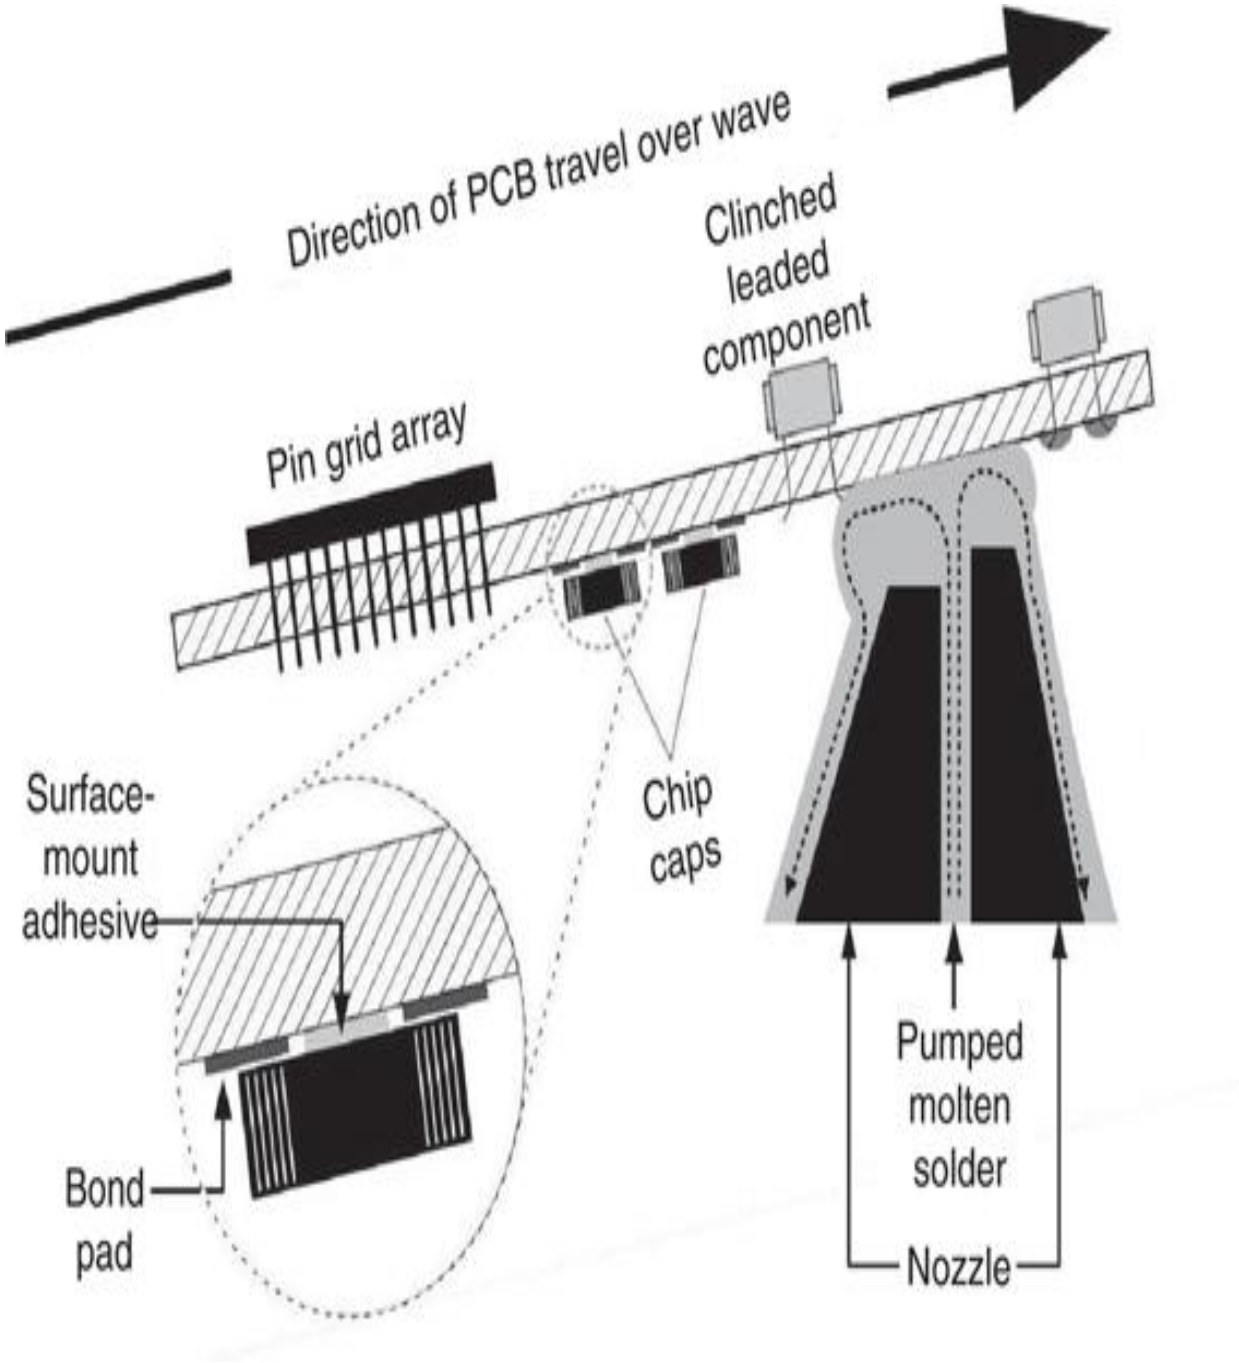

FIGURE 49.25 Schematic of a board going over a solder wave. The board is conveyed over the pumped standing wave of molten solder. The wave height is adjusted to contact the bottom of the board only. Some components are inserted, others inserted and clinched. Surface-mount adhesive can be used to hold small passive components to the bottom of the PCB for wave soldering.

When exposed to the wave, the adhesive-attached surface-mount devices pick up solder on their metal contacts

and the solder bridges from the contact to its corresponding bonding pad on the bottom-side of the PCB. In the case of solder-tail components, the molten solder is drawn by capillary action between the lead and the PTH barrel. If the barrel and lead (pin) are hot enough, well fluxed and properly sized, the solder fills up the barrel and wicks to form fillets from pin to barrel. As the board continues past the wave, it cools, solder solidifies, and joint formation is complete. One attribute of this process is the speed at which solder joints are formed. Much quicker than oven reflow soldering, the wave-solder process allows little time for preheating, fluxing and solder joint formation. This partially explains this process's variability.

49.4.2 Wave-Solder Machine Subsystems

There are six basic subsystems to a wave soldering machine, including: conveyor; fluxer; PCB preheater; solder circulation system (solder pot, heaters, pump, nozzles); ventilation. If alcohol-based fluxes are being used, it is wise to install a fire suppression system on the wave soldering machine, also.

49.4.2.1 Conveyor. As for the reflow oven, the wave solder machine is generally equipped with a mechanized, speed-controlled conveyor to transport the board at a constant velocity through the soldering process. In the case of wave soldering, the board is always held by a width adjustable edge-finger conveyor, which grabs the board by its edges and neither occludes solder exposure nor interferes with wave dynamics. The stainless-steel edge fingers need to be cleaned routinely to avoid flux build-up.

49.4.2.2 Fluxer. The fluxer is responsible for delivering a uniform application of soldering flux in a sufficient quantity

for solder joint formation. The short preheat and liquidus times characteristic of the wave-soldering process dictate the use of slightly stronger fluxing agents than are used in reflow soldering. Although this is the case, the vast majority of wave solder applications have migrated to the use of no-clean fluxes. For the flux to do its job, it must be heated to an ample temperature to permit best reactive conditions without drying or denaturing it. For the sake of economy and to minimize resulting flux residues, the thinnest flux application is deposited. The flux quantity has to be sufficient to remove oxides from the PTH barrels, solder, and component leads. On the other hand, since post-wave solder no-clean flux residues can confound in-circuit test probe contact, the thinnest application that still permits adequate fluxing is recommended.

Flux quantity may also be of concern in the wave-soldering process for yet another reason: fire hazard. Flux-laden boards are preheated going into the wave. If the flux application is too heavy, the flux may drip onto pre-heater elements. This may cause the flux to volatilize rapidly, combine with oxygen in the atmosphere, and provide the right conditions for flame initiation. Even if there is not direct exposure of the liquid flux to preheaters, if the quantity of volatile flammable components is sufficient and exposed to an ignition source (spark), then an explosive condition may develop. With the advent of more eco-friendly, water-based fluxes, fire hazard is less of a concern. Foam and wave fluxing have given way to spray fluxing as the predominant flux application method. All three techniques are discussed here.

49.4.2.2.1 Foam Fluxer. Foam fluxing is accomplished by pumping and aerating a stream of liquid flux through a porous metal nozzle, a fritted glass, or porous stone. The nozzle, also called a chimney, shapes the flow of the aerated flux. The board to be soldered is run over the foaming flux and then heated to activate the flux before reaching the

solder wave. As it moves past the solder wave, the solder wets to solderable metals and solidifies to complete the soldering process. Foam fluxing is particularly effective for soldering of PTH assemblies. Surface tension draws the foam into the PTH barrels, just as is the case with solder. The resulting flux deposit on the pin and barrel is thin and uniform.

49.4.2.2.2 Wave Fluxer. The wave fluxer works much as the solder wave itself. The PCB is moved over a standing wave of solder flux. The height of the flux wave and depth of the board penetration into the flux wave are adjusted to allow for proper flux application thickness. Capillary action, as in all the fluxing methods for through-hole components, draws the flux into the interstice between component lead and the PTH barrel. As with foam-fluxing, it is difficult to control the amount of flux delivered. For the most part, flux applied for wave soldering is largely removed by the turbulence of the solder wave; however, it is possible to bake on the flux if the pre-heater temperatures are set to too high. Resulting residues may inhibit fluxing or solder wetting to otherwise solderable surfaces.

49.4.2.2.3 Spray Fluxing. Because of its economy and accuracy, atomized spraying has grown to be the predominant flux deposition technology. Precise amounts of a low-solids flux can be applied generally to a board or can be selectively delivered to small areas of the board to be soldered. There are two principal methods of spray fluxing: air-spray and ultrasonic. Both are effective and well tested. Ultrasonic methods minimize flux volumes consumed in manufacturing.

If not set properly, spray fluxing may result in a flux-laden airborne mist that deposits wherever the air currents or process gases carry it. Flux contamination of card-edge gold fingers and contacts within connectors is most notable. This can disrupt proper electrical contact when a daughter-card is inserted into a connector. It is wise to cover any exposed

gold fingers with an acrylic adhesive polyimide tape[3] or other shielding to prevent contact fouling by flux droplets.

49.4.2.2.4 Fluxer Maintenance. As fluxes are exposed to the atmosphere, they are vulnerable to evaporation of volatile constituents. This is the case even with water-based fluxes. Evolution of volatiles is significantly enhanced in systems such as wave-fluxer or foam-fluxer. In these flux deposition systems, the flux is open to the atmosphere or the processing environment, has significant exposed flux surface area, and is constantly being recirculated. Therefore, the flux needs to be monitored and maintained. Although some automatic systems are available, most require routine measurement of the flux's specific gravity with a hydrometer and adjusted with a proper flux thinner to restore the specific gravity to compensate for these evaporative losses. In addition, the volume of the flux in the system must be monitored and adjusted to the proper level. The fluxer must be maintained to prevent impact on process yield. The flux manufacturer can provide information as to the proper specific target and also recommend an appropriate thinning formulation.

The flux reservoir should be emptied, cleaned thoroughly, and refilled with a fresh charge of flux periodically. Sometimes the flux develops a residue that changes the flux's surface tension characteristics, clogs nozzles, or dispensing pores in foaming systems. In addition, flux may become contaminated with debris conveyed by the PCB to be soldered, which may impact assembly quality. Since the PTH relies on a minute capillary to be filled first by flux and ultimately by solder from the solder-wave process, any small particulates entrained in the flux or the solder may impede PTH barrel fill. Also, while the flux reservoir is empty, it is a good idea to inspect it to ensure that the materials of construction are holding up to the rigors of system operation and prolonged contact with fluxing agents which may prove corrosive in the long term. An inspection of the materials of

construction for the entire system should be made prior to committing to the purchase of a wave-soldering machine. Unfamiliar or untested materials should be avoided unless there is sufficient literature, test results, or customer experience to ensure compatibility with fluxes that will be used in that system.

In the case of spray fluxing, since the flux is not exposed to the atmosphere until it is sprayed onto the PCB, specific gravity and “thinning” are not an issue as for foam fluxing or wave fluxing. However, care must be taken to ensure that the spray nozzle is kept clear of clogs and that it is spraying the correct volume for each PCB.

Gravimetric methods can be used to determine uniformity and reproducibility of spray. One such method utilizes identical witness pieces, such as microscope slides, attached the bottom side of a PCB or other rigid material with two-sided tape. Each slide is identified with a scribed designation, weighed ahead of time with micro-balance; its weight and position recorded (Fig. 49.26).

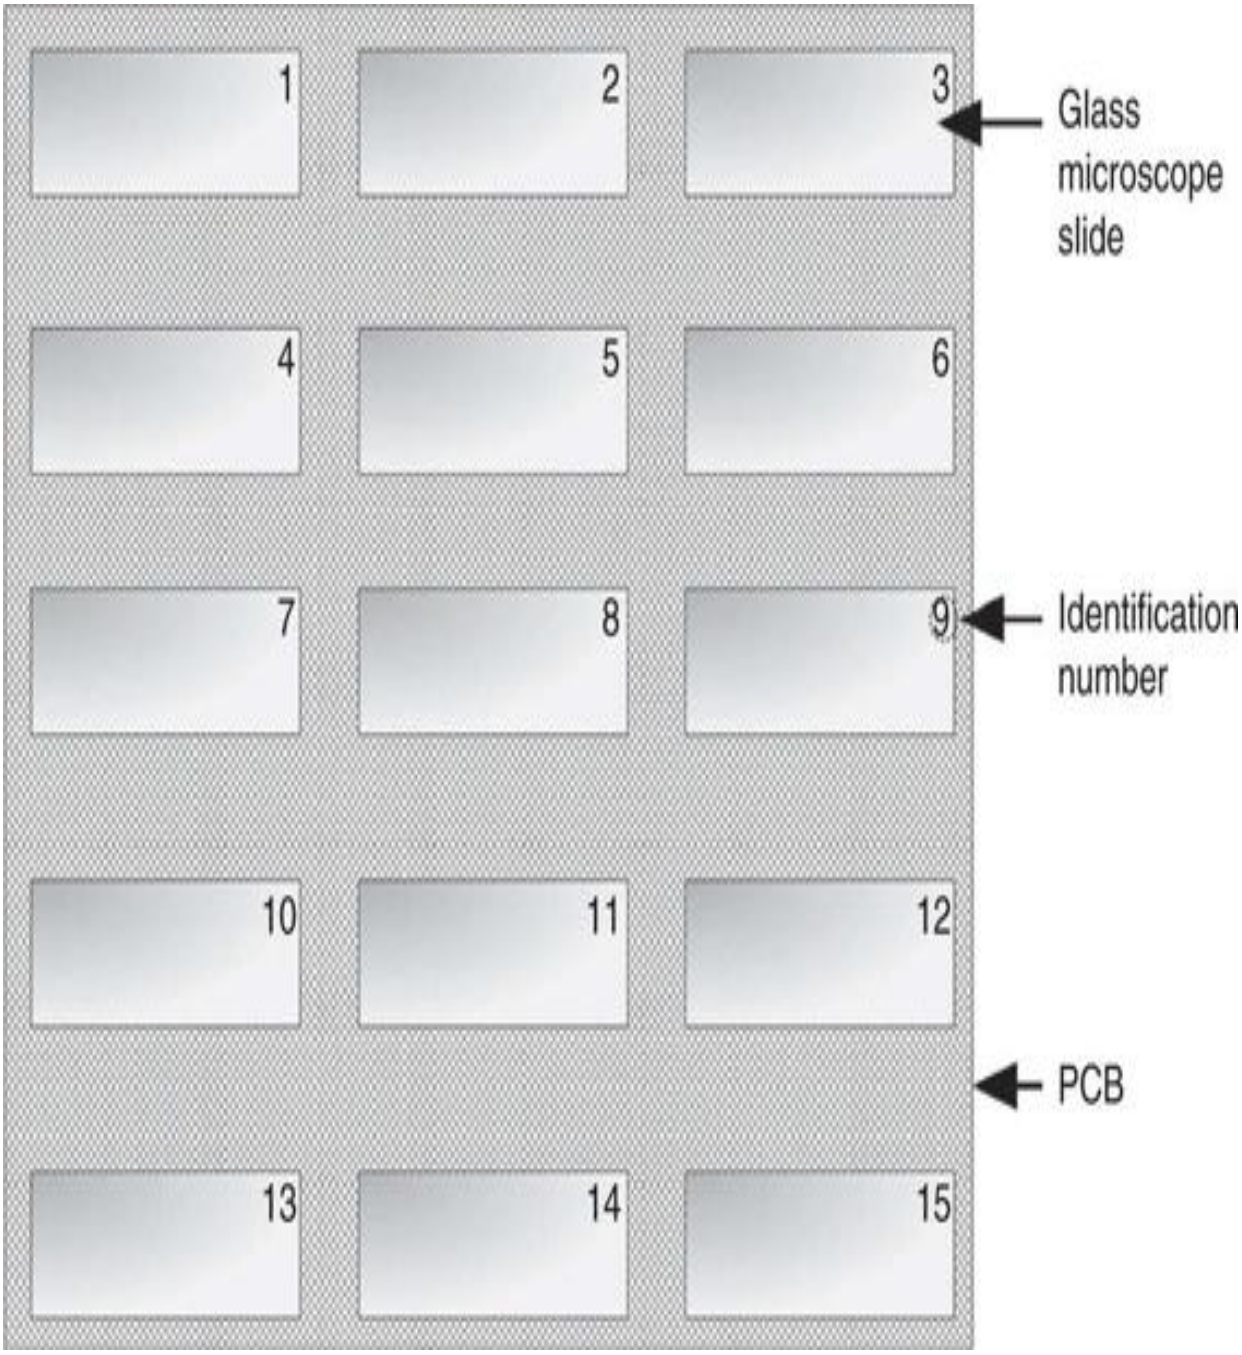

FIGURE 49.26 Microscope slides arrayed on the bottom-side of a circuit board for evaluation of flux deposition and uniformity.

Once set on the wave machine's moving conveyor, the spray fluxer is activated (generally, automatically by means of sensors), the flux is sprayed onto the bottom-side of the PCB and the attached glass slides. After spraying, the board must be removed before preheat and should not be exposed

to the solder wave. Next, it should be dried at low heat in a box oven to gently evaporate volatiles. Once dried and cooled to room temperature, each slide is weighed again and compared to its original, dry weight. Differences in uniformity from edge-to-edge and from front to back can be determined from this method. Compare the volume of flux dispensed to the flux manufacturer's recommended volume. Most manufacturers will provide guidance as to the dried-weight of their sprayed liquid flux.

49.4.2.3 PCB Preheating. Preheating the PCB and components serves three purposes in the wave soldering process:

1. Helps the board and components reach a temperature sufficient for the flux to activate. The activated flux cleans surfaces to be joined in preparation for wave soldering.
2. Lessens thermal differentials and decreases the likelihood of components cracking due to thermal shock when impacted by the intense and sudden heat of the molten solder wave.
3. Allows the board to ramp quickly to solder-melting and wetting temperatures when it comes in contact with the solder wave.

A component's resident time in the solder wave is 10 to 30 times shorter than for a comparable solder joint formed during reflow oven soldering, so everything in wave soldering has to happen very rapidly. On the other hand, heating time-temperature ramps must be observed in accordance with the component manufacturer's specifications. Components and PCB bonding pads must be fluxed sufficiently to allow adequate solder joint formation, yet there must be enough flux left on the circuit board after preheating to protect the newly fluxed surfaces from reoxidizing until the assembly reaches the solder wave.

Just as in the reflow soldering oven, there are multiple solder-wave preheater styles, but only two are in prevalent use: radiant preheaters (direct and indirect IR) and forced-air convection preheaters. Both are effective and both have their advantages. In fact, the best configuration is a combination of the two. Some wave-soldering machines can be equipped with both top and bottom preheaters. This can be advantageous for thermally massive boards.

49.4.2.4 The Wave. Numerous solder-wave configurations are available. Rather than provide a detailed discussion of each, this section offers a basic overview of the elements of the process in relation to the wave. As previously mentioned, the molten solder is pumped to form a standing wave. This is accomplished by a pump (and spinning impeller) on the bottom or side of the solder reservoir. Once the solder is molten, the impeller motor is activated and the solder wells up between baffles and nozzle that reside within the solder reservoir. A combination of impeller speed and baffles-and-nozzle configuration dictates overall standing-wave shape characteristics. The nozzles and baffles are generally adjustable, as are impeller speed, molten solder temperature, board introduction angle, and board conveyor velocity. These, along with flux type, flux deposition amount, preheater settings, define the process profile parameters or process variables that must be tamed to accomplish high-yield wave soldering. The quantity of process variables accounts for the difficulty in set-up, control and reproducibility of the wave soldering process.

Since the solder in the wave is a molten, turbulent, high conductivity liquid, thermal uniformity is generally not difficult to achieve as long as the wave contact area along the width of the PCB’s underside is adjusted to be uniform. Since the solder is in contact with the underside of the PCB and since the underside of the PCB is coated with flux, the molten solder has the opportunity to wet to PCB lands and

component leads. As the process progresses, solder wicks between the pin and barrel. After leaving the wave, the board cools rapidly, liquid solder solidifies, and solder joints result.

49.4.2.5 Wave-Soldering Accessories. Solder-wave manufacturers have devised a number of options that may be helpful to the process. Some of these have extended wave-soldering capability to allow finer-pitch soldering or permits wave soldering of thicker PCBs.

49.4.2.5.1 Gas Knife. The gas knife, more commonly called the air knife, directs a high-velocity stream of heated air or nitrogen at a glancing angle to the bottom-side of the board directly after the board emerges from the wave, while the solder is still molten. It can be effective in relieving solder bridges from tight interstitial component pin fields or closely spaced passive device fields. When the gas knife is used with air instead of nitrogen, increased rates of dross formation may result. Also, if the angle is wrong and the velocity is too high, the exit gases may disrupt the solder wave, resulting in solder opens or shorts. If it is set too cool, the knife will have little effect or may exacerbate solder bridging. Since the advent of the air knife, there has been less dependence on the use of tear-drop-shaped trailing pads used to minimize trailing edge solder bridges.

49.4.2.5.2 Sonic Assist. Although not in common use, this accessory imparts high-amplitude sonic pulses into the solder wave. This can help drive solder into PTHs and increase wetting, especially on thick PCBs. Care must be taken during setup, as very high amplitudes may pump so much solder into the PTH barrel that top-side solder flooding, bridging or solder splashing may occur. Its value is limited, since it does not affect board heating, which is the primary factor in barrel fill. This accessory is not in widespread use but could be considered for problematic wave soldering of thick boards.

49.4.3 Wave-Solder Diagnostics

As in all cases of mass soldering, the use of a product-specific, fully populated time-temperature profile board is necessary to ensure that critical areas of the board to be soldered are maintained at proper temperatures for each stage of the process. Top-side SMT component solder joints must be kept well below the melting point of the solder used to join them to the PCB. At the same time, PTH barrels and PTH components must surpass liquidus temperature to guarantee sufficient wetting and capillary rise of the molten solder. With the complexity of today's mixed-mount boards, this is more of a challenge than ever. A profile board should be constructed and instrumented just as for oven reflow soldering. Thermocouples should be attached to both sides of the board and monitored simultaneously during the wave-solder profile run. Connector bodies should be monitored to ensure that they are not overheated.

Generally, for most Pb-free surface-mount solder alloys, the PCB pre-heat temperature prior to wave should be about 50 to 70°C less than the liquidus temperature of the soldering alloy used for SMT. Of course, this thermal limit varies greatly with board size, thickness, component type, number of PCB layers, number of connections to inner planes, thickness of inner planes, component layout density and other factors. For SAC305 alloy with a melting range of approximately 217 to 221°C, it is best to keep the top-side temperature of the PCB in the 160 to 170°C prior to exposure to the wave. When the board reaches the wave, the board temperature will spike to at or near liquidus of the surface-mount solder alloy. The use of wave pallets (shields) to thermally mask the PCB will be discussed later in the context of selective wave soldering.

In addition to the profile board, there are numerous useful diagnostic tools commercially available for dynamically measuring the wave height and wave contact area, wave

depth and assessing resident time in the wave for a given conveyor speed.

49.4.4 Dross

Hot solder is prone to rapid oxidation at the air-liquid solder interface. Although the wave is in constant motion, the solder is actually flowing beneath a thin, stationary, plastic film of solder metal oxides. In Sn/Pb, Sn-Cu, or Sn-Ag-Cu systems, the skin is composed primarily of tin oxide but also contains oxidized traces of other alloy constituents or contaminants. The oxide skin on the surface of the wave and atop the solder in the reservoir is called dross. The dross has a beneficial aspect in that it helps to limit oxidation of the recirculating solder in the solder pot, but it also interferes with solder-wave dynamics and solder wetting.

When adjusted properly, the board meets the crest of the wave and disrupts the oxide skin. In doing so, the fluxed components and board are immersed in the flowing, oxide-free, molten solder. If all steps are carried out properly, the solder wets to the fluxed, oxide-free component leads, component pads, and PTH barrels. Upon exiting the wave solder machine, the assembly cools below the solder liquidus temperature and solder joints are formed. There are four factors that will determine the amount of dross produced:

1. System use (the number of hours of wave on-time)
2. Speed of the wave pump
3. Turbulence of the wave system
4. Temperature of the solder pot

Mostly, dross is the result of exposure of the molten solder to the atmosphere. It is worthwhile to work at minimizing any or all of these to lessen the effects of dross on the process.

49.4.4.1 Impact of Dross. Dross is of concern from three points of view:

- *Process impact:* Presence of excessive dross can result in shorts, opens or retard wetting.
- *Economics:* In high-volume manufacturing, the amount of solder lost to dross can mean hundreds of dollars of lost solder per week per machine. Of course, the actual cost depends on machine use, solder alloy, and quantity of boards soldered and the price of the original solder. However, the dross can be sold back to some solder manufacturers for recycling.
- *Sn (tin) drift:* Excessive dross on the surface of the solder can disrupt normal wave dynamics. In the case of Sn/Pb solder, Sn oxidizes more easily than Pb. The solder can become Sn-depleted over the long term. This is known as Sn drift. The same is true of Sn-based Pb-free solder alloys, but since some alloys are nearly all Sn (SAC305, 96.5 percent Sn by weight), this effect will be less dramatic. However, other Pb-free alloy perturbations such as dissolution of Cu become much more important. For example, in the case of the eutectic Sn-Cu alloy, the copper content is only 0.7 weight-percent. Small changes in the copper content by means of copper dissolution of copper pads on the board can have a dramatic effect on the melting temperature of the solder. The major cause of Sn drift is from depletion of Sn from contact with copper or species being soldered, but dross creation furthers the depletion of tin.

49.4.4.1.1 Dross-Related Process Defects. Dross can generally change the dynamics at the wave/bond-pad/component lead interface, discouraging adequate pull-back of the solder and encouraging defects. Molten solder droplets can become entrapped in the dross as a result of wave turbulence. Once the droplets are oxidized, they are

unable to rejoin solder in the reservoir. As the dross passes through a PTH pin field intended for soldering, the pins act as a strainer, raking the solder-laden dross, resulting in pin-to-pin short circuits (drossy shorts). This dross-thickened layer can also block the solder wave from effectively contacting PCB land and component lead, and opens (skips) may result.

49.4.4.1.2 Taming Dross. Various schemes have been devised to control dross, such as co-mixing the pumped solder with a mineral oil, which floats to the surface, blanketing the solder from the atmosphere. Liquid reducing agents can be added to the solder as well as fluxes. In the long term, none of these has proven popular. The most widespread method of dealing with dross is manually scooping dross from the surface of the solder reservoir with a ladle at routine intervals based on machine runtime. Machines that vacuum dross are also available and useful.

The use of an inert cover gas has been shown to be effective in reducing dross formation and ensuring best fluxing from no-clean or other weakly activated fluxes. Nitrogen is widely used in this regard. R. Iman et al.[4] have explored the use of formic acid in gaseous form as an additive to the nitrogen atmosphere for the soldering process. The fundamentals of this process were demonstrated by H. H. Hartmann,[5,6] who had shown formic acid to be an effective gaseous fluxing agent for soldering. Dross forms when the solder is exposed to the atmosphere, so limiting atmospheric contact limits dross production. As mentioned previously, nitrogen blanketing of the solder pot and the wave will help limit dross production. Another simple but effective method is to turn off the wave pump(s) when the solder wave is not in use as wave turbulence increases exposure to the atmosphere and increased dross production. Most wave soldering machines have sensors that can detect when a PCB is on its way to the wave. The sensor activates the wave in time for soldering and shuts it down when the board has passed.

49.4.5 Metal Contaminants

Metal contaminants can also affect wave soldering. These stem from three sources: (1) contaminants from the bar solder used to charge the solder pot, (2) slow dissolution of components of the wave solder machine (solder pot, nozzles, etc.) and (3) from the materials joined during the soldering process. As the hot, circulating wave washes over component leads and PCB through-hole lands and pads, materials are dissolved into the solder. Even if leads and pads are solder-plated or solder-dipped, there is the opportunity for adulteration of the solder in the reservoir, dependent on coating composition, thickness, underlying basis metals and impurities within surface finishes as well as resident time in the wave and wave temperature. Copper, gold, silver, additional tin or lead, and intermetallic compound precipitates are all common contaminants derived from the slight dissolution of component lead and pad or coatings during soldering. Refer to the previous chapter on flux for a discussion of these metals in the solder process.

Solder reservoir contamination can have significant process impact, eventually altering melting range of a solder, injecting particulates into solder joints, and altering wetting characteristics. This may lead to an increase in shorts or opens or even result in solder joint embrittlement. The composition of the wave reservoir can be assayed by a testing service to determine its impurity content by scooping a small amount of solder and checking its solidus and liquidus points (melting range) against a pure standard. This method is less accurate than chemical analysis for contamination assessment and is inadequate for detecting the presence of some impurities such as intermetallic precipitates that may not affect the solder alloy composition.

Excessively high temperatures in the solder reservoir and low speeds through the wave should be avoided to limit dissolution of component leads, PCB pads, and PTH barrel

materials. Note that the solder wave is maintained at fairly high temperatures, generally 245 to 270°C, depending on the solder alloy and thermal mass of the assembly being soldered, but board exposure is short (2 to 10 s). Compare this to oven reflow, where time above liquidus is typically 30 to 90 s. As in oven reflow, thermal shock in wave soldering can lead to component cracking or degradation problems, so the preheating rate should be tempered to match component vendor recommendations—sometimes to as little as 2°C/s.

Bar solder impurities such as aluminum, gold, cadmium, copper, and zinc can increase surface tension of the solder and make the process more prone to bridging. D. Bernier[7] reviews some of these contaminant effects and describes empirically derived impurity limits.

49.4.6 Hygiene

Airborne tin, metal oxide fumes, and other metal particulates are unhealthy to breathe. Risks associated with lead oxide intake are well documented, but inhalation of any particulate should be considered potentially hazardous. The health risks associated with working with Pb-free alloys are not as well-known as those of the Sn-Pb system, but likely less of a risk than the latter. With any alloy, precautions should be taken, especially during wave-solder system maintenance procedures, to preclude particulate inhalation. Donning a personal particulate mask and washable or disposable outer garments (contamination suit) is recommended. Proper hygienic venting of the work area, not only during maintenance procedures but for normal soldering operation, is necessary.

49.4.7 Wave Solder Machine Configuration

In most factories, defect levels at the wave step are higher than those for the oven mass reflow process. The defects can generally be correlated to process setup, inadequate process control, bad PCB design, or any combination of the three. Although wave soldering has been around for a long time, it is still not a very well controlled process, due mainly to varying machine configurations and number of process variables associated with this process.

Many wave designs are available from the various wave-solder machine manufacturers. There are wave machines that provide multiple smaller, turbulent wave(s), which are best for leadless components such as surface-mount passive devices (resistors, capacitors, etc.). Smoother-flowing waves are recommended for components with leads and through-holes as well as coarse-pitch surface-mount devices. Often a combination is used where the board first travels over a turbulent standing wave and then immediately over a smooth wave. This is a very effective method as the first (turbulent) wave not only ensures good soldering of passive devices in tight fields, this strategy initiates wetting of the PTH components which is completed in the second (smooth) wave. The extra boost of the first wave can is useful for boosting the temperature of the board for soldering of PTH pins but it also has to be controlled carefully so as not to induce re-reflow of top-side SMT components.

Wave dynamics are dictated by process values as well as the materials in contact with the wave. As the solder wets to the circuit board materials, solder wetting contact angle and solder viscosity impose wave peel-off characteristics (Fig. 49.27).

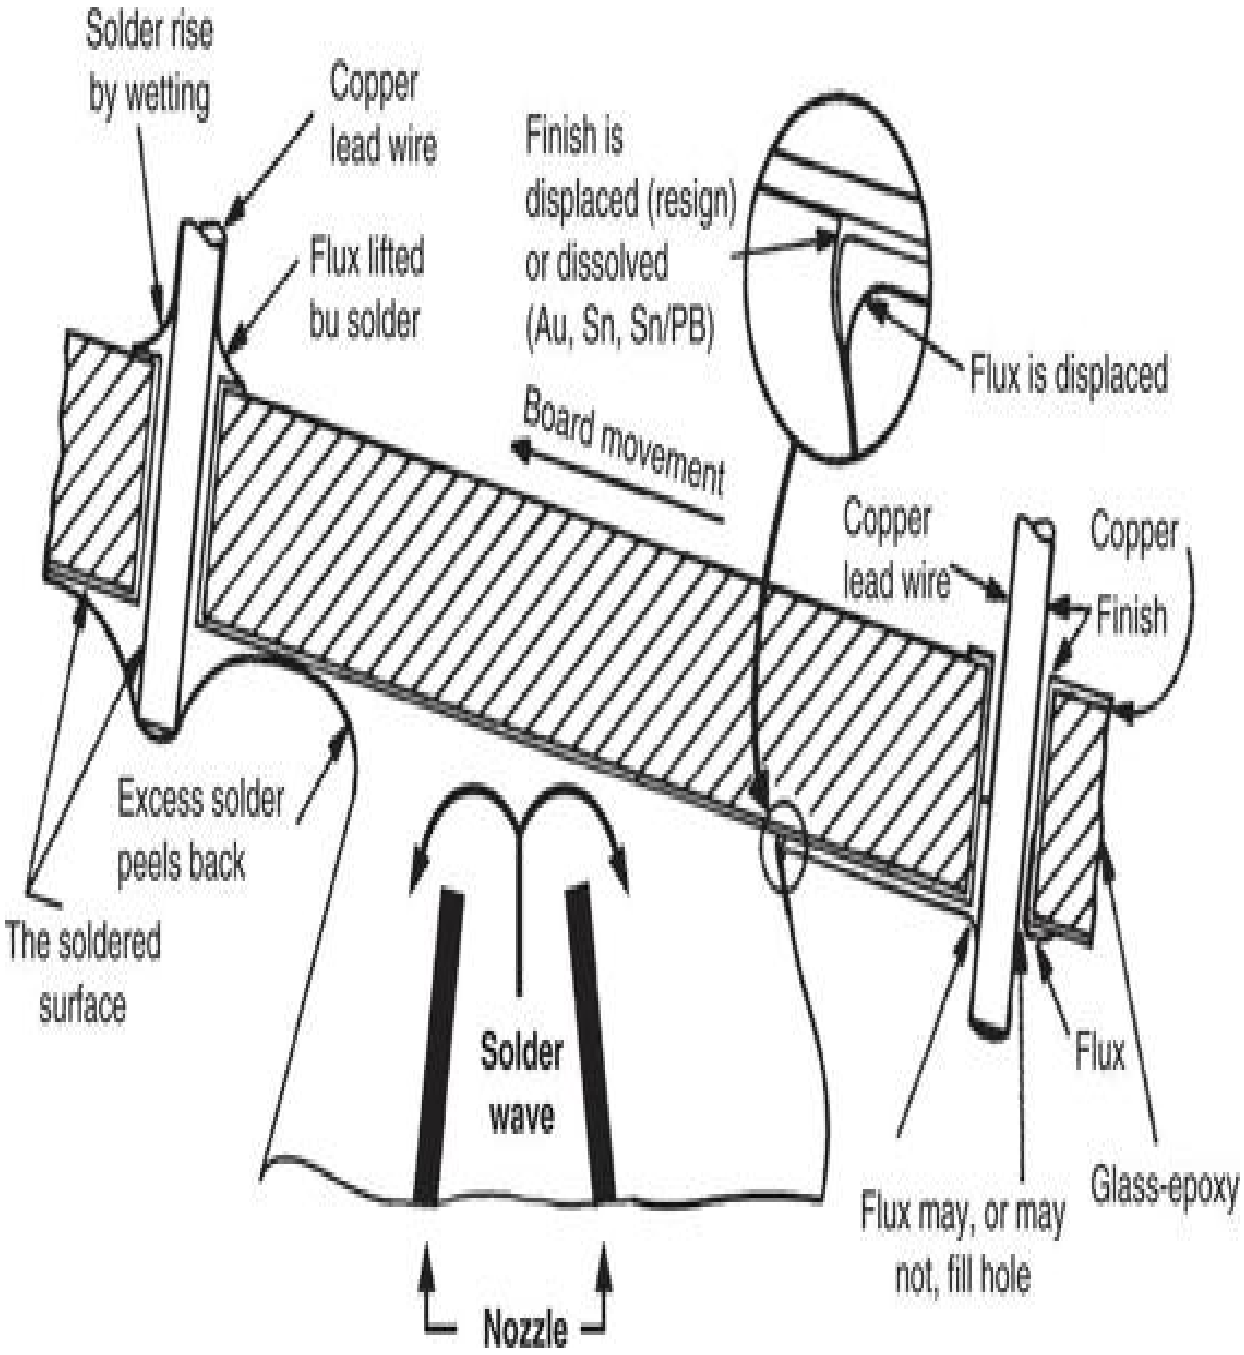

FIGURE 49.27 PCB passing over a solder wave. Flux, sprayed or foamed onto the bottom of the PCB and helped by the process heat, is wicked between the PTH barrel and the component pin. Note the tendency to pull a web of solder from the wave as the board passes over. The solder-wettable lead-pad combinations become one with the wave as the board passes through it. Good soldering relies on flux-aided wetting and the ability of the solder web to break cleanly from the wave when surface tension forces are exceeded as the board moves away from the wave and the solder meniscus stretched to its breaking point. (*Courtesy of Alpha Metals, Inc*.)

The hot-air knife, as previously described, is sometimes useful in removing unwanted solder bridges from between component leads while the solder is still molten. This is especially useful in connectors and PGAs with interstitially arrayed pin fields (Fig. 49.28).

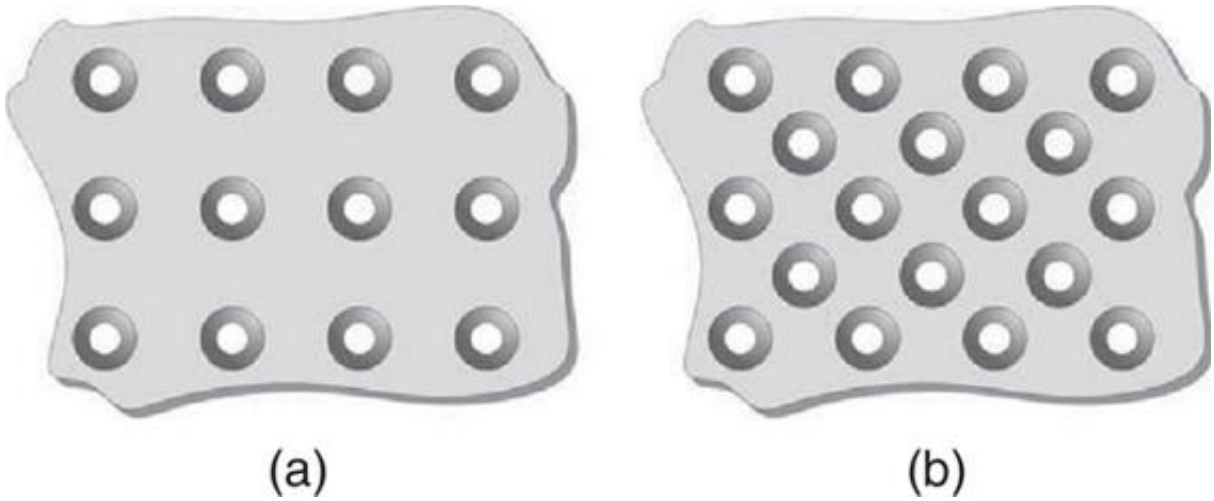

FIGURE 49.28 Pin field types. Circuit board segments with (*a*) orthogonally arrayed connector PTH pattern and (*b*) interstitially arrayed connector PTH pattern.

As the wave moves through the frustrated pin field of the interstitial array, some fluid flow stagnation may occur resulting in solder opens or insufficient PTH barrel fill. In addition, the interstitial pin field may not drain solder well enough in other areas, causing solder bridge formation (shorting multiple pins together with solder). Numerous wave solder machine designs and standing wave shapes are aimed at improving the soldering yields of these large packages, but there is no clear choice in wave style for all applications.

In designing circuit boards for the wave-soldering process, it is important to anticipate the flow of the wave over the bottom surface of the board. Placing tall components in front of short component fields should be avoided and component spacing should be maximized; otherwise, solder from the wave may be blocked from washing over the targeted joining

area. The taller component may shadow the flow of the wave, causing areas of flow eddying or stagnation in the vicinity of shorter components behind it. Also, if the SMT pad via extends all the way through the PCB, then its placement should be as far away from the leads as is practical to avoid the aforementioned problems of re-reflow.[8] Ideally the bottom-side via pad is shielded from the solder wave with a fixture (pallet) or by applying a mask such as tape or a peelable liquid masking agent that gels and dries at or near room temperature and leaves no appreciable residue when removed. Such peelable masks are made for wave soldering and rework applications. Other methods of shielding the PCB will be discussed in the next section.

49.4.8 Wave-Solder Pallets

The pallet, also known as the selective soldering pallet, or shield is a masking device meant to protect certain secondary (bottom-side) components, features or areas of the PCB during the wave soldering process. It is used to shield specific areas of the board from flux during flux application and from heat and solder during the wave solder process. Its top-side is designed with a recessed nest for the PCB and retention features to hold the PCB flat within the nest and tight against the shielding material. There are cutouts that expose those areas to be soldered to the flux and the standing solder wave (Figs. 49.29 and 49.30).

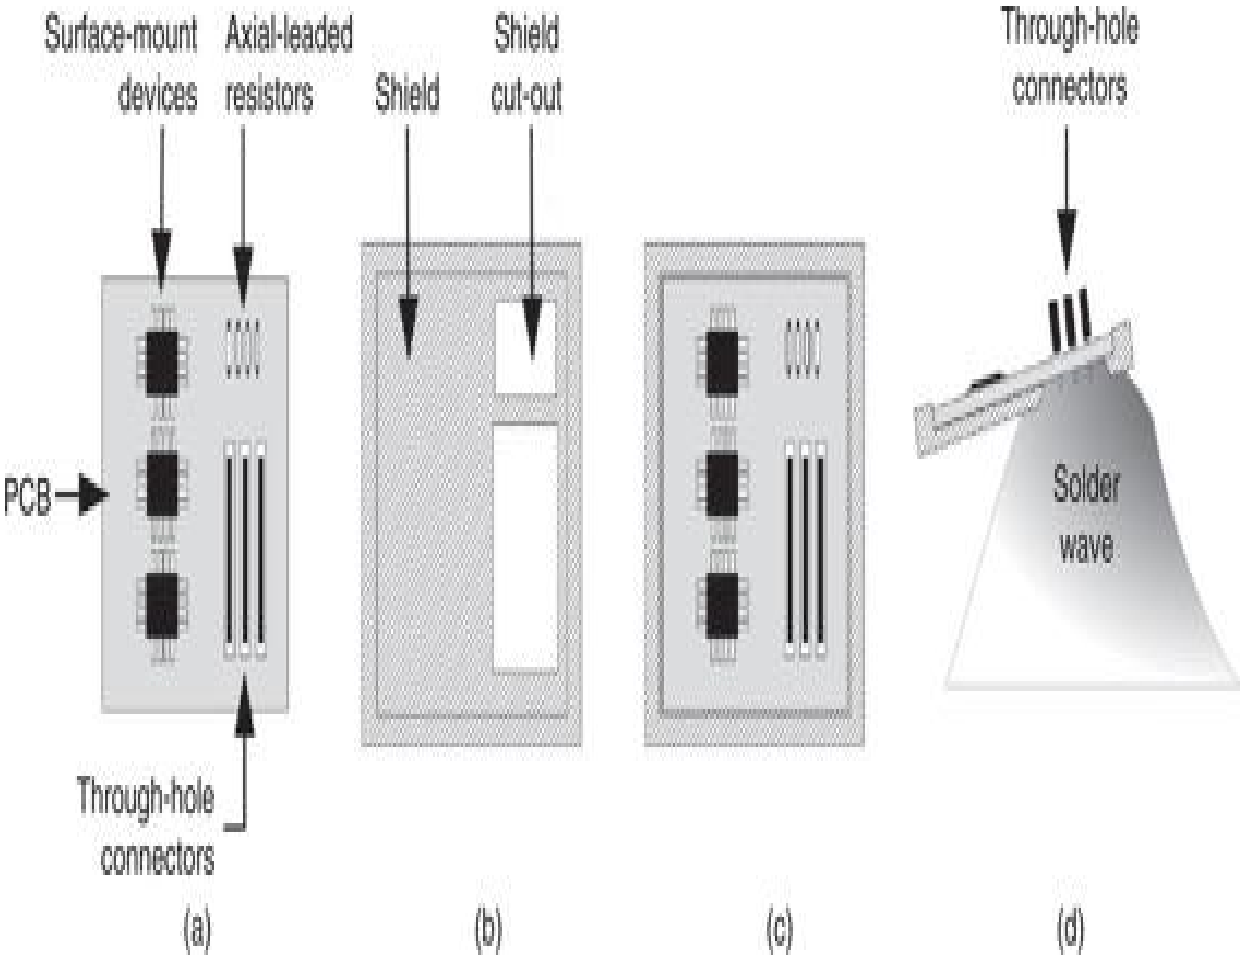

FIGURE 49.29 (*a*) PCB with SMDs and PTH part. (*b*) Shield (pallet) with cut-outs for PTH components. (*c*) PCB nested into shield. The shield protects SMDs from exposure to the solder wave. The cut-outs allow the wave to contact solder-tails. (*d*) The shielded PCB passing over the solder wave. The cut-out allows the PTH connector solder-tails to contact the wave for soldering.

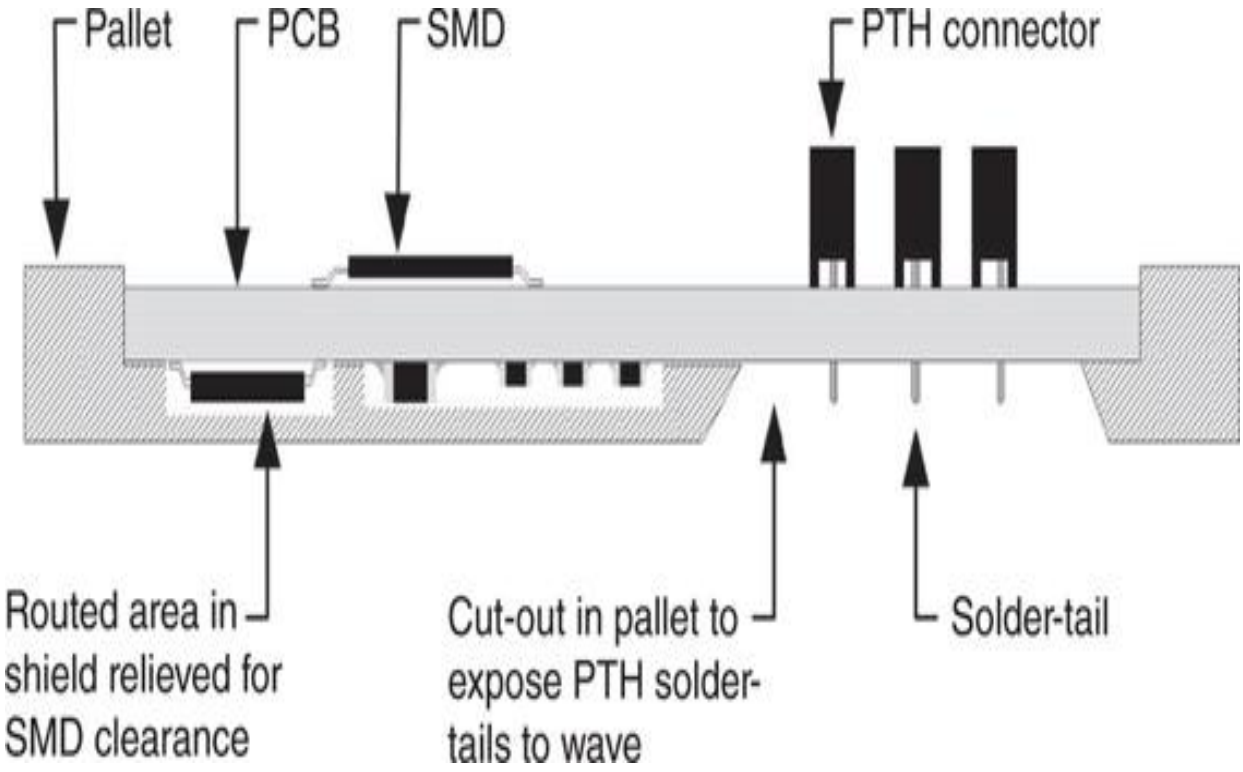

FIGURE 49.30 A wave-solder pallet for a mixed-mount PCB. Note the routed area to accommodate SMDs on the bottom-side of the PCB and the open area to allow exposure of solder-tails to the solder wave.

Wave solder pallets are generally is made of a non-wetting, electrostatic discharge (ESD) safe, thermally insulating material such as Delmat or other high-temperature epoxy-glass composites. Titanium has been shown to be useful for shielding also, although such pallets are very expensive.

Pallets are designed for repeated use but will degrade with time. Some fluxes will attack the epoxy of the glass-epoxy lay-up over time. Pallets may warp. If not cleaned routinely, they may build up hardened flux residues that will prevent proper seating of the PCB. They also may decompose with age and use. Pallets should be inspected after each use and before reuse.

49.4.8.1 Pallet Uses. A pallet may serve several purposes, including the following:

- Protection of bottom-side SMD components and their previously manufactured solder joints
- Shielding pad vias and via fields from solder[8]
- Masking edge-card gold fingers from solder (note: additional protection may be needed beyond the pallet, but the pallet is a first line of defense)
- Protecting press-fit connector sites by preventing solder from filling these holes
- PCB distortion prevention
- Protection of in-circuit test-points from flux and solder
- Shielding of plated mounting holes for attachment to the chassis
- Preventing flux deposition from where it is not needed

49.4.8.2 Wave-Solder Pallet Design. Although the wave solder pallet can prevent damage to a board, if not properly designed it can also interfere with soldering. Here are some design guidelines:

- *Thickness must be limited* such that the PCB will be in contact with the wave.
- *Must be thick enough* to provide the rigidity needed to hold the board flat during the process.
- *Must be flat enough* such that the PCB will seal against the pallet to prevent solder from flooding where it does not belong.
- *Pallet support must* include enough areas of support under the board so that a thin, large PCB will not sag as it traverses the wave.
- *Has to be durable* to survive the temperature regime, repeated use and direct exposure to flux (an acid) and molten solder.
- *Openings on the underside of the pallet should be chamfered* to promote solder wave contact in areas to be

soldered. The chamfers help prevent “gas lock,” enhancing the ability of air to be displaced by the molten solder ensuring smooth entry and exit at each pallet opening (Fig. 49.31).

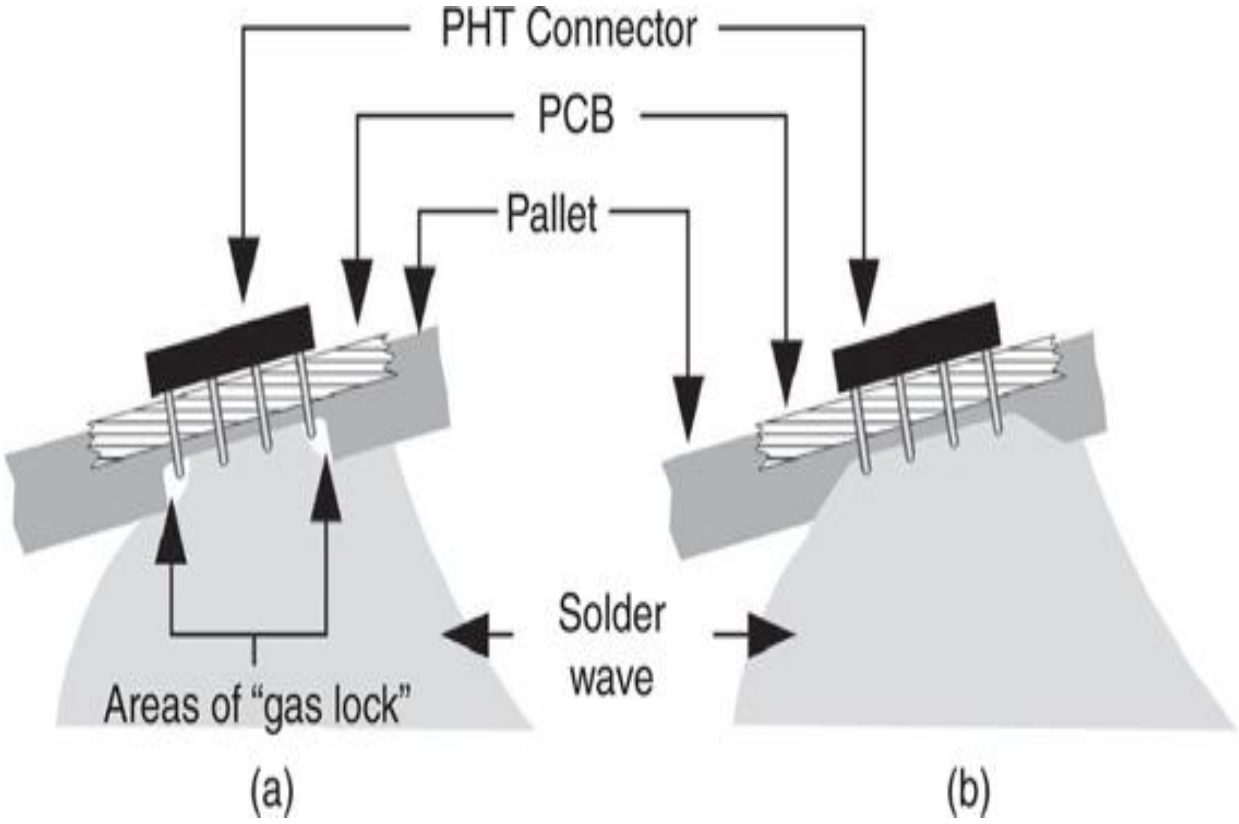

FIGURE 49.31 Openings on the bottom of wave solder pallets should be chamfered in order to promote flow of the molten solder from the wave. “a” depicts a pallet without a chamfered opening. “Gas lock” or “gas pockets” (entrapped air) may prevent the solder wave from touching some of the connector pins. No soldering or poor soldering will occur here. “b” has a pallet opening that is chamfered to promote complete solder coverage, minimizing “gas lock”, and enhancing solder flow to all pins.

- *Pallet openings should be as large as possible* for good PCA preheating and to permit-free access of the molten solder wave to the targeted areas for solder joint formation. The larger the pallet opening, the better the heating from preheaters and also from contact with the wave. If solder-tails are too close to a pallet opening, the molten solder of the wave may not make good contact

with pins to be soldered (Fig. 49.32). Further, the pallet will act as a thermal sink and may inhibit local heating. If solder-tails and plated through-holes are not heated sufficiently they will not solder properly.

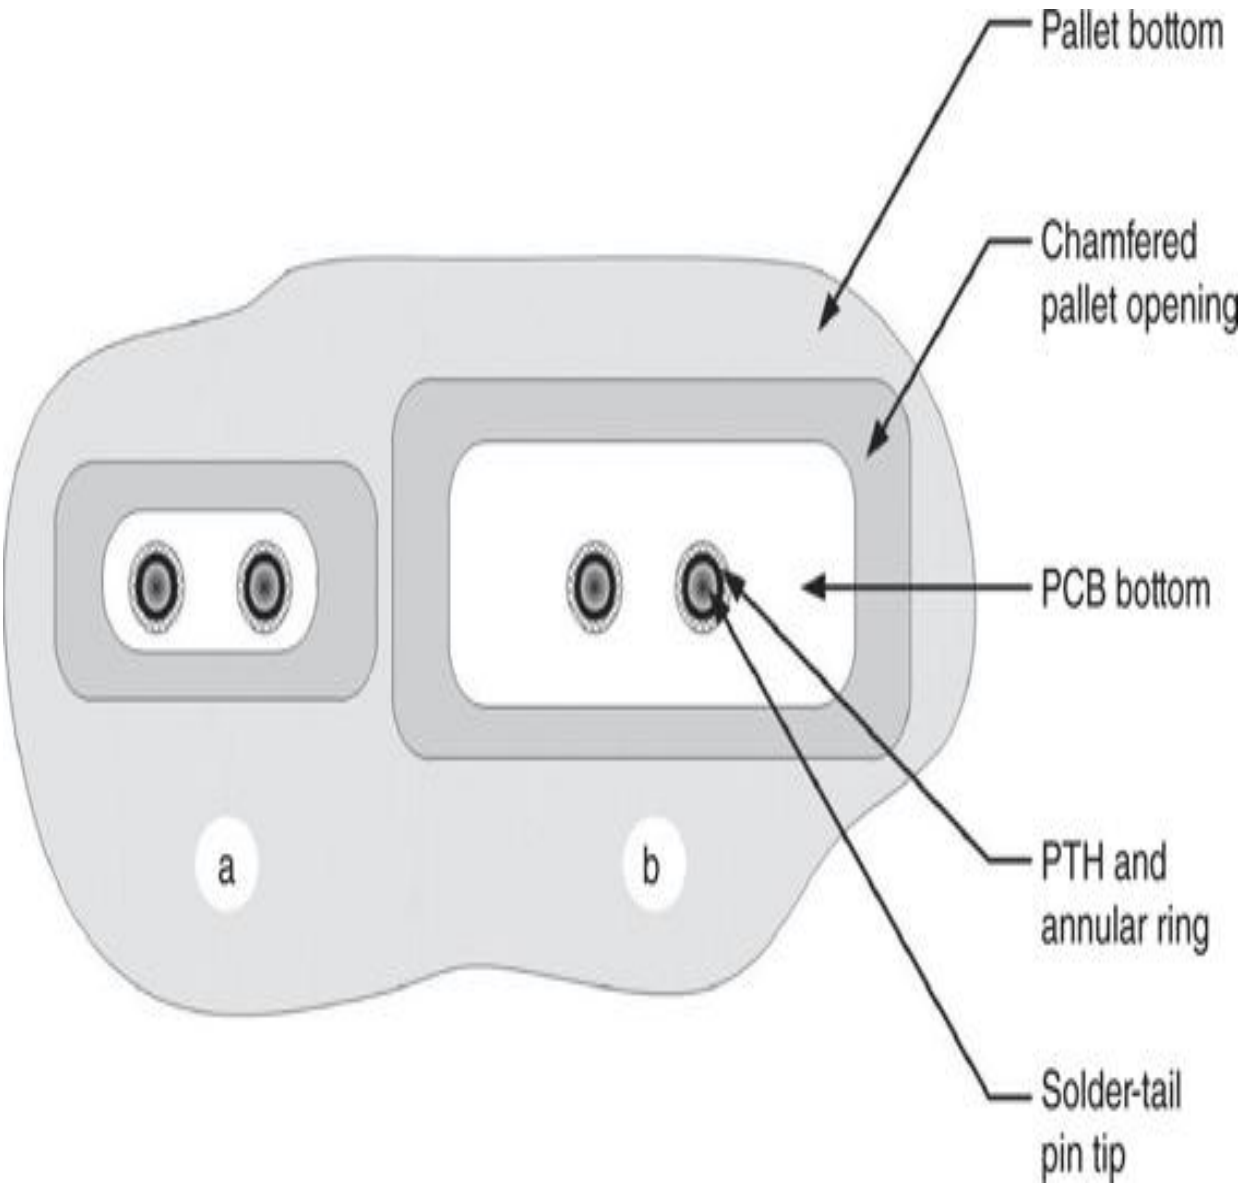

FIGURE 49.32 Small pallet opening vs. large pallet opening. Depicted is the bottom-side of a wave pallet showing two chamfered pallet openings. Within each opening is the bottom-side of a PCB and a set of plated through-holes with pins. Wave soldering success for “b” will be better than “a” since “b” has more surface area for better heating and significantly more accessibility to the solder wave.

- *Board-locks and over-clamps* should be incorporated into the pallet design (Fig. 49.33). The board-locks clamp the PCB into the pallet and seal it against the surface of the pallet. This prevents solder from intruding between the pallet and the PCB. Board-locks are rigid, spring-loaded, high-temperature fingers that can be rotated out of the way or removed to permit loading and removal of the PCB.

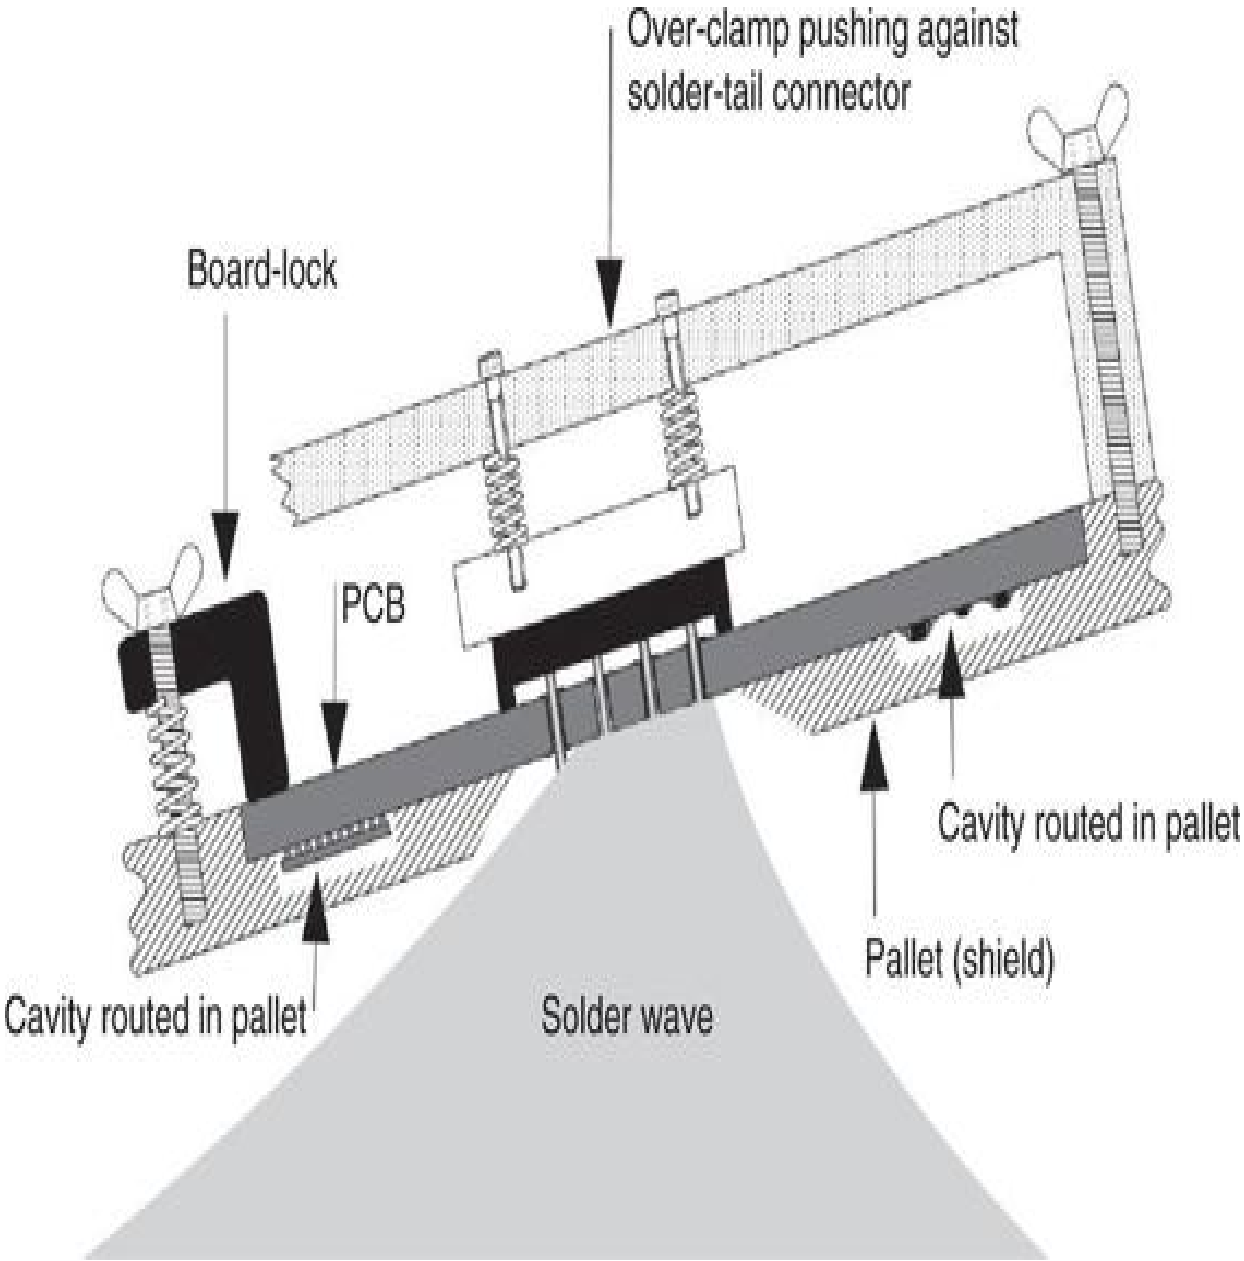

FIGURE 49.33 Advanced features of a wave solder pallet (shield). The pallet is cut out to expose solder-tails of the connector. The cut-out is chamfered to enhance the flow of solder over the connector pins. There are cavities on the bottom-side of the shield to allow clearance for previously soldered surface-mount components. One of several spring-loaded board locks is depicted, holding the PCB flat against the pallet. There is a partial view of an over-clamp, used to prevent the PTH connector from floating up when exposed to the molten solder wave.

- Over-clamps further help to seal the board to the pallet especially in the middle of large PCBs. They are generally incorporated for holding connectors and other nonclinched parts from buoying up when contacted by the molten solder wave. The design must take into consideration the thermal mass of the clamp and its influence on proper heating of the PCB during the wave process. Many PTH connectors have staking pins which hold the part by friction-fit onto the board. When this is the case, an over-clamp may not be necessary.

49.4.9 No-Clean Flux Residue and In-Circuit Test

During wave soldering, most of the flux from the process is either consumed or washed off the bottom-side of the board by the action of the molten solder wave. Any flux residue that seeps between the pallet and the board, will not be removed by the wave process. If this residue were to cover in-circuit test pads, it would inhibit in-circuit test probe contact. Care should always be taken to minimize flux deposition for wave soldering for this reason and to minimize flux usage and associated expense. Pallets should be inspected and cleaned frequently to ensure that flux residues are not being transferred to in-circuit test points from a poorly maintained pallet.

49.4.10 Designing PCBs for Wave Soldering

Complex PCAs with area array devices and fine-pitch SMT components (mixed-mount assemblies) on boards thicker than about 2.36 mm (0.093 in) may be difficult to wave-solder if care in layout is not observed. There are many important PCB design criteria that should be considered to enhance PCB wave soldering:

- *Clearance from the edge of the board to previously soldered SMT components* must be sufficient such that the wave solder machine's edge-hold conveyor does not interfere with these components.
- *PTH component spacing from the edge of the board* is dictated by wave flows and the surrounding structure. The wave dynamics at the outer edges of the wave may be different than inward body of the wave. Place difficult to solder components inward for best success at soldering. F. W. Kear's review[10] of the thermal aspects of through-hole solder joint formation offers a glimpse of the physical phenomenon of the wave-soldering process.

When possible, avoid placing PTH components directly against the edge of the board. There must be clearance from the PCB edge to the pallet to allow the board to nest within the pallet. A selvage edge (a removable and disposable board-edge extension that is part of the board itself) can be designed into the PCB or PCB panel (Fig. 49.34). After wave soldering, the selvage edge can be removed by rotary cutter or routing. Note that post-solder routing is not preferred, especially for no-clean soldered assemblies. The abrasive router dust may remain within connectors and scratch connector contact surfaces or mating connector contacts. The vibration, especially from poorly maintained routers or

from inadequate router fixtures, may also affect the reliability of certain components.

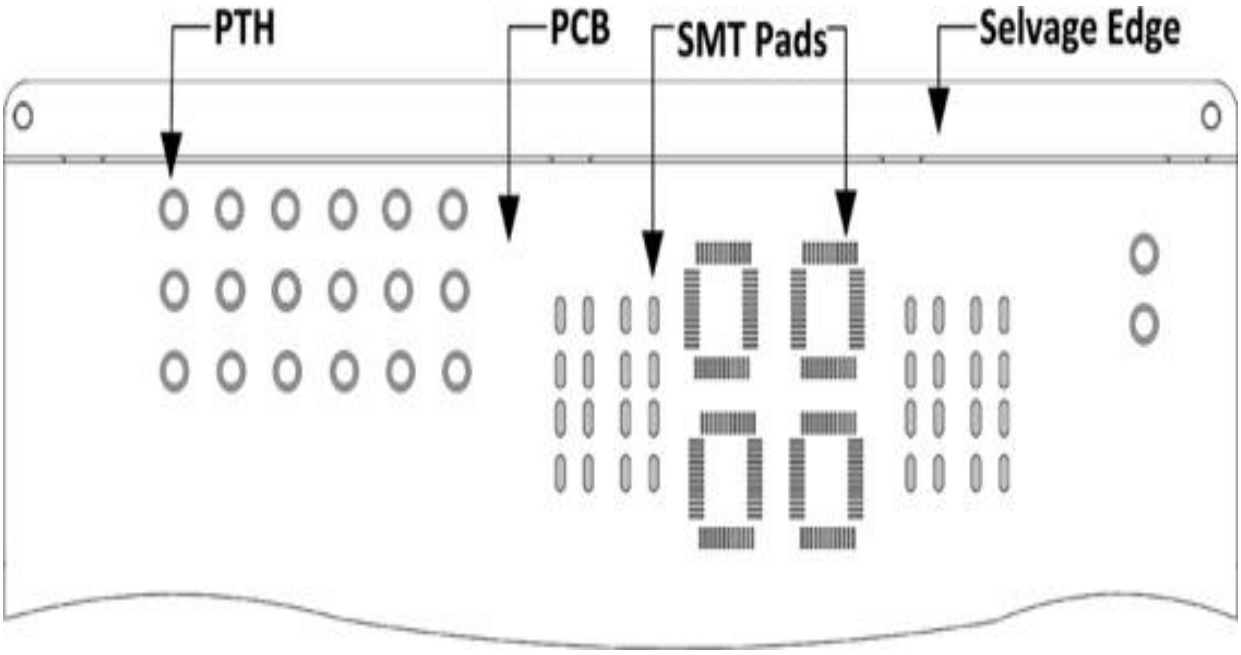

FIGURE 49.34 Board schematic showing a removable selvage edge; a disposable edge. In this case it was useful to enable wave soldering of the PTH connector near the finished edge of the board.

- *PCB width must be appropriate for the wave solder machine:* It must physically fit on the machine and components that will be wave soldered must be within reach of the solder wave.
- *Components should be oriented in directions favorable to good soldering:* Long connectors are generally oriented with their long axis parallel to the long axis of the solder wave (perpendicular to the direction of travel on the wave machine) to minimize solder bridging. The same applies to passive devices and device fields. The field should be oriented with the long axis perpendicular to the direction of travel through the wave solder machine. The device itself should be oriented with long axis perpendicular to direction of travel.

- *Minimize PCB thickness:* Since thicker boards are more difficult to wave solder. Boards thicker than about 2.54 mm (0.100 in) are notably difficult to wave solder IF there are surface-mount devices on the primary side of the board. Getting the board hot enough for good PTH barrel fill on such boards will often result in re-reflow of previously soldered surface-mount devices. Care in profiling and appropriate thermal shielding are a must for thick PCBs. It should be noted that very thick PCBs (even >6.35 mm (0.25 in) can be effectively wave soldered. Such boards rarely carry intricate SMDs and re-reflow of SMDs is of less concern so aggressive preheating and slow transit times through the wave are not a problematic.
- *Plated through-holes should be specifically tailored for the component pin* (also called solder-tail): Component manufacturers will generally provide such information, but there are industry standards and recommendations dealing with this topic such as IPC-2221.[11]
- The clearance between component pin and PTH barrel wall must be small enough to provide proper conditions for good capillary wicking of the solder from the wave as it wets to pin and barrel. If made too small, volatiles from the flux will easily expel the wicked solder from the PTH resulting in large voids that may detract from reliability. If made overly large, the hydrostatic pressure from the wave may cause solder to flood to the top-side of the PCB and cause solder shorts (bridges).
- *Avoid PTH components on both sides of the board:* Restrict the design such that wave soldering occurs only on the secondary side (bottom-side) of the board. PCBs with wave soldering on both sides are notably difficult to process. Bottom-side component height may interfere with machine clearances. Determine whether SMT or press-fit components can be used in the design to obviate the need for a second wave-soldering operation. The industry-

standard preference is to restrict all wave-soldered components to one side (components inserted through the primary side) of the PCB.

- *Incorporate heat-relief features into the PCB*, especially around power and ground pins of PTH components. Such pins are generally connected to multiple, thick copper conduction planes within the PCB. These planes are buried in the board and glass-epoxy circuit boards are somewhat thermally insulating, therefore they are difficult to heat sufficiently for proper soldering. The process heat applied during wave soldering (preheat and from the wave itself), instead, is conducted through the PTH barrels and into any attached power and ground planes. If the PTH barrel is not heated sufficiently, neither good fluxing nor proper solder wetting will occur.

Heat-relief structures are designed around the point where the PTH barrel is connected to a copper ground or power plane. These features resemble spoked pads; or more appropriately “anti-pads.” In the heat-relief design the PTH barrel is connected to the plane by spokes of copper rather than a broad, planar connection (Fig. 49.35). These spokes are designed to provide sufficient electrical conduction and at the same time are designed to limit thermal conduction away from the PTH barrel (the soldering target).

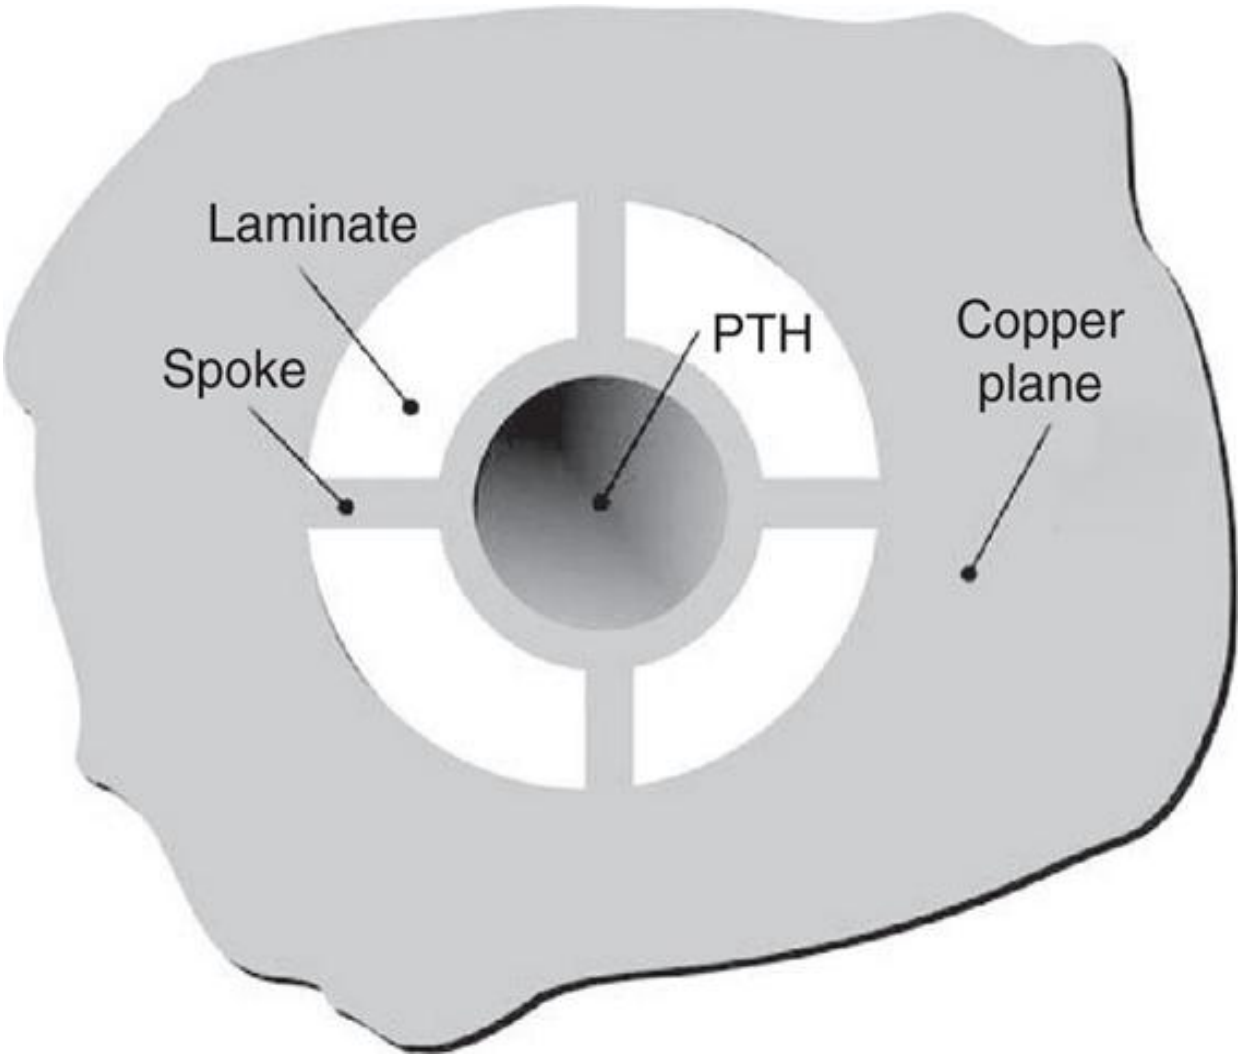

FIGURE 49.35 Schematic of a thermal relief features (antipads) within a PCB. The spokes connect the PTH barrel to the electrical conduction plane and limit thermal transfer from the PTH barrel to the conduction plane. The limited thermal path enhances heating of the PTH for soldering. Care must be taken in the design so that there is sufficient electrical conduction through the spoke for proper circuit operation and to avoid ohmic heating.

- *Limit the number of PTH barrel attachments to power and ground planes within the PCB* when feasible. Each attachment point will result in thermal dissipation into the copper plane even with antipad construction. This thermal loss will detract from the soldering process making the job of preheating and solder wetting all the more difficult.
- *Cluster PTH components and provide sufficient clearance between them:* Group wave-soldered components together

so there are fewer and larger openings in the pallet. It also may save time and materials at spray-fluxing. Avoid interspersing nonwave soldered surface-mount components within wave-soldered component fields. Conversely, avoid designs that place an isolated PTH component amid a field of SMD components. Such placements necessitate small wave pallet openings that inhibit: solder-wave fluid flow; preheating; wave contact.

- *Do not place wave soldered components near gold fingers:* Clearance from gold fingers is required so as not to contact the gold fingers with solder or foul them with flux. The gold finger should be away from pallet nest edges. Covering the gold fingers with an acrylic-based, high-temperature adhesive tape will help to keep solder and flux from contacting the gold fingers. The tape is not an effective mask if exposed directly to the solder wave.
- *Test pads positions should be designed as far from intended wave-solder pallet openings as possible* to avoid contacting them with solder or covering them with flux. No-clean flux residue is an effective electrical insulator and will inhibit good electrical contact by in-circuit test probes.
- *Restrict tall components to the primary side of the PCB:* Tall SMT components on the bottom-side of the board may interfere with wave soldering and prohibit adequate wave pallet design.
- *Keep the most complex SMT components as far from PTH components sites as is practical:* Devices such as fine-pitch SMDs, area-array devices, etc., may re-reflow if too close to wave soldered components. Re-reflow of these components may melt previously formed solder joints causing electrical opens, or the solder from the joints may be drain down pad vias compromising solder joint reliability.

49.5 WAVE SOLDER DEFECTS

There are many types of wave-soldering systems, each with its unique advantage as claimed by the manufacturer. The soldering engineer has to assess these improvements as they relate to the type of assembly being soldered. Wave soldering has had over 60 years to mature, but the degree of equipment intricacy and large number of process variables attest to the complexity of this process. If the machine and processes are not understood or not properly controlled, wave-soldering defects such as skip soldering (electrical opens) and bridges (electrical shorts) will occur. Another important defect is the influence of secondary-side wave soldering on primary-side surface-mounted components. If parameters are not controlled properly, it is possible to cause primary-side SMDs to reach reflow temperatures. This can induce solder opens, shorts, or solder-starved joints. This phenomenon is most commonly associated with thin, densely populated, double-sided PCBs with fine-pitch surface-mount devices such as quad flat packs and BGAs soldered to the primary side of the board. Thermal conduction from the wave through the board itself, through electrical vias and along electrical traces in and on the board, may provide enough heating to cause previously soldered parts to reflow again. Solder can be drained away through vias or wicked-up surface-mount component leads, resulting in opens or weakened soldered joints with an extreme hourglass-shaped attachment of solder from the bottom of the lead to the bonding pad.

A common defect associated with no-clean wave soldering is the seepage of flux between the pallet and the board. The resulting flux residue may inhibit in-circuit test probe contact. Care should be taken to ensure that the board fits well into the pallet nest, is rigidly indexed within the nest of the pallet, and is adequately retained against the pallet

surface. As a pallet ages, it may shrink, take on twist, or bow and even delaminate. All of these may interfere with proper board seating. Buildup of flux residues on the pallet may also prevent proper seating of the PCB into the pallet nest and allow board contamination by solder or flux.

If a PTH component body is seated tightly against the surface of the PCB, a gas pocket may form at the primary side of the hole. The pressure from gases evolved from the flux or just from entrapped air may work to either block or expel molten solder wicked into the PTH barrel. This results in either inadequate PTH fill or excessive solder void formation.

This can be remedied by applying a small spacer under the component to keep it from contacting the PCB as shown in Fig. 49.36. The spacer must be made of a heat-resistant material such as silicone or a dot of SMT glue on the PCB surface. If SMT glue is used, it should be cured prior to component placement, otherwise efforts to remove the component during rework, if required, will be confounded. Ensure that the glue does not foul solderable surfaces.

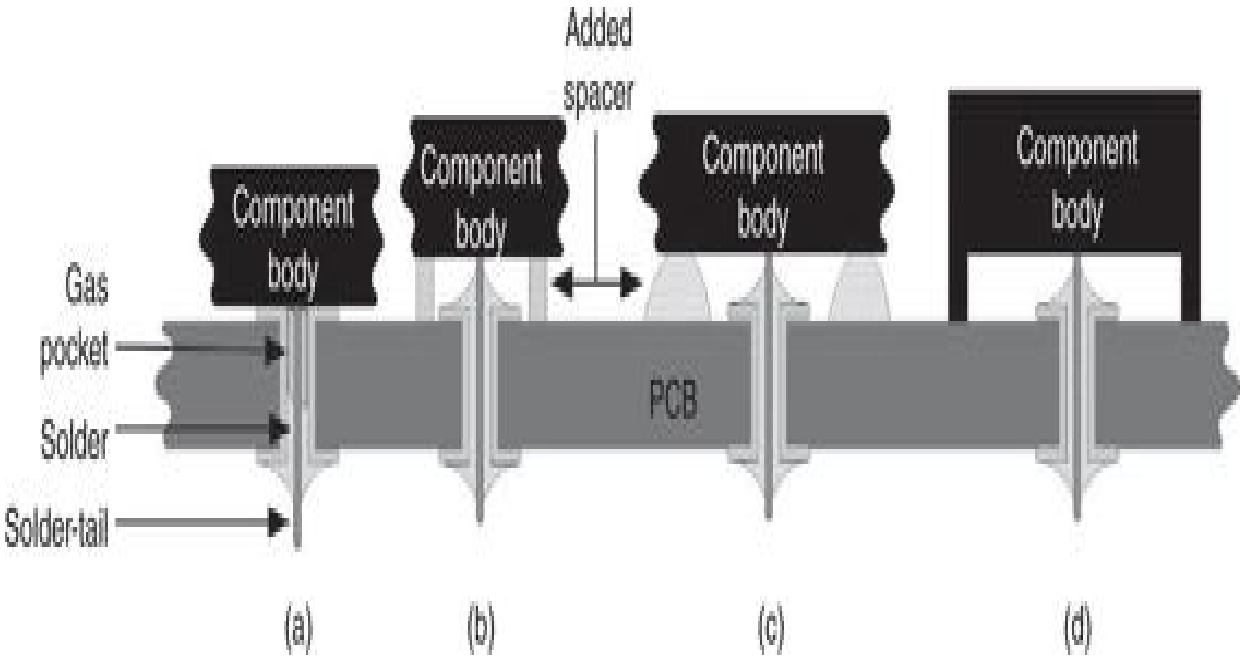

FIGURE 49.36 A component body tight atop a PTH can seal it causing “gas-lock” which retards or expels molten solder. (*a*) Component tight on PCB with large solder void; (*b*) silicone bumpers added to space the connector body off the PCB; (*c*) surface-mount glue can be used as a spacer also, however care must be taken not to contaminate solder surfaces; (*d*) many PTH connectors and parts have stand-offs molded in to prevent “gas-lock.”

When a stand-off is add as depicted, it is important that the sufficient solder-tail protrude to initiate solder wicking and to allow for good solder fillet formation. Both are needed for adequate PTH solder joint strength. Some connectors come with features molded into the insulator body to allow proper stand-off when the component is mounted properly.

Probably the most common defect in PTH soldering is the void; a lack of wetted solder within the PTH and on its accompanying solder-tail. Use the latest version of IPC-A-610[12] as a guide to assess the quality of PTH solder joints. There are several reasons why voids may be present in the PTH solder joint that fall into several broad categories (Table 49.2):

TABLE 49.2 Origin of Poor Wave Soldering as a Result of Solder Void Formation

Effect	Reason	Comment
Thermal	Board too hot	• Solder flux has burned off and either the PTH or the solder-tail has re-oxidized or the flux has reached such a high temperature that it has "caramelized" (denatured and created a lacquer) coated what should be solderable surfaces • Too much preheat • Too much dwell time in wave

	Board too cool	• Inappropriately low temperature caused solder to solidify before it can fully wet pin and barrel.
		  • From board design (PTH barrel connected to too many thick, conductive planes)
		  • From inappropriate wave solder pallet design (prevents proper PCB preheat or results in too little exposure of solder-tails to the molten solder wave).
		  • Insufficient preheat
		• Insufficient dwell time in wave
		• Temperature too low for proper flux activation. The flux has not stripped oxides from solderable surfaces and the oxides inhibit solder wetting

Material	Bad plating	• Poorly plated PTH or solder-tail will not allow solder to wet for joint formation
	Contaminated surfaces	• Contaminated PTH or solder-tail will not allow solder to wet for joint formation
Inadequate Flux Coverage	Inappropriately low volume of flux dispensed	• Too little flux dispensed prior to wave soldering • Improper distance of spray-flux nozzle to PCB
	No flux dispensed	• Improper fluxer set-up • Fluxer malfunctioned during the flux application process (clogged spray-fluxer nozzle)
Expulsion	Solder expelled from PTH by soldering flux	• Too much flux within the PTH may volatize and expel molten solder from the PTH during the solder-wetting process
	Expulsion from "gas-lock"	• Inadequate stand-off: if component sits too tightly atop PTH flux or entrapped air may expel flux and molten solder • If wave pallet design is poor, gas pockets may inhibit free flow of the wave over PTH solder-tails
	Porous PTH	• If the PTH barrel has pin-holes in its plating that are open to the laminate (glass/epoxy layer), the laminate may outgas during the soldering process and produce enough gas to displace solder in the barrel

Defects such as bridging and opens have been discussed previously.

49.6 VAPOR-PHASE REFLOW SOLDERING

Because of safety, environmental concerns and compliance with the Montreal Protocol for the reduction of ozone-depleting chemicals, this soldering technique had fallen out of favor. With the advent of Pb-free soldering, interest increased in vapor-phase soldering for SMT applications, but it is likely that it will continue to remain a niche application. Due to its continued diminished status, vapor-phase reflow is covered only briefly.

49.6.1 Basic Process

As for other reflow techniques, the board must be supplied with sufficient solder and flux for solder joint formation. Most commonly, solder paste is stenciled onto circuit board pads. Components are placed onto the solder paste in preparation for reflow. The board is conveyed into the reflow chamber, where it is exposed to the vapor phase of a boiling liquid. This liquid is inert with respect to the solder and board. It is a dense synthetic organic chemical of high molecular weight and high boiling point (slightly higher than that of solder liquidus but not high enough to damage the circuit board or components). Historically, chlorofluorocarbons were used, but now only hydrofluorocarbons (HFCs) are acceptable due to environmental concerns. Material cost for such chemicals are high, at several hundred dollars per pound.

When conditions are optimized, the hot vapors begin to condense on the cooler PCB, heating it. When sufficient

energy is transferred, the solder paste is activated and the solder melts wetting to the component leads and PCB pads. As the heat is lowered or the board is removed from the hot vapor, the molten solder solidifies, bonding component leads to circuit board pads.

49.6.2 Machine Subsystems

The vapor reflow soldering machine is composed of four main subsystems: conveyor, reservoir vessel, cooling coils, and heaters. The heated vessel has cooling coils surrounding it, placed well above the level of the liquid in the reservoir. These condense the vapors, returning the majority to the reservoir, as shown in Fig. 49.37.

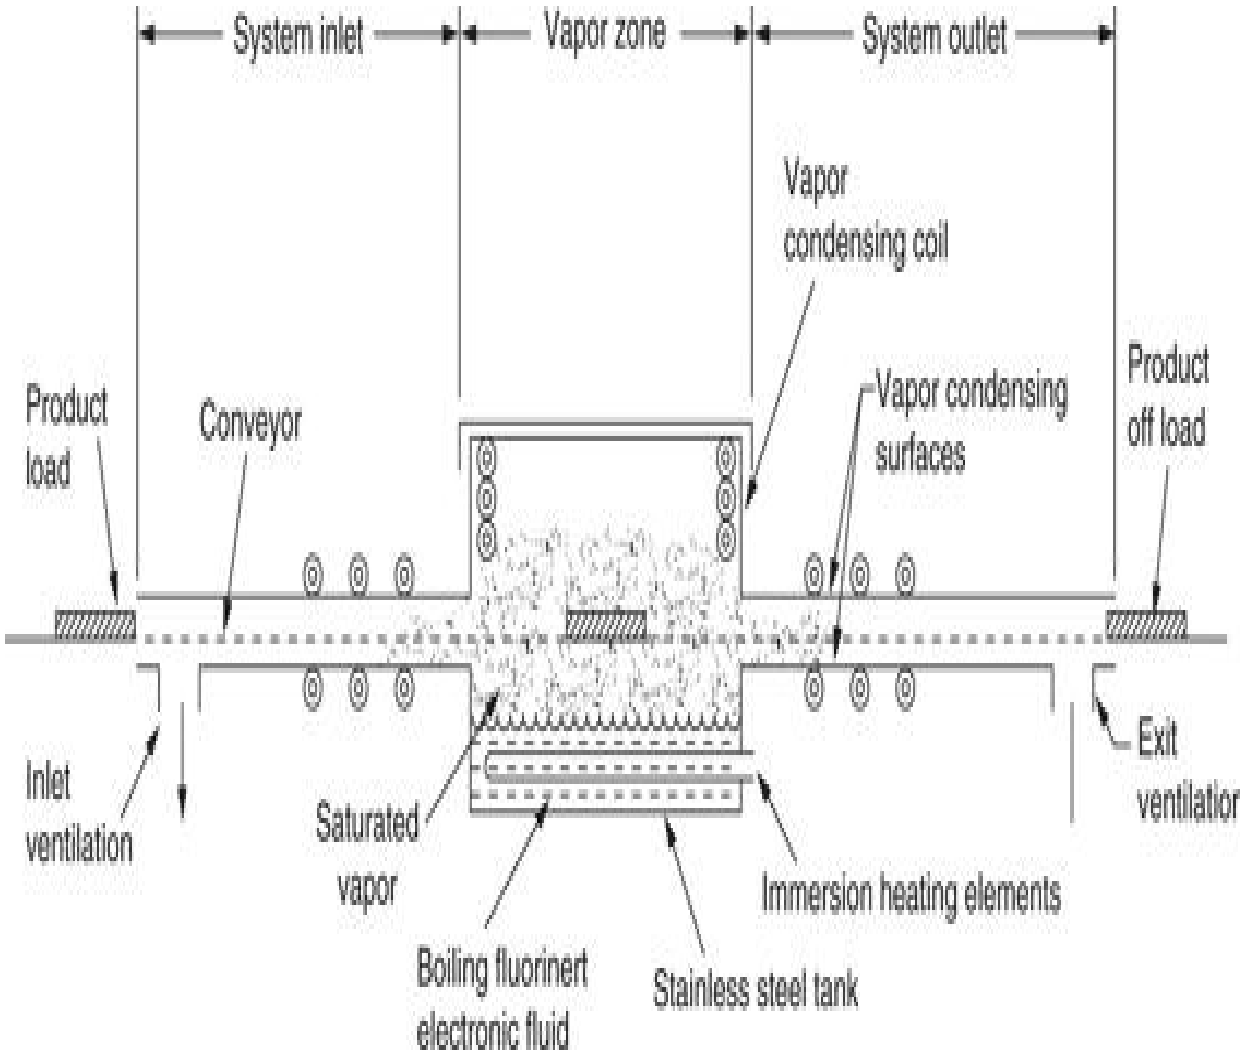

FIGURE 49.37 In-line single-vapor heating system schematic. (*Reprinted with permission from Electronic Packaging and Production, November 1982, p. 63, Fig. 1.*)

49.6.3 Advantages and Disadvantages of Vapor-Phase Reflow Soldering

The process is very precise in temperature and as long the as the boards to be assembled are not overly massive, they can be heated uniformly and rapidly by this method. Since the soldering occurs in an inert atmosphere, fluxes of lower

activation level can be used. In the absence of air, solder joint quality is generally excellent with low void content.

Although vapor-phase reflow has the appearance of being a fast process, solder paste reflow recommendations must still be followed. If the paste is heated too rapidly, paste volatiles may boil, resulting in explosive solder ball formation. As in other soldering methods, the maximum heating and cooling ramp rates must be commensurate with component manufacturer recommendations to prevent component damage. Components must be dried out prior to soldering to remove any moisture from within the devices. This is no different than for any other soldering method. A phenomenon known as “popcorning” may damage non-hermetically sealed packages. This occurs when moisture entrapped in the package is heated and expands. The pressure within may be high enough to rupture the plastic molded package body. When this occurs, the silicon die and associated wire bonds may be stressed and damaged as they are moved by deformation of the over-molded plastic package material.

Besides legislated environmental issues, there are health risks associated with vapor-phase reflow soldering. With the continued recycled use of HFCs, toxic materials such as hydrofluoric acid and perfluoroisobutylene are formed and concentrated. These must be neutralized and properly disposed.

When massive, densely populated boards are introduced to the vapor-phase reflow chamber, vapor collapse can occur—a condensation rate that outpaces that of vaporization. The result is that the internal atmosphere of the vapor-phase chamber thins dramatically to the point that it cannot sustain adequate reflow. Vapor-phase machines that rely on immersion heaters are prone to this phenomenon. More recent machines include massive heating element housings that surround the reservoir providing sufficient thermal inertia to preclude this problem.

Increased incidence of tombstoning, solder ball formation, and component displacement has been noted in this method of reflow. The condensing vapor transfers heat directly and rapidly to the best thermal conductors, component leads, and pads. Excessive solder wicking may occur, transporting solder from between the lead and pad up the lead, where it is not needed. This may result solder bridges proximal to the component body. Excess solder on the component lead decreases the lead's flexural compliance, making it less reliable. Furthermore, if the solder is wicked up the lead, the lead-pad interface may be solder-starved, resulting in an inferior solder joint. Additional information can be gleaned from older reference books and other authoritative publications, including previous editions of this book.[13,14]

49.7 LASER REFLOW SOLDERING

The laser has proven to be a versatile tool in many industries. For circuit board assembly, it can be used for marking, single-point soldering, or rework. Lasers can accommodate bonding of the finest or coarsest peripherally leaded surface-mount packages, and its performance and applicability are independent of device population density on the board, the thickness of the PCB, or the presence or absence of package heat sinks as long as there is a direct view of component leads. It can be used with most any PCB pad or component lead surface finish and any solder, including Pb-free alloys. When laser soldering is implemented properly, high soldering yields and exceptional bond characteristics are possible.[15] Its use is generally relegated to low-volume soldering applications. For successful laser soldering, it is necessary to use tooling to force or hold component leads in contact with circuit board pads.

Laser-based reflow is used for both primary soldering and as a rework tool. Some laser systems are packaged expressly for the purpose of rework and sold commercially. In such systems, PCBs are preheated to about 100°C within the system by means of a bottom-side resistance heater or by a hot-air stream. A diffuse laser beam is then scanned around the package by a rapidly moving galvanometer. The impinging energy heats surface-mount leads or an entire BGA to the point of solder reflow for package removal. This system has the advantage of such localized heating that only the package targeted for rework reaches reflow temperature. Everything around it stays close to the system preheat temperature with almost no thermal spill-over from the laser. This is a distinct advantage over conventional hot-air repair methods, where the hot gas stream used for package heating and reflow can inadvertently melt solder joints on adjacent components or components on the opposite side of the board.

Laser soldering requires no hot zones to profile or maintain, does not induce substrate warpage, and requires no heated bonding head that can degrade or vary with usage. Components can be spaced exceptionally close to one another—closer than currently permitted for other techniques, especially when one considers rework.

Delivery optics, placed in the path of the laser beam, direct it to the circuit board or, more specifically, the leads, pads, or lead-pad combinations. The beam can be easily steered by means of wavelength-appropriate mirrors and can be focused to the required spot size via a final objective lens to concentrate the beam density sufficient for the thermal rise to accomplish soldering. The delivery optics can be held fixed and the circuit board moved beneath or, conversely, the optics can be moved to direct the beam as needed. Either can be done with great precision sufficient for any PCB soldering task. Moving the beam and moving the board both have their own advantages. Moving the optics in any

direction is very simple and will not interfere with any PCB or surface-mount device fixturing requirements. Also, moving the circuit board may cause misalignment of component leads and circuit board pads. Fixed optics are more stable and require fewer adjustments, although, if engineered properly, moving optic beam delivery systems can be exceptionally stable and accurate. Fiber-optics are in vogue for laser beam delivery for Nd:YAG or laser diode systems, but it should be noted that, when dealing with high-energy-density laser beams as required for soldering, fibers are subject to damage if not precisely maintained. Fiber delivery has the advantage of allowing for easier steering of a beam in a complex machine that may preclude the use of orthogonal mirror beam steering.

The choice of laser for soldering is predicated on emission wavelength, required power, required beam diameter, machine reliability, and price. The optical properties of the target material are of primary importance in the laser selection process. In the case of surface-mount soldering, the absorption, reflection, and transmission characteristics of the PCB laminate as well as the reflectivity and absorptivity of the metallics (leads, pads, and solder) involved in the soldering process must be considered. The majority of circuit boards produced are composed of glass fiber-reinforced epoxy resin, although there are others. Each laminate has its own unique optical properties and characteristic laser damage threshold (LDT). LDT can be defined as the energy required to alter or damage the target material. In the case of an organic-based laminate PCB, it would be the necessary laser energy to char the board or cause the bonding pads to lift from the surface. Most any lead-pad surface finish on most any circuit board material can be soldered. For the purpose of this section’s discussion, the focus will be on industry-standard glass-epoxy laminate and most any tin-based solder.

49.7.1 Laser Choices

There are few practical choices for laser selection, since only a few possess the characteristic energy, production-tested reliability, and economics necessary for PCB assembly. The most common are the neodymium-drifted yttrium-aluminum-garnet (Nd:YAG) laser, an example of a solid-state laser, and the carbon dioxide (CO_2) laser, which has a gaseous lasing medium. While there are others, these two types of lasers are among the most common of the industrial tools. Each has been on manufacturing floors in various industries since the early 1980s. They are versatile in terms of applications and capable of the output required to weld, braze, solder, cut, and mark. Although other lasers could be used for soldering, the Nd:YAG and CO_2 types are the most commonly available. They have proven track records and are also the most commonly reported in terms of application to soldering.

There are excellent classic supplemental texts available for additional detail and instruction in laser technology. Those by S. Charschan,[16] Hecht,[17] and Ready[18] are particularly useful. Additional information on CO_2 lasers in the realm of soldering can be found in several references.[19–24]

49.7.2 Effects of Laser Wavelength

The long wavelength (10,600 nm) of the CO_2 laser is readily absorbed by organic materials (e.g., glass-epoxy laminate, polyimide, solder flux and plastics used for over-molded ICs). The shorter wavelength (1064 nm) of the Nd:YAG laser is more readily absorbed by metals such as tin plating and solder. There is yet another consequence of wavelength on the process: the shorter wavelength the smaller the achievable spot size.

The theoretical diffraction-limited spot size of a focused beam is directly proportional to the beam wavelength and lens diameter, as described in Eq. (49.1).

$$S = F\lambda/D \tag{49.1}$$

where S = diffraction limited spot size
F = focal length of the lens
λ = wavelength of the laser
D = lens diameter

Table 49.3 shows theoretical spot size for a 25 mm CO_2 or YAG laser beam focused by a wavelength-appropriate 25 mm diameter lens of 100 mm focal length:

TABLE 49.3 Theoretical Spot Size versus Laser Type*

Laser Type	Laser Emission Frequency, nm	Approximate Theoretical Spot Size	
		nm	μm
CO_2	10600	42,000	42
Nd:YAG	1064	4,200	4.2
Nd:YAG (frequency-doubled)	532	2,100	2.1

*For this example, the laser beam diameter is sized to fill the focusing lens diameter (D).

Imperfections in the lens or beam shape and other factors prevent practical achievement of these minimal spot sizes. Generally, the attainable focused beam diameter on the factory floor is about two to three times larger than the

ideally calculated spot size. Note that for an Nd:YAG laser, the spot size is at least 10 times smaller than that of the CO_2 laser, providing a fine, high-energy-density spot for soldering.

49.7.3 Laser-Soldering Fundamentals

There are relatively few variables associated with the laser in its application to soldering. This is one of the advantages for laser processing. Beam wavelength, irradiation time, and beam power are important to the process, as are the properties of the materials being joined. Reflectivity, thermal conductivity, and laser damage threshold must be understood before soldering is attempted. The wavelength will be fixed by the laser of choice, and the shorter the wavelength, the smaller the theoretical spot size, as discussed. Generally, the reflectivity of a metal is lower at shorter wavelengths, thus a metal is more easily heated by an Nd:YAG laser than with a CO_2 laser. The converse is true for many polymeric materials, which are more absorptive at longer wavelengths and therefore more prone to damage with increasing wavelength. Many polymeric materials are also absorptive at the UV end of the spectrum. A CO_2 laser beam is more likely to impart damage to a circuit board than the beam of an Nd:YAG laser, but either laser can inflict damage if the energy density is sufficient. In fact, either laser can easily cut through a component lead or drill through a circuit board if parameters are not adjusted properly.

The reflectivity of metals varies widely with composition and surface condition. Every metal can be heated with a laser as long as the energy density of the beam and dwell time are sufficient. This is also the case with laser-irradiated

component leads, board bonding pads, and solder during the laser bonding process. Measurement of the reflectivity of Sn-based solder shows that a eutectic alloy can be as high as 75 percent at 10,600 nm or as low as 25 percent at 1064 nm. Therefore, in the case of the CO_2 laser at 10,600 nm on a Sn or Sn/Pb-plated lead and solder-coated pad, much energy will have to be directed at the metals to start the absorption process, since so little laser energy is absorbed by the solder and converted to heat; the rest of the energy is lost to reflection. The reflected or multiply reflected beam may impinge on adjacent components and damage package bodies or even the circuit board itself, causing charring. Therefore, Nd:YAG is preferable for circuit board soldering.

49.7.3.1 Through-Lead and Through-Pad Bonding. Generally, the laser beam is directed at the component lead to accomplish soldering, but when the lead material is highly reflective, as would be the case with a gold-plated finish, as found in some flex-circuits, heating is slow and irradiation times impractically long. An alternative, "through-pad bonding," has been demonstrated whereby the beam is directed at an extended fluxed, tin-plated or solder-coated circuit board bonding pad (Fig. 49.38*b*). In through-pad bonding, the beam is directed at the more absorptive solder or on the circuit board land, increasing process efficiency and locally melting the solder in the vicinity of beam impingement. Since the molten solder is in intimate contact with the lead and pad, the heat from the bonding process is efficiently transferred. The process can result in rapid soldering along the entire length of the component lead and circuit board pad with rich solder fillets evident if the process is conducted properly. Compare this to the usual beam impingement on the component lead, or "through-lead bonding" (Fig. 49.38*a*).

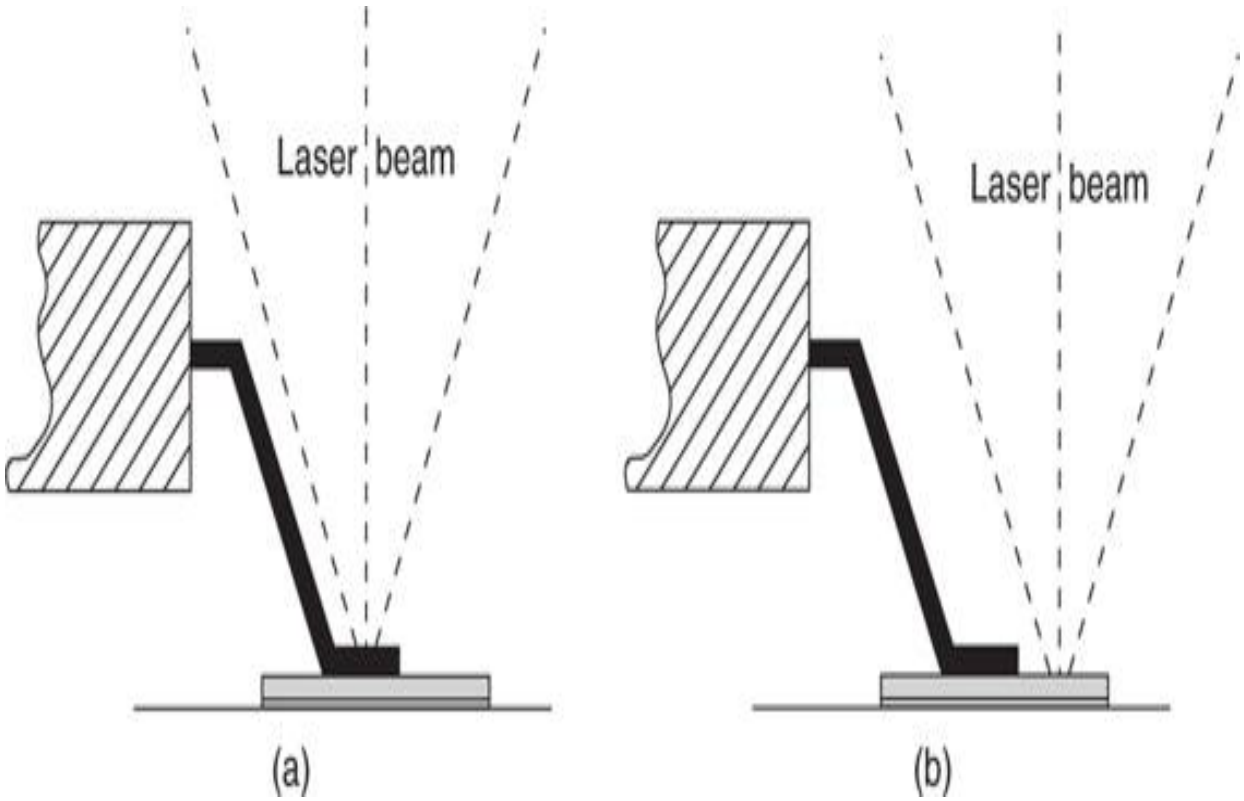

FIGURE 49.38 Through-lead versus through-pad laser soldering: (*a*) For through-lead laser soldering, the laser's beam is directed at the foot of the component. (*b*) For through-pad laser soldering, the beam is directed at a pad extension; this heats the solder directly.

49.7.3.2 Single-Point Laser Soldering. This method requires a laser beam that is smaller in diameter than the length or width of the component lead or bonding pad. The beam is stepped to each lead-pad combination and delivered with sufficient energy to result in solder reflow. The beam can be continuous-wave, pulsed, or multiply-pulsed to accomplish soldering as long as there is enough radiation delivered to cause the solder to undergo the phase change required for soldering and wetting. Due to the small beam diameter, as required by this technique for fine-pitch components, the energy density can be exceptionally high. In fact, it can be so high that if the lead is not in good contact with the bonding pad, then the laser's beam can melt or vaporize it. Overly intense irradiation can also cause a bonding pad to delaminate from the PCB.

In any laser soldering technique where very small spot size is required, the beam diameter must be precisely controlled. A small variation in beam diameter, either through change in laser parameters or in working distance (focus), can dramatically affect the delivered energy density. In the cases of a 10 W Nd:YAG laser beam focused to a spot of 0.1 mm (0.004 in) and a spot of 0.2 mm (0.008 in), this seemingly small change in spot-size will result in a large difference in power density [refer to Eq. (49.2)].

Equation (49.2), change in spot size and resultant difference in power density:

$$P = p/d \tag{49.2}$$

where P = power density
p = average power
d = focused beam diameter

For this example, the power density would vary from 1273 W/mm^2 for the 0.1 mm diameter beam to 318 W/mm^2 for the 0.2 mm beam diameter. This represents a fourfold reduction, emphasizing the criticality of strict maintenance and process control when working with a small spot size.

In most cases, a Gaussian distribution of the beam's energy distribution across the focused diameter is assumed. It is customary to measure the beam at the $1/e^2$ point (13.5 percent of the peak height), so, in fact, the beam is impinging on a slightly larger area. However, the most intense portion of the laser's beam is confined to the region bounded by the $1/e^2$ points in two dimensions, as shown in Fig. 49.39.

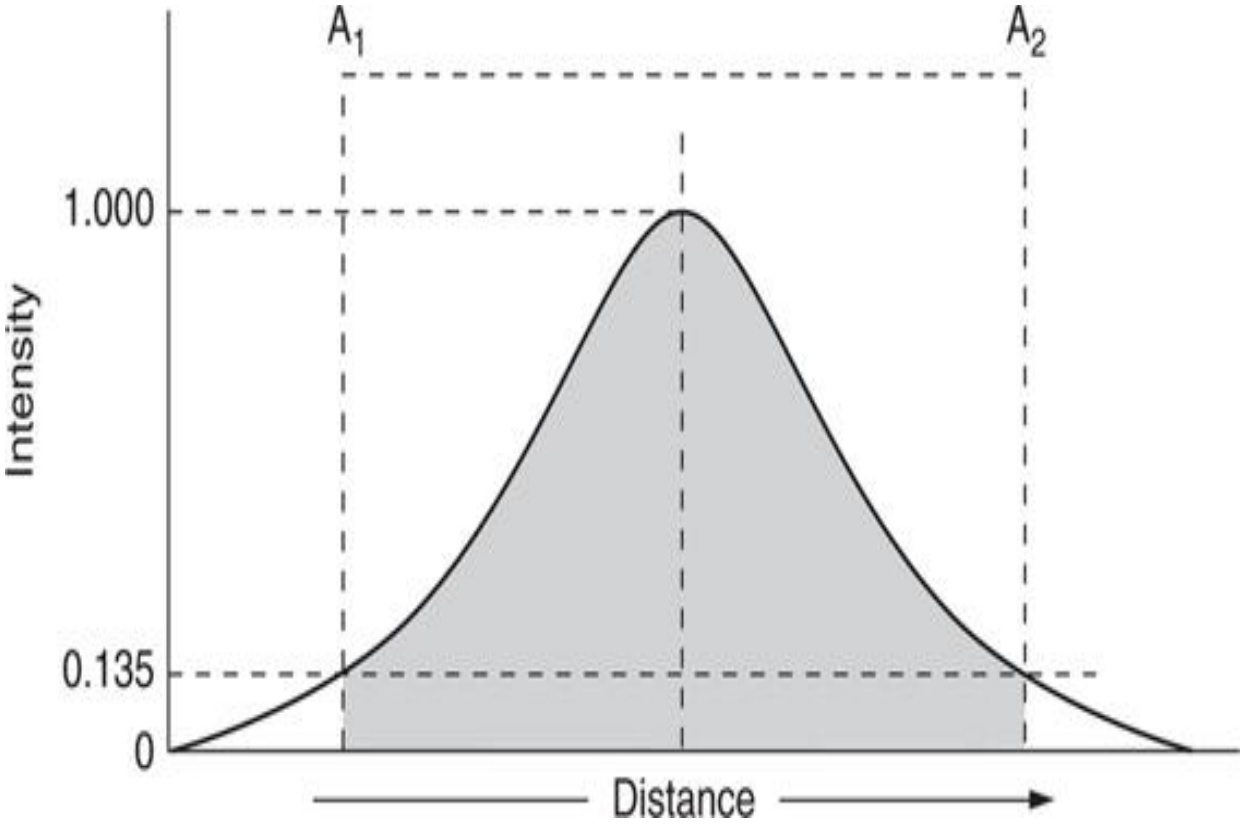

FIGURE 49.39 Gaussian energy distribution. Laser energy density is measured from points on the distribution curve where the beam's intensity is $1/e^2$ (13.5 percent) of peak intensity or between points A1 and A2 in this plot.

Single-point laser bonding has been used for soldering tape-automated- bonded (TAB) lead-frames to silicon die, TAB leads to PCB, or multi-chip modules[25] as well as for soldering gull-wing leaded components to circuit boards. This technique is not suited for bonding area-array devices such as BGAs or CBGAs to PCBs since there is no access to inner balls or columns.

49.7.3.3 CW Scanning. In sharp contrast to single-point laser soldering, this technique relies on a larger, defocused moving beam to accomplish the heating. The beam may be many times the size of the narrowest lead or pad dimensions. In this technique, the laser beam generally spills over onto the substrate material, irradiating the lead, pad, or lead-pad combinations as well as inter-pad PCB surfaces.

Because of the larger beam diameter, a long focal-length lens can be employed. This results in a wide process window in terms of final beam diameter and working distance of lens to the circuit board surface. The laser spot is moved at a rate such that the beam exposure to the board is below the laser damage threshold limit. It heats the lead-pad combination, the solder flux, and the board sufficiently to cause the solder to change state.

A variation of this technique utilizes orthogonally mounted galvanometers to move an Nd:YAG laser beam around the periphery of a surface-mount device sitting atop solder lands on a circuit board. The beam is repetitively scanned at high velocity around the surface-mount device until all leads are heated to the point of solder liquidus. As the beam is turned off, the solder solidifies and solder joints result. This same galvanometer-driven technique has gained commercial acceptance as a BGA rework tool. A slightly defocused laser beam is aimed at the body of the BGA. The beam is rapidly moved around the package body at an irradiance below the laser damage threshold of the packaging material. With each pass, the component heats up a little more, eventually melting the BGA solder joints. The package is removed with an automated vacuum pickup tool while the solder is still molten. A new BGA can be attached using this same technique. This method can be applied to any type of rework, although component leads and pads would be targeted rather than the body, as was the case for the BGA.

49.7.3.4 Multiple-Beam Laser Soldering. One of the attractions of working with a laser is the fact that its beam can be split for multiple use within one station or even shared between two or more stations. The split can be accomplished by the use of bifurcated fibers or beam splitting mirrors. The beam of a single laser cavity can be duplexed to solder two sides of a surface-mount component simultaneously. It is entirely possible to share a common

beam between two or more laser soldering stations either simultaneously or in a time-shared manner.

49.7.3.5 Tooling and the Need for Coplanarity and Intimate Contact. In all modes of laser bonding, the component leads must be in contact with solder lands on the PCB to accomplish joint formation. It is therefore necessary, in most cases, to use a specialized hold-down tool to ensure that leads contact pads. This detracts from the ideal of “noncontact” laser bonding. Several techniques have been developed and reported. One such method uses a transparent hold-down medium such as glass, quartz, or transparent high-temperature plastics. There are several problems with this approach, which can result in an inconsistent soldering process. First, these materials are rigid, making it impossible to hold a lead down to a low-lying pad abutted by normal height pads or, conversely, a high pad abutting lower pads (Fig. 49.40).

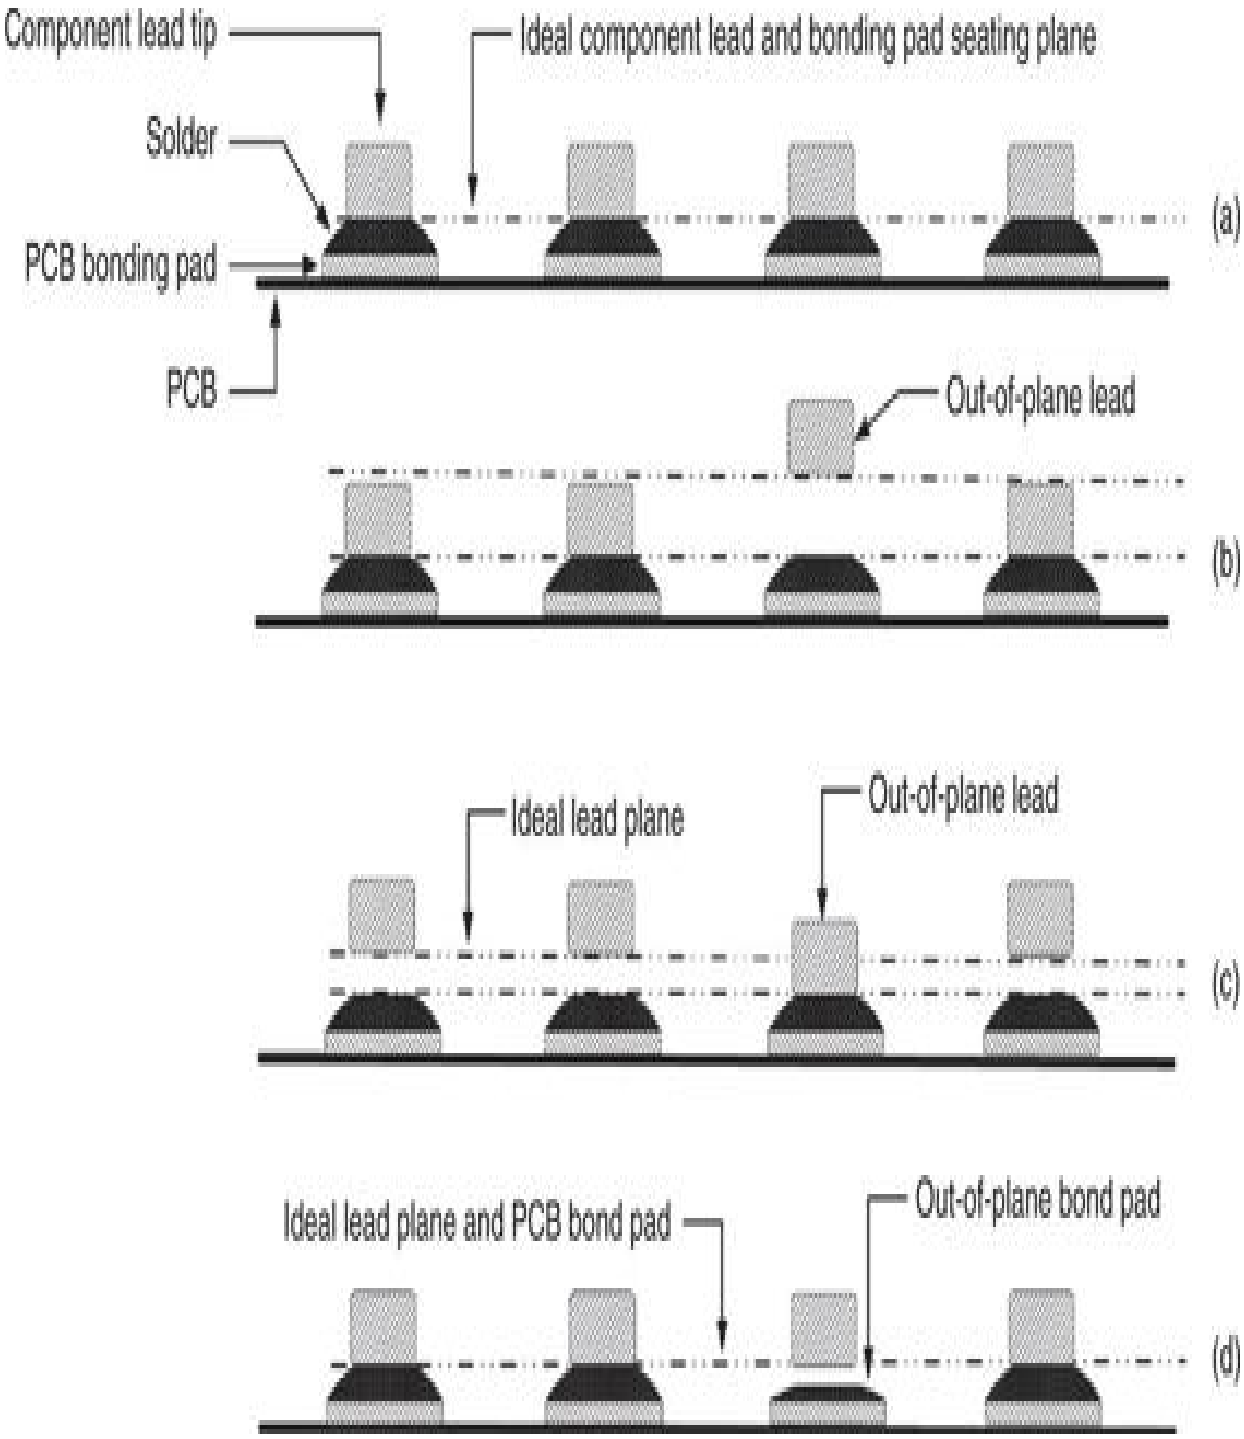

FIGURE 49.40 For laser soldering to be effective, it is necessary to have component leads in contact with PCB bonding pads as in “a.” If either component leads or PCB bonding pads are out of plane, then soldering will not occur (b, c, d). For this reason either a perfect part must be used or a fixture must be employed to hold leads in contact with bonding pads.

During the soldering cycle, the glass or other window material can accumulate spattered flux and flux by-products that may change the delivered laser beam intensity, adding variability to the process.

Comb or pin arrays have been applied that match the lead configuration of a package. This type of fixture is expensive and easily damaged; especially if the soldering flux “glues” the comb teeth to the bonded component lead.

The most common method for laser soldering of rigid-leaded surface-mount packages is the “body-push” method, in which a force is applied to the component body, springing the leads just slightly against PCB bonding pads. As the solder melts below the lead, the lead drops down to board level, where it is frozen in the cooling solder. It is necessary to control the amount of push such that too much stress is not frozen into the resultant solder joint. This is particularly important when laser bonding rigid leads of coarse-pitched component, where much force may be required to overcome lead coplanarity problems on stiff leads. When board pads and component leads are reasonably coplanar, then the “body push” method is adequate for high-yield, high-reliability soldering as long as any component lead non-coplanarity is not in a positive direction, as indicated in Fig. 49.40*b* as there is no mechanism to force the out-of-plane lead against its matching bonding pad.

A compliant hold-down method has been developed[26] (Fig. 49.41), which is inexpensive to fabricate and easy to implement. It is an aluminum fixture body with compliant silicone rubber feet that align with component leads. When pressure is applied to the fixture, component leads are forced against PCB pads. A slot in the aluminum fixture allows the beam unobstructed access to the lead-pad combination. It accommodates non-coplanar PCB pads and non-coplanar component leads. It has proven effective for TAB as well as for rigid-leaded surface-mount device laser soldering. This method obviates the problems associated

with transparent hold-down methods in terms of flux build-up on the window and does not have the fragility of comb hold-down methods.

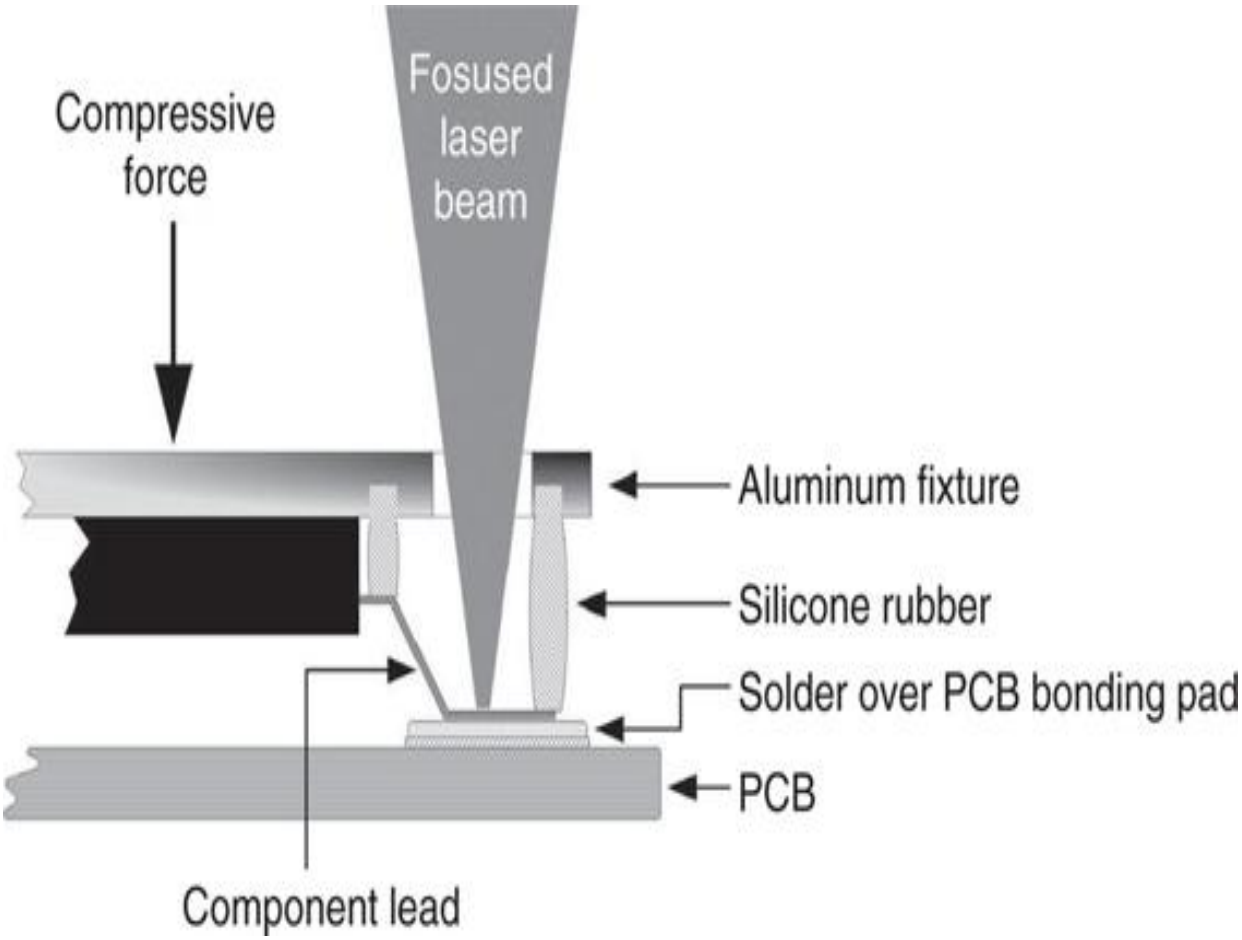

FIGURE 49.41 Window-less laser fixture with polymeric hold-down. The beam is focused through a slot in the aluminum fixture

49.7.3.6 Solder for Laser Soldering. Choice of solder alloy will have little to no influence on laser soldering. It should be noted that high-temperature solders are compatible with this bonding technique. There are systems where a single joint is soldered using an automated solder-wire dispense system. In that case the flux-cored solder wire is automatically pushed into contact with the component lead/PCB pad combination and then the laser is activated to

effect the soldering. The flux-cored solder wire provides the flux and the solder for the bonded connection.

It is also possible to preplate solder or otherwise predeposit solder onto circuit board pads. With this type of assembly, bonding pads are coated with a fluxing agent compatible with laser soldering. This will be discussed in a subsequent section. When the lead/pad combination is laser-heated to liquidus and cooled, the solder joint will be formed. The use of solder-foil pre-forms can also be used. Applying flux to the PCB prior to pre-form placement will keep the foil in place until the device to be soldered is placed on it.

Since laser soldering relies on a very high temperature for a very short duration, solder paste is not recommended for this process. A large fraction of solder paste is composed of liquids or gels that enhance its printability. When exposed to the rapid thermal rise and high process temperature of laser soldering, the solder paste is prone to spattering and solder ball formation. For that reason the use of predeposited solder and liquid solder flux is preferred.

49.7.3.7 Flux for Laser Soldering. Requirements are much the same as for other reflow methods. Flux must be active enough to remove oxides from the component lead, bonding pad, and the solder. But in the case of laser solder, the flux’s optical characteristics in terms of reflection, absorption, and transmission must not interfere with the laser beam or solder process. If too absorptive, the flux could char, overheat and damage the underlying circuit board. Also, if denatured by the intense laser beam, it may lose its chemical effectiveness as a fluxing agent. In laser soldering, particularly in the scanned methods, the flux adds a path of heat transfer to the board and preheats the next joint to be soldered. In the absence of a liquid flux, the PCB is more likely to be damaged if the laser impingement is not stringently controlled. During soldering, the laser beam’s output is quick and intense. The high energy of the process

results in exceptionally high process temperatures for very short durations. The high thermal excursion may aid in flux activation, making even the mildest of no-clean flux an aggressive oxide stripping agent.

49.7.3.8 Fluxless Laser Soldering. There have been many reports of fluxless laser soldering as used for inner-lead bonding to silicon die. Such bonding is done with a high-peak-energy, short-duration laser pulse. Under these conditions, when the mass of the lead and the bonding pad is small enough, the process is more akin to welding with the component lead melting and alloying with an underlying metal pad. To accomplish conventional reflow soldering by means of a laser, or any other technique, it is necessary to employ a solder flux to bond effectively. Plasma cleaning and inert storage may be one such method, but even the briefest exposure to air will start the re-oxidation process. Ultrasonic assisted laser soldering is another technology that can be effective, but is slow, requiring precise placement of an ultrasonically agitated head with the laser beam concentric to the ultrasonic tool or precisely adjacent to it. The ultrasonic agitation breaks up the oxides on component leads, bonding pads and the molten solder making conditions right for solder wetting.

The use of gaseous-phase carboxylic acid fluxing with laser bonding has been demonstrated.[27] This method precludes the need for conventional liquid fluxes and leaves no visible residues on the circuit board. No cleaning is required and the assembly reliability is not degraded from the use of a gaseous fluxing agent. Because liquid flux is not present, it is recommended that the laser’s beam impinge only on the lead-pad combination. Were the beam to hit the PCB, it would surely exceed the damage threshold limit and the board would char. Any charred material may be mildly conductive and an electrical short may result or become problematic in the long term.

49.7.3.9 Laser Solder Joint Characteristics. There are very few differences between solder joints prepared by laser as compared to those formed by other methods. Laser soldering results in intermetallic formation, but the layer is extremely thin if the laser soldering cycle heating is kept short; much thinner than found in solder joints manufactured by more conventional methods. Since the heating is highly localized, cooling is rapid resulting in exceptionally fine solder grain growth. The fine grain growth leads to greater joint strength initially. The strength advantage, although significant in initial magnitude, tapers off as the solder joint ages due to grain-coarsening of the solder and intermetallic layer thickening. Coarsening rate and intermetallic growth both depend on ambient temperature, device operating temperature and time.

49.7.3.10 Solder Sources and Defects Associated with Laser Reflow. Solder requirements are the same as for any other process. There are no alloy composition requirements specific to laser soldering, as this soldering method is compatible with leaded or lead-free solder alloys. Even high-temperature alloys can be soldered effectively. When single-point laser reflow is applied, the board quality and integrity are not compromised if parameters are appropriately chosen and adequately controlled.

Laser soldering is not prone to solder bridges and if component leads are held down to solder-coated PCB lands, then soldering defects are rare. Perhaps the most common characteristic defect unique to laser soldering is charring or burning of the circuit board, which occurs if too high an energy density is used and the laser damage threshold of the PCB is exceeded. Charring or burning of the PCB can also occur if the circuit board is grossly contaminated with grease or other organic contaminants. This is not to say that boards for laser soldering have extraordinary requirements for

cleanliness. Requirements should be considered the same for this technique as for any other reflow process.

A hidden defect associated with laser soldering is PCB bond pad delamination. If the PCB bond pad reaches too high a temperature during the laser soldering process, it may lose its adhesion to the laminate. This may result in reliability problems. It is best to check the process by doing lead pull testing to ensure that the laser process has not compromised bond pad adhesion strength.

49.7.3.11 Laser Safety Issues. Lasers are categorized by their safety hazard potential. For a full review consult ANSI Z136.1[28] in the United States and IEC 60825[29] internationally. Sufficed it to say, Class 1 is an intrinsically safe laser, posing no intraocular danger, while Class 4 lasers pose the greatest hazard. All lasers considered for soldering use are of the Class 4 variety. Because of this, they are generally embedded in appropriate interlocked cabinets with laser-safe viewing ports or a video camera incorporated for viewing the process to preclude direct ocular exposure to the laser's intense beam. When the Class 4 system is embedded in an appropriately interlocked cabinet, it is considered a Class 1 system and poses no hazard. Laser-safe eyewear need not be worn during normal operation except when interlocks are overridden for system maintenance. As mentioned previously, lasers, especially Nd:YAG, are known for their high uptime and lack of required expendables.

49.8 HOT-BAR SOLDERING

Specifically suited to surface-mount assembly of packages with lead-frames, hot-bar soldering has been in use for several years. The technique relies on a resistance-heated element to push component leads into contact with solder

and bonding pads, simultaneously reflowing the solder. Compression of the lead/pad combinations is continued as the heat is ramped down. Upon cooling, the solder solidifies and the heating element is withdrawn from the newly formed solder joints. The heated element, commonly referred to as the hot-bar, is also known as a “thermode.”

Hot-bar soldering is best suited for low-thermal-mass, single-sided surface-mount assemblies. Each component type requires its own hot-bar bonding head assembly. These can be expensive, with the price dependent on the complexity, materials of construction, precision required, and overall size of the bonding head.

49.8.1 Solder Application

The use of solder paste is discouraged because hot-bar heat-up is fast and bar temperature is typically well above solder melting temperature; conditions favorable for rapid volatilization of solder paste constituents and explosive solder ball formation. Also, the paste is likely to squeeze out from between the component lead and circuit board pad, which can cause the solder to bridge to adjacent conductors during fine-pitch component soldering. In fact, even with solid solder coatings on the circuit board, bridging can be problematic in hot-bar bonding for the same reason. This is usually a function of the volume of solder on the pad, the quantity of flux, its degree of activity, and lead/pad pitch. As the solder is melted and displaced by the hot-bar, it bulges laterally to the point that the solder masses of two or more adjacent pads may touch one another, forming a solder bridge. Once the bridge has formed, the forces associated with lead-to-pad wetting and capillarity will not be strong enough to overcome the surface tension conditions established during the solder bridge formation. If that is the

case, the bridging defect(s) will persist (Fig. 49.42). Bridges are easy to form and difficult to break.

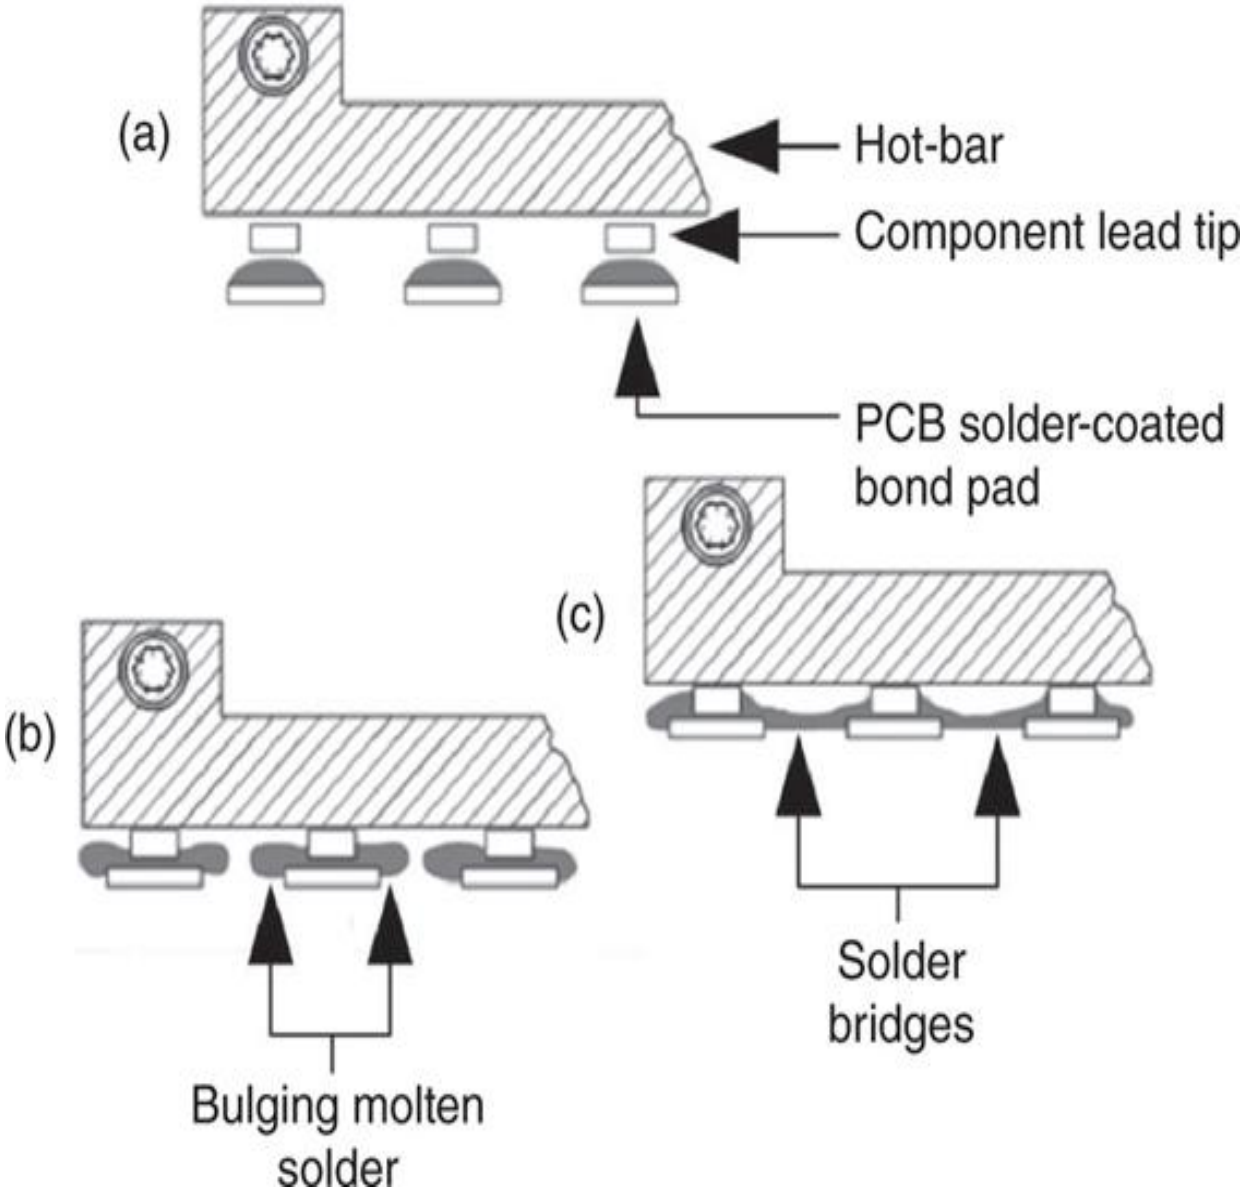

FIGURE 49.42 Hot-bar induced solder bridge formation. (*a*) Hot-bar aligned over lead tips and PCB bonding pads. (*b*) As the hot-bar is forced into contact with component leads and circuit board pads the molten solder may be forced out from under the compressed leads bulge laterally. (*c*) If adjoining molten solder bulges contact one another, solder bridges will form and persist upon solidification. Careful control of solder volume, controlled hot-bar pressure and temperature profile during hot-bar soldering is required to preclude this defect.

Solid solder coatings such as hot air-leveled pads, solder-plated boards, or stenciled and reflowed solder paste are preferred for this bonding method.

49.8.2 Fluxes and Fluxing for Hot-Bar Soldering

Soldering flux is applied prior to component placement and soldering. Tacky fluxes may be useful to hold components in place prior to hot-bar soldering. Flux choice should be tailored to the hot-bar process. The flux can be either liquid or paste. The flux chosen should be tested to resist charring and the development of polymerized decomposition products, or lacquers that may adhere to either the circuit board or the hot-bar or both. Residue build-up on the bar can adversely inhibit hot-bar performance by diminishing thermal transfer. The residue can also become thick and uneven enough to prevent the hot-bar from squarely contacting component leads. Baked-on aqueous-clean flux residues can make flux cleaning difficult. With no-clean flux, overheated residues may detract from the visual appearance of the printed circuit assembly.

49.8.3 The Hot-Bar Soldering Operation

Generally, the board is preheated on a hot stage beneath the hot-bar, off to the side or even in a box oven prior to soldering. Sometimes hot air is used for preheating. This step is generally done after flux application, so the thermal profile has to be adjusted to prevent complete flux dry-out. Once component leads are aligned with solder-coated PCB pads, the hot-bar is pressed against the lead-pad combinations and heated to reflow. Precise control of the

heating process is required to prevent flux spattering or solder bridging as discussed. A mechanical stop is employed to keep the bonding head from exerting too much force on the lead/pad combination. Excessive force can cause the component leads to slide off pre-reflowed (domed) solder-coated pads. It can also enhance solder bridge formation. Excessive force will displace solder from between leads and pads and resultant joints may be solder-starved.

One approach to preventing bridged or solder-starved joints is to retract the hot-bar by several hundredths of a millimeter once the solder liquidus begins to wet to component leads and PCB pads. Surface tension coupling of wetted solder between lead and pad reduces the propensity for solder bridge formation. Additionally it relieves compressive forces that would be incorporated into the final solder joint. Upon cooling, robust solder joints result. As in any other soldering process, it is important to maintain proper reflow time-temperature characteristics. In hot-bar soldering, it is of paramount importance that the blade seating plane is maintained normal to the surface plane of the PCB. On the other hand, it should be noted that the coplanarity of solder on the PCB pads does not have to be exact. The hot-bar will first reflow high solder spots. Once all the solder has melted, it will self-planarize and remain that way upon solidification.

49.8.4 Hot-Bar Construction and Effects

The hot-bar bonding head can be composed of one or several blades. They are designed to solder one side, two sides, or all four sides of a lead-frame simultaneously. Generally the hot-bar assembly is configured to accommodate the maximum span of a lead set, permitting simultaneous bonding of all leads on a package side. In the

case of some very long connectors or other large packages, the thermal uniformity of a single blade may not be adequate for the process. This is sometimes remedied by using a smaller hot-bar and stepping it along the length of the lead set until all leads are bonded. This may induce lead misalignment as the stepping progresses. Another approach uses multiple hot-bars side by side, each individually controlled, to achieve the span and required thermal uniformity. Bar configuration is designed for the lead-form to be bonded. It should sit flatly on the foot of the lead, neither contacting the radiused area of the lead-form nor significantly overhanging the lead toe, as shown in Fig. 49.43.

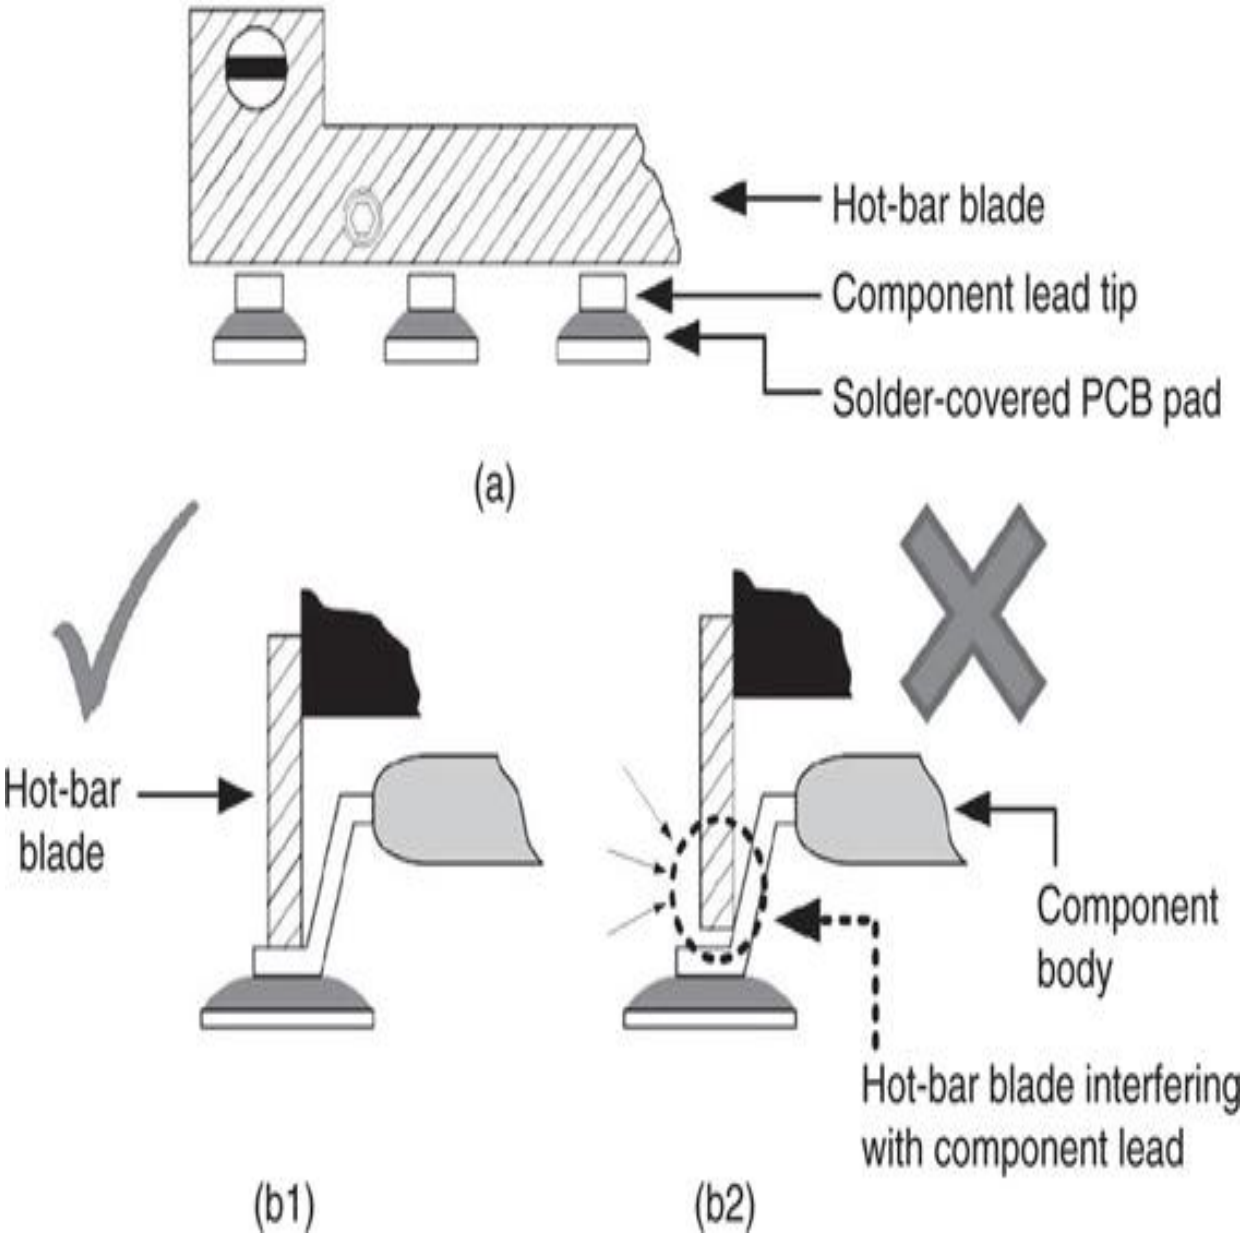

FIGURE 49.43 A hot-bar ready for bonding gull-wing component. (*a*) Transverse view; (*b1*) lateral view with the hot-bar appropriately contacting component lead toe, (*b2*) hot-bar incorrectly positioned interfering with the leg of the formed component lead (see arrow).

The bar itself can be manufactured to nearly any dimension, but there are limitations on its size; the longer the blade, the worse its longitudinal thermal uniformity. Variations in blade temperature may cause it to distort due to differential thermal expansion and contraction. Thermal

uniformity is critical for consistent lead-to-lead soldering and joint quality per component side. The allowable variation in bar temperature is limited by the component specification, the damage threshold of the board to be soldered, the solder, and product reliability requirements. As in any other soldering process, the variation in process temperature must be understood and controlled to ensure highest board assembly yields and best-quality solder joints. Most hot-bar systems are configured with a fine-gauge thermocouples welded to the bar, an integral part of a closed-loop, temperature-controlled hot-bar heater system. There may be more than one thermocouple per bar, especially on long bars.

Numerous bar designs and materials of construction are available; tungsten, titanium, and molybdenum are commonly chosen for their electrical resistance, durability, thermal conductivity, immunity to flux damage, and solder nonwetting characteristics. Some ceramics are also used for blade construction. The bar must be designed for uniform heating across its length and it must be able to shed heat rapidly to allow the solder to resolidify within a reasonable time. The blade has to expand and contract uniformly throughout the soldering cycle. Some blades have been seen to develop a “frowning” or “smiling” profile in their *z*-axis during heating due to differential thermal expansion or built-in stress in the metal, as shown in Fig. 49.44. For the same reasons, transverse warpage of the blade is also commonplace.

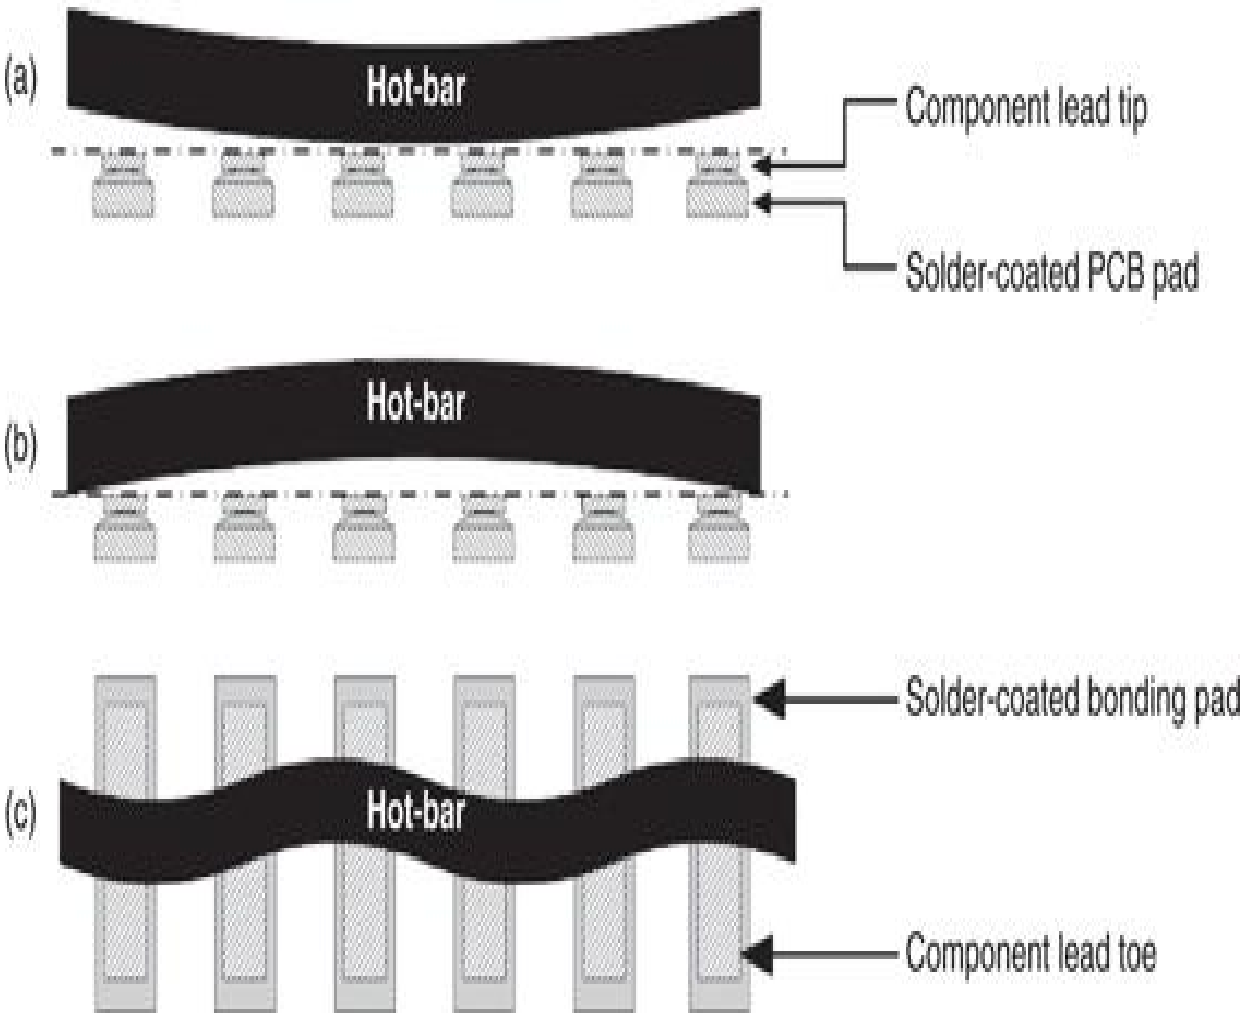

FIGURE 49.44 If not constructed properly, the hot-bar may distort: (*a*) "smiling" profile, transverse view; (*b*) "frowning" profile, transverse view; and (c) longitudinal warpage, plan view. The dashed line in (*a*) and (*b*) shows the desired hot-bar seating plane. All views have been exaggerated for illustrative purposes.

Such conditions detract from proper blade contact with lead and pad combinations and are indicative of poor hot-bar design or poor choice of materials. Blade warpage, if the curvature is sufficiently large, may result in solder opens. There have been many solutions proposed in the realm of structure, materials of construction, and electrical input to permit highest uniformity of blade heating and contact to the bonding pads. D. Waller et al. have patented a rigid molybdenum truss blade that has been found to be stable

dimensionally and thermally uniform over long spans (in excess of 76 mm).[30]

Usually the hot-bar blade is attached to a self-leveling, spring-loaded bonding head that allows each blade to self-planarize in relation to the underlying component leads and circuit board surface. Nonetheless, variations in board contour, such as a localized high or low spot, can render the concept of self-planarization useless and solder opens may still result. Rigid-member hot-bars are excellent for accommodating differences in lead coplanarity because the blade forces lead to pad. Driving a heavily sprung lead onto its corresponding bonding pad can, however, lock stress into the resultant solder joint because the solder is working to resist the spring force of the lead. This condition may result in premature joint failure.

49.8.5 Maintenance and Diagnostic Methods

As with any process equipment, it is important to maintain the hot-bar properly. Check it frequently for distortion. Ensure that it remains flat and perpendicular to the circuit board to be bonded. Scrub the hot-bar on a ceramic flat to remove any baked-on flux residue. This may need to be done every few bonding cycles, depending on the flux and the criticality of the assembly.

Several diagnostic tools can be applied to assess hot-bar conditions. The two most important characteristics that must be understood and monitored are thermal performance and blade planarity.

49.8.5.1 Thermal Monitoring. One of the most common methods of assessing hot-bar performance is to use a thermocouple-instrumented board, as is the case with any other soldering method. Preparing such a board for hot-bar

use has its own requirements. Fine-gauge thermocouples are attached to leads of the component or the bonding pad of the circuit board to be soldered. Positioning thermocouples at both ends of the lead set and also near its center helps quantify the longitudinal thermal uniformity of the hot-bar during soldering. It is also useful to deploy thermocouples on surrounding components to ensure that the hot-bar soldering process does not overheat closely adjacent, previously soldered joints.

When preparing the thermal profile board for hot-bar soldering, avoid placing the thermocouple bead(s) between component lead and bonding pad. The added height of the bead would prevent the bar from contacting adjacent component leads and results in point-contact heating that is not indicative of the bar's normal operation. Instead, place the thermocouple bead at the pad extension area in front of the lead tip or at the lead heel as indicated in Fig. 49.45.

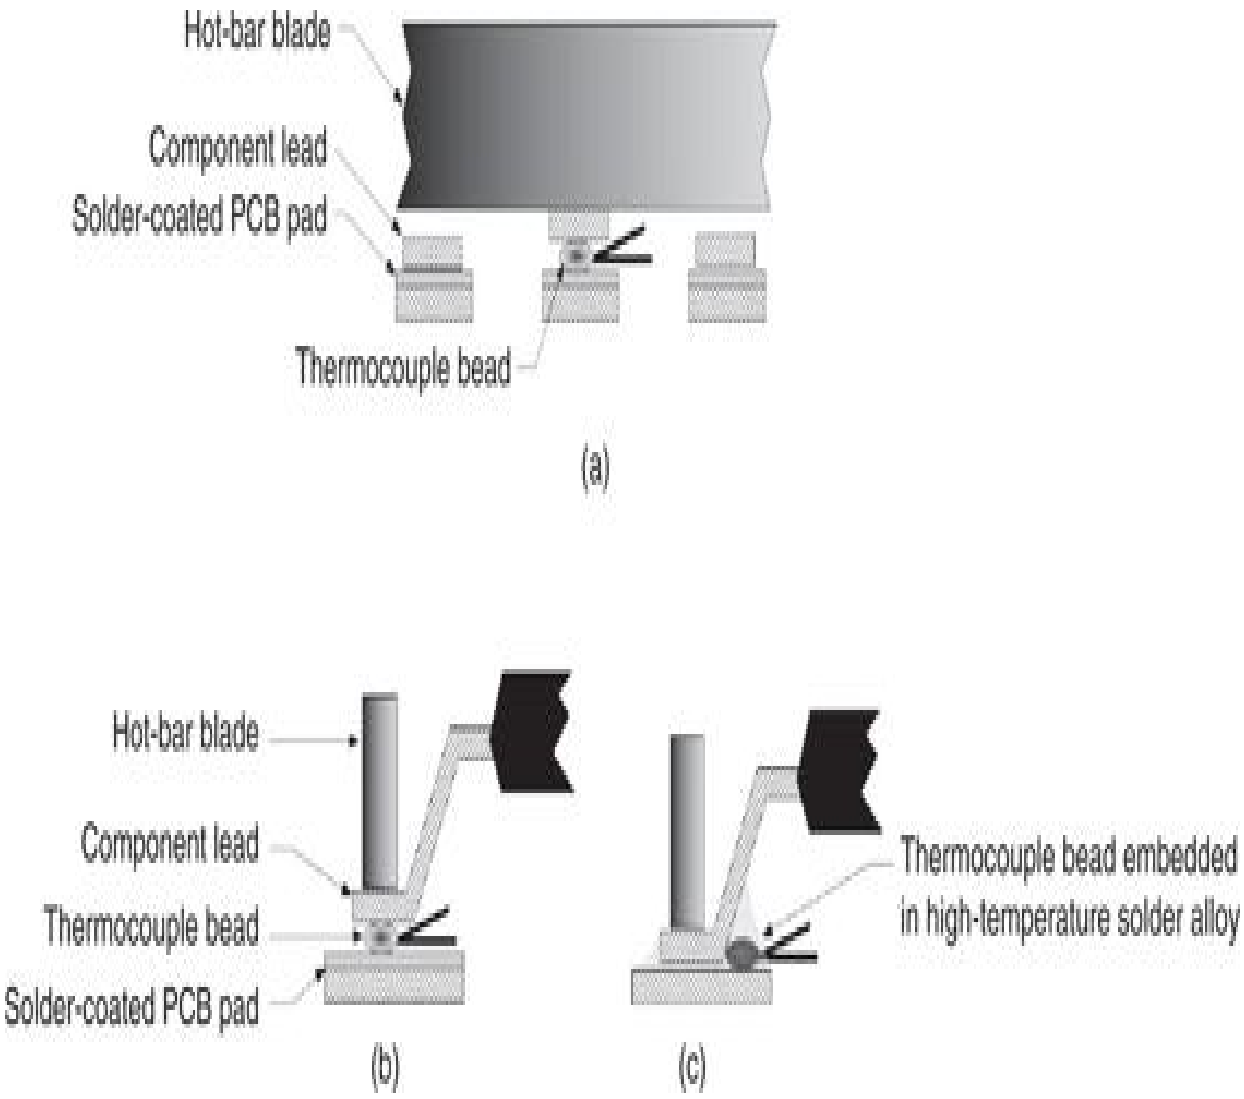

FIGURE 49.45 Hot-bar thermometry. A thermal profile board is needed for hot-bar soldering. (*a, b*) The thermocouple bead must not interfere with seating of lead to bonding pad or with the hot-bar blade to the lead/pad combination. (*c*) The thermocouple can be attached with a high-temperature solder alloy in front of or behind the component lead so that a common lead, pad, and bar seating plane is maintained.

If the high temperature solder alloy mixes with lower temperature solder alloy, its melting point or melting range will be depressed and the thermocouple may come loose and perturb the measurement.

49.8.5.2 Blade Planarity. As stressed throughout this section, the coplanarity of the hot-bar blade or multiblade

hot-bar assembly with respect to the bonding surface is of extreme importance to preclude solder opens during hot-bar soldering. There are numerous measurement methods that can help diagnose this; unfortunately, though, they are meant for evaluation of the blade(s) at room temperature, not at bonding temperature. As previously mentioned, a blade may distort temporarily or permanently during heating, but planarity measurements on hot blades are impractical. Therefore, the majority of techniques encountered are performed at room temperature.

Wilkins[31] suggests the use of a colorant, such as from a marking pen, applied to the cold bonding surface of a freshly cleaned hot-bar. Once the ink is dry, the blades are then scrubbed over a clean, flat ceramic plate. Low spots on the bar are indicated by the presence of colorant remaining on the bar after several circular swipes on the ceramic flat. Single-bar and two- or four-sided blade assembly planarity can also be evaluated using an array of ground, leveled, rigidly mounted pressure transducers. Bar pressure differential, an indicator of blade planarity, can be adjusted so as to be uniform from end to end and from blade to blade on two-up or four-up hot-bar assemblies. The use of pressure transducers has poor spatial resolution. Of course, some hot-bar assemblies are self-leveling, but even these should be checked for planarity and force per blade to ensure best uniformity during soldering.

49.8.6 Hot-Bar Process-Induced Defects

49.8.6.1 Solder Bridging. This is the most prevalent problem associated with hot-bar soldering. Recall that molten solder may squeeze out of adjacent solder joints and bridge, especially on fine-pitched components.

Bridges may also arise if the device being soldered moves off bonding pads, dragging molten solder with it.

As pressure is applied to component leads by the hot-bar prior to the onset of solder liquidus, leads are sometimes forced to slide down any domed solder deposits prior to reflow. This displacement causes misregistration of component leads to bonding pads. If the forces are great enough, it may also cause the whole package to move causing misalignment of the entire lead set and bridging on a massive scale.

49.8.6.2 Solder Opens. Result from lack of coplanarity between the hot-bar and the plane of the circuit board surface of component lead.

49.8.6.3 Brittle Solder Joints. Because of the thermal mass of the hot-bar as compared to the PCB being soldered, the hot-bar temperature is necessarily well above the solder liquidus temperature. If the time-temperature cycle is not carefully controlled, an overly thick intermetallic compound layer may form. This is especially true in this process, where the solder may be largely displaced from between lead and pad, and bond lines are excessively thin. Within the joint, the volume of intermetallic compound (hard and brittle) may be large compared to the remaining solder (soft and compliant). If this is the case, solder joints will be less reliable and more susceptible to brittle fracture. All of these obstacles have prevented the widespread acceptance of hot-bar bonding in manufacturing except in some niche applications where soldering by other methods may be difficult. Hot-bar bonding is most useful for low-volume, fine-pitch surface-mount soldering and rework.

49.8.6.4 PCB Pad Delamination. High localized temperature of hot-bar soldering may threaten the integrity of the bond between the PCB pad and the board laminate.

Destructive testing, such as pull/peel analysis and/or mechanical cross-sectioning should be employed to verify that the process is not impugning the PCB.

49.9 HOT-GAS SOLDERING

As the name implies, hot-gas soldering method relies upon a heated gas stream to effect reflow. This noncontact, directed-energy method is most suited to bonding surface-mount components. Although hot-gas soldering has been around for years and after numerous machine offerings, it is not a popular method for soldering despite its evolutionary improvements. Instead, it has made its mark in the area of component rework; removal of previously soldered devices from a circuit board and replacement of same with a good one.

There are three main disadvantages of this technique: (1) its thermal energy is not well localized, (2) it is a slow process, and (3) generally requires preheating of the PCB to be soldered. Most machines typically emit a hot-gas jet too large to be isolated to reflow only the device of interest. The impinging gas jet is deflected and its backwash may cause unwanted reflow of previously formed joints on closely spaced, adjacent components. This can be overcome by the use of baffles that are either applied to adjacent components or by a singular baffle that confines the gas jet to the component to be soldered.

The PCB to be soldered usually sits atop a preheating nozzle or preheating platen. This is necessary to heat the PCB sufficiently so components can be soldered with a hot-gas stream of modest temperature. If the air stream is too hot, it would scorch the PCB or degrade the reliability of the components to be soldered.

The use of hand-held hot-air soldering “irons” is not recommended as there is no consistency in process. Use of such systems often results in scorched circuit boards, damaged devices or poor solder joint quality.

49.9.1 Hot-Gas Soldering Nozzles

Available in a variety of forms, the simplest nozzles is the single orifice, which can be translated around the entire periphery of a component (Fig. 49.46*a*). Some machines offer a double translatable nozzle assembly that can solder two opposing sides of a component simultaneously (Fig. 49.46*b*).

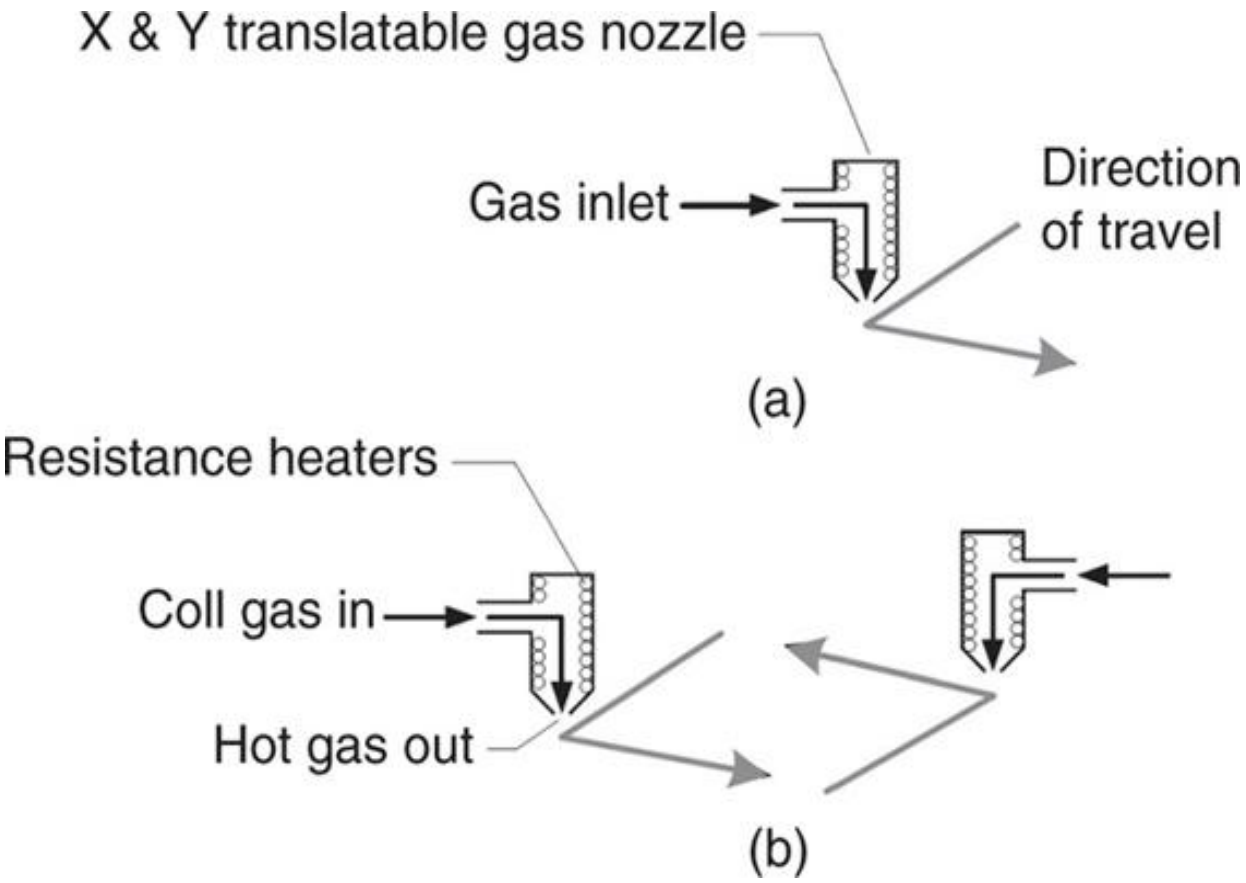

FIGURE 49.46 Hot-gas soldering nozzles. (*a*) Programmable moving nozzle translates hot gas in *x* and *y* axes; (b) double nozzles, each programmable, allow simultaneous soldering of all four sides of a component.

The shielded nozzle (Fig. 49.47) is commonplace, especially for rework. It directs the hot-gas to the components and vents it either laterally or out the top to minimize re-reflow of adjacent components. This will be discussed more fully in the section entitled Soldering Repair and Rework.

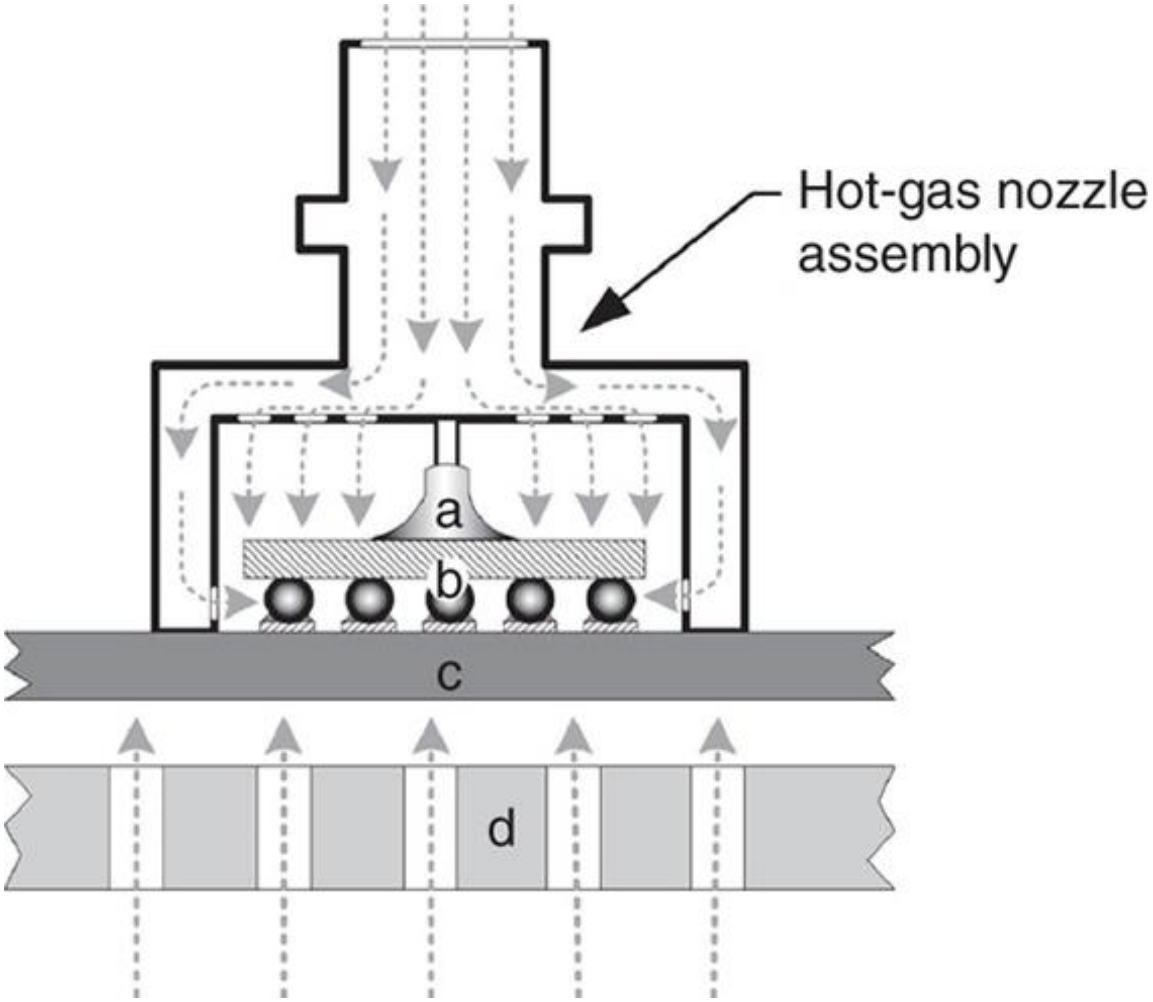

FIGURE 49.47 Cross-section of a hot-gas workstation composed of a shielded hot-gas nozzle and PCB preheater. (a) Integrated pick-up tool, (*b*) BGA, (*c*) PCB, (*d*) hot-gas preheat platen. Hot air flow indicated by dashed arrows

49.9.2 Solder for Hot-Gas Soldering

Solder can be applied to the board as a paste, solid pre-form foil, or solder-coated pad. In all cases, the component must be held down during the soldering process to ensure contact of component leads with bonding pads until the onset of liquidus. Proper gas pressure, temperature, nozzle translation speed (if in a moving system as illustrated in Fig. 49.48), and flux are required to effect solder joint formation. Otherwise, the same reflow considerations are required for this technique as for any other. Heating ramp rate, PCB and solder paste preheating, peak temperature, liquidus duration, etc., must be observed for successful joint formation and for reliable solder joints.

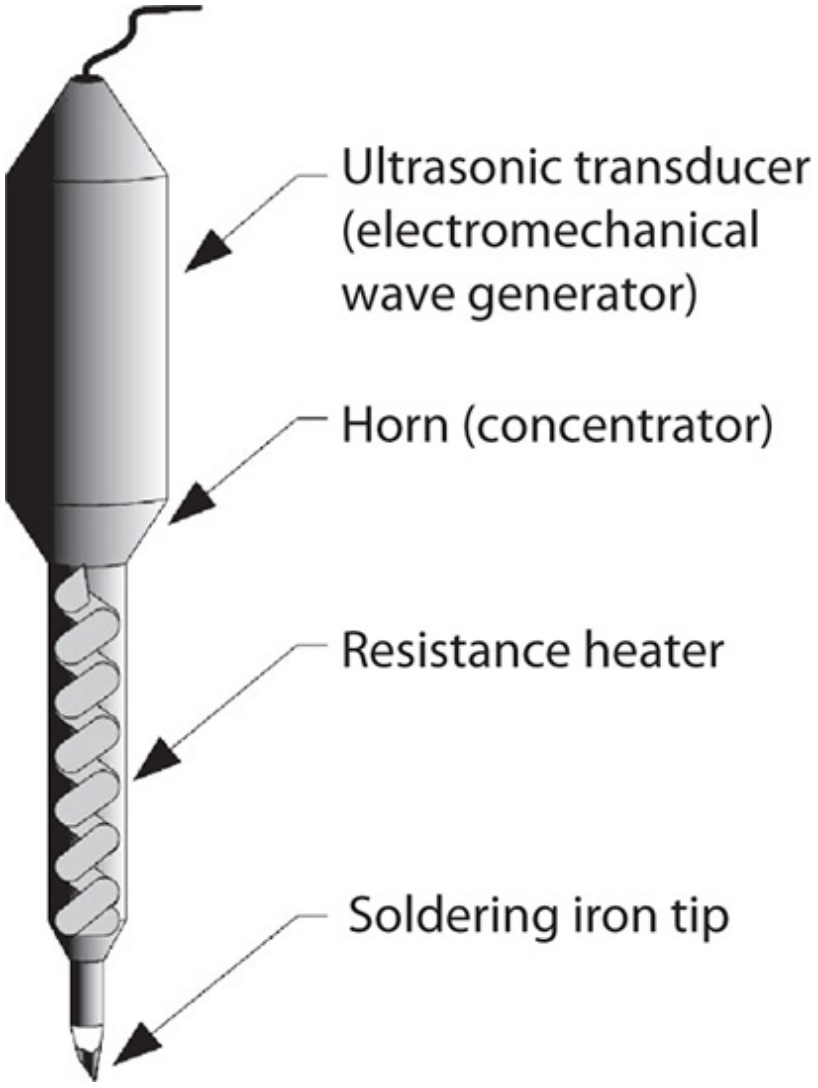

FIGURE 49.48 The ultrasonic soldering iron is composed of four main components: an ultrasonic transducer; a horn for concentrating and directing ultrasonic energy; a resistance heater; and the soldering tip, which emits both thermal and ultrasonic energy.

A thermocouple-instrumented profile board populated with components is needed to determine the proper soldering time-temperature recipe. Adding thermocouples to some solder joints on closely adjacent components is recommended to ensure that the soldering or component removal profile will not inadvertently re-reflow neighboring components.

49.9.3 Flux for Hot-Gas Soldering Nozzles

Solder fluxing agent for this technique is the same for any other soldering application. Solder paste, paste flux or liquid flux can all be used. Care must be taken to heed flux manufacturer's reflow profile recommendations.

If hot-air is being used for component removal/replacement, the flux should be the same used for the initial soldering so as to preclude flux interactions that may lead to corrosion and reliability degradation.

49.9.4 Gas for Hot-Gas Soldering

Two gases are commonly used in use in association with this soldering technique; air and nitrogen. By far, air is the more common of the two, but there are distinct advantages to the use of nitrogen (N_2).

N_2 provides an inert cover during the soldering process. In the absence of an oxidizing agent (air), fluxing agents are more effective and the molten solder is largely without oxide skins that restrict its ability to flow and wet. N_2-shielded

solder joint formation typically results in better wetting and more complete solder fillet formation. However, the cost of nitrogen has to be factored into the needs of the process. It can be used to effectively and more efficiently solder and normally results in better quality solder joints. This alone, may offset the cost of using N_2. It is also effective where soldering is most difficult as it promotes wetting, permits slightly lower process temperature, less flux application and sometimes results in a shorter process duration.

49.10 ULTRASONIC SOLDERING

This method relies on a heated, ultrasonically vibrated soldering tip that simultaneously melts and agitates the solder (Fig. 49.48). The ultrasonic energy is transferred from the soldering tip through the molten solder droplet beneath it and ultimately to the component lead and circuit board pad.

The high-energy agitation of the solder droplet helps to disrupt films of bond-inhibiting oxides and other contaminants from the solder, PCB pad and component lead at solder-metal interfaces. If soldering temperature is appropriate, any exposed solderable metal surfaces are rendered solder-wettable by this technique. Ultrasonic soldering precludes the need for chemical fluxing agents. Aluminum and other difficult-to-join metals can be joined by this method. The viability of this technique has been well proven on a commercial scale in the manufacture of air conditioner heat exchangers.[32,33]

Ultrasonic soldering has also been applied as a batch or continuous mass reflow process. In these instances, the molten solder is ultrasonically agitated while the assembly to be soldered is immersed in it. Similar arrangements have been made for ultrasonically vibrating the part while dipping

it in a molten bath or wave of solder. These mass processes are more common for nonelectronic assembly.

Care must be taken in ultrasonic soldering to tune the tip amplitude and/or frequency to the mass of the system being soldered. Excessive agitation may result in cavitation and splashing of the liquid solder resulting in solder voids and solder balls. The former may detract from joint reliability especially if voids are at a solder/metal interface. Solder balls may pose a risk for shorting fine-pitched leads or pads. Additionally, ultrasonic agitation increases the dissolution rate of any soluble metals into the solder for any given temperature as opposed to other soldering methods. If there is enough dissolution of soldered components, it may change solderability or solder alloy properties, such as melting point or melting range and perhaps negatively influence solder joint reliability.

This technique can be useful for the repair of opens or the installation of new or change-order components onto completed circuit assemblies because no flux is required. A previously cleaned board will stay clean through repair or upgrading operations. This technique is applicable to all peripherally leaded surface-mount components that are not susceptible to ultrasonic energy damage. It can also accommodate through-hole device soldering. Equipment availability is limited, with only a few manufacturers worldwide. Several past and recent publications provide a comprehensive review of this technology's applicability and attributes.[34–37] If this soldering method is employed, studies should be done to ensure that the application of ultrasonic energy combined with heat does not degrade PCB or electronic device performance or long-term reliability.

CHAPTER 50

SOLDERING REPAIR AND REWORK

Gary M. Freedman
Colab Engineering LLC, Stow, Massachusetts

50.1 INTRODUCTION

As printed circuit assemblies (PCAs) become more densely populated, the probability of rework increases. So does the complexity of rework steps. Rework deserves consideration both in terms of board design as well as in conducting the repair. Deep preheating cycles, careful thermal profiling, and thermal masking of adjacent components become critical. PCAs are often mix-mount [surface-mount technology (SMT) and plated through-hole (PTH)] assemblies. Additionally, they may contain press-fit components or other subassemblies that may be sensitive to overheating. Aside from hand repair with a soldering iron, there are two techniques that are mainstays of repair: solder fountain and hot-gas. The former is a variant of wave soldering and is tailored to removal or post-soldering addition of PTH (solder-tail) components. Hot-

gas (also known as hot-air) soldering is used primarily for removal and replacement of SMT components.

Because repair of dense assemblies is difficult, this chapter covers some of the finer points of rework. The onset of Pb-free soldering has increased the difficulty of repair processes due to generally higher melting temperatures and slower wetting times that are characteristic of the most prevalent Pb-free solder alloys. Otherwise, repair involving Pb-containing solders and Pb-free solders is the same.

50.2 HOT-GAS REPAIR

This technique consists of directing a heated stream of air or other process gas such as nitrogen (N_2) at the component to melt solder for removal or replacement of a component. Modern hot-gas repair stations are sophisticated, with computer controlled heaters, programmable thermal cycles, predictive reflow profiling, vision systems to assist in component alignment to bonding pads on the printed circuit board (PCB) and preheating stations or stages. Hot-gas repair is most often used for SMT components but can be adapted for certain PTH component removal.

50.2.1 Hot-Gas Repair Equipment

50.2.1.1 Hot-Gas Nozzle. The heated gas is generally delivered through a component-specific nozzle. The gas stream is directed at the top of the component, under the component (between the PCB and component bottom), or a combination of the two, depending on the nozzle design (Fig. 50.1).

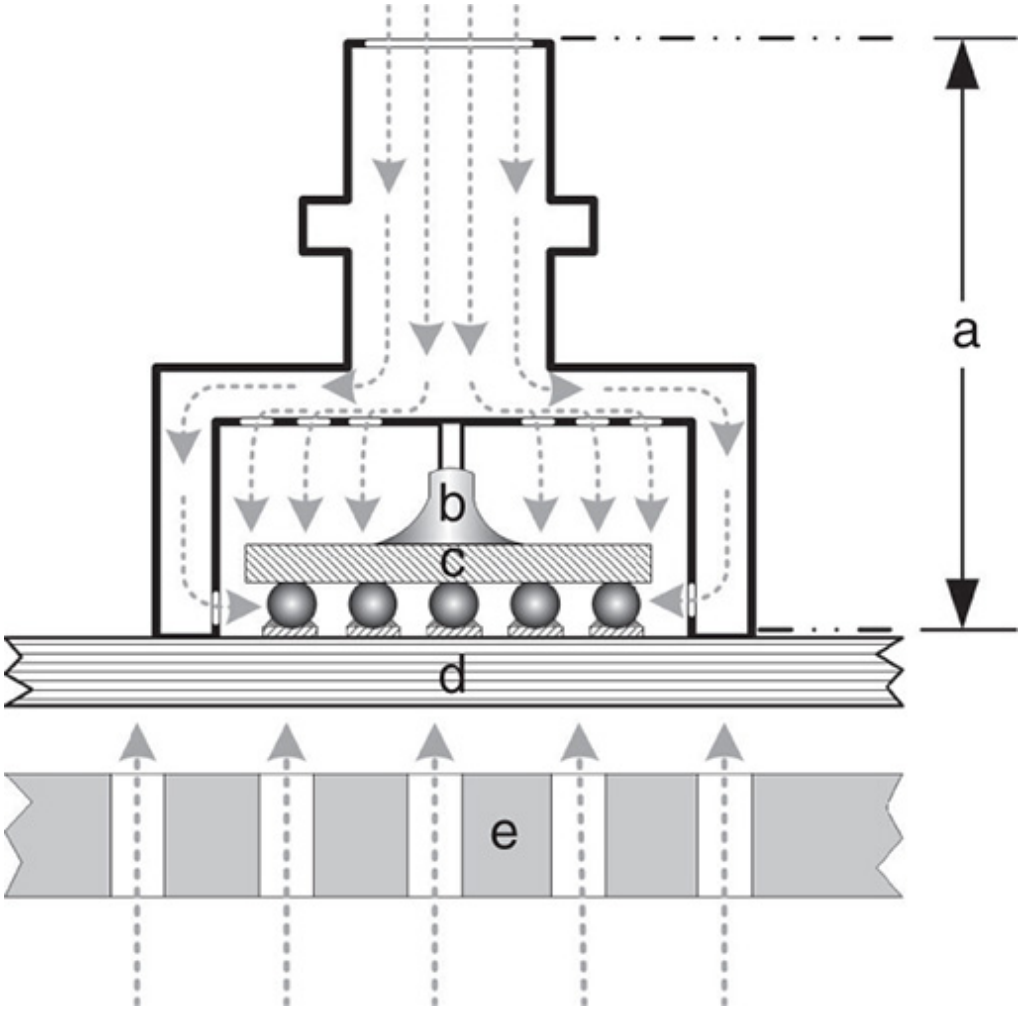

FIGURE 50.1 Schematic of hot-gas repair apparatus for removal and replacement of a surface-mount component. It is comprised of a baffled nozzle (*a*) which directs hot-gas at the component to be removed; in this case a BGA (*c*). Hot-air is also directed through a heated platen (*e*) on the underside of the PCB (*d*) directly beneath the component to be repaired in order to preheat the circuit board, lessening the thermal load and shortening the rework cycle. A heat-resistant suction cup (*b*) is used to remove the BGA once all solder joints have reached reflow temperature. It is also used to pick and place the new component to be soldered. Gas flows are shown as dashed arrows.

50.2.1.2 Preheater. Preheaters are used to help overcome the thermal inertia of the board. Since the nozzle exposes only a small amount of the board to a high-temperature gas stream, heating through this mechanism is limited due to the heat-sinking effect and large thermal mass of the PCA. The preheater uses hot gas or infrared lamps to heat a large area of the board. The preheating is set to a

temperature much lower than the reflow temperature of the solder, but high enough that reflow can take place on the targeted component in a reasonable period of time. Preheating helps to avoid overheating the component to be replaced or other components adjacent to the repair site. Most hot-gas repair machines have a built-in bottom-side preheater.

50.2.1.3 Vacuum Pickup Device. This is generally a silicone rubber suction cup or a metal tube nested within the nozzle and connected to a vacuum pump. Silicone is chosen for its heat resistance and compliance. The vacuum can be toggled on and off to pick up and release a component. The vacuum pickup device serves two purposes. First, it is used to remove a component from the circuit board once the component has been heated by the hot-gas to the point of solder reflow. Following preparation of the repair site, the suction cup is used to hold the replacement component rigidly so that it can be aligned to bonding pads and accurately placed.

50.2.1.4 Adjustable Stage or Adjustable Nozzle Assembly. This permits alignment of the nozzle to the component in need of repair. Such stages or gantries are generally adjustable in the *x, y, z*, and θ axis. It is important for component removal but even more critical for component replacement and alignment of component leads to PCB bonding pads.

50.2.1.5 Vision System. This is used to align component leads to PCB bonding pads. Usually a split-image video system permits a simultaneous view of both component leads and board bonding pads. The images are superimposed and the operator manually adjusts them for the best lead-to-pad alignment.

50.2.1.6 Computer Control. This is the heart of most hot-gas machines. It monitors and controls the various operations of the system, including preheat and thermal profile steps. The rework engineer programs the profile manually or uses a predictive routine to rough out a thermal profile and perfect it.

50.2.2 Hot-Gas Repair Process

50.2.2.1 Nozzle Selection. A hot-gas nozzle appropriate for the part is selected. Sometimes a nozzle can be useful for a family of parts but the nozzle must be size-appropriate so as not to interfere with other adjacent parts on the PCA. It must also be matched to deliver the right amount of hot gas for soldering the part. Most hot-gas station manufacturers have a standard set of nozzles available and can custom make nozzles appropriate for the task. Even some long connectors can be removed and replaced with hot-gas soldering with an appropriate custom nozzle.

50.2.2.2 Thermal Profiling. As with any reflow process, whether for first-pass build or for repair, it is necessary to construct a thermal profile board as previously described to assess the impact of heating and to ensure that the heating is adequate, in accordance with the thermal limits described by the solder paste manufacturer, the component specifications for thermal exposure, best solder wetting, and minimized intermetallic formation. In the case of repair, a dummy (profile) board is used with thermocouples attached to the component to be removed and critical adjacent components to ensure that reflow conditions are correct. For large ICs, multiple thermocouples are used to gauge the temperature in the center of the device and along the edges of the IC. Multiple thermocouples are also embedded in the profile board both to ensure that reflow conditions are met

and that adjacent components are not overheated through the rework process.

50.2.2.3 Component Removal Preheat. As discussed previously, preheating may be necessary to overcome the thermal mass of the assembly and to ready the board for the reflow step. This is accomplished with a heat source under the PCB such as hot-gas heater, heated platen or an infrared heater. Preheat temperature is set well below liquidus onset for the solder alloy in use. The goal should be to confine reflow to the device being removed or replaced and to discourage widespread reflow of component solder joints adjacent to the repair site.

50.2.2.4 Reflow and Removal. The same considerations apply for this as for any reflow step. The ramp, soak, peak temperature and time above liquidus are dictated by the solder alloy used and should roughly match the time-temperature profile parameters as for the initial assembly of the board. Once the component has reached complete reflow, the vacuum pickup tool is engaged and the component is lifted vertically. Care should be taken to minimize the time above liquidus to minimize intermetallic compound thickness, bond pad lifting or other PCB damage.

50.2.2.5 Site Dressing. During the component removal step, solder surface tension capriciously allows some of the solder from the joints to remain on package leads and some is left on the PCB bonding pads. In the case of some area-array packages [BGA, ceramic ball grid array (CBGA), mico-BGAs, etc.], the ball may remain with the package or with the land. This can make solder land dressing a labor-intensive operation. Care at this step is critical for success in reattaching a fresh component and for PCA reliability.

Following component removal and while the board is still hot, the solder lands on the PCB can be prepared for

component replacement by means of a hand soldering iron and a braided copper solder wick or a solder vacuum machine that simultaneously heats the pad by hot gas and vacuums up any excess solder. The goal is to roughly even out solder remaining on the pads making them smooth enough so as not to interfere with fresh component placement. If solder paste is to be added for component replacement, bond pad surface topography is even less critical because the solder paste will add significant vertical compliance and any remaining solder on the pad will melt into the solder mass of the solder imparted by the paste. The pads do have to be flat enough to allow the mini-stencil to sit flat on the board if solder paste is added in that manner. Too much pad dressing only encourages intermetallic build-up. If using the copper wicking braid, care must be taken not to allow the solder to freeze before the braid is pulled from the pad otherwise when the braid is lifted the pad from the board will be pulled up with it and the board will have to be scrapped.

50.2.2.6 Part Bake-Out. As with first pass soldering, it is important to observe rules governing component bake-out to remove any absorbed moisture and preclude part cracking (popcorning) during the reflow heating cycle. Guidance for part baking can be found in IPC/JEDEC J-STD-033.[1]

50.2.2.7 Solder Paste or Flux Deposition. For most SMT components, solder paste is added to either the board or the component to effect a reliable solder joint for component replacement. This is generally done by mini-stencil similar to what is used for SMT solder paste deposition for the PCB, but on a smaller scale; the stencil is only slightly larger than the component footprint. The paste is pushed through the stencil apertures with a razor blade or a miniature stainless-steel squeegee. Programmable syringe-dispenser machines are sometimes used, but solder paste is

known to separate when under pressure, that is, solder alloy separates from the solder flux. Choosing the largest needle bore, slowest dispense rates, and lowest pressures will help to mitigate paste separation. Also, use of direct drive auger pump rather than an air-pressure-driven dispenser will help to reduce paste separation. As a rule, the amount of solder paste used for repair should be roughly the same as for the initial build.

Instead of stenciling or depositing solder paste on the dressed pads, some choose to add flux to the pads following site dressing and use the solder from the BGA balls to effect solder joints. Another methodology is to print or dispense solder paste on the BGA balls then place the component onto the dressed site. Yet another variant is to dip the BGA balls into solder paste and then place the device on the dressed pads. For some applications these alternate techniques may be adequate but there are reliability concerns which will be discussed later in this chapter.

50.2.2.8 Soldering Preheat. After solder paste or flux deposition, the board is preheated to a temperature about 50 to 70°C below solder liquidus. Preheating of component and PCB is an important part of the reflow profile. Preheating should mimic the original SMT soldering cycle and align with solder paste or flux requirements as specified by the solder paste or solder flux manufacturer. Heating ramp rate should fall within the manufacturer's specification for the component to be soldered just as in SMT reflow.

50.2.2.9 Component Pickup. During the PCB preheat cycle, the component is picked up and readied for placement. After the component is placed on a pickup nest adjacent to the PCB, the nozzle with vacuum pickup is aligned and lowered over the component. Next the vacuum pick-up is activated. The component is raised up and brought over to the dressed site in preparation for placement.

50.2.2.10 Component-to-PCB Alignment. A split-vision optics system, part of the rework station, is used and the semi-transparent video image of the picked component is superimposed over the video image of the PCB bonding pads at the placement site in preparation for placement.

50.2.2.11 Placement. Once component leads are aligned to PCB bonding pads, the component is lowered on to the dressed, solder-pasted or flux-coated bonding pads and the thermal cycle continues.

50.2.2.12 Reflow. Heating to the component is increased by ramping up the temperature and volume of the hot-gas. Heating of the solder paste (or flux), the device to be soldered and the PCB should be in accordance with paste (flux), device and PCB manufacturer specifications. Just as in the original SMT oven reflow cycle, heating ramp-rates for the solder paste and for the IC being soldered must be observed.

50.2.2.13 Cooling. After reflow has been achieved through the preset profile, PCB and component heating is turned down or off in accordance with prescribed profile ramp-rate as is appropriate for the solder paste and the device being soldered. Once the solder joints have reached solidus, the PCB with its newly soldered replacement component can be removed from the hot-gas repair station ending the repair cycle.

50.2.2.14 Inspection. Due to the manual nature of hot-gas repair, it is even more important to inspect soldering results. For area array devices (BGAs, etc.), transmission x-ray inspection is suggested to ensure that all contacts are soldered and bridge-free. Visual inspection should be done looking for evidence of PCB charring, delamination, component cracking or unusual bulging (evidence of popcorning). Check adjacent components to ensure they are

still soldered, not cracked, scorched or otherwise damaged. Inspect bottom-side components for damage and solder joint integrity especially in the case of back-to-back BGAs when one is involved in removal and replacement. If in-circuit testing or functional testing is done on the first-build product, then it should be applied to the reworked product also.

50.2.3 Hot-Gas Rework Guidelines and Reliability

A repaired part will be less reliable than a part soldered in the initial surface-mount process. The key in all reflow steps is to limit the amount of time at or near solder liquidus in order to minimize intermetallic compound (IMC) formation. IMC thickness increases with each reflow cycle and its formation is temperature-dependent also. IMC is the weakest link in terms of solder joint structure. Due to its brittle nature, the thicker the IMC the more vulnerable the solder joint to shear, shock and vibration. Therefore, during component rework and replacement, minimizing thermal excursions to limit IMC thickness is all important. Strive to keep the reflow cycle similar to what was used during original SMT oven reflow soldering for that PCA.

When a component is removed and replaced, IMC from previous soldering operations or other thermal excursions remains on the pad. IMC cannot be removed from the pad since it a result of solder alloying with the pad and is an integral part of the pad. For illustrative purposes, consider the case of a surface-mount component with a copper lead-frame and copper bonding pad on the bottom-side of the PCA. During initial SMT assembly, the bottom-side of the board is built first. During that soldering process, an intermetallic layer forms where the solder is in contact with the joined metals (bond pad and component lead). During

top-side soldering of the same PCB, the components on the bottom side of the board undergo a second reflow and the IMC further grows. Assume that a part soldered during the bottom-side assembly fails and requires removal. The removal and replacement processes necessitate additional reflow cycles to the affected component site. Steps include (1) component removal, (2) site dressing, and (3) component replacement and re-soldering. In total, from the onset of the SMT build to the end of removal and replacement of the failed component, the PCB will have undergone five reflow cycles at the site of the replaced component. With each soldering cycle, the intermetallic layer builds and reliability generally degrades with increasing intermetallic layer thickness. Therefore, careful process control is needed to minimize time above solder liquidus. Figure 50.2 depicts soldering and repair steps and hypothetical impact to intermetallic layer thickness common to any soldering and repair cycle.

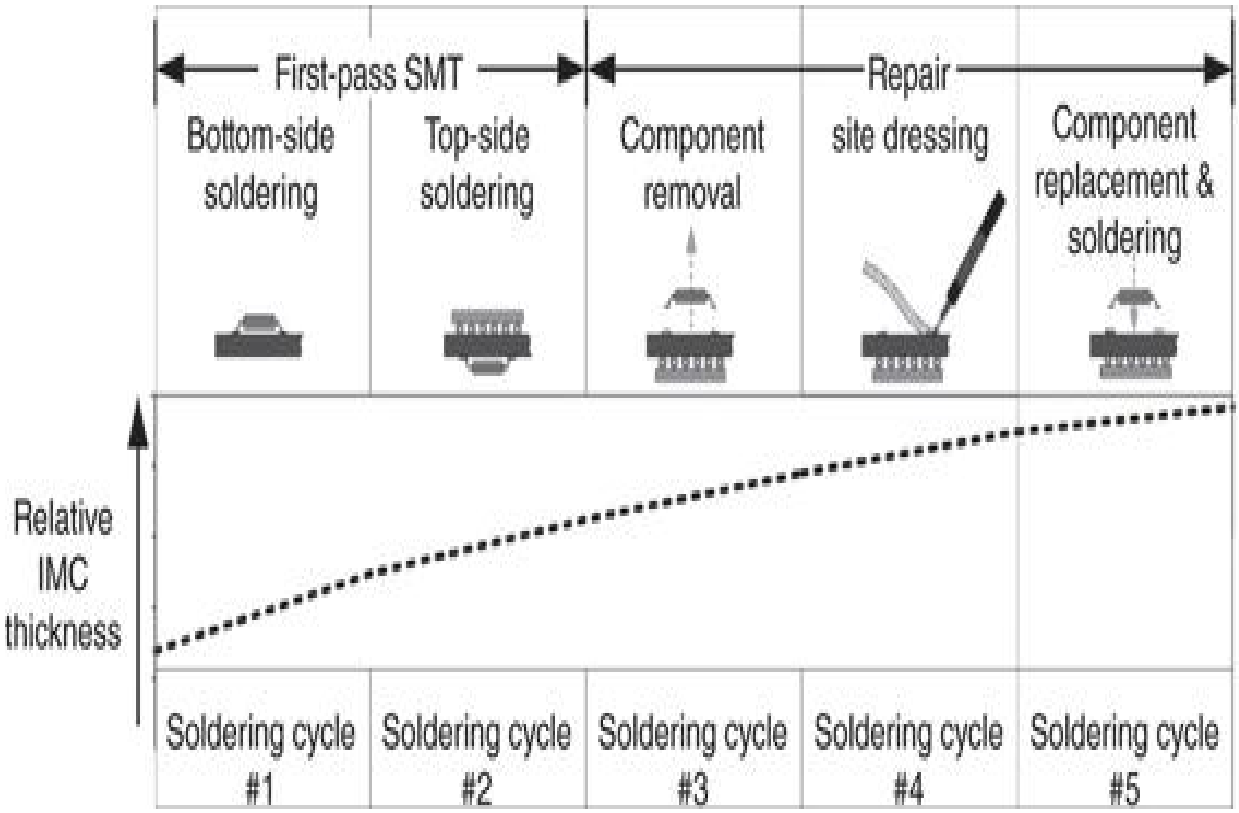

FIGURE 50.2 Intermetallic (IMC) thickness as a function of soldering cycles: the thermal history of bond pads. Soldering steps required for first-pass soldering of a bottom-side component on a PCB and successive reflow and pad treatment steps encountered during repair. Note that the intermetallic compound formation thickness is not truly linear with each step. IMC thickness is dependent on materials of the soldering system, time above solder alloy liquidus, peak temperature, etc. The illustration is meant to show that with each reflow cycle there is increased intermetallic layer thickness.

Generally the number of SMT solder rework cycles per component per board is kept to two or three. Beyond that, the board should be scrapped to avoid reliability problems.

The thermal profile used for component replacement should be predicated on the four things: (1) the solder paste manufacturer's recommendations for reflow; (2) component manufacturer's specification for peak temperature and heating and cooling ramp rates; (3) results of thermal profile established from trials with an instrumented product profile board; and (4) optimization of the reflow profile.

For no-clean boards, the same solder paste used for the initial assembly should be used for the repair. If solder paste is not added, then a paste flux (identical to that comprising the solder paste) should be used. This will obviate solder chemistry interactions reducing the likelihood of long-term corrosion. For aqueous-cleaned boards, no-clean solder chemistry is often used for repair to preclude the need for another wash cycle.

Sometimes in BGA repair, solder paste is not used. Instead, solder from the BGA ball provides solder for the bond. This technique requires the use of flux for the soldering. The flaw in this methodology is that resultant solder volume is lower as compared to the original joints where solder paste was utilized. Without the added solder (from the paste), BGA reliability is diminished. In fact, any repaired joint is less reliable than a first-pass solder joint due to thickening intermetallic layer formation that comes with each reflow cycle as previously discussed. Addition of solder paste compensates for small differences in BGA ball sizes. If the

component is light enough to float on the molten solder, as will most plastic BGAs, it will result in a taller solder joint which has more columnar compliance making it less prone to failure by mechanical perturbation. Eliminating solder paste is not an option for area-array devices with noncollapsible interconnects, such as ceramic column grid arrays (CCGAs) or ceramic BGAs (CBGAs) since their interconnects (balls or columns) are of a high-temperature solder alloy or metal and will not reflow under normal PCA soldering conditions. Therefore, solder has to be added for re-bonding of this type of component.

Often an attempt is made to salvage BGAs and other parts removed during the rework process. They are re-balled or solder paste is added to either the PCB or the part to re-solder it. Unless an IC device is qualified for the extra reflow cycles during rework (removal, re-balling, replacement on the PCB), then its reliability will be unknown. When IC manufacturers sell ICs, their technical specification for each device lists the intended number of reflow cycles. Beyond that number, device performance is either unknown or degraded in performance, reliability or both.

50.3 MANUAL SOLDER FOUNTAIN

PTH components are generally repaired by solder fountain, which is akin to a wave-soldering system with a vertically pumped jet or stream of solder. It is significantly smaller than a wave-soldering machine and can be configured with or without conveyor, fluxer, and preheaters. It can be so small that it is bench-top mounted. It permits an operator to manually remove parts and replace them. The classic solder fountain is a manually controlled system. Nozzles are chosen to shape the molten solder jet to match closely the size of the area to be soldered. Nonetheless, a shield or pallet

should be used to localize the soldering and to prevent contact of the molten solder to other previously soldered components on the board.

The board requiring repair is shielded, except in the area of component replacement, and positioned over the solder fountain. The shaped solder fountain is directed at the repair site. Once the component solder joints go molten, the component can be pulled out with gloved hand or pliers, some flux can be added, and a new component can be inserted to complete the rework within one thermal excursion. Flux used at repair should be the same as the one used for first-pass soldering of the device being reworked. If not the same flux, one from the same flux family should be chosen in order to prevent adverse interactions and corrosion in the long-term. Care must be taken to ensure that all solder joints have gone molten on the component being removed. If not, PTH barrels can be ripped out of the board or barrel annuli can be damaged resulting in a scrapped PCA.

To aid the solder fountain process, dense assemblies can be batch-heated in a box oven to make the repair process more efficient and limit exposure of the board to the turbulence of the molten solder wave. Limiting the soldered assembly’s time near or above solder liquidus is key for solder joint and product reliability. As mentioned previously, time above solder liquidus along with peak temperature will define the intermetallic thickness for a given metals system, and intermetallic thickness will in part define the solder joint reliability. The turbulence of the solder fountain, like its kin the wave solder machine, is known to cause the dissolution of metals, such as copper, into the molten solder. The manual nature of some solder fountains results in an out-of-control and irreproducible process entirely dependent on operator vagaries. Copper PTH barrels, barrel annuli (bonding pads atop the PTH) and PTH solder-tails can be thinned or completely dissolved, impairing electrical interconnect or degrading long-term solder joint or device

reliability. For this reason, precise process control, including strict exposure time limits and minimized solder pot temperature, must be imposed for such manual operations. This process is best suited for repair and should be avoided, if at all possible, for first-pass soldering of printed circuit assemblies. There are automated, commercially available systems that help to limit the potential damage of solder-fountain rework and provide a reproducible process.

50.4 AUTOMATED SOLDER FOUNTAIN (SINGLE-POINT SOLDERING)

This version of the solder fountain incorporates a programmable head and is used mostly for first-pass soldering, but can be an effective soldering repair tool. Once the PTH component is removed, the site is prepped, fluxed and a new component is inserted into the solder-cleared plated through-holes. A programmable nozzle emitting a precise jet of molten solder is directed at leads of the component to be soldered on the backside of the PCA. The nozzle allows point soldering of very fine PTH pitches en masse or even one lead at a time.

50.5 LASER

Laser is a recent innovation in rework and repair. In the commercial incarnation of this technique, a laser beam is quickly scanned repeatedly around component leads or, package surface to heat it. It is most effective for low thermal mass packages (small area-array devices such as BGAs and chip-scale packages (CSPs) but has been applied to thermally massive CBGAs, CCGAs, etc. Since the energy of

the laser beam is more tightly confined to the area it irradiates, the heating can be highly localized as compared to hot-gas repair methods. This can be advantageous when trying to remove or replace a component on a densely populated, double-sided PCA. Preheating of the PCA may be required to enhance reflow and package removal.

The same caveats must be kept in mind regarding IMC formation and pulling a component before it is fully reflowed. If irradiating component leads, care must be taken to assess the assembly for its laser damage threshold so as not to char components or carbonize the PCB surface during either removal or component re-soldering. Addition of flux to the component leads will help in the thermal transfer, aid in preheating the next lead to be unsoldered. It also minimizes the possibility of charring damage to the PCB surface.

50.6 CONSIDERATIONS FOR REPAIR

50.6.1 Mixing Aqueous with No-Clean Chemistries

Care must be taken when using fluxes for the rework and repair processes. If an aqueous-clean solder chemistry is used for building the PCA, then either no-clean or aqueous flux formulations can be used. If an aqueous chemistry is used for the repair, then the board must be subjected to another aqueous cleaning cycle. Be sure to check that all components at that stage are compatible with the aqueous cleaning process.

No-clean solder flux formulations can be used for rework and repair even if the PCA was manufactured with a water-clean chemistry and already cleaned, although the reverse is not recommended. Sometimes when a no-clean board is subjected to an aqueous cleaning process, the no-clean flux

residue takes on a white, gummy characteristic that is conducive to dendritic corrosion and ensuing soft or hard electrical shorting. Saponified aqueous cleaning can be used, but must be tested for effectiveness in removing the polymerized flux residue from the no-clean process and for compatibility with the selected no-clean flux to avoid generation of corrosive byproducts. This is particularly important under connectors, area-array devices, and other components with low headroom between the underside of the body and the PCB surface.

50.6.2 Pooled Flux

Another consideration when using no-clean solder chemistries is that of pooled, unactivated flux residue. No-clean solder flux is generally harmless after it has gone through the thermal cycle associated with solder reflow. It is activated and denatured by the heat of soldering. If the flux is applied generously and the flux pool does not see the high temperatures associated with solder joint formation, acids remaining in the unheated flux residue can cause reliability problems. These acids are normally denatured, evaporated, or sublimed through the high-temperature excursions of the soldering process. If the flux acids remain, corrosion can occur in the long term. There are commercial flux solvents that can be used to dilute and wash away excess flux; otherwise, the assembly can be baked briefly to about 120°C to denature the flux. Check with the flux manufacturer for specific recommendations regarding flux residue management and activation time and temperature. The problem can be avoided totally by eliminating the use of liquid flux and using small amounts of paste flux instead. In the case of flux-cored solder wire, use the smallest diameter practical to limit flux residue.

50.6.3 Component Bake-Out

Components that have been exposed to the factory atmosphere may be subject to water absorption. When they are heated during rework, where the heating cycle is more localized and perhaps more extreme than in the slow heating experienced during mass oven reflow soldering, moisture-induced popcorning may be a more serious problem. Follow IPC, JEDEC or component manufacturer recommendations for pre-soldering moisture bake-out regimes.

50.6.4 Gold Finger Protection

There is ample opportunity to ruin gold edge-connector fingers on a circuit board during the repair operation. Keep both solder and flux away from gold fingers during repair. Mechanical shields or acrylic-adhesive polyimide tape can be used to protect fingers from smeared solder paste, loose solder debris, or flux. If solder comes into contact with gold and heated to reflow, the gold will rapidly dissolve into the solder mass and the solder will spread on the finger. The solder cannot be removed from the gold finger without replating; a costly process that can also be a source of corrosion on the finished PCA. Solder is not a reliable connector contact material, especially with today’s high-density, low normal-force electrical connectors.

Keep solder away from gold fingers. Keep gold finger temperature as low as possible. Ensure that gold fingers are never handled, even with gloved hands. Avoid lint and fibers. If required after rework, clean gold fingers with a suitable solvent to dissolve any flux residue. Use a soft brush, lint-free cloth, or other nonabrasive material for this cleaning. Clean gold fingers on each side of the board separately. Avoid folding the lint-free cloth over both edges and wiping repeatedly; the cloth will wear against the glass-epoxy edge

and shred, leaving lint on the board. A better alternative is to use a soft, ESD-safe brush with solvent to clean the gold finger followed by a filtered, ionized air blow-off to dry and remove any remaining solvent, lint, fibers or bristles from the cleaning process. Avoid any materials that will scratch the gold surface finish on the fingers. The underlying nickel, if exposed to the atmosphere will oxidize and, is known to be problematic for separable contact reliability.

PART 9

NONSOLDER INTERCONNECTION

CHAPTER 51
PRESS-FIT INTERCONNECTION

Gary M. Freedman
Colab Engineering LLC, Stow, Massachusetts

51.1 INTRODUCTION

Electronic connectors are attached to printed circuit boards (PCBs) in four ways (see Fig. 51.1):

1. Oven reflow surface-mount technology (SMT) soldering
2. Wave soldering (for solder-tail components)
3. Pressure interconnect, a solderless method relying on mechanical forces to hold interconnect elements together to make contact
4. Press-fit, another mechanical, solderless technique (the subject of this chapter)

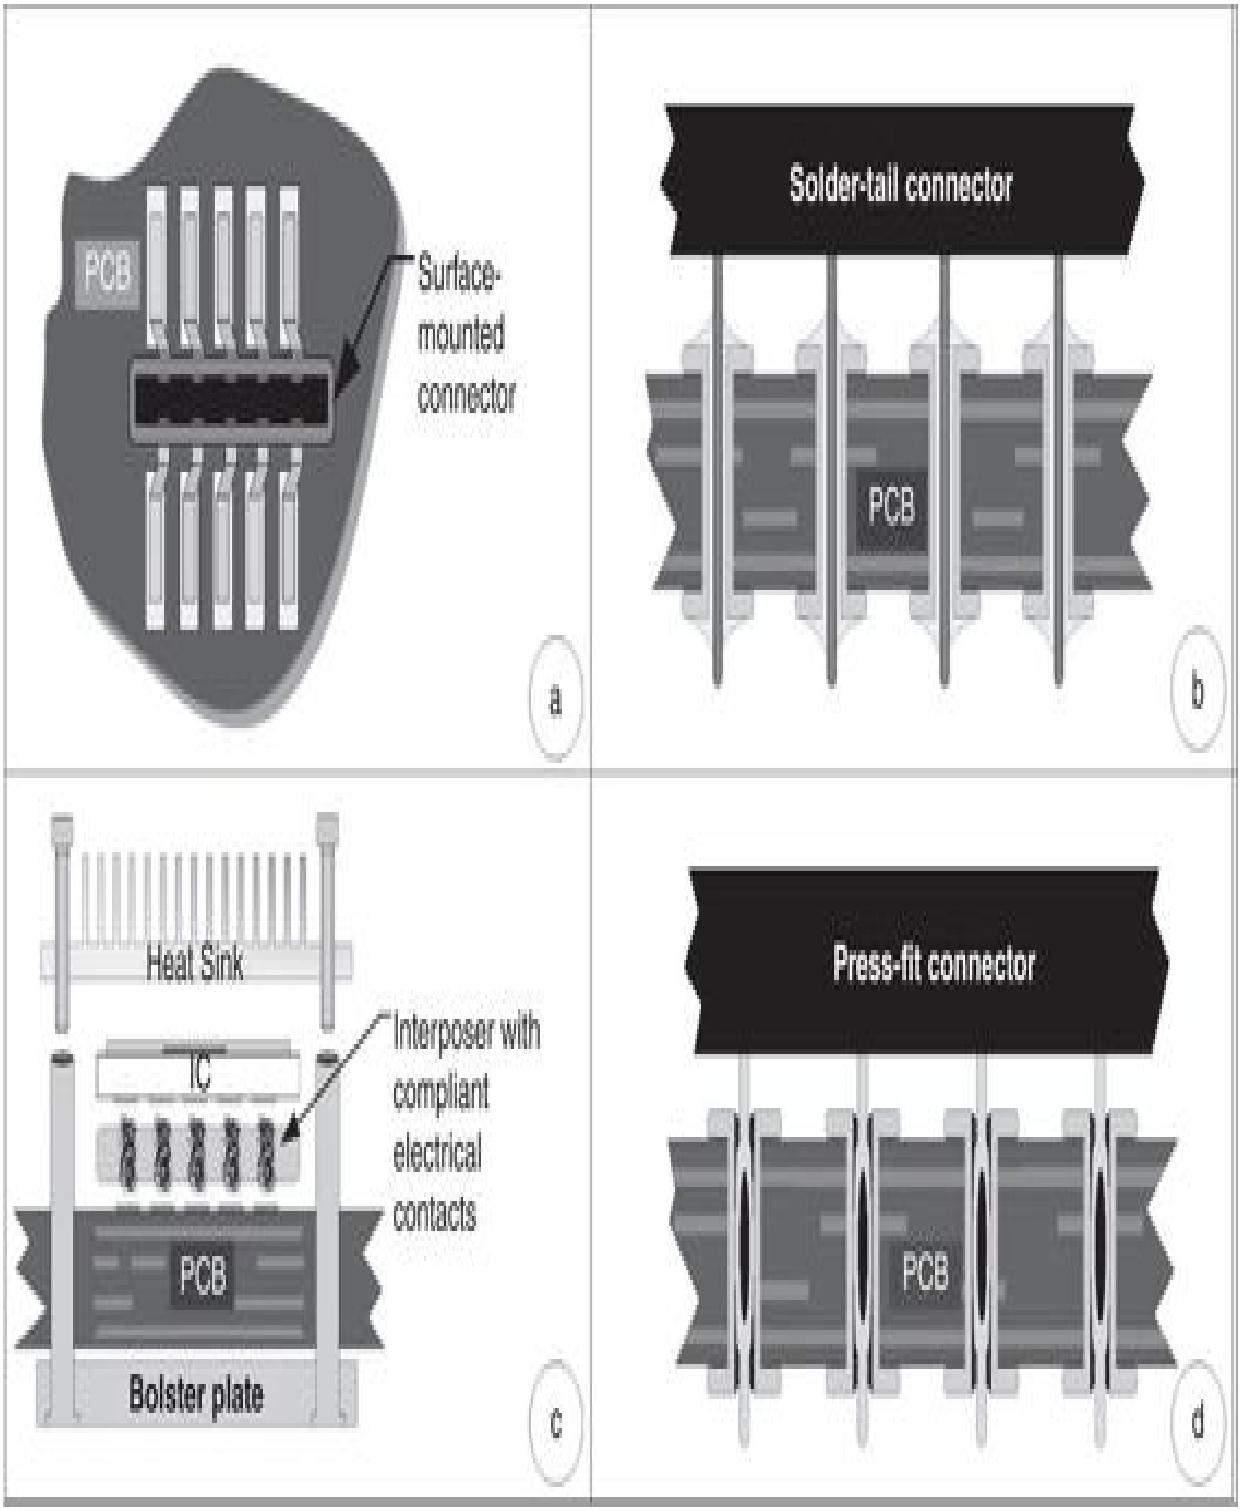

FIGURE 51.1 Four methods of connector attach to PCB: (*a*) SMT applied by oven reflow soldering; (*b*) plated through-hole (PTH) solder-tails that are wave-soldered; (*c*) pressure-interconnect, which relies on mechanical forces for electrical contact; and (*d*) press-fit, which relies on mechanical deformation of the connector lead and/or PTH barrel to make intimate electrical contact.

Press-fit, also referred to as *press-pin, compliant-pin*, and a number of other trade names, has been in use for many years and is a proven and reliable interconnect method. Once used exclusively for passive backplanes, more recently press-fit connectors have gained in popularity and are commonly incorporated on complex motherboards and daughter-cards. Just as circuit boards have become more complex (thicker, higher layer counts, densely routed circuit traces, and high component counts), so too, press-fit connectors are available with high pin density (pin pitch down to 1 mm) and pin counts in the thousands per connector and even strip-line shielding for enhanced high-speed signal performance. Press-fit connectors can be applied to either or both sides of a PCA and are repairable, although first-pass assembly yields are always near 100 percent. Press-fit is easier and more reliable than soldering and does not subject the printed circuit assembly (PCA) to additional thermal or chemical processes—an advantage for reliability, and especially advantageous for today's dense circuitry. Since it requires very little energy (no soldering), minimizes materials (no solder), and calls for no chemicals for its application, the press-fit process is environmentally favorable. The process is simple in theory and generally so in practice, relying on oversized connector leads forced into in plated through-holes (PTHs) in the PCB. The plated through-holes are sized specifically for the press-fit connector. As the connector pin is forced into the PTH barrels, there is slight deformation to the PTH barrel and the press-fit pin. The result is a mechanically stable, environment-impervious electrical contact.

51.2 THE RISE OF PRESS-FIT TECHNOLOGY

There is resurgence in the popularity of press-fit connectors driven by (1) increasing board complexity, (2) the component density of today's PCAs, (3) the appearance of hybrid backplanes populated with active components, and (4) new offerings of high-density, high-speed press-fit connectors. Press-fit connectors are typically used on very thick boards that would be difficult or impossible, to wave-solder. Elimination of wave soldering increases manufacturing yield and allows a denser component layout on the bottom side of the board.

Connector bodies may or may not be compatible with the thermal rigors of reflow or wave, so press-fit connectors are typically applied after all mass soldering (reflow and wave) of the PCA is completed. Further, press-pin connectors are not generally soldered into place since rework would be rendered impractical. Rework of press-fit connectors will be discussed later in this chapter.

51.3 COMPLIANT PIN CONFIGURATIONS

There are many different press-fit pin configurations, far too many to review. Instead, four styles will be described as an introduction to press-fit technology.

51.3.1 Square Pin

Composed of a pin of square or rectangular cross-section, it is sized to deform the board's plated through-hole slightly upon insertion. This is the proverbial "square peg in the round hole." The lead is tapered at its tip to facilitate initial PTH insertion (Fig. 51.2).

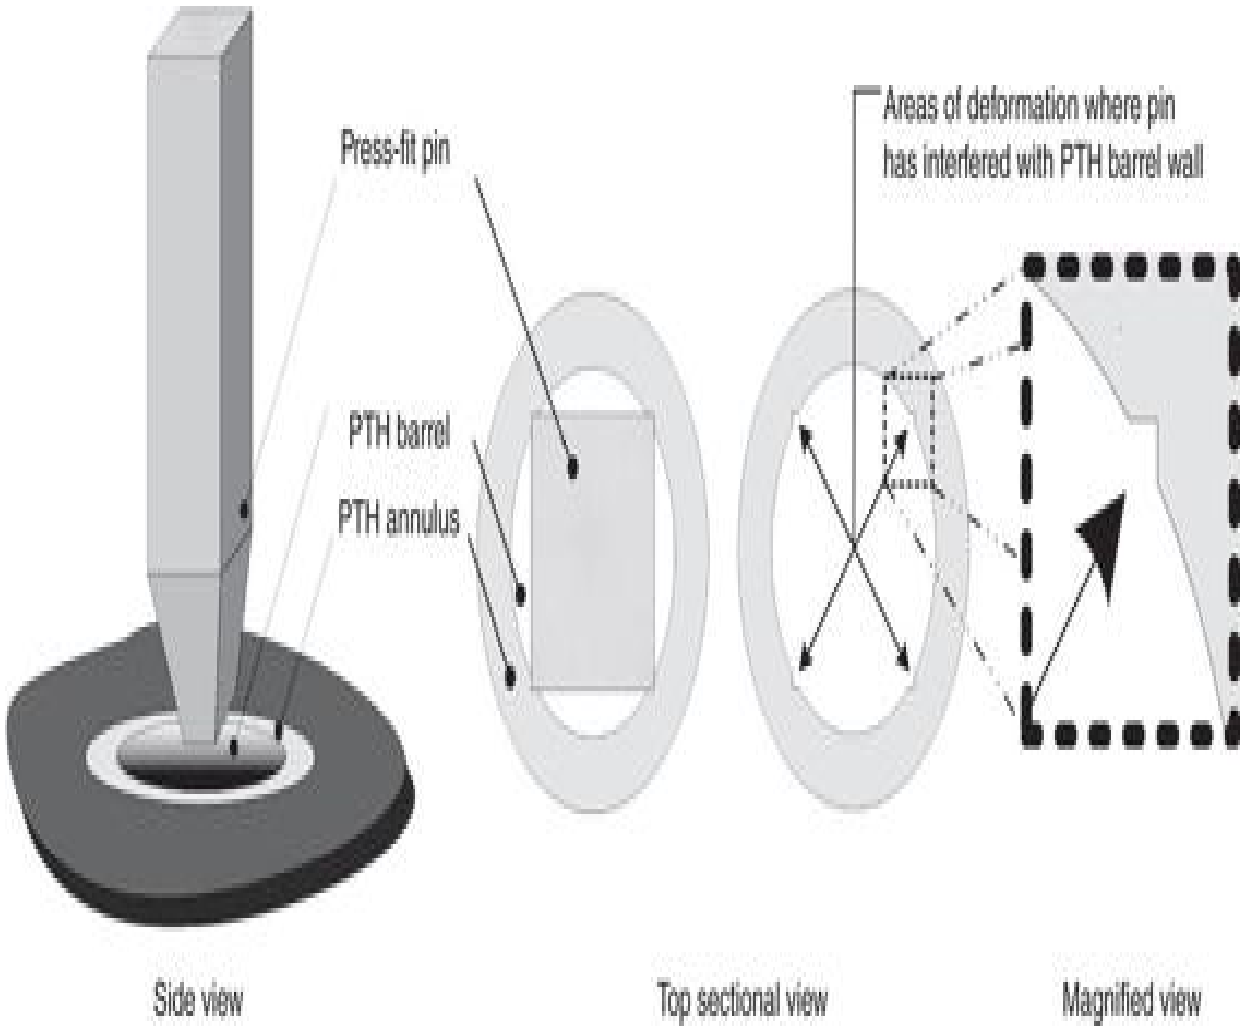

FIGURE 51.2 Tapered square or rectangular pin forced into a round hole. This is the most primitive of press-fit techniques and has been largely supplanted by “compliant-pin” technology.

51.3.2 H-Section

This is a variant of the square-pin. It consists of a sculpted rectangle; an “H” in cross-section. Its design imparts a slight amount of compliance as the tops and bottoms of the “H” section are meant to deform upon pressing into the PTH (Fig. 51.3).

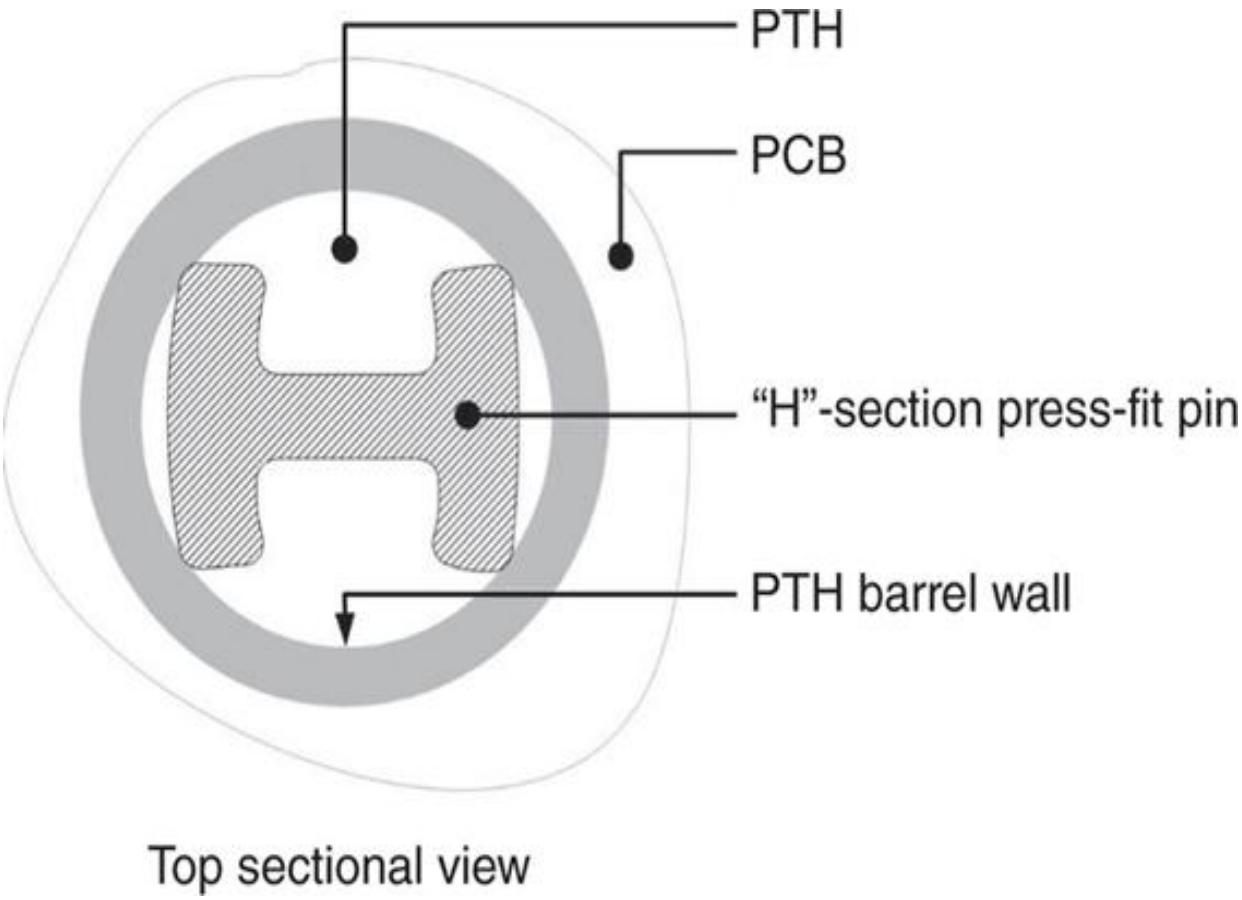

FIGURE 51.3 “H”-section press-fit pin. The sculpted cross-section of the pin allows it to deform slightly. This deformation, along with some deformation of the PTH barrel upon insertion, results in reliable mechanical and electrical contact.

51.3.3 “Action Pin”

It is composed of two separate blades, individually angled, one in front of the other. Upon pressing, the blades slide past each other in opposite directions and spring against the PTH wall to impart electrical contact and mechanical stability (Fig. 51.4).

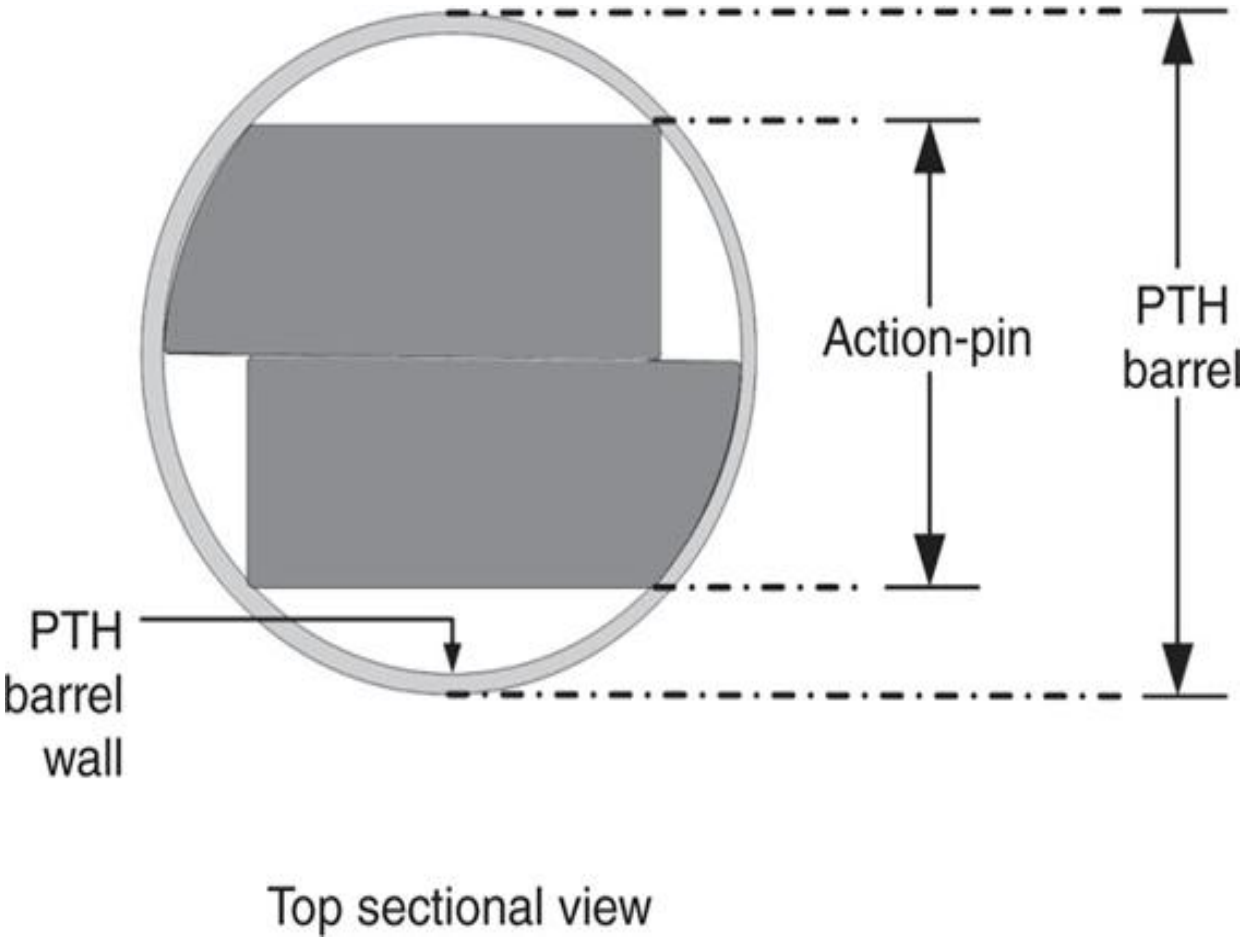

FIGURE 51.4 “Action-Pin”. Two independent blades, one in front of the other, slide past one another and are forced against PTH barrel wall for electrical contact and mechanical anchoring.

51.3.4 “Eye-of-the-Needle”

The fourth and most prevalent press-pin design is the collapsible pin known as “eye-of-the-needle” (EON) (Fig. 51.5). Upon insertion and pressing into the PTH, the compliant section of the pin folds upon itself axially in a controlled manner, as depicted in Fig. 51.6.

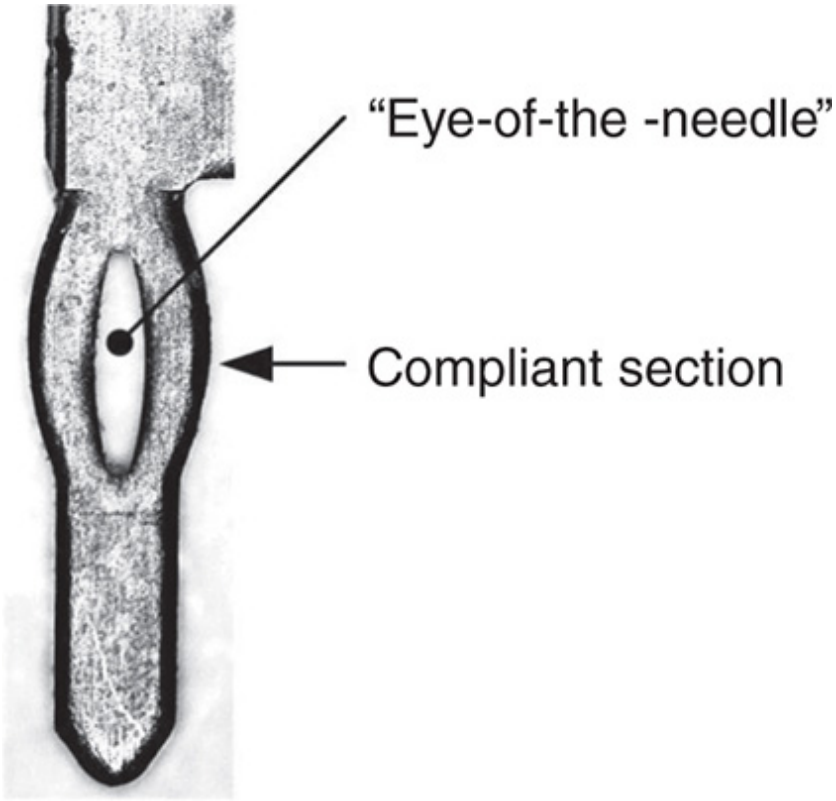

FIGURE 51.5 “Eye-of-the-needle” configuration press-fit pin, shown before compression. The compliant section is meant to deform into and against the PTH barrel upon pressing.

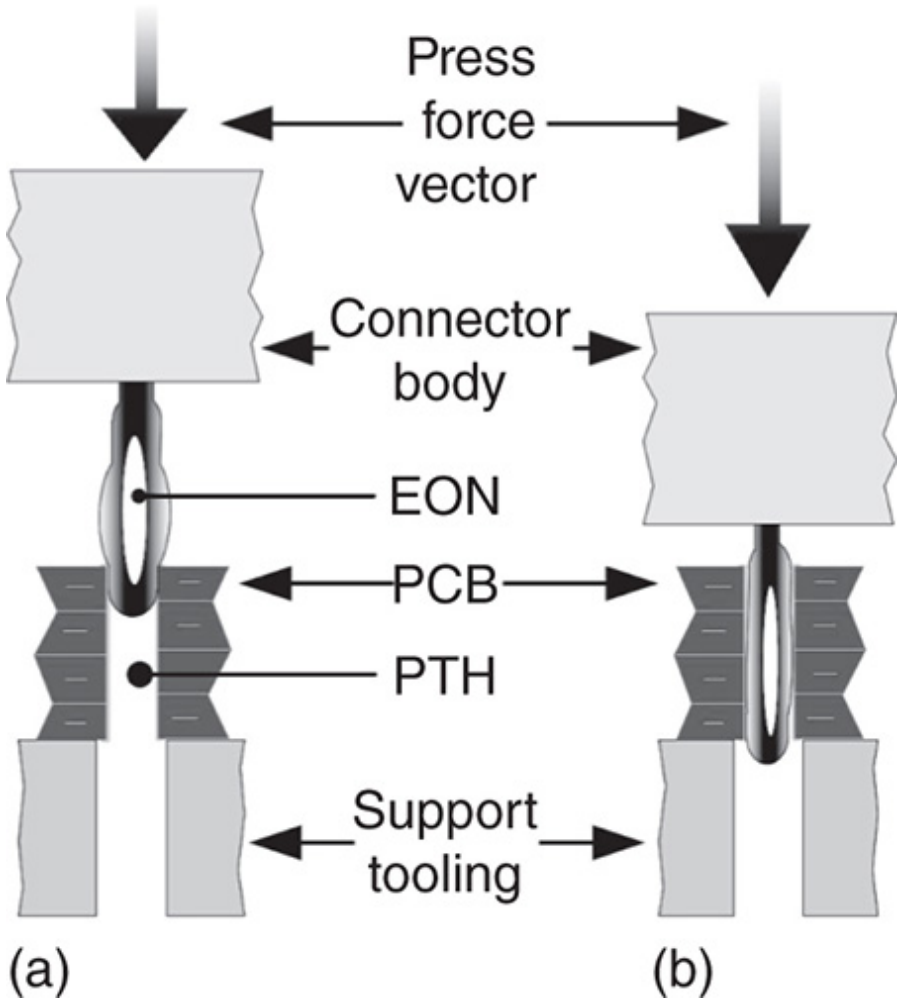

FIGURE 51.6 EON-type pin pressed into a PTH barrel. (*a*) Onset of the press cycle, (*b*) EON pin fully driven into the PTH barrel. Its compliant section collapsed inward upon itself. The resultant forces between the pin and the PTH barrel wall result in stable, intimate mechanical and electrical contact.

As a result of the pressing, the compliant pin deforms the plated through-hole barrel slightly due to mechanical interference of the press-fit pin against it. The resultant forces from the collapsed press-fit pin against the PTH barrel wall result in stable, long-term mechanical and electrical contact.

51.4 PRESS-FIT CONSIDERATIONS

51.4.1 Seating Force

The load necessary to apply a press-fit connector depends on a variety of factors, including pin design, pin material, pin size, pin surface finish (plating), PTH surface finish, PTH plating thickness, PTH finished hole size, and the number of pins per connector. The connector manufacturer should provide the required per-pin loading force for each connector and the force needed for proper insertion and connector seating.

51.4.2 Correct Design and Size

Press-fit connector leads are designed to work within a tight range of PTH barrel diameters. The compliant pin normal force exerted against the PCB plated through-hole barrel wall must be maximized to anchor the connector into the PCB reliably both for mechanical stability and electrical contact. The connector manufacturers will recommend proper PTH diameter, mechanical tolerances and PTH surface finish as tested for their product. The resultant press-fit coupling is analogous to the solder joint providing both electrical and mechanical functions.

If the pin and barrel are sized properly and materials are appropriately finished, the anticipated joint life will be better than that of soldered assemblies. Also if the pin and barrel are sized correctly, the pin-to-barrel normal force will be high enough to form a gas-tight seal for long-term electrical and environmental contact reliability. The pin must be strong enough longitudinally to prevent buckling during the pressing operation. Pin normal forces must be optimized so as not to damage the PTH barrel; high enough for good contact, but light enough that the pin insertion will not damage or eject the barrel or the PCB during the press-fit operation.

51.4.3 Reproducible Connector Press

Pressing force generally ranges from some tens of grams to kilograms per lead. The machine used for applying press-fit connectors must be range-appropriate and reproducible in operation. Manual presses or presses that impart significant variation in press speed and press force may lead to excessive process variation and less than satisfactory process results. Press attributes will be discussed subsequently.

51.5 PRESS-FIT PIN MATERIALS

51.5.1 Base Material

For purposes of affordability, mechanical integrity, electrical properties, and materials conservation, all electrical contacts, regardless of assembly methodology, are made from inexpensive base metals and plated with a minimum thickness of a more precious or more practical material. Many press-fit connectors were made of beryllium-copper alloy, but due to beryllium dust toxicity, a factor in press-fit lead manufacture, the switch to safer phosphor-bronze or other copper alloys has occurred throughout the industry.

51.5.2 Surface Finishes: Pin and Barrel

Press-fit connector compliant pins surfaces can be plated with a variety of metals with the two most common being gold and tin but other surface finishes are offered also. All circuit board surface finishes are suitable for press-fit

application, although some are more favorable than others. This will be discussed later in this chapter. “Organic solderability preservative” (OSP) copper, tin, gold, silver, tin-lead PCB surface finishes are all acceptable.

With soldering there is reliance on a fluxing agent to remove naturally occurring oxides from the surfaces to be joined prior to and during the solder alloying process. In a solder joint, the component lead and pad interface materials are wetted by and sealed in solder. Solder gives the interconnection mechanical rigidity and protects contact surfaces from degradation due to the environment (oxidation, corrosion, etc.). This is not the case with press-fit technology. Even though oxide may be present on the press-fit pin and PTH barrel (as would be the case of tin-plated pins and tin-plated PCB), the high frictional forces encountered during the press-fit process displaces oxides from both the compliant pin and the PTH barrel in the path of pressing, so generally there is little concern for oxidation on either part.

51.5.3 The Gas-Tight Seal

In the case of the press-fit connector pin, there is neither a physical wetting of materials nor metallic encapsulation to protect the interconnection as there is in soldering. Additionally, no chemical fluxing agents are used to remove native oxides from the PTH barrel or the compliant (press-fit) pin. Instead, the press-fit pin is anchored solely by the mechanical interference between connector lead and the PTH barrel of the PCB. Oxides on the surface of the press-fit pin and mating PTH barrel are broken loose by the high frictional forces associated with this type of assembly, so nobility of materials, oxide build-ups, and material shelf-life are less critical considerations than in soldering. If conditions are proper in terms of sizing and materials, the press-fit process results in a gas-tight contact between the connector

pin and the PTH barrel wall. Gas-tight is one of the most important concepts to understand in the press-fit connection.

The notion of a gas-tight seal as the product of a proper press-fit is crucial to connection reliability. If an electrical contact is to be reliable, the interface between the two mating surfaces must remain chemically and mechanically stable. The gas-tight, smeared, metal-to-metal contact attained during the press-fit operation mitigates oxidation of either contact (PTH barrel or press-fit pin) and prevents ingress of any atmospheric gaseous contaminants. Mechanisms such as fretting corrosion, a common failure mechanism for mechanically mated contacts, especially those subjected to vibration, is not a factor in a proper press-fit contact system. Press-fit interconnection is considered at least as reliable as a soldered connection and there is no solder joint to degrade or crack with time. Press-fit pins are designed and sized to result in long-term electrical and mechanical stability. Pin compression and resultant normal force are designed for a small range of PTH barrel diameters to achieve the long lasting press-fit gas-tight contact. The gas-tight seal prevents atmospheric gases (oxygen, gaseous contaminants such as sulfur, chlorine and water vapor) from contacting the freshly scraped surfaces that comprise the interconnection; a product of the press-fit process. If, for instance, a PTH barrel is sized too large for a given press-fit pin, the gas-tight seal may not form and the interconnection will not be reliable in the long term. If a PTH barrel is undersized, it may cause the press-fit pin to either crush beneath the connector or buckle in such a way that a gas-tight seal is not achieved. Care in reviewing specifications and inspection to ensure compliance to same is critical for the press-fit process.

51.6 SURFACE FINISHES AND EFFECTS

Surface finish of the PCB's plated through-holes has a significant effect on the force required to seat a press-fit connector and can have an effect on press-fit connection reliability.

51.6.1 Tribology

Every material has frictional (tribologic) properties. Some are naturally lubricating, such as lead (Pb) and its alloys and gold. Others are notably nonslippery, such as tin or copper. Copper is one of the least slippery of the surface finishes and in the context of press-fit, it typically requires more pressing force than Sn-Pb or gold surface finishes for a comparably sized hole. Tin's crystalline structure is also resistant to sliding. Regardless of surface finish chosen, the board shop should be alerted to the fact that holes are being placed in the board for press-fit connections, so more attention is paid to finished hole size (FHS), hole profile and surface finish conditions. For less slippery materials (Sn, Cu, etc.), the holes could be specified for the upper end of its FHS as expressed by the connector vendor to aid insertion and proper compliant section collapse.

If frictional forces are too great during press-fitting, then

- The PTH barrel can be pushed out of the board or otherwise damaged.
- Press-fit pins can buckle beneath the connector never making it into their respective through-holes.
- If they make it into their through-holes, pins may distort to the point that proper normal force is not adequate for a gas-tight seal.

- Contacts within the connector’s molded housing may be impacted imparting a change to the contact gap or even pushing the contacts out of alignment or out of the housing.

Trial boards and pressing parameters should always be assessed before full manufacturing commences. Only very small changes or imperfections can interfere with the typically high yields of press-fit connections. The process is dependent on having all material conditions right for pressing as well as having the proper process parameters too.

51.6.2 PTH Barrel Finish

Barrel finish can have a profound impact on the press-fit operation. If a PTH barrel is too thin or poorly sized for the compliant pin, the pin may pierce the barrel wall or break internal connections to it. OSP-copper finish—since it is a thin, watery, topical coating—adds no appreciable thickness to the PTH lands or barrel, so its control in high-aspect-ratio holes is not an issue in terms of press-fitting. Nonetheless, the copper thickness comprising the PTH barrel must be relatively uniform the entire length of the barrel. Electroless/immersion surface finishes are generally thin and self-limiting in thickness, and as with OSP-copper, such platings add no significant change in PTH hole diameter and no impact to the press-fit process other than the tribology issue already discussed.

At the other end of the spectrum are hot-air solder leveling (HASL) and electroplated finishes, which may add substantial material thickness to PTH barrel walls and annular rings. Too thick a HASL coating can result in PTH barrel diameter reduction. At the onset of the press cycle, compliant pin sections may be overcompressed, causing them to yield and

collapse beneath the connector rather than slide down their respective through-holes. Sometimes solder from the HASL surface finish can redistribute during SMT reflow cycles, causing a bulging meniscus within the PTH (Fig. 51.7*a*). This too may result in pin collapse or buckling. Compare this illustration to that in Fig. 51.7*b*, which shows a normally finished PTH with a relatively uniform barrel diameter, and an evenly coated primary-side annular ring.

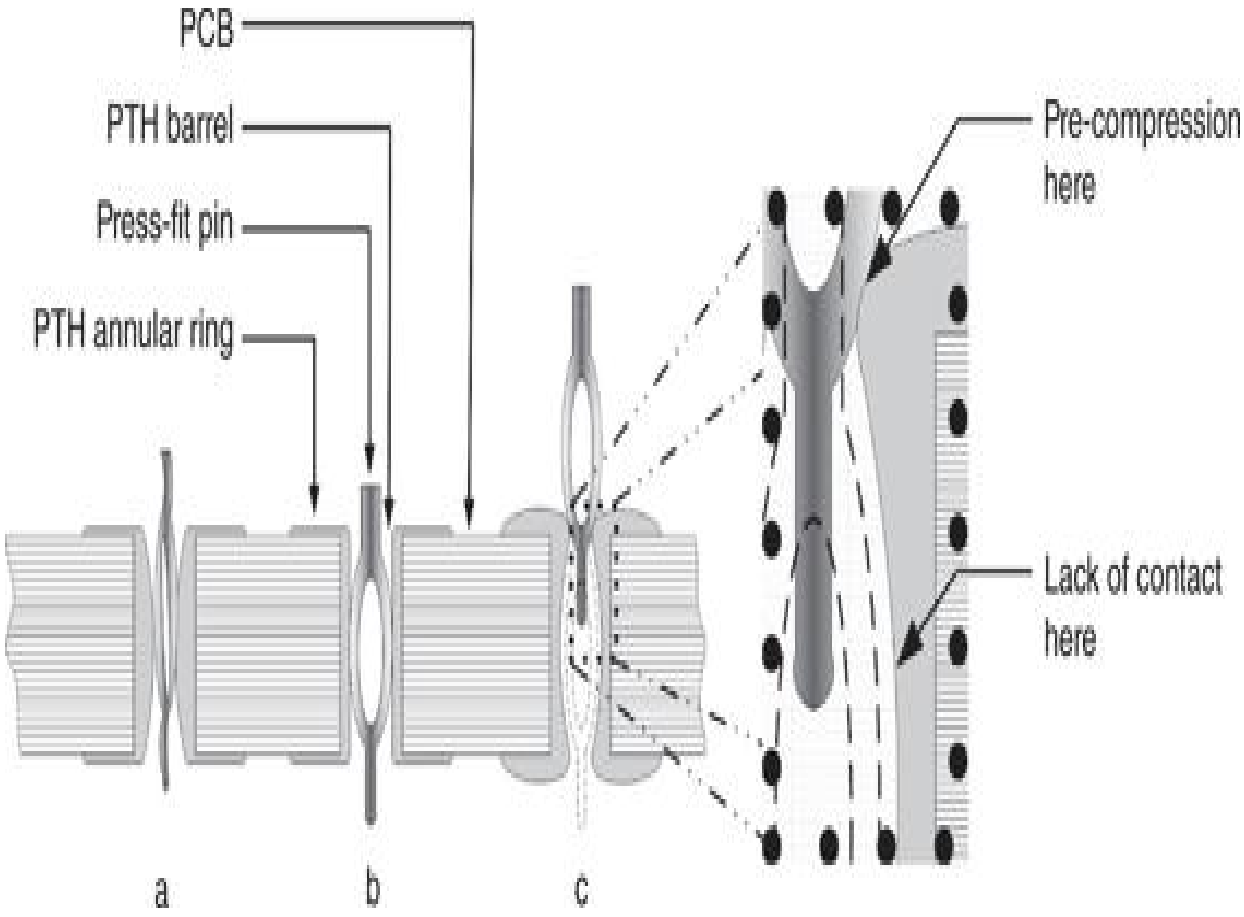

FIGURE 51.7 Barrel profile as a result of surface finish coating: (*a*) PTH barrel with excess surface finish from HASL, which formed a meniscus upon solder reflow within the PTH barrel. This resulted in crushed or distorted press-fit pin. (*b*) Normal PTH barrel with evenly coated walls and annular rings and a proper press-fit connection. (*c*) Excessive plating at top of barrel caused precompression of the EON pin. When the pin was fully inserted there was either insufficient normal force of the pin against the PTH barrel or no contact as shown in the magnified view (fully inserted pin shown in phantom). Both "*a*" and "*c*" pose reliability risks.

Figure 51.7*c* depicts the consequence of too much plating or solder deposit on the top-side annular ring. In this diagram, the compliant “eye-of-needle” is precompressed to the point of excessive plastic deformation of the pin. Once past the bottleneck at the top of the PTH it cannot make proper contact to the PTH barrel for reliable contact. Initially if electrical connection is detected, it may only be an asperity contact with either not enough conduction path for the application or it may be at risk for fretting corrosion in the long term due to lack of proper normal force of the pin to the barrel. With the advent of EU RoHS legislation limiting Pb use, HASL finishes for PCBs are less common, but press-fit may be needed for some exempted applications where Sn-Pb solder is still in use or when Pb-free HASL is chosen as a PCB surface finish. Excessive plating or deposits on PTH barrel walls and annular pads will register as excessive pressure during the press-fit process; another reason why precise equipment is needed for pressing as opposed to a manual machine such as an arbor press. Equipment will be discussed subsequently.

High-aspect-ratio holes (PCB thickness:PTH diameter) may have irregular plating where the thickness closest to the board’s outer layers is within acceptable thickness limits, whereas plating thickness in the middle of the PTH may be abnormally thin. These thin deposits are caused by plating bath stagnation and exhaustion—a zone of poor electrolyte circulation within the high-aspect-ratio PTH barrel. This condition may also lead to poor contact of the press-fit pin against the PTH barrel wall and contact reliability issues. The opposite can be detrimental also, where the PCB vendor strives to attain the proper plating thickness within the PTH barrel, but plates too much material at the barrel openings and on annular rings leading to the condition shown in Figures 51.7*c* and 51.8.

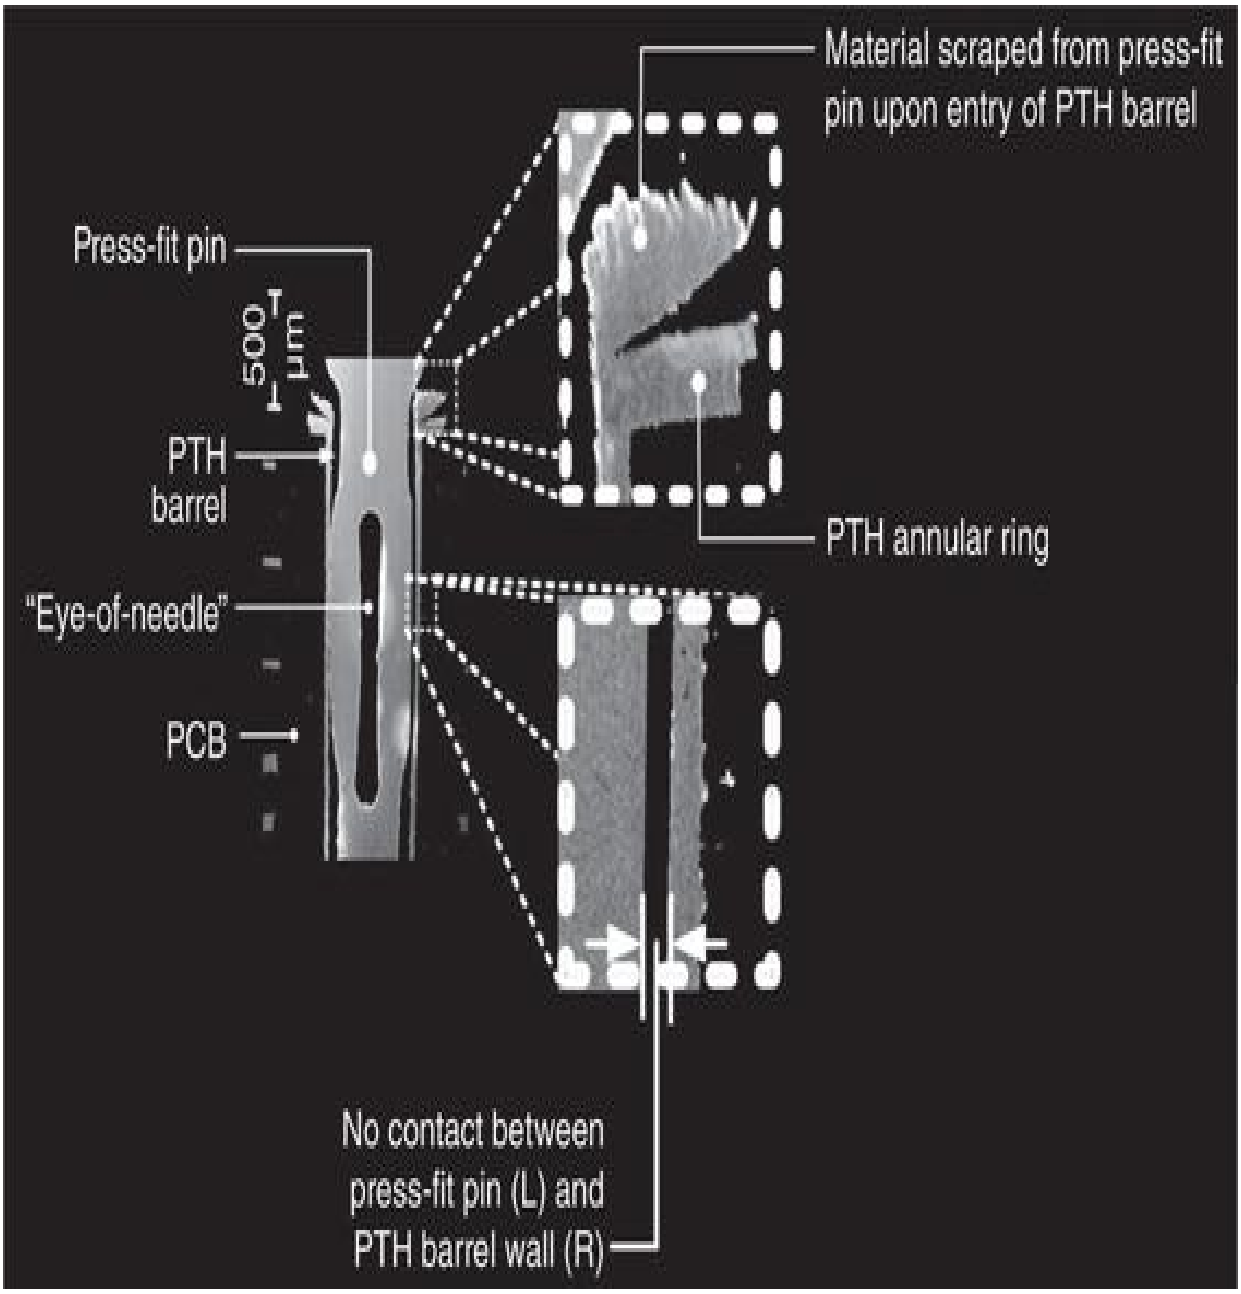

FIGURE 51.8 Excessive nickel plate on the PTH annular ring and at the PTH barrel entrance has caused an undersized finished hole at the top of the barrel. This has triggered three problems: (1) at the onset of the pressing process, the tight fit shaved the press-fit pin resulting in a metal mass that could become a shorting hazard were it to break free (top inset). (2) Forces were so great that it deformed the barrel and lifted the PTH annular ring slightly off the PCB surface (top inset). (3) It has overcompressed the EON section of the pin at the top of the barrel and there is a gap between the pin and the PTH barrel (bottom inset). (*Scanning electron microscope (SEM) micrographs courtesy of A. Alexander, Jabil Circuits, Penang, Malaysia*.)

51.6.3 Slivers

The Pb of Sn-Pb solder-coated barrels is known to reduce the force required for press-fit connector insertion and seating. Although Sn-Pb coating is one of the best surface finishes for pressing, if it is thick, then the press-fit connector pin may skive a thin sliver of solder and push it out the secondary side of the PCB (Fig. 51.9).

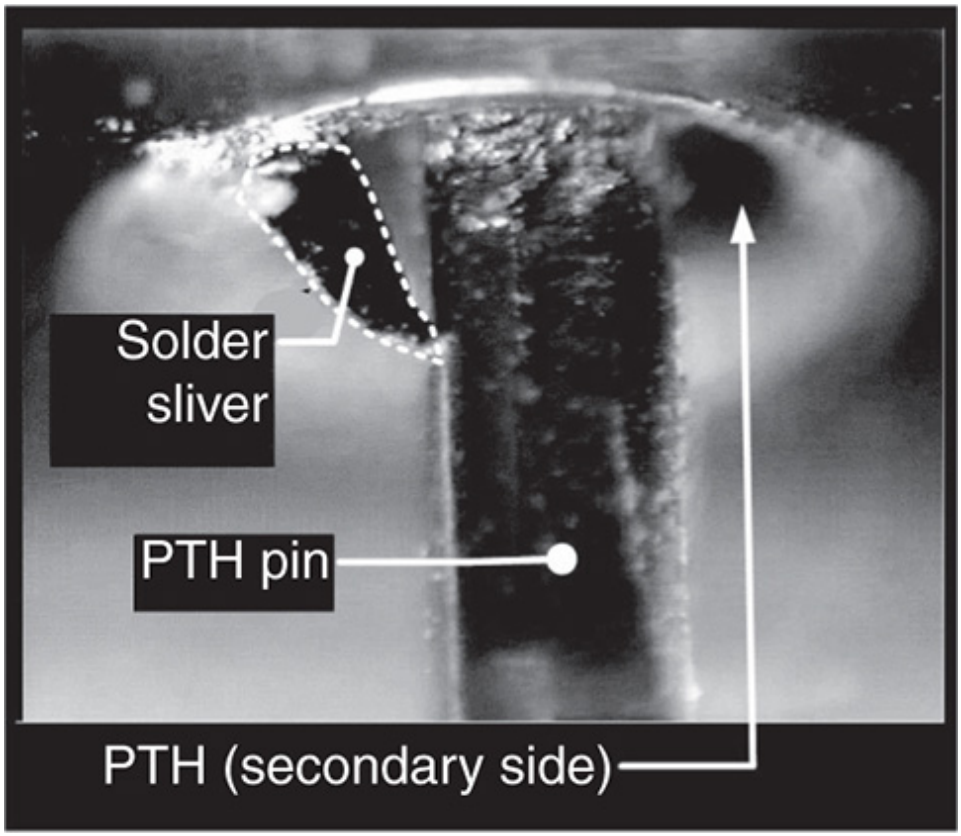

FIGURE 51.9 Micrograph showing a solder sliver on the bottom-side of a PCB. The sliver, if broken off may pose a shorting hazard to the PCA or to the system into which the PCA is installed.

Very often these slivers remain attached to the pin or the PCB, or they become jammed between the pin and barrel. The sliver may break free of its source and cause an electrical short locally or elsewhere in the system. Inspect for slivers after press-fitting especially with a new process, a new lot of PCBs, a new lot of connectors or when using the

same connector style from a different connector manufacturer.

51.7 EQUIPMENT

Several types of mechanical presses are used for applying press-fit connectors to PCBs. The lever-activated arbor press is the most primitive but may suffice for simple, low-lead-count, coarse-pitch connectors, although this is not recommended. One step up is the pneumatically driven press. Although it is easier to operate than the lever-activated arbor press, it does little for process control or assembly repeatability. Higher on the evolutionary scale is the pneumatic/hydraulic combination (the so-called “air-over-oil” press), which offers a somewhat more controllable process.

High-precision pressing cycles are mandated by the latest press-pin connectors with their delicate, molded body features, fragile electrical shielding, and fine pin pitch, so it is advisable to use a machine that is computer-controlled. Aside from force and speed precision for process reproducibility, the latest machines have data loggers that can store press cycle data; an invaluable tool for statistical process control and useful for press cycle root-cause defect analysis or machine troubleshooting. Computer-based machines store process recipes for ram force, speed of compression, ram position and component location if the machine has programmable axes for moving the PCA beneath the ram. The state-of-the-art connector press is electromechanically actuated, relying on a motor-driven lead screw with tachometer speed control, *z*-axis positional encoders, and load cell feedback for an accurate pressing cycle and excellent process repeatability (see Fig. 51.10).

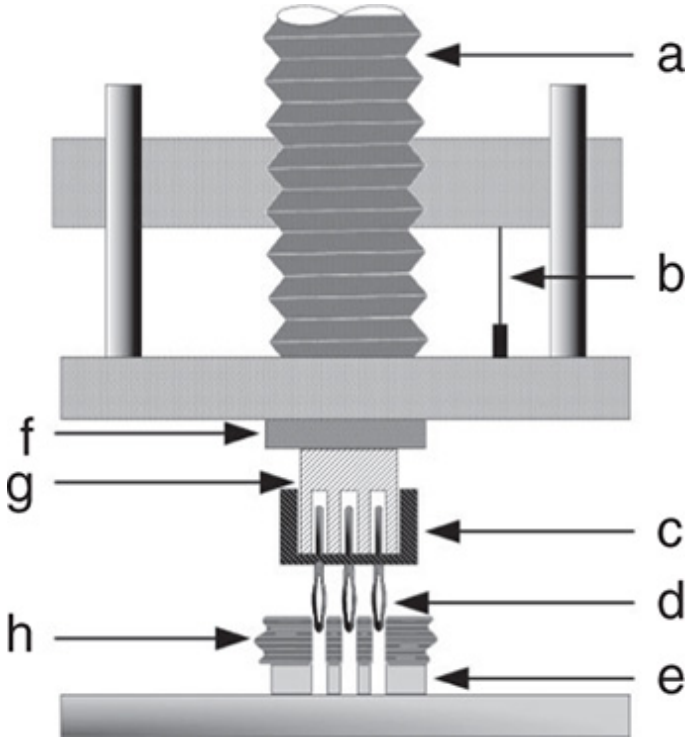

FIGURE 51.10 Schematic of electro- mechanical press used for press-fitting: (*a*) motor-driven ram screw, (*b*) z-axis encoder, (*c*) press-fit connector, (*d*) press-fit connector's compliant pins, (*e*) support tooling, (*f*) pressure transducer, (*g*) connector-specific pressing tool, and (*h*) PCB with plated through-holes.

Some commercially available machines are automated even to the point that they are able to shuttle boards into the press, pick and place connectors, select a connector-appropriate pressing tool and supporting tool anvil, rotate the tools to the proper orientation, and press multiple connectors sequentially on a single board or multiple nested boards. There are several ways to control the press-fit process. Methods and merits of each are discussed in the remainder of this chapter, but first a more detailed review of the mechanics of the press-fit process is in order.

51.8 ASSEMBLY PROCESS

Press tool and support plate are fabricated to match connector requirements and PCA layout. The PCB is placed on the press-fit tooling fixture support plate. The support plate is PCA-specific. It has tooling pins or a nesting feature to locate and immobilize the PCB during the process and has clearances to accommodate any soldered bottom-side components. The operator manually places the connector into the appropriate plated through-holes in the PCB. The ram and tool are aligned manually or automatically to the connector to be pressed. When press-fit connector leads are forced into PCB plated through-holes during a pressing cycle there is a characteristic fingerprint of force versus vertical distance traveled for each connector and PCB type. The various events and slopes that comprise the fingerprint are depicted in Fig. 51.11.

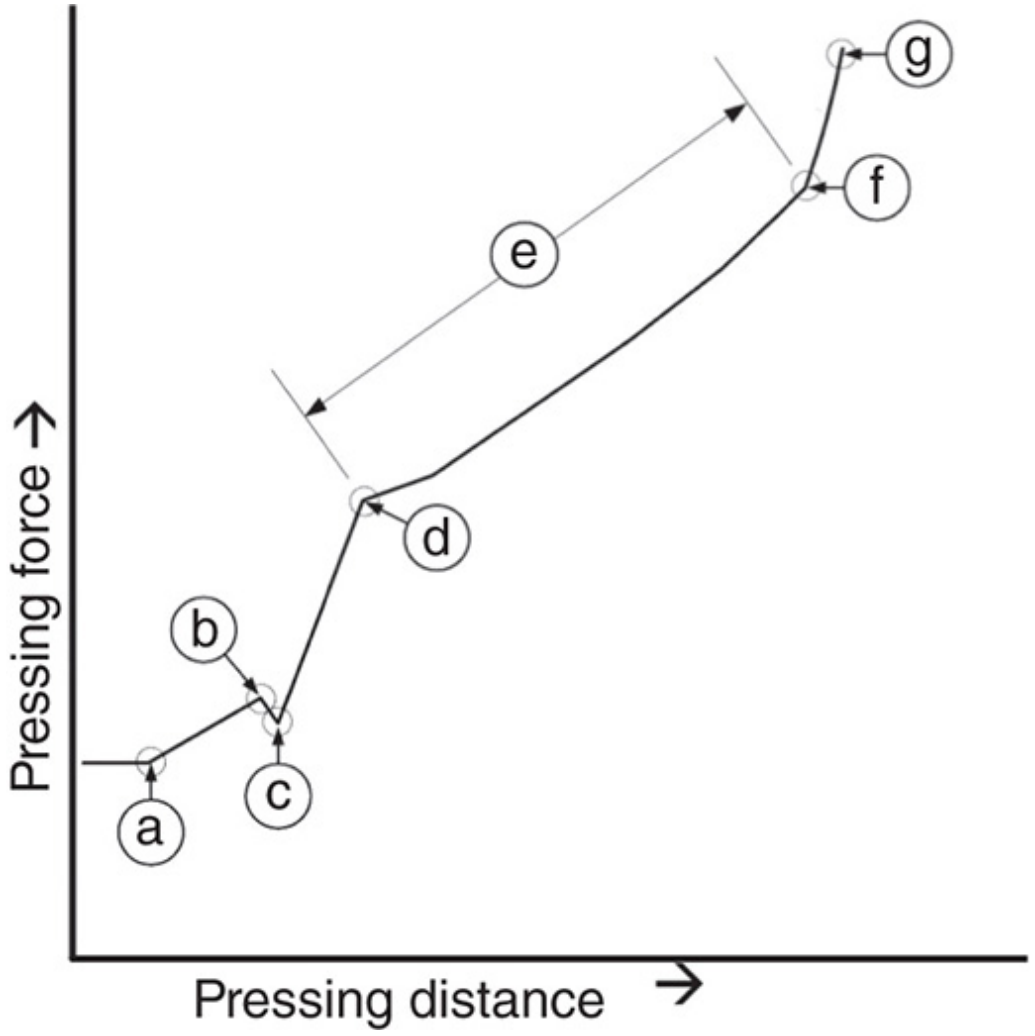

FIGURE 51.11 Force versus distance plot of a press-fit cycle. Inflection points and regions are as follows: (*a*) initial force applied to the press-fit connector and resistance is registered; (*b*) compliant section of pin starts to collapse; (*c*) further pin collapse allows pin to slide into the PTH barrel; (*d*) the pin continues to travel within the barrel resulting in increasing friction (region “e”); (*f*) connector fully seated; and (*g*) continued pressing makes little change in press distance signaling the end of the pressing cycle.

As pressing progresses, connector leads are forced into the plated through-holes and the compliant sections of its pins deform elastically, then plastically to some degree. Although there is plastic deformation, the pins and holes are sized so there is still elastic force present normal to the PTH barrel wall; enough to impart and maintain a gas-tight seal. Continued resistance is encountered due to the friction of the collapsed pins sliding along the PTH barrel walls. A final

inflection in the force/distance plot occurs when the connector housing is fully seated against the top surface of the PCB. Further force affects little or no change in vertical distance and the press cycle is ceased. Were the cycle to continue much after this final inflection, damage to the PCB or to the connector housing would result.

51.8.1 Press Routines

For best results, a method that allows real-time measurement and control of the pressing process is preferred and is available on today's commercial presses. There are four commonly used pressing routines, but only three take advantage of force-sensing, distance-sensing, or real-time feedback control of the modern connector press. Connector complexity and equipment availability dictate press-fit assembly methodology.

51.8.1.1 Uncontrolled Pressing. This was the most prevalent technique for a long time, but it rapidly lost ground to more sophisticated pressing methods, as described later in this section. It commonly relies on an arbor press and human muscle to force the press-fit connector into the PCB. There is neither force sensing nor speed control. It is the least reliable way to press connectors into PCBs and is not recommended for complex connectors or fragile boards. If too high a ram speed is used on a delicate connector, its pins may buckle. Also, this method may not provide enough force for some high-lead count connectors.

Although this type of pressing is discouraged, it may be adequate for low lead-count, coarse-pitch connectors in noncritical assemblies. As with any press routine, a suitable support fixture must be used beneath the board to keep the assembly from breaking or flexing. It should incorporate support to counter the forces of the ram, and relieved areas

to accept protrusion of press-pins below the bottom-side of the board and clearances for secondary-side components as shown in Fig. 51.12.

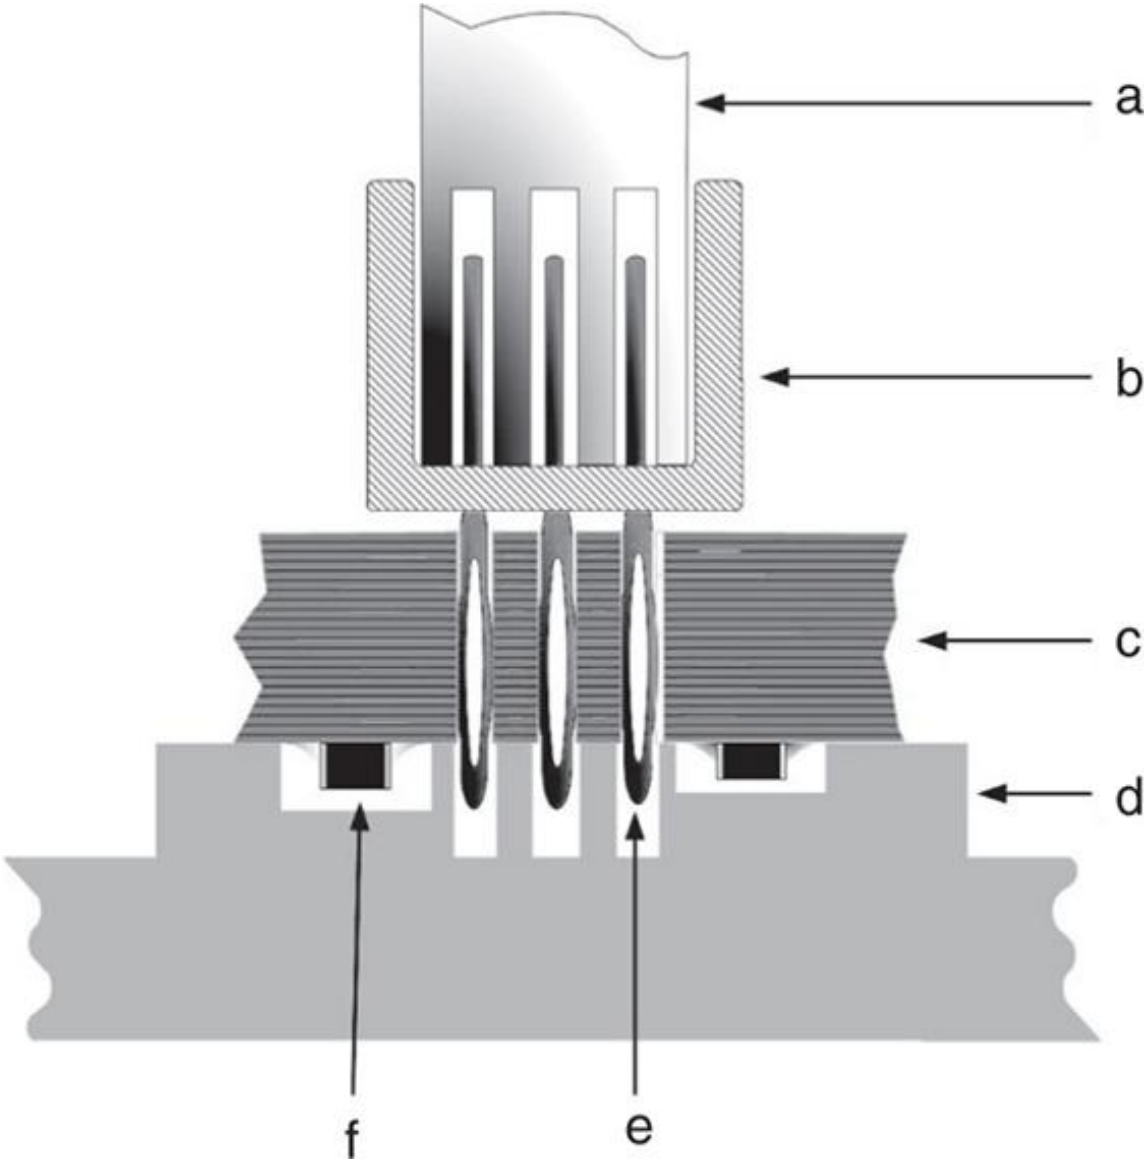

FIGURE 51.12 A rigid and properly designed support fixture is critical for a good press-fit process: (*a*) connector-specific pressing tool, (*b*) press-fit connector, (*c*) PCB, (*d*) support plate, (*e*) clearance in support plate to accommodate and clear press-fit pin tails, and (*f*) routed pocket in support plate to clear soldered bottom-side components.

51.8.1.2 Height-Limited Pressing. As previously described, connector presses have matured into

sophisticated machinery; improved greatly over the arbor press. Some are capable of precisely determining ram height above a datum such as the top surface of the PCB. If board-to-board thickness is consistent, then the connector can be forced into the board to a predetermined standoff height as required by the connector specification. Just as connector pin dimensions vary from connector to connector, so do plated through-holes in the PCB. Pressing to a predetermined height (i.e., *press to height*) ensures that the connector will be seated the same way each time, regardless of the pin or hole condition and the resultant force required to seat the connector (Fig. 51.13). Variations in PCB thickness, variability in the molded cross-section of the press-fit connector body, or molding flash can result in imprecision and negate some of the benefits of this approach.

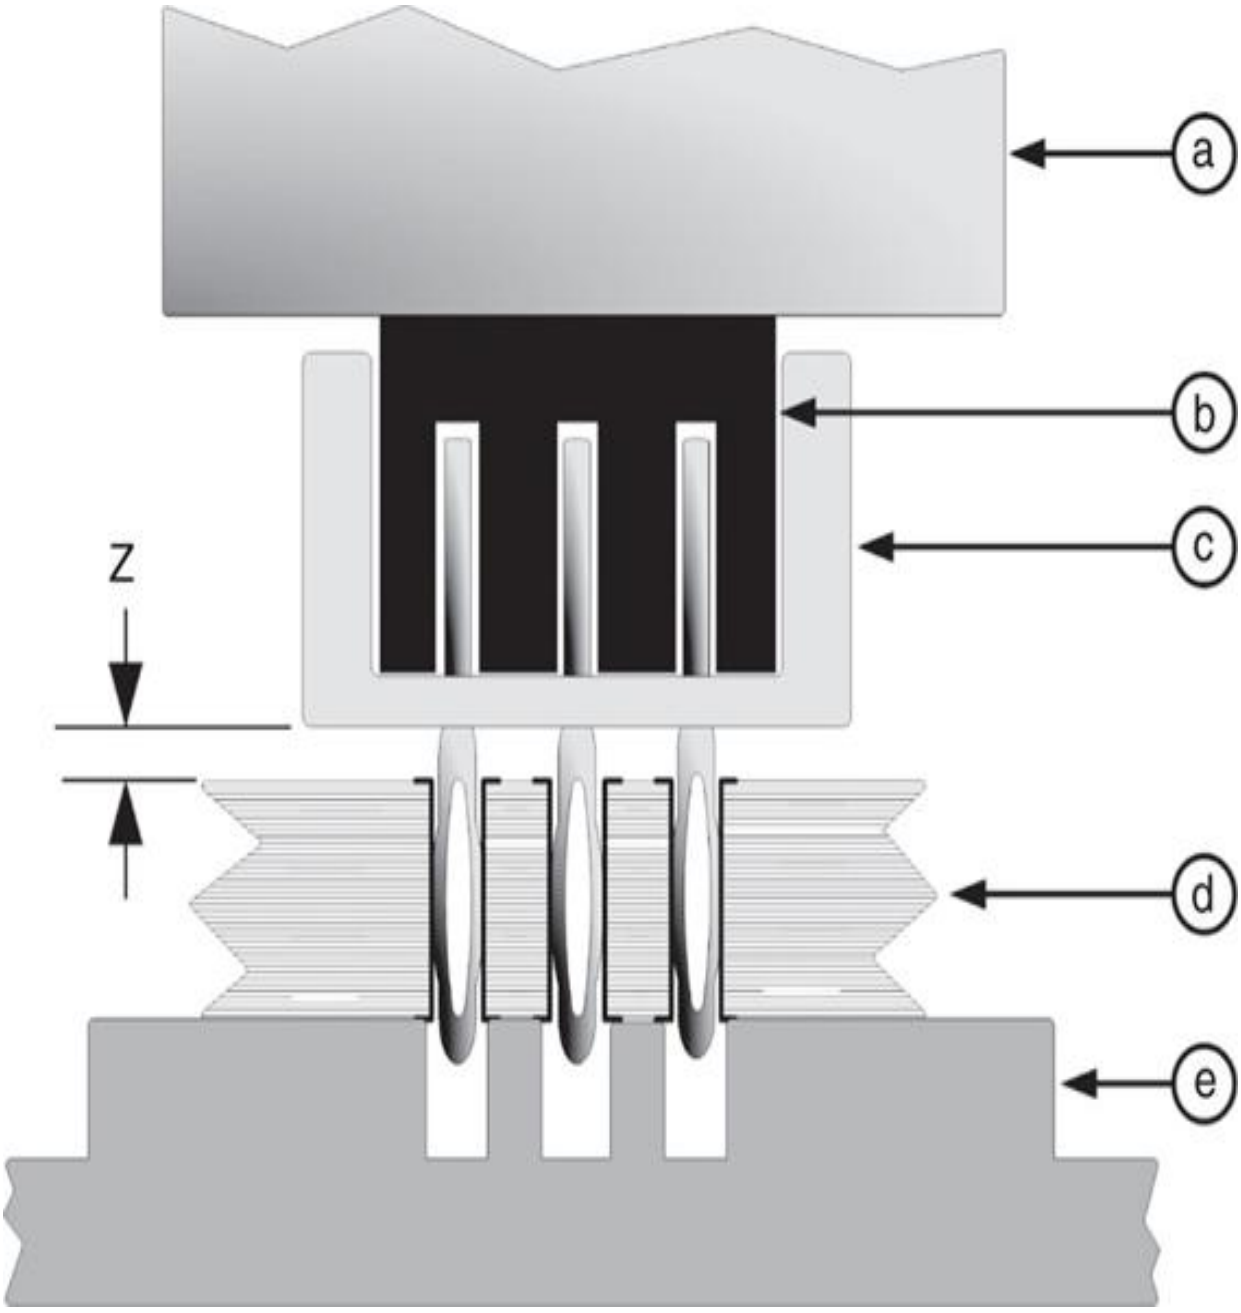

FIGURE 51.13 The “height-limited pressing” routine forces the connector to a predetermined standoff distance, “Z,” from the surface of the PCB. (*a*) Press machine ram, (*b*) connector-specific pressing tool, (*c*) press-fit connector, (*d*) PCB, (*e*) board-specific press-fit support plate (anvil).

51.8.1.3 Force-Limited Pressing. Force-limited pressing (or *press to force*) relies on the intelligence of an instrumented connector press to sense that a predetermined force limit has been reached, at which time the pressing

cycle is terminated. The force limit can be roughly set to coincide with the average force required per compliant pin (available from the press-fit connector manufacturer's specification) multiplied by the number of pins per connector. Application of upper and lower tolerances of specified force per pin coupled with knowledge from empirical trials will help refine the acceptable press force envelope for a given set of materials. This technique is highly sensitive to the material conditions of the compliant pins and the plated through-hole diameters.

51.8.1.4 Gradient-Limited Pressing. Also dependent on having an intelligent press machine, the slope or gradient of the final portion of the force-versus-distance plot (refer to Fig. 51.11 and the inflection labeled "f") can be used to trigger the end of the press cycle and retract the ram. This routine ensures that regardless of pin size, PTH condition, board or connector variations, the connector will not be over-pressed. This is most reliable when a very steep slope is chosen and refined empirically. Gradients in the range of ≥75 percent are generally favored. This routine is also known as *press to gradient*.

51.9 REWORK FOR PRESS-FIT CONNECTORS

The press-fit operation is inherently high yielding, but problems with the process or a bad press-fit connector or a crushed connector contact in the housing post-process may necessitate the removal and replacement of the failed connector. As a result of the press cycle, the compliant pins of a press-fit connector are plastically deformed. Therefore, once removed, the same connector cannot be reused. It must be scrapped. However, most press-fit connectors are

designed to be reworked—that is, removed or replaced. In some cases, individual leads or contacts can be replaced or banks of leads or contacts can be substituted. Most press-fit connectors require complete removal of the damaged connector for replacement with a new one. Many different press-fit connectors are on the market, and each has its own manufacturer-recommended repair strategy.

The through-hole in PCBs can generally accommodate two press-fit connector replacement cycles if sized properly in accordance with the press-fit connector manufacturer's specification. The two cycles are predicated on (1) the normal force exerted by the press-pin's compliant section on the PCB's plated through-hole barrel wall and (2) the quality and condition of the PCB's plated through-hole barrel surface after subsequent press-fit connector removals and replacements. Were the normal force of the compliant section on the PTH barrel of a press-pin excessive, it might cut through the barrel, damage surrounding inner layer interconnects or traces or push the PTH barrel out of the PCB. Instead, the press-fit connector normal force is optimized to permit gas-tight seal without excessive deformation or deep skiving of the barrel wall. Once a connector or connector pin is replaced, the new connector/pin must result in a gas-tight pin-to-barrel seal for reliable contact. Each time a new press-pin is inserted into a plated through-hole, there is opportunity for the barrel to deform; the more insertions into the barrel, the deeper the deformation. It is for that reason that the industry standard design goal for compliant-pin connectors is generally targeted at only two replacement cycles. Beyond two replacements, there is the possibility that the barrel will be thinned and damaged, impairing press-pin contact reliability or compromising PCB inner-layer trace-to-barrel interconnections.

Press-pin rework tools vary greatly. In some cases, they are designed to remove and replace a single pin. In other cases,

the tool may be designed to help dislodge an entire connector from a circuit board. In many cases, contacts are “bottom-loaded”; inserted into the bottom-side of the molded press-fit connector housing. For such connectors, the molded connector body (insulator) is pulled with pliers or a specialized tool, and then individual pins are pulled by pliers one by one in preparation for replacement. Sometimes multiple press-pin ground or power leads are stamped into discrete wafers, and then the wafers are inserted into the plastic molded connector body to form a single press-fit connector. In this case, individual wafers can sometimes be removed and replaced rather than having to replace single leads or the entire connector. Repair tools and repair strategies are generally available from the connector manufacturer.

A fixture can be constructed to facilitate removal of some types of connectors. A rigid board support is built to hold the PCB upside down with clearance machined into it to accommodate the failed part. A flat-rock tool (a piece of flat, hard metal stock) is positioned over the pins of the connector to be removed. The presses ram is slowly lowered onto the pin tails displacing them until they are flush with the bottom-side of the PCB. Although this does not remove the connector completely, very often it will push the compliant sections out of the PTH far enough out that it only takes a small force to remove the connector or the connector’s pins (Fig. 51.14).

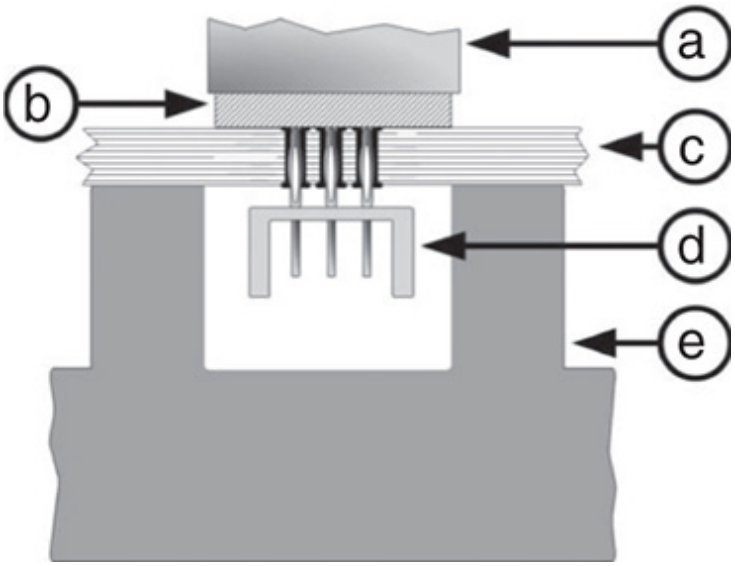

FIGURE 51.14 Pressing on connector pin tails will aid in removal of a failed press-fit connector. Pins can only be pressed flat to the PCB surface but this generally makes connector removal easier. Care must be exercised not to damage components or flex the PCB during component removal. (*a*) Press machine ram, (*b*) flat-rock tooling, (*c*) PCB, (*d*) failed press-fit connector, and (*e*) support tooling.

Removal of the connector or the pins is still relegated to a manual operation. Pliers or a special tool may be required for this.

Building a tool to fit inside the PTH barrel to completely remove pins is not recommended. There is danger of scraping the PTH barrel, pushing the barrel out of the PCB or damaging inner-layer interconnects to the PTH barrel wall if the tool is not sized properly, damaged or is even slightly out of alignment.

To avoid damage to the board, components, or solder joints during press-fit connector removal, the PCB must be supported so that it is not flexed. PCB flexure will break or crack solder joints and the damage will not be visually evident. It is a good practice to verify circuit integrity by electrical test before and after repair to ensure that it is not degraded as a consequence of the repair cycle. If a connector is replaced because of pin stubbing on the surface of the circuit board (Fig. 51.15), ensure that the surface and

underlying traces of the circuit board have not been damaged by an errant lead.

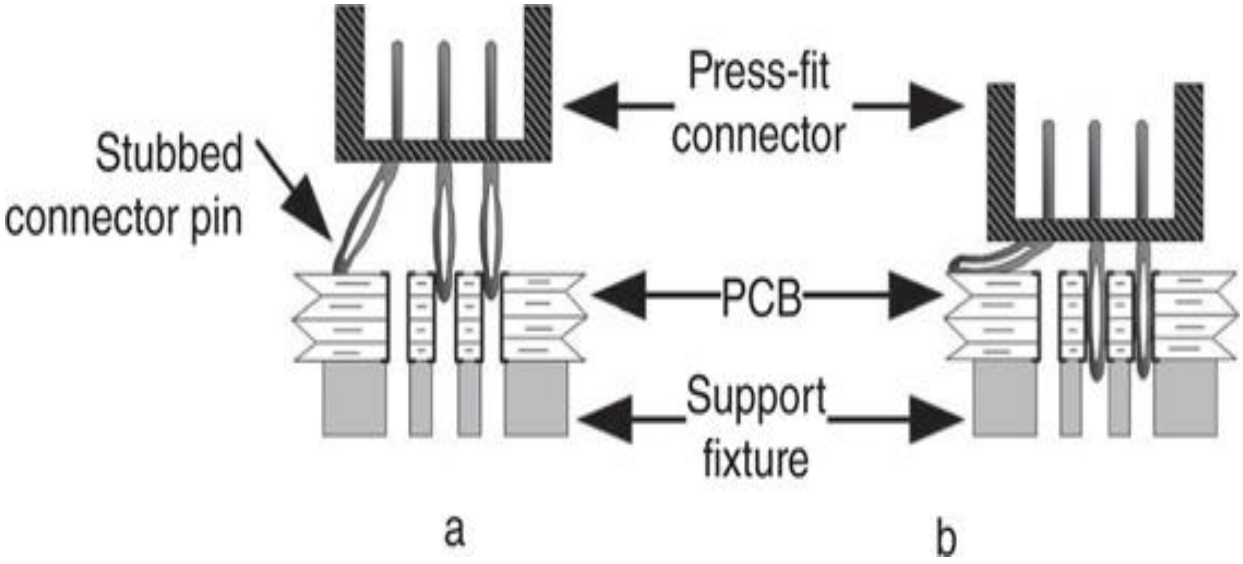

FIGURE 51.15 Stubbing: (*a*) misaligned pin impacting the surface of the PCB, and (*b*) stubbed pin folded under the connector as more seating force is applied by the press. Stubbing may damage surface or subsurface electrical circuitry.

Another defect occasionally seen at rework is surface damage caused by a leaning connector or by overpressing a connector into a board. Figure 51.16 depicts the leaning connector condition while the inset shows a micrograph of the damage to a subsurface trace.

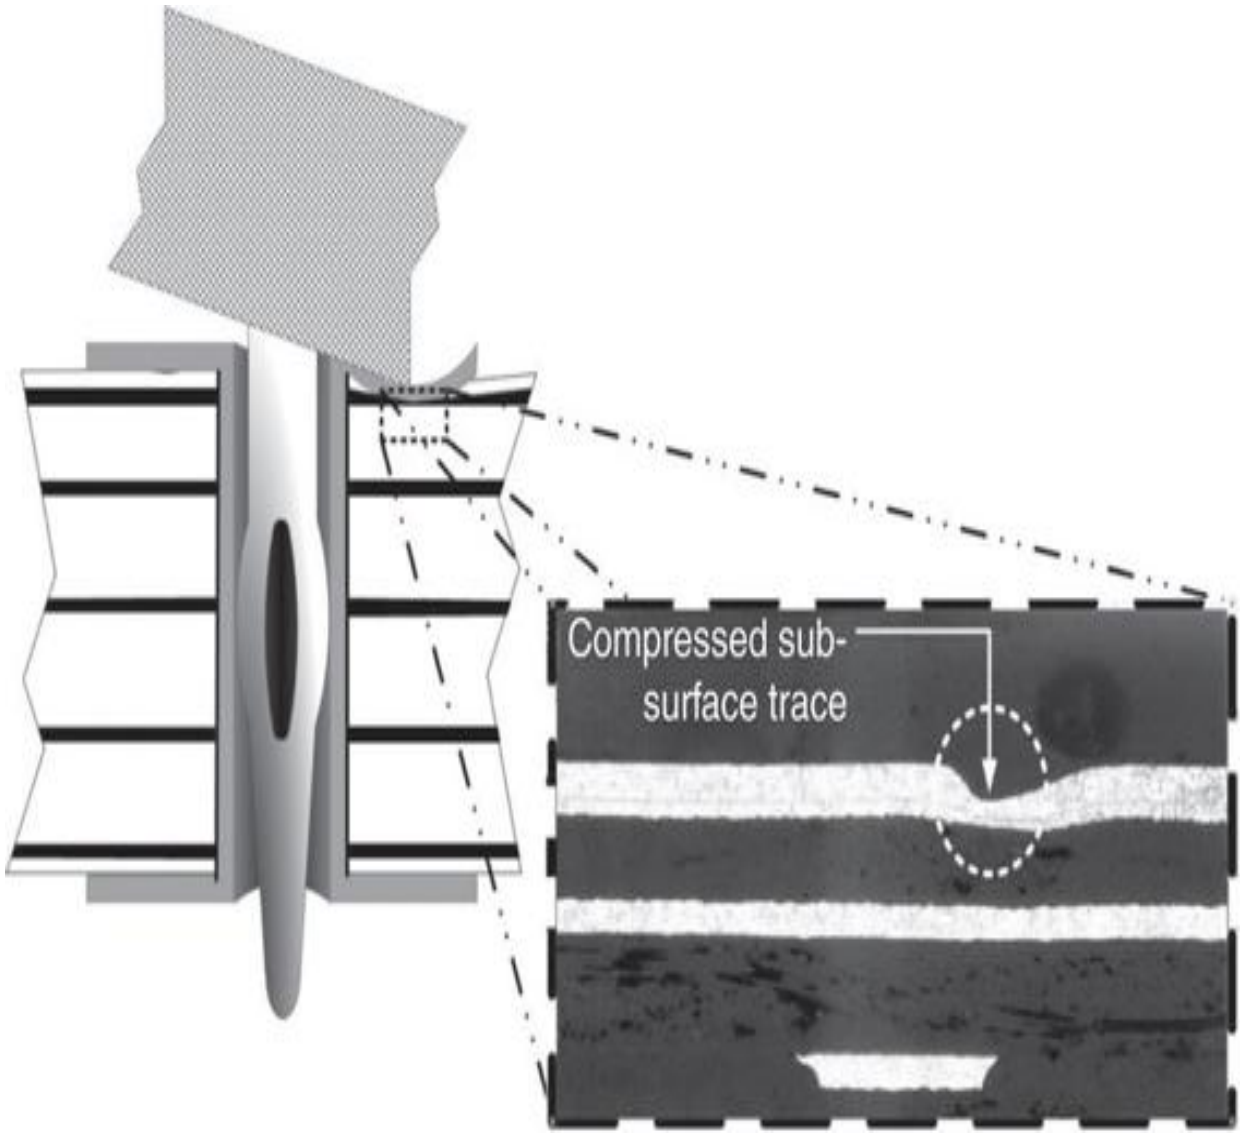

FIGURE 51.16 Canted connector during pressing caused sub-surface damage. The cross-sectional micrograph shows a copper trace below the PCB surface that was compressed to the point that it was no longer an appropriate conductor. In this case, circuit heating resulted due to the diminished cross-section of the trace and surrounding damage.

Compression of a conductor may sever it or thin it to the point that it can no longer conduct properly and excessive heating may ensue. While it is not practical to look for subsurface damage, there should be ample evidence of impact on the PCB surface.

51.10 PCB DESIGN AND BOARD PROCUREMENT TIPS

51.10.1 Clearance for Press-Fit Tools for Assembly

To avoid process problems and damage to adjacent components, there should be sufficient clearance in the board layout design to accommodate pressing tools and board supports.

51.10.2 Long Pins Preferred

When possible, use press-pin contacts slightly longer than the board thickness so that connector pins will protrude from the bottom-side of the board after the pressing cycle. Pin protrusion permits easy inspection of the finished assembly. A missing pin is evidence of pin stubbing, buckling or pin damage.

51.10.3 PTH Size and Surface Finish

Follow the press-fit connector manufacturer’s recommendation for PTH finished hole size, tolerances, and acceptable or tested surface finishes. Cross-section sample boards (mechanical scraps from board shop) to qualify the PCB vendor and determine typical PTH barrel profile. This is particularly important for PCBs with high-aspect-ratio (depth:diameter) holes. Ensure that wall thicknesses of plated through-holes are uniform through-out their depth and meet connector specifications. Make certain that the surface finish on the PTH annular ring does not interfere with

insertion of the compliant press-fit pin as may be the case with HASL or thick electroplate coatings.

51.10.4 Avoid Circuits Beneath Press-Fit Connector Stand-Offs

During press-fitting, molded connector housing stand-offs may crush any electrical traces or planes on or the near the surface of the PCB. Design in keep-out areas to avoid damaging circuit traces below.

51.10.5 Properly Space Connectors for Rework

Ensure that there is enough space between and around connectors to allow for rework. Devise the rework method before PCB lay-out so the designer can provide clearances in accordance with the rework strategy and requisite tooling.

51.11 PRESS-FIT PROCESS TIPS

51.11.1 Use a Proper Press

Use of an electromechanical press is recommended for best precision and process feedback. This will eliminate uncontrolled press cycles as from an arbor press. It will also improve the reproducibility of pressing as compared to using and “air-over-oil” type of pneumatic press.

51.11.2 Rely on Data Logging and Force Graphing

Today’s presses come with data logging options that enable statistical process control and diagnosis of press cycle failures. After pressing, examine the press-cycle force/distance graph to better understand the process. Set flags and warning on the press so that the operator is alerted when the process exceeds a process limit.

51.11.3 Check Connector Pins for Damage and Alignment

Prior to insertion into the board, visually inspect press-fit connector pins for straightness and integrity. An inexpensive go/no-go gauge (Fig. 51.17) can be machined to check that connector pins are in proper alignment. This is particularly advantageous for connectors that are complex, high lead-count, have delicate pins, of high value or are pressed into a high-value PCA. The gauge should be constructed so that it neither compresses the compliant section of the press-fit pin nor damages its surface coating. This is especially helpful for fine-pitch press-fit connectors (1 mm centers) and is better than relying solely on visual inspection for pin field integrity.

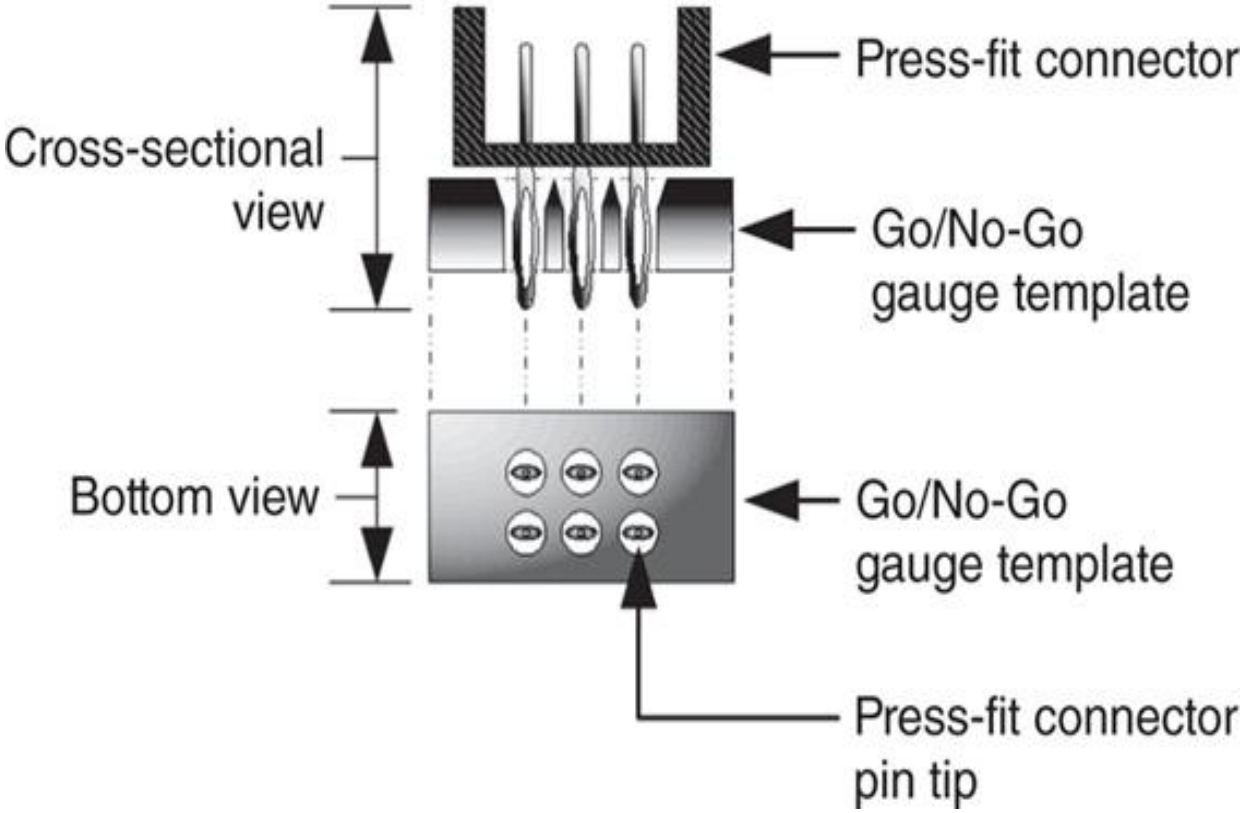

FIGURE 51.17 Gauge for checking connector pin positions prior to pressing. This is best used for high lead count, fine-pitch pin press-fit connectors. Clearance holes in the gauge should be just large enough to offer no mechanical interference when the connector is inserted. It should be made out of an ESD-safe material that will not cause any surface finish damage. If the connector slides in readily, it is an indication that pins are aligned and ready for the press-fit operation.

51.11.4 Keep the Press-Fit PTH Clear of Foreign Material

Protect press-fit PTH holes from extraneous solder, flux, surface-mount adhesive, spot mask, or other contaminants from surface-mount, wave-solder, or hand-solder processes. Use of a wave pallet or high-temperature masking tape (e.g., polyimide tape) to shield press-fit locations during other processing is advisable. If tape is used, inspect first articles to ensure that high-temperature masking tape residue does not foul press-fit holes. Polyimide tape with acrylic-based

adhesive is best for this application, as residues will be absent or minimal.

51.11.5 Use the Proper Press Tooling

Use hardened-steel pressing tools as sold or recommended by the connector manufacturer to avoid damage to the connector or the PCA. Aluminum tools wear out quickly and are easily damaged or deformed. Board supports can be made of aluminum.

51.11.6 Provide Proper Board Support

Adequately support the PCA during the pressing operation so that connectors can be fully homed and that the board is not overflexed. Excessive board flexure may cause solder-joint cracking, broken PCB circuit traces, and board delamination. This is especially important for the characteristically inflexible ball- or column-based solder joints of area-array devices such as BGAs and CCGAs.

The best support will be localized directly under the connector to be pressed. Ensure that the support includes clearance for backside pin protrusion; otherwise, pins will stub and bend on the supporting anvil. Support tooling design should carry appropriate relief features for bottom-side components and fixturing features such as tooling pins to accurately locate the PCA and hold it in position during the pressing process. Tooling pins should be kept as short as possible to facilitate removal of the PCA without inadvertent flexure. Tooling pins should have rounded (bullet) tops to enhance loading the PCA on the fixture and to avoid damage to the PCA due to sharp features as from a squarely cut pin.

51.11.7 Inspect Parts after Pressing

Set the press profile to match the connector manufacturer's instructions. After set up of the profile, press some sample parts to ensure that the pressing routine is not damaging the PCB surface, the connector or tooling. Do not overcompress.

Check the connector after pressing for even bottom-side pin protrusion, top-side connector body seating height, damage to the connector body or movement of contacts or electrical shields (if so equipped) within the connector.

51.11.8 Sliver Inspection

Check the bottom-side of the board for sliver formation (skived material from the pin or PTH barrel). If they are found, check PTH for finished hole size and uniformity of plating within it. Metallurgical cross-sectioning will be necessary for this inspection. Work with the board shop to ensure that drilled and plated holes are sized appropriately for the press-fit process and that excess material (HASL solder or plating) does not adversely alter the finished hole size or hole profile. Gauge the connector pins to ensure that they are within specifications also.

Loose slivers may cause electrical shorting on the board or other boards within the system enclosure. Brush any slivers with a soft, ESD-safe brush and use filtered, ionized air to blow-off the bottom-side of the PCA once silvers are removed.

51.11.9 Electrical Testing

In the case of high-friction surface finishes, such as OSP-copper or tin, forces applied during the press-fit process may be so great as to cause damage to the PTH barrel or adjacent

inner- or outer-layer circuit traces. Check the board visually and by electrical test (in-circuit and functionally) as part of a first article inspection.

51.11.10 Check Tooling Frequently

Check for excessive tool wear or damage. A damaged tool can ruin a connector or PCB and replicate the damage over many boards.

51.11.11 Soldering and Press-Fit Pins

Apply press-fit connectors after all SMT and wave-soldering operations. Do not try to solder press-pin connectors in place. Press-fit connector bodies may not be reflow-compatible. Soldering a press-fit connector will also make rework difficult or impossible.

CHAPTER 52

PRESSURE-INTERCONNECT LAND GRID ARRAY SYSTEMS

Gary M. Freedman
Colab Engineering LLC, Stow, Massachusetts

52.1 INTRODUCTION

The solderless land grid array (LGA) device is a package that relies upon pressure contact to connect it mechanically and electrically to the printed circuit board (PCB). Interconnection is accomplished through a socket or interposer that is sandwiched between the LGA integrated circuit (IC) package and the PCB. The socket has compliant, conductive contacts that match LGA and PCB contact land patterns, all of which match each other in position and pitch. A system of insulators, stiffeners, and fasteners keeps the LGA in intimate mechanical and electrical contact with the PCB. Care in assembly and cleanliness are of utmost importance for successful interconnection and subsequent assembly reliability. The reader should be aware that there are leadless soldered packages also called land grid arrays, but this

chapter will deal with the pressure-interconnect variety of leadless package.

Most often, an LGA-type interconnect is used for mounting a central processor unit (CPU) chip or other active device to a PCB. It is also used for some connectors. An advantage of this type of interconnect is that it facilitates exchange of a chip or connector without the need to unsolder and re-solder it. This enables rapid rework or field upgrades without soldering and without degradation in reliability as may be the case for devices exposed to multiple soldering cycles. Although the technique has been in use for several years, it is still a niche technology but will likely increase in importance as input/output (I/O) counts continue to rise and package size limitations for soldering are encountered.

52.2 LGA AND THE ENVIRONMENT

Since the LGA connection to the PCB is solderless, it is environmentally friendly, requiring no unsoldering for rework. With no need for solder or other hazardous materials, such systems are generally compliant with the European Union’s (EU) Restriction of Hazardous Substances (RoHS) requirements and similar regulatory requirements around the world.

52.3 ELEMENTS OF THE LGA SYSTEM

There are five key essentials and several subelements that make the LGA system practical and reliable. A generic stack is pictured in Fig. 52.1. Key elements will be described in a generic sense in this chapter.

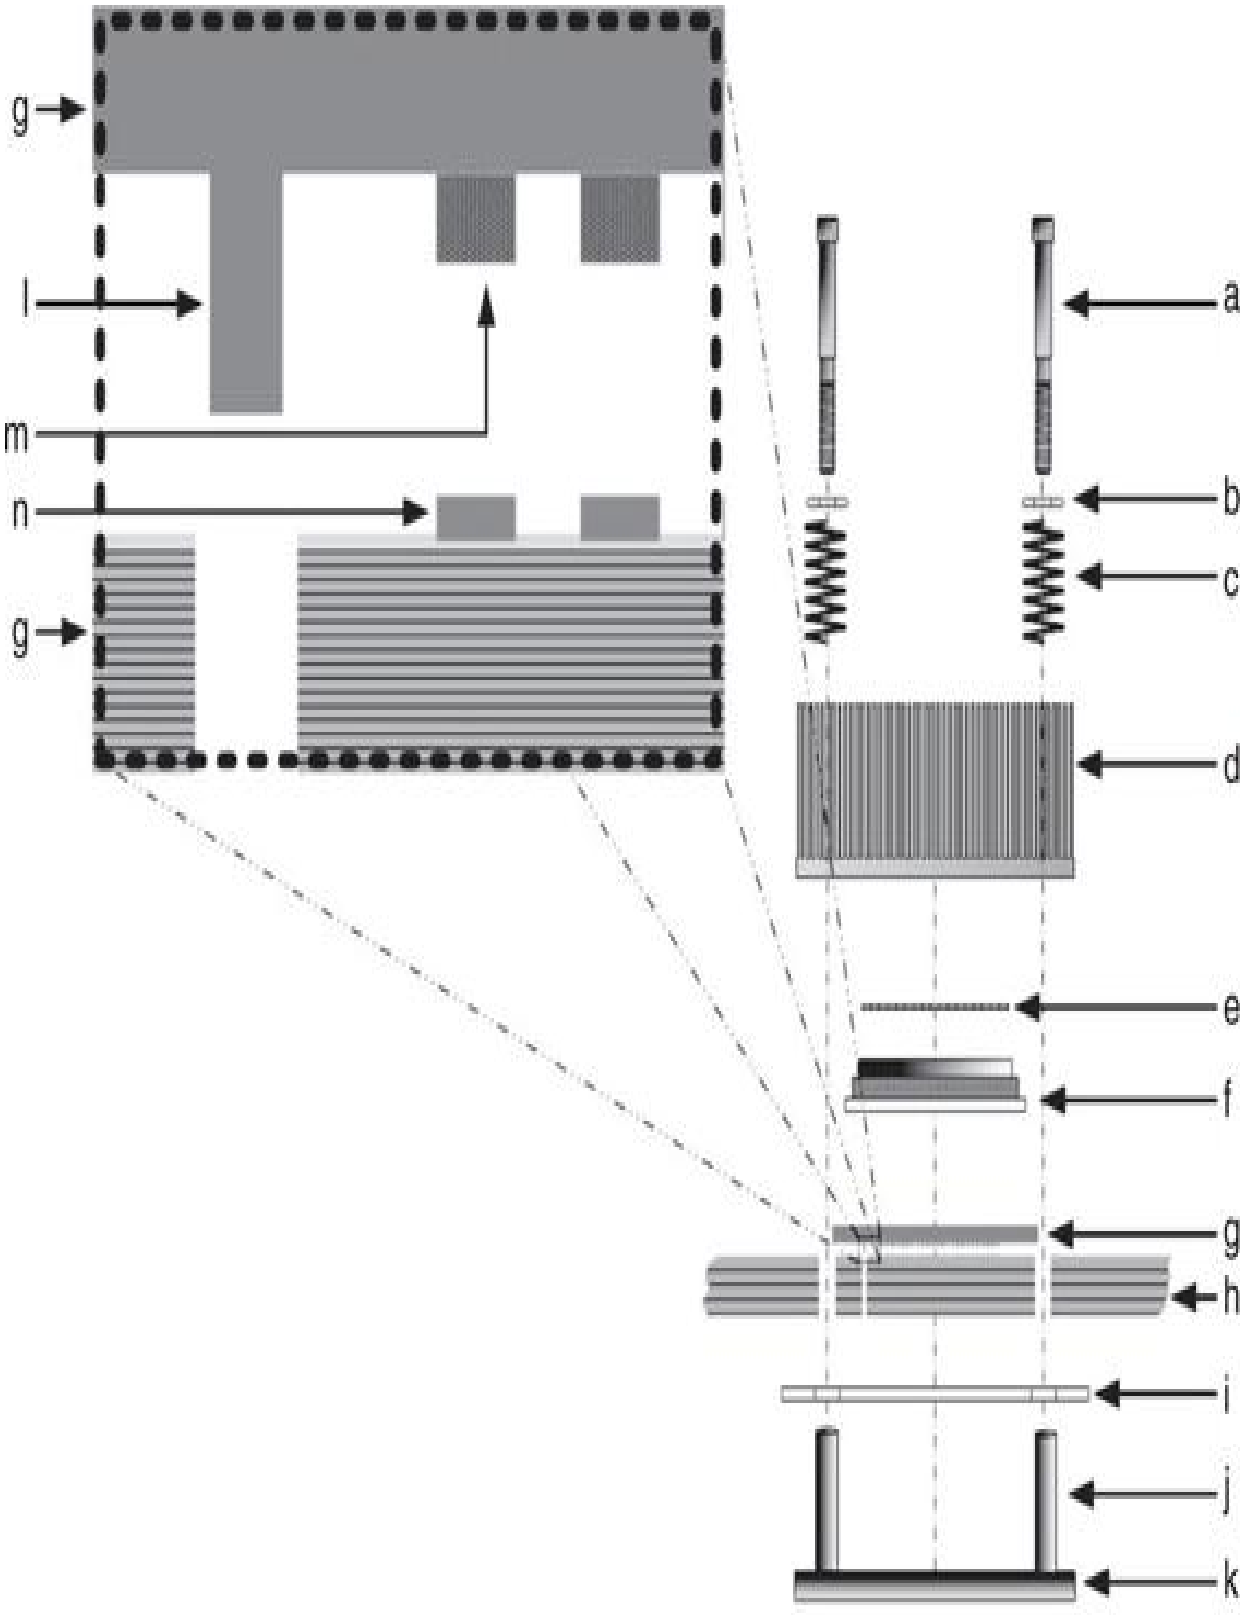

FIGURE 52.1 Exploded view of a typical pressure-interconnect system: (*a*) fastening screw, (*b*) washer, (*c*) compression spring, (*d*) pressure plate (in this

case a heat-sink), (*e*) thermal interface material, (*f*) IC package (LGA), (*g*) interposer (LGA socket), (*h*) PCB, (*i*) insulator, (*j*) bolster plate's threaded posts, (*k*) bolster plate, (*l*) socket alignment post, (*m*) compliant contact of interposer, and (*n*) plated PCB contact land.

52.3.1 PCB and LGA Issues

52.3.1.1 Contact Lands. The PCB is much like any other board and has surface lands to accommodate electrical interconnect of the LGA socket to it. The lands correspond in size and shape to socket requirements. Most often, the LGA lands on the PCB are electrolytic nickel covered by electrolytic gold. These pads are often plated with hardened gold for added contact durability and reliability. Other surface finishes can be used, but should be tested for reliable and long-lasting electrical contact.

52.3.1.2 Drilled Holes. LGA sockets have the requirement for two sets of drilled holes in the PCB. One set is used to accommodate fastening of the bolster plate through the PCB. The second set is used to orient and retain the socket on the PCB. The closely toleranced orientation holes correspond to molded locating posts on the LGA socket. These ensure alignment of the socket contacts to LGA lands on the PCB. The socket manufacturer will provide guidelines and drill pattern recommendations for the socket posts. Most often the LGA sockets come with two different sized posts. These polarize the socket so that it cannot be misapplied to the board.

52.3.1.3 PCB Layout Considerations. There are some layout considerations such as avoidance of components in the vicinity of the LGA socket, bolster plate, and pressure plate. Tall components under an overhanging heat-sink would also be problematic. PCB flatness should be considered so that best contact can be made to the board once the LGA interconnect system is fully assembled. Ensure

that test points will be accessible once the LGA stack is assembled.

52.3.2 Bolster Plate

The bolster plate is the rigid back-side element that serves to anchor the LGA system to the PCB. It is inserted through predrilled holes in the circuit board and provides the means for fastening the clamping mechanism that holds the LGA stack together. It is typically fashioned from a stiff metal such as stainless steel or thick aluminum (Fig. 52.2).

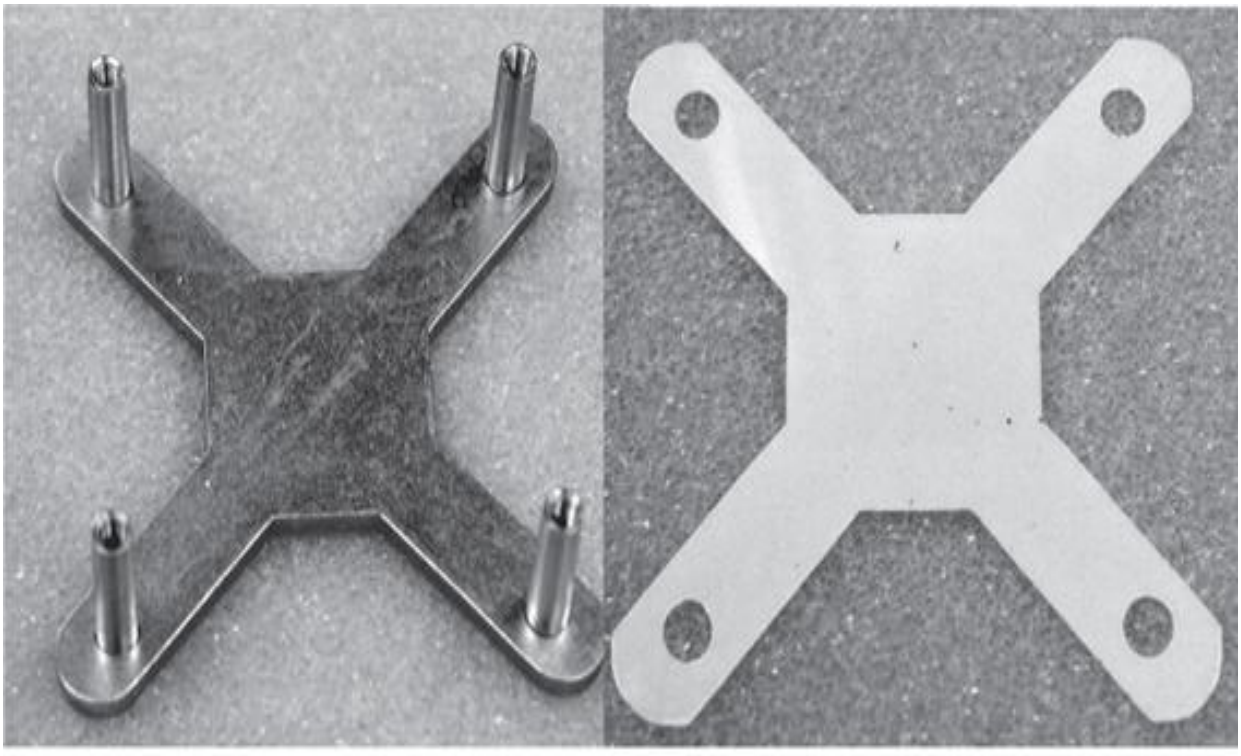

FIGURE 52.2 Stainless steel bolster plate with threaded posts (*a*) and insulator (*b*). (*Courtesy of Hewlett-Packard*.)

The bolster plate may be orthogonal or sculpted to accommodate components in the vicinity or to permit access

to test points for in-circuit testing (ICT) or diagnostics. It should be rigid and once fastened it must flatten out any local PCB bow or warpage in the vicinity of the LGA contact field. It has to impart mechanical stability to the assembled LGA stack to ensure consistent electrical contact over time and through various environmental conditions. Usually an ESD-safe insulator is applied over the surface of the bolster plate, positioned between it and the underside of the PCB. It prevents shorting of the metal bolster to any electrical features on the bottom-side of the PCB such as through-hole vias, test pads, etc.

Placement of electrical devices within the footprint of the bolster should be avoided. If components must be placed within its footprint, the bolster plate needs to be relieved to clear them, otherwise these components would be crushed during LGA assembly and they would also hinder the bolster plate from sitting flatly to the bottom of the PCB. If the bolster plate is relieved to accommodate bottom-side component clearances, it may require thickening so its rigidity is maintained in light of the removed material.

52.3.3 Active Component (LGA IC)

The LGA is an IC package usually made from a rigid substrate such as ceramic. It looks like a ceramic ball grid array (CBGA) without solder interconnects (balls) on its underside (Fig. 52.3). It typically has gold pads on its underside that serve as contact points for the LGA socket. In all other respects, it is like any other ceramic package. The contacts are usually electrolytic nickel over-plated with electrolytic gold. Often, a hardening agent such as cobalt is co-plated with the gold to enhance contact durability for improved long-term reliability.

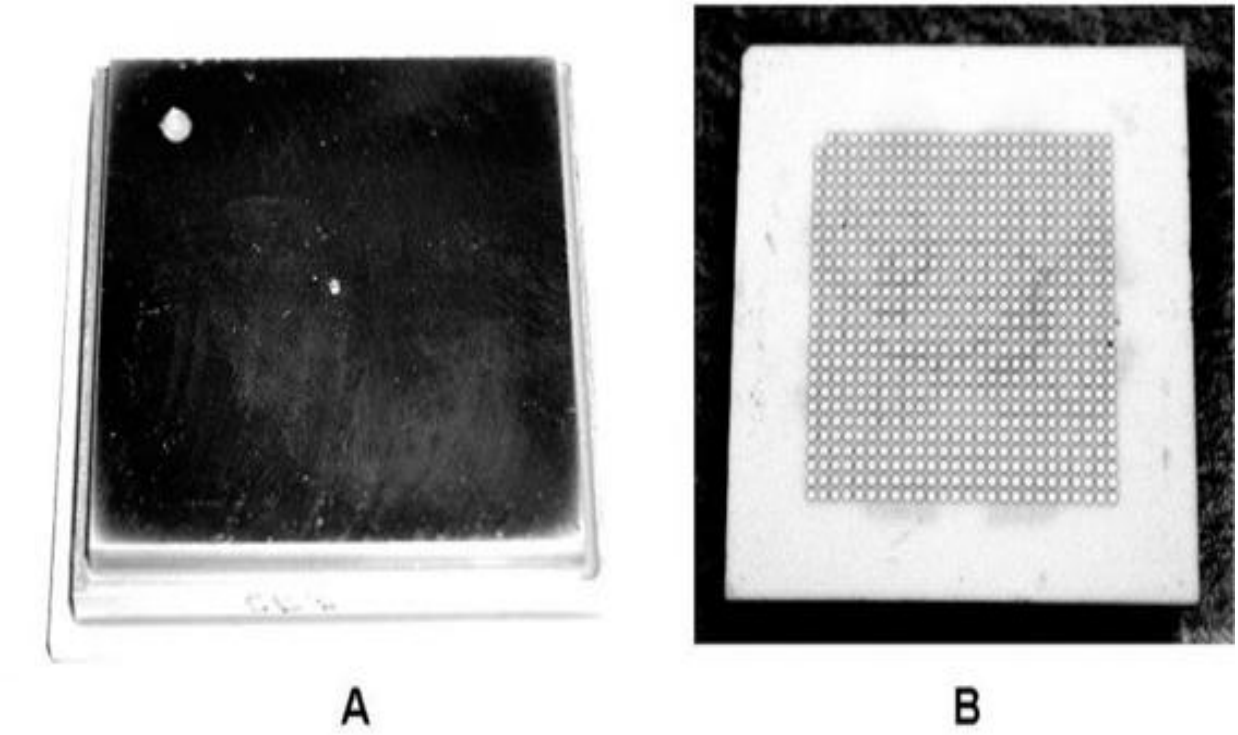

FIGURE 52.3 LGA IC package: (A) top-side of a ceramic LGA package, (B) bottom-side of same package with an array of gold contact. The package is similar to a CBGA without any solder balls. (*Courtesy of Hewlett-Packard*.)

52.3.4 Socket

Many types of LGA sockets (also referred to as *interposers*) are available. There are interposers with traditional dimpled leaf-spring contacts, “Fuzz-Button” contacts, and even metal-filled polymer connections. The contacts are held on a molded insulating substrate (Fig. 52.4). The contacts and socket frame are customized to fit the LGA package pattern and a corresponding footprint pattern on the PCB.

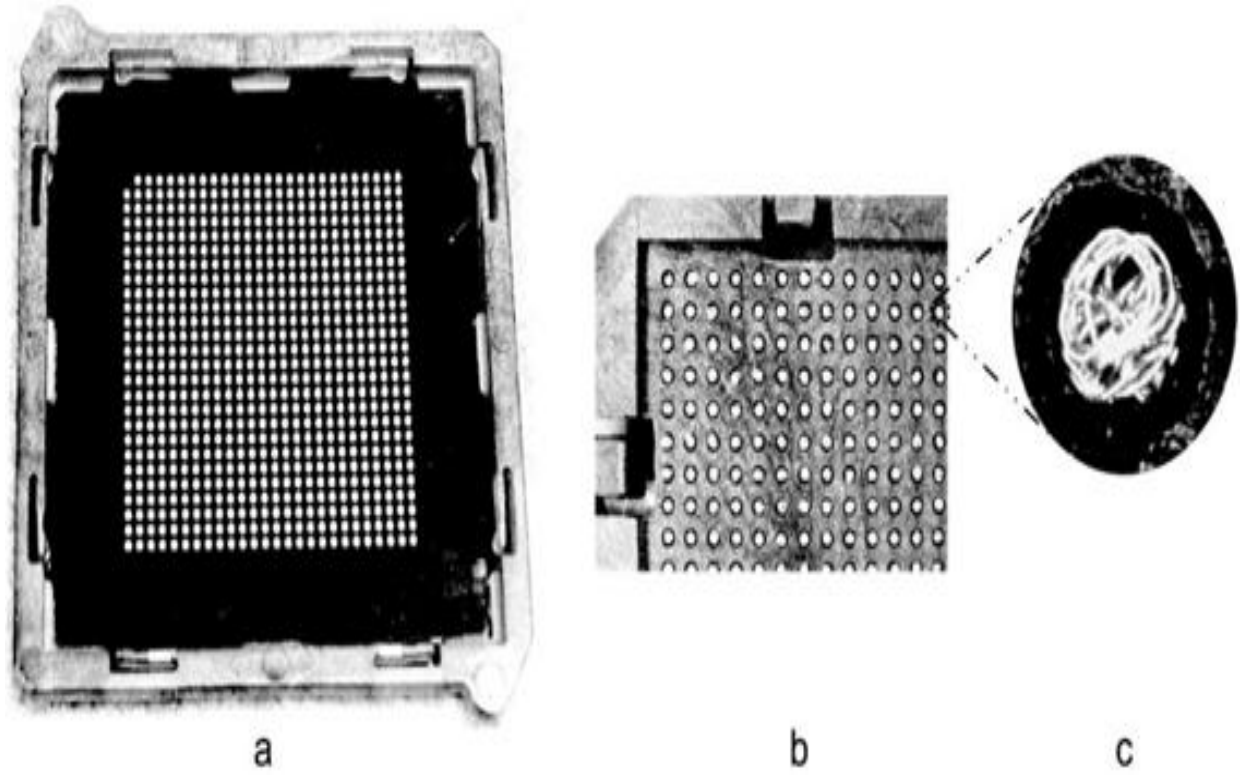

FIGURE 52.4 LGA socket: (*a*) a socket with metal-filled polymer contacts, (*b*) a socket with Fuzz-Button contacts, and (*c*) high-magnification view of a single wire-wound Fuzz-Button.

Each contact is interconnected through the molded substrate in some fashion so that one side connects to the IC and the other side to the PCB (Fig. 52.5).

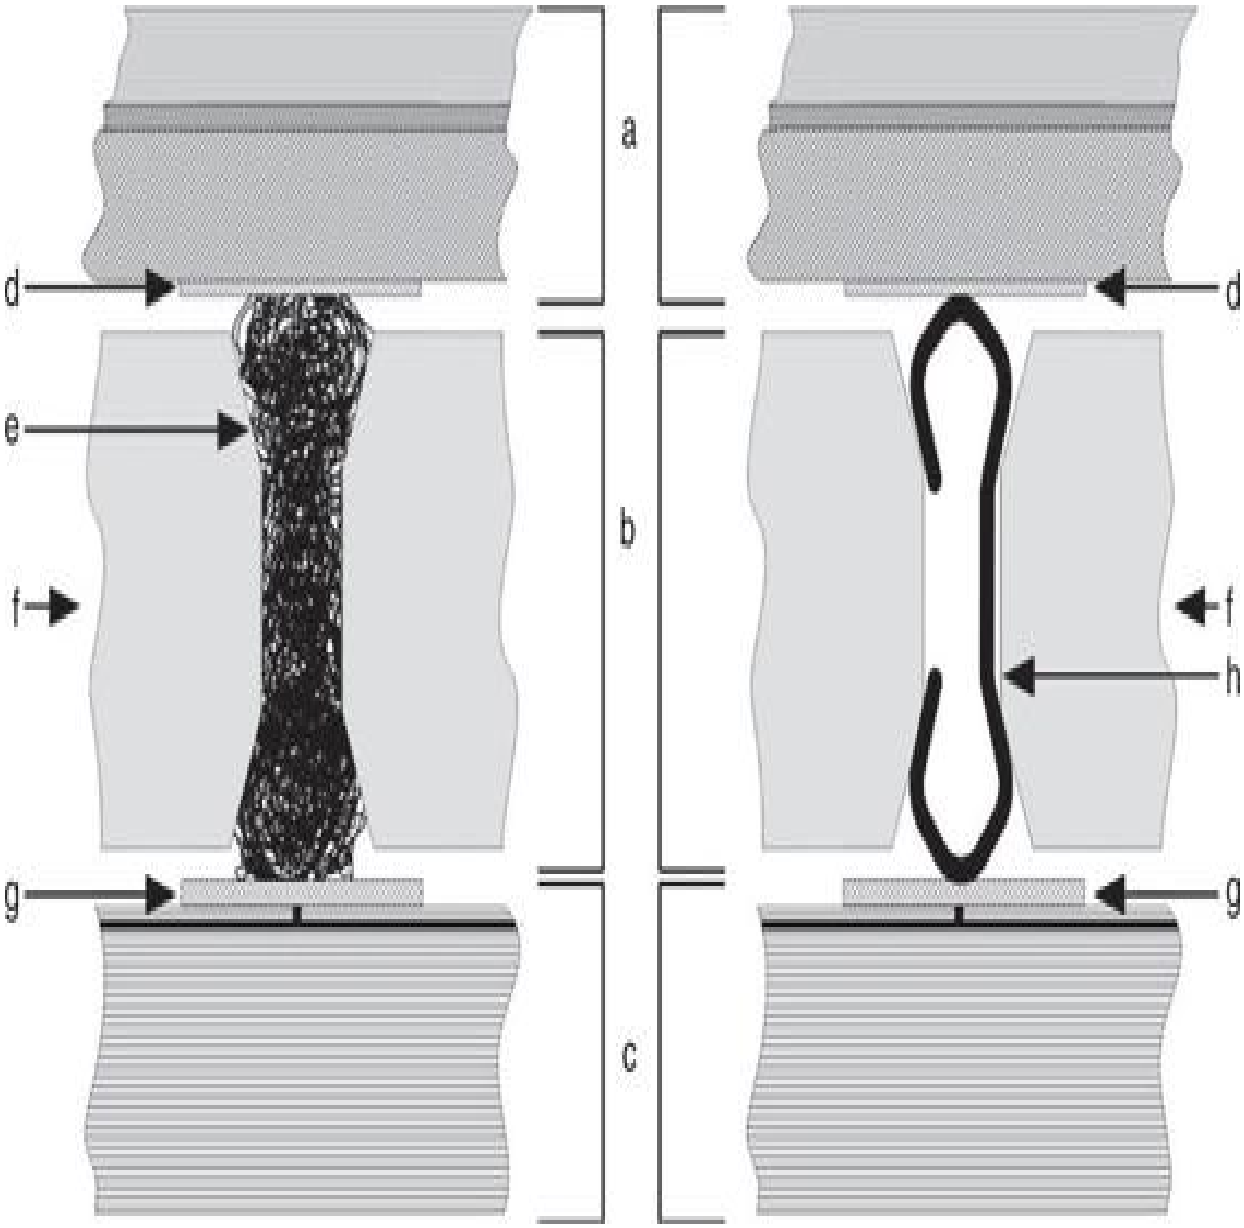

FIGURE 52.5 Interposer sockets electrically connecting an IC with a PCB: (*a*) land-grid array(LGA) IC, (*b*) LGA socket (interposer), (*c*) PCB, (*d*) contact on bottom of IC, (*e*) Fuzz-Button contact, (*f*) socket insulator, (*g*) contact pad on PCB, and (*h*) spring contact.

Additional subelements such as fasteners, washers and springs are required for assembly and to enhance shock and vibration resistance or for thermal management.

Although Fuzz-Button technology is among the most reliable of LGA interconnect schemes, some defects are common to this socket style. Pulled wires (Fig. 52.6) as well

as leaning and missing contacts can occur, although the interconnect reliability is quite high if the socket is in good condition prior to assembly and if the LGA stack is assembled correctly.

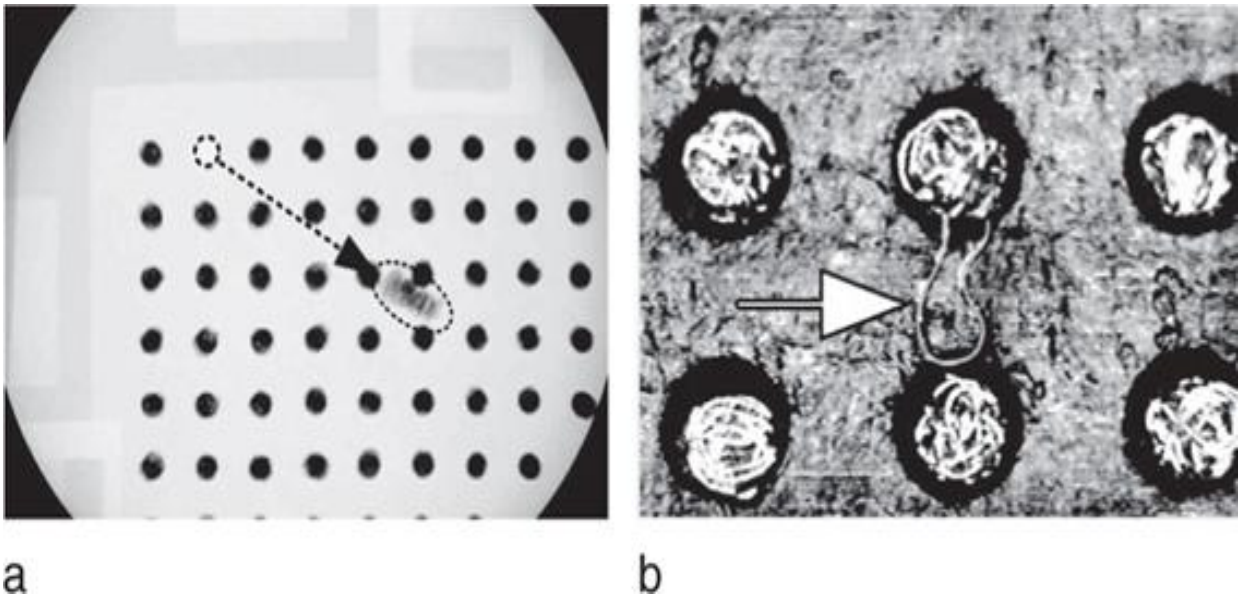

FIGURE 52.6 Defects associated with Fuzz-Button contacts. (*a*) X-ray image of an assembled LGA IC. The dashed circle denotes an empty contact position. The dislodged contact (within the dashed ellipse) lies between the IC and the socket. (*b*) Photograph of a Fuzz-Button contact with a pulled wire that is near shorting.

If too much pressure is applied to metal-filled polymer contacts, they can deform and flow over time, lessening contact pressure. As a result an open or intermittent contact failure may occur.

52.3.5 Pressure Plate

The pressure plate is fastened atop the LGA package and couples to the bolster plate under the PCB. It forces the LGA package in contact with the socket and the socket to the lands on the PCB for completion of the electrical circuit. Besides being responsible for interconnecting the socket to package and board, it imparts the necessary mechanical

rigidity to the LGA stack for shock and vibration resistance and dependable operation. Reliability of this stack is highly dependent on the materials chosen and mechanical design of same. Force on the stack has to be moderated to preclude damage to the IC package or the PCB. Guidance is needed from the LGA package manufacturer and from the LGA socket manufacturer as to how much force can be applied without damaging any elements of the pressure-interconnect stack.

52.3.6 Thermal Management

Frequently, thermal management solutions are built into the LGA stack. The heat-sink, if constructed properly, can serve as the pressure plate. A thermal interface material such as graphite foil or other thin thermal transfer material can be sandwiched between the heat-sink and the IC package to enhance heat dissipation from the IC package.

52.4 ASSEMBLY

In addition to good design, proper process strategy and precise assembly are crucial to LGA interconnect reliability. The following steps should help the engineer achieve good results, but as stated previously, if the design is flawed, interconnect reliability will be flawed as well.

52.4.1 Order of Assembly

LGA assembly should be done after all other soldering, press-fit and mechanical assembly steps are completed. LGA sockets are not rated for high-temperature excursions. The

stress of other manufacturing procedures may be enough to disrupt pressure-interconnection.

Gold pads on the PCB must remain as clean as possible—free of solder, flux deposits, chemicals, and contaminants. Once assembled, all chemicals must be kept away from the LGA socket. The heat of solder rework can also cause interposer damage or LGA device failure, so rework is best completed, where feasible, before LGA assembly or after removal of the LGA. If the LGA is removed for rework, use a shield to protect LGA pads on the PCB from solder, flux, or tool damage.

52.4.2 Prior to PCB Processing

A high-temperature masking tape can be used to cover LGA lands on the PCB. This will protect it from flux residue, spattered solder, stray solder beads, etc. The tape should be capable of sustaining multiple reflow cycles. A polyimide tape with acrylic adhesive[1] is recommended to minimize tape adhesive residue. Thoroughly test any tape before using it to confirm that it does not leave adhesive residue. Inspect PCB pads after tape removal to ensure no residue was left behind. Silicone-based adhesives have been found to leave deposits that can interfere with electrical interconnect. Since silicone is largely insoluble in most common solvents, attempts to clean any residue will be futile.

52.4.3 PCB and LGA Land Cleaning

Cleanliness is one of the most important attributes for successful pressure-interconnect assembly. Pads on the LGA IC and on the PCB should be cleaned and inspected prior to application of the socket. Even if a masking tape is used on the board during processing, there is the opportunity for

materials to condense under the tape. A wipe with isopropyl alcohol, methanol, or a Vertrel-based cleaner is useful for normal flux condensates and process residues. Do not flood the area with solvent. Instead, use a solvent-saturated lint-free wipe or non-shedding sponge. Even lint-free materials can snag on PCB pads, board edges, and drilled holes and leave fibers or debris. Tests should be made to find the most appropriate and abrasion-resistant wipe. Ensure that the cleaned lands are perfectly dry before assembly. A Vertrel-based cleaner is ideal for this due to its inherently low boiling point (generally below room temperature). Because it boils so quickly, it can cause some local moisture condensation which may leave a slight, localized, innocuous discoloration on land surfaces, but its quick drying nature ensures that there will be no liquids within the stack to short at in-circuit test (ICT) or power-up.

52.4.4 LGA Socket Cleaning

Although it is important for the socket to be clean, never wipe it as this could damage fragile contacts. Even the use of compressed air to remove dust may dislodge or damage a contact. It is best to work with the socket supplier to ensure that interposers arrive clean and ready for use.

52.4.5 Inspection

Inspect LGA pads on the PCB and on the LGA prior to assembly. Inspect both sides of the interposer to ensure that contacts are present and in good condition. Holding the interposer socket up to the light will quickly show whether there is a missing contact.

52.4.6 Socket Application

The socket seating plane must be kept parallel to the surface of the PCB. Applying it at an angle can cause damage to the delicate contacts of the socket and compromise contact reliability. The same can be said about sliding the socket on the board; it is likely to result in socket contact damage.

The socket must be oriented properly on the board so that the contact pattern of the socket matches the land pattern on the PCB. There are molded guide pins on the socket that help with this, with one peg larger than the other to match a similar drilled pattern in the PCB. The socket usually has a missing corner contact to match the LGA IC package and corresponding LGA land pattern on the printed circuit assembly (PCA). It is important not to drop the LGA IC package on the socket or slide it on the socket, as doing so could damage delicate socket contacts.

52.4.7 Fastening

So many mechanical designs are available that listing any particular method for LGA stacking is impractical. Some rely on spring clips whereas others use traditional screw fasteners, as shown previously. If held by four screws, as often is the case, then a “tire lug” torque pattern should be employed to ensure even tightening (Fig. 52.7).

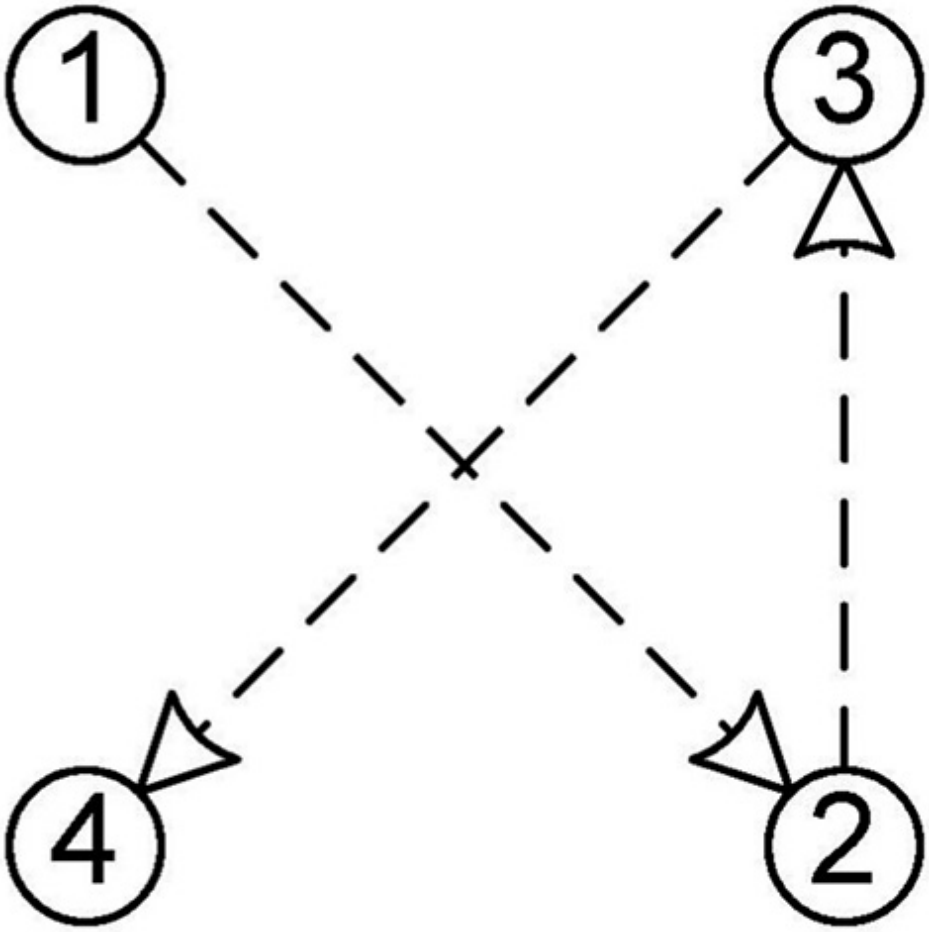

FIGURE 52.7 Manual torque pattern for even fastening of a four-screw LGA stack. Each fastener should receive the same number of turns or partial turns to ensure even seating of the LGA stack.

Slow and even tightening is important to avoid damage to the LGA IC device, the LGA socket or the PCB and to ensure proper compression for reliable electrical contact. The number of revolutions per fastener depends on the pitch of the screw and socket requirements. Ideally a four-headed torque driver should be used with each head rotating at the same speed and a calibrated slip-clutch on each driver to prevent overtightening of the stack.

A tooling plate with strategically located board supports should be created to hold the PCA during LGA stack assembly in order to both retain the board and minimize board flexure for the preservation of solder joints on the PCA.

52.4.8 LGA Socket Rework and Reuse

Ease of device replacement for upgrade or repair is one of the key benefits of using pressure-interconnect technology. Most pressure-interconnect sockets are designed for reuse. Check with socket manufacturer for the permissible number of reuses per their design. Some are specified for as many as twenty replacement cycles. Reliability and reuse depend on a number of factors, including mechanical robustness of the socket, thermal exposure history, shock and vibration experienced during operation, proper initial assembly and exposure to degrading contaminants from the initial process and during field use. Note that there are usually no reuse limits on other elements of the system (LGA IC package, printed circuit assembly, bolster plate, heat-sink, or pressure plate). After each disassembly all parts should be carefully inspected to ensure that contact platings are in good condition and that mechanical fasteners are not showing signs of excessive mechanical wear.

Sometimes, due to the malleability of gold (as used for LGA pads and PCB pads), interposer contacts may stick to this soft metal. Therefore when removing the LGA IC device from the socket or the socket from the PCB, ensure that the socket contacts have not pulled free or distorted. If there is a single contact sticking, this may be indicative of other bent, broken, or displaced socket contacts. Any of these symptoms may compromise interconnect integrity of the stack on reassembly. Sticking is prevalent with filled-polymer or Fuzz-Button contacts and there can be enough adhesion of plated spring contacts to LGA IC or PCB-plated lands to result in damage to these fragile elements.

52.5 PCA REWORK

If soldered joints on the PCA need to be reworked in the vicinity of the pressure-interconnect stack, use a thermal profile board, perform a mock solder repair, and measure the thermal effect on the socket. Ensure that the LGA IC and socket temperatures are maintained within their respective manufacturer’s thermal limit guidelines. Ensure that process chemicals (flux, cleaners, etc.) do not run under the LGA socket.

52.6 DESIGN GUIDELINES

52.6.1 Traces Beneath LGA Elements

It is advisable to keep active traces off the surface of the PCB where they could get crushed by the bolster plate or the socket. Since bolster plates are generally flat and large, the forces are spread out. The molded socket frame exerts a more concentrated force on the PCB surface due to its narrow outline and may compress any surface traces running beneath it.

52.6.2 Clearance for Tall Components

The pressure plate or heat-sink usually overhangs the LGA IC package. For this reason, tall components should be kept outside of the pressure plate/heat-sink footprint to prevent mechanical interference with the LGA stack.

52.6.3 Components under the Bolster Plate

As previously mentioned, placing components under the bolster plate should be avoided. If components are required in this area, then the bolster plate should be relieved to allow for appropriate clearances. This may require the use of an extra-thick bolster plate to preserve its stiffness after relief machining.

PART 10

QUALITY

CHAPTER 53

ACCEPTABILITY AND QUALITY OF FABRICATED BOARDS

Robert (Bob) Neves
Microtek Laboratories, Changzhou, China

53.1 INTRODUCTION

53.1.1 Reasons for Appropriate Acceptance Criteria

Other than the financial tie between the user and supplier, nothing affects the relationship between these two more than product acceptability and quality. These issues define the relationship. As the printed circuit board (PCB) is the foundation for almost all electronic products, the user cannot tolerate defective boards. At the same time, cost is always a critical issue and imposing expensive and unnecessary acceptance criteria can be a major disadvantage. Failure to provide acceptable and quality product is the largest factor that affects the deterioration of the relationship between user and supplier. All of the components in an electronic

product rely on the PCB to get information and power from place to place. An interruption of this process because of a defective PCB results in a failed product. In other words, a poor quality product at a low price is worthless.

53.1.1.1 Customer Satisfaction. Brand name is one of the most valuable things that the original equipment manufacturer (OEM) possesses. A product's success or failure is quite dependent on the perceived quality that the brand name suggests. OEMs rely on getting products quickly from the design programs to market, and a slowdown due to quality issues can significantly impact a product's introduction and thereby affect their brand. The negative publicity from field failures can also have a significant effect on a brand. Agreed upon acceptance and quality criteria reduce the likelihood of nonconforming PCBs.

53.1.1.2 Reduction of Cost. If the PCB buyer clearly states the required acceptability and quality criteria to the manufacturer, the manufacturer can more clearly understand the buyer's costs. Cost reductions are a permanent fixture in the manufacturing environment. For companies to survive in this competitive market, they must address costs. Unacceptable, low-quality product that cannot be sold is a direct and significant cost.

53.1.1.3 Liability and Litigation. Showing that the PCB was purchased to mutually agreed upon "standards" goes a long way to reducing litigation and financial liability.

53.1.2 Printed Circuit Board Functions

A PCB is required to do three things for the buyer when it is received:

1. The PCB physical form should match the intended design. The dimensions and placement position of the interconnection points along with the quality of the coating on these interconnection points must be acceptable and of high quality to facilitate the attachment of components.
2. The PCB should provide proper interconnection between components. This allows the assembly to function properly as intended.
3. The PCB should provide insulation between interconnection points that should not be connected.

These three items should be “acceptable and of high quality” at the time of purchase and continue to remain “acceptable and of high quality” throughout the expected life of the product. There are a lot of details between the few preceding lines defining those three things. The rest of this chapter will define the details of “acceptability” and “quality” for the PCB in order to fill in the spaces created by the three previously listed requirements.

53.1.3 Industry versus Customer Standards

Properly implemented acceptability and quality criteria give both user and supplier a clear picture of what is expected. Without clear instructions on how the acceptability and quality of the PCB should be implemented at the supplier, the user is unlikely to get a product that meets his or her needs. A clear definition of what the user wants can help make the relationship between the two much more successful, especially as complexity of the PCB makes acceptability and quality criteria more critical and challenging. In general, PCB manufacturers have gotten larger and produce many more PCBs. This makes the user’s

individual PCBs a much smaller part of the big picture and their uniqueness may be lost. Therefore, it is essential to define what is required for acceptability and quality clearly and early in the relationship between the user and supplier.

53.1.4 Objectives of Acceptability and Quality Criteria

The PCB needs to be supplied at a quality level that is capable of withstanding the assembly process, as it will undergo several operations to mount and rework components and connectors. This assembly and rework process has gotten more complicated and damaging to the PCB, especially with the introduction of lead-free products. The acceptability criteria should attempt to anticipate the conditions of the soldering process to ensure the PCB will survive the assembly and rework process and still function as intended.

53.2 SPECIFIC QUALITY AND ACCEPTABILITY CRITERIA BY PCB TYPE

Many unique inspection properties for PCBs are dependent on their type of manufacture. There are two major classifications of printed circuits: rigid PCBs and flexible PCBs.

53.2.1 Rigid PCBs

Rigid PCBs make up the bulk of what is built around the world. Rigid PCBs are used in a variety of applications and products. The materials and testing procedures for each type

of PCB can be dramatically different. These manufacturing details are thoroughly covered elsewhere in this book and are only touched on here. The processing for multilayer PCBs is a multiple of that required for single- and double-sided PCBs, plus indexing and lamination processes are needed. The additional processes required for each additional layer introduce opportunity for anomalies to creep into the PCB.

53.2.1.1 Single-Sided PCBs. These contain no plated-through holes (PTH), eliminating the need to inspect the attributes associated with PTHs. These PCBs are much simpler to manufacture and PCB shops specializing in these types of PCBs have fewer processes to manage. Many single-sided PCBs are manufactured using a punching process to make part mounting holes and create the outline of the PCB. Single-sided PCBs are typically the least expensive type of PCBs and are usually used in simple and inexpensive applications.

53.2.1.2 Double-Sided PCBs. These differ from single-sided PCBs in that the circuitry is on both sides of the PCB and there are PTHs connecting the top to the bottom. Moving from single-sided to double-sided PCBs requires the manufacturer to keep consistency of the image from top to bottom, and also requires drilling and through-hole-plating processes. These additional processes also require increased inspection, as the attributes they represent can significantly affect acceptability and quality of the PCB.

53.2.1.3 Multilayer PCBs. These are much more complex than double-sided PCBs as they require that circuitry be embedded within the PCB. The PTHs must also make connection to internal layers as well as top and bottom layers. Multilayer PCBs also introduce the lamination process, which is where the manufacturer actually creates

the composite PCB from layers of circuitry in a lamination press under high pressure and heat.

53.2.1.4 Backplane PCBs. These multilayer PCBs have connector arrays installed that hold other PCBs. These arrays must be rigid enough to ensure that insertion of PCBs does not affect their performance and reliability. They usually have many layers and tend to be large and thick. Here, again, the manufacturing processes differ from those of traditional multilayer PCBs, and additional requirements for the connector area and PTH areas are necessary.

53.2.1.5 High-Frequency PCBs. These can be any of the preceding types of PCBs and have unique properties that allow high-speed electrical signals to travel within or on the PCB without significant degradation. The materials used and geometry of the circuit are critical to produce the correct impedance for these signals to maintain integrity. Additional testing is typically performed to verify the more precise nature of the requirements for these types of PCBs, such as controlled impedance.

53.2.2 Flexible PCBs

Flexible PCBs must be capable of bending and flexing, either for installation or continuously throughout the product's life, and come in single-sided, double-sided, multilayer, and high-speed versions just like the rigid PCBs previously described.

53.2.3 Rigid/Flexible PCBs

Rigid/flexible combination PCBs combine the benefits of the rigid PCB with integrated flexible parts. This type of PCB requires evaluation of both the rigid and flexible sections for acceptability.

53.3 METHODS FOR VERIFICATION OF ACCEPTABILITY

53.3.1 Production PCB

Most acceptability criteria are evaluated on the production PCB by visual or dimensional means. Visual inspection is typically done under low magnification by human operators. Although the human eye is very capable of catching inconsistencies in the circuit patterns and surface materials, it is not always consistent and can allow nonconforming attributes to slip through. Because of this, many companies have turned to using automated optical inspection (AOI) machines to check pattern integrity, consistency, and dimensions. AOI provides a much more consistent evaluation of circuit geometry than the human eye, but is a slower and more costly option. Many visual inspection attributes have dimensional attributes attached them. It is important to note that magnification for inspection of dimensional attributes should be sufficient to make an accurate measurement to determine acceptability.

53.3.2 Test Coupons and Patterns

For testing purposes, there are several reasons to utilize test coupons and patterns that are representative of the PCBs rather than the PCBs themselves. The downside of using coupons is that they take up space on the manufacturing panel and therefore increase the overall cost of the PCBs. Also, the test coupons are not actually part of the PCB and are typically placed at the edges of the production panel, whereas test patterns may be produced totally separately from the production panel. This can cause the coupons and patterns to reflect different attributes than the PCBs they are

attempting to represent. It is very important to take steps to ensure that the test coupons and patterns are actually manufactured in a manner that is representative of all the attributes of the PCBs associated with them. It is important to ensure that any holes in the coupon are drilled with the same tools and parameters as those on the corresponding PCB. Coupons and patterns are typically used in situations where using a PCB for testing would either not provide the information required or the PCB would have to be destroyed in order to get the information. Coupons and patterns can be used for microsectional analysis, electrical measurements, environmental simulation, and reliability evaluation. See Fig. 53.1 for an example of test coupons taken from IPC-2221. [Unless noted otherwise, figures in this chapter are courtesy of the Association Connecting Electronics Industries (IPC), and are taken from the publication IPC-600, “Acceptability of Printed Circuits.” These figures can be found in that document under the headings noted in this chapter for specific topics. Figures credited to the author of this chapter are taken from presentations made by him. Other figures are from the sources noted in the captions. For further details on design and placement of coupons, see IPC-2221.]

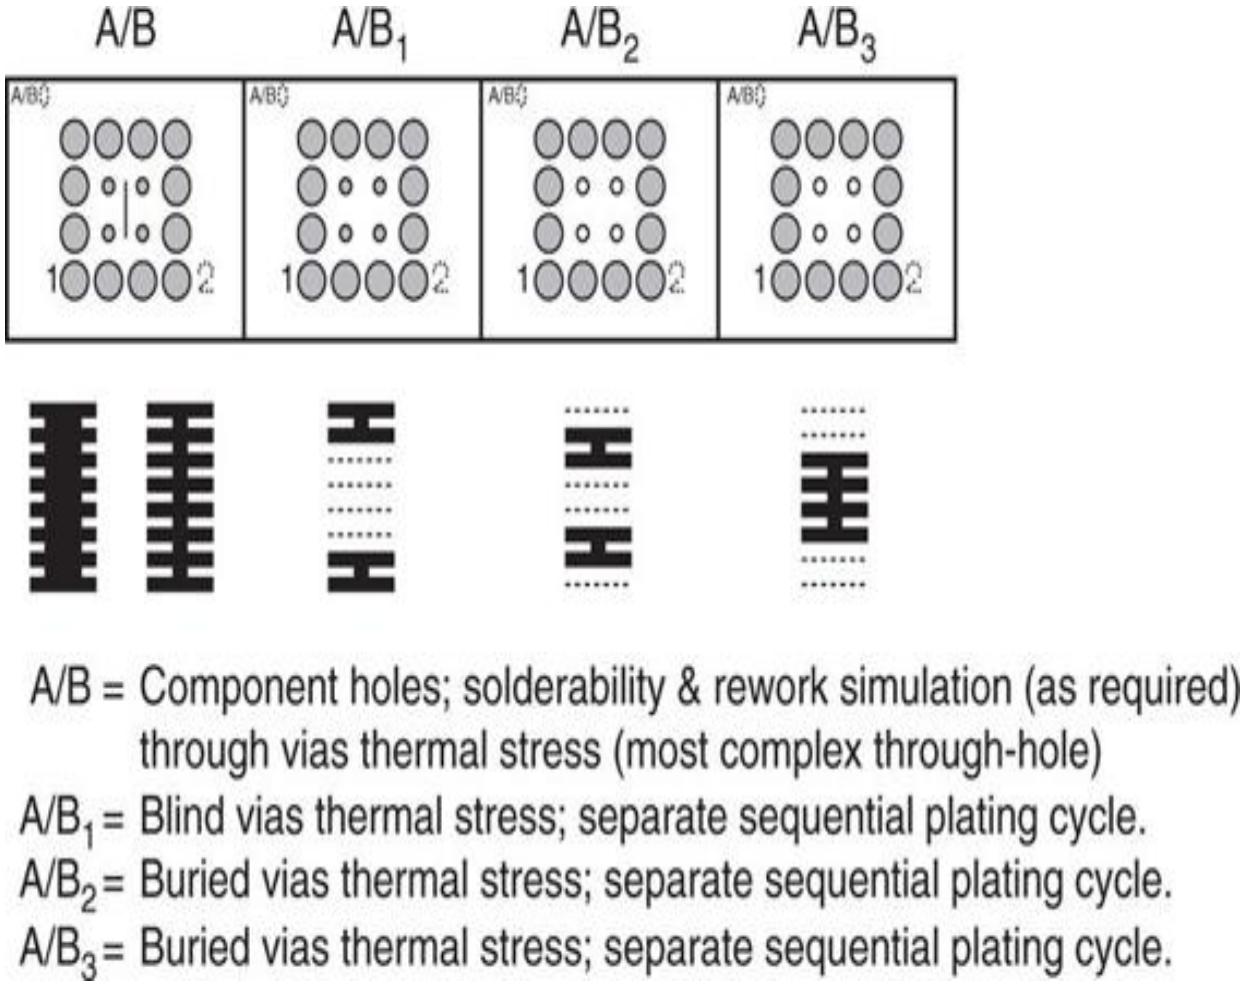

FIGURE 53.1 Quality conformance test coupons taken from IPC-2221. (*Courtesy of IPC*.)

53.3.3 Microsection

Microsectioning the holes from a PCB provides a cross-sectional view of the construction of the PCB. Microsectioning a PCB with a design that removes nonfunctional pads makes it virtually impossible to inspect all the interconnecting layers in the hole, so microsections are typically done on associated and optimized coupons containing PTHs that contain pads on all the layers. Microsectioning PCBs requires great skill, as the PCB contains both hard and soft materials and the area of interest is very small. Improper microsection technique can either create or

hide anomalies. For example, interconnection separation can be created or hidden by improper microsection preparation techniques.

53.4 INSPECTION LOT FORMATION

An inspection lot consists of all the PCBs fabricated from the same materials, using the same processing procedures and constructions that are produced under the same conditions. Differing PCBs can be combined to form an inspection lot, but then they must all be submitted together for inspection. It is the PCB manufacturer's responsibility to maintain traceability for all the PCBs in an inspection lot along with any corresponding test coupons that were separated from the production panels. The success of inspections greatly depends on how the inspection lot is formed. The goal of forming the inspection lot for a particular attribute is to allow, if applicable, a smaller sampling of the inspection lot to be representative of the entire lot. In forming inspection lots and sampling groups, the methodology for producing the attribute and the consistency of that methodology or process must be taken into consideration. Some PCB processes are done in batch form and others are done on a panel-by-panel basis. Understanding process techniques is critical in forming inspection lots and sampling groups that are representative of the product.

53.4.1 Sampling Inspection

For some attributes, 100 percent inspection is not necessary or prudent. In these cases, a sampling of the PCBs from the inspection lot is allowed to represent the entire inspection lot. Most performance specifications specify which attributes can use sampling inspection and to what extent sampling

may be performed. There are many sampling plans available; the most widely known, and historically used, is MIL-STD-105, which describes an acceptable quality level (AQL) for samples of an inspection lot. However, it allows a small amount of defective material to be considered “acceptable” and has typically been replaced by sample plans where defective parts that are found during inspection cause the lot to be termed “nonconforming.” This style of plan is defined as defective parts (C) equals zero (C = 0). If the inspection lot is considered “nonconforming” during a sampling procedure, the supplier may elect to screen 100 percent for the nonconformance, removing only the nonconforming PCBs from the inspection lot.

53.4.2 Inspection Tool Calibration

It is important that the all inspections be carried out with equipment that is calibrated and traceable to internationally recognized standards. Two of the documents that govern inspection equipment and facilities are ISO-17025 and IPC-QL-653.

53.5 INSPECTIONS CATEGORIES

53.5.1 Materials Inspection

This inspection usually consists of certifications from the material supplier, supported by data from the supplier’s own inspections. The materials used must be inspected by the PCB manufacturer to ensure compliance with customer requirements.

53.5.2 Qualification Inspection

The PCB supplier must provide proof to the user of its qualifications to build the product specified. The user must then review this proof in order to minimize the risk associated with buying from the PCB manufacturer. This process usually includes the PCB manufacturer supplying a self-declaration of capabilities such as those found in the IPC-1710, and then supplying some kind of physical sample or testing data to support the assertions made in the self-declaration. It is up to the PCB user to determine the level and detail of qualification required. This approach can leave things unverified or unaudited and recognizing the need from the PCB user community, the IPC has set up a PCB Supplier Validation Program that lists qualified manufacturers and products that have been tested and inspected to IPC standards like the IPC-6012 and IPC-A-600. Matching PCB user needs to the IPC Validation Services database is one way to significantly improve the chances of getting good information about the capabilities of a PCB supplier. More details regarding the program can be found on the Web at IPCValidation.org.

53.5.3 Quality Conformance Inspection

These product verification inspections use specified acceptability criteria and are performed prior to shipment of the PCBs to the customers. These inspections can be defined either by industry or customer standards, or a combination of both.

53.5.4 Reliability Testing

This testing consists of looking for imperfections in the PCB that may show up some time during the product’s field life.

They include accelerated life testing for both the interconnection and insulation attributes of the PCB. Please see Chaps. 59, 60, and 61 for a detailed discussion of reliability testing.

53.6 ACCEPTABILITY AND QUALITY AFTER SIMULATED SOLDER CYCLE(S)

The user expects the PCB to survive the assembly and rework process and still perform its job during the expected life of the product. Temperature excursions that approach or exceed the base material's glass transition temperature (T_g) can significantly affect some attributes of the PCB. For these attributes, it is important that the PCB be examined after solder cycling that simulates the type and quantity of soldering operations (rework included) that the PCB is expected to undergo during the assembly process. It is important to note that each rework process usually includes two soldering cycles: one to desolder the affected part, and one to reattach a new part.

53.6.1 The Effects of Lead-Free Assembly on PCB Acceptability and Quality

The lead-free assembly process can have a significant and detrimental effect on the PCB's reliability and quality, as it increases both the soldering temperature and the time the PCB is exposed to that temperature. This will accelerate degradation of the base material and can have significant impact on the PCB. Figure 53.2 shows damage related to time and temperature above T_g. It is essential to establish

that the PCB was capable of being assembled and was acceptable when it was delivered to the assembly organization, as poor assembly techniques can severely compromise the integrity of the PCB. It is almost impossible to look at a PCB after assembly and definitively state that the fault lies entirely with the PCB manufacturer or with the assembly organization.

FIGURE 53.2 Damage done to PCBs during typical leaded and lead-free solder cycles. (*Courtesy of Microtek Laboratories*.)

53.6.2 PCB Issues Created by Lead-Free Assembly

Copper reduction: Lead-free solder, when molten, rapidly dissolves copper into it. One must be very careful when using lead-free solder on copper surfaces without a protective barrier of some type (e.g., nickel); otherwise, the copper conductors and plated through holes may be reduced to a point where they are not adequate for the design.

Base material degradation: Base materials begin to degrade and decompose during soldering and can reduce the insulating properties and cohesion of the resin system in the base material causing electrical failure or delamination.

Conductive anodic filament: As the base material system degrades, the resistance to Conductive anodic filament (CAF) formation decreases.

Increased expansion causing premature PTH failures: Base materials expand when exposed to soldering temperature. This expansion becomes pronounced above the T_g of the resin system in the base material. The increased temperature of lead-free soldering can cause premature failure of the PTHs due to this increased expansion. See Fig. 53.3 for PTH expansion characteristics with temperature.

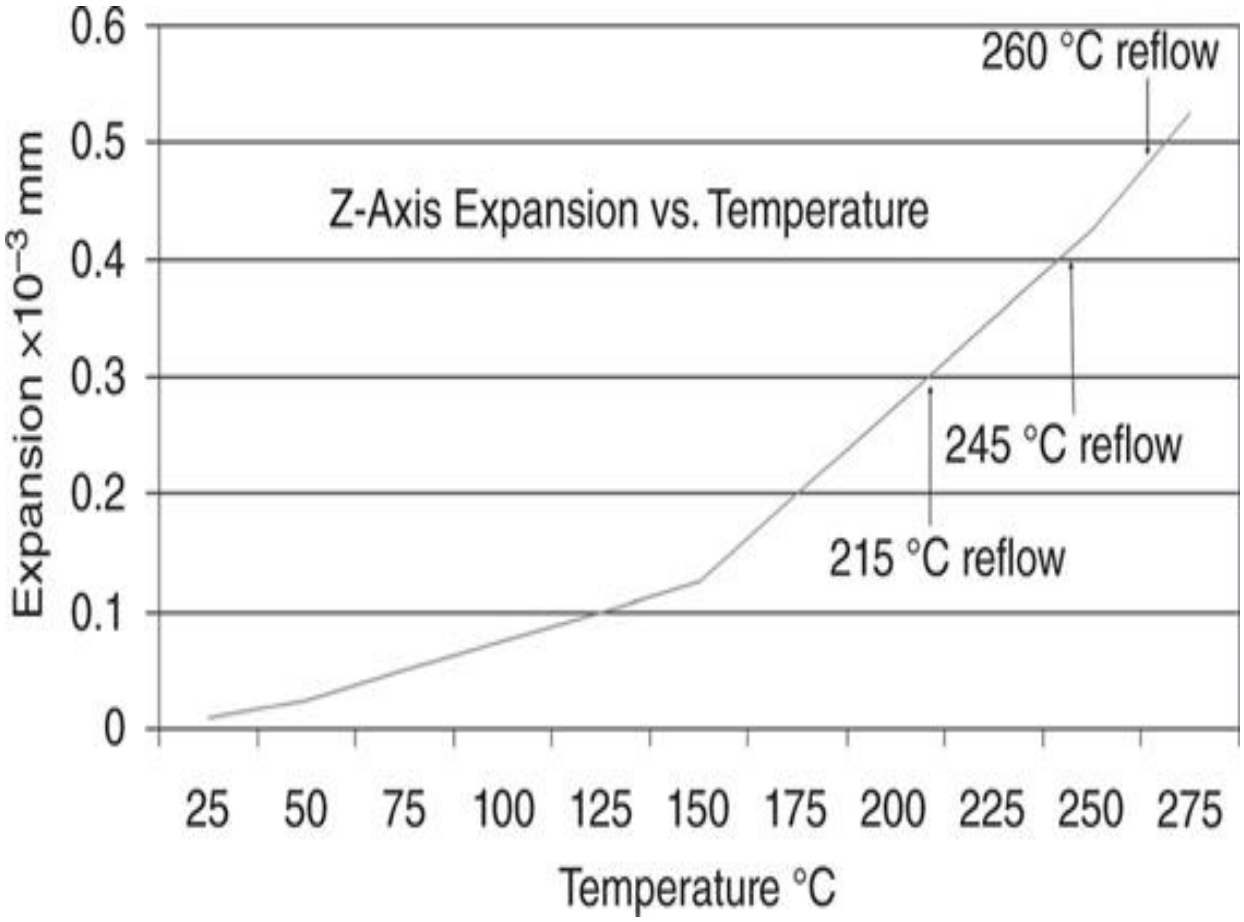

FIGURE 53.3 *Z*-axis expansion characteristics of 150°C T_g PCBs versus temperature. (*Courtesy of Microtek Laboratories*.)

Solderability: Lead-free solder does not wet as well to solderable surfaces as leaded solder does, so pad size, solder volume, and flux type and quantity must be taken into account.

53.7 NONCONFORMING PCBs AND MATERIAL REVIEW BOARD FUNCTION

Standards and customer documentation establish minimum quality and acceptability requirements for the inspections performed. If the PCB does not meet these requirements, it becomes nonconforming. This does not necessarily mean the

PCB is scrapped, although this often what happens to nonconforming PCBs. What it does mean is that with a generic standard, samples that do not meet the stated requirements must be “dispositioned” outside the standard. To determine whether a nonconforming PCB is or is not “scrap,” a material review board (MRB) must be established to evaluate the nonconformance(s). The MRB is usually made up of one or more representatives from the departments of quality, production, and design. The purpose of the materials review board is to disposition nonconforming products and effect positive corrective action within a short time to eliminate the cause of recurring discrepancies. The MRB’s responsibilities include

- Reviewing questionable PCBs or materials to determine conformance with acceptability, quality, and design requirements
- Reviewing nonconforming PCBs for effects on design functionality
- Authorizing repair or rework of nonconforming PCBs when appropriate
- Establishing responsibility and/or identifying causes for nonconformance
- Authorizing the scrap of excessive quantities of materials

When all else fails and the PCBs do not meet the intended end product use, they need to be scrapped.

53.8 THE COST OF THE ASSEMBLED PCB

The cost of the assembled PCB continues to increase because of density, complexity, and rising material and component costs. The value added to the PCB can be 10 to

20 times the cost of PCB. If it is found that a nonconforming PCB is the cause of failure, the total cost of the assembly process is likely to be passed on to the PCB manufacturer as their responsibility.

53.9 HOW TO DEVELOP ACCEPTABILITY AND QUALITY CRITERIA

53.9.1 Using Industry Standards

There are both advantages and disadvantages to using industry standards for acceptability and quality requirements.

53.9.1.1 Advantages

- International standards represent a consensus of what is possible and common for acceptance.
- They increase the likelihood of PCB users getting what they expected.
- The PCB manufacturer is unlikely to become as expert in complying with a “customer” specification as it would an industry standard.
- The repeated experience of inspecting to an industry standard means the quality personnel at the PCB manufacturer are more likely to spot nonconformance.
- Industry standards are a great place to start developing company-specific requirements for acceptability and quality.

53.9.1.2 Disadvantages

- International standards are developed by a cross section of the industry. The resultant standards often represent the “least common denominator” requirements in order to satisfy the broad range of participation.
- Although these standards may meet most of a PCB buyer’s needs, they often leave deficiencies that necessitate additional requirements being imposed upon the PCB supplier.
- By nature, international standardization efforts always lag the state-of-the-art in the industry.
- Standards can over- or underspecify requirements for an industry segment’s needs.

53.9.2 Industry Specifications

The following are lists of the most commonly used specifications for PCBs. IPC standards are the most widely used in the industry and therefore are referenced in this chapter as examples.

53.9.2.1 Defense Supply Center Columbus (DSCC)

MIL-PRF-55110, “Printed Wiring Board, Rigid, General Specification for”

MIL-PRF-31032, “Printed Circuit Board/Printed Wiring Board, General Specification for”

MIL-P-50884, “Printed Wiring Board, Flexible or Rigid-Flex, General Specification for”

53.9.2.2 International Electrotechnical Commission (IEC)

IEC-61188, “Design of Printed Boards and Printed Board Assemblies”

IEC-62326, “Printed Board Performance for Capability Approvals”

IEC-61189, “Test Methods for Printed Boards and Printed Board Materials and Printed Board Assemblies”

53.9.2.3 Institute for Interconnecting and Packaging Electronic Circuits (IPC)

ANSI/J-STD-003, “Solderability Tests for Printed Boards”

IPC-1710, “OEM Standard for Printed Board Manufacturer’s Qualification Profile (MQP)”

IPC-4552, “Specification for Electroless Nickel/Immersion Gold (ENIG) Plating for Printed Circuit Boards”

IPC-4553, “Specification for Immersion Silver Plating for Printed Circuit Boards”

IPC-4554, “Specification for Immersion Tin Plating for Printed Circuit Boards”

IPC-A-600, “Acceptability of Printed Boards”

IPC-6011, “Generic Performance Specification for Printed Boards”

IPC-6012, “Qualification and Performance Specification for Rigid Printed Boards”

IPC-6013, “Qualification and Performance Specification for Flexible Printed Boards”

IPC-6016, “Qualification and Performance Specification for High Density Interconnect (HDI) Layers or Boards”

IPC-6202, “IPC/JPCA Performance Guide Manual for Single- and Double-Sided Flexible Printed Wiring Boards”

IPC-TM-650, “Test Methods Manual”

53.9.2.4 Japan Printed Circuit Association (JPCA)

JPCA-PB01-2004, “Printed Wiring Boards”

JPCA-HD01-2004, “HDI Printed Wiring Boards”

JPCA-DG01-1997, “Design Guide for Multilayer Printed Wiring Boards”

JPCA-DG02-2006, “Performance Guide for Single- and Double-Sided Flexible Printed Wiring Boards”

53.9.2.5 Underwriters Laboratories (UL)

UL-94, “Flammability Testing”

UL-796, “Standard for Safety for Printed Wiring Boards”

UL-796F, “Flexible Materials Interconnect Constructions”

53.9.3 Using Customer Standards

Customer standards should reflect the unique nature and needs of the company’s products. Unfortunately, company history often can affect these criteria and overemphasize criteria for failures that were previously experienced. It is recommended that customer standards be used to augment, not replace, industry standards. Consider the following when creating a customer standard:

- Understanding where and how the product will be used can influence the use of extended or reduced criteria in specific requirement areas.
- Understanding the stresses to which the assembly process exposes the PCB is fundamental in defining the acceptability criteria. Process elements such as leaded or lead-free reflow or wave solder, double-sided reflow, hand-soldering, and rework all significantly impact the requirements of the PCB.

53.10 CLASS OF SERVICE

Functionality through operational life should be the ultimate criteria for acceptance. To account for the fact that a PCB will see different end-use environments and conditions, acceptance criteria are typically broken into three classes of service. Each company must establish the level of acceptance as it is dependent on the functional criteria to which the PCB will be subjected. The IPC has established recommended guidelines for acceptance, based on end use, categorized as Classes 1, 2, and 3. The following subsections describe the classes.

53.10.1 Class 1: General Electronic Products

Class 1 includes consumer products and some computer and computer peripherals suitable for applications where cosmetic imperfections are not important and the major requirement is the functioning of the completed PCB.

53.10.2 Class 2: Dedicated Service Electronic Products

This class consists of communication equipment, sophisticated business machines, and instruments for which high performance and extended life are required, and for which uninterrupted service is desired but is not critical. Certain cosmetic imperfections are allowed.

53.10.3 Class 3: High-Reliability Electronic Products

Equipment and products for which continued performance or performance on demand is critical belong in Class 3. Equipment downtime cannot be tolerated, and the equipment must function when required (e.g., life support systems, flight control systems). PCBs in this class are suitable for applications in which high levels of assistance are required and service is essential.

53.11 INSPECTION CRITERIA

When inspecting PCBs, the requirements can be separated into externally observable attributes (those where acceptability can be determined from the outside of the PCB) and internally observable attributes (those that require microsectioning to determine acceptability). The actual requirements vary by specification, but the requirements stated in this chapter generally follow IPC document guidelines.

53.11.1 Externally Observable Attributes

Visual examination for applicable attributes is typically conducted at 3 diopters (~1.75× magnification). If it is not possible to determine whether the condition is acceptable at this magnification, progressively higher magnifications should be used to confirm acceptability. Dimensional requirements such as conductor spacing or width may require different magnifications and devices with measurement scales or reticules as part of the inspection

tool to allow accurate measurement(s) of the specified dimensions. The PCB users may also specify other magnifications and inspection tools. Note that the use of higher magnifications for visual-type attributes can produce false results due to illumination and attribute contour effects. Visual inspection criteria are difficult to define grammatically. An effective way to define visual inspection criteria is to use line illustrations and/or photographs. The IPC utilized this method in the publication IPC-A-600, “Acceptability of Printed Boards,” to “visually standardize” the many individual interpretations to specifications on printed boards.” Of the different types of inspections specified, surface visual inspection is the least expensive. Visual inspection is performed on 100 percent of the PCBs or on a sampling based on an established sampling plan. Inspection for visual imperfections, following a sampling plan, is done on the premise that the PCBs were 100 percent visually screened during the fabrication process. Externally observable imperfections can be divided into 10 groups:

1. Surface imperfections in the insulating material such as burrs, nicks, scratches, gouges, cut fibers, weave exposure, and voids
2. Subsurface imperfections such as foreign inclusions, measling/crazing, delamination, and base material voids
3. Conductive pattern imperfections such as loss of adhesion and reduction of conductor width or thickness due to nicks, pinholes, scratches, surface plating, or coating imperfections
4. Hole characteristics such as diameter, misregistration, foreign material inclusions, and plating or coating imperfections
5. Marking imperfections affecting such characteristics as location, size, readability, and accuracy

6. Solder resist surface coating, coverlayer, and coverfilm imperfections such as misregistration, blisters, bubbles, separations, adhesive squeeze out, delamination, adhesion, physical damage, and thickness
7. Flawed dimensional characteristics affecting such characteristics as PCB size and thickness, hole size, pattern accuracy and registration, conductor width and spacing, and annular ring (dimensional inspection is usually performed using a sampling plan)
8. An unclean PCB surface due to such materials as ionic and organic contaminates
9. Poor solderability of the PCB including wetting, dewetting and nonwetting
10. Electrical discontinuity, circuit shorts, and if required, impedance mismatch

53.11.1.1 Surface Imperfections in the Insulating Material. Surface imperfections include burrs, nicks, scratches, gouges, cut fibers, weave exposure, and voids. The imperfections, when minor, are normally considered to be cosmetic issues, and usually have little or no effect on functionality. However, they can be detrimental to function in the edge board contact area and if they reduce the insulating properties of the material below acceptability limits.

53.11.1.2 Subsurface Imperfections. Subsurface imperfections are those that are visible from the surface of the PCB but are below the surface of the PCB (see Fig. 53.4).

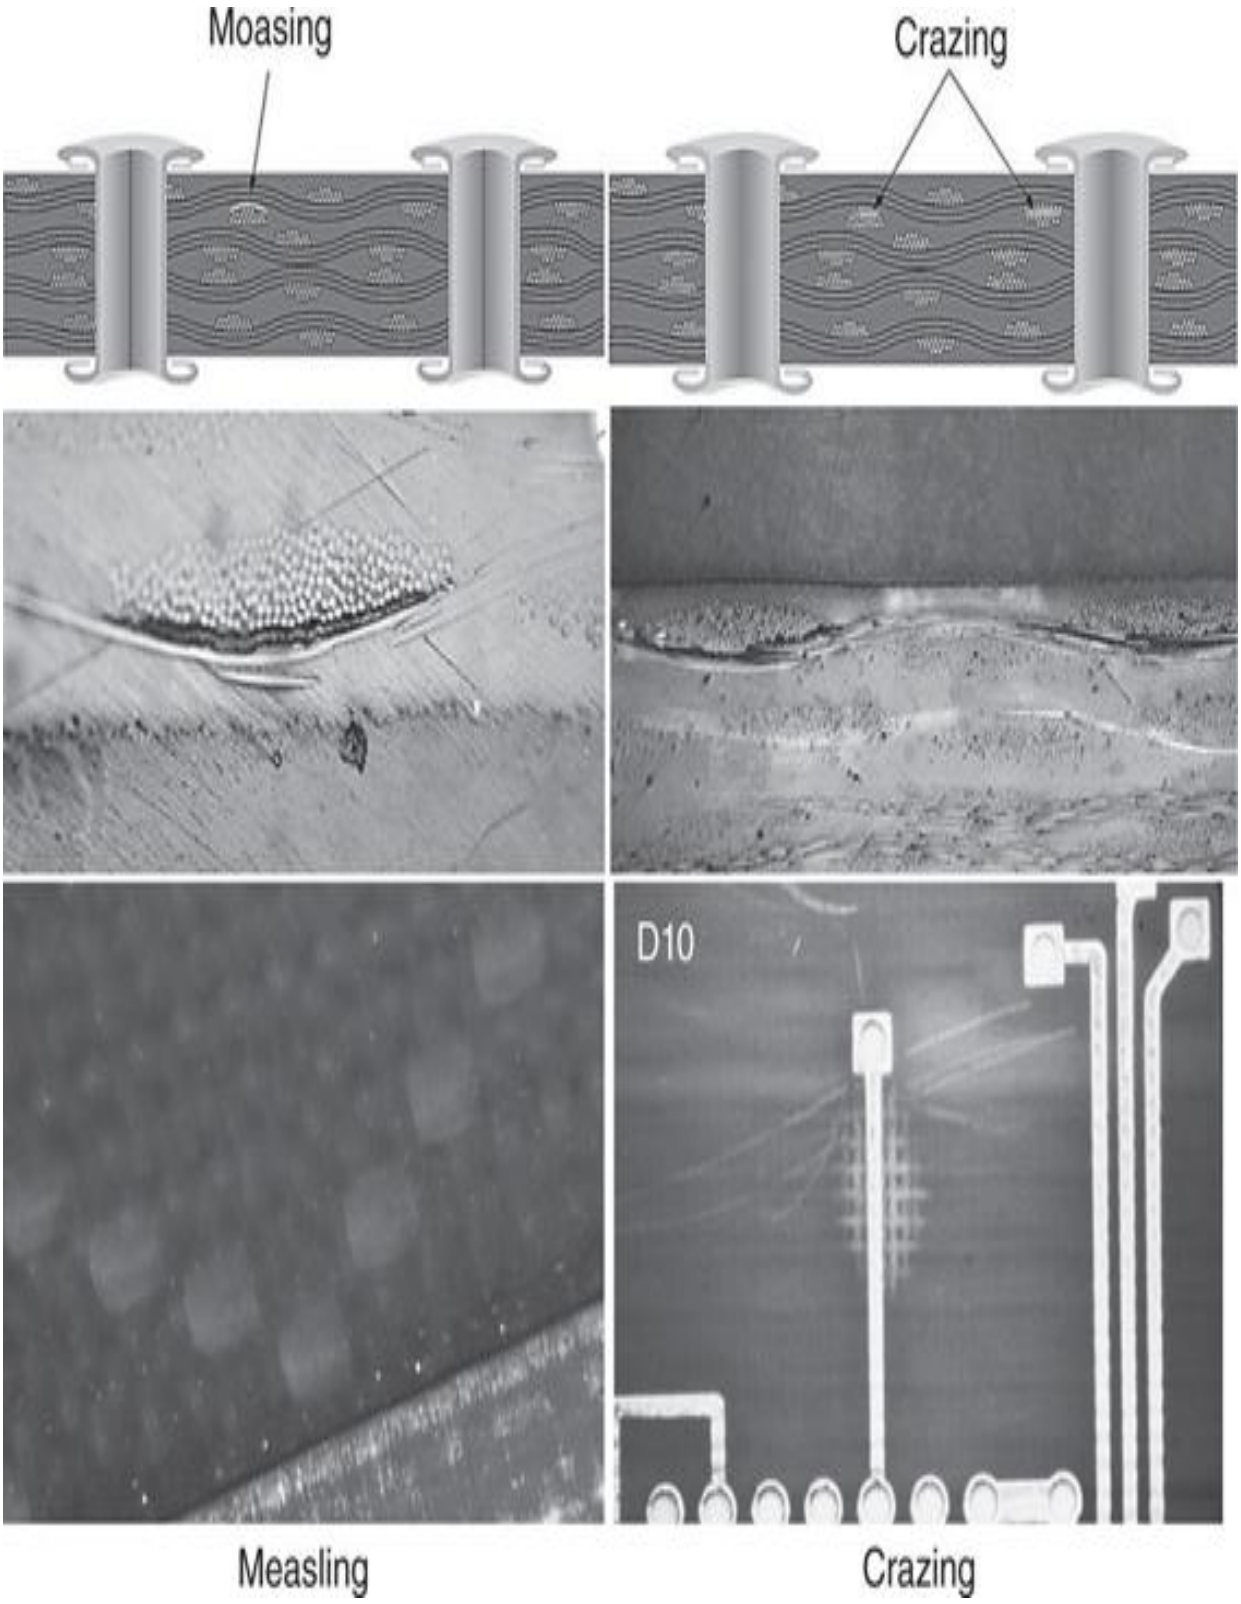

FIGURE 53.4 Base material defects: measling, crazing. (*Courtesy IPC*.)

53.11.1.2.1 Inclusion. An inclusion is a foreign particle, metallic or nonmetallic, in a conductive layer, plating, or base material. Inclusions in the conductive pattern, depending on degree and material, can affect plating adhesion or circuit resistance. Inclusions in the base material are put into the categories of translucent/nonmetallic and opaque/metallic. Translucent particles are acceptable. Opaque particles are acceptable as long as they do not reduce the minimum conductor spacing below the minimum requirement.

53.11.1.2.2 Measling/Crazing, Delamination, Blistering, and Weave Texture/Exposure. The IPC formed a special committee in 1971 to consider base material imperfections and to define them better with illustrations and photographs. The conditions are defined and discussed here:

- *Measling:* This internal condition occurs in the woven-fiber-reinforced laminated base material in which the bundles are separated at the weave intersection. Measling manifests itself in the form of discrete white spots or "crosses" below the surface of the base material. A report compiled by the IPC, "Measles in Printed Wiring Boards," was released in November 1973. The report stated that "measles may be objectionable cosmetically, but their effect on functional characteristics of finished products are [sic], at worst, minimal and in most cases insignificant." The IPC Acceptability Subcommittee readdressed the subjects of measles and crazing in 1994 and verified the 1973 findings. IPC standards allow measles in PCBs with the exception of "high-voltage" applications. As hole spacing has continued to decrease, new attention has focused on measles. There is a concern that measling could contribute to the formation of CAF on designs with close hole spacing, and the requirements for measles will likely adjust to accommodate these designs. In order to address this concern the IPC formed a blue ribbon committee which performed testing to determine if

measles contributed to CAF failure. In 2007 this committee presented a report based upon their testing that concluded that measles did not contribute to CAF growth.

- *Crazing:* An internal condition occurring in the woven fiber-based base material in which the glass fibers within the yarn are separated, crazing can occur at the weave intersections or along the length of the yarn. This condition manifests itself in the form of connected white spots or crosses below the surface of the base material, and is usually related to mechanical and/or thermally induced stress. Limited crazing is an acceptable condition as long as it does not reduce the space between conductive patterns below the minimum conductor spacing, the distance of crazing does not span more than 50 percent of the distance between adjacent conductive patterns, and no propagation results from thermal testing that replicates the manufacturing process. If crazing is present at the edge of the PCB, it should not reduce the minimum distance between PCB edge and conductive pattern.
- *Delamination:* This is a separation between plies within the base material, between a material and the conductive foil, or between any other planar separations within a PCB. Blistering and delamination are considered to be major imperfections. Whenever a separation of any part of the PCB occurs, a reduction in insulation properties and adhesion occurs. The separation area could house entrapped moisture, processing solutions, or contaminants, and could contribute to electrochemical migration or produce other detrimental effects in certain environments. The delamination or blister area may also propagate to the point of complete PCB separation, normally manifesting during assembly operations. Last but not least is the effect on solderability in PTHs. Entrapped moisture, when subjected to soldering temperatures, has been known to create steam that blows holes through the plated side

walls, exposing the resin and glass of the PTHs and creating large voids in the solder fillet.

- *Blistering:* A localized swelling and separation between any of the layers of a laminated base material or between a base material and a conductive foil or protective coating, blistering is a form of delamination.
- *Weave texture:* In this surface condition of base material, a weave pattern of glass cloth is apparent although the unbroken fibers of the woven cloth are completely covered with resin. Weave texture is an acceptable condition and should not be confused with weave exposure.
- *Weave exposure:* In this surface condition of base material, the unbroken fibers of woven glass cloth are not completely covered by resin. Weave exposure is considered a major imperfection. The exposed glass fiber bundles allow wicking of moisture and entrapment of processing chemical residues into the base material.

53.11.1.2.3 Haloing. A mechanically induced fracturing or delamination on or below the surface of the base material, haloing is usually exhibited by a light area around holes, other machined areas, or both. Haloing should not penetrate more than 50 percent of the distance to the nearest conductor and should not reduce electrical spacing below the given requirement.

53.11.1.3 Conductor Pattern Integrity. Several methods can be used to determine conductor pattern integrity. Comparison equipment, overlays, and AOI machines are routinely used compare the pattern to the digital image of the pattern. The most common conductor pattern inspection tool is the aided human eye using low (<3×) magnification. The loss of adhesion and imperfections that reduce the conductor volume or spacing make up this category of imperfections. Voids in conductors and lands can be detrimental to function, depending on the degree of

imperfection. Voids or pinholes reduce the effective conductor width, reduce current-carrying capacity, and can affect other design electrical characteristics, such as inductance and impedance. Voids in lands are also detrimental to solderability. Pinholes or voids in the conductor or land can undermine the finish coating. The presence of conductive elements in areas in which they were not intended can reduce spacing to a point where the insulation between conductors can be jeopardized. The degree that these imperfections affect the PCB depends on the intended design of the circuit. The imperfections in this group are defined as follows (see Fig. 53.5).

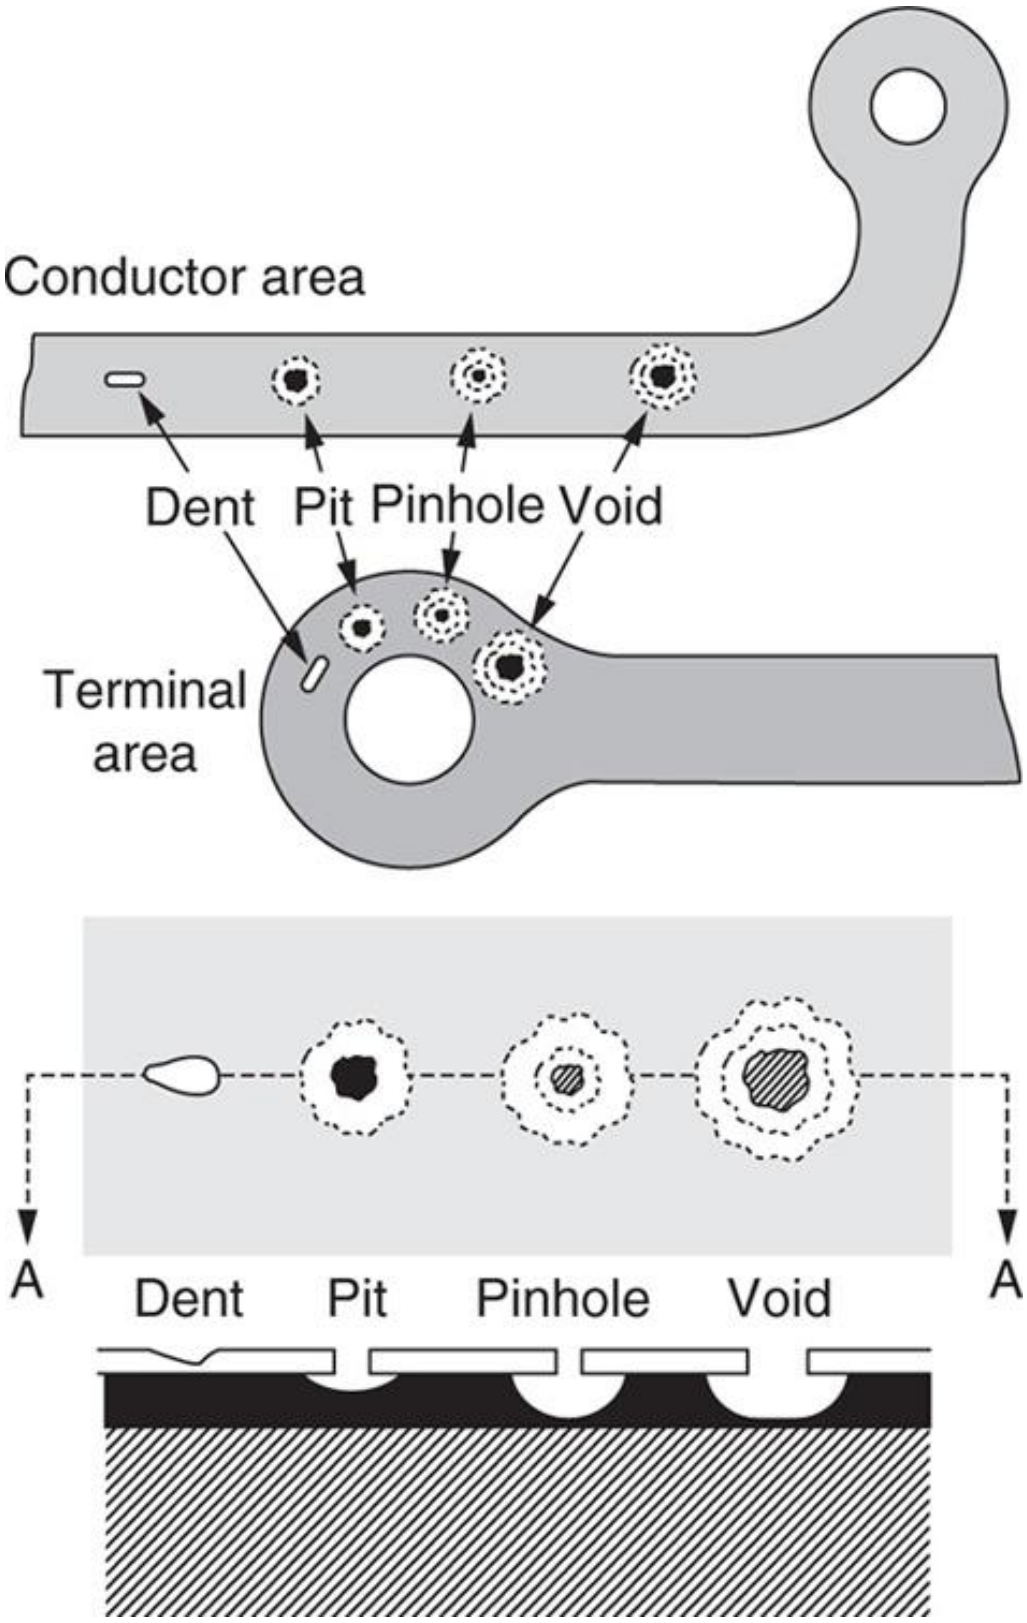

FIGURE 53.5 Dents, pits, pinholes and voids. (*Courtesy of Sandia Laboratories*.)

- *Dent:* This is a smooth depression in the conductive foil that does not significantly decrease foil thickness.
- *Pit or dish-down:* This is a depression in the conductive layer that does not penetrate entirely to the base material but does reduce the cross sectional area of the conductor. These imperfections are almost impossible to detect as they rarely give visual cues to the inspector.
- *Scratch:* This is a slight surface mark or cut that may or may not go all the way through to the base material.
- *Void or pinhole:* This is the absence of conductive material in a localized area going all the way to the base material.

53.11.1.3.1 Conductor Width. The conductor width is the observable width of a conductor at any point chosen at random on the PCB, normally viewed from vertically above unless otherwise specified. The conductor width affects the electrical characteristics of the conductor. A decrease in conductor width decreases current-carrying capacity and increases electrical resistance. Although the conductor width definition is very basic, there are two different interpretations as to where on the conductor the measurement is performed. The minimum conductor width (MCW) is measured at the minimum observed width of the conductor, and the overall conductor width (OCW) is measured at the observable width. Plating outgrowth of the top of the conductor during pattern plating can prevent the minimum width from being seen unless cross-sectioning is performed. The OCW is nondestructive and easily measured. The difference between the MCW and the OCW (see Fig. 53.6), which is measured from vertically above, can have an effect on the current-carrying capacity, inductance, and impedance of the circuit. IPC-6012, “Qualification and Performance Specification for Rigid Printed Boards,” addresses conductor width requirements and allows added width reductions for edge roughness, nicks, pinholes, and

scratches of 30 percent (Class 1) and 20 percent (Classes 2 and 3) from the minimum specified on the procurement documentation. The document states that this reduction also applies to the MCW reflected on the procurement documentation, and this allowance should be carefully considered against design needs.

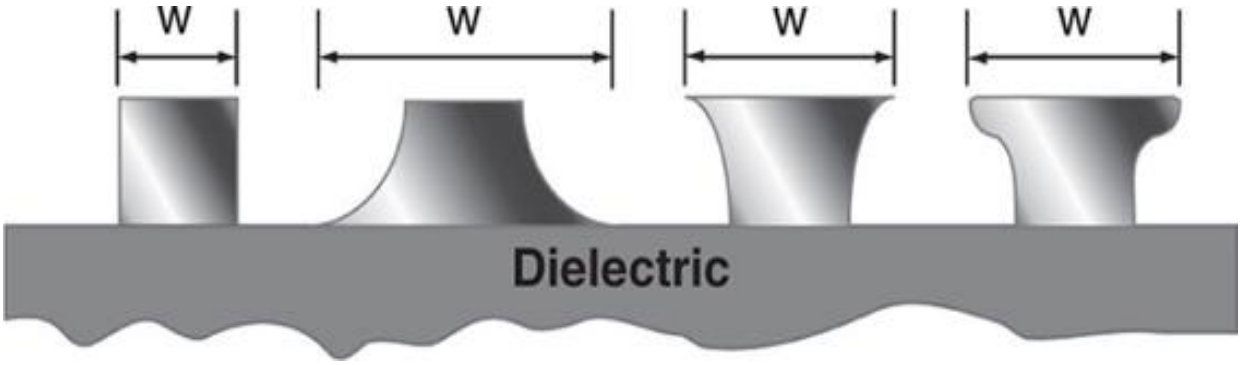

FIGURE 53.6 Overall conductor width measurement "W." (*Courtesy of IPC*.)

53.11.1.3.2 Conductor Spacing. Conductor spacing is the distance between adjacent edges (not centerlines) of isolated conductive patterns or features. The spacing between conductors and/or lands is designed to allow sufficient insulation between circuits. A reduction in the spacing can cause electrical leakage or affect the capacitance of the circuit. The cross-sectional width of conductors is usually nonuniform. Therefore, the spacing measurement is taken at the closest point between the isolated conductors and/or external *annular ring* (the portion of conductive material completely surrounding a hole). The primary purpose of the annular ring is that of a flange surrounding the hole; it provides an area for the attachment of electronic component leads or wires and acts as an anchor for the circuit. The PCB user must define the minimum annular ring dimension, which differs based on the function of the holes and whether they are plated.

53.11.1.3.3 External Annular Ring. The portion of conductive material completely surrounding a hole is called

the annular ring (see Fig. 53.7). The primary purpose of the annular ring is that of a flange surrounding the hole; it provides an area for the attachment of electronic component leads or wires and acts as an anchor for the circuit. The minimum annular ring dimension needs to be defined by the PCB user and will differ based upon the function of the holes and whether they are plated or not. Annular ring dimensions that are less than those specified can interfere with attachment of the component, and a pad breakout (zero annular ring) condition associated with the area where the circuit enters the pad can reduce the current-carrying capacity of the circuit. After verifying the dimensions of the PCB and then verifying that the minimum widths of the annular rings on all other lands are within the procurement documentation requirements, the pattern is found to be in registration with the drilled hole location. Front-to-back pattern registration can also be inspected in this manner.

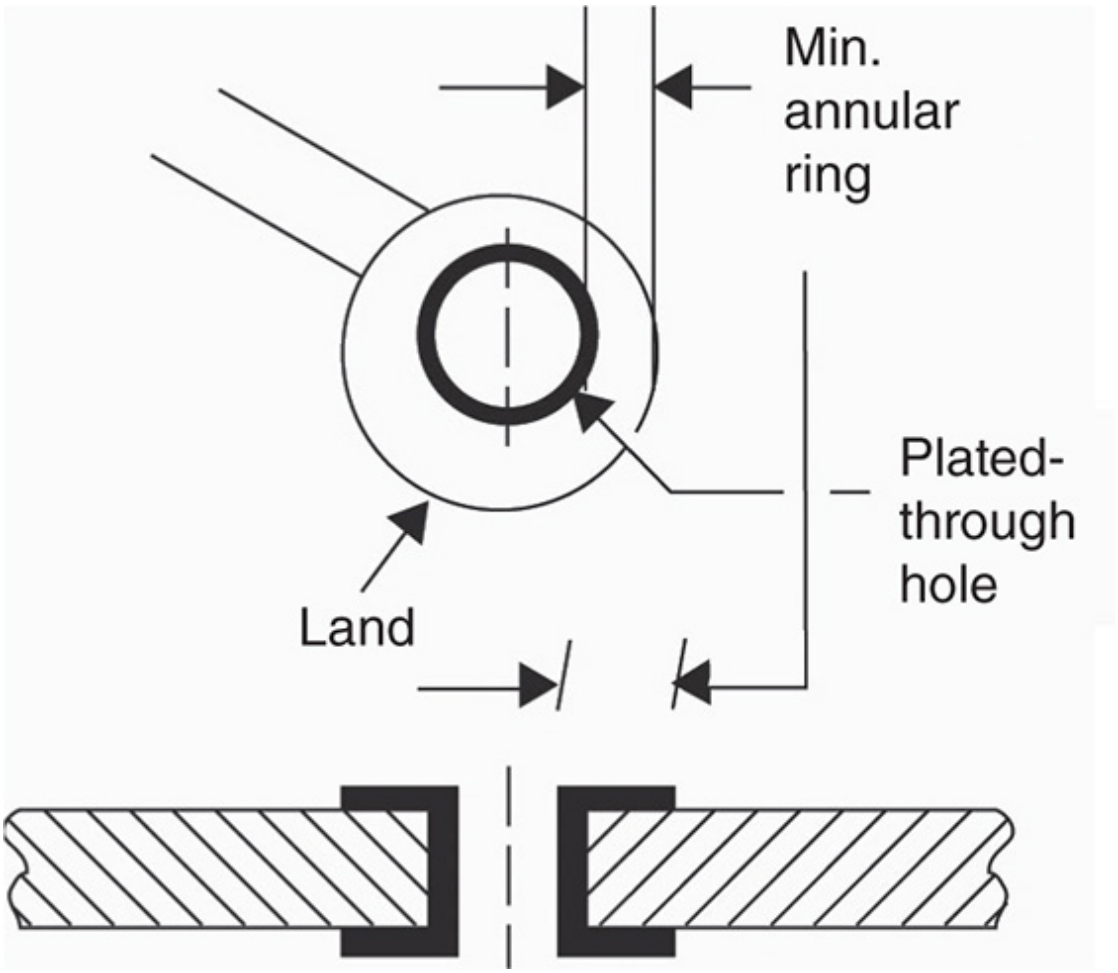

FIGURE 53.7 Minimum external annular ring (includes plating). (*Courtesy of IPC*.)

53.11.1.3.4 Plating Adhesion. A common method of inspecting for plating adhesion is the tape adhesion test, which is described in detail in the IPC test method IPC-TM-650,2.4.1. The basic test method is performed by adhering tape of known properties onto the plating, rapidly removing the tape, then inspecting the tape for removed plating on the tape adhesive.

53.11.1.3.5 Peel Strength. Peel strength is the force per unit width required to peel the conductor or foil from the base material. It is usually associated with the acceptance testing of copper-clad base material upon receipt, but it is sometimes used to test the adhesion of the conductors to the finished PCB. Peel strength tests of conductors are

usually performed after the specimens have been dip or reflow soldered. Peel strength tests of conductors are a good method of ensuring that the conductor-to-base material adhesion is sufficient to withstand assembly and rework operations.

53.11.1.4 Hole Characteristics. PTHs provide circuit interconnection from the surface of the PCB to internal layers and to circuitry on the opposite side. For this reason, much attention is correctly focused on the acceptability and quality of these holes. Nonconformance in the PTHs is a serious concern.

53.11.1.4.1 Roughness and Nodulation. Roughness is an irregularity in the side wall of a hole; nodulation is a small knot or an irregular lump found in or on the plating. Although roughness and nodulation are not desirable, they are allowable in small amounts. Roughness and nodulation create one or more of the following nonconforming conditions:

- Reduced hole diameter
- Impaired lead insertion
- Impaired solder flow through the hole
- Voids in solder fillet

53.11.1.4.2 Voids in the Plating and Finished Coating. A void is the absence of material where it is intended to be. Copper-plating voids are evaluated again during microsectional analysis, but this sampling is very small and this attribute should be thoroughly evaluated during visual inspection of the PCB. When visually evaluating voids in the PTH copper, no more than 5 percent of the holes on the PCB should exhibit evidence of voids. In holes that have voids (see Fig. 53.8), there should be no more than one void that is less than 5 percent of the hole length. Voids in the finish coating of the PCB (see Fig. 53.9) are allowed in larger

quantities than voids in the copper plating. There should again be surface finish voids in no more than 5 percent of the PCB holes, and these holes should have no more than three voids that are each less than 5 percent of the hole length.

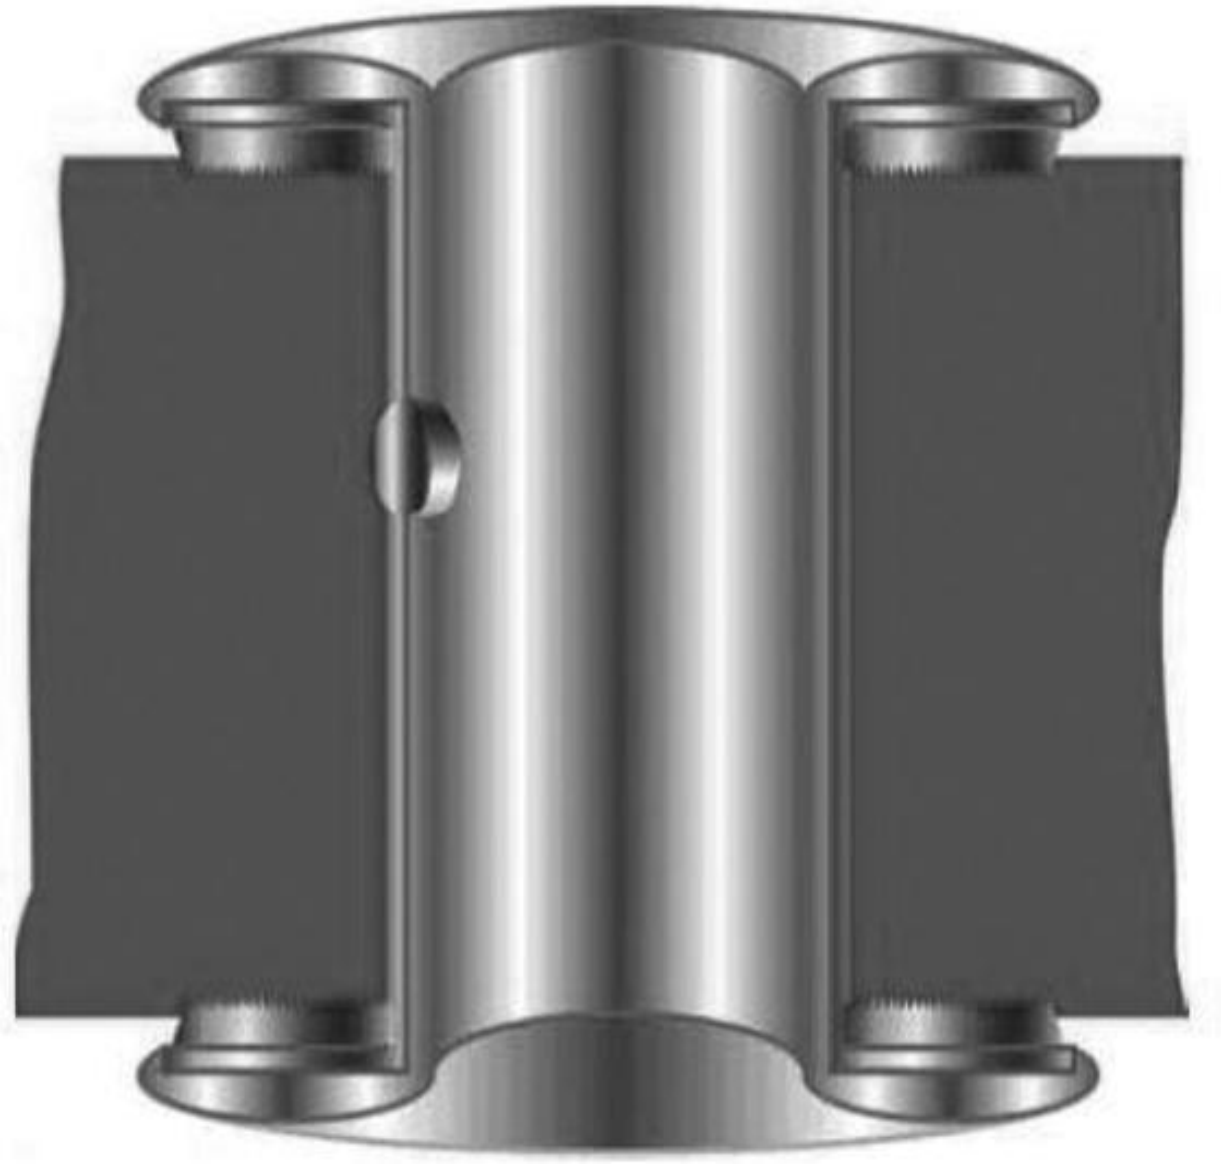

FIGURE 53.8 Plating void. (*Courtesy of IPC*.)

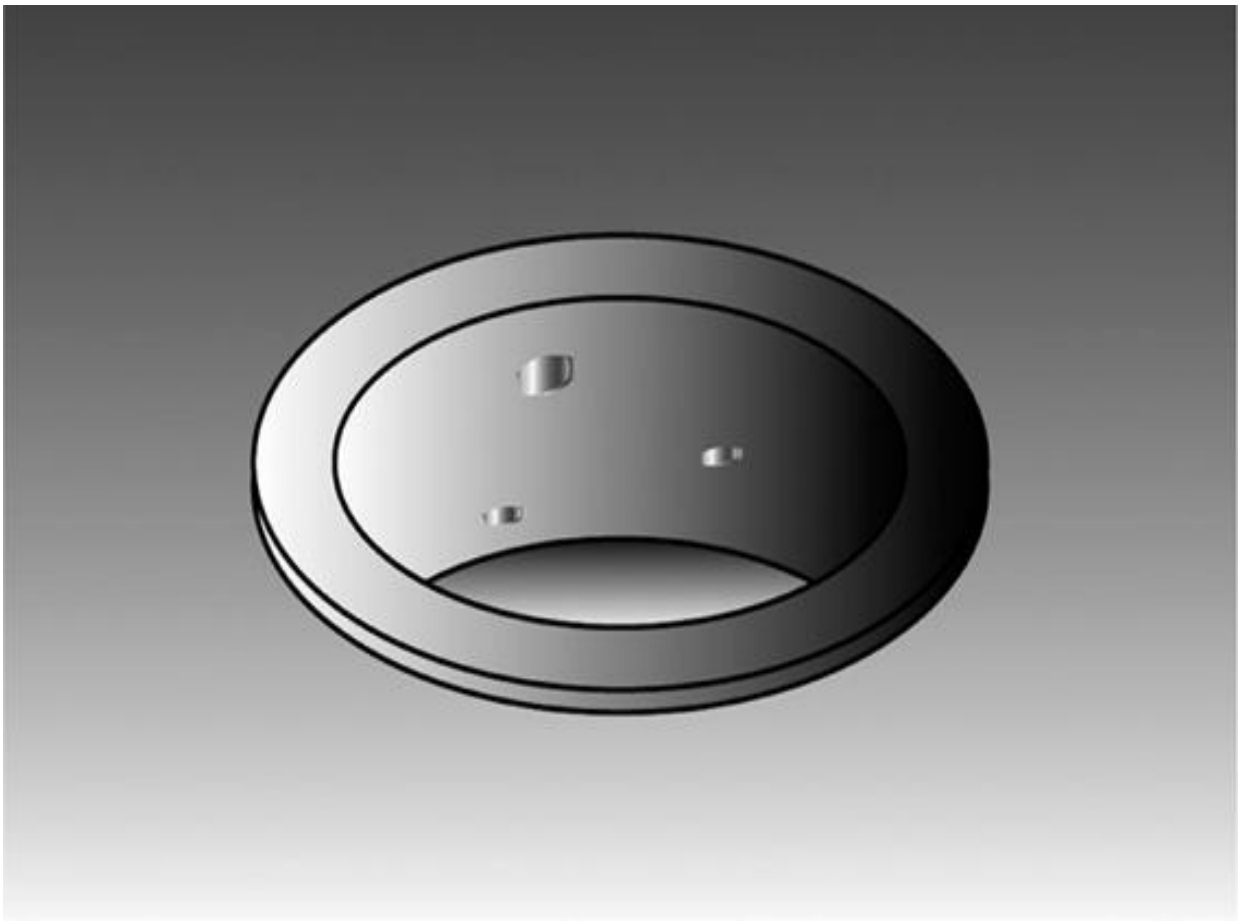

FIGURE 53.9 Voids in finished coating. (*Courtesy of IPC*.)

53.11.1.4.3 Hole Diameter. Hole size is the inner clearance diameter of the finished plated-through or unplated hole. A PTH is a hole in which electrical connection is made between internal or external conductive patterns, or both, by the deposition of metal on the wall of the hole. An unplated hole, termed an unsupported hole, is a hole containing no conductive material. Hole size measurement is performed to verify that the hole meets the intended design requirements. This size requirement is usually associated with the fit of component leads, mounting hardware, etc., plus adequate clearance for attachment metal. PTHs providing layer-to-layer interconnections, where no components are soldered into the hole, are called “via” holes. Via holes do not have a fit requirement, so only the

plating integrity is critical. Drill blank plugs and optical magnifiers are used to verify hole diameter. The latter method is utilized when soft coatings over the copper are used. The optical method prevents deformation or removal of the soft coatings within the hole. When drill blank plug gauges are used, the inspector should use a soft touch to prevent damage to the hole. The drill blank gauges should be cleaned prior to use to prevent solderability degradation. Plating nodules are sometimes present in the hole and restrict the penetration of the gauges. Forcing the gauges into the holes causes the nodules to be dislodged, resulting in voids in the PTH side wall.

53.11.1.4.4 Lifted Lands. During visual examination there should be no evidence of the lifting of lands from the base material surface. Lifted lands can trap contaminates during the assembly process and are considered undesirable for assembly.

***53.11.1.5 Marking (Legend/Silkscreen) Imperfections*.** The marking of part number, revision letter, part mounting information and orientation, etc., on a PCB is evaluated for location, size, readability, and accuracy. Marking imperfections are usually considered minor, but markings that are missing, incorrect, or partially obscured could have an effect on functionality. Marking that encroaches into the soldering area can also be a significant issue and should not reduce the solderable areas below what is stated in the procurement documentation.

***53.11.1.6 Solder Resist Coating Imperfections*.** A solder resist is a coating material used to mask off or to protect selected areas of a pattern from the attachment of solder. A solder resist can also be used as electrical insulation between isolated conductors or to define the soldering area for ball grid array (BGA) patterns. Attributes inspected are registration, blisters, bubbles, adhesion,

wrinkles, tenting, soda strawing, and delamination. Misregistration at land areas reduces or prevents adequate solder fillet formation or can expose adjacent conductors. The minimum land area to obtain adequate solder filleting should be reflected by the minimum acceptance criteria. Wrinkles, flaking, peeling, and delamination provide sites for moisture absorption and contaminants to settle on or into the PCB and can reduce the insulation between adjacent conductors, increasing the potential for electrochemical migration (ECM). When solder resist is used to define BGA patterns, the shape and position on or around the land is important to proper soldering of the BGA (see Fig. 53.10).

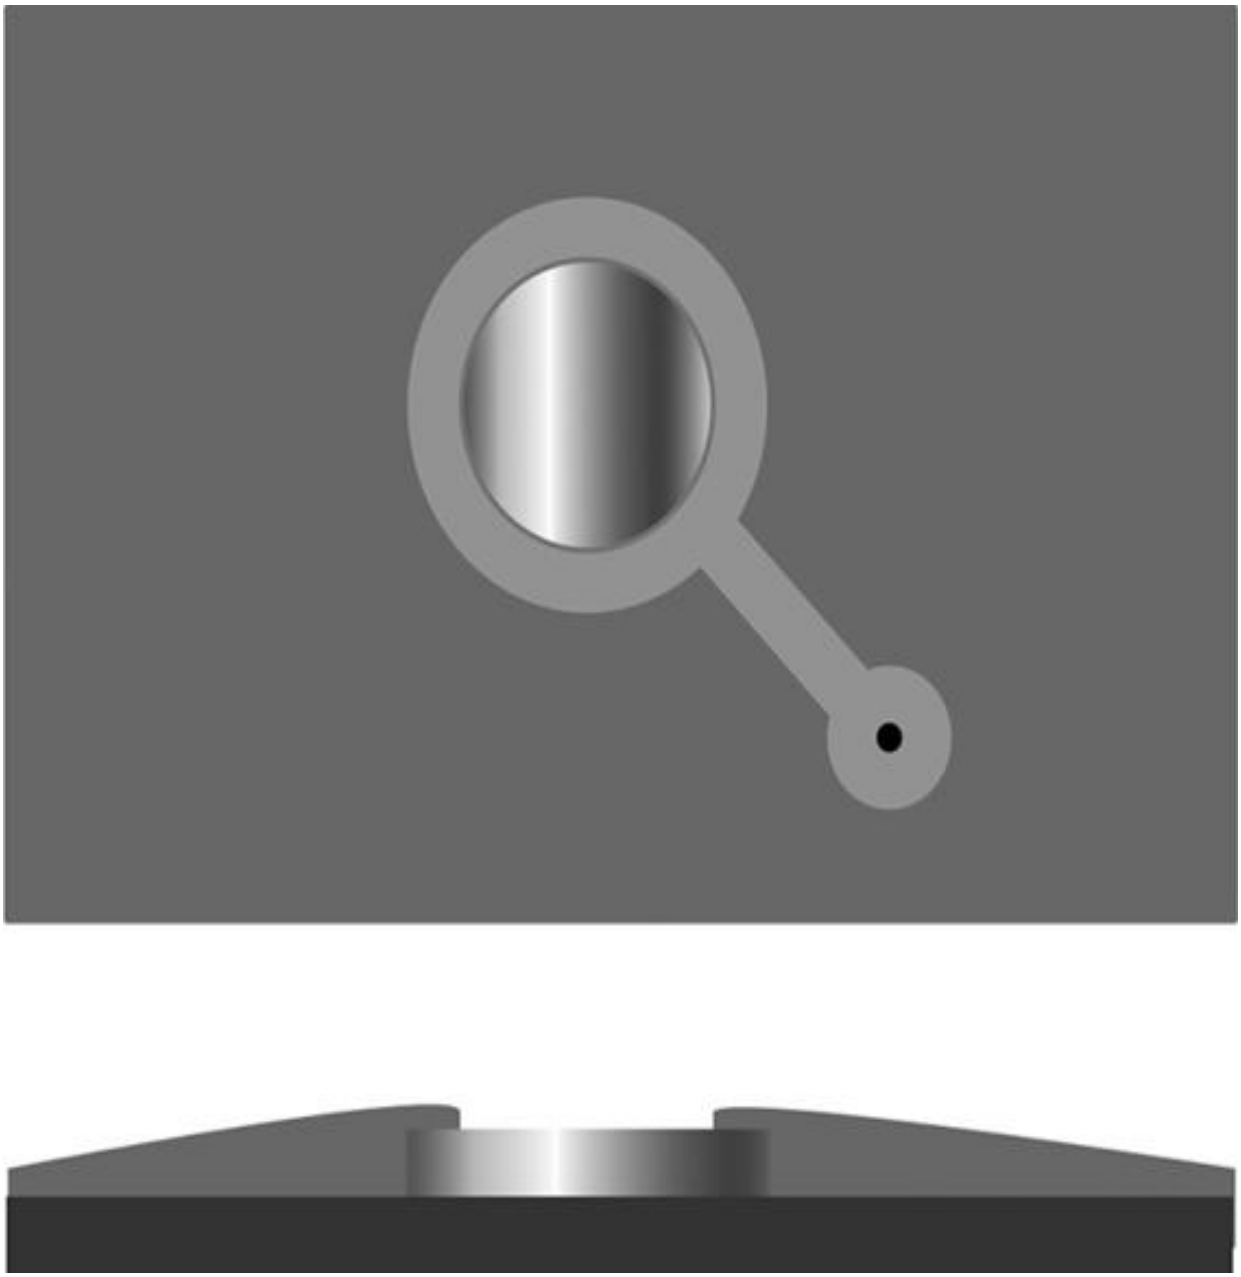

FIGURE 53.10 Soldermask defined BGA land. (*Courtesy of IPC*.)

53.11.1.6.1 Tenting of Vias. Tenting of via holes is the process of covering holes with solder resist without filling the holes, where soldering is not required or desired. This is done to prevent the potential for shorting during the assembly process and to allow for vacuum-based test fixtures to draw the assembly down onto test pins for functional test. The

requirement here is that all vias that are required to be tented are covered by resist.

53.11.1.6.2 Soda Strawing of Solder Resist. A soda straw is a long tubular void along the edges of conductive patterns where the solder resist is not bonded to the base material surface or edge of the conductor (see Fig. 53.11). If this void is allowed to reach the point where the solder resist meets the outside environment, fluxes, fluids, and other contaminates may end up trapped in the soda straw, leaving the potential for future ECM or corrosion.

FIGURE 53.11 Soda strawing between copper trace and soldermask. (*Courtesy of IPC*.)

***53.11.1.7 Coverlayer Characteristics*.** Flexible and rigid/flexible PCBs are covered with either a coating similar to solder resist or a coverfilm adhered to by acrylic adhesive. Covercoat acceptability requirements are the same as those for solder resist.

53.11.1.7.1 Coverfilm Separations. When a film is adhered to the flexible PCB surface, separations between the film and PCB surface can occur. There should be no more than three small separations that do not reduce the spacing between conductors by 25 percent or below the minimum stated in the procurement documentation. Separations along the edge of the PCB are not allowed, as they can trap contaminates.

53.11.1.7.2 Adhesive Presence on Attachment Surfaces. The presence of adhesive from the coverfilm should not reduce the solderable surfaces below the minimum reflected on the procurement documentation.

***53.11.1.8 Dimensional Characteristics*.** Contour dimensional inspection verifies that the outside border dimensions, cutouts, and key slots meet the procurement documentation requirements. Contour dimension requirements can be considered fit requirements. Both undersized and oversized PCBs can affect functionality, depending on the degree of requirement violation. Incorrect placement or size of key slots prevents the proper mounting of the PCB. Measuring methods vary from the use of a ruler or calipers to sophisticated coordinate measurement machines (CMMs). The sophistication of the method is naturally dependent on the required dimensions and tolerances.

53.11.1.8.1 External Dimensions. The external dimensions of a PCB are usually measured by calipers and micrometers. They can also be measured with a CMM or comparison gauges and templates. Tolerances for these dimensions should be reflected on the PCB procurement documentation. It is important to ensure that the measurement tools being used have sufficient accuracy to perform the intended measurements.

53.11.1.8.2 Registration, Layer to Layer, X-Ray Method. The x-ray method provides a nondestructive way to inspect layer-to-layer registration of internal layers of multilayer PCBs. It utilizes an x-ray machine and either Polaroid film or camera sensors to image the internal layers. The multilayer PCB is x-rayed in a horizontal position. The x-ray images are then examined for evidence of hole breakout of the internal lands. The lack of an internal annular ring denote severe misregistration of layers (see Fig. 53.12).

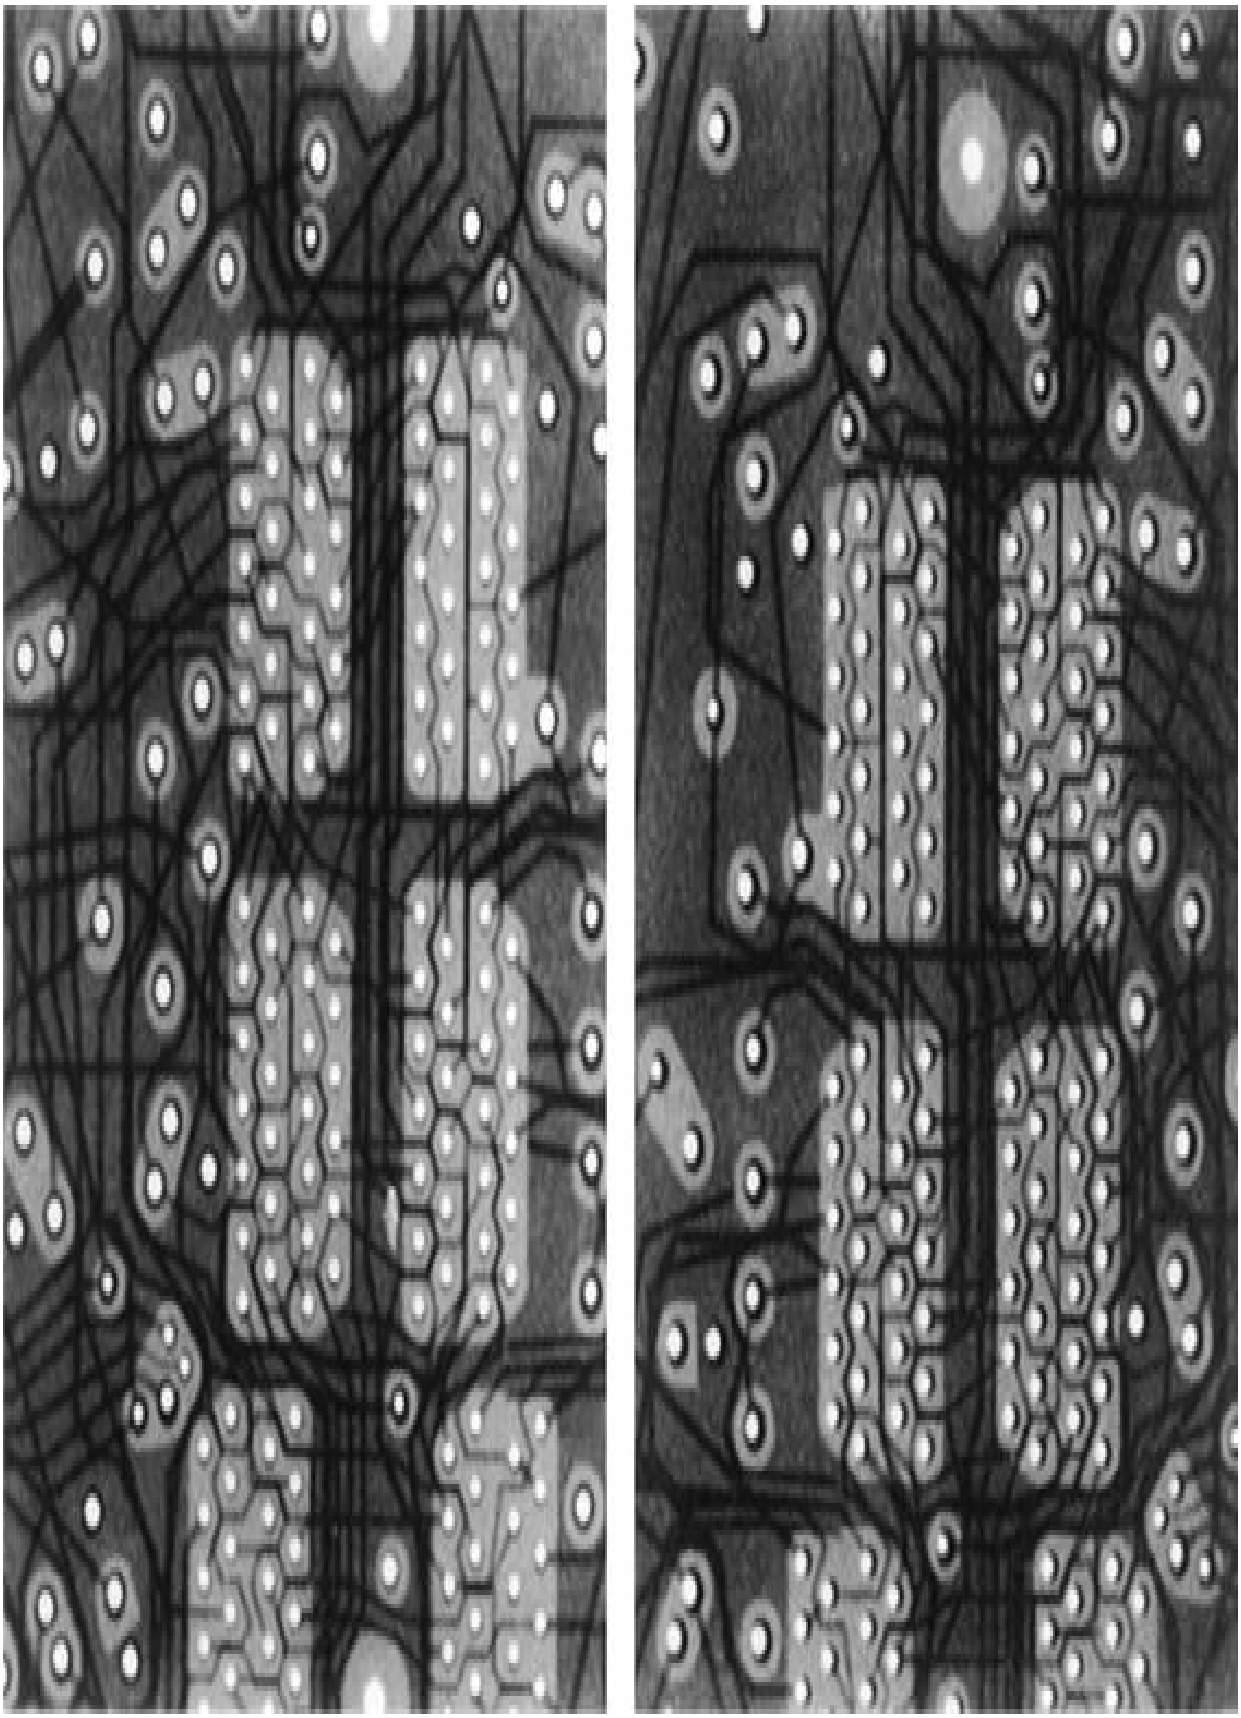

FIGURE 53.12 Layer-to-layer registration, x-ray method. (*Courtesy Sandia Laboratories*.)

53.11.1.8.3 Flatness (Bow and Twist). *Bow* is the deviation from flatness of a PCB characterized by a roughly cylindrical or spherical curvature such that, if the PCB is rectangular, its four corners are in the same plane (see Fig. 53.13). *Twist* is the deformation parallel to a diagonal of a rectangular sheet such that one of the corners is not in the plane containing the other three corners (see Fig. 53.14). Excessive bow and/or twist on a PCB are detrimental to the assembly process when the PCB must fit into card guides or packaging configurations in which flatness is critical. It can also interfere with the proper mounting of the assembly into the intended case. The method for bow and twist measurement can be found in IPC-TM-650 method 2.4.22. The maximum bow or twist allowed is 1.5 percent unless the PCB has surface-mounted devices (SMDs) attached where the requirement is reduced to a maximum allowable of .75 percent.

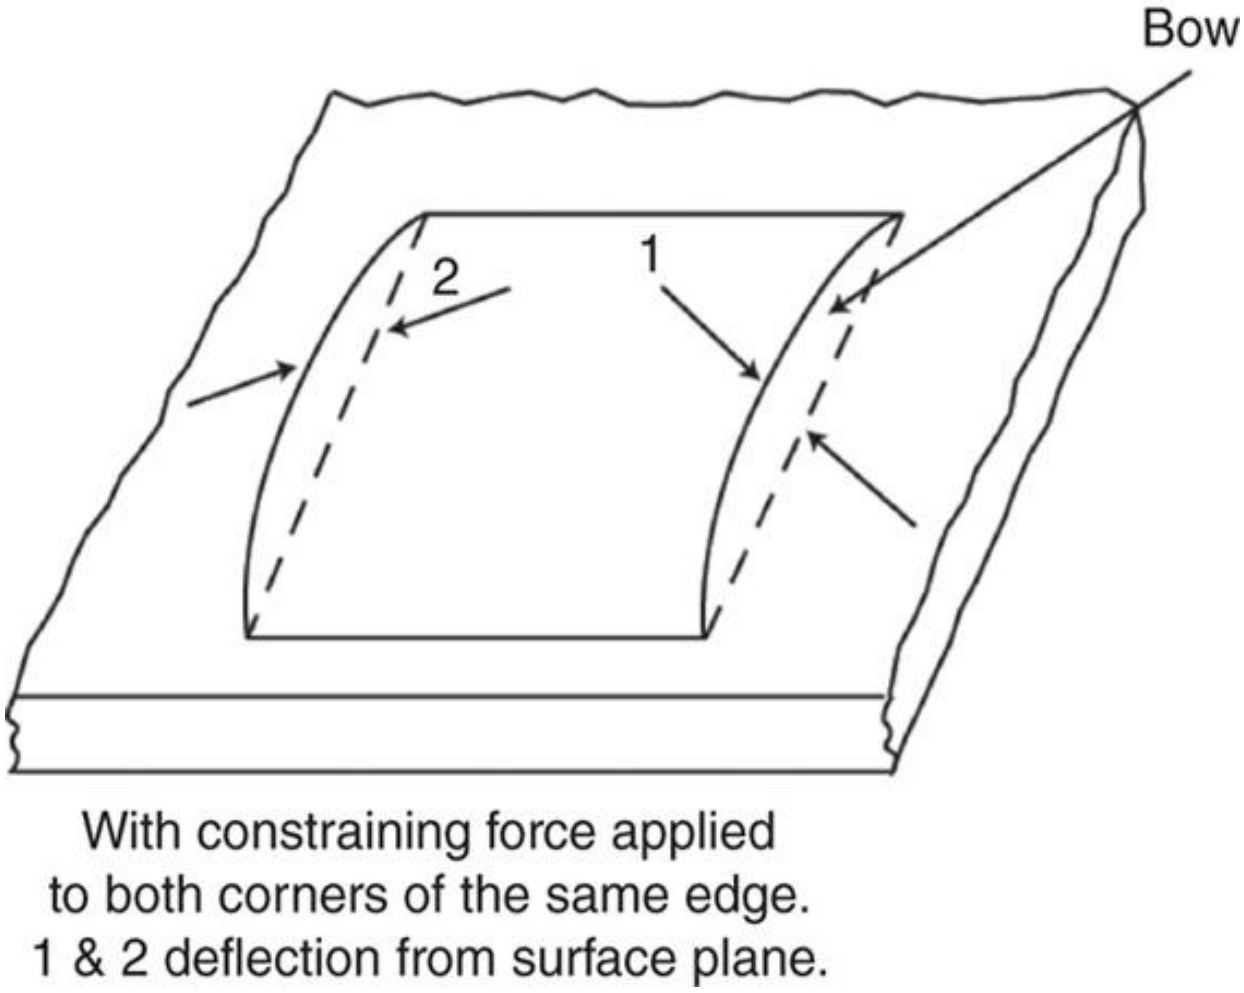

FIGURE 53.13 Bow measurement of PCB. (*Courtesy of IPC*.)

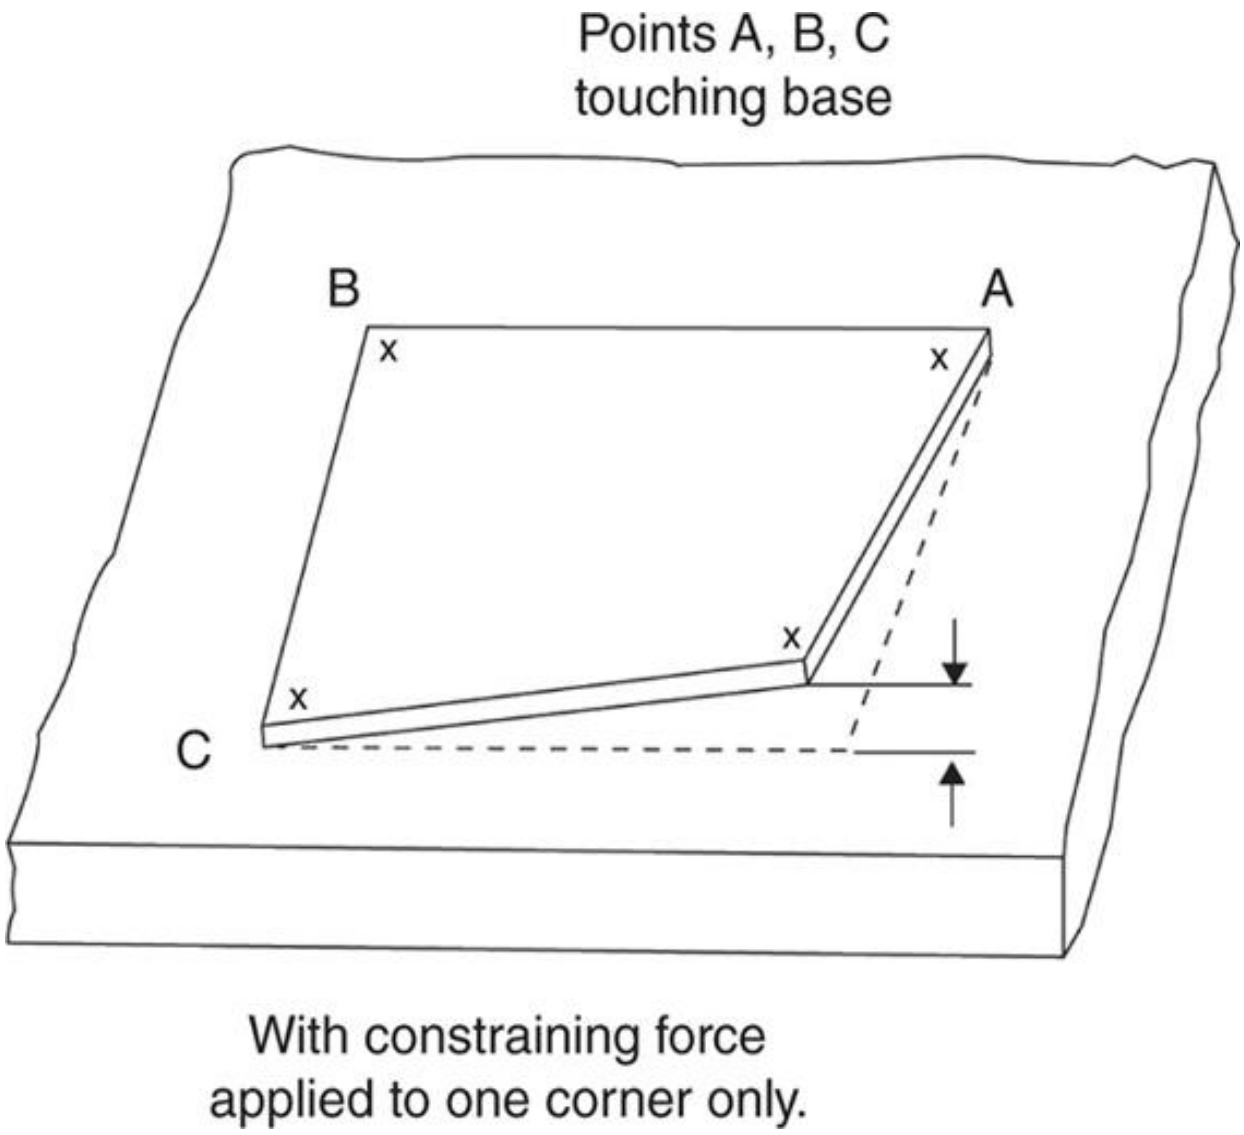

FIGURE 53.14 Twist measurement of PCB. (*Courtesy of IPC*.)

53.11.1.8.4 Cleanliness (Solvent Extract Methods). PCBs are fabricated using wet chemistry and mechanical techniques. Some of the chemical baths contain metallic salts and organic materials. These chemicals, if left on the surface, could affect the functionality of the PCBs by reducing electrical insulation resistance and promote corrosion or ECM on the conductor pattern. This condition is usually associated with low operating voltage (10 V or less) and requires three components: moisture, metallic contaminants, and voltage. The ionic cleanliness test

measures the conductivity of a deionized water and alcohol solution used to wash the PCB. Commercial equipment is available to perform ionic cleanliness testing. The organic cleanliness test uses an organic solvent wash (e.g., acetonitrile) to remove “loose” organics from the surface of the PCB. This wash solution is collected on a glass plate and the solvent is allowed to evaporate. Any organic contamination in the wash solution leaves a cloudy residue on the glass that can be subsequently analyzed for composition using ion chromatography. These two tests are mutually exclusive in that the organic test cannot detect ionic contamination and vice versa. Note that when a solder mask is required on PCBs, an additional cleanliness test is performed on the uncoated PCBs before coating.

53.11.1.9 Solderability Inspection. Solderability inspection measures the ability of the attachment points to be wetted by solder in the areas for the joining of components to the PCB. Three terms are used to describe acceptability of solderability:

- *Wetting:* The formation of a relatively uniform, smooth, unbroken, and adherent film of solder to a basis material, wetting is the preferred and acceptable condition.
- *Dewetting:* This condition results when molten solder has coated the attachment surface and recessed, leaving irregularly shaped mounds of solder separated by areas covered with a thin film of solder that fully covers the basis metal. Dewetting is not acceptable for attachment points but is allowed on ground or voltage planes for Class 1 and 2 products.
- *Nonwetting:* This nonconforming condition is the partial adherence of molten solder to a surface that it has contacted, leaving some of the basis metal exposed.

53.11.1.9.1 Solderability Testing and Coating Durability. Many methods for inspecting PCBs for solderability both quantitatively and qualitatively have been established. However, the most meaningful method is that used in the actual assembly soldering operation (hand, wave, drag, reflow soldering, etc.). ANSI/J-STD-003, “Solderability Tests for Printed Boards,” addresses the recommended test methods and subsequent storage conditions that have no adverse effect on the solderability of those portions of the PCB intended to be soldered. Test coupons or PCBs are subjected to accelerated aging for a length of time defined by a coating durability requirement reflected on the procurement documentation, followed by solderability testing. Solderability is acceptable when the surfaces to be soldered have fully wetted. See Fig. 53.15 for acceptable criteria for PTHs, and Fig. 53.16 for examples of nonwetting.

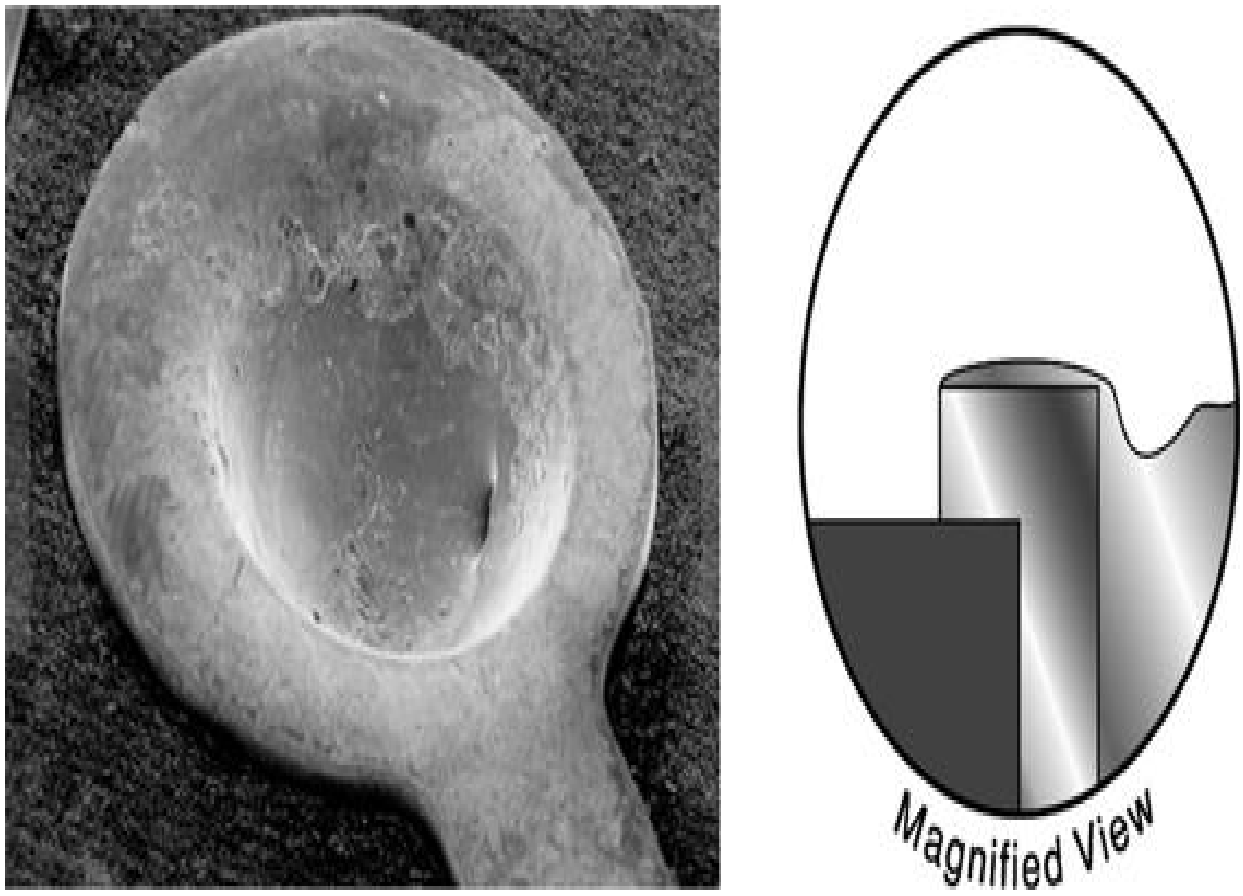

FIGURE 53.15 "Wetted" solder joint. (*Courtesy of IPC*.)

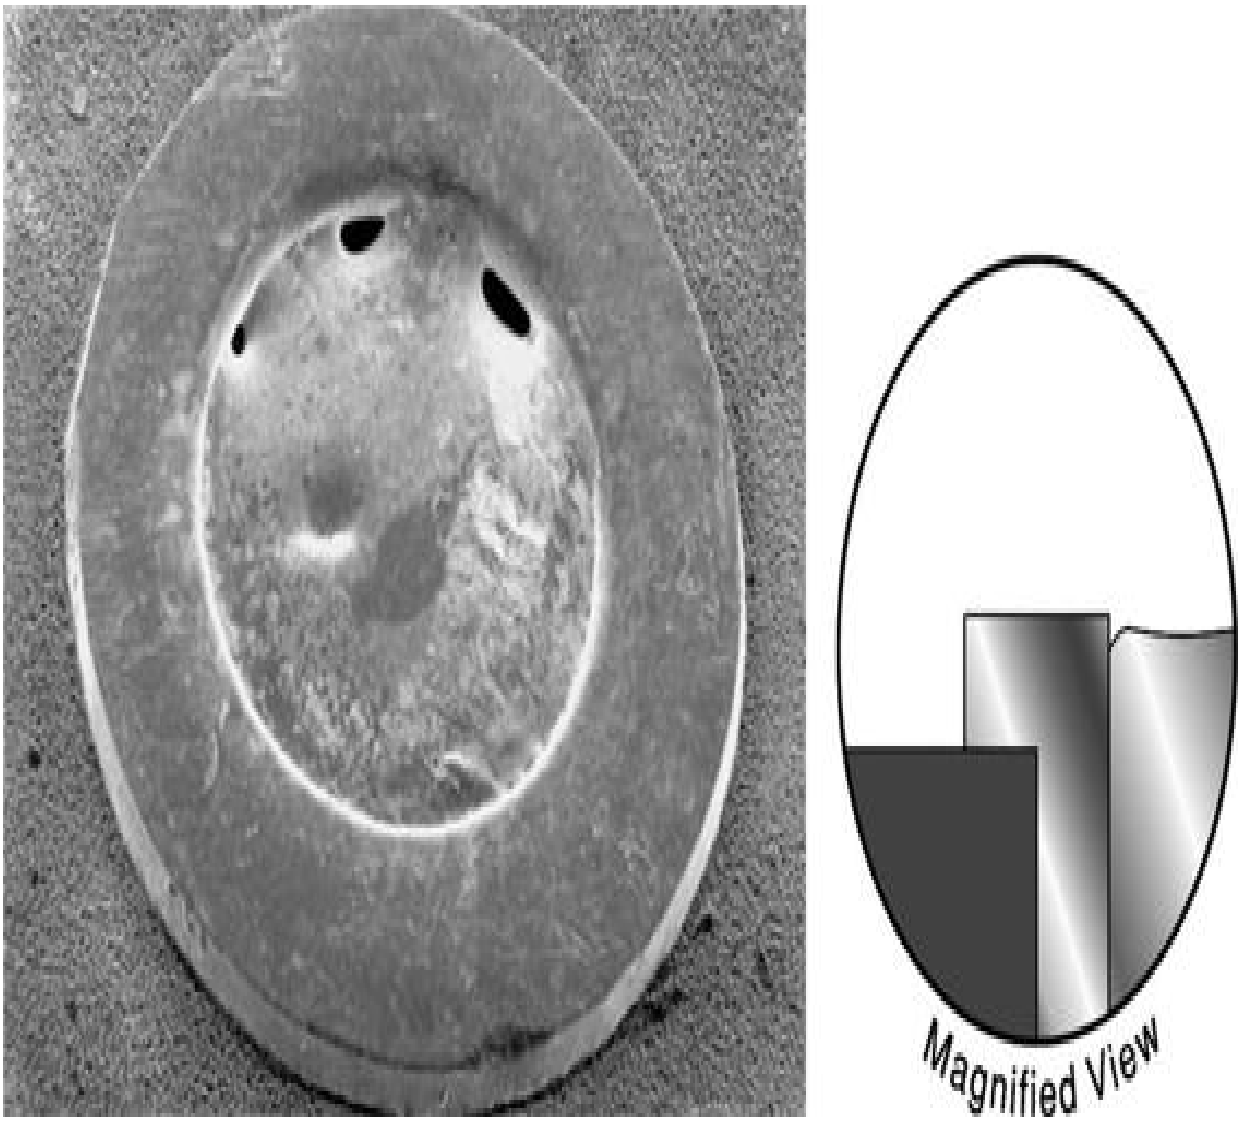

FIGURE 53.16 Non-“wetted” solder joint. (*Courtesy of IPC*.)

53.11.1.9.2 Coating Durability Requirements. The coating durability requirements are classified into three categories:

Category 1: Minimum coating durability is required. The PCB is intended to be soldered within 30 days from time of manufacture and likely to experience minimum thermal exposure.

Category 2: Average coating durability is required. This classification is intended for PCBs likely to experience

storage of up to 6 months from the time of manufacture and moderate thermal or solder exposure.

Category 3: Maximum coating durability is required. This classification is intended for PCBs that are likely to experience long storage (over 6 months from time of manufacture) and that may experience severe thermal or solder processing steps, etc. It should be recognized that there may be significant difficulty involved, a cost premium, or delivery delay associated with PCBs specified to meet this durability level.

53.11.1.9.3 Surface Finishes. Lead-free alloys are the most popular alloy used for surface finishes on PCBs due to RoHS requirements. There are many different compositions of lead-free alloys and they behave differently in practice. Other surface finishes are rapidly finding their way onto the PCBs. IPC-6012 lists more than 25 different surface finishes that are now in use for PCBs. Tin-lead solder alloys (e.g., 63/37) are also still appearing on PCBs where RoHS restrictions do not apply. It is important to understand that the composition and type of the surface finish influence solderability. The procurement documentation must state specifications for surface finish. Methods available for analyzing the alloy composition on the plated PCB include wet analysis, atomic absorption, and x-ray fluorescence (XRF). XRF is popular because of the ease of obtaining the alloy composition and thickness nondestructively.

53.11.1.10 Electrical Inspection. These inspections are performed to verify circuit integrity after processing and substantiate that the electrical continuity, signal integrity, and isolation characteristics of the PCB meet the design specifications. Electrical inspection methods are typically performed on the production PCBs, but evaluation of signal integrity is routinely performed on specially designed test coupons. Two popular nondestructive electrical tests are

insulation resistance and circuit continuity tests. These are usually performed on 100 percent of complex PCBs, especially multilayer ones. Automated electrical test equipment with either stationary or moving test probes allows the probes to make contact with the all parts of the circuit pattern in order to verify the continuity and isolation characteristics of the PCB.

53.11.1.10.1 Circuit Continuity. Continuity tests are performed on PCBs to verify that the printed circuit pattern is interconnected as designed. Testing can be performed with an inexpensive multimeter for simple PCBs or with more elaborate automated equipment such as a computer-enhanced bed-of-nails or flying probe tester. These types of automated testers can either be preprogrammed with the circuit interconnection information derived from the computer design files or can use a known good “golden” PCB as a test template to learn the interconnection information. The preferred method is to perform the continuity test on all PCBs submitted for acceptance. This method is especially recommended for multilayer circuitry, where the internal patterns and interconnections cannot be inspected visually after fabrication.

53.11.1.10.2 Insulation Resistance (Circuit Shorts). The purpose of this test is to measure the resistance offered by the insulation system of a PCB to an applied voltage. Low insulation resistances can prevent proper operation of circuits by permitting the flow of leakage current. This test can also reveal the presence of contaminants from processing residues. The test is performed by applying voltage to isolated nets and measuring the current flow between these nets. Test voltages of 40 to 500 V DC and minimum insulation resistances of 100 to 500 MΩ are popular. As with continuity testing, insulation resistance testing typically employs automated test equipment using stationary or moving probes.

53.11.1.10.3 Impedance. Impedance (see Fig. 53.17) is the amount of resistance a circuit offers alternating current (AC) signals. High frequency AC circuits require that the impedance of PCB circuits be matched to that of the components in order to transfer the most signal between the components on the assembly. Proper impedance matching also reduces radio wave emissions (EMF) from the assembly. Impedance is measured using Time Domain Reflectometry (TDR) and is typically measured using a specially designed test circuit on a coupon. Requirements for impedance as well as test circuit design must be supplied to the PCB manufacturer. Variations in impedance of up to 10 percent around the nominal value are expected and are not unusual do to standard process variations in circuit geometry and insulation make up. Tighter control of impedance is possible, but special attention must be made to processes and materials to achieve reductions in variation.

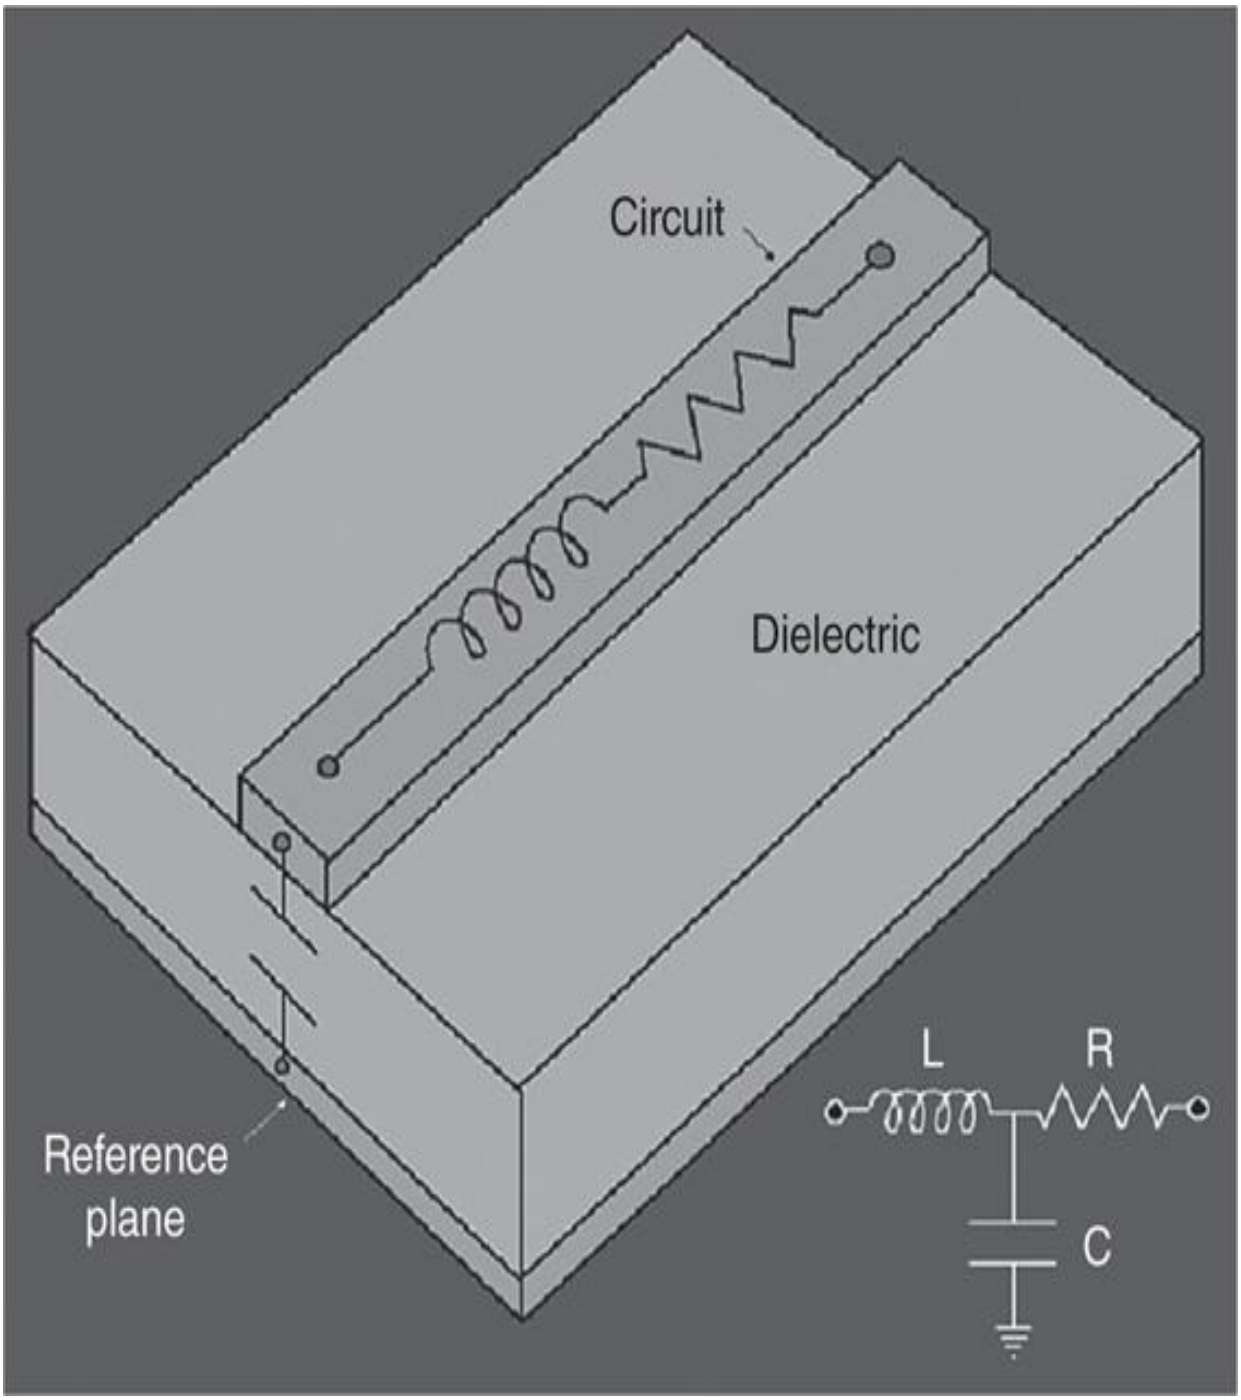

FIGURE 53.17 Impedance diagram of a PCB. (*Courtesy of Microtek Laboratories*.)

53.11.2 Internally Observable Imperfections

These are imperfections where evaluation from the outside of the PCB is not possible. They require the preparation of a microsection in order to view and evaluate conformance. Proper preparation of a PCB microsection requires a great deal of skill. The method of sample removal, the microsection materials used and the grinding/polishing techniques all significantly affect the ability to produce a microsection that will reveal and not hide imperfections. The basic methodology for the preparation of microsections can be found in IPC Test Methods 2.1.1 and 2.1.1.2, but numerous papers and articles have been written on the art of the microsectional preparation process. The use of test coupons to perform microsections is optimal due to the fact that internal layer connections do not always appear for every layer in holes on the PCB, whereas they always appear in a properly designed microsection test coupon. See Fig. 53.18 for a microsection of a multilayer PTH.

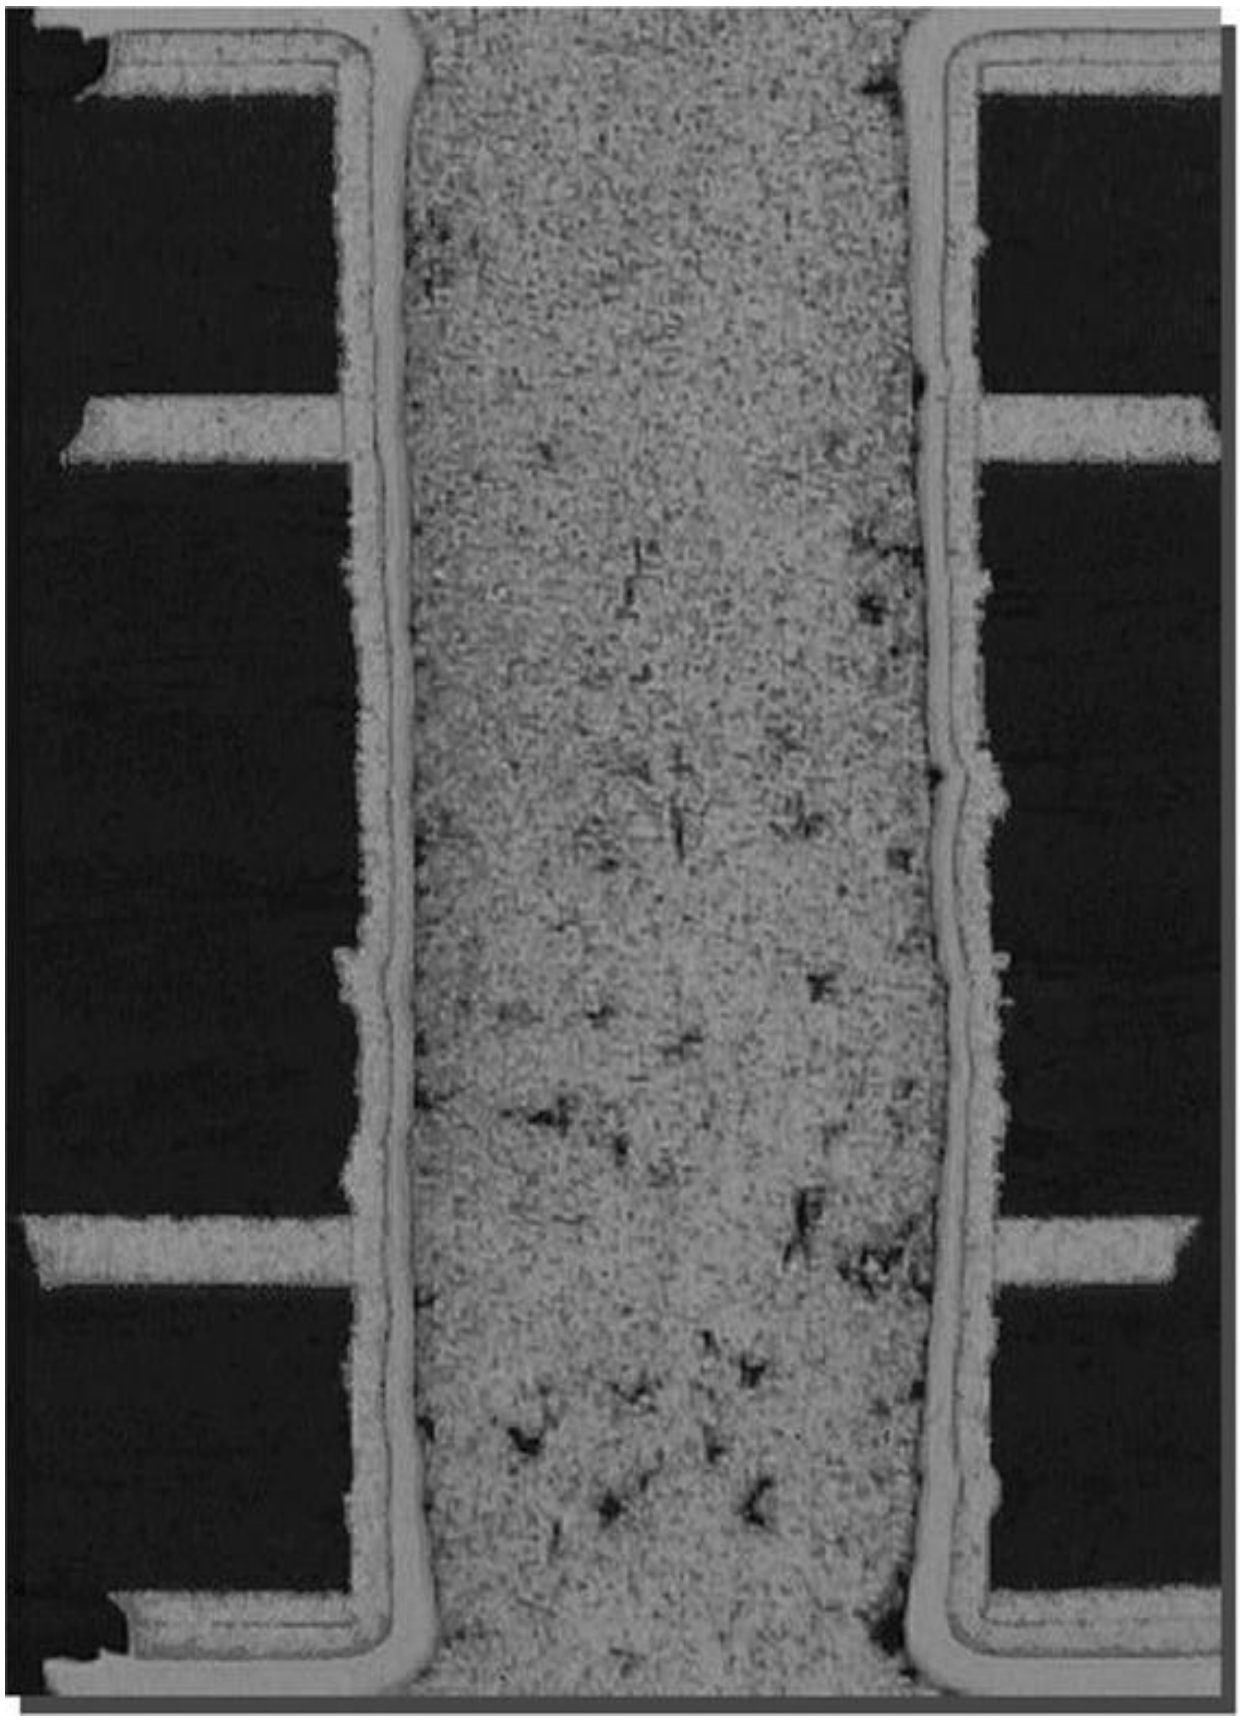

FIGURE 53.18 Vertical PTH microsection of a multilayer PCB. (*Courtesy of Microtek Laboratories*.)

53.11.2.1 Microsectioning. Samples for microsectioning are removed from the PCB or test coupon. The removed specimen should contain at least three of the smallest holes in a line that will allow microsectioning. Because shearing or punching of microsection samples from a PCB or coupon can result in creating failure mechanisms that are not truly present in the production PCB, the practice is not recommended. Routing or sawing microsection samples is the preferred method for sample removal. The samples should be mounted in a resin-based medium that does not produce too much heat during curing and does not shrink away from the surface of the holes being evaluated. Holes should be fully filled, as partially or nonfilled holes result in poor mount conditions, difficult sanding/polishing processes, and possibly erroneous thickness results. Examination under a microscope for internally observable attributes should be performed at 100× magnification. If it is not possible to determine whether the condition is acceptable, progressively higher magnifications should be used until accurate determination of acceptance is determined. Polishing vertical PTH cross sections to the center of the hole ±10 percent is critical. If the hole is polished less than or more than the center of the hole, the measured plating thickness will be artificially high. Horizontal plane, PTH cross sections are recommended as references for internal-layer interconnection quality and are prepared by grinding from the top down through the hole to the inspection area. See Fig. 53.19 for an example of a horizontal microsection.

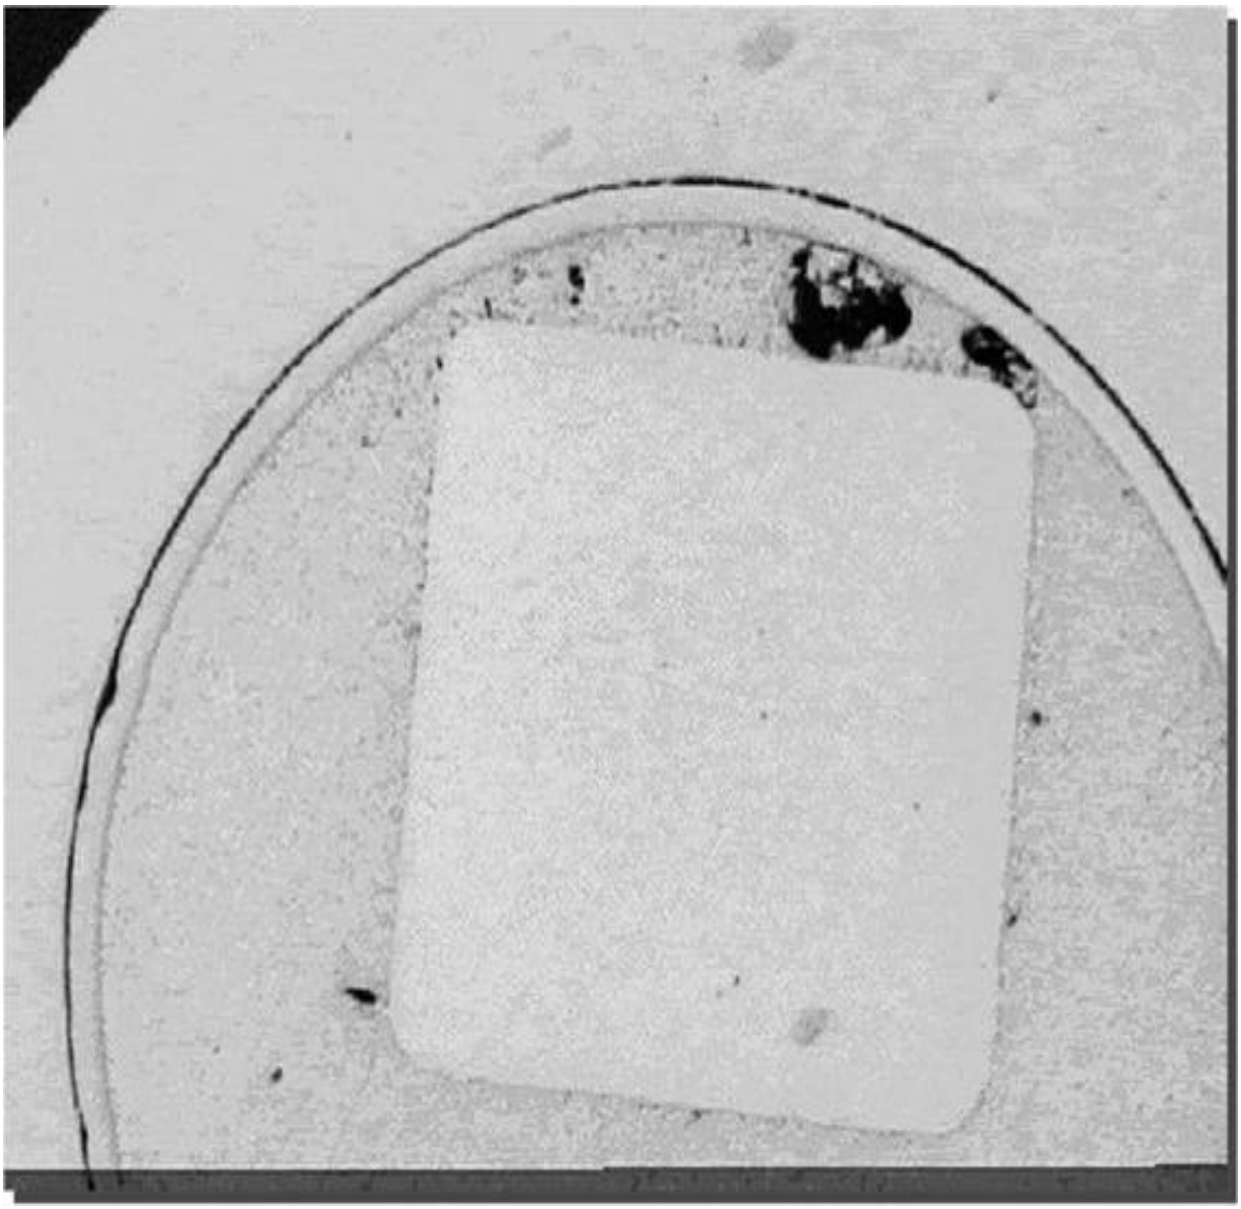

FIGURE 53.19 Example of interconnection separation in a horizontal microsection. (*Courtesy of Microtek Laboratories*.)

Although horizontal PTH cross sections are usually more accurate for plating thickness, interconnection separation, and annular ring measurements, they do not allow adequate inspection of other attributes such as voids, plating uniformity, adhesion, etchback, and nodules. Surface plating thickness measurements are taken from vertical cross sections of conductor areas. Microsection mounts are usually etched with an appropriate etchant to show grain boundaries

between the copper-clad foil and copper plating and to remove copper smearing introduced during the polishing process.

53.11.2.1.1 Thermal Stress Solder Float Test. The temperatures associated with component attachment and rework process expose PCBs to thermal and mechanical stress and may deform the PCB shape and cause premature degradation of the base material which in turn causes stress to the plating in the PTH. Thermal stress inspection is performed to predict the acceptability of the PCBs after the component attachment and rework process. PTH degradation, separation of platings or conductors, and base material delamination are induced or amplified by the thermal stress test. The PCB specimen is oven-conditioned to reduce moisture, placed in a dessicator on a ceramic plate to cool, fluxed, floated in a solder bath, and placed on an insulator to cool. Visual inspection for imperfections is followed by microsectioning of the PTHs and inspection under a microscope for integrity. Test coupons are typically used for thermal stress inspection.

53.11.2.2 Microsection Evaluation. The evaluation of internally observable attributes in the microsection consists of the following set of inspections:

- Subsurface attributes in the PCB material such as delamination, blistering, cracks, ground plane clearance, and layer-to-layer spacing
- Internal conductor attributes including over- and underetch, conductor cracks and voids, and foil thickness
- PTH attributes including size, annular ring, plating thickness, plating voids and nodules, plating cracks, resin smear, etchback, wicking, innerlayer (post) separation, and solder thickness

53.11.2.3 Subsurface Imperfections in the PCB Material

53.11.2.3.1 Base Material Voids after Thermal Stress. Heat from component attachment and rework process will transfer quickly through the copper holes and pads in a PCB to the base material in close proximity to the copper. This rapid heat movement can easily cause imperfections to occur in the base material and this area near the holes is exempted from evaluation for base material imperfections. This area is defined as the “thermal zone” and described in detail by IPC-A600. Outside this thermal zone, base material voids should not exceed 0.08 mm for rigid PCBs and 0.5 mm for flexible PCBs or flexible portions of rigid-flexible PCBs. Base material voids found in the same plane of flexible or rigid-flexible PCBs should not have a combined dimension greater than 0.5 mm (see Fig. 53.20).

53.11.2.3.2 Clearance of Holes to Power/Ground Planes. Electrical isolation between power/ground planes and nonconnected holes is necessary to ensure that shorting does not occur. This is especially true with holes that are nonplated and used for mounting of the PCB to a frame, as without proper clearance, the mounting hardware can cause shorting to the frame or between power and ground. The minimum distance of this clearance should reflect the minimum electrical spacing requirement on the procurement documentation (see Fig. 53.21).

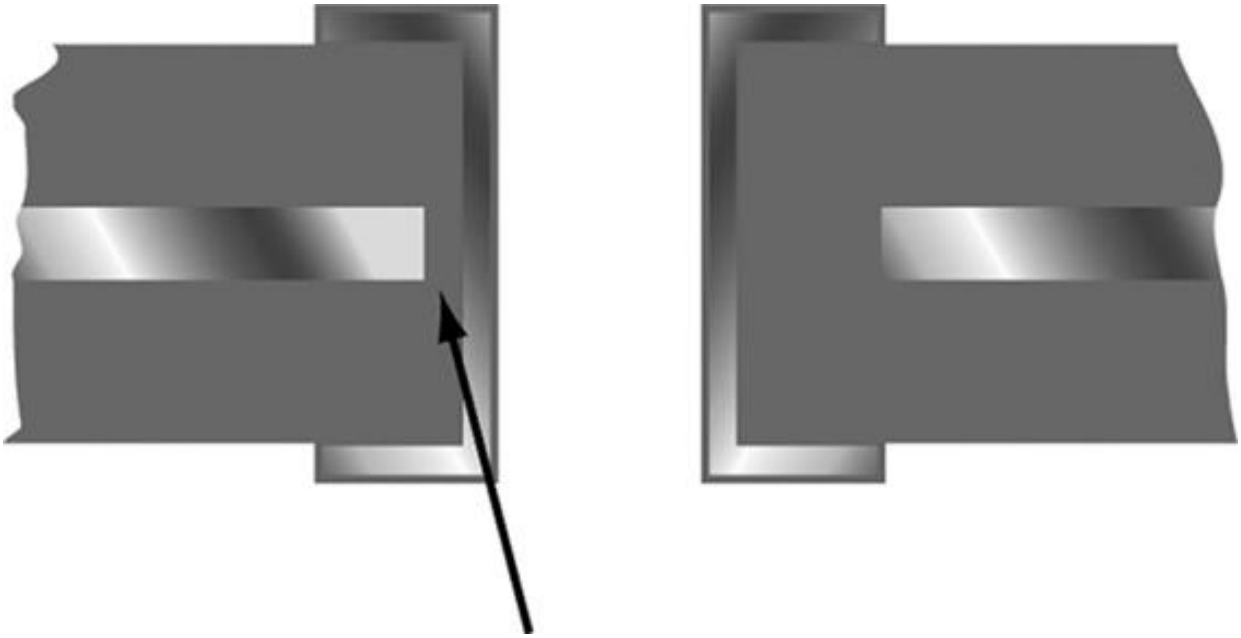

FIGURE 53.21 Clearance between PTH and power/ground plane. (*Courtesy of IPC*.)

53.11.2.3.3 Delamination and Blistering. Delamination or blistering observed in the microsection is a nonconforming condition and the inspection lot should be rescreened in accordance with the externally observable visual requirements for delamination and blistering set forth earlier in this chapter.

53.11.2.3.4 Resin Smear. Resin smear is transferred from the base material onto the surface or edge of the internal conductive pattern during the drilling process. Excessive heat generated during drilling softens the resin in holes and smears it over the exposed internal copper areas. This condition creates a resin insulator between the internal land and subsequent plating in the holes, and the result is open or poorly connected circuits. The imperfection is removed from the holes by chemical or plasma cleaning prior to metallization. Inspection for resin smear is per formed by viewing vertical and horizontal microsections of PTHs. And any evidence of it is nonconforming. (See Fig. 53.22 for an example of resin smear prior to etchback.)

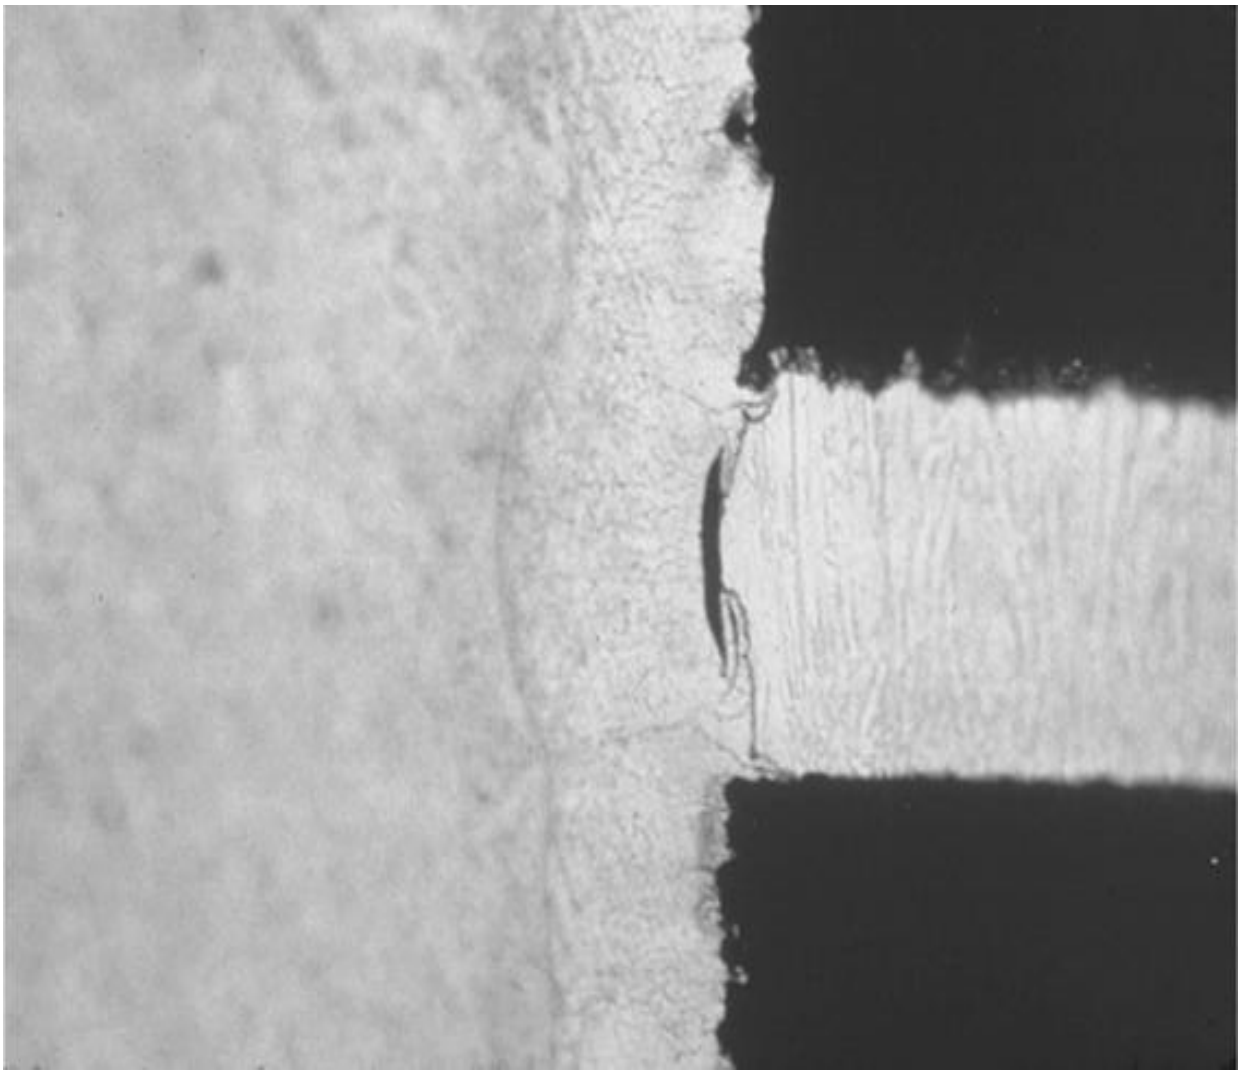

FIGURE 53.22 Resin smear in PTH, vertical microsection. (*Courtesy of IPC*.)

53.11.2.3.5 Etchback. Etchback is a process for the controlled, positive removal of nonmetallic materials from side walls of holes to a specified depth. It is used to remove resin smear and then to remove the reinforcement material laterally to expose additional internal conductor surfaces. The degree of etchback is critical to function. Too much etchback creates excessively rough hole side walls and causes weak PTH structures. Etchback requirements range between 0.0002 and 0.0031 in (0.005 and 0.08 mm). The degree of etchback is measured by evaluating vertical PTH cross sections of multilayer PCBs and is determined

“effective” if at least one of the top or bottom surfaces of the internal conductor is attached to the plated copper on both visible sides of every conductor layer. (See Fig. 53.23 for an example of acceptable etchback for all classes.)

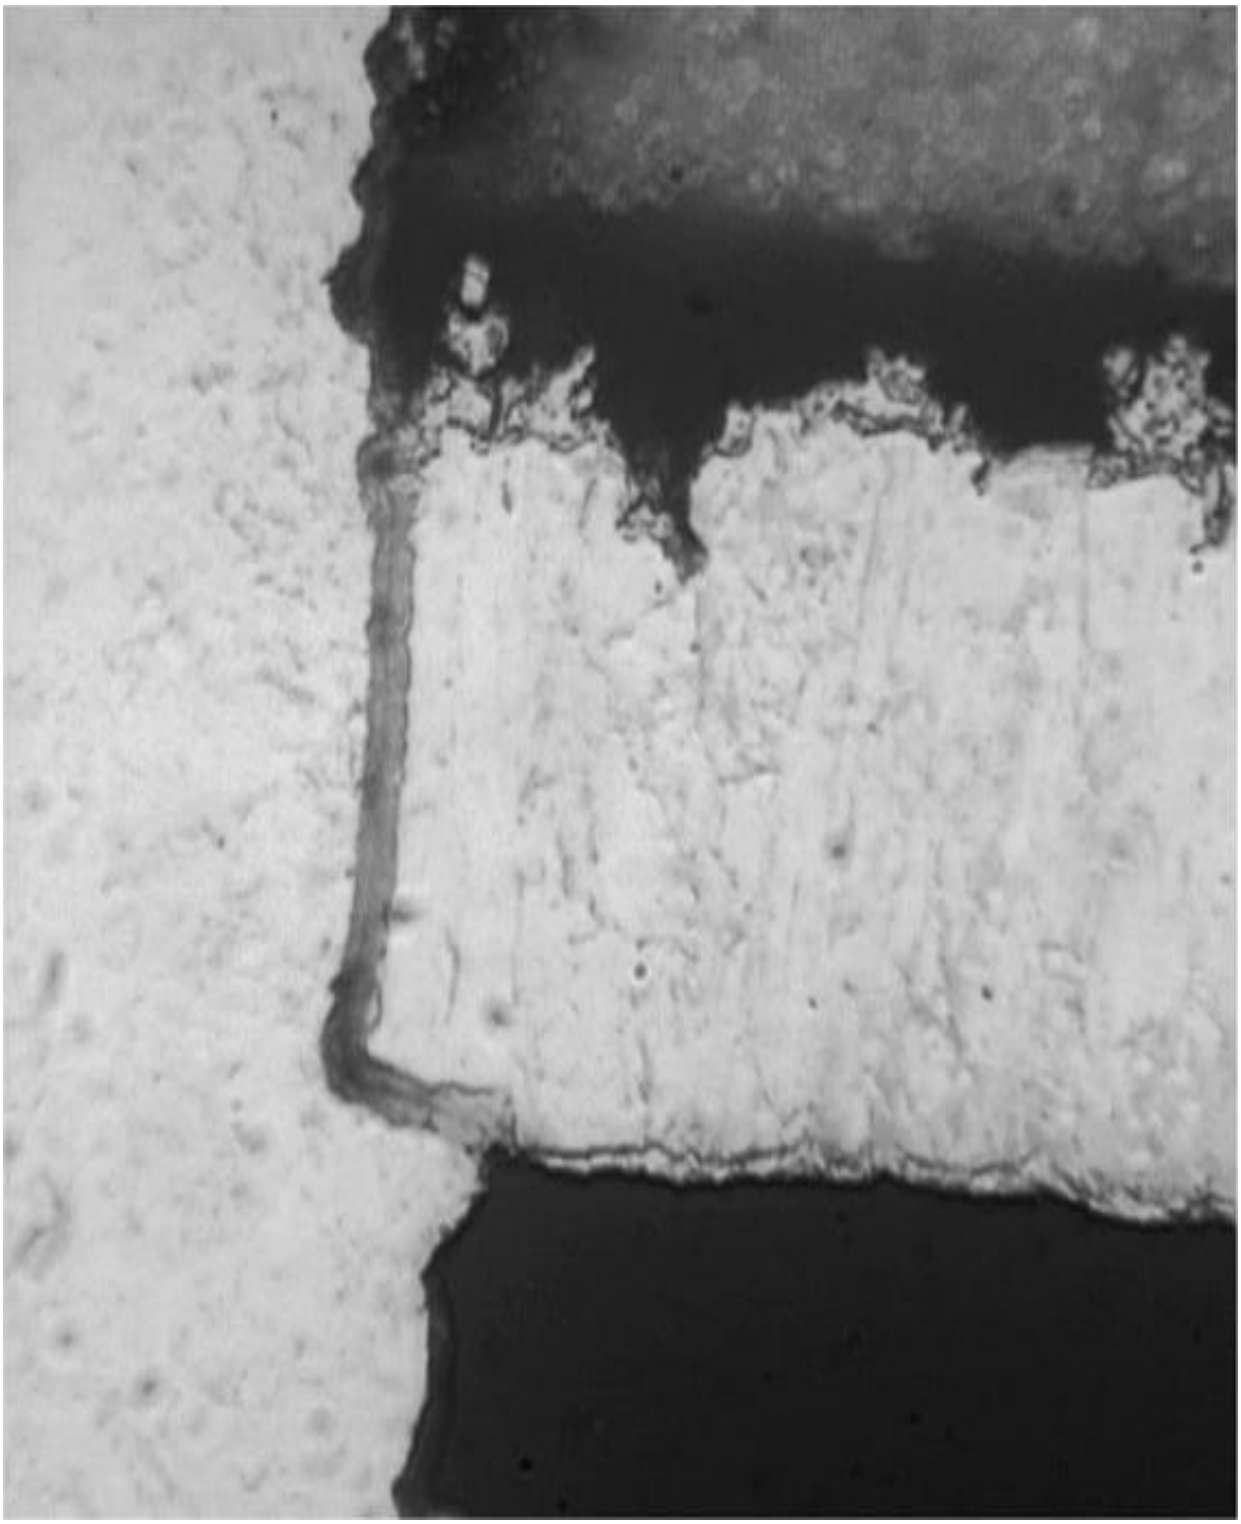

FIGURE 53.23 Effective etchback in PTH, vertical microsection. (*Courtesy of IPC*.)

53.11.2.3.6 Negative Etchback. This is a condition where the internal copper conductors rather than the insulating material in the hole have been laterally removed. This condition is not allowed when positive etchback is required. In all other cases, negative etchback should be minimal or nonexistent.

53.11.2.3.7 Layer-to-Layer Spacing. The minimum spacing between two consecutive layers in the PCB is determined by drawing an imaginary plane between the two most eccentric points of each of the two layers in the field of view and measuring the distance between these two planes. (See Fig. 53.24 for an example of minimum dielectric thickness between layers.)

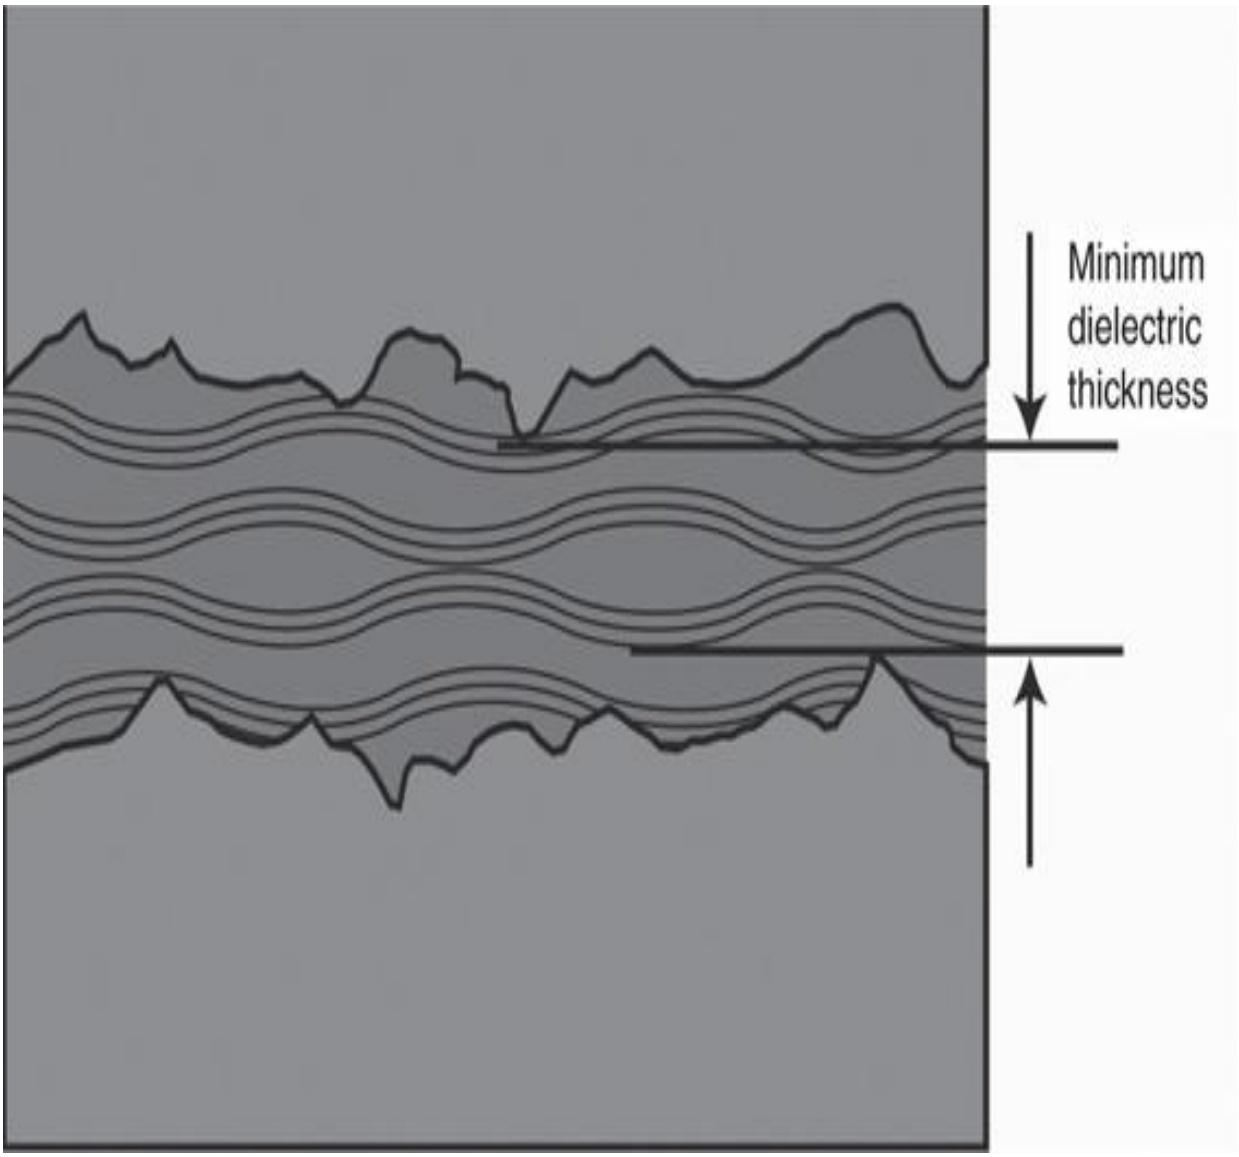

FIGURE 53.24 Layer-to-layer spacing, minimum dielectric thickness, vertical microsection. (*Courtesy of IPC*.)

53.11.2.4 Internal Conductor Imperfections in the Microsection. In theory, circuits should be rectangular. Circuits are usually designed with this rectangular shape in mind. In practice, circuits are trapezoidal. Depending on how the circuit is formed, this shape could be close to a rectangle or differ significantly from it. The further from a rectangle that the shape is, the less volume the circuit has to conduct current compared to a corresponding rectangular circuit. Terms like *outgrowth, undercut, overhang*, and *etch factor*

are used to define the attributes of these shapes (see Figs. 53.25 and 53.6).

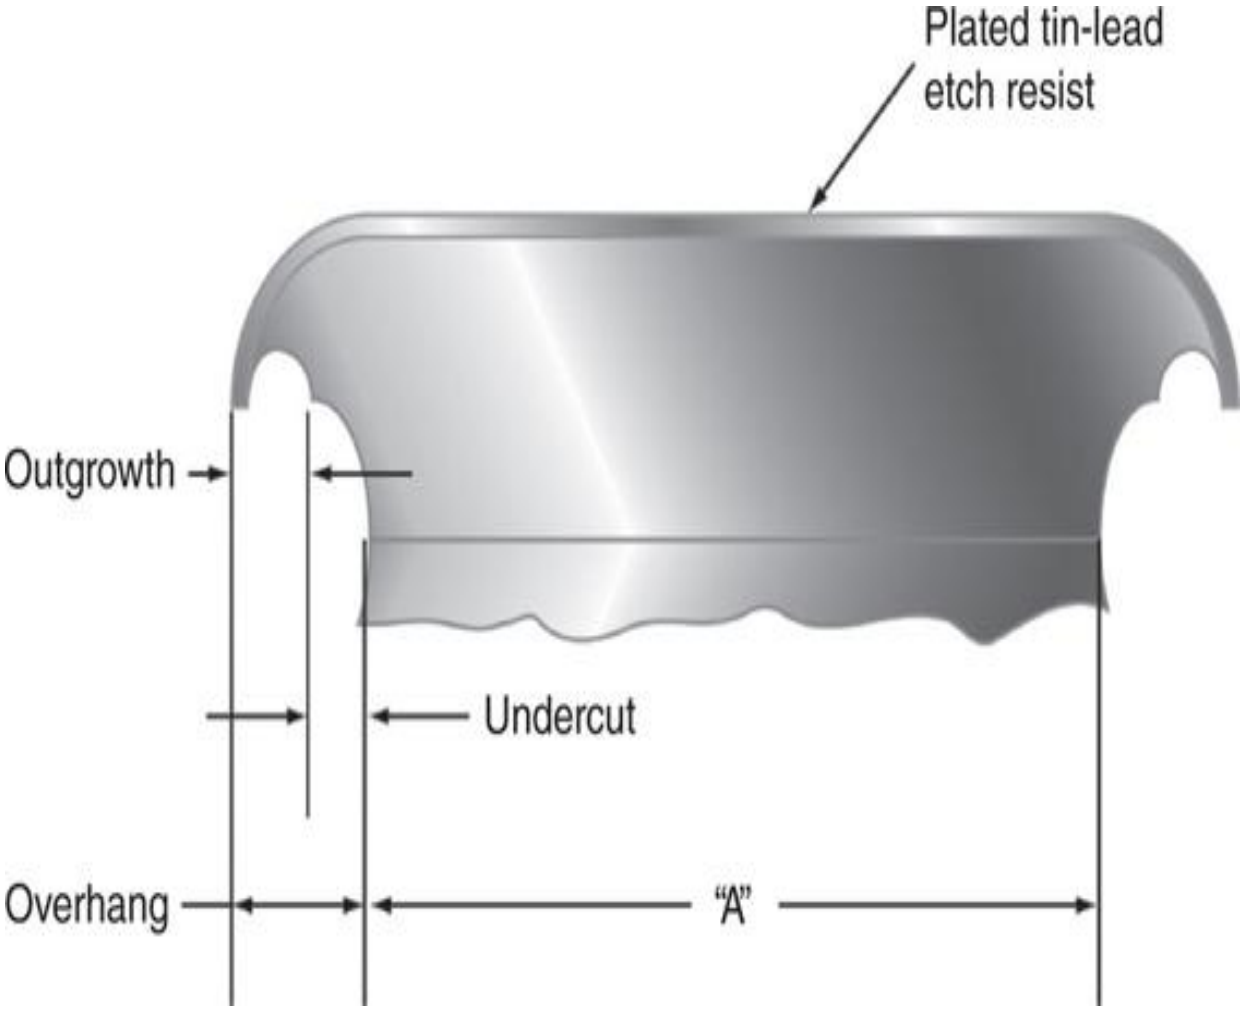

FIGURE 53.25 Circuit geometry. (*Courtesy of IPC*.)

53.11.2.4.1 Conductor Width. This attribute is measured at the widest point of the circuit in the microsection. The procurement documentation should state the minimum allowable width (see Fig. 53.6).

53.11.2.4.2 Conductor Thickness. Conductor thickness depends on the thickness of the base foil used and the additional plating added to the surface during any plating processes. Allowances for expected reduction of both foil and plating thicknesses due to manufacturing processes must be

considered. A detailed table of these minimum acceptable conductor thicknesses with allowances for manufacturing processing can be found in IPC-A-600.

53.11.2.5 PTH Imperfections. Nothing affects the function of the PCB more than imperfections in the PTH. These imperfections are usually not observable from the surface, and microsectional sampling of holes is limited to almost statistical insignificance. Despite this, evaluations of the microsection represent one of the most important evaluations that can be done on a PCB.

53.11.2.5.1 Annular Ring. Minimum internal annular ring is evaluated on the internal copper land that exhibits the shortest distance between its outer edge and where it ends in or at the plating in the hole. It should be noted that a microsection identifies layer shift in only one direction and that microsections in both *x* and *y* directions should be evaluated to better determine the actual shift that may be present. Horizontal sections from the top of the PCB down to the layer in question give a 360° view of the pad and can be used to exactly identify minimum annular ring and layer shift. The procurement documentation should specify the requirement for minimum annular ring (see Fig. 53.26), and in cases where the allowable annular ring is zero or “breakout,” the breakout cannot be allowed in the area where the circuit enters the pad (conductor-to-land junction area), as this will reduce the circuit’s current-carrying capacity.

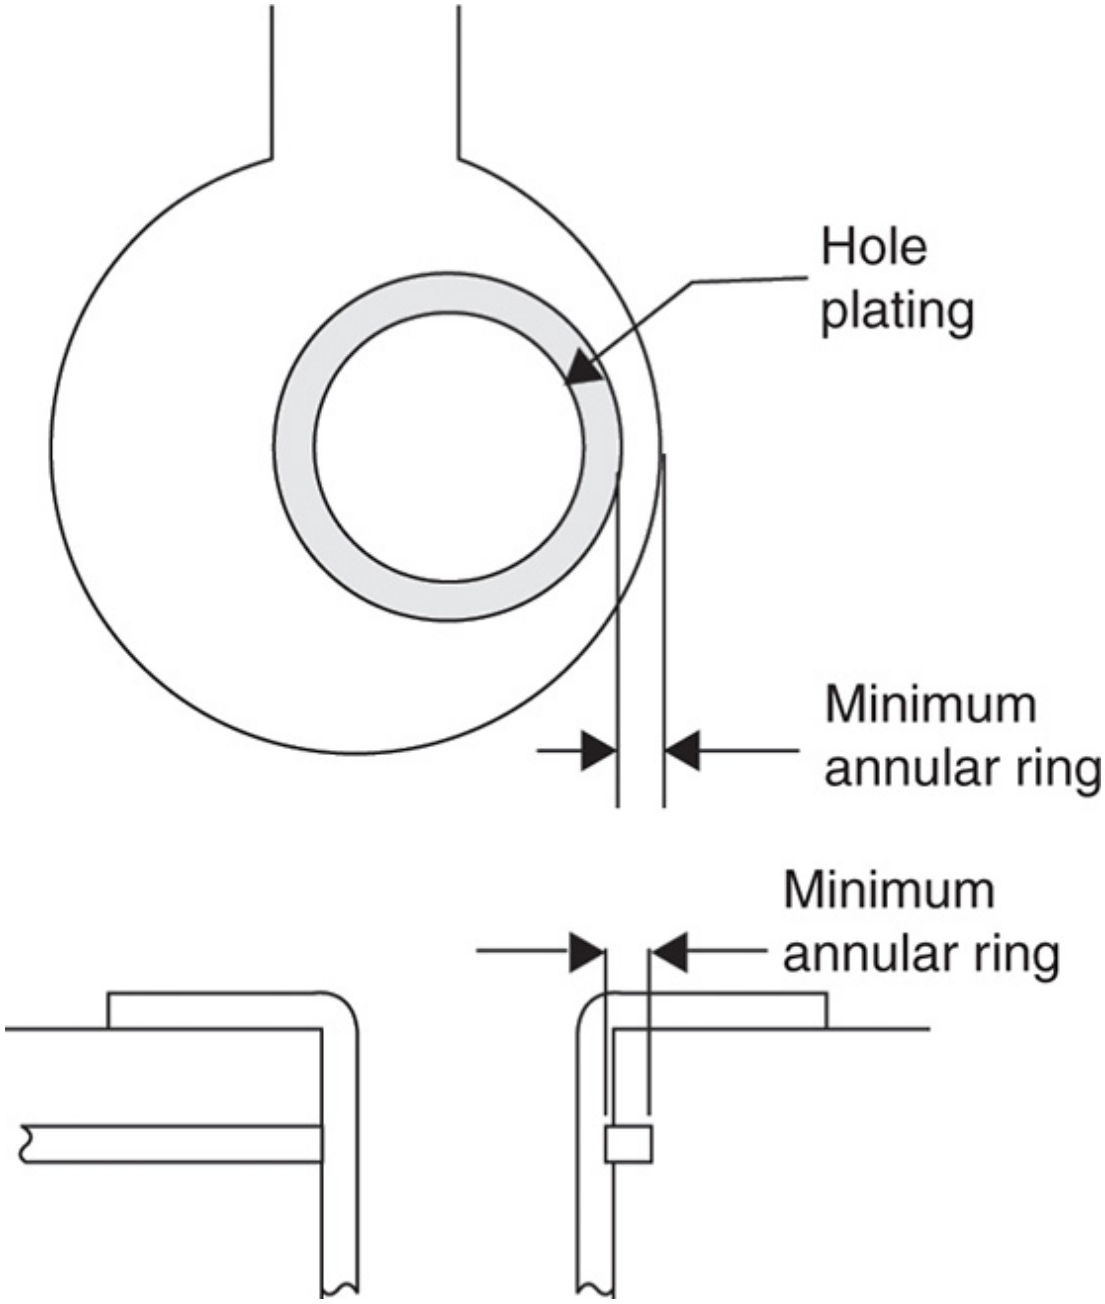

FIGURE 53.26 Internal annular ring measurement, horizontal and vertical microsection (does not include plating). (*Courtesy of IPC*.)

53.11.2.5.2 Lifted Lands. Lifted lands on the PCB surface prior to thermal stress are not allowed and if found, the entire inspection lot should be reevaluated to the externally observable visual requirements for lifted lands described earlier in this chapter. Lifted lands after thermal stress are allowed.

53.11.2.5.3 Cracks. Cracks in the foils and platings in the microsection are broken into the following six categories (see Fig. 53.27):

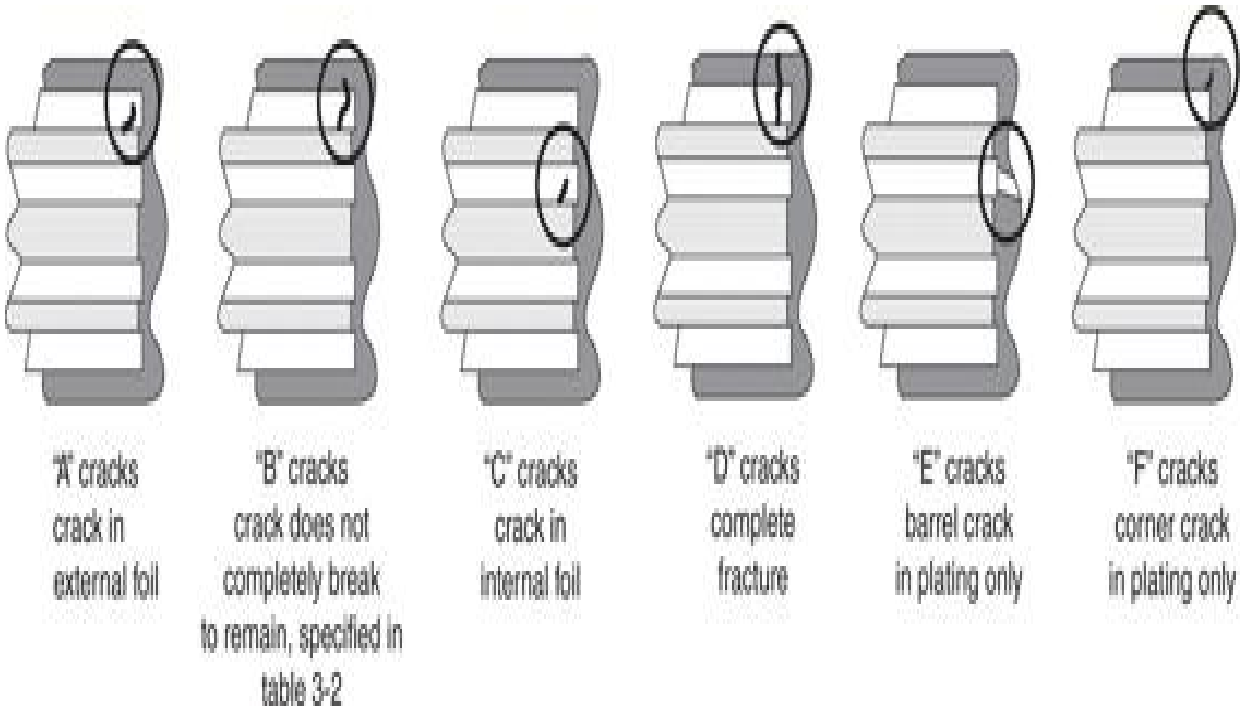

FIGURE 53.27 Types of cracks in the PTH, vertical microsection. (*Courtesy of IPC*.)

"A" type cracks occur in the external foil. They do not extend into the plating and are acceptable for all classes of PCBs.

"B" type cracks occur in the external foil. They go completely through the foil and extend into, but not completely through, the plating and are acceptable only for Class 1 PCBs.

"C" type cracks occur in the internal foil and are nonconforming for all classes of PCBs.

"D" type cracks completely penetrate the external foil and plating and are nonconforming for all classes of PCBs.

"E" type cracks occur in the barrel plating of the hole. They are nonconforming for all classes of PCBs.

"F" type cracks occur in the corner of the plating of the hole and are nonconforming for all classes of PCBs.

53.11.2.5.4 Plating Nodules. Plating nodules should not reduce the PTH diameter below the minimum requirement specified in the procurement documentation.

53.11.2.5.5 Plating Thickness. Plating thickness should be measured at three places in the plated hole and averaged. The absolute minimum plating thickness observed should also be recorded. The minimum plating thickness requirements for the three-area average along with the absolute minimum thickness observed are defined in IPC-6012 (see Fig. 53.28).

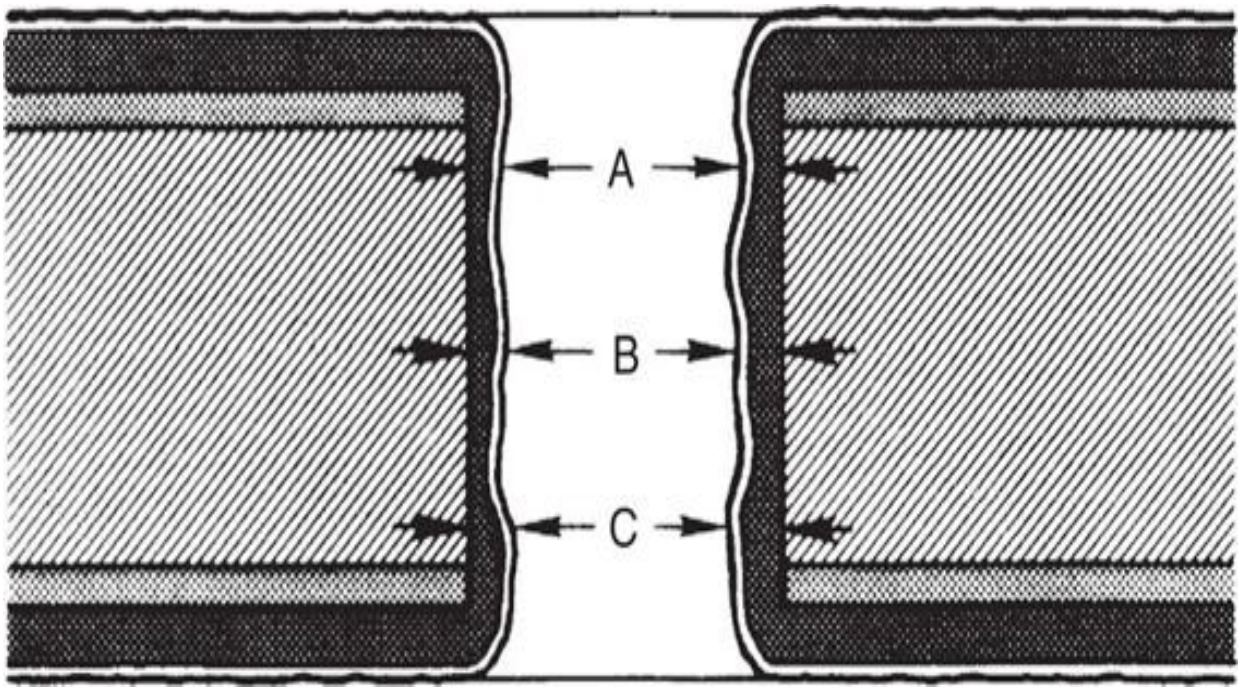

FIGURE 53.28 Measurement of plating thickness in PTH, vertical microsection. (*Courtesy Sandia Laboratories*.)

53.11.2.5.6 Plating Voids. When found in the microsection, plating voids should be limited to one per

microsection. No void should span more than 5 percent of the PCB thickness or be present at the interface of internal copper foil to the plating.

53.11.2.5.7 Solder Resist Thickness. When the procurement documentation specifies this thickness, it should be measured at the thinnest area observed between the copper and the surface of the solder resist. This is usually at the corner of the copper trace.

53.11.2.5.8 Wicking. During the drilling and hole cleaning process, glass fibers from the base material can be removed inward from the hole surface. During the copper-plating process, the copper will follow this glass removal topography, creating pockets of plating that extend laterally from the hole into the base material. This wicking can significantly reduce the electrical conductor spacing between holes or between holes and internal circuits. The maximum allowances for wicking can be found in IPC-A-600 (see Fig. 53.29).

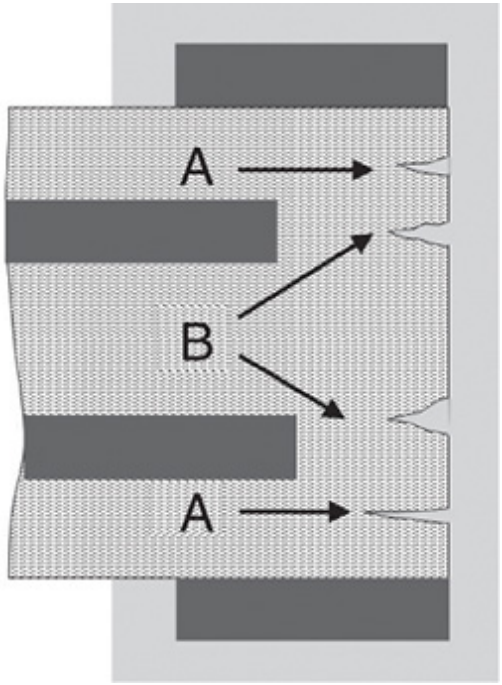

FIGURE 53.29 Wicking, vertical microsection. (*Courtesy of IPC*.)

53.11.2.5.9 Interconnection Separation. This is defined as the separation between the internal copper foil and the copper plating in the hole. It is also sometimes referred to as post separation. Any evidence of this imperfection in the microsection makes the associated PCBs nonconforming. This imperfection is a severe issue that will likely reduce the service life of the PCB (see Fig. 53.30).

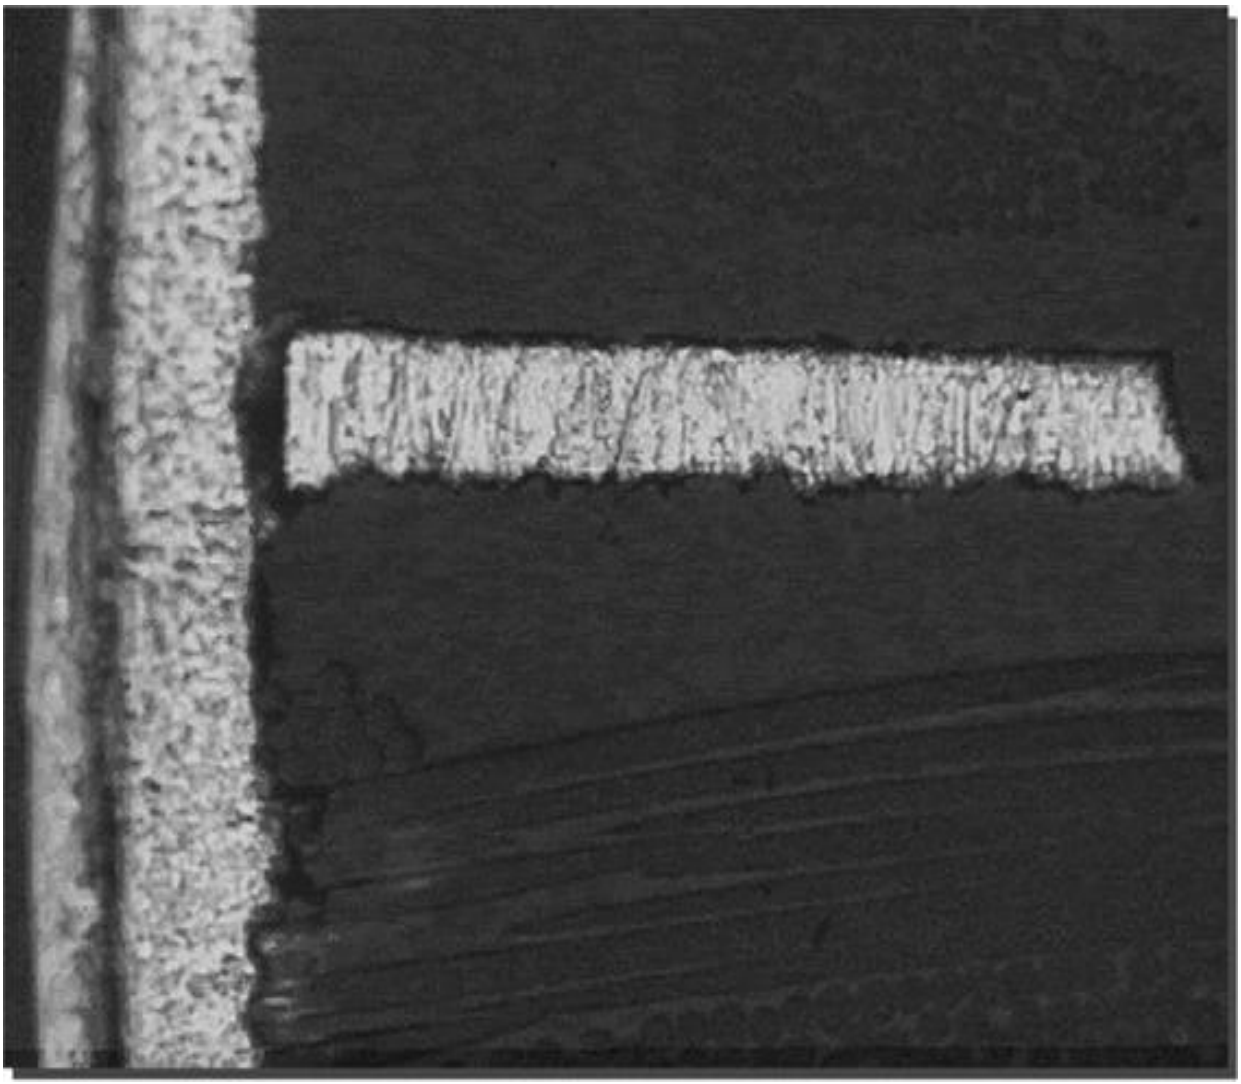

FIGURE 53.30 Interconnection separation, vertical microsection. (*Courtesy of Microtek Laboratories*.)

53.11.2.5.10 Material Fill of Blind and Buried Vias. When blind or buried vias are present in a PCB, it is important that

they be microsectioned and evaluated in addition to any through holes evaluated. Buried vias are typically filled with resin, and this resin should fill a minimum of 60 percent of each buried via.

53.11.2.5.11 Cap Plating over Filled Holes. For via holes that are designed to be filled and subsequently plated over, there should not be any plating voids exposing the via fill material. The copper wrap plating of the via structure which is located below the cap plating shall be continuous from the filled plated hole onto the annular ring and needs to extend at least 25 µm from the edge of the drilled via (see Fig. 53.31) and have a minimum thickness which is specified by IPC-A-600.

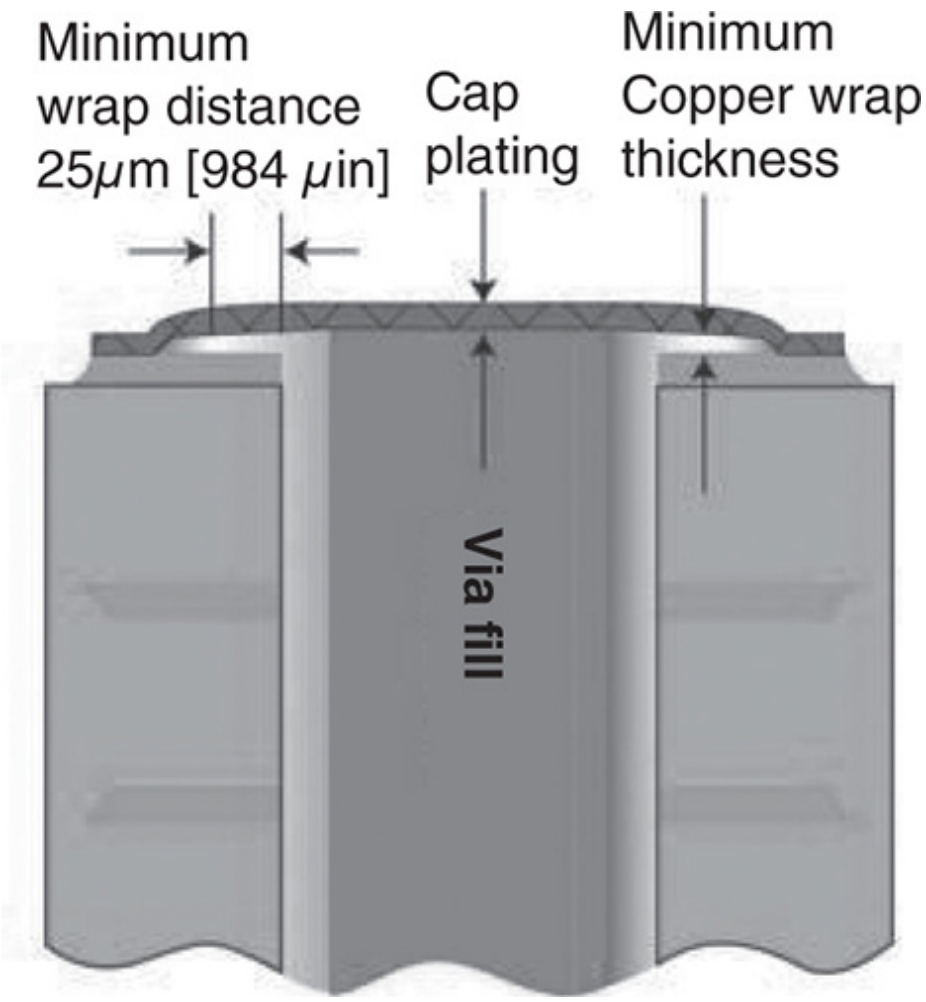

FIGURE 53.31 Surface copper wrap measurement (*applicable to all filled PTHs*).

53.12 RELIABILITY INSPECTION USING ACCELERATED ENVIRONMENTAL EXPOSURE

Reliability inspection consists of performing specific tests to ensure that the PCB will function under the influence of the climatic and/or mechanical forces to which it will be subjected during its expected lifetime. Environmental tests are performed on preproduction PCBs or specifically designed test coupons to verify design adequacy and manufacturing process control. Specific tests are sometimes specified as part of the PCB acceptance procedure to expose a prospective failure situation. Specific environmental testing, as part of the acceptance procedure, is prevalent in high-reliability products where long term life is desirable or necessary. Prior to performing reliability inspection, it is recommended that a simulation of the cycles required for component attachment and rework be performed as a preconditioning. Test results then relate to the actual condition of the PCB after the assembly process. Specific test methods for performing these tests can be found in IPC-TM-650.

53.12.1 Thermal Shock

The thermal shock test is particularly efficient in identifying (1) PCB designs with areas of high mechanical stress and (2) the resistance of the PCB to exposure of high- and low temperature extremes. This test is periodically required in IPC-6012 for product acceptance and is also used for PCB

supplier qualification inspection. A thermal shock is induced on a PCB by exposure to severe and rapid differences in temperature. The test is usually performed by transferring the PCB from one temperature extreme (e.g., 125°C) to the other (e.g., −65°C) rapidly, usually in less than 2 min. A resistance difference in excess of 10 percent between the stabilized hot side measurement at the 1st and 100th cycles is considered nonconforming, but requirements in the thousands of cycles are sometimes specified for high-reliability PCBs. The thermal shock test can produce cracking of plating in the holes and base material delamination (refer to IPC-TM-650, method 2.6.7.2, for the procedure). Note that continuous electrical monitoring during thermal shock cycling will detect intermittent electrical circuit anomalies that may not be detected with periodic measurement techniques. Intermittent circuit anomalies usually occur at the high-temperature extreme.

53.12.2 Surface Insulation Resistance

Surface insulation resistance (SIR) testing evaluates the electrical resistance between two surface electrical conductors separated by dielectric material. This test detects the bulk conductivity and electrical leakage through surface electrolytic contaminants when the samples are exposed to a high-humidity environment that allows the contaminates to become mobile on the surface. The test conditions are a relative humidity of 85 to 92 percent at a temperature range of 35 to 45°C without the use of an electrical forcing potential during the exposure. (See Fig. 53.32 for example of a SIR test pattern.)

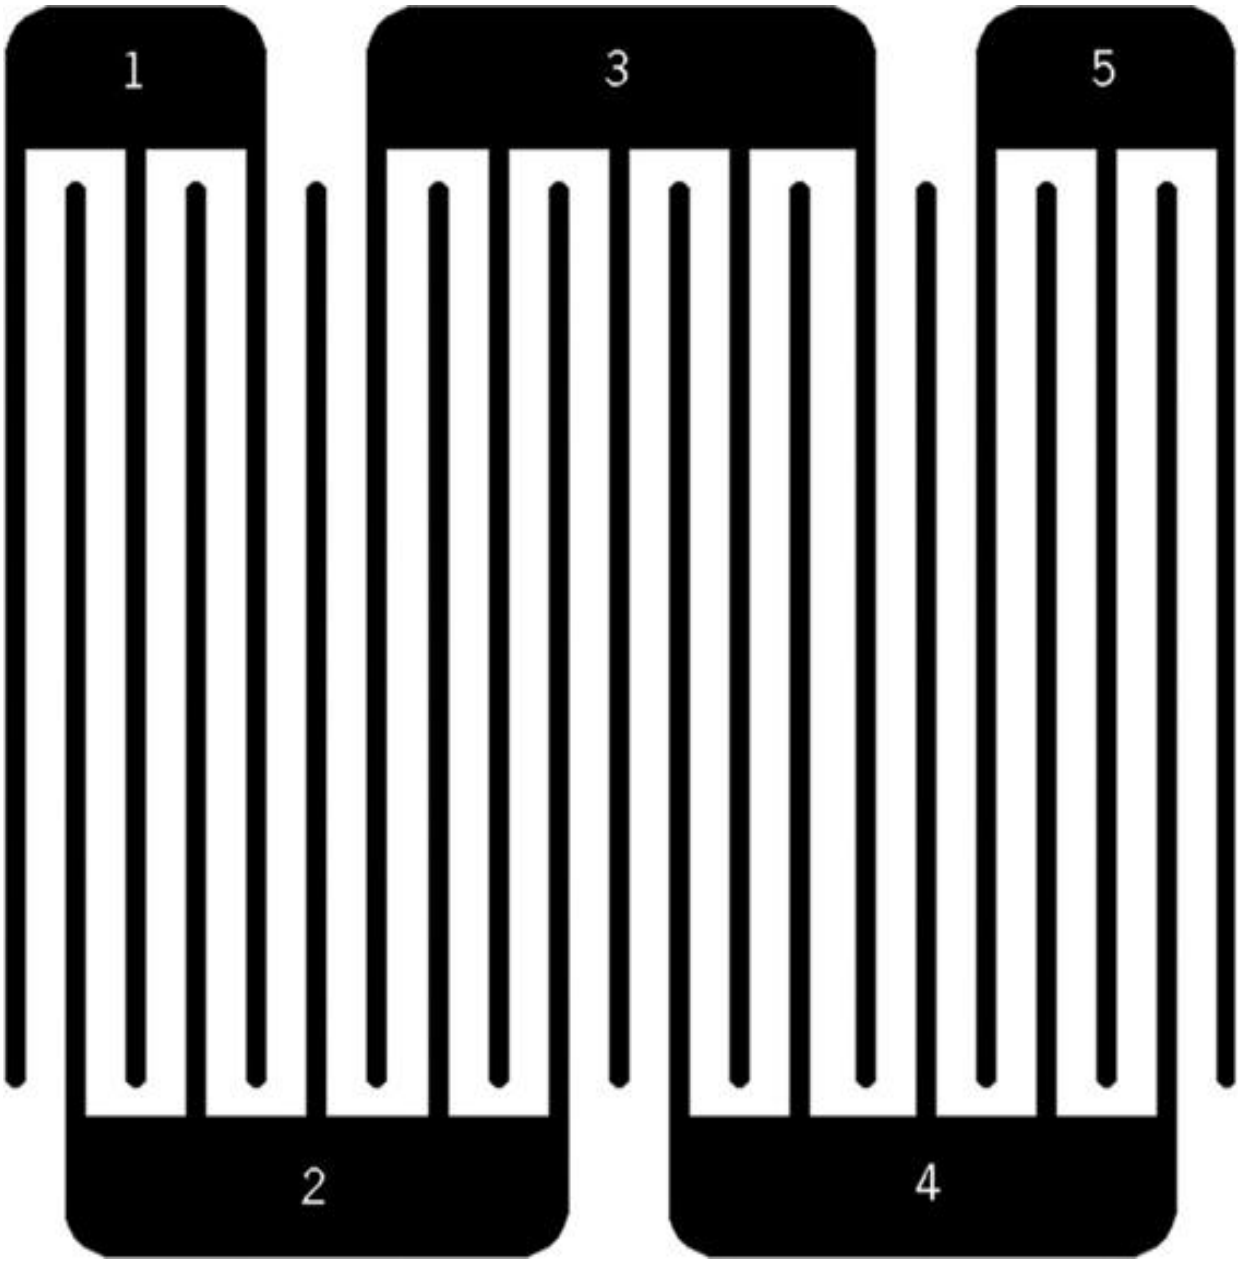

FIGURE 53.32 Basic SIR test pattern. (*Courtesy of Microtek Laboratories*.)

53.12.3 Moisture and Insulation Resistance

This is an accelerated method of testing the PCB for the deteriorative effects of condensing high humidity and heat conditions typical of tropical environments. The test

conditions are a relative humidity of 90 to 98 percent at a cycling temperature range going back and forth from 25 to 65°C with a forcing voltage potential of 10 to 100 VDC applied to the test circuit(s). After the required test cycles are completed, the PCB is subjected to insulation resistance testing. Test specimens should exhibit no blistering, measling, warp, or delamination after the MIR test.

53.12.4 Dielectric Withstanding Voltage

This test is used to verify that the component part can operate safely at its rated voltage and withstand momentary overpotentials due to switching, surges, and similar phenomena. It also serves to determine whether insulating materials and spacings on the PCB are adequate. The test is performed on either an actual PCB or a test coupon. Voltage is applied between mutually insulated conductors on the specimen or between insulated conductors and power/ground planes. The voltage is increased at a uniform rate until the specified value is reached. The voltage is held for 30 s at the specified value and then reduced at a uniform rate. Visual examination of the specimen is performed during the test for evidence of flashover or breakdown between contacts. The test can be either destructive or nondestructive, depending on the degree of overpotential used.

53.12.5 Electrochemical Migration and Conductive Anodic Filament Testing

Electrochemical migration (ECM) and conductive anodic filament (CAF) tests are intended to detect the growth of conductive metal filaments on or in a PCB under the influence of a direct current (DC) voltage bias. This filament growth may occur at either an external or internal surface or interface between dissimilar materials. Growth of the metal filaments is by electrolytic deposition from a solution containing metal ions that are dissolved from the anode in the test circuit and then transported by the electric field toward the cathode. ECM comes in two forms. First are surface dendrites, which form on the internal or external surfaces between the two oppositely charged electrodes. The second form of ECM is CAF, in which filaments form along the interface between the glass-fiber reinforcement and resin system between a hole and another hole or conductor along the path of the fiber. ECM and CAF testing is done at a relative humidity of 85 to 92 percent at a steady-state temperature range between 35 and 85°C using forcing potentials ranging from 10 to 100 V DC during the test depending on the end product application.

CHAPTER 54

ACCEPTABILITY OF PRINTED CIRCUIT BOARD ASSEMBLIES

Mel Parrish

STI Electronics, Inc., Madison, Alabama

54.1 UNDERSTANDING CUSTOMER REQUIREMENTS

When determining the acceptance criteria to use in building or manufacturing a printed circuit board assembly (PCBA), one first and foremost must look at the contract between the supplier and the purchaser of the product. Always determine the needs and/or wants of the customer through contractual communications or, less formally, by talking to the customer if a contract is not detailed enough or does not even exist.

In some situations, contracts are not the norm, such as for consumer electronics built for retail sale or captive production efforts where the customer and producer are one and the same. In these cases, the company must determine the level of quality desired based on company culture and goodwill, reputation for quality products, and the desired life

cycle of the product. Consequences for an unintended or unexpected failure may be a significant driver in this consideration. An electronic medical device used for life support has much greater consequence attached to continued successful operation than a disposable electronic device such as a toy that is intended to be discarded after a short term of use. Additionally, the intended operational environment may have an even greater impact on what should be expected for the acceptability of production. Consider that a product used for military operations such as space travel, arctic conditions, or tropical environments is subjected to much harsher conditions than an office product that sits on a desk in a temperature-controlled environment where the temperature will not vary more than 10°F during its expected life cycle. The range of these expectations is significant and is a paramount consideration for what can be defined as acceptable or nonconforming.

Most standards that define acceptability have roots traceable to the various Department of Defense (DoD) military standards established in the 1960s and 1970s. The advent of complex electronics systems required a standardized approach to acceptability based on lessons learned through testing and product failure analysis that was accomplished by laboratory or research activities. The resulting definitions for acceptance became very restrictive, and although the requirements were initially intended only for harsh environment exposure or products that have a significant consequence for failure, they were used successfully to increase performance of all soldered electronic assemblies. Most commercial production did not share the need for critical continued performance and the accompanying significant impact on production cost. Despite an effort to approach acceptance from a cost-prevention or value-added viewpoint, the military standards are no longer maintained and the DoD research sources for maintaining technology currency were eliminated. The demise of military

standards allowed the industry to develop consensus standards for soldering processes and also acceptability. Undoubtedly the most significant of these is IPC-A-610, which creates varying levels of acceptability for broad application ranging from medical and military products to disposable electronics. Not all products need to survive after an explosion or operate for 30 years without interruption.

Each company should decide whether to build its product to an industry standard such as IPC-A-610, “Acceptability of Electronic Assemblies,” or develop its own workmanship manual that would closely match IPC-A-610 levels for quality. The advantage of adopting a common standard is the universal understanding of expectations it supports between the customer and producer and thus circumvents the need for lengthy negotiations over individual interests. Where individual custom standards are used, the production processes must be adjusted for each customer or product as it is addressed for production. On the other hand, common standards can be transitioned from one project to the next without significant change. The use of a common standard can take into account the perspective of collective experiences of the consensus participants who are involved in the development. Creating an individual standard can also be a rather daunting and expensive task that can provide limited return without the broad application to bear the cost. In any case, the workmanship manual decision must support the company’s objectives to achieve customer expectations for quality with regard to its product.

Detailed specifications may be called out in a drawing or contract, or there may not be any documentation that identifies requirements. In the latter case, the recommendation is to revert to accepted industry standards or an internal quality requirement such as a workmanship manual.

54.1.1 Lead-Free Soldering

Any acceptance criteria decision should define lead-free materials and processes acceptability. Until the advent of the European Union's adoption of the Directive on Restriction of Hazardous Substances (RoHS), which went into effect in July 2006, all electronic design and also production control was based on the precedent that soldering processes would be accomplished with tin-lead (SnPb) soldering materials. Tin-lead solder has specific properties that were instrumental in the multitude of component attachment methods that evolved for production of electronics. Had the solder of choice over the years been other than tin-lead, many of these common configurations might have evolved differently. The current reality is that component designs intended for tin-lead attachments are being soldered with various lead-free alloys, driven by the requirement to remove lead from electronic products. Acceptability for these designs has not changed that much, as reflected in current IPC acceptability standards. The attachments still need to have solder that flows over the connection interface surfaces, forms a fillet, and wets to the constituents that form the attachment. What has changed significantly is the surface appearance of the resulting solder connection. Most lead-free solders exhibit surface roughness that would cause concern for those accustomed to the normal appearance of tin-lead. In fact, if solder finishes created by tin-lead had the same surface appearance, they would have rightly been considered contaminated or overheated. The current IPC-A-610 standard provides a side-by-side contrast of similar solder connections accomplished with both tin-lead and lead-free solder alloys for appearance perspectives.

Outside of the considerations of acceptability appearance, there are additional concerns for materials compatibility issues and adverse properties such as hot tear, tin whisker, tin pest, accelerated and increased process temperature

exposure, and others. These considerations should be developed elsewhere in this reference.

This section presents common possibilities for acceptance criteria.

54.1.2 Military, Space, and Commercial Specifications

Reference to these types of specifications is common in the applicable markets. No great amount of detail will be discussed; however, they are all worthy of some discussion since they can provide a great deal of insight into the rationale of “product acceptability” and its origin.

54.1.2.1 Military Specifications. Military specifications have been widely accepted for use in many markets outside of their intended military products. The one with the most relevance to workmanship or acceptability criteria at the assembly level was MIL-STD-2000, a unified standard created from several individual services and production standards. It was created to combine the various requirements into a single standard to make it easier for military contractors to implement a single performance requirement. Many lower-level supporting specifications for components, designs, materials, and printed circuit boards (PCBs) were part of the family of documents to support performance and acceptance requirements as a package. Each specification was designed to be compatible with the eventual success of the end product. In an effort to increase understanding by all of the parties involved, and to ease compliance issues, the services provided training and certification at various locations throughout the country, and even at some international locations. The typical training audience often included customer representatives as well as producers. The title of MIL-STD-2000 was “Standard Requirements for Soldered

Electrical and Electronic Assemblies.” However, all of the military soldering requirements standards, including MIL-STD-2000, have been rescinded for future production through DoD acquisition reform initiatives. Nevertheless, some products still use the requirements because they have been adopted internationally and because they provide relative benefit for the product’s specific industry segment.

MIL-STD-2000 was an extensive document that defined the nonconformance conditions that required disposition as rework, repair, or use as is. This of course required some action by the manufacturer to evaluate a given defect anomaly and make a decision regarding its impact on the form, fit, or function of the intended use. It also allowed some level of customer involvement concerning these decisions if the contract prescribed it. MIL-STD-2000 also limited the assembly materials for a manufacturer in terms of the solder alloys, flux activity levels, cleanliness, conformal coating, solder mask, and their acceptance conditions, either through a flow down to a supporting specification or internal requirements. Any deviation from standardized process and materials as specified in these documents required qualification and/or customer consent before use. However, the document allowed flexible contractual application dependent upon the product demands for performance. “General Requirements” for standard production were much less stringent than “Detail Requirements,” which were used for demanding performance or consequence products such as those intended for missile or space applications. Contracts were required to specify “Detail Requirements” before they were imposed; otherwise, only the “General Requirements” were required as a default. The intent of flexible requirements was to allow the use of a single standard for everything from complex weapon systems to office equipment. Unfortunately, they were not commonly applied that way, and the overly stringent requirements originally intended for critical systems were

attached to applications such as office or communication products that did not benefit from the more stringent and costly production effort.

Solder connection characteristics for both plated through-hole and surface-mount devices were defined by solder finish, fractures, voids, solder coverage and quantity, and wetting and filleting. The PCB requirements after assembly were detailed in terms of conductor finish and condition, conductor separation from the board, cleanliness of the assembly, weave exposure, delamination, measles, haloing, and bow and twist. In addition, part markings were expected to remain legible even after assembly processing.

If specifically imposed by individual contract, the services provided, through established training resources, traceable training and certification of the people making decisions. This training provided a cadre of qualified instructors who in turn could train people for their company or organization. Its interesting that prior to elimination of these schools, the majority of students attending the certification-training program were from commercial production companies with no contractual performance for DoD. In addition to establishing product acceptance criteria, the specification also detailed methods for process control and defect reduction to be used in assembly. One hundred percent inspection was required unless specific conditions were met, so that sample-based inspection might be used with confidence.

As a result of elimination of the various military standards, most DoD and termed high-reliability production is defined through contractual implementation of the commercial IPC equivalent standards, such as J-STD-001, and IPC-A-610.

54.1.2.2 Space Production Requirements. Standards associated with space applications have significantly different purposes than process control documents commonly used for large-volume production electronics. For

the purpose of space applications, there is seldom a large enough production volume to benefit from process development, and each individual product must be acceptable based on the environments experienced with space applications. These could be quite similar to the initial developments for DoD acceptance discussed earlier since they also involved space considerations. Current space application standards have evolved from NHB 5300 through to NASA-STD-8739.3, “Soldered Electrical Connections.” Additionally, the space user community has created a space addendum to the commercial standard J-STD-001 for the opportunity to employ consensus standards used by many of their contractors for various other programs. The addendum modifies requirements to a degree consistent with space interests and in effect makes the performance and acceptance requirements similar to that of the NASA-generated standard.

54.1.2.3 J-STD-001 and IPC-A-610 Industry Standards. These consensus industry association standards are widely recognized as the most common standards for requirements and workmanship for PCB assemblies, both nationally and internationally. They allow flexible definition of requirements based on three distinct classes of product, and the acceptability and performance requirements change based upon the contract provisions for the individual product as these classes are applied.

54.1.2.3.1 J-STD-001, “Requirements for Soldered Electrical and Electronic Assemblies.” Since “acquisition reform” and elimination of the very commonly adopted military standards, IPC standards have filled the resulting void and have also brought with them additional valuable practices and perspectives from commercial producers. J-STD-001, “Requirements for Soldered Electrical and Electronic Assemblies,” was first released in April 1992 as a modification of the previous IPC-S-815, which had limited

application, likely due to the competition from contractually imposed military and other industry-unique standards that were available to the users and managers at the time. IPC-S-815 had very similar criteria to that of the military baseline or “General Requirements” discussed earlier.

The resulting J-STD-001 defines three levels of electronic assemblies based on the intended end-item use. The three classifications were established to reflect differences in consequences of failure, harshness of the operating environment, and expected term of operation. The three classes are summarized as follows:

- *CLASS 1: General Electronic Products* This class includes products suitable for applications where the major requirement is function of the completed assembly.
- *CLASS 2: Dedicated Service Electronic Products* Class 2 includes products where continued performance and extended life is required, and for which uninterrupted service is desired but not critical. Typically the end-use environment would not cause failures.
- *CLASS 3: High-Performance Electronic Products* These include products where continued high performance or performance-on-demand is critical, equipment downtime cannot be tolerated, end-use environment may be uncommonly harsh, and the equipment must function when required. Examples include life support or other critical systems.

J-STD-001 addresses many of the same subjects as MIL-STD-2000, and in most cases for Class 1 and 2 production, the requirements are again similar to the “General Requirements” of the previous standards. The Class 3 requirements for the majority of the subject areas are similar to MIL-STD-2000, “Detail Requirements.” Since the deactivation of MIL-STD-2000 and the associated revisions, many contract performance requirements have been

transitioned to this document and family of IPC standards. As with the predecessor documents, it should be recognized that a successful soldering process requires consistent materials and the ability to select the materials for a given process that will perform well in combination with compatibility for the application. As with acceptability, users may have the flexibility to establish their own requirements for these materials, but it would be difficult to find suppliers willing to create materials qualifications for anything other than a standardized definition. The following discussion provides a brief overview of the “family of standardized criteria” for materials associated with acceptable production standards.

54.1.2.3.2 J-STD-002, “Solderability Tests for Component Leads, Terminations, Lugs, Terminals, and Wires.” This standard prescribes the recommended test methods, defect definitions, acceptance criteria, and illustrations for assessing the solderability of electronic component leads, terminations, solid wire, stranded wire, lugs, and tabs.

Solderability evaluations are made to verify that the solderability of component leads and terminations meets the requirements established in J-STD-002 and that subsequent storage has had limited adverse effect on the ability to solder components to an interconnect. Determination of solderability can be made at the time of manufacture, at receipt of the components by the user, or just prior to assembly and soldering.

Similar to J-STD-001, J-STD-002 has its origin with military standards, which in this case was MIL-STD-202, Method 208. It defines standardized methods of evaluating the ability of a surface to accept solder and in addition defines the durability of the solderable surface with three categories of product and related conditioning to determine the product performance before soldering. Category 1 is the least demanding performance, where the product would be used soon after testing, and Category 3 is applied where the

product may be stored for extended periods of time before soldering. The intent is to identify solderability problems before the expense of production is added or the production schedule is delayed while waiting for solderable replacement parts.

For a more detailed discussion of solderability and the related issues, refer to Sec. 54.5.

54.1.2.3.3 J-STD-003, "Solderability Tests for Printed Boards." J-STD- 003, "Solderability Tests for Printed Boards," was released in April 1992 to complement the requirements of J-STD-001. This standard prescribes the recommended test methods, defect definitions, and illustrations for assessing the solderability of printed board surface conductors, attachment lands, and plated-through holes.

The solderability determination is made to verify that the PCB fabrication processes and subsequent storage have had no adverse effect on the solderability of those portions of the PCB intended to be soldered. This is determined by evaluation of the solderability specimen portion of a board, or representative coupon, that has been processed as part of the panel of boards and subsequently removed for testing per the method selected.

The objective of the solderability test methods described in J-STD-003 is to determine the ability of printed board surface conductors, attachment lands, and plated-through holes to wet easily with solder and to withstand the rigors of the PCB assembly processes.

For a more detailed discussion of solderability issues, refer to Sec. 54.5.

54.1.2.3.4 J-STD-004, "Requirements for Soldering Fluxes." J-STD-004 prescribes general requirements for the classification and testing of soldering fluxes for high-quality interconnections. This standard is a flux characterization, quality control, and procurement document for solder flux and flux-containing material.

This standard defines the classification of soldering materials through specifications of test methods and inspection criteria. These materials include liquid flux, paste flux, solderpaste flux, solder-preform flux, and flux-cored solder. It is not the intent of this standard to exclude any acceptable flux or soldering aid material; however, these materials must produce the desired electrical and metallurgical interconnection.

54.1.2.3.5 J-STD-005, "Requirements for Soldering Paste." This standard prescribes general requirements for the characterization and testing of the solderpastes used to make high-quality electronic interconnections.

54.1.2.3.6 J-STD-006, "Requirements for Electronic Grade Solder Alloys and Fluxed and Non-Fluxed Solid Solders for Electronic Soldering Applications." This standard prescribes the nomenclature, requirements, and test methods for electronic grade solder alloys; for fluxed and non-fluxed bar, ribbon, and powder solders, for electronic soldering applications; and for "special" electronic grade solders.

54.1.2.3.7 Other Standards. There are many standards that comprise the necessary content for successful production practices that lead to acceptability. Each represents an element of the foundation that supports a complete and successful production effort. One example is moisture susceptibility and the procedures to ensure that the components are not damaged by popcorning during reflow. J-STD-020 and J-STD-033 provide classification and control for moisture-sensitive components. Others, such as IPC-CC-830, "Qualification and Performance of Electrical Insulating Compound for Printed Wiring Assemblies," deal with material acceptability of conformal coating. Each of the elements is important and should be considered as a package for overall acceptability.

Many of the material specifications reference test methods. Rather than include the actual test method with the publication of the specification, the IPC posts them on its

website, where they can be easily accessed and kept current without extensive revision of the various reference standards. This prevents possible conflict with outdated procedures. Criteria for the acceptance levels, however, are provided by reference standards such as J-STD-001, J-STD-004, and so on.

54.1.2.4 IPC-A-610, "Acceptability of Electronic Assemblies". Many companies use IPC-A-610, "Acceptability of Electronic Assemblies," as the standalone workmanship standard for their products. J-STD-001 establishes the requirements for soldering processes, whereas IPC-A-610 depicts the pictorial acceptability criteria for production, including soldering as identified in the J-STD-001 document. IPC-A-610 also addresses additional, broad criteria to define handling and mechanical workmanship requirements, among others. A large percentage of the acceptability criteria defined in this chapter is that which is illustrated in the IPC-A-610 standard.

The popularity of IPC-A-610 is apparent considering that it is available in many different languages and used throughout the world as the acceptance reference of choice for electronics.

The IPC-A-610 standard describes the acceptability criteria for quality electronic assemblies. It does not define process requirements, although the methods used must produce a completed solder joint conforming to the acceptability requirements as defined. Consistent with other IPC standards, the IPC-A-610 document details the acceptance criteria for each of three classes.

The three classes of product allow flexible application of the conditions for which the standard provides acceptance criteria. The customer should provide the inspector with the intended class for acceptability before the product is considered for acceptance. The three classes are 1, 2, and 3

and are the equivalents of the definitions provided by J-STD-001.

In addition, this standard discusses and visually illustrates degrees of compliance, such as “Target,” “Acceptable,” “Defect,” and “Process Indicator,” for each condition relative to the three classes of product. The importance of the condition varies with the expected performance of the class based on the preceding class criteria.

Acceptance definitions are summarized as:

- *Target* This condition is close to perfect or preferred; however, this desirable condition is not always achievable and may not be necessary to ensure reliability of the assembly in its service environment. Although this condition is not a requirement for performance based on the standard, it is provided to illustrate to users the desired condition that the creators of the criteria thought they should strive to achieve.
- *Acceptable* This condition, although not necessarily perfect, will maintain the integrity and reliability of the assembly in its service environment.
- *Defect* This condition may be insufficient to ensure the form, fit, or function of the assembly in its end-use environment. Defect conditions need to be dispositioned by the manufacturer based on design, service, and customer requirements. Disposition may be to rework, repair, scrap, or use as is. Repairing or using the assembly as is may require customer concurrence. A defect for Class 1 automatically implies a defect for Class 2 and 3. A defect for Class 2 implies a defect for Class 3.
- *Process indicator* A process indicator is a condition (not a defect) that identifies a characteristic that does not affect the form, fit, or function of a product. Such condition is a result of material, design, and/or operator- or machine-

related causes that create a condition that neither fully meets the acceptance criteria nor is a defect.

As established by the predecessor military standards, process indicators are not intended to be reworked or even dispositioned, and they can be included in product delivery without correction of the product. They are, however, not desirable and indicate the relative success of the process and materials; if the process or materials could lead to defect conditions, the process may need to be adjusted or corrected for future production. Process indicators should be monitored as part of the process control system. Should the number of process indicators indicate abnormal variation in the process or identify an undesirable trend, the process should be analyzed. This analysis may result in action to reduce the variation and improve yields before there is a defect trend that may require rework or scrap or, worst of all, result in customer dissatisfaction.

54.1.3 Workmanship Manuals

Many companies use a workmanship document of some sort to describe what the operations should achieve during production. IPC-A-610 is used frequently by manufacturing and also quality personnel to determine acceptable quality levels of their product. Some companies have also developed very good workmanship manuals for their own use, especially to cover unique or uncommon design requirements. If a need exists to develop a unique workmanship manual, then this manual should reflect the intended contract requirements. It is certainly desirable to use a manual already in existence since it can become extremely costly to develop your own, and because customer review is unnecessary since the customer should already be aware of the common requirements definition. If

minor changes are necessary to standard performance due to process, product or material limitations, they can often be addressed as a contractual waiver, addition, or exception to the standard definition.

54.2 HANDLING TO PROTECT THE PCBA

The handling of PCBs both before and after the soldering operation can be very important in terms of inducing possible damage to the board or contaminating the board such that subsequent operations are affected. There are three subjects that should be well thought out and controlled in an assembly operation for PCBAs: electrostatic discharge (ESD) protection, contamination prevention, and physical damage prevention.

54.2.1 ESD Protection

ESD is the rapid discharge of a voltage potential into an electronic assembly from a static energy source. The presence of a static discharge in the area of a sensitive device can damage the device even without actual contact. ESD-sensitive (ESDS) components found on the assembly and the amount of current generated by the discharge will determine whether immediate failure takes place. All types of ESD damage can be difficult to troubleshoot, but the most costly scenario is one in which the component is assembled and passes functional test only to fail later due to latent conditions resulting from ESD. This could cause the loss of a customer and even in some cases recall of the product.

Some electronic devices are more sensitive to electrostatic overstress (EOS) damage than others. The degree of such

sensitivity within a particular device is related directly to the manufacturing technology employed. The trend for electronic components is smaller size, wider band pass, and lower voltage. These are all contributors to the ESD protection problem and increased sensitivity of the component.

Where sensitive components are handled, protective measures must be taken to prevent component damage. Improper and careless handling accounts for a significant portion of ESD damage to components and assemblies. Before handling ESD-sensitive components, equipment should be carefully tested to ensure that it does not generate damage-causing spikes. The preferred workstation to be utilized in electronic assembly is shown in Fig. 54.1.

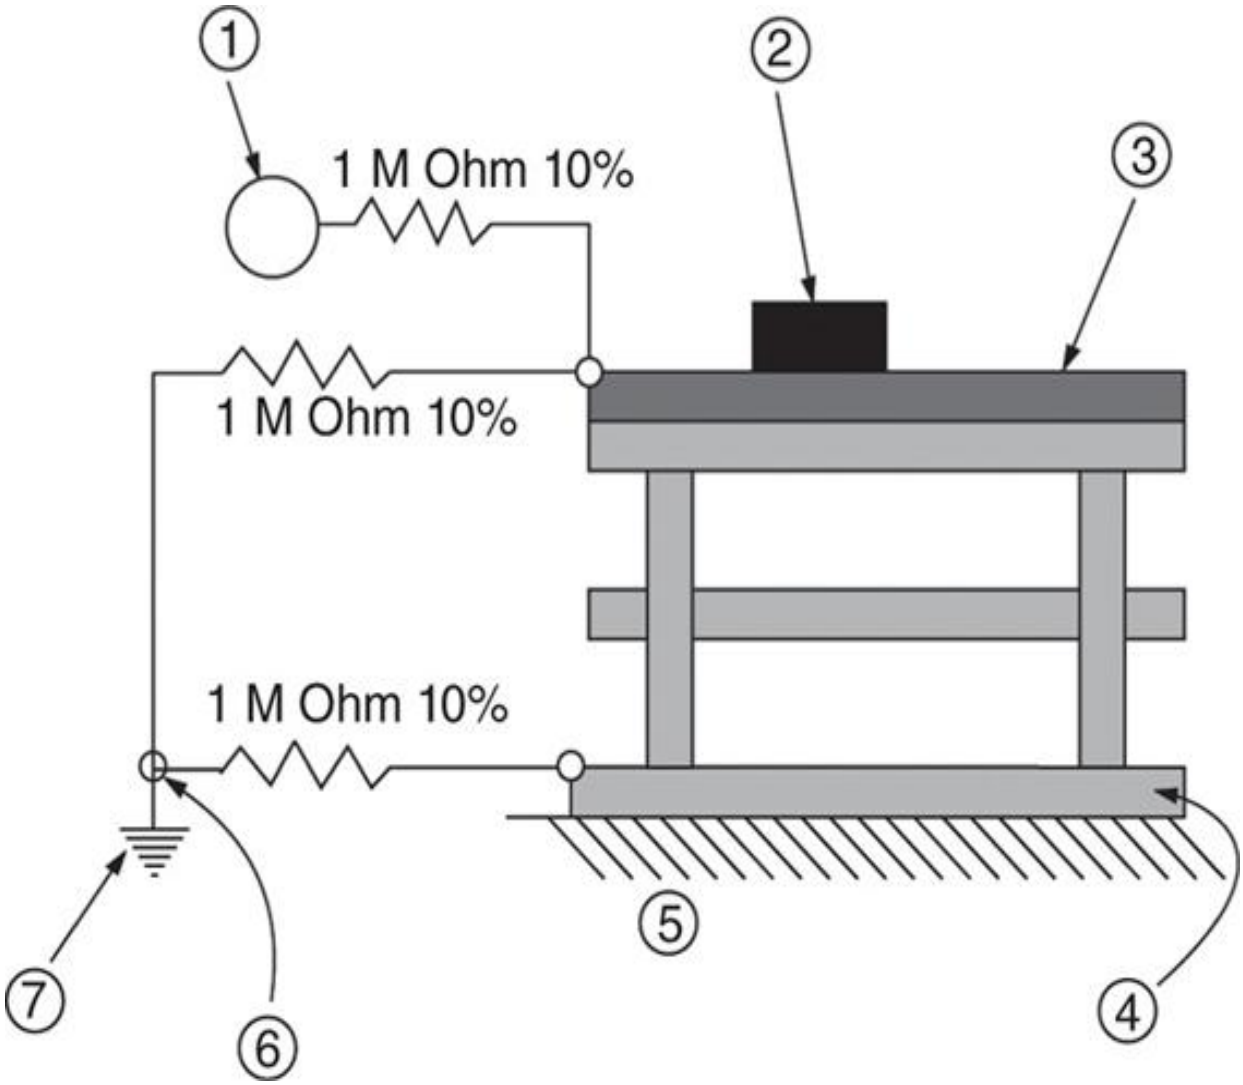

FIGURE 54.1 Target condition for EOS/ESD workstation (1) Personal wrist strap (2) EOS protective trays, shunts, etc. (3) EOS protective table top (4) EOS protective floor mat (5) Building floor (6) Common ground point (7) Ground. *(IPC)*

Static charges are created when nonconductive materials are separated. Destructive static charges are often induced on nearby conductors, such as human skin, and discharged as sparks passing between conductors. This can happen when a person having a static charge potential touches a PCBA. The electronic assembly can be damaged as the discharge passes through the conductive pattern to a static-sensitive component. Static discharges may be too low to be

felt by humans (less than 3,500 volts) and still damage ESD-sensitive components.

Sensitive components and assemblies must be enclosed in conductive, static-shielding bags, boxes, or wraps when not being worked on, unless otherwise protected. ESD-sensitive items must be removed from protective enclosures only at static dissipative or antistatic workstations.

For ESD safety, a path to ground must be provided for static charges that would otherwise discharge on a device or board assembly. Provisions are made for grounding the worker, preferably via a wrist strap or a heel strap, provided conductive flooring is used.

54.2.2 Contamination Prevention

The key to any contamination problem is to prevent it from happening. The cost of subsequent operations required to clean a product or rework a product is orders of magnitude more than any cost associated with preventing the contamination from occurring. These contaminants can cause soldering and solder mask or conformal coating problems. There are any number of possibilities for inducing contamination in an assembly environment, such as dirt, dust, machine oils, and process residues; however, in many cases, contamination is caused by the human body, specifically the salts and oils on the skin.

In a high percentage of assembly areas, good housekeeping will take care of contamination from the environment. It should be a common event on each shift to clean workstations, sweep floors, dust fixtures, empty trash, and so on. This not only prevents contamination, but it also helps to keep personnel morale at a higher level. After all, we all desire to work in a nice, clean environment. It will also serve as a positive point if visitors or possible customers visit the assembly area.

To prevent contamination from the human body, every individual must be aware of the possibility of contaminating the PCBA. Printed circuits should be touched only on the edges away from any edge connectors prior to the soldering operation (see Fig. 54.2). Where mechanical assembly procedures require a firm grip on the board, gloves or finger cots should be worn. If the PCBA is to be conformal coated after the soldering operation, the handling of the assembly should be prevented. In some cases, using finger cots, gloves, or fixtures can reduce the contamination. Many producers utilize cleanliness testing to ensure that contamination levels remain within an acceptable range before the coating process, and to ensure adhesion and eliminate localized contaminants that could impact circuit operation and long-term performance. J-STD-001 provides levels for cleanliness acceptability.

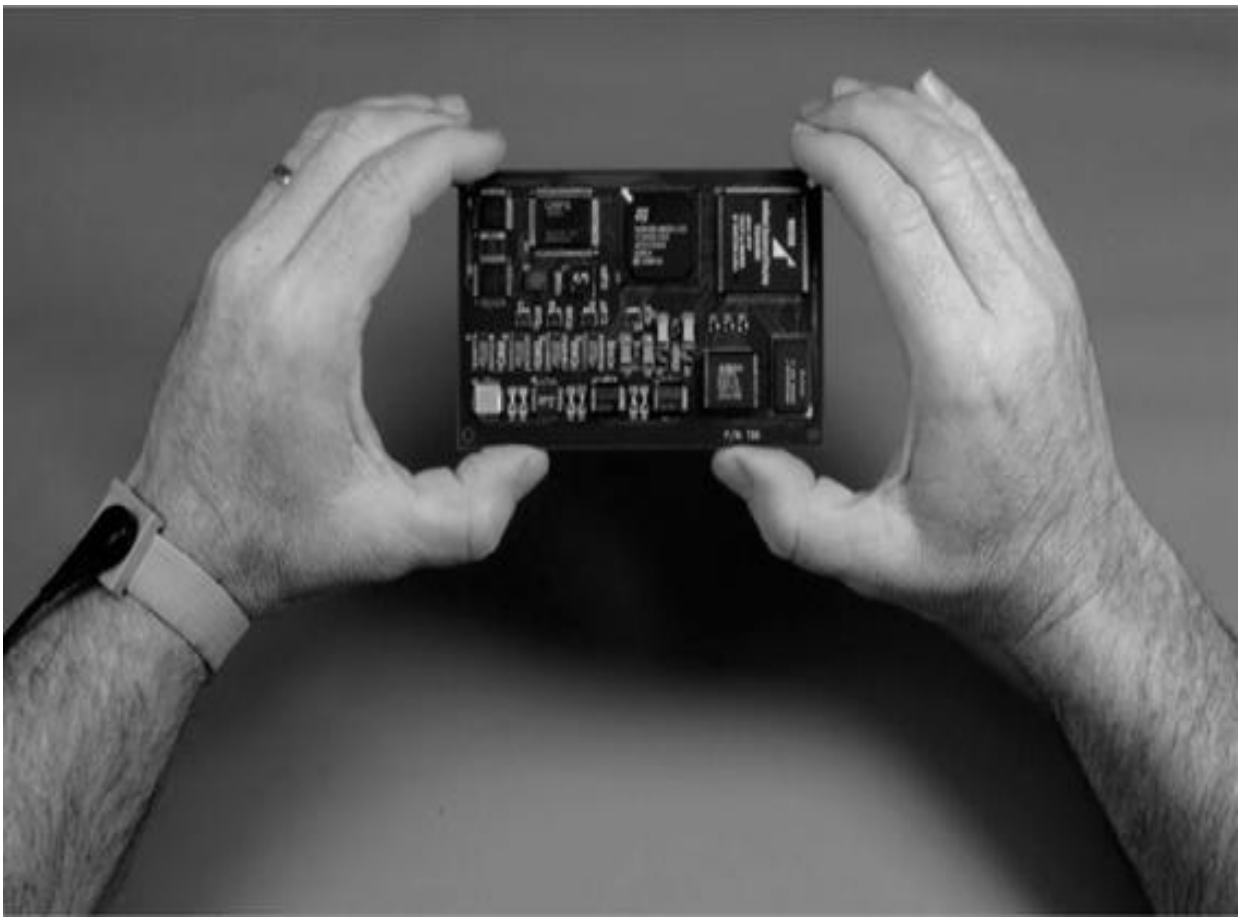

FIGURE 54.2 Appropriate method of handling board to avoid contamination and electrostatic discharger damage. Note position of fingers and the use of a grounding wrist strap.

54.2.3 Physical Damage Prevention

Improper handling can damage components and assemblies. Typical defects associated with handling are cracked, chipped, or broken components; bent or broken terminals; scratched board surfaces; damaged traces or lands; fractured solder joints; and missing surface-mount technology (SMT) components.

Physical damage caused by handling can ruin assemblies and cause a high scrap rate of components or assemblies. Scrap is costly and must be avoided to achieve an efficient and high-quality operation.

Well-maintained handling equipment is also very important in preventing physical damage. One good example is conveyor systems. PCBAs can be caught in conveyors and damaged beyond rework or repair capability and, unless the area of operation is staffed, the conveyor system can damage many assemblies in a very short period of time.

Care must be taken during assembly and acceptability processes to ensure product integrity at all times. The following guidelines provide general guidance:

- Keep workstations clean and neat. There must not be any eating, drinking, or use of tobacco products in the work area.
- Minimize the handling of electronic assemblies and components to prevent damage.
- When gloves are used, they need to be changed as frequently as necessary to prevent contamination from dirty gloves.
- Solderable surfaces are not to be handled with bare hands or fingers. Body oils and salts reduce solderability and promote corrosion and dendritic growth. They can also cause poor adhesion of subsequent coatings or encapsulant.
- Do not use hand creams or lotions containing silicone, because they can cause solderability and conformal coating adhesion problems.
- Never stack electronic assemblies, because physical damage may occur. Special racks need to be provided in assembly areas for temporary storage.
- Always assume the items are ESDS even if they are not marked.
- Personnel must be trained and follow appropriate ESD practices and procedures.
- Never transport ESDS devices unless proper packaging is applied.

54.3 PCBA HARDWARE ACCEPTABILITY CONSIDERATIONS

Most electronic assembly designs include a small percentage of mechanical assembly that requires hardware of various types. Some of the more common component types and the acceptability criteria associated with each are discussed in the following sections.

54.3.1 Component Types

54.3.1.1 Threaded Fasteners. Hardware stack-up for all threaded fasteners must be identified on engineering documentation. The stack-up can be critical, depending on the types of material used for both the hardware and the PCB. Any missing hardware must be found or replaced. Any damage to hardware that prevents it from accomplishing what it was designed to do is unacceptable. A good example of this is any screw or nut that has been stripped, cross-threaded, or damaged to the point that a screw or nut driver is no longer able to tighten or loosen the part (see Fig. 54.3).

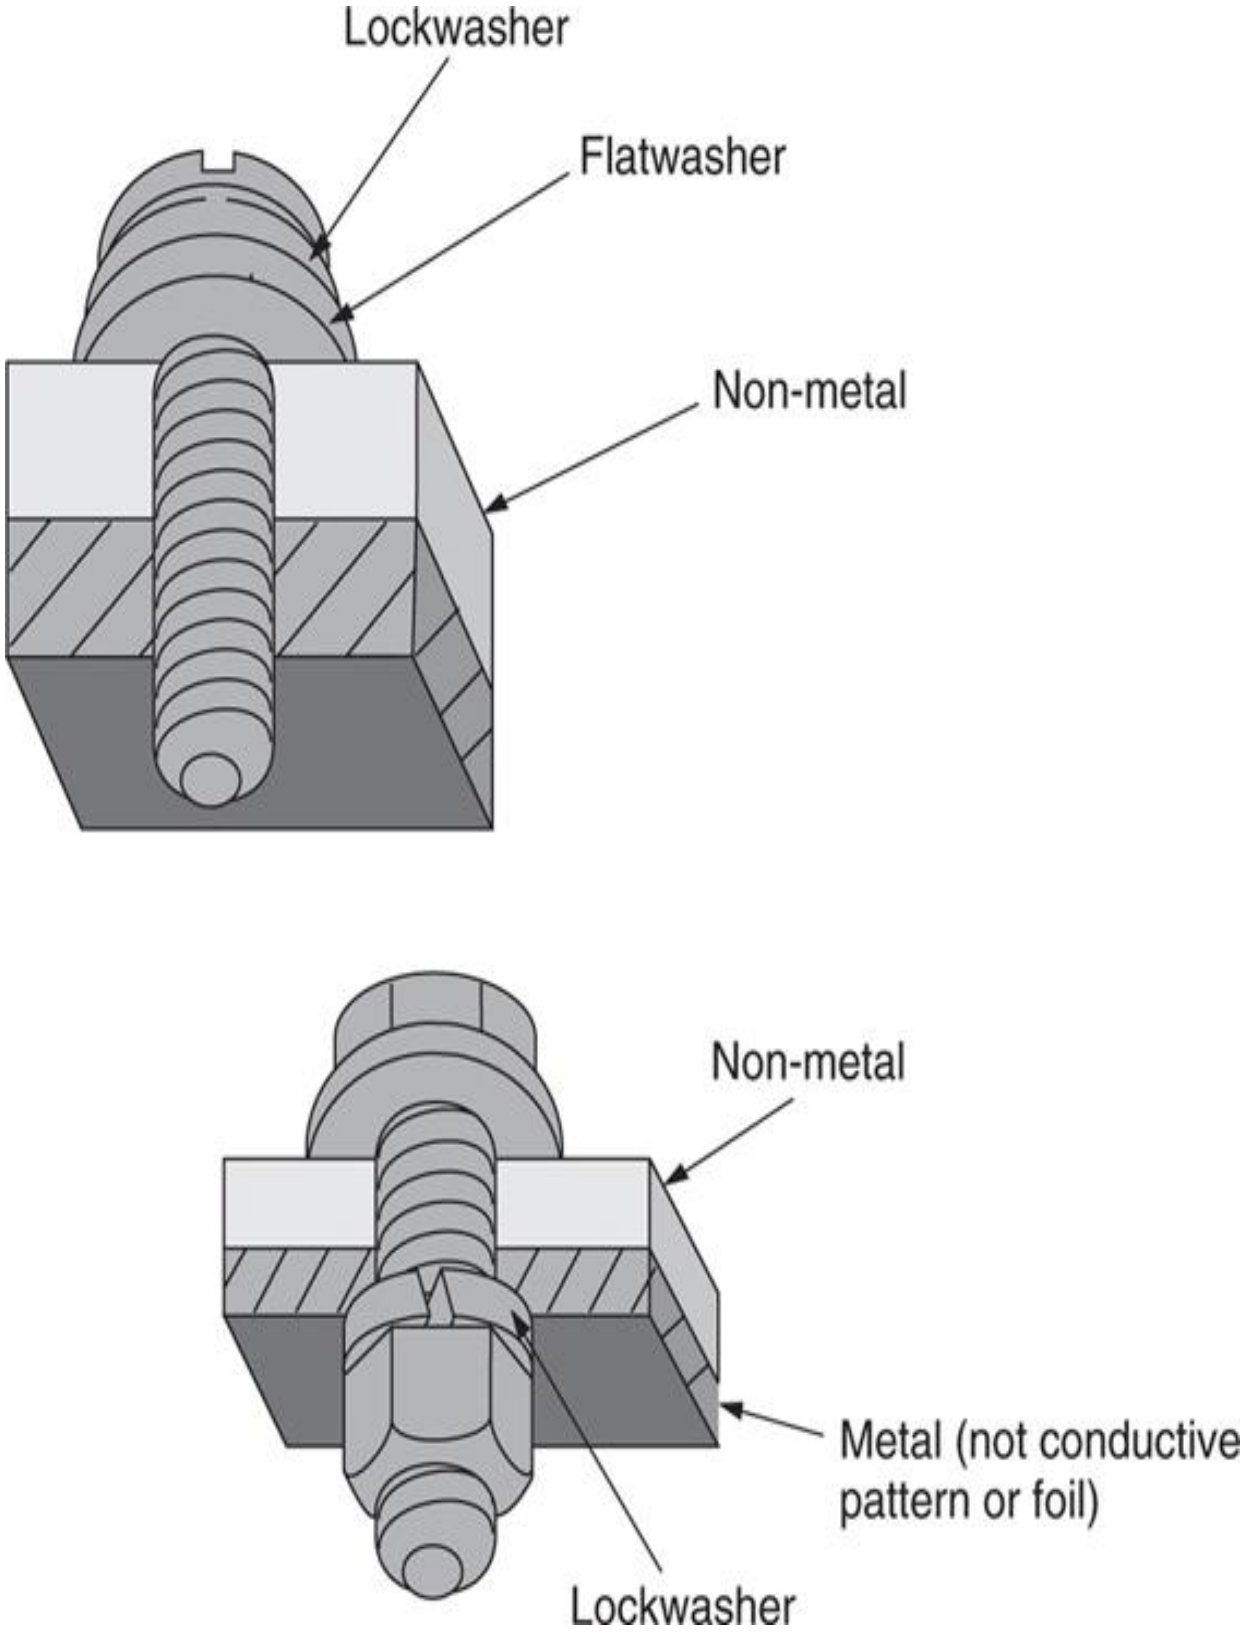

FIGURE 54.3 Hardware mounting for threaded fasteners (1) Lock washer (2) Flat washer (3) Nonconductive material (base laminate) (4) Metal (not conductive

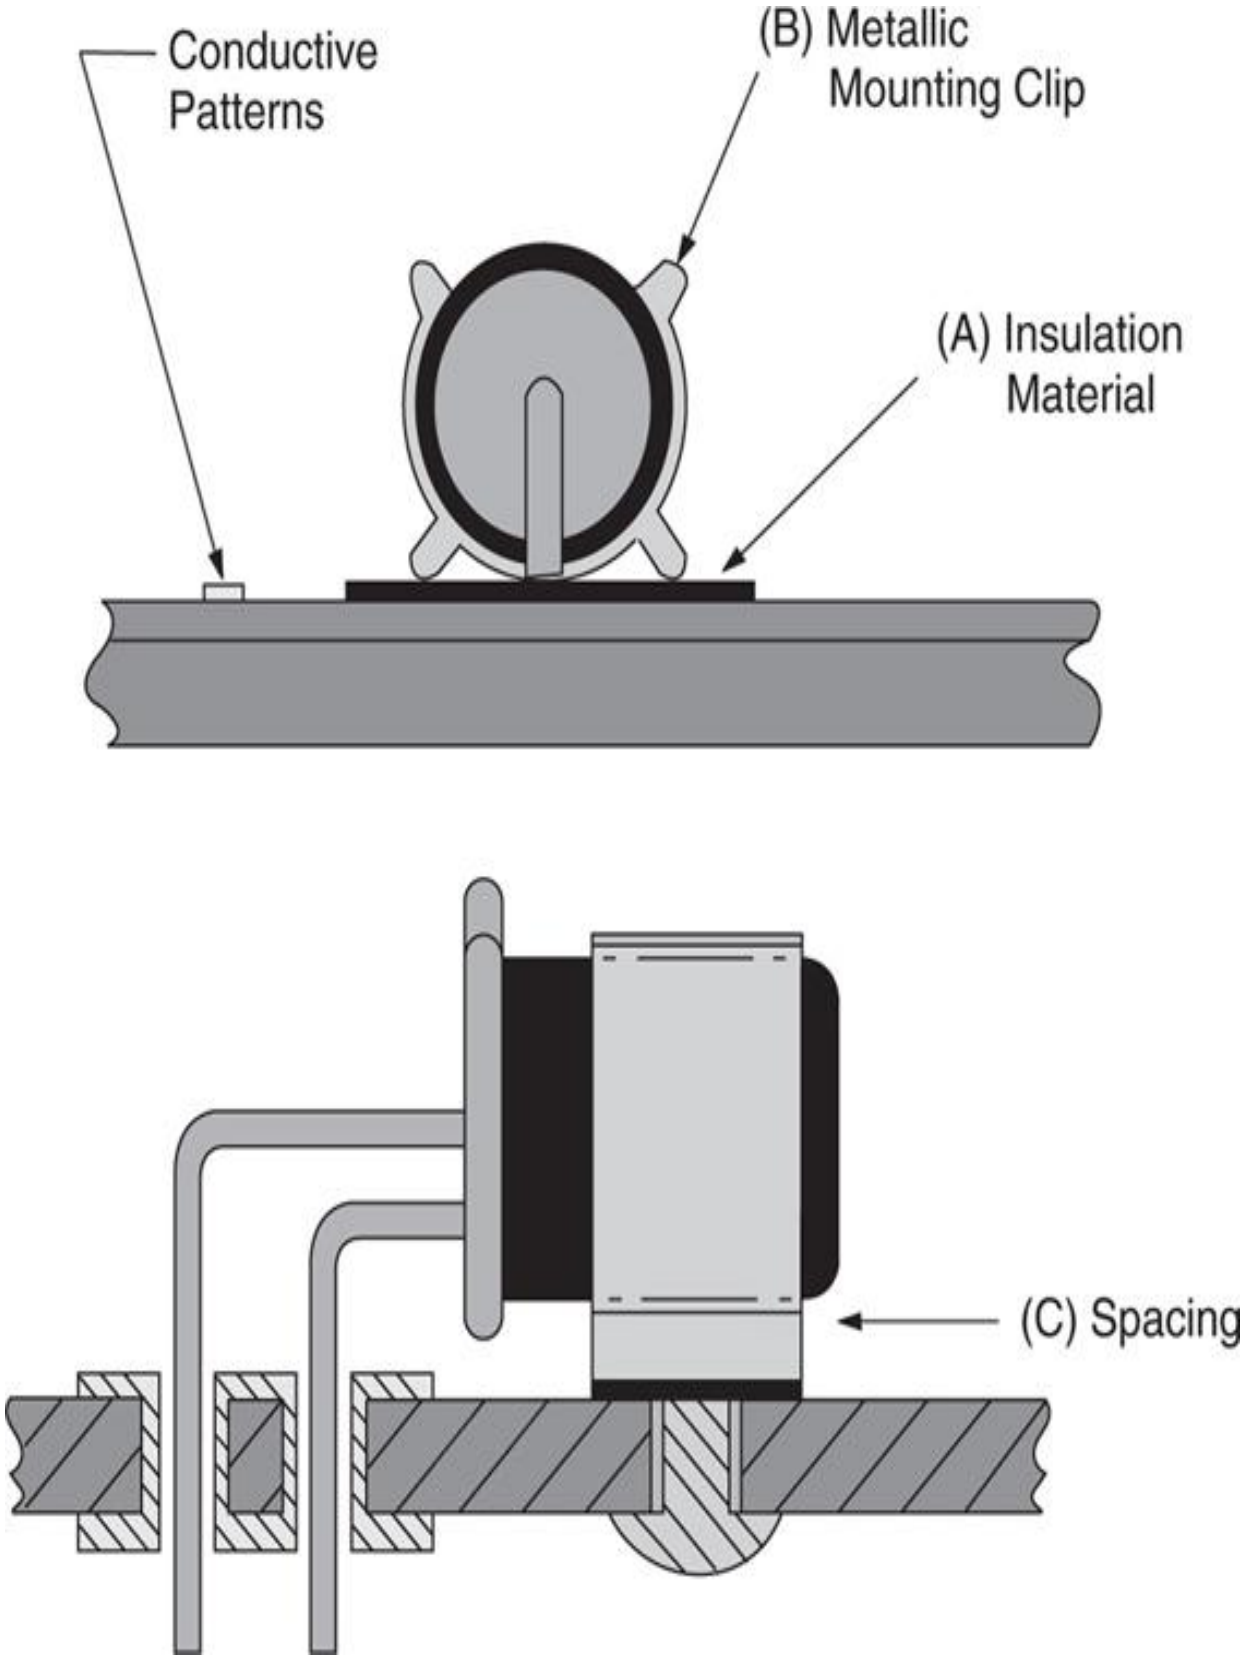
pattern or foil). *(IPC)*

A minimum of 1½ threads should extend beyond the threaded hardware unless the hardware could interfere with other components. The maximum extension of threaded hardware is 3 mm plus 1½ threads for hardware up to 25 mm long and 6.3 mm plus 1½ threads for hardware greater than 25 mm long.

Threaded fasteners should be tight to the specified torque on engineering documentation. If torque is not specified on engineering documentation, a generic torque table should be available for use in the assembly environment. Such a table is sometimes included in a workmanship manual.

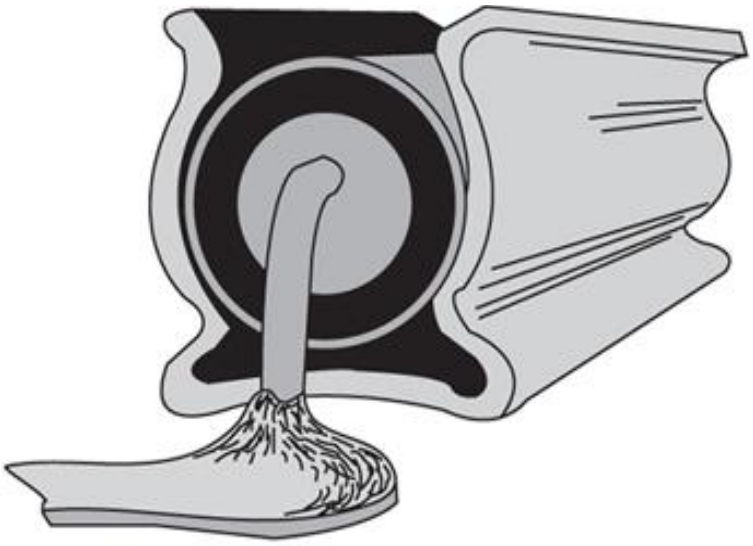
54.3.1.2 Mounting Clips. Uninsulated metallic components, clips, or holding devices must be insulated from underlying circuitry. Minimum electrical spacing between land and uninsulated component body must not be violated (see Fig. 54.4).



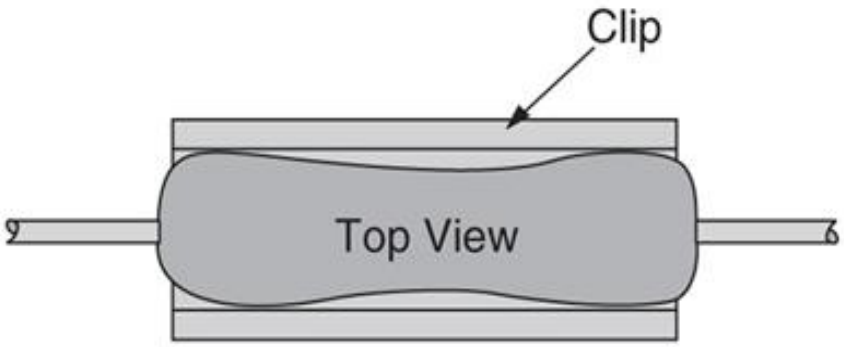
Conductive
Patterns
(B) Metallic
Mounting Clip
(A) Insulation
Material
(C) Spacing

FIGURE 54.4 Component mounting clip insulaton requirements (1) Conductive patterns (2) Metallic mounting clip (3) Insulation material (4) Clearance. *(IPC)*

The clip or holding device must make contact with the component sides on both ends of the component. The component must be mounted with its center of gravity within the confines of the clip or holding device. The end of the component may be flush or extend beyond the end of the clip or holding device if the center of gravity is within the confines of the clip or holding device (see Fig. 54.5).

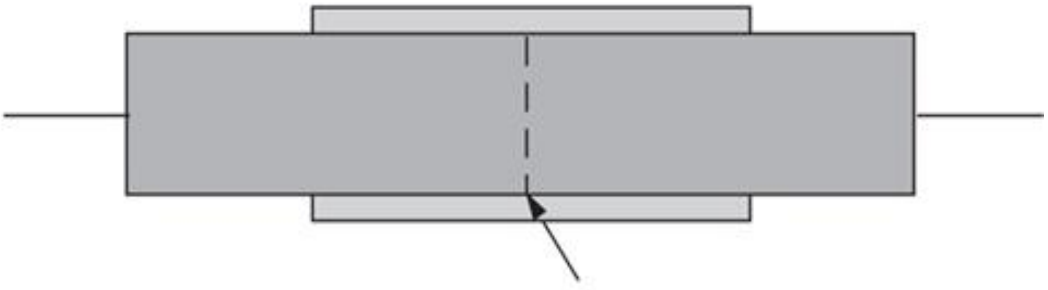


1.



Nonsymmetrical Body

2.



3.

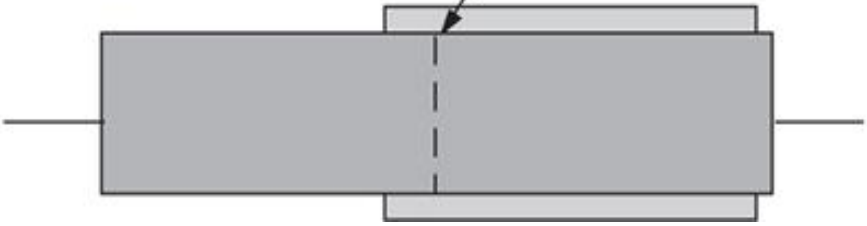


FIGURE 54.5 Component mounting requirements (1) Clip (2) Nonsymmetrical body (3) Top view (4) Center of gravity. *(IPC)*

54.3.1.3 Terminals. Terminals that are to be soldered to a land may be mounted such that they can be turned by hand, but should be stable in the z-axis. Terminals may be bent if the top edge does not extend beyond the base and no other mechanical damage such as fractures or breakage to the terminal or the solder joint have occurred (see Fig. 54.6). Common terminals utilized are turret, bifurcated, hooked, and pierced or perforated terminals. See Fig. 54.7 for an example of a damaged turret terminal and a cross section of an assembled board.

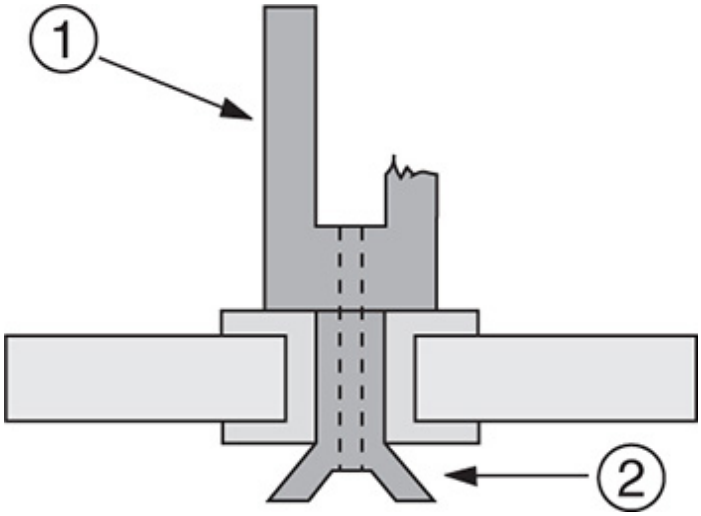

FIGURE 54.6 Bifurcated terminal (1) top edge and (2) base, swaged. Post is broken, but sufficient material is left to attach the specified wires/leads for class I. If both posts are broken, it is unacceptable. *(IPC)*

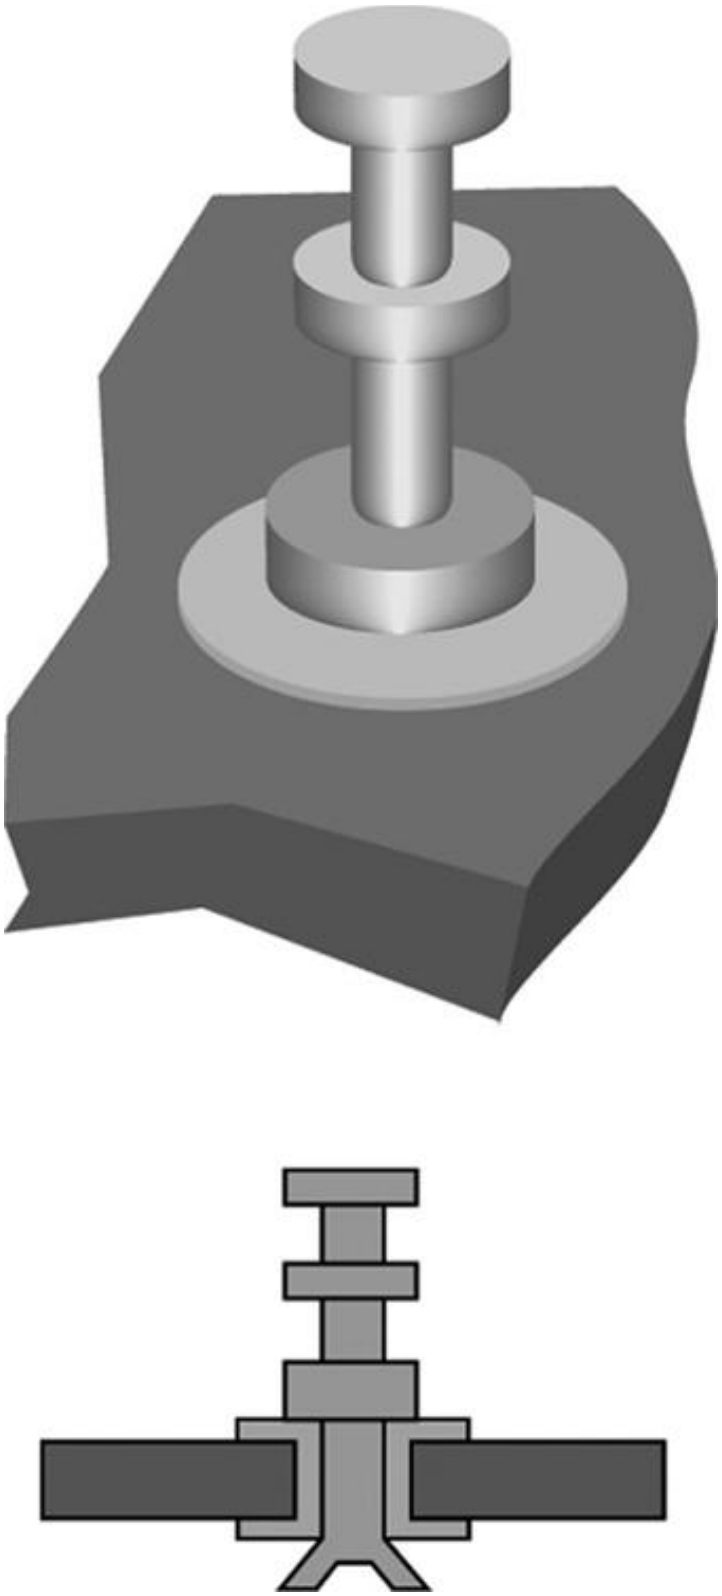

FIGURE 54.7 Acceptable installed turret terminal and cross section of assembled board. Terminal is intact and straight. *(IPC)*

54.3.1.4 Swaged Hardware, Flared Flange. The shank extending beyond the land surface is swaged to create an inverted cone, uniform in spread and concentric to the hole. The flange should not be split, cracked, or otherwise damaged to the extent that mechanical strength is compromised or allows contaminating materials to be entrapped in the rivet or funnel (see Fig. 54.8).

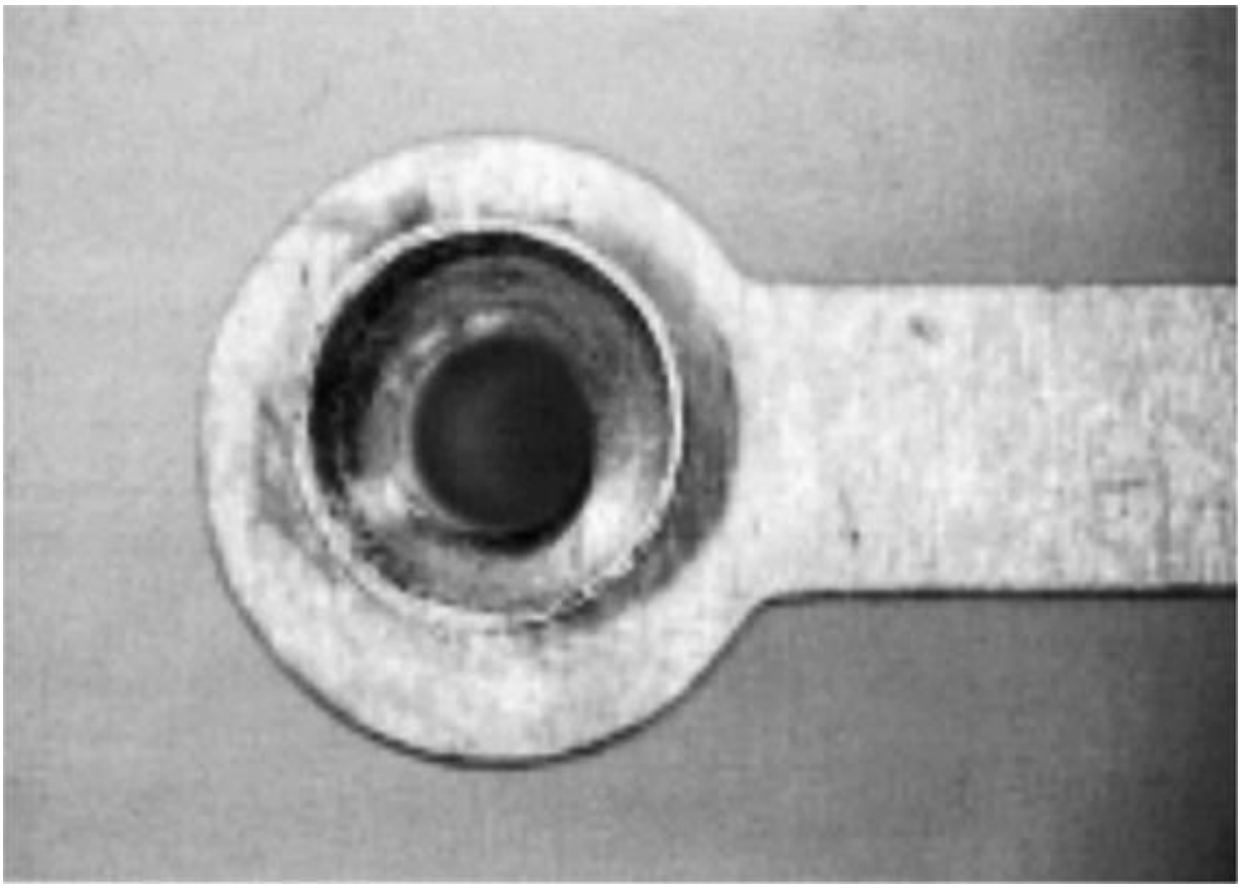

FIGURE 54.8 Flared flange. Acceptable for all Classes.

After swaging, the area should be free of circumferential splits or cracks. It may have a maximum of three radial splits or cracks, provided that the splits or cracks are separated by at least 90° and do not extend into the barrel of the rivet or funnel (see Fig. 54.9).

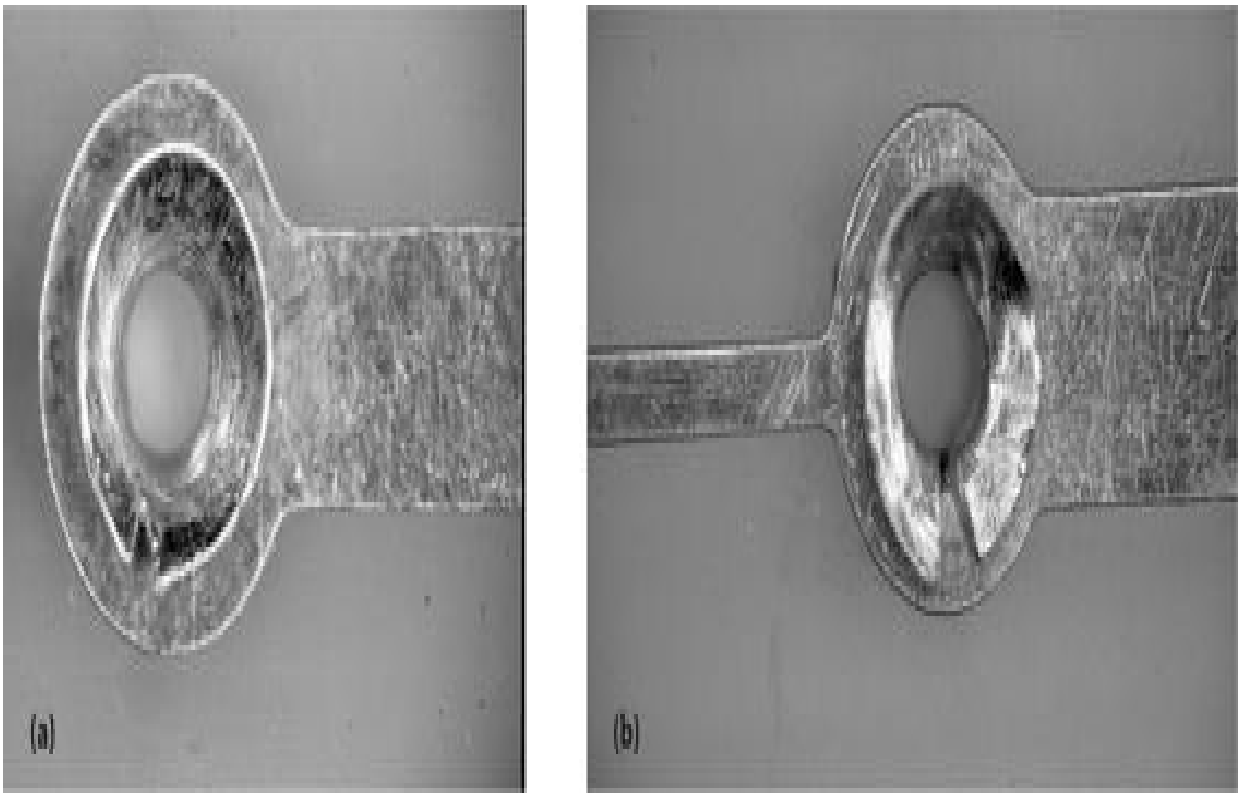

FIGURE 54.9 (a) Shows an example of acceptable flared swage-split while (b) shows an unacceptable split into barrel.

54.3.1.5 Connectors, Handles, Extractors, and Latches. Ejectors, handles, and connectors should not exhibit any cracks in the component material emanating from the roll pin or rivet that mounts the component to the PCBA.

Roll pins should not protrude more than 0.015 in. from the surface of the ejector, handle, or connector. The major consideration for roll pins should be to ensure that any protrusion does not mechanically interfere with any other assembly. Damage to the part, PCB, or securing hardware is unacceptable.

Connector damage can also affect the pins of the connector being pushed or bent out of specification. When connectors are mated, there is the chance that the female portion of the connector pin will be pushed backward and bent. This prevents adequate contact area between the male

and female pins of the connector, if they will mate at all. This circumstance is an unacceptable condition.

The male connector pins might also be bent. When the male pin is bent significantly, the mating of the female and male connectors can cause mechanical damage to the connector casing due to the male pin being forced into the wrong female connector slot. In most cases, the damage is deformation, cracking, or breaking of the connector casing material, all of which are unacceptable.

When connector pins are installed (such as compliant pin, press fit), the pins must be straight within 50 percent of the pin thickness from the perpendicular. For Class 1 and 2 equipment, the PCB land may be lifted less than or equal to 75 percent of the annular ring width. Any land that is lifted across more than 75 percent of the annular ring or has been fractured is unacceptable. For Class 3 equipment, no lifted or fractured lands are acceptable. For all classes, visibly twisted pins, damaged pins, or pins inserted such that there is a nonstandard pin height beyond a specified engineering tolerance is unacceptable.

54.3.1.6 Faceplates. Faceplates must be clean and free of scratches or damage on the front surface. This is important since this is the surface that is commonly viewed by the customer and presents the cosmetic appeal to the product being purchased. An exaggerated example of this is the purchase of an automobile. Few if any consumers would be willing to accept a new automobile with noticeable scratches in the painted surface.

A good rule of thumb for scratch criteria that some companies have adopted as a workmanship standard includes the following:

1. A scratch must be visible when viewed under the following conditions to be considered a defect:

a. From a distance of 18 in.

b. With no magnification utilized

c. With normal room lighting used in the assembly area

2. A scratch must be visible from more than one angle to be considered a defect.

3. Metal or plastic faceplate scratches that exceed 0.125 in. in length are considered defects.

Surfaces exposed to frequent viewing should be free of blisters, runs, nicks, gouges, blemishes, or other abrasions that would detract from the general appearance of the finish. Faceplates must also be securely fastened to the PCB, that is, tightly enough to prevent physical movement.

54.3.1.7 Stiffeners. Stiffeners are commonly used on PCBA designs that are large in dimension to prevent warpage of the PCBA before, during, or after assembly operations. If a stiffener has kept a PCBA from warping outside acceptability criteria, it has done its job; however, the stiffener must meet the following criteria to be acceptable:

- Any marking or color coatings must be permanent. Loss of marking such that it is not legible, or fading or loss of color outside the color standard being used, is unacceptable.
- The stiffener must be properly seated and mechanically fastened. If the soldering operation is used to mechanically fasten the stiffener to the PCBA, then good wetting to the stiffener such that the stiffener is mechanically sound is required.
- It is unacceptable to have a loose stiffener on a PCBA. The stiffener must be securely fastened to the PCBA.

54.3.2 Electrical Clearance

Electrical clearance of hardware to components or electrical traces must be controlled by the design based on the expected voltage and environment’s exposure. As a default, design standards such as IPC-2221 create a spacing requirement unless it is specifically defined for the particular PCBA (see Fig. 54.10 for examples). Minimum electrical clearance can be referenced throughout the acceptability requirements such as with contaminants or board laminate defects related to the conductors. Any violation of minimum electrical clearance is cause for a defect disposition consideration for any class, since it will directly impact the electrical performance of the product. Any condition that compromises the clearance should be verified by assemblers or inspectors to ensure that a shorting condition does not occur.

FIGURE 54.10 Examples of acceptable and unacceptable electrical clearance-hardware. (a) Acceptable where: (1) Metallic hardware; (2) Conductor pattern; (3) Specified minimum electrical clearance; (4) Mounted component; (5) Conductor; (b) Unacceptable where hardware reduces clearances to less than specified electrical clearance; (1) Metallic hardware; (2) Conductor pattern; (3) Spacing less than minimum electrical requirements; (4) Mounted component; (5) Conductor; (c) Unacceptable as lead is clinched toward a noncommon electrical conductor (1) and violates clearance; (C) requirement.

54.3.3 Physical Damage

Physical damage to hardware components in most cases refers to enough damage to a component to render it unusable in its application—for example, threads that are damaged to the point that mechanical fastening cannot be performed or a component that is fractured or broken such that it cannot perform the function for which it was intended.

Subjective judgments are common in this area since it is very much dependent on the application of the hardware in the given design, the environment in which the final product will be used, and life cycle expectations of the product.

54.4 COMPONENT INSTALLATION OR PLACEMENT REQUIREMENTS

Component installation or placement is the first step in the assembly of the PCBA. It may begin by preparation of the leads of a given package type in order to provide the correct lead protrusion, form the leads to fit the PCB plated-through holes or pads, or put a bend in the leads that will serve as a standoff from the component to the PCB.

54.4.1 Plated-Through Hole Lead Installation

Several requirements apply to all Plated-Through Hole (PTH) components. When using a polarized component, it must be oriented correctly. In all cases, if the orientation is incorrect, the board is unacceptable (see Fig. 54.11). When lead forming is required, the lead form must provide clearance and stress relief (see Fig. 54.12). Physical damage to the lead itself cannot exceed 10 percent of the diameter of the lead. Exposed basis metal as a result of lead deformation is a process indicator but does not render the board unacceptable.

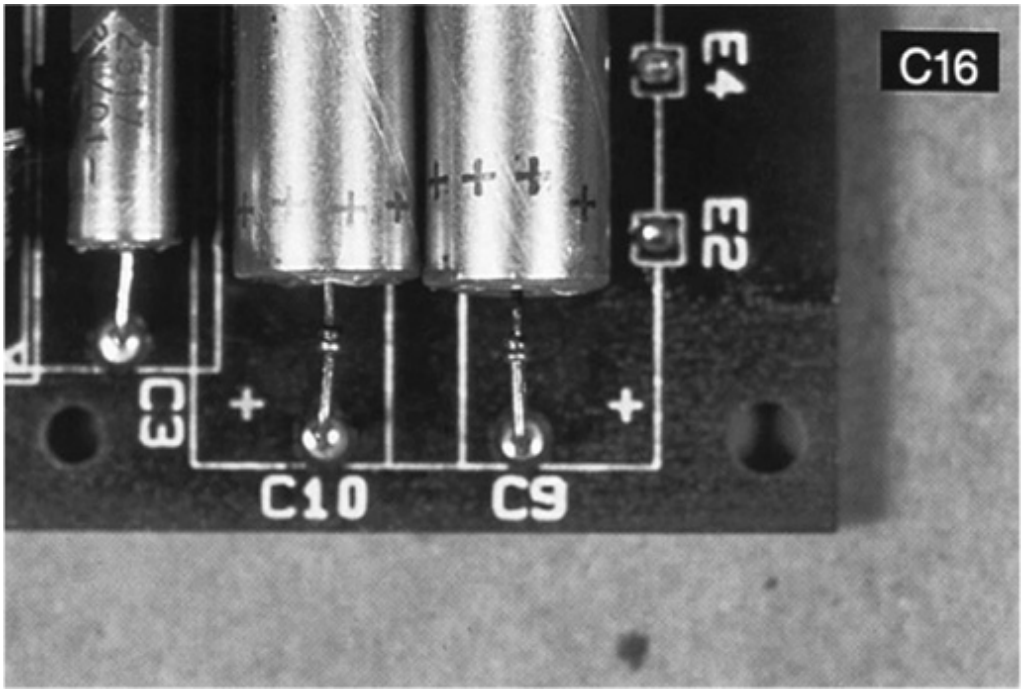

FIGURE 54.11 Component orientation–polarity. *(IPC)*

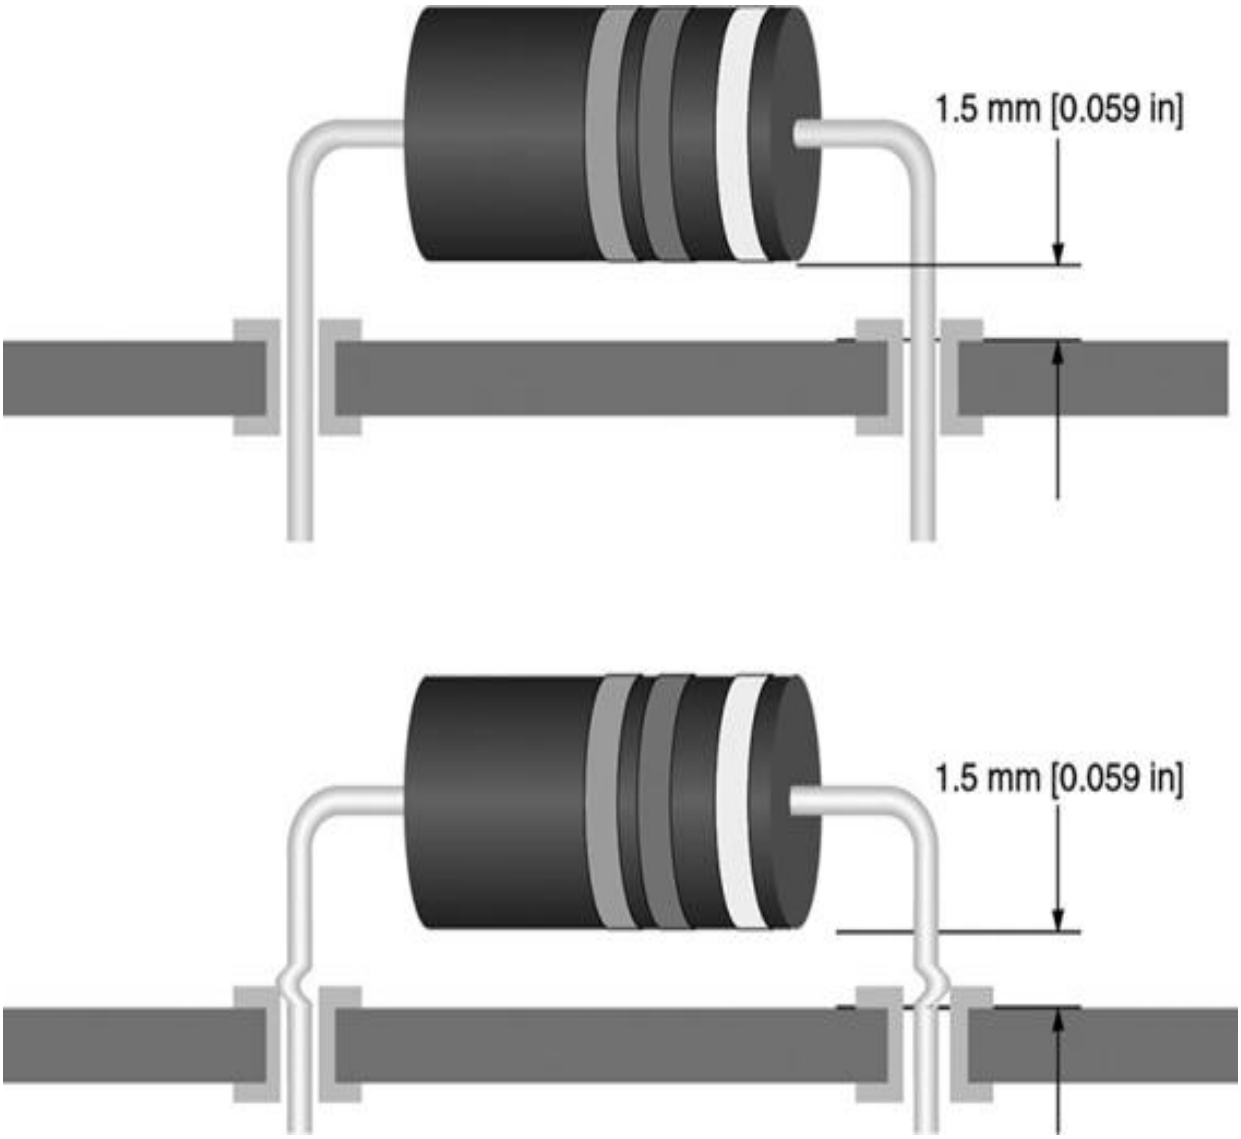

FIGURE 54.12 Examples of acceptable clearance and stress relief for PTH components. *(IPC)*

54.4.1.1 Axial Leaded Components. The target condition for axial components is that the entire body length of the component should be parallel and in contact with the board surface (see Fig. 54.13 for tolerances). If the component is required to be spaced above the board to avoid overheating the laminate, it must be mounted a minimum of 1.5 mm above the PCB surface. The maximum space between the component and the PCB surface should not violate the requirements for lead protrusion and cannot

be greater than 3.0 mm for Class 1 and 2 and 0.7 mm for Class 3 equipment (see Fig. 54.13).

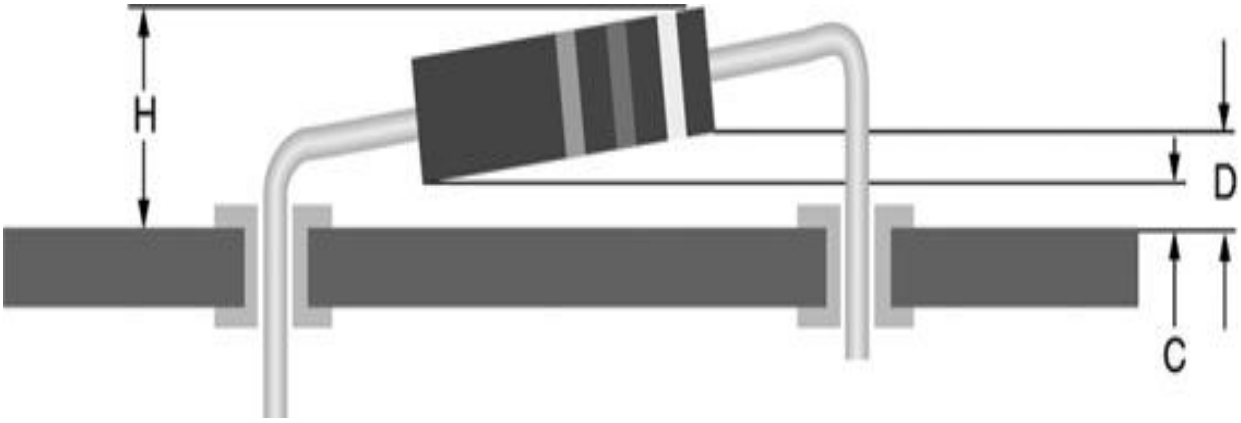

FIGURE 54.13 Amount of nonparallel allowed varies by class but is measured: (H) is component height, (C) is clearance between component body and board, and (D) is the farthest distance between the component body and the board.

Leads must extend from the component body at least one lead diameter (L) or thickness, but not less than 0.8 mm from the body or weld, before the start of the lead bend radius (see Fig. 54.14).

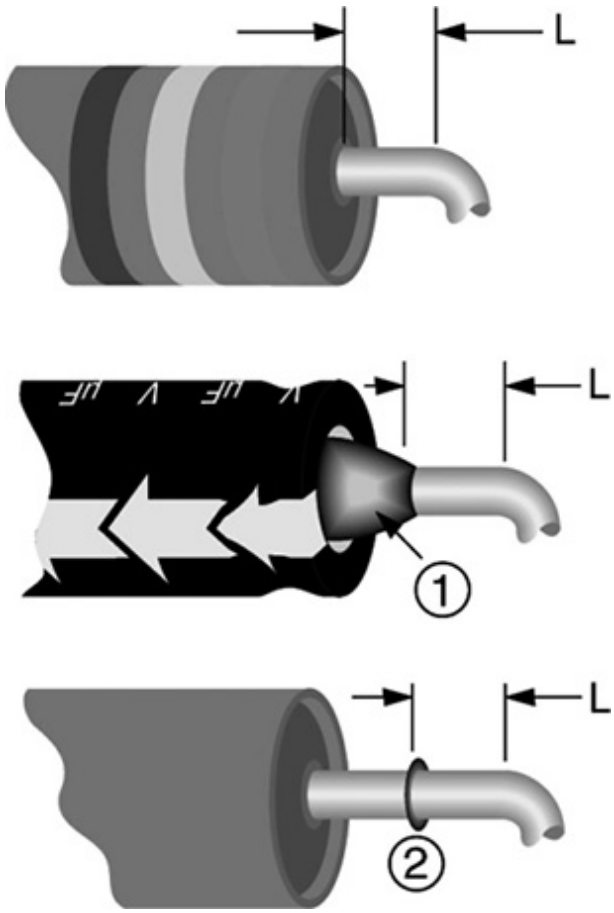

FIGURE 54.14 Lead extension from component body, where (1) is solder bead, (2) is weld. L is the distance from the effective component body to the bend. *(IPC)*

No physical damage, such as chips or cracks to axial components, should be allowed; however, it is acceptable to allow minor damage. It becomes unacceptable if the insulating cover is damaged to the extent that the metallic element is exposed or the component shape is deformed (see Fig. 54.15).

FIGURE 54.15 Example of physical damage to component after insertion. This is a “defect” condition and cause for rejection. (a) Axial lead component, (b) Chip component. *(IPC)*

54.4.1.2 Radial Leaded Components. The target condition for vertical radial components is that the body is perpendicular to the PCB and the component base is parallel to the PCB. It is an acceptable condition to have the component tilt from the perpendicular as long as it does not violate electrical clearance. The space between the component base and PCB should be between 0.3 and 2.0 mm (see Fig. 54.16) but it is considered a process indicator only if it exceeds that dimension. Some components, such as light-emitting diodes (LEDs) and switches, may need to be perpendicular due to mating requirements.

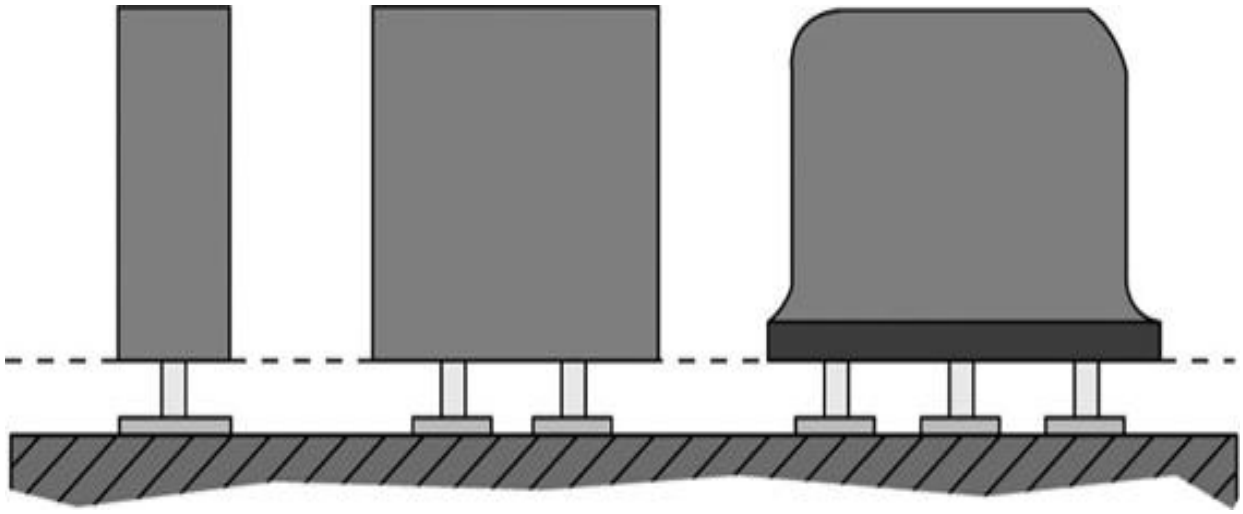

FIGURE 54.16 Radial leaded components spacing. Component is perpendicular and base is parallel to board. Acceptable clearance varies with Class. *(IPC)*

54.4.2 SMT Placement

Coplanarity is very important in the placement of SMT components with leads. Occasionally, lead preparation to form the leads of SMT components is necessary to achieve the proper coplanarity for manual or automatic placement of components on the PCB. Most times, however, the components are purchased packaged with leads prepared and ready to be automatically placed by pick-and-place equipment. Another critical parameter for all surface-mounted components is the accuracy of placement of the components onto the pads of the PCB.

54.4.2.1 Chip Components. Side overhang is acceptable up to one-half (one-quarter for Class 3) the width of the component end cap or PCB pad. End-cap overhang is not acceptable for all classes. The end-cap solder joint width is acceptable with a minimum solder joint length of one-half (three-quarters for Class 3) the component end cap or PCB land, whichever is less.

A side solder joint length is not required; however, a properly wetted fillet must be evident.

The maximum solder fillet height may overhang the land or extend onto the top of the end-cap metallization; however, the solder should not extend farther on the component body. The minimum solder fillet height must cover one-quarter the thickness, or height, of the component end cap for Class 3 but is required to be evident only for Classes 1 and 2. The component end cap must have overlap contact with the PCB pad. There is no minimum contact length specified see (see Fig. 54.17 and Table 54.1 for an example and list of specifications).

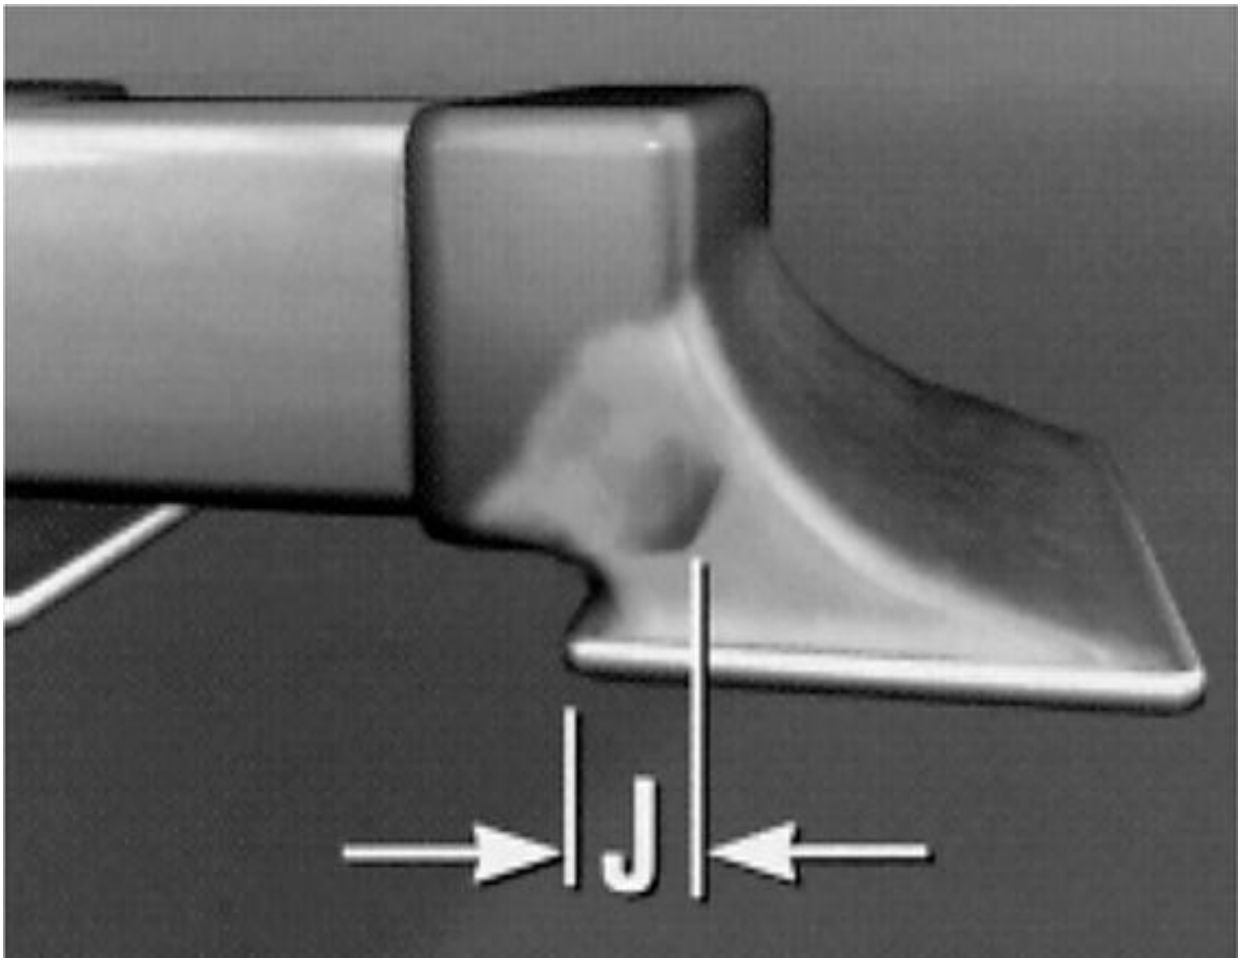

FIGURE 54.17 Example placement and solder fillet for surface mount chip component. Evidence of overlap of contact (J) between the component termination and the land is required. *(IPC)*

TABLE 54.1 Dimensional Criteria for Chip Components, Rectangular or Square End Components—One-, Three-, or Five-Side Terminations

Feature	Dim.	Class 1	Class 2	Class 3
Maximum Side Overhang	A	50% (W) or 50% (P) whichever is less[a]		25% (W) or 25% (P), whichever is less[a]
End Overhang	B	Not permitted		
Minimum End Joint Width	C	50% (W) or 50% (P), whichever is less[b]		75% (W) or 75% (P), whichever is less[b]
Minimum Side Joint Length	D	Wetting is evident		
Maximum Fillet Height	E	The maximum fillet may overhang the land and/or extend onto the top of the end-cap metallization; however, the solder does not extend further onto the top of the component body		
Minimum Fillet Height	F	Wetting is evident on the vertical surface(s) of the component termination[c]		(G) + 25% (H) or (G) + 0.5 mm (0.02 in.), whichever is less[c]
Solder Thickness	G	Wetting is evident		
Termination Height	H	Unspecified dimension, determined by design		
Minimum End Overlap	J	Required		
Width of Land	P	Unspecified dimension, determined by design		
Termination Width	W	Unspecified dimension, determined by design		
Side mounting/billboarding[d,e]				
Width to Height Ratio		Does not exceed 2:1		
End Cap and Land Wetting		100% wetting land to end metallization contact areas		
Minimum End Overlap	J	100%		
Maximum Side Overhang	A	Not permitted		
End Overhang	B	Not permitted		
Maximum Component Size		No limits		1206
Termination Faces		Three or more faces		

Notes:

[a] Does not violate minimum electrical clearance.

[b] C is measured from the narrowest side of the solder fillet.

[c] Designs with via in pad may preclude meeting these criteria. Solder acceptance criteria should be defined by the user and the manufacturer.

[d] These criteria are for chip components that may flip (rotate) onto the narrow edge during assembly.

[e] These criteria may not be acceptable for certain high-frequency or high-vibration applications.

54.4.2.2 Metal Electrode Leadless Face or Cylindrical Termination. Side overhang is acceptable up to one-quarter the diameter of the end cap. This dimension is different from the other SMT components due to the cylindrical feature of the component. End-cap overhang is not acceptable for all classes. The end-cap solder joint width is acceptable with a minimum solder joint length of one-half the diameter of the component end cap for Classes 2 and 3 but is required to be discernable only for Class 1. A side solder joint length must be a minimum of one-half (three-quarters for Class 3), but again is required to discernable only for Class 1. The maximum solder fillet height may overhang the land or extend onto the top of the end-cap metallization; however, the solder should not extend farther on the component body. The minimum solder fillet height must cover one-quarter the thickness, or height, of the component end cap for Class 3, and for Classes 1 and 2 the minimum solder fillet must exhibit proper wetting. The component end cap must have 75 percent of the cap dimension overlapping the land for Class 3 and 50 percent for Class 2. There is no minimum contact length specified for Class 1 (see Fig. 54.18 and Table 54.2).

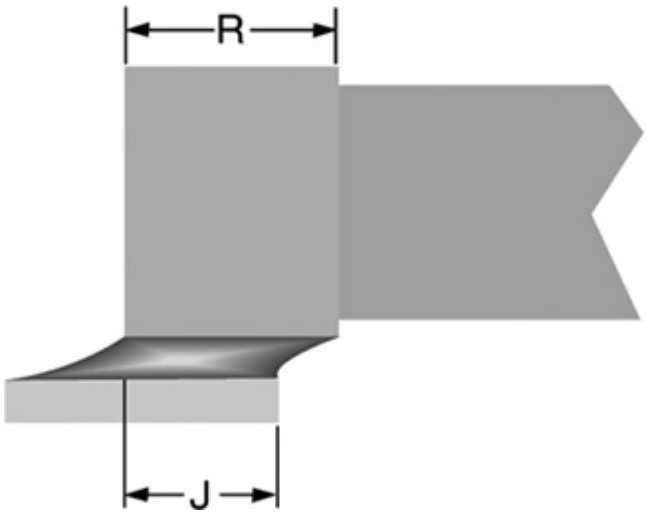

FIGURE 54.18 Cylindrical end cap (MELF) termination. “J” represents the overlap between component termination and land, “R” is length of component

termination. *(IPC*)

TABLE 54.2 Dimensional Criteria: Cylindrical End-Cap Metal Electrode Leadless Face (MELF) Termination

Feature	Dim.	Class 1	Class 2	Class 3
Maximum Side Overhang	A	25% (W) or 25% (P), whichever is less[a]		
End Overhang	B	Not permitted		
Minimum End Joint Width[b]	C	Wetting is evident	50% (W) or 50% (P), whichever is less	
Minimum Side Joint Length	D	Wetting is evident[c]	50% (R) or 50% (S), whichever is less[d]	75% (R) or 75% (S), whichever is less[d]
Maximum Fillet Height	E	The maximum fillet may overhang the land or extend onto the top of the component termination; however, the solder does not extend further onto the component body		
Minimum Fillet Height (End and Side)	F	Wetting is evident on the vertical surface(s) of the component termination[d]		(G) + 25% (W) or (G) + 1.0 mm (0.0394 in.), whichever is less[d]
Solder Thickness	G	Wetting is evident		
Minimum End Overlap	J	Wetting is evident[c]	50% (R)[c]	75% (R)[c]
Land Width	P	Unspecified dimension, determined by design		
Termination/Plating Length	R	Unspecified dimension, determined by design		
Land Length	S	Unspecified dimension, determined by design		
Termination Diameter	W	Unspecified dimension, determined by design		

Notes:

[a]Does not violate minimum electrical clearance.

[b]C is measured from the narrowest side of the solder fillet.

[c]Does not apply to components with end-only terminations.

[d]Designs with via in pad may preclude meeting those criteria. Solder acceptance criteria should be defined by the user and the manufacturer.

54.4.2.3 Castellated Terminations. Side overhang is acceptable up to one-half (one-quarter for Class 3) of the castellation width. End overhang of the castellation is not acceptable for all classes. The castellation end solder joint width is acceptable with a minimum solder joint length of one-half (three-quarters for Class 3) of the castellation width (see Table 54.3). A minimum side solder joint length is required to extend beyond the edge of the component for all classes. The maximum solder fillet height is not a specified parameter for this type. The minimum solder fillet height must be 50 percent of the castellation height for Class 3 and 25 percent for Class 2. The only height requirement for Class 1 is that at least one fillet is visible.

TABLE 54.3 Dimensional Criteria: Castellated Terminations

Feature	Dim.	Class 1	Class 2	Class 3
Maximum Side Overhang	A	50% (W)[a]		25% (W)[a]
End Overhang	B	Not permitted		
Minimum End Joint Width	C	50% (W)		75% (W)
Minimum Side Joint Length	D	wetting is evident	Depth of castellation	Depth of castellation
Maximum Fillet Height	E	G + H		
Minimum Fillet Height	F	wetting is evident	(G) + 25% (H)	(G) + 50% (H)
Solder Thickness	G	Wetting is evident.		
Castellation Height	H	Unspecified dimension, determined by design		
Land Length	S	Unspecified dimension, determined by design		
Castellation Width	W	Unspecified dimension, determined by design		

Note:
[a]Does not violate minimum electrical clearance.

54.4.2.4 Flat Ribbon, L, and Gull-Wing Leads. Side overhang is acceptable up to one-half (one quarter for Class 3) of the width of the component lead. Lead toe overhang is acceptable for all classes provided it does not violate minimum electrical clearance. The end-joint solder width is acceptable for Class 2 with a minimum solder-joint length of one-half (three-quarters for Class 3) of the component lead width. The lead-side solder-joint minimum length is one-time the lead width for Class 1. It must be three times the width when the lead length is greater than three times its width. If the lead length is less than three times its width, the side joint width must be equal to the length. For Classes 2 and 3,

the maximum solder fillet height on components such as small-outline integrated circuits (SOICs) or small-outline transistors (SOTs) may touch the package body or end seal, but not that of ceramic or metallic components. The minimum solder heel fillet height must cover one-half of the lead thickness for Class 2 and must be equal to the lead thickness for Class 3 (see Table 54.4).

TABLE 54.4 Dimensional Criteria: Flat Ribbon, L, and Gull-Wing Leads

Feature		Dim.	Class 1	Class 2	Class 3
Maximum Side Overhang		A	50% (W) or 0.5 mm (0.02 in.), whichever is less[a]		25% (W) or 0.5 mm (0.02 in.), whichever is less[a]
Maximum Toe Overhang		B	Does not violate minimum electrical clearance		
Minimum End Joint Width		C	50% (W)		75% (W)
Minimum Side Joint Length[b]	When (L) Is ≥3 W	D	(1W) or 0.5 mm [0.02 in.], whichever is less	3 (W) or 75% L, whichever is longer	
	When (L) Is <3 W			100% (L)	
Maximum Heel Fillet Height		E	See Section 52.4.2.1		
Minimum Heel Fillet Height		F	Wetting is evident	(G) + 50% (T)[c]	(G) + (T)[c]
Solder Thickness		G	Wetting is evident		
Formed Foot Length		L	Unspecified dimension, determined by design		
Lead Thickness		T	Unspecified dimension, determined by design		
Lead Width		W	Unspecified dimension, determined by design		

Notes:

[a] Does not violate minimum electrical clearance.

[b] Fine-pitch leads require a minimum side fillet length of 0.5 mm (0.02 in.).

[c] In the case of a toe-down lead configuration, the minimum heel fillet height (F) extends at least to the midpoint of the outside lead bend.

54.4.2.5 J-Leaded Components. Side overhang is acceptable up to one-half (one-quarter for Class 3) of the width of the component lead. Lead toe overhang is not specified for any class.

The end lead solder-joint width is acceptable with a minimum solder-joint length of one-half (three-quarters for

Class 3) of the component lead width. A side solder-joint length must be a minimum of 1½ times the lead width for both Class 2 and 3, but Class 1 requires only a visible fillet. The maximum solder fillet height is not specified; however, the solder fillet may not touch the component package body. The minimum heel solder fillet height must cover one-half of the thickness of the component lead or the lead thickness for Class 3 (see Table 54.5).

TABLE 54.5 Dimensional Criteria: J–Leads

Feature	Dim.	Class 1	Class 2	Class 3
Maximum Side Overhang	A	50% (W)[a]		25% (W)[a]
Maximum Toe Overhang	B	Unspecified dimension, determined by design[a]		
Minimum End Joint Width	C	50% (W)		75% (W)
Minimum Side Joint Length	D	Wetting is evident	150% (W)	
Maximum Fillet Height	E	Solder does not touch package body		
Minimum Heel Fillet Height	F	(G) + 50% (T)		(G) + (T)
Solder Thickness	G	Wetting is evident		
Lead Thickness	T	Unspecified dimension, determined by design		
Lead Width	W	Unspecified dimension, determined by design		

Note:
[a] Does not violate minimum electrical clearance.

54.4.2.6 Ball Grid Array Components. Ball Grid Array (BGA) package components are a very popular design due to significant packaging density. This allows designers to get more function in a smaller space. The component package is virtually impossible to inspect visually as traditionally allowed with other components since the solder spheres are

located beneath the component. If cost justification exists, either due to volume or reliability provisions such as could be the case on Class 3 equipment, x-ray equipment can be used to verify the position quality and integrity of the solder joints. This could be costly in terms of the upfront capital investment of the x-ray equipment, but may pay for itself many times over in customer satisfaction or the prevention of defective product. Other options may use the x-ray as a process development tool where once the process is stabilized, the inspection is reduced to sampling or eliminated completely.

X-ray inspection can provide a visual depiction of the solder connection that must not contain solder bridges, incomplete reflow, attachment fractures, misalignment that violates minimum electrical clearance, or missing or damaged spheres. It's also considered defective for solder voids to displace more than 25 percent of a sphere (see Fig. 54.19).

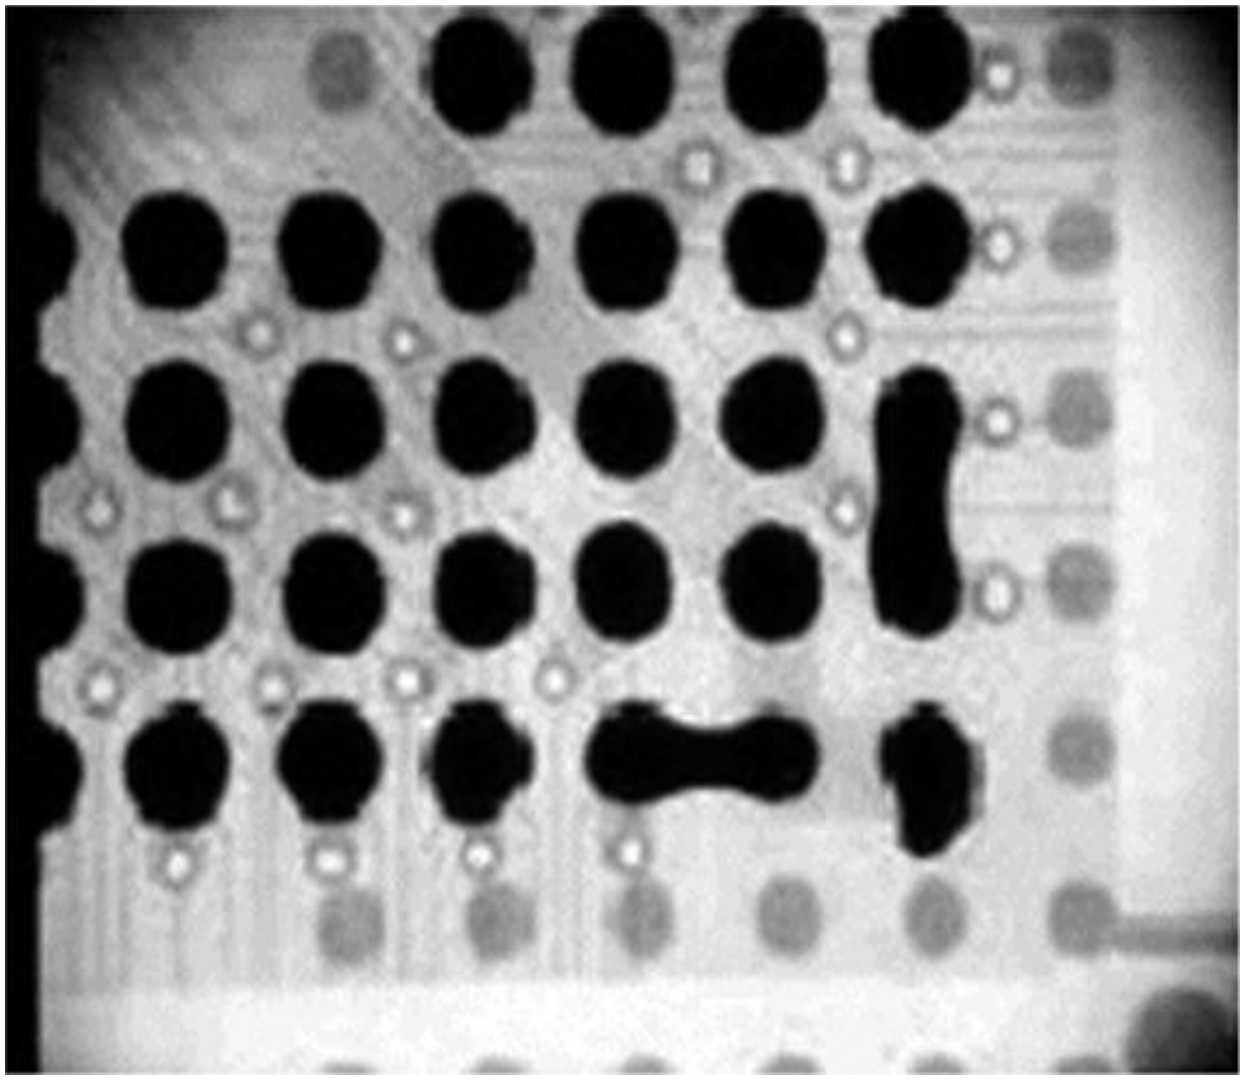

FIGURE 54.19 Ball grid array (BGA), bottom view showing solder ball connection. *(IPC)*

54.4.3 Use of Adhesives

Adhesives can often be used in SMT and PTH applications.

For SMT components, adhesive may be used to attach components to the bottom side of the PCB for mixed technologies (those containing both through-hole and SMT components). In some process flows, the SMT components are placed with adhesive between the solder pads; the PCB is processed through an adhesive curing cycle; then the

components are wave soldered or reflowed onto the PCB along with the PTH components. In some processes, the adhesive is a temporary (soluble) attachment to stabilize the components during soldering and is to be removed after the solder is attached. In some extreme cases, the adhesive is used for both through-hole and SMT components to support the physical attachment of the components for severe operational conditions such as physical shock or vibration. Where intended to support the component physically, the attachment is specifically defined by drawing or individual requirements. The SMT components are acceptable as long as the adhesive has not contaminated the solder joint. If adhesive has contaminated the component solderable surface, lead, end cap, or PCB pad such that an acceptable solder joint is not achieved, the PCBA is not acceptable (see Fig. 54.20).

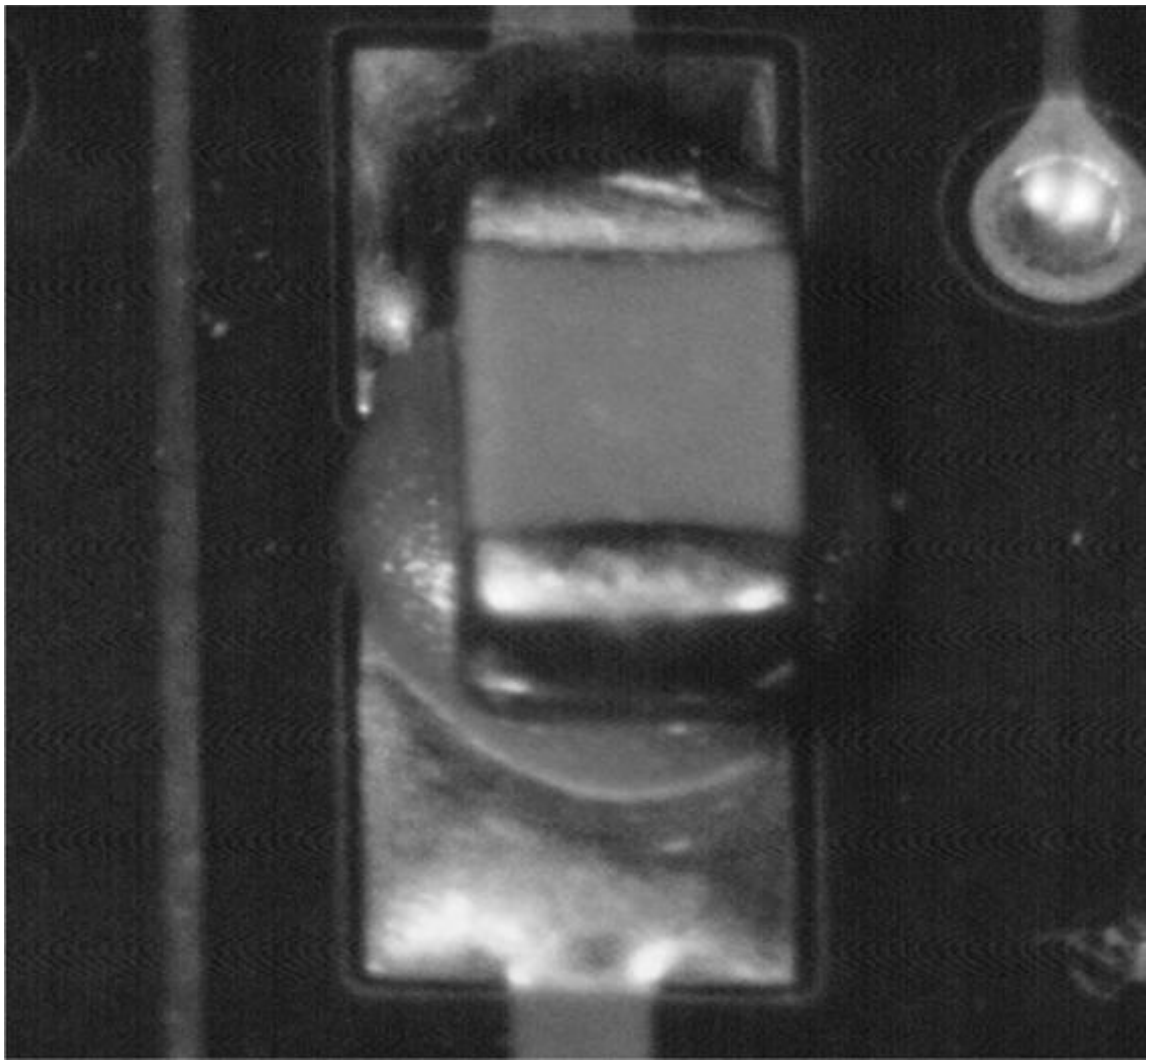

FIGURE 54.20 Adhesive visibly extended from under the component and visible in the terminal area. *(IPC)*

Normally in PTH component applications, adhesive is used to give large-profile and/or heavy components more mechanical stability. When adhesives are used in this manner, the following adhesive acceptance criteria apply:

- The adhesive must adhere to a flush-mounted axial component for 50 percent of the component length and 25 percent of its diameter on one side. The build-up of adhesive should not exceed 50 percent of the component diameter, and adhesion to the mounting surface must be evident (see Fig. 54.21).

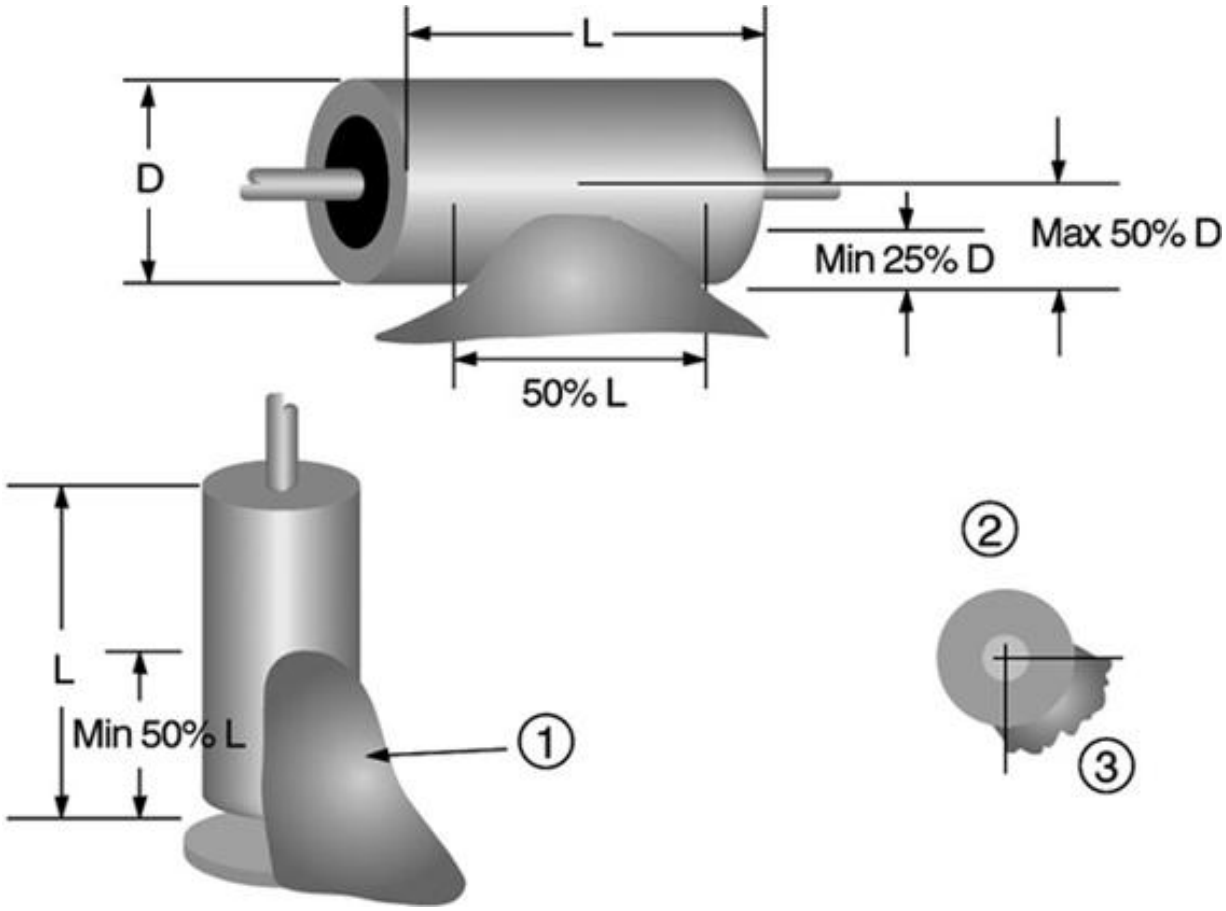

FIGURE 54.21 Adhesive on horizontal and vertically mounted components. (1) Adhesive, (2) Top view, (3) 25 percent circumference.

- The adhesive must adhere to a vertically mounted axial component for 50 percent of the component length and 25 percent of its circumference, and adhesion to the mounting surface must be evident (see Fig. 54.22).

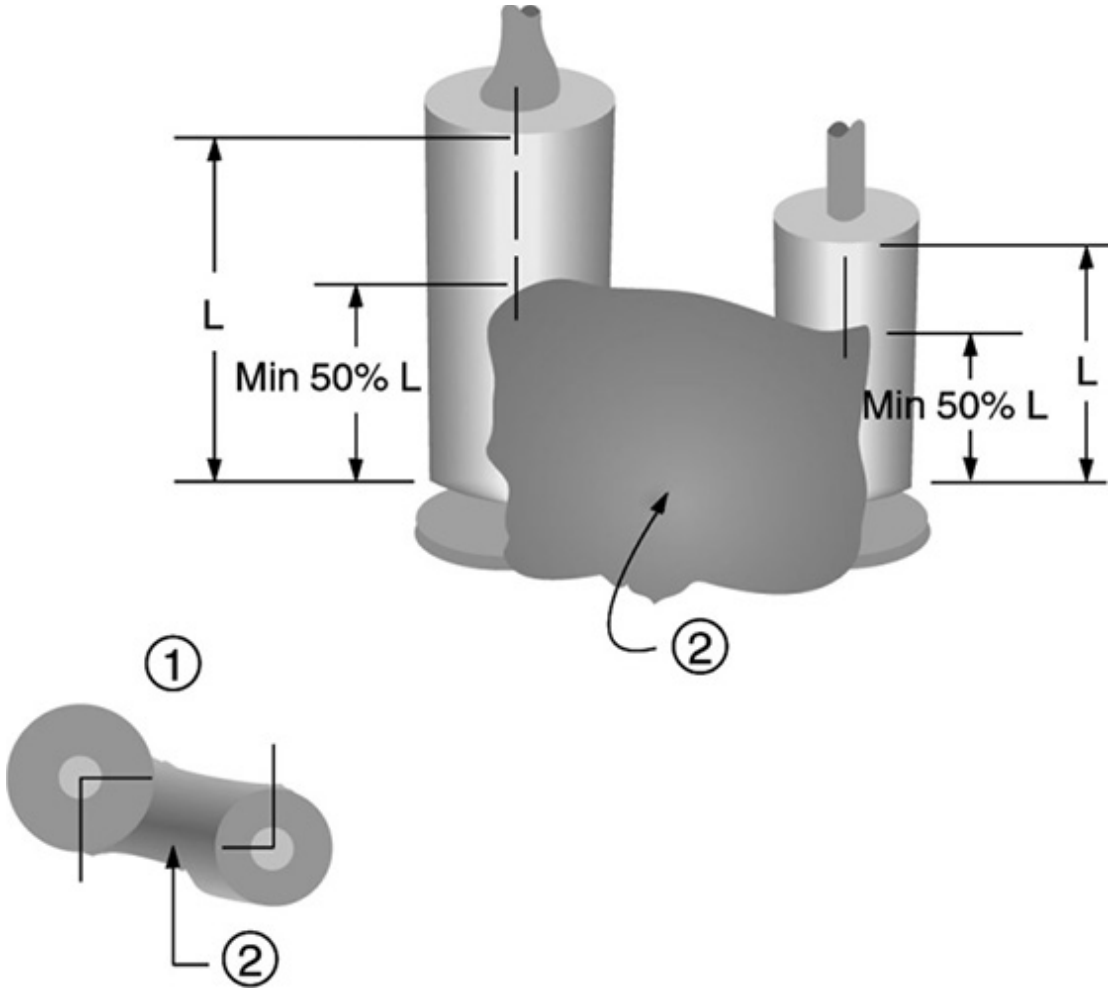

FIGURE 54.22 Adhesive on vertically mounted components. (1) Top view, (2) Adhesive. *(IPC)*

54.5 COMPONENT AND PCB SOLDERABILITY REQUIREMENTS

Component solderability, which includes the solderability of the PCB, is probably the most important single characteristic to consider when building PCBAs. To be successful in soldering PCBAs, good wetting must be achieved. It is an ongoing effort to ensure that all boards and electrical components purchased and received from suppliers maintain good solderability.

The key to success in this all-important task is to have an excellent working relationship with the suppliers and manufacturers of the components to ensure good, solderable components.

Until partnership relationships are achieved, there should be a sample of each lot or batch of components received that are subjected to solderability testing. This testing should be conducted in accordance with J-STD-002 and J-STD-003. These documents were written specifically to address solderability requirements for electronic assembly components and PCBs. The intent of the solderability testing is to qualify the surface to accept solder with less-than-optimum conditions. Additionally, artificial conditioning (aging) is used to simulate a normal aging period that the components might experience before use. Identification of weaker components can reduce the possibility of a solderability problem or production issues later on in the production cycle. Based on this lack of lead solderability, the components should be rejected and returned to the supplier, before they can be placed in the assembly process.

Packaging and handling of components are also important to maintain good solderability since many contaminants that could affect solderability can be transferred to solderable surfaces as a result of handling by equipment or personnel or the storage environment. Storage contamination may result from airborne contaminants, moisture, temperature, and also time. As tin-lead or lead-free component lead finishes age, they can oxidize, and this oxidation will affect solderability of the component. A rule of thumb used by many companies is to suspect the solderability of components two or more years old. In some cases, this age can be tracked easily for components marked with a date code. Other components too small to mark or that for some other reason are not marked with a date code cannot be traced as easily. Often companies keep records on the date of receipt and base the age of the component on this date.

Although these records may not be completely accurate, they still serve the purpose. If components are known to be over two years old, a new solderability sample may be pulled to determine whether the components are still usable before production. Often they are not usable due to oxidation, intermetalic growth, or some other contaminant that the component has been exposed to over time.

54.6 SOLDER-RELATED DEFECTS

All solder joints should exhibit wetting as shown by a concave meniscus between the component and PCB being soldered. The outline of the component being soldered should be easily determined. The most common solder defects produced by the soldering process are discussed in the following sections.

54.6.1 PTH Solder-Joint Minimum Acceptable Conditions

Table 54.6 shows the minimum acceptable PTH solder-joint criteria. Fig. 54.23 shows the basic elements of solder fill for all classes.

TABLE 54.6 PTHs with Component Leads: Minimum Acceptable Solder Conditions[a]

Criteria	Class 1	Class 2	Class 3
A. Vertical fill of solder[b,c] Note: Less than 100 percent older fill may not be acceptable in some applications: e.g., thermal shock. The user is responsible for identifying these situations to the manufacturer	Not Specified	75%	75%
B. Wetting on primary side (solder destination side) of lead and barrel Target for Classes 1,2, and 3 is 360° wetting present on land and barrel	Not Specified	180°	270°
C. Percentage of land area covered with wetted solder on primary side (solder destination side) The land area does not need to be wetted with solder on the primary side	0	0	0
D. Fillet and wetting on secondary side (solder source side) of lead and barrel	270°	270°	330°
E. Percentage of land area covered with wetted solder on secondary side (solder source side)	75%	75%	75%

Notes:

[a]Wetted solder refers to solder applied by the solder process.

[b]The 25 percent unfilled height includes both source and destination side depressions.

[c]Class 2 may have less than 75 percent vertical hole fill.

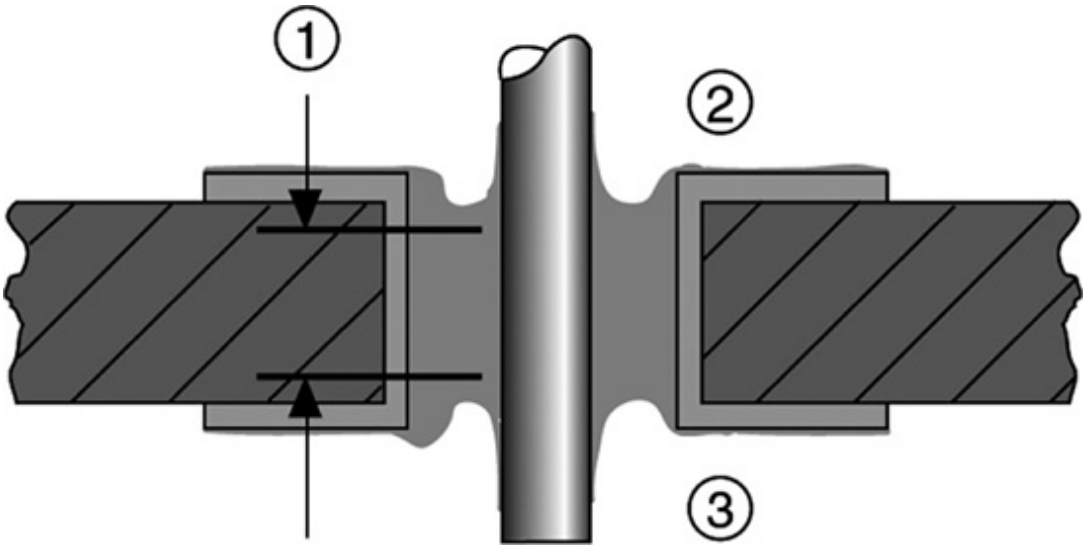

FIGURE 54.23 (1)–Vertical fill meets requirements of Table 54.6 (2)–Solder distination side (3)–Solder source side. *(IPC)*

54.6.2 Solder Balls or Solder Splash

Solder balls and splashes that violate minimum electrical design clearance, are not encapsulated in a permanent coating, or are not attached (soldered) to a metal surface are unacceptable (see Fig. 54.24).

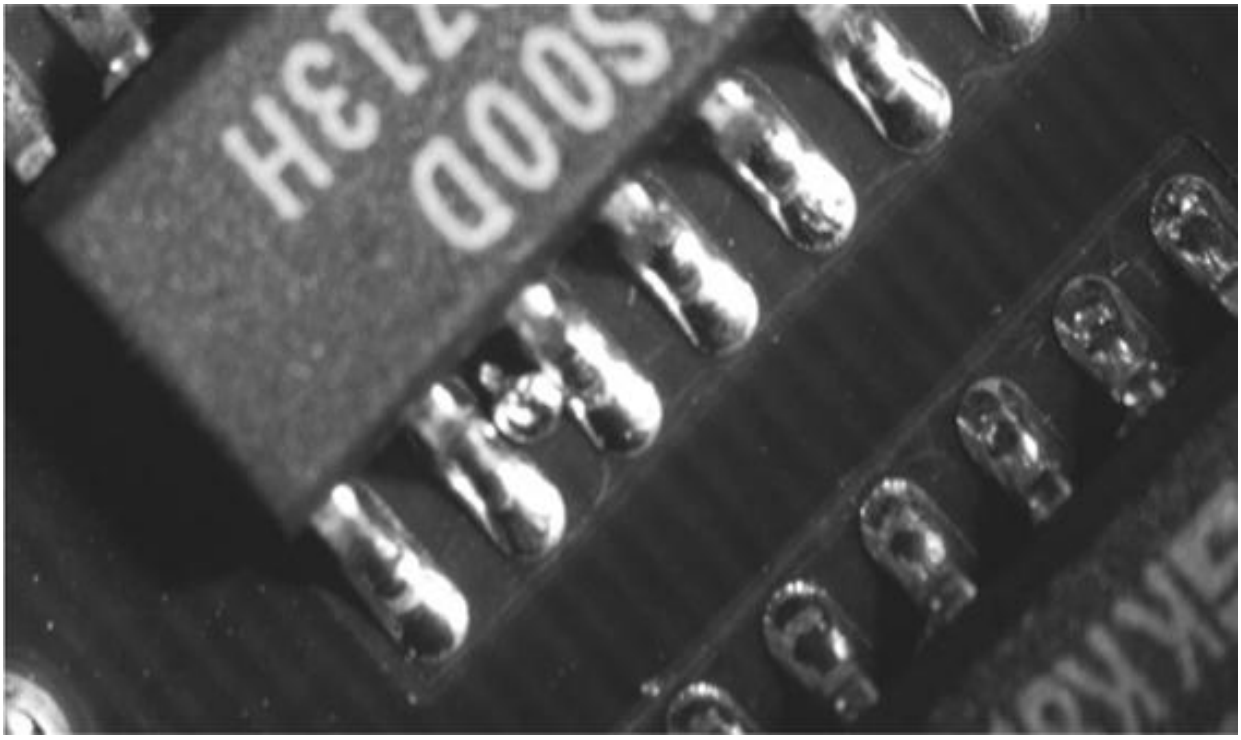

FIGURE 54.24 Solder ball causing a short circuit between pins in SOIC.

54.6.3 Dewetting and Nonwetting

Dewetting is a condition that results when molten solder coats a surface and then recedes to leave irregularly shaped mounds of solder that are separated by areas that are covered with a thin film of solder and with the basis metal not exposed (see Fig. 54.25). Nonwetting is the partial adherence of molten solder to a surface that it has contacted, while the basis metal remains exposed (see Fig. 54.26).

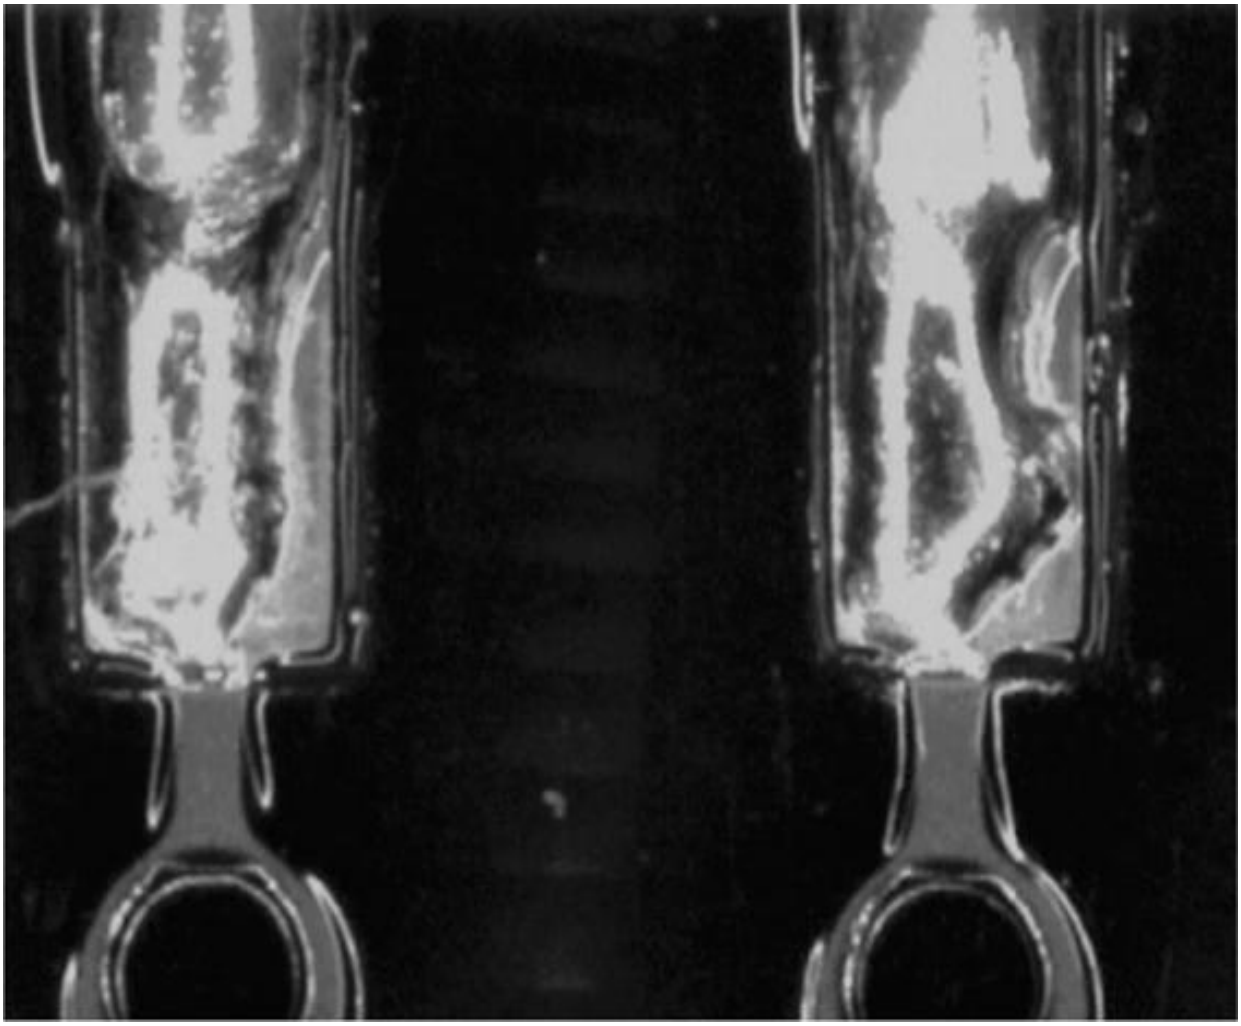

FIGURE 54.25 Example of dewetting. *(IPC)*

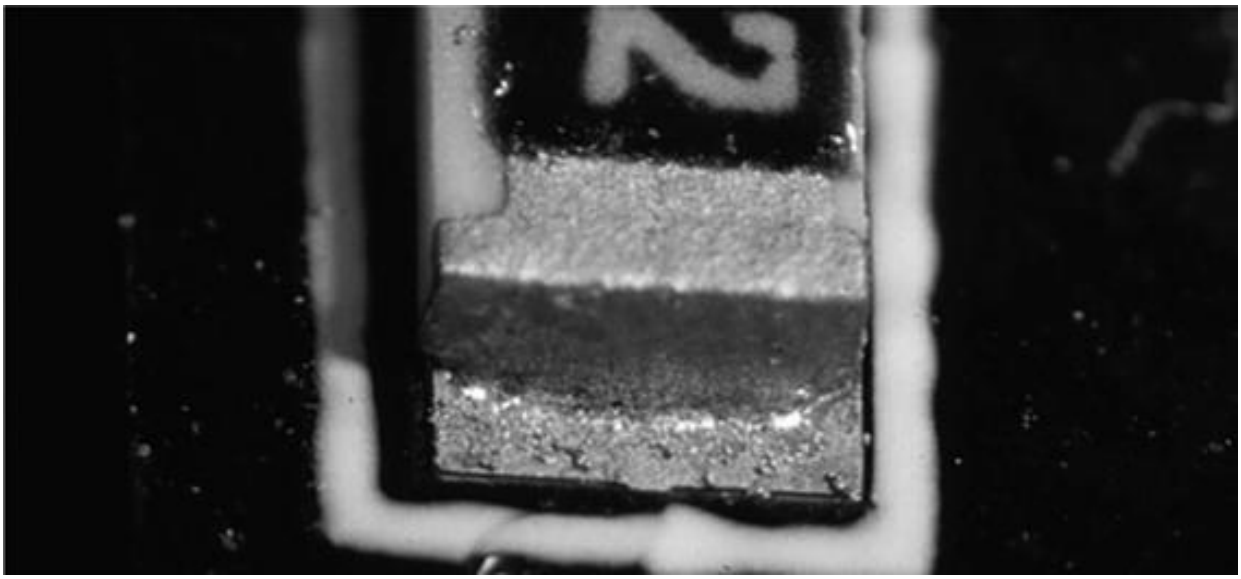

FIGURE 54.26 Example of non wetting. *(IPC)*

Dewetting and nonwetting of solder joints is generally caused by contaminants on either the component leads or on the PCB PTH or pads. A minimum of dewetting is allowed on solder joints assuming that the solder joint meets minimum requirements as defined in Table 54.6 and Sect. 54.4.2 by component package type, and good wetting is evident on the portion of the solder joint that does not display dewetting. Nonwetting is unacceptable since adequate wetting is not achieved and indicates a serious solderability problem on the component or the PCB.

54.6.4 Missing and Insufficient Solder

Missing solder is an obvious unacceptable condition since solder provides electrical continuity and some measure of mechanical attachment of the component to the PCB.

Insufficient solder becomes an unacceptable condition for SMT components when the minimum solder fillet requirements defined in Sec. 54.4.2 are not achieved. Insufficient solder becomes unacceptable for PTH components when the minimum requirements of section 54.6.1 and Table 54.6 are not achieved.

54.6.5 Solder Webbing and Bridging

Solder bridged between electrically noncommon conductors creates a shorting condition and is an unacceptable condition (see Fig. 54.27). Solder webbing is a continuous film of solder that is parallel to, but not necessarily adhering to, a surface that should be free of solder. Solder webbing is also an unacceptable condition (see Fig. 54.28).

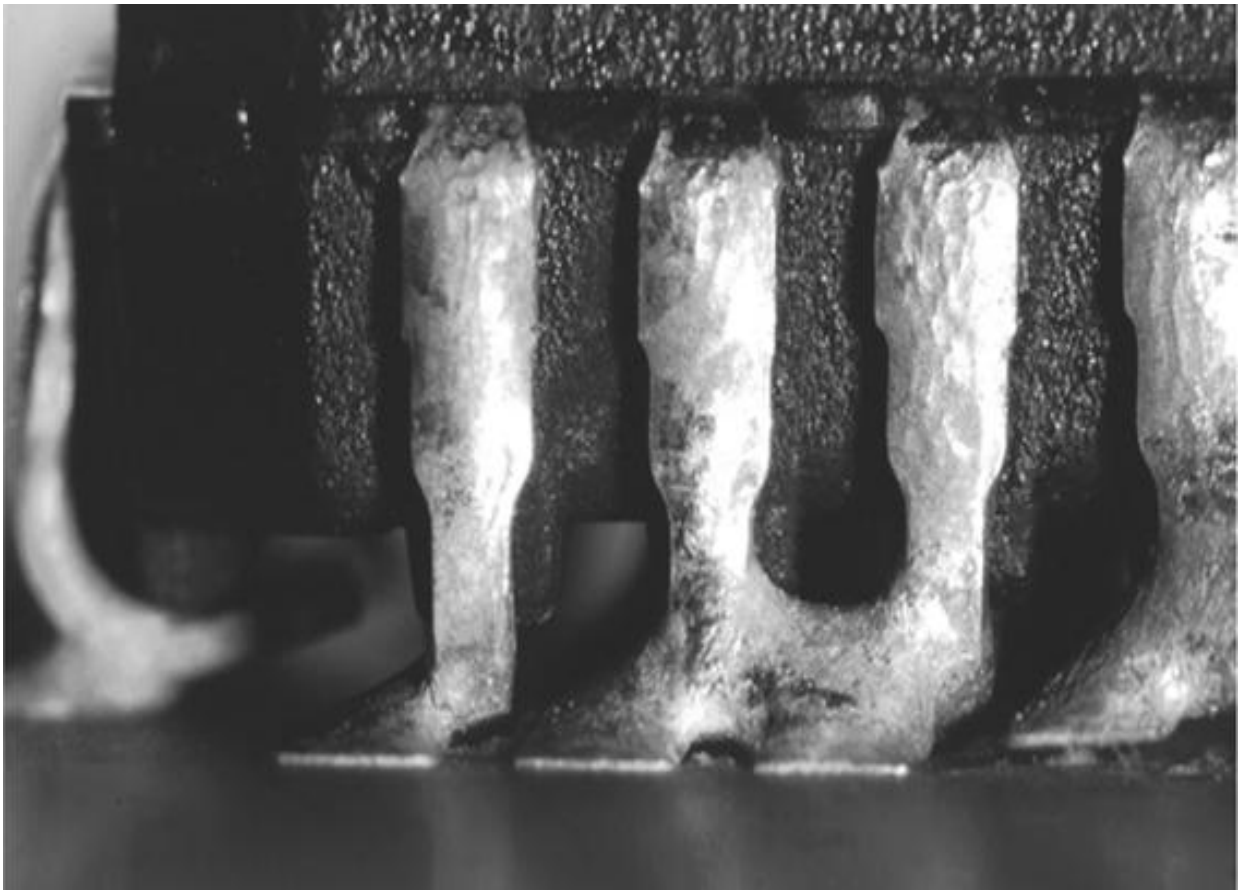

FIGURE 54.27 Solder connection across conductors that should not be joined. *(IPC)*

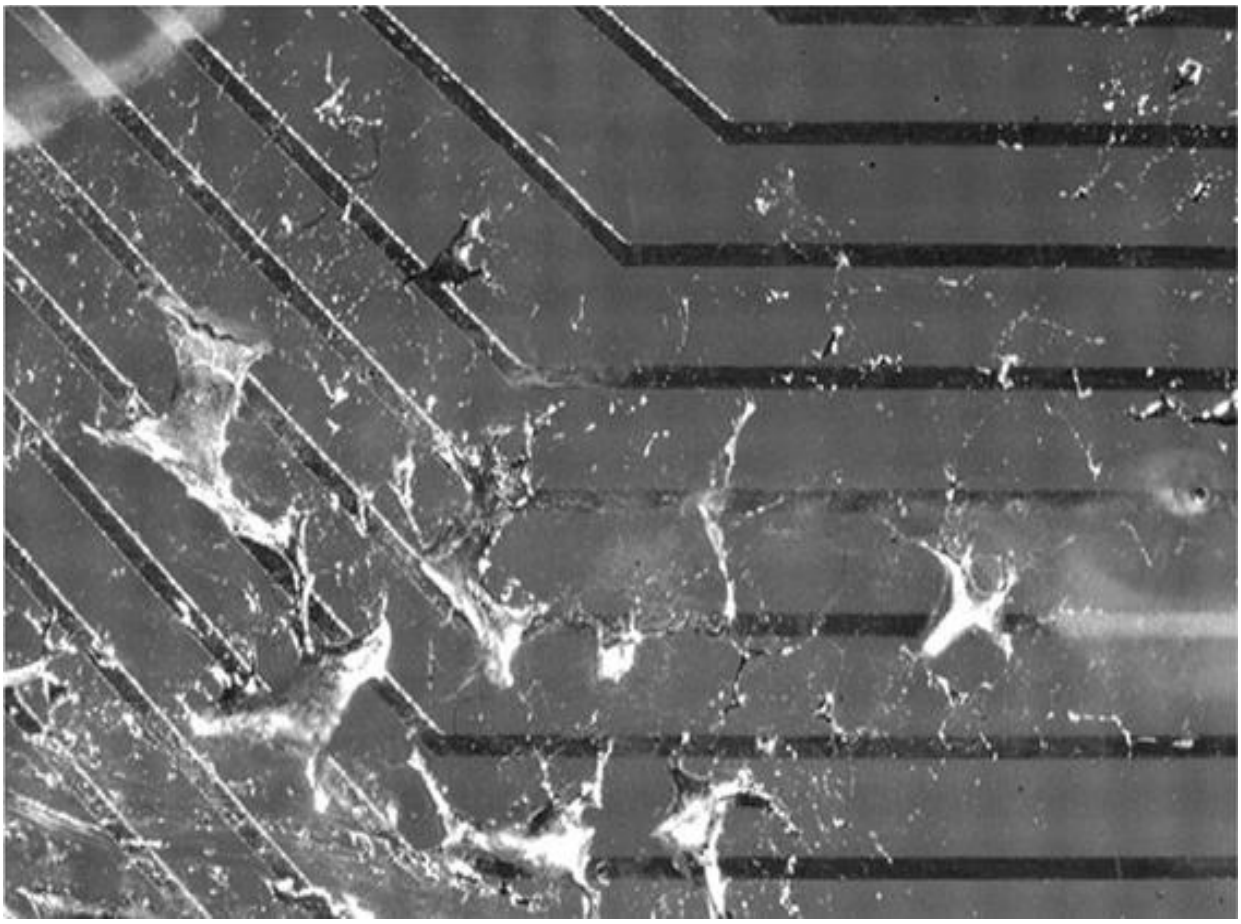

FIGURE 54.28 Examples of solder splashes and webbing. *(IPC)*

For components with leads, with the exception of criteria stated in sec. 54.4.2.4, solder cannot come into contact with the component body or end seal. Solder contacting the component body or end seal is generally unacceptable.

54.6.6 Lead Protrusion Problems

Measurement of lead protrusion is defined as the distance from the top of the PCB land to the outermost part of the component lead, which can include any solder projection from the lead.

Solder projections (icicles) are unacceptable if they violate lead protrusion maximum requirements or electrical clearance, or if they pose a safety hazard; otherwise, solder

projections are an acceptable condition on both SMT and PTH components (see Fig. 54.29).

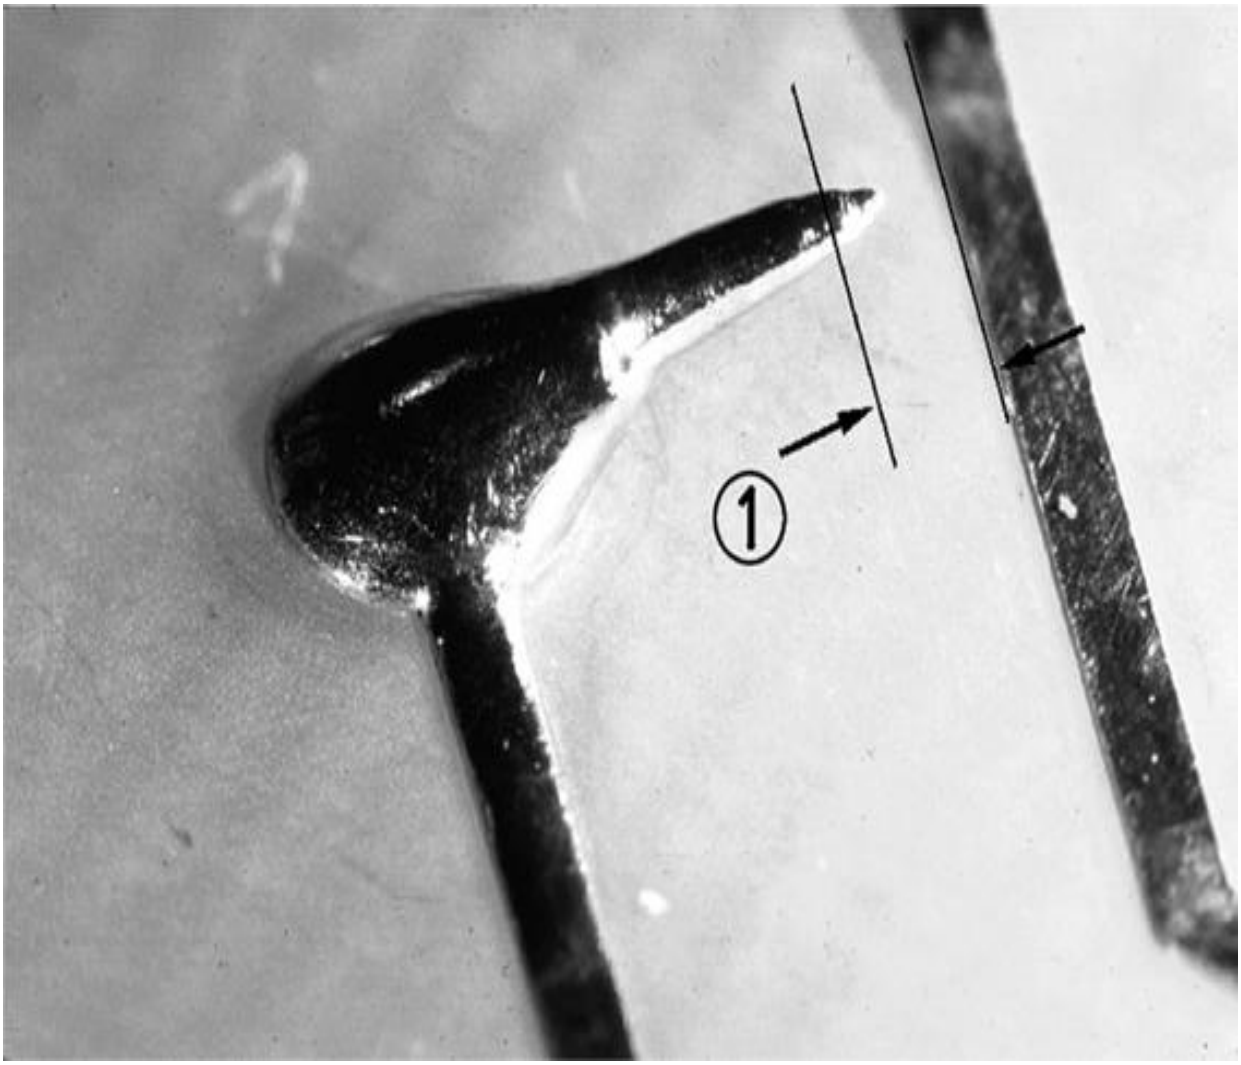

FIGURE 54.29 Projection violates minimum electrical clearance (1). *(IPC)*

For single-sided PCBAs, lead or wire protrusion must be visible in the solder for Classes 1 and 2, and must allow a clinch for Class 3. For double-sided and multilayer PCBAs in all classes, the minimum lead protrusion is for the lead end to be visible in the solder. The maximum lead protrusion for Class 1 is that there be no danger of shorts when the PCBA is used in its assembly application. For Class 2, the maximum

lead protrusion is 2.5 mm, and for Class 3 the maximum lead protrusion is 1.5 mm (see Fig. 54.30).

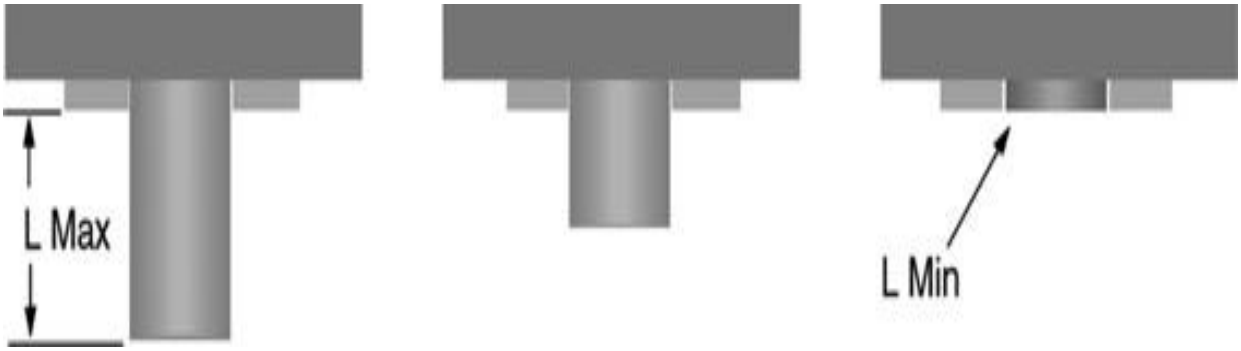

FIGURE 54.30 Lead protrusion violates minimum clearance requirements. Lead protusion exceeds maximum design height requirements. *(IPC)*

54.6.7 Voids, Pits, Blowholes, and Pinholes

Solder cavities (voids, pits, blowholes, pinholes) are acceptable for Class 1 and process indicators for Classes 2 and 3, provided the lead and land/pad are wetted and solder fillets meet requirements specified in Table 54.6.

54.6.8 Disturbed or Fractured Solder Joints

Solder joints may not be disturbed due to movement of the solder connection during solidification. However, a rough, granular, or uneven appearance, provided the wetting coverage criterion in Table 54.1 is met, is acceptable. Solder connections accomplished using many of the lead-free solder alloys and surface preparations will normally exhibit the rough or granular appearance more than eutectic tin-lead. Solder joints that are fractured or cracked are unacceptable for all classes of equipment.

Cutters cannot damage solder joints in which leads have been trimmed after soldering, due to physical shock transmitted through the lead. If lead cutting is required after soldering, the solder joint must be reflowed or visually inspected at 10 × magnification to ensure that the cutting operation did not damage the solder connection. No fractures or cracks are allowed between the lead and solder (see Fig. 54.31).

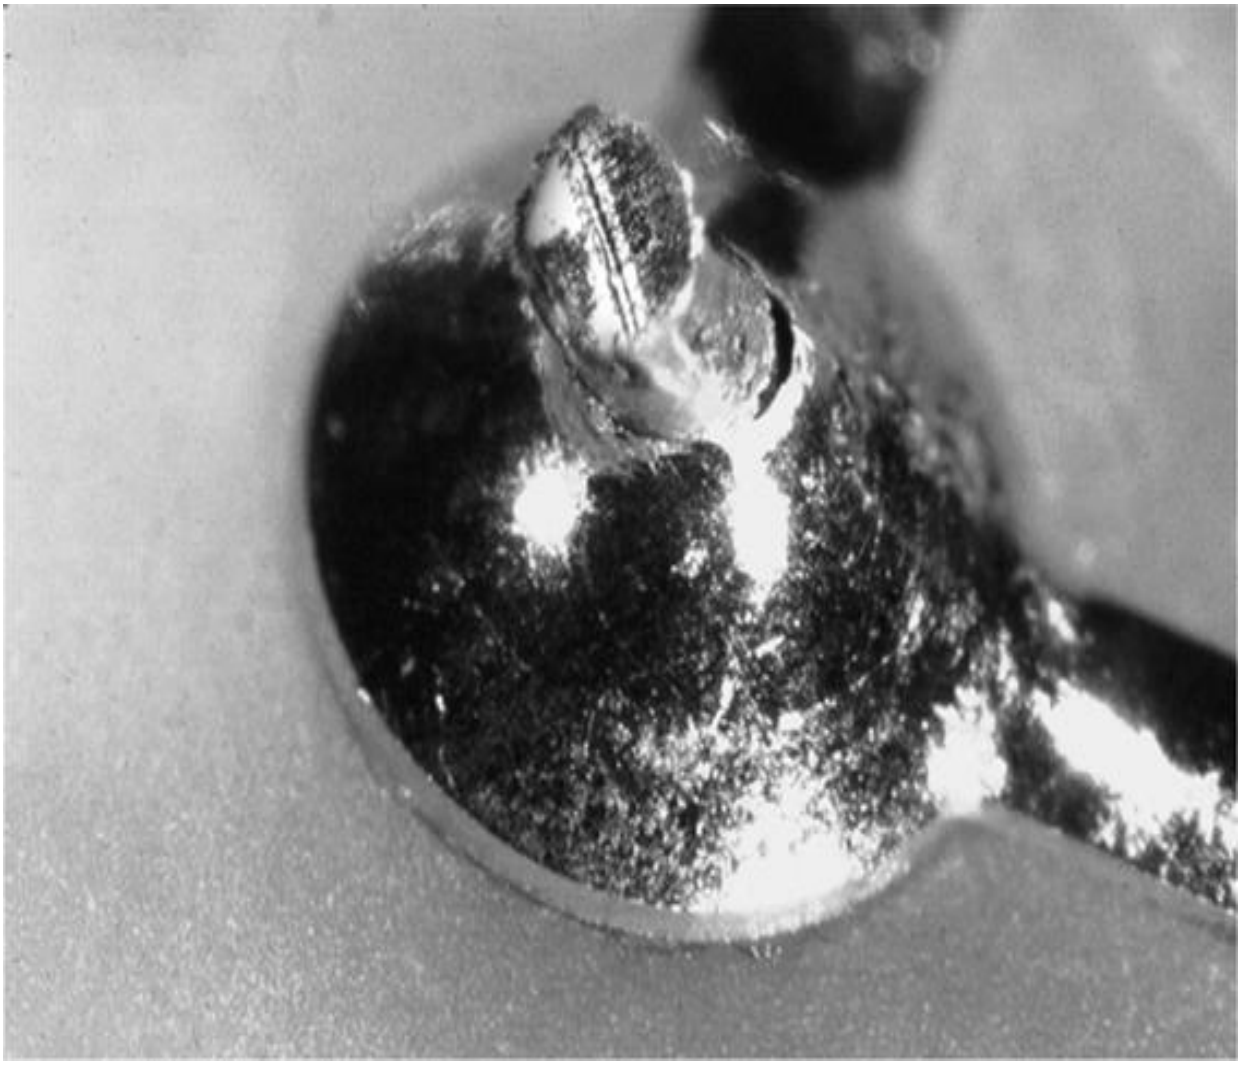

FIGURE 54.31 Example of disturbed solder joint on through-hole component joint. Note evidence of fracture between lead and solder fillet. *(IPC)*

54.6.9 Excess Solder

Excess solder conditions that produce a solder fillet that is slightly convex or bulbous and in which the lead is no longer visible are considered defects for unsupported hole lead termination. The solder should not flow onto the body of SMT components or touch the component body for through-hole components.

54.6.10 Solder Requirements for Vias

Plated-through via holes used only for interfacial connection do not need to be filled with solder. To prevent solder fill, manufacturers usually place temporary or permanent masks over the vias during the soldering process. PTHs or vias without leads when exposed to solder should meet the following acceptability requirements:

- The target condition is to have the holes completely filled with solder and the top of the lands showing good wetting.
- The minimum acceptable condition is to have the sides of the PTH wetted with solder.
- Solder that has not wet the sides of the PTH is considered a process indicator and product is not rejected (see Fig. 54.32).

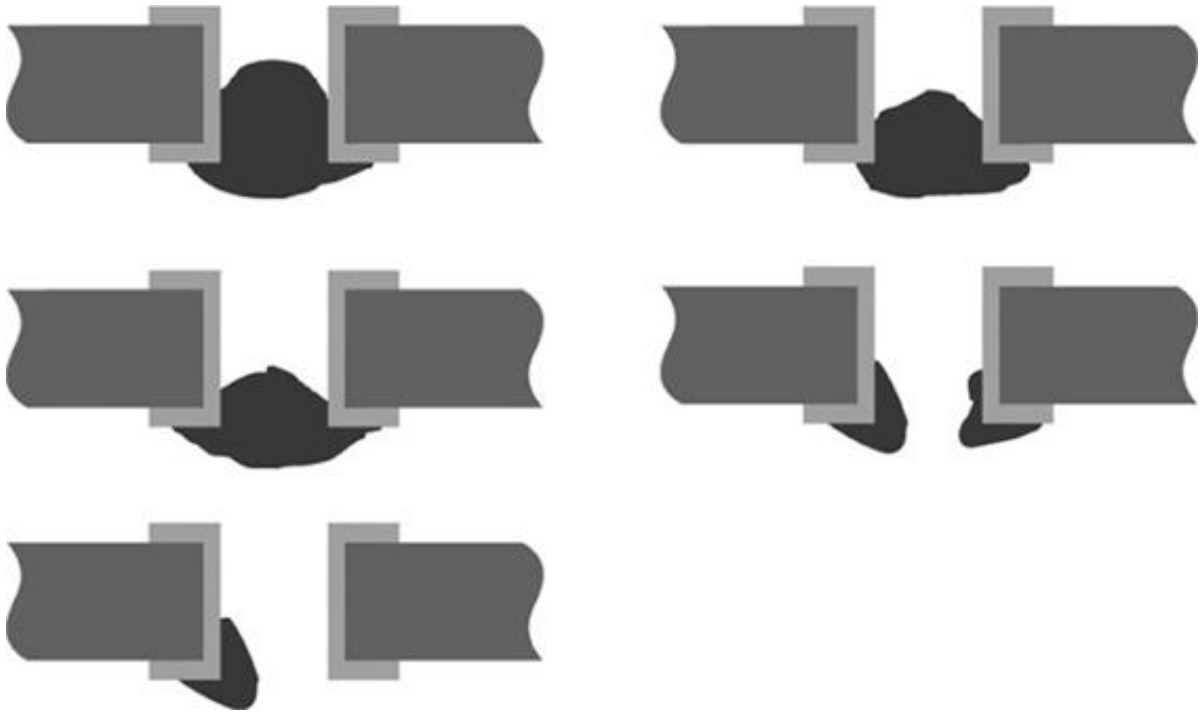

FIGURE 54.32 Via hole solder fill requirements. *(IPC)*

54.6.11 Soldering to Terminals

When soldering wires to terminals, the lead outline must be visible and good wetting between the wire and terminal must be evident to be acceptable. The wire insulation gap can be near zero if the insulation has not melted into the solder joint. Slight melting of the insulation is acceptable. If the insulation gap is too large and allows potential shorting of wire to an electrically noncommon conductor, the joint is unacceptable. If the wire insulation is severely burned and the melt by-product intrudes into the solder joint, the joint is unacceptable

For round post terminals, the contact of wrap must be 180° for Class 3 and 90° for Classes 1 and 2. Most of the other terminal types, such as pierced terminals, require 90° of wire wrap (see Fig. 54.33).

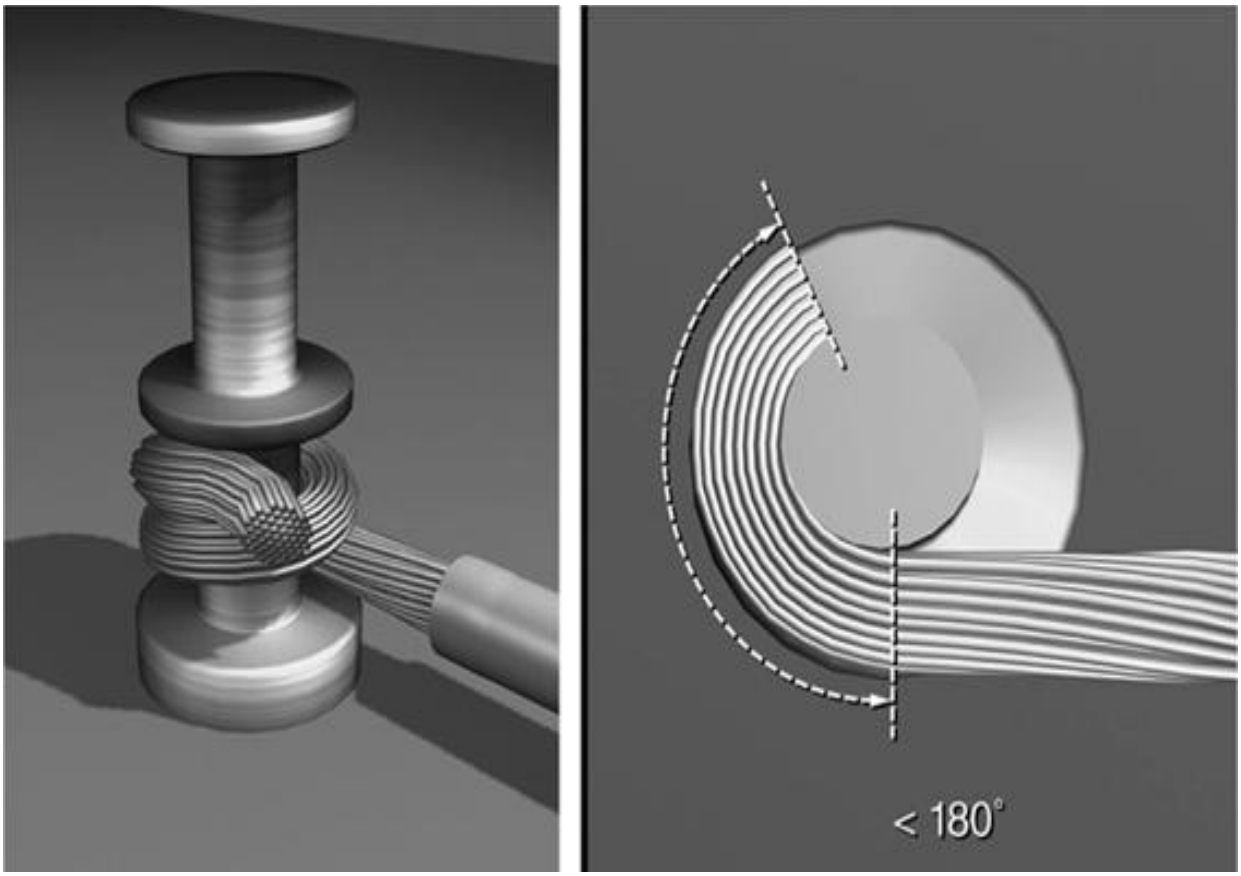

FIGURE 54.33 Minimum requirements for wrap of exposed wire on terminal for acceptable solder joint by class.

For solder cup terminations, the wire should be fully inserted to the bottom of the cup and solder fill must be greater than 75 percent of the milled edge.

54.7 PCBA LAMINATE CONDITION, CLEANLINESS, AND MARKING REQUIREMENTS

54.7.1 Laminate Conditions

Laminate defect conditions may be caused by the laminator, PCB fabricator, or assembly of the PCB. The major laminate

conditions seen are measling, crazing, blistering, delamination, weave exposure, and haloing.

54.7.1.1 Measling and Crazing. Measling is an internal condition occurring in laminated base material in which the glass fibers are separated from the resin at the weave intersections. This condition manifests itself in the form of white spots or crosses below the surface of the base material and is usually related to thermally induced stress.

Crazing is an internal condition occurring in laminated base material in which the glass fibers are separated from the resin at the weave intersections. This condition manifests itself in the form of connected white spots or crosses below the surface of the base material and is usually related to mechanically induced stress (see Fig. 54.34).

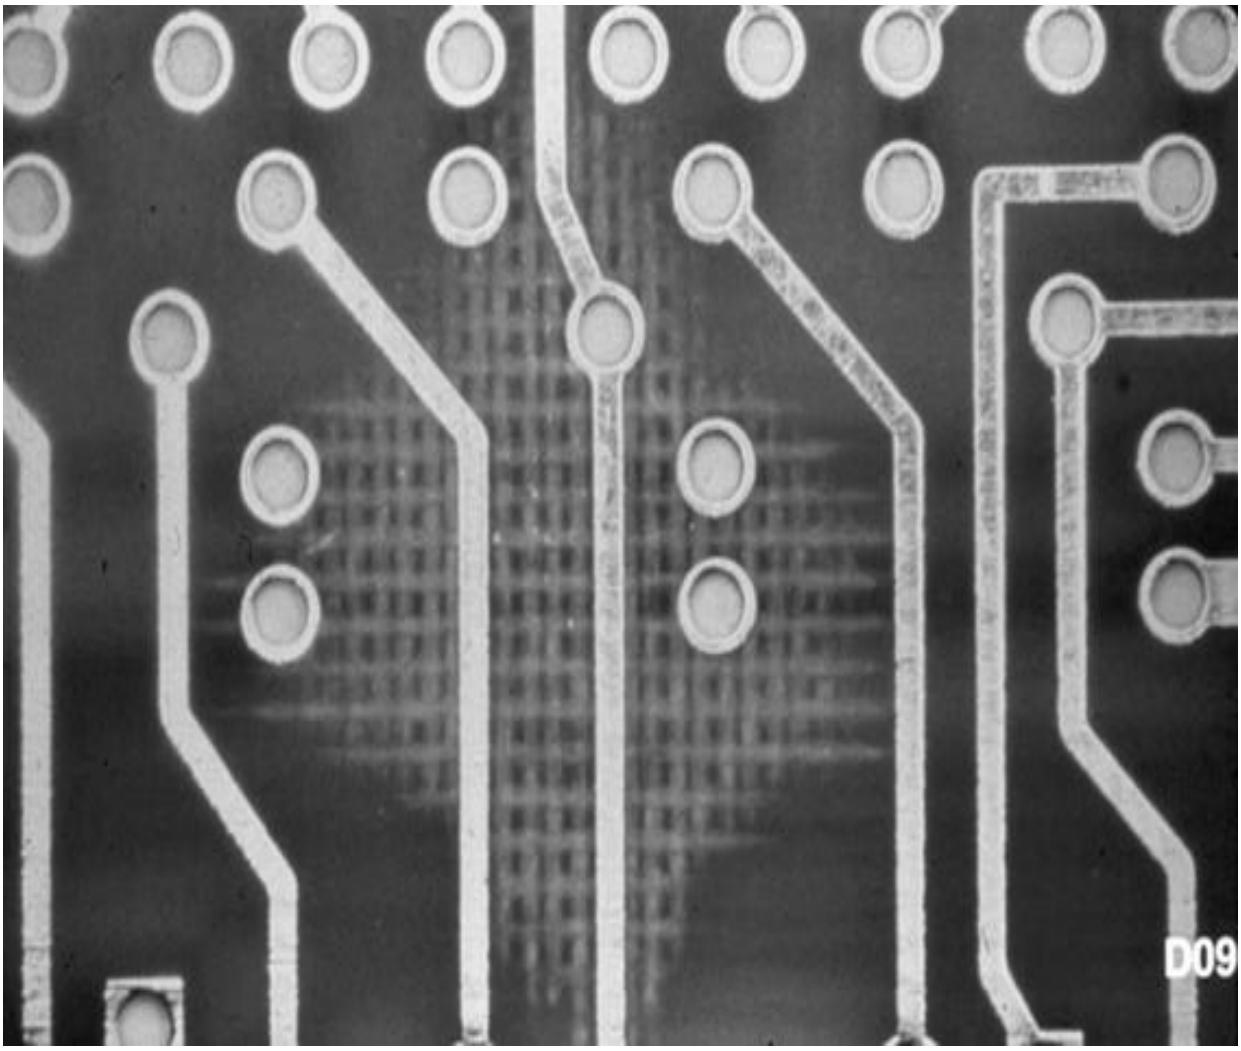

FIGURE 54.34 Crazing in base laminate. Crazing exceeds 50 percent of the physical space between internal conductors. *(IPC)*

Measling or crazing that occurs as a result of an inherent weakness in the laminate is a warning of a potentially more serious problem. If measling or crazing occurs in the assembly process, it usually will not propagate further. Measling is considered a defect for Classes 2 and 3 if the measle condition extends more than 50 percent of the span between internal conductors. The concern is in regard to the ability of the laminate to maintain dielectric integrity after exposure to high humidity and active chemistries and environments.

By the time that a PCB enters an assembly process, the operator who observes measling or crazing cannot determine the source of the problem. This fact places even more importance on getting high-quality PCBs from suppliers. This can be done through increased receiving inspection, source inspections, or a comprehensive qualification program and partnership with suppliers. In such a program, process control is exercised in the PCB fabrication, and parametric data from the supplier are sent to the buyer to review for compliance with requirements. This kind of information can also be used to justify a dock-to-stock program if desired.

54.7.1.2 Blistering and Delamination. Blistering is a localized swelling and separation between any of the layers of the base material or between the material and the metal cladding. Delamination is a separation between any of the layers of the base material or between the base material and the metal cladding. In contrast to measles that do not propagate, blisters and delamination conditions can increase in size with use.

Blistering and delamination cannot exceed 25 percent of the distance between PTHs or subsurface conductors (see Fig. 54.35).

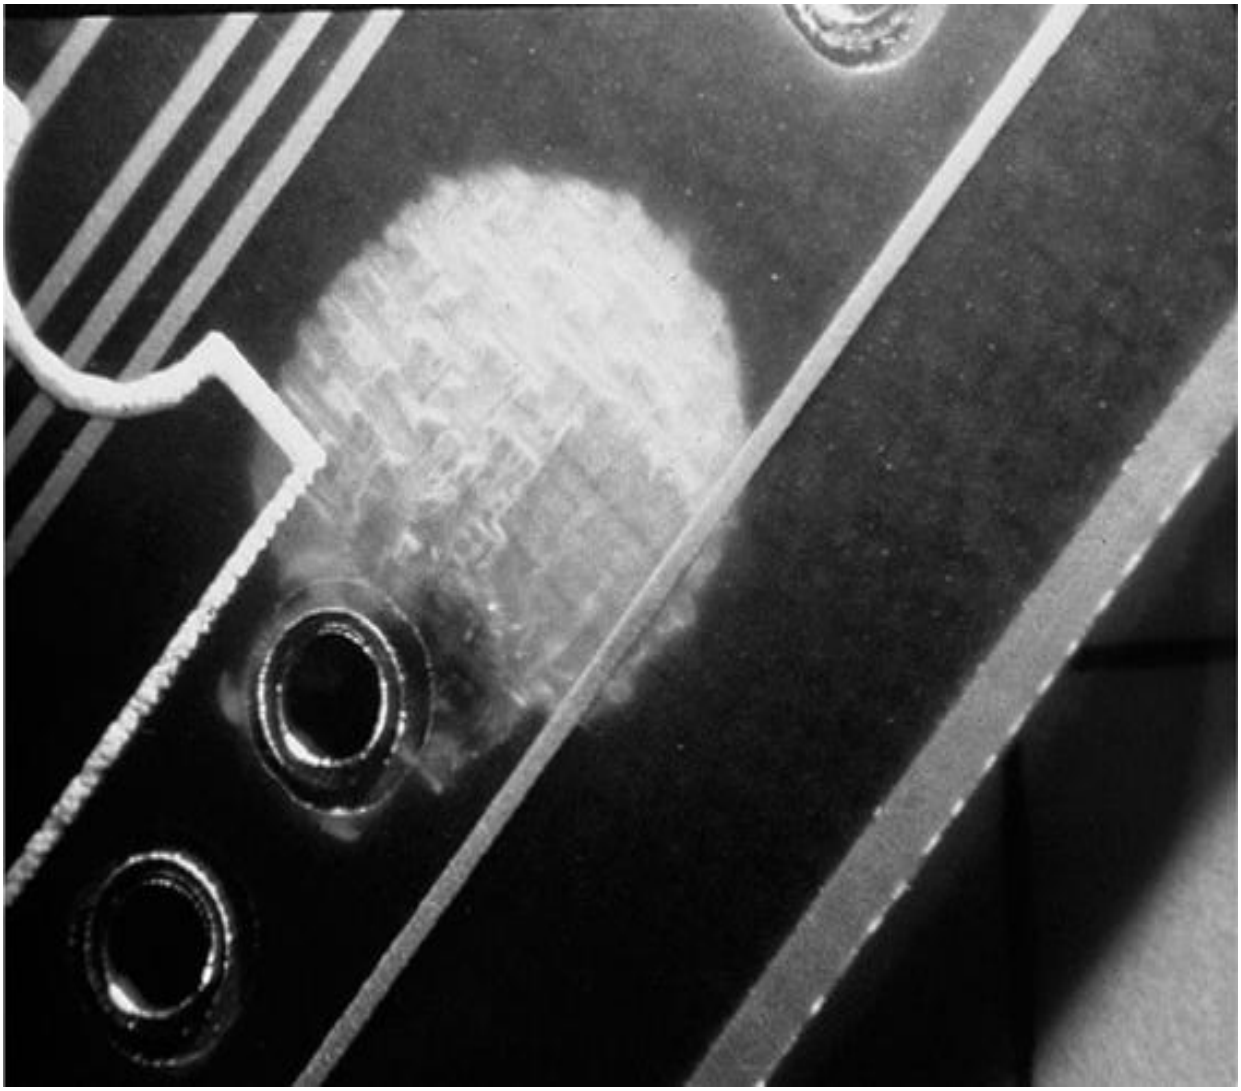

FIGURE 54.35 Example of blister in base material. *(IPC)*

54.7.1.3 Weave Exposure. Weave exposure is a surface condition of base material in which the unbroken fibers of woven glass cloth are not completely covered by resin. Weave exposure is acceptable if it does not reduce dielectric spacing below the minimum electrical clearance.

54.7.1.4 Haloing and Edge Delamination. Haloing occurs on or below the surface of the base material, appearing as a light area around holes or other machined areas. This condition is acceptable if the penetration of the haloing or edge delamination does not reduce edge spacing

more than 50 percent of that specified in the drawing or other documentation or 2.5 mm maximum.

54.7.2 PCBA Cleanliness

Board cleanliness is needed to ensure sufficient removal of contaminants that could affect functionality at present or in the future. Some contaminants can actually promote growth of undesirable substances on the PCBA that can cause shorting or corrosion that would affect the PCBA’s electrical functional integrity and dielectric properties over a period of time. These contaminants can be in the form of surface dendrites, internal conductive anodic filaments, and so on.

No visible residue from cleanable or any activated fluxes is allowed. Production operations may not be required to remove cleanable residues if qualification testing is performed that demonstrates no need for cleaning the assembly. No-clean or low-residue flux chemistries may be allowed during the soldering process. However, it is critical that the cleanliness of the elements such as the bare boards and components be specified, controlled, and closely monitored; otherwise, the contaminant build-up can far exceed allowable limits for the end item’s functional performance.

For processes utilizing potentially corrosive rosin based fluxes, simple test options to determine cleanliness such as resistance of solvent extract (ROSE) tests can be used. Other more significant tests may be required to determine the residue properties of organic residue fluxes, such as those commonly used during hot air solder leveling (HASL) of boards. The most common of these are ion chromatography tests that can characterize the residuals and their potential hazards to the product.

In the event of test failure, immediate process corrections for the cleaning process or elimination of the source of

residues must be accomplished before any additional product is assembled.

Particulate matter such as dirt, lint, dross, lead clippings, and such is not acceptable on PCBAs. Metallic areas or hardware on the PCBAs may not exhibit any crystalline white deposits, colored residues, or rusty appearance.

54.7.3 PCBA Marking Acceptability

Marking provides both product identification and traceability. It aids in assembly, in-process control, and field repairs. The methods and materials used in marking must serve the intended purposes and must be readable, durable, and compatible with the manufacturing processes as well as the end use of the product.

Fabrication and assembly engineering drawings should be the controlling documents for the locations and types of markings on PCBAs. Marking on components and fabricated parts should withstand all tests, cleaning, and assembly processes to which the item is subjected and must remain legible. Acceptability of marking is based on whether it is legible. If a marking is legible and cannot be confused with another letter or number, it is acceptable. Components and fabricated parts do not have to be installed so that reference designators are visible after installation. Missing, incomplete, or illegible characters in markings are unacceptable.

54.8 PCBA COATINGS

It should be noted that not all PCBA designs use conformal coating; however, when used, conformal coating must meet the following acceptability criteria. All PCBAs that utilize top- or bottom-layer etch (trace) runs have a solder mask over them if a solder wave or static solder bath process is used to

solder components onto the PCB. Without the solder mask, the solder would bridge between many solder wettable surfaces, causing short circuits.

54.8.1 Conformal Coating

Conformal coating is an insulating protective covering that conforms to the configuration of the objects coated when it is applied to a completed PCBA. The purpose of conformal coating is to provide a temporary barrier to environmental exposure of chemicals, humidity, and condensation. It is also a barrier from surface contact of contaminants caused by handling, and can provide physical support for components from shock and vibration. It is not, however, a hermetic seal and is eventually permeable. To be most effective, conformal coatings should be homogeneous and transparent. Most coatings will contain an ultraviolet (UV) tracer to make inspection easier through the use of a black light. The conformal coating should be properly cured and not exhibit tackiness. Defects associated with conformal coating are as follows:

- Applied where not required
- Not applied where required
- Bridging of conductors due to:
  - Mealing (adhesion)
  - Voids
  - Dewetting
  - Cracks
  - Ripples
  - Orange peel/fisheye
- Inclusions
- Discoloration

- Incompletely cured
- Wicking into connectors or mating surfaces

Conformal coating thickness requirements for five types of coatings are listed in Table 54.7. The thickness is commonly measured on a coupon that has been processed with the assembly.

TABLE 54.7 Coating Thickness

Type	Material	Thickness
AR	Acrylic Resin	0.03–0.13 mm (0.00118-0.00512 in.)
ER	Epoxy Resin	0.03–0.13 mm (0.00118-0.00512 in.)
UR	Urethane Resin	0.03–0.13 mm (0.00118-0.00512 in.)
SR	Silicone Resin	0.05–0.21 mm (0.00197-0.00827 in.)
XY	Paraxylyene Resin	0.01–0.05 mm (0.00039-0.00197 in.)

54.8.2 Solder Resist

Solder resist or solder mask is a heat-resistant film coating used to provide mechanical shielding during soldering operations. Solder resist material may be applied as a liquid or a dry film.

Solder resist would be ineffective and considered a defect when there are blisters, scratches, or voids that bridge noncommon circuits, or if the exposure has the potential to allow solder bridges. It could be considered a process indication if blisters or flaking expose bare copper.

54.9 SOLDERLESS WRAPPING OF WIRE TO POSTS (WIRE WRAP)

Many applications of wire wrap are still utilized in equipment design, and standards of acceptance should be consistent. Standards of acceptance in this area are shown in IPC-A-610 and in other standards.

54.9.1 Wrap Post

The wrap post cannot be bent or twisted before or after the wire is wrapped to the post. The wrap straightness may not exceed approximately one post diameter or thickness from its perpendicular position.

54.9.2 Wire Wrap Connection

Table 54.8 shows the number of wire wrap turns of insulated and uninsulated wire used on the wrapped connection. The connection is made using automatic or semiautomatic wire wrapping devices. For this requirement, countable turns are those turns of bare wire or insulated wire in intimate contact with the corners of the terminals starting at the first contact with a terminal corner and ending at the last contact with a terminal corner (see Fig. 54.36).

TABLE 54.8 Minimum Turns of Bare Wire

Wire Gauge	Turns
30	7
28	7
26	6
24	5
22	5
20	4
18	4

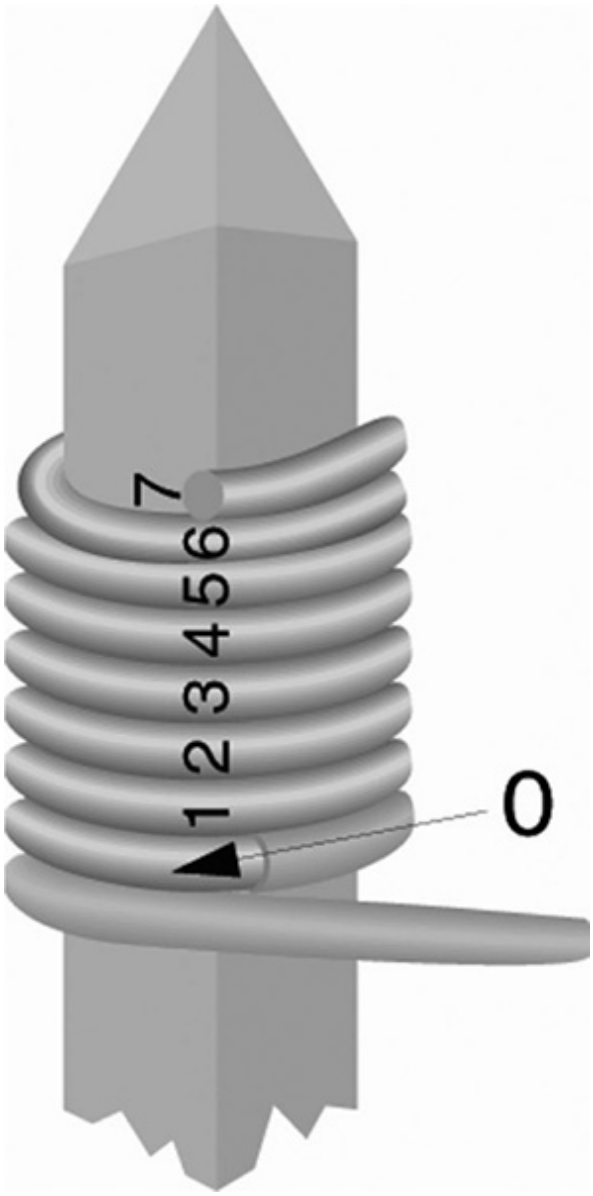

FIGURE 54.36 Solderless wrap acceptability. *(IPC)*

Maximum turns of bare and insulated wire are governed by the tooling configuration and space available on the terminal. The minimum countable turns must be as stated in Table 54.8. Electrical clearance between terminals as specified by engineering documentation must be maintained. Wire ends should in no case project to the extent that the required electrical clearance is compromised. The wire end should never project more than 0.12 in. (one wire diameter for Class 3) away from the terminal.

The wrapped conductors should be free of gaps (that is, each wrap should be in contact with the previous wrap), with turns not overlapping. The first and last one-half turns may have a space between turns, provided that the space does not exceed one diameter of the conductor wire. Excluding the first and last one-half-turns, the wrapped conductors may have a single space between them, if the opening does not exceed one-half the nominal diameter of uninsulated wire (see Fig. 54.37).

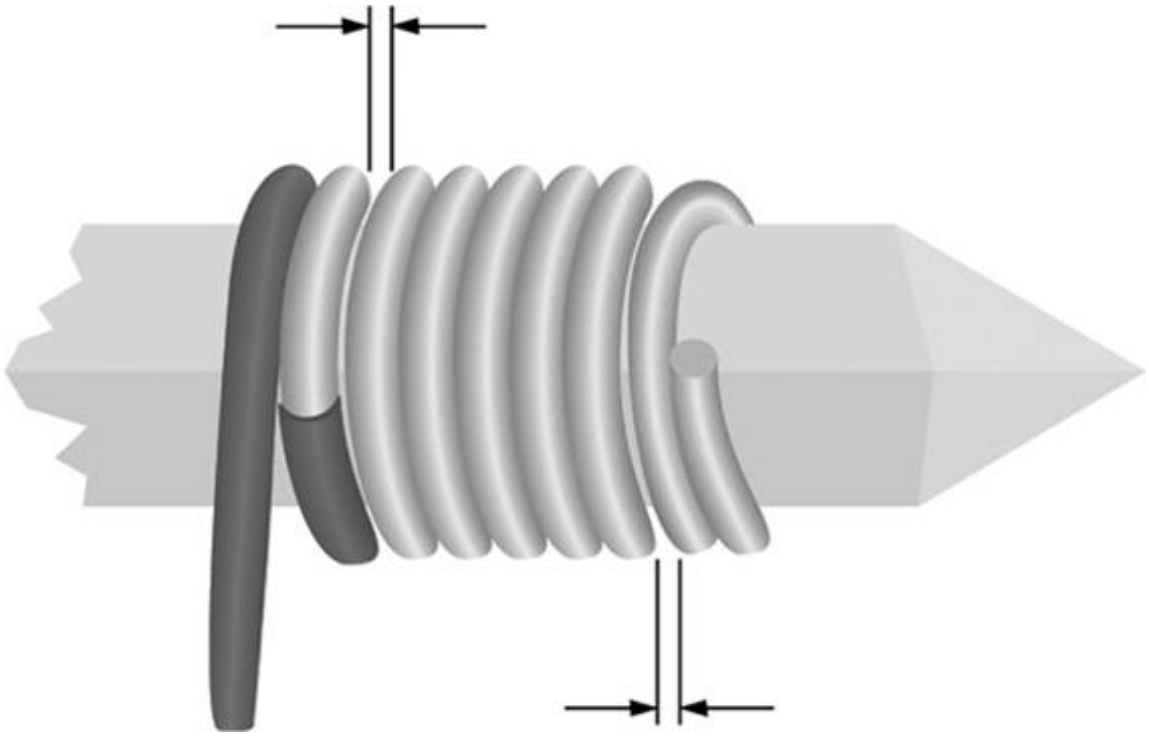

FIGURE 54.37 Solderless wrap with more than one space. Acceptability depends upon Class of product. *(IPC)*

54.9.3 Multiple Wire Wrap Spacing

Typically no more than three wires are wrapped to a single post. When more than one wrap is used on a single post, there should be visible clearance between consecutively wrapped wires. The final wire wrap turn on a post must not extend beyond the working length of the post (see Fig.

54.38). The first insulated turn of a higher-level wire wrap may overlap the last turn of uninsulated wire on a lower-level wrap by a maximum of 1 turn for Class 3.

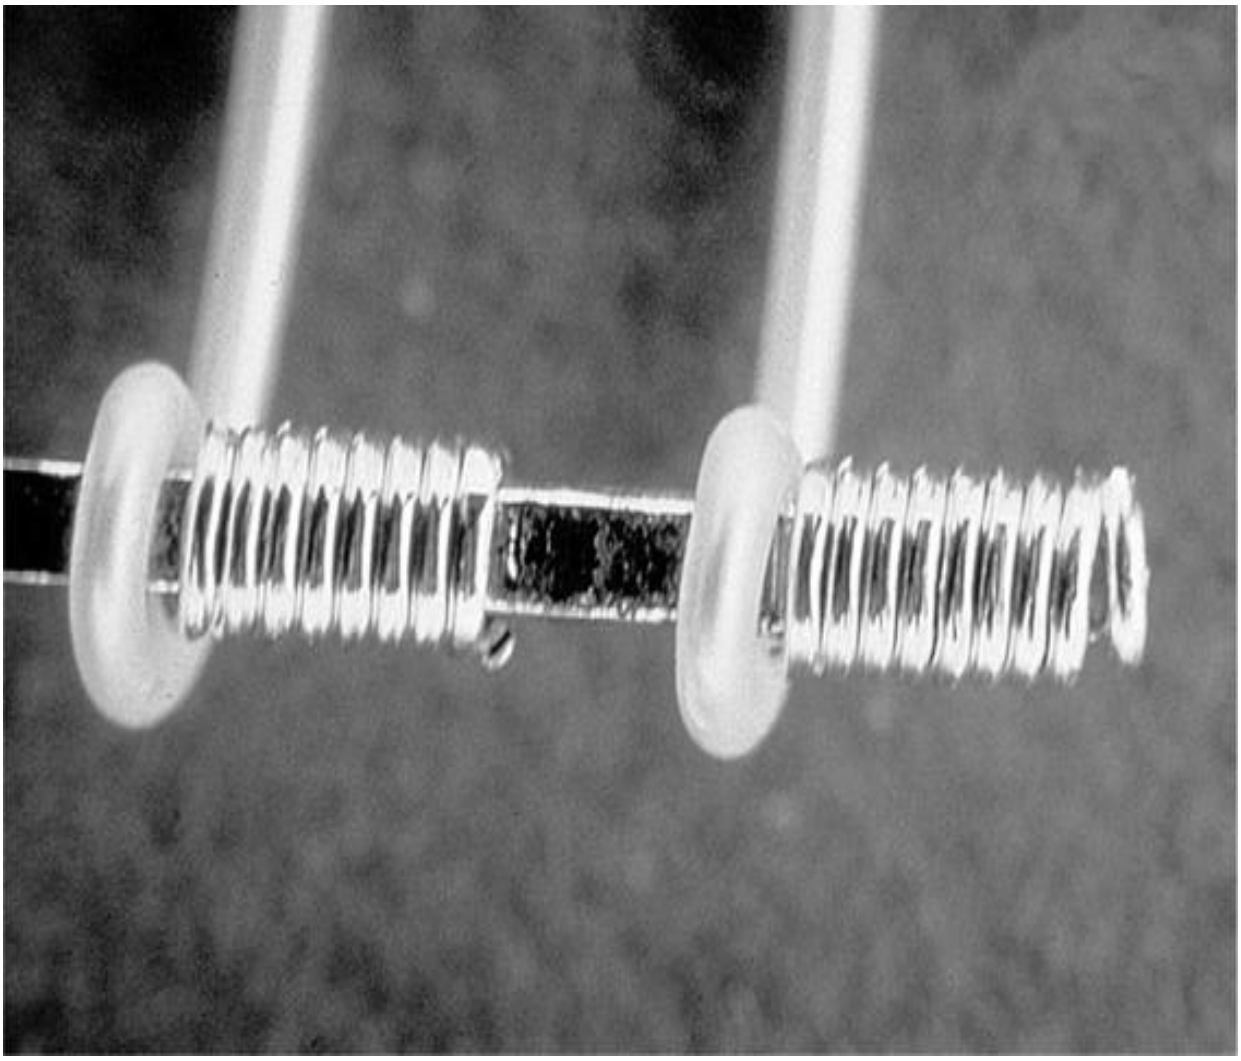

FIGURE 54.38 Multiple solderless wrap example. *(IPC)*

54.10 PCBA MODIFICATIONS

All modifications to PCBAs should be defined and detailed in approved engineering and/or methods documents. Jumper wires are considered components and are defined by

engineering documentation for routing, termination, staking, and wire type.

54.10.1 Cut Traces

Trace cuts should be at least 0.030 in. wide, with all loose material removed. They should also be sealed with an approved sealant to prevent absorption of moisture.

Care should be taken when removing etch from PCBs to prevent damaging the laminate material.

54.10.2 Lifted Pins

Lifted pins should be cut short enough to prevent the possibility of being shorted to the pad from which they were lifted should they be pushed back down. If the component hole from which the pad was lifted does not contain a jumper wire, it should be filled with solder.

54.10.3 Jumper Wires

Jumper wires may be used on all classes of equipment electronic assemblies and in thick-film hybrid technology. The wire may be terminated in PTHs, on terminal standoffs, on circuit lands, or on component leads. It should be noted for Class 3 equipment that a wire cannot be placed into the same PTH with a component lead.

Recommended jumper wire is solid, insulated, plated copper wire. It should be the smallest wire diameter that can reliably carry the required current, and the insulation should be capable of withstanding soldering temperatures.

Jumper wires should be routed in the shortest x-y route possible (see Fig. 54.39). Wire routing must be documented

for each part number. Assemblies having the same part number must be routed in the same pattern.

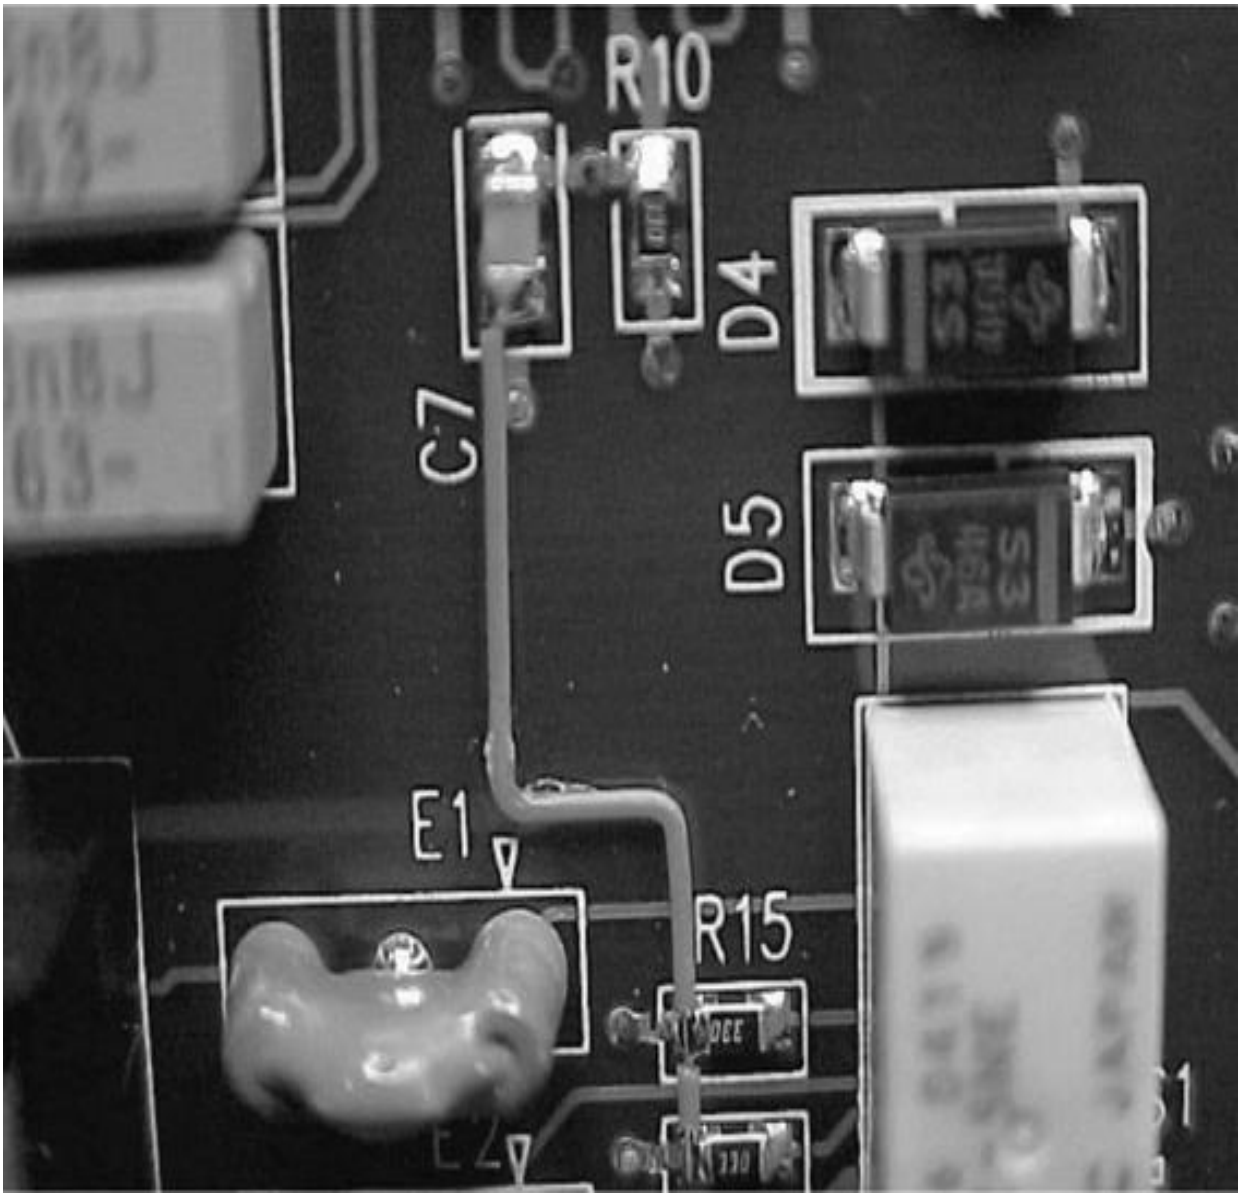

FIGURE 54.39 Example of X-Y routing of jumper wires. *(IPC)*

When jumper wires are used on the primary side (component side) of the PCBA, no wire is to pass over or under any components for Class 2 or 3. The wire may pass over lands, provided the wire can be moved away from the land for component replacement. To prevent damage to the

wire from excessive heat, care must be taken to avoid running wires near heatsinks or components that generate high temperatures.

When jumper wires are used on the secondary side of the PCBA, the jumper wire should not pass through component footprints unless the layout of the assembly prohibits routing in other areas. If this condition occurs, it should be considered a process indicator. There is an exception to this is rule for edge connectors on the PCBA. Jumper wires should not pass over test points or vias used as a test point.

Jumper wires should be staked to the base material with an approved adhesive or tape dots or strips intended for this purpose. If adhesives are used, they must be fully cured as part of the completed PCBA. The wire should be spot-bonded along its route and must not be applied to lands, pads, or components. The interval of staking must be defined in the applicable engineering documentation, but the wire must be staked at all changes in direction of the wire. No jumper wires may be staked to components that are socketed or any moving part. Jumper wires must be staked or taut enough to prevent the wire from rising above the height of adjacent components. No more than two jumper wires may be stacked on a given route.

When a jumper wire is attached to leads on the secondary side of the PCBA or to axial components on the primary side of the PCBA, it must form a full 180 to 360° loop around the component lead. When a jumper wire is soldered to other component package styles, the wire should be lap-soldered to the component lead.

Jumper wires may be installed into a PTH with another component lead for Class 1 and 2 equipment; however, this is unacceptable for Class 3 equipment. Jumper wires may also be installed into via holes (see Fig. 54.40).

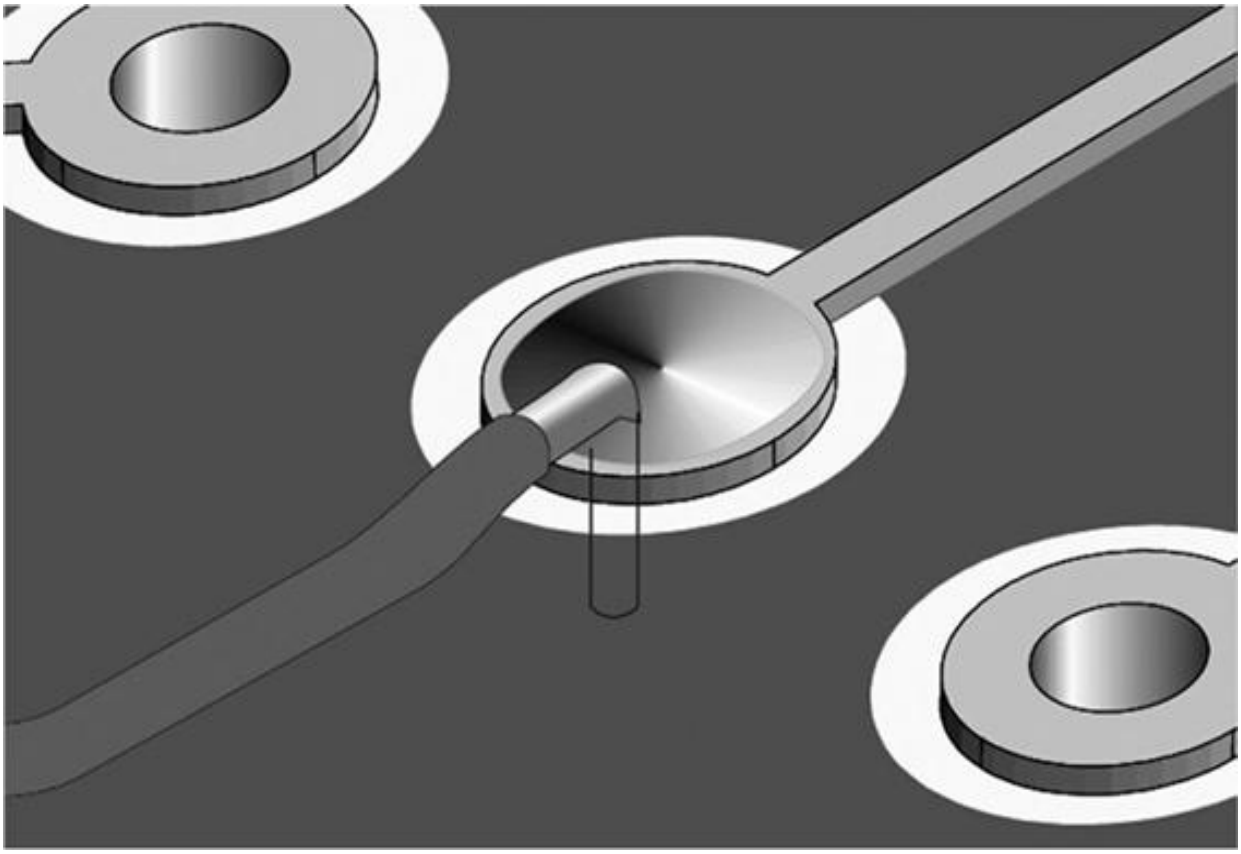

FIGURE 54.40a Example of jumper wire connected to plated through-holes (IPC).

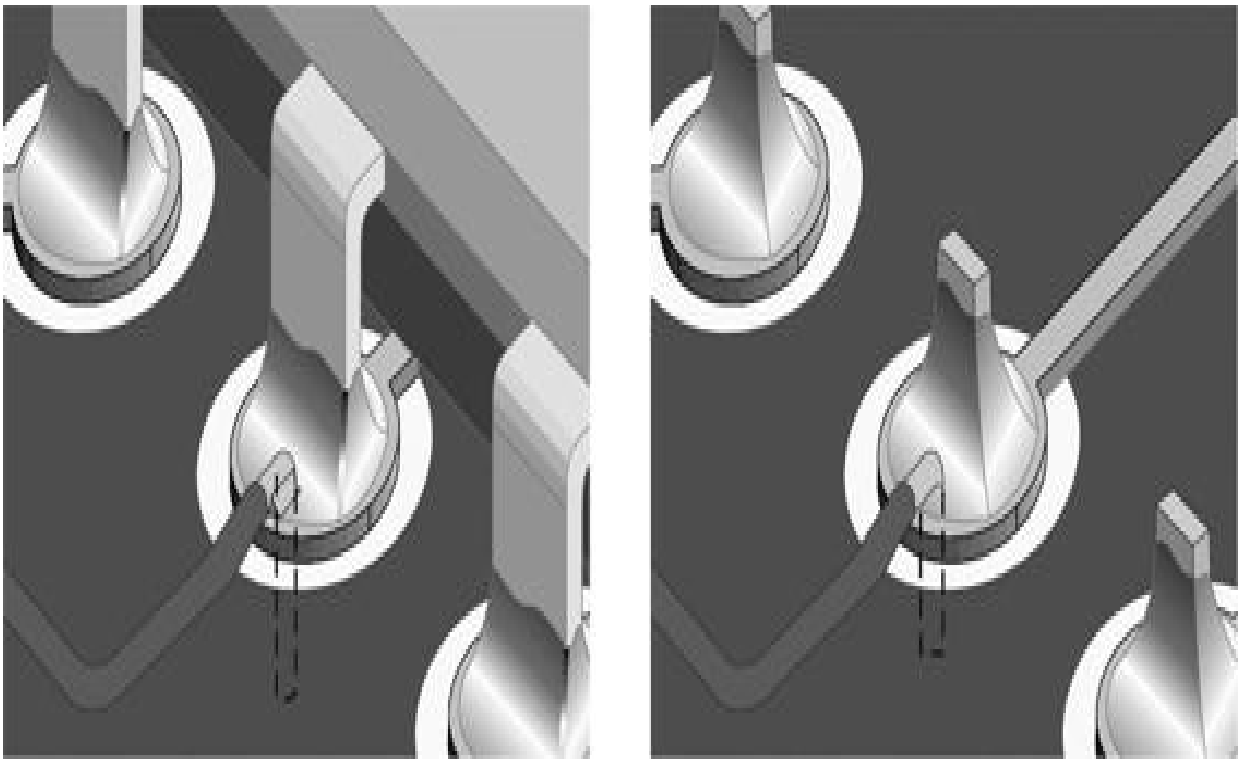

FIGURE 54.40b Example of wire connected to a via hole with a lead installed.

CHAPTER 55
ASSSEMBLY INSPECTION

Stacy Kalisz Johnson
Agilent Technologies, Gilbert, Arizona

Stig Oresjo
Agilent Technologies, Loveland, Colorado

55.1 INTRODUCTION

This chapter covers why manufacturers inspect printed circuit assemblies, how they have implemented and enhanced visual inspection, what automated inspection systems they are using, and how they have implemented these automated systems. The scope of this chapter includes only inspection of printed circuit assemblies during the assembly process, as typically shown in Fig. 55.1. Thus, it includes inspection of solder paste after the paste printing process step, components after the component placement process step, and solder joints after the solder reflow process step. Not included, however, is incoming inspection of components and the bare printed circuit board (PCB). The focus of this chapter is on production use of inspection, not

the collection of measurements during process development in a research and development (R&D) environment.

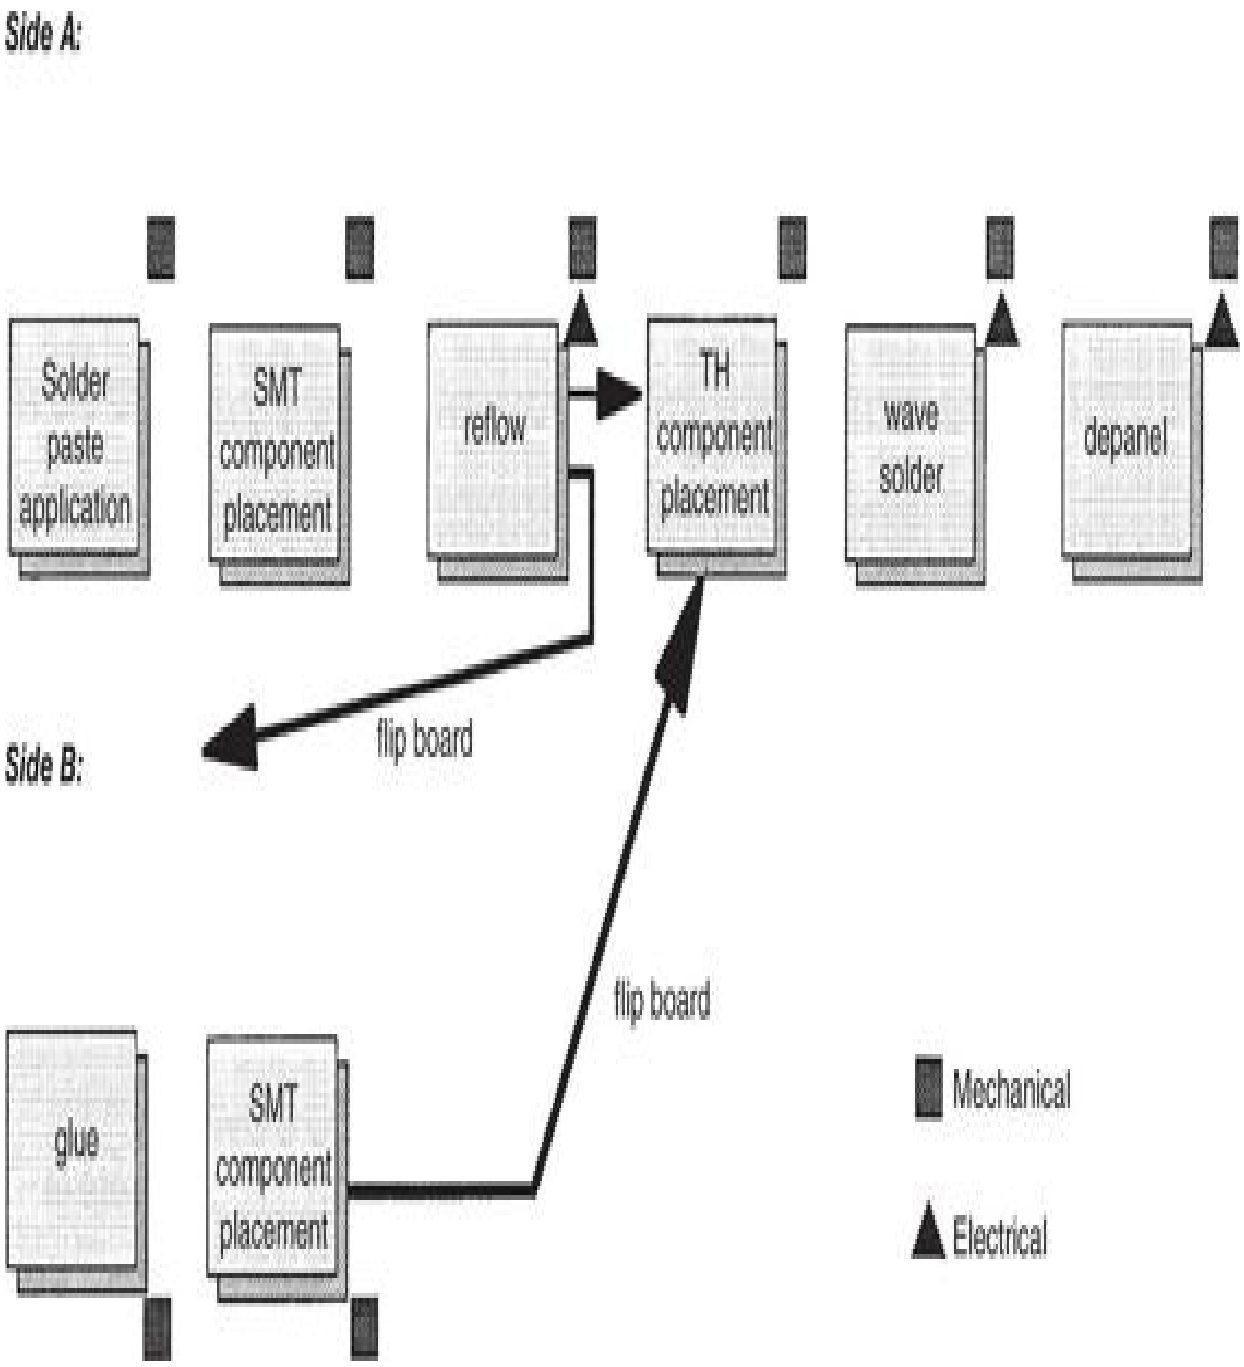

FIGURE 55.1 Generic manufacturing process for surface-mount technology printed circuit assemblies, including the possible locations within the process for inspection or testing of mechanical or structural attributes and electrical characteristics of an assembly.

55.1.1 Visual Inspection

Manufacturers of printed circuit assemblies have always visually inspected their boards at various points in the assembly process. There are a variety of reasons for visual inspection of assemblies, including eliminating obvious process defects quickly and meeting military specifications. With the advent and growth of surface-mount technology (SMT), visual inspection of printed circuit assemblies has also grown in importance and prevalence. SMT solder joints must carry a much bigger burden for mechanical or structural reliability than do plated-through-hole (PTH) solder joints. The pin-in-through-hole solder joint carries much of the mechanical burden, helping to keep the component attached to the printed circuit board. However, with SMT solder joints, it is often only the solder that keeps the component attached to the board. In some cases, only visual inspection could judge the mechanical reliability of an SMT solder joint.

As SMT geometries have continued to shrink and solder joints have become denser on printed circuit boards, visual inspection has become more difficult and thus its results have become less consistent and reliable. In addition, components such as pin grid arrays (PGAs) or ball grid arrays (BGAs) completely hide their solder joints from view, which makes visual inspection not possible at all for those joints. As Fig. 55.2 indicates, achieving a high assembly process yield is more important as the number of solder joints per assembly increases.

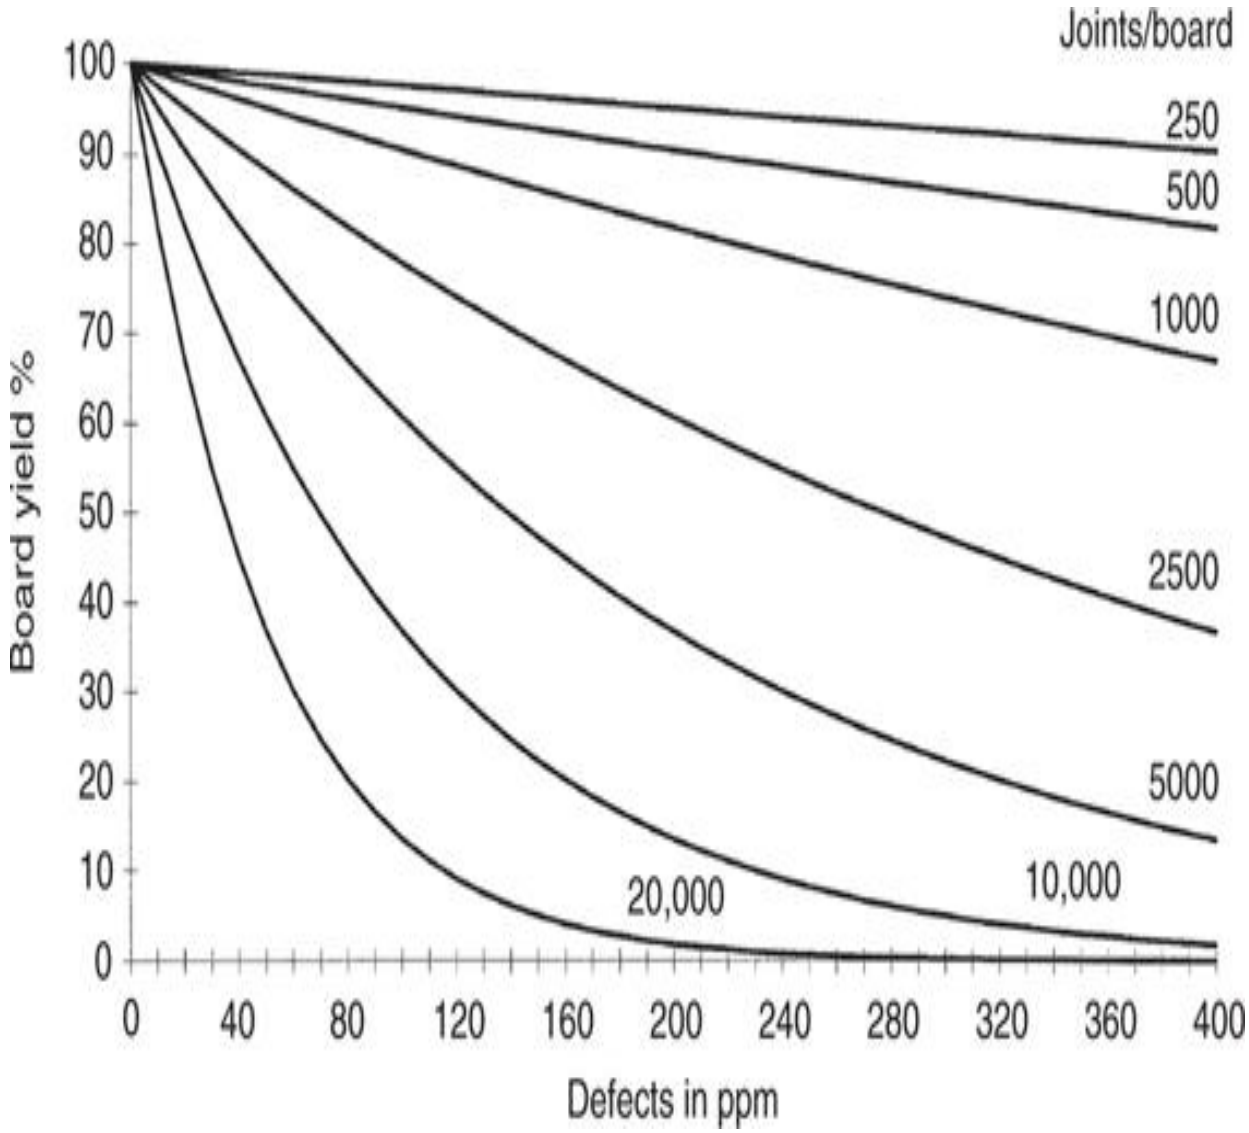

FIGURE 55.2 Printed circuit board yield decreases dramatically with increases in the number of solder joints per assembly if the defect rate per solder joint remains constant. For instance, at a 40 defects per million opportunities (DPMO) defect rate, the yield drops from 96 percent at 1,000 joints per assembly to 45 percent at 20,000 joints.

55.1.2 Automated Inspection

Inspection is an important source of process information without which high yields are difficult to obtain. Consequently, manufacturers have employed the following

range of techniques either simply to enhance visual inspection or automate inspection fully:

- Microscopes, mono- and stereoscopic, with magnification from 4× to 10×
- Real-time video images created using simple light, x-rays, thermal imaging, or acoustics
- Fully automated inspection systems using light, laser, or x-ray imaging

The automation of inspection has evolved into systems that resemble the automated test equipment used to make electrical measurements and find electrical defects (faults). These automated inspection systems acquire real-time images, process the images to find and measure features within the image, and make accept/reject decisions based on this image processing. Additionally, they provide data that can be used for long-term statistical process analysis. Thus these automated systems remove the human—and human judgment—from the inspection process altogether.

55.2 DEFINITION OF DEFECTS, FAULTS, PROCESS INDICATORS, AND POTENTIAL DEFECTS

Faults, defects, process indicators, and *potential defects* are terms that are important when discussing test and inspection, so this section will define and explain them:

- *A* fault *is a manifestation of a defect* An example is a digital device output pin that does not toggle correctly. For simplicity, think about a two-input OR-gate whose output is stuck high. This is a fault and is a manifestation of a defect. The causing defect can be any one of several,

including a defective component, an incorrectly placed component, an open input pin, or an open output pin. The fault class is a subset of the defect class. Electrical tests such as in-circuit test (ICT), boundary-scan, built-in-self-test (BIST), functional test (FT), and system test mainly detect faults.

- *A* defect *is, at the end of the manufacturing process, an unacceptable deviation from a norm* There may be defects that do not show up as faults. Examples are insufficient solder, a misaligned component, a missing bypass capacitor, and an open power pin. Inspection systems such as automated optical inspection (AOI) and automated x-ray inspection (AXI) detect many of the defects and also some of the same faults as electrical test. The definition includes the phrase “at the end of the manufacturing process,” which is important when compared with “potential defect.”

All defects, which also include the faults, need to be corrected before the product is shipped, if high quality standards are to be followed.

- *A* process indicator *is, at the end of the manufacturing process, an acceptable deviation from a norm* Good examples are insufficient solder or misaligned components. The insufficient solder may not be so lacking that it requires a repair action. However, if many of these conditions exist, a process improvement action may be required.
- *A* potential defect *is, in the manufacturing process, a deviation from a norm, that may or may not be a defect at the end of the manufacturing process* This category needs to be understood. An example is a pre-reflow misaligned chip component. This component may or may not self-align in the reflow oven. Another example is an insufficient

paste volume that may not end up as a defective solder joint at the end of the manufacturing process.

Test and inspection engineers at the end of the line are mainly interested in finding faults and defects. Process engineers responsible for improving the manufacturing process are mainly interested in potential defects, process indicators, and systematic defects. Systematic defects are typically defects that occur on a larger number of boards and are due to some systematic problem, such as a bent nozzle on a pick-and-place machine, soldering issues with one type of component, or a design for manufacturing (DFM) issue.

It is important to realize that electrical test at the end of the manufacturing line only finds faults. It is therefore important to complement the test strategy with steps that find all defects. Finding all defects is critical if shipping high-quality, reliable products is a priority. Identifying potential defects and process indicators can also help in adjusting the manufacturing process to result in lower defect levels, higher yields, and lower cost. Inspection is therefore a very important complement to electrical test.

55.3 REASONS FOR INSPECTION

Manufacturers inspect printed circuit assemblies during production for a variety of reasons. Most of these reasons fall into the following categories:

- Improvement of process defect coverage
- Improvement in ability to meet customer specifications
- Detection of process defects as quickly as possible after they occur
- Ability to decrease process defect rates through statistical process control (SPC)

55.3.1 Process Defect Coverage

The goal of higher defect coverage is to prevent any defective printed circuit assemblies from reaching assembly of the board and making it into the final product, whether final assembly is at the same site or at a separate customer site. Figure 55.3 shows a typical spectrum of SMT process defects. Some of these defects, such as misaligned solder joints and solder balls, can be discovered only by inspection, not by electrical, functional, in-circuit, or boundary-scan test. For instance, marginal solder joints are those that pass electrical tests just after assembly completion, but eventually fail because of inferior mechanical strength. Insufficient solder and components partially misaligned with printed circuit pads are the two most common causes of low mechanical strength.

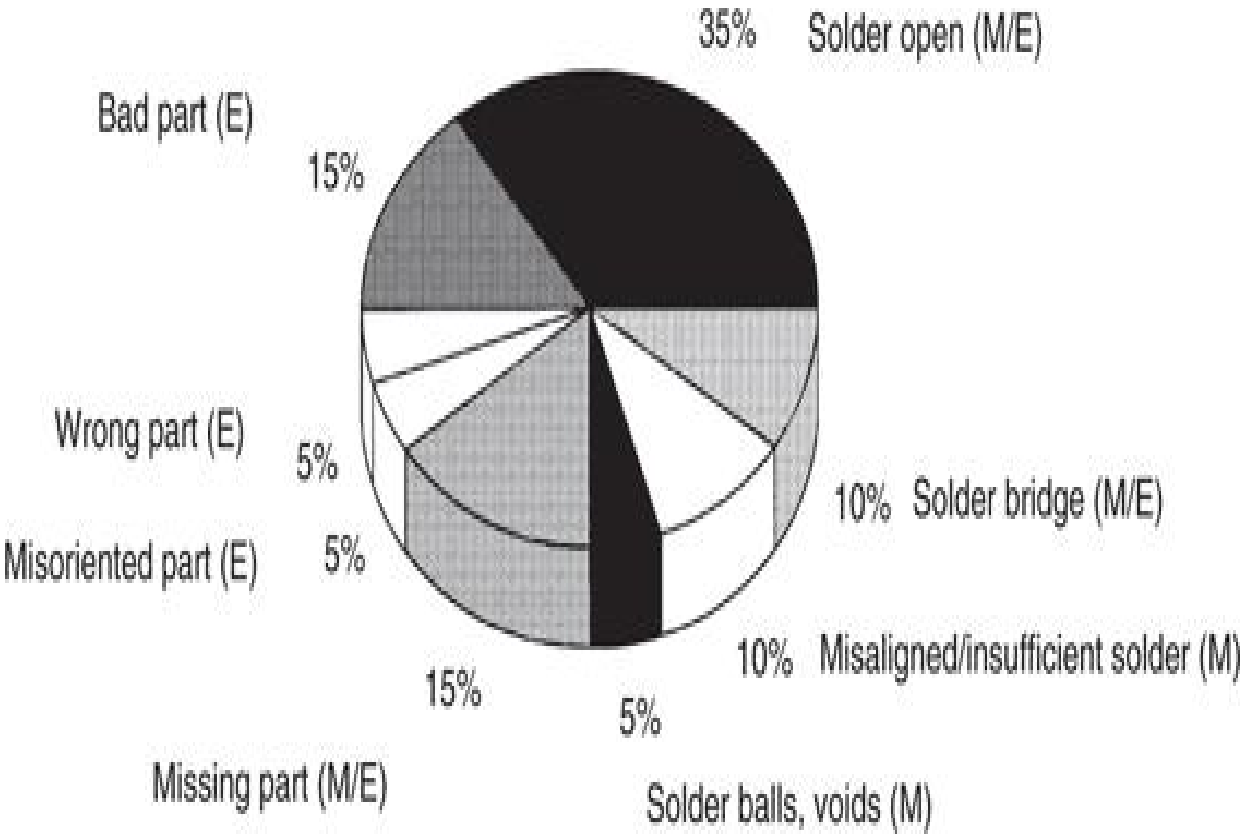

FIGURE 55.3 Typical process defect spectrum for surface-mount assemblies. Process defects marked "*E*" can be detected by electrical tests, those marked "*M*" can be detected by mechanical or structural inspection or testing, and those marked by "*E*" and "*M*" can be detected by either method.

Voids in solder joints, solder balls away from solder joints, and "cold" or dull solder are other examples of defects that can be found only by some kind of inspection.

55.3.2 Customer Specifications

Many printed circuit assembly workmanship specifications—including MIL-STD-2000A, IPC/EIA J-STD-001C, and, more recently, IPC-A-610D—require inspection of solder joints to ensure conformance to these specifications. For instance, MIL-STD-2000A prescribes, for all defense and aerospace government contractors, the attributes of solder joints to be inspected and describes the conditions that result in nonconformance. Most commercial customers of contract manufacturers also have very specific solder joint specifications that require some type of inspection of printed circuit assemblies. Although process control is theoretically preferred over 100 percent inspection, practically speaking, a majority of printed circuit production lines include some kind of inspection to ensure conformance to specifications. As the inspection speeds of the automated inspection systems have improved in recent years, this has become even more prevalent. It is likely that this trend will continue in light of the continued usage of finer pitch devices and the dawn of material challenges, such as lead-free implementation.

55.3.3 Quick Defect Detection and Correction

Quick detection of process shifts or defects can lower rework costs.

55.3.3.1 Preventing Defects. If a particular process step has drifted out of its control limits or specification limits, discovering this fact as soon as possible will prevent more defects from occurring. If the problem is found quickly enough and corrected immediately, perhaps no actual defects will occur.

55.3.3.2 Lowering Rework Costs. Defects found earlier in the process are often easier to repair. For instance, if a defect in solder paste deposition is found before a component has been placed in the paste, it is fairly inexpensive to wipe the solder paste off and start over. If this same defect is found after the solder is reflowed, the solder joint itself will have to be touched up, a more difficult and expensive rework step. The same is true for repairing component placement defects before the solder is reflowed, particularly for missing or misaligned components. Additionally, when organic solderability preservative (OSP) boards are being utilized for lead-free soldering, for example, they cannot be reworked as easily. Using process control and defect prevention can prevent a large number of non-reworkable boards in this case.

55.3.3.3 Making Defect Diagnosis Easier. Defects found earlier in the assembly process are often more easily diagnosed, shortening the overall repair time. An example is the inspection of solder joints. Inspection of solder joints detects defects specific to the solder joints and quickly determines each defect’s exact location and characteristic. Waiting until a later electrical test stage could make diagnosis more difficult because at that point there could be several causes of the defect, such as a defective component

and defects in other connections, in addition to the actual defective solder joint.

55.3.4 Statistical Process Control

SPC requires reliable data that can be analyzed either in real time or historically. Visual inspection collects defect data, such as the number of solder joint defects per assembly right after the solder reflow process (either reflow or wave soldering). Some manual and automated inspection techniques also take quantitative measurements of key assembly parameters, such as solder paste volume or solder joint fillet height. To the extent that these data are repeatable, manufacturers use defect data or measurements to characterize the amount of process variation from assembly to assembly or from solder joint to solder joint. When the amount of variation starts to drift outside its normal range or outside its control limits, manufacturers can assess the assembly process and monitor or choose to take action until the process is adjusted to eliminate this drift. Historical analysis of the defect or measurement data also helps discover the cause of process variation. Eliminating the sources of process variation reduces the process defect rate, thus creating savings in rework costs and increasing product reliability. As shown in Fig. 55.4, various charts to display available data from the automated inspection can be made available for corrective action and process control.

55.4 LEAD-FREE IMPACT ON INSPECTION

Other chapters of this book have covered the lead-free process, but this section covers the lead-free process from an inspection point of view. In general, the lead-free process is a less forgiving one because the wetting forces for lead-free alloys are not as strong as for tin-lead, which means that defect levels are likely to increase and the need for inspection for process control and defect containment will increase. The figures illustrate wetting issues of the lead-free process. Figures 55.5 and 55.6 show x-ray close-ups of two gull-wing joints on the same type of quad flat pack (QFP) device.

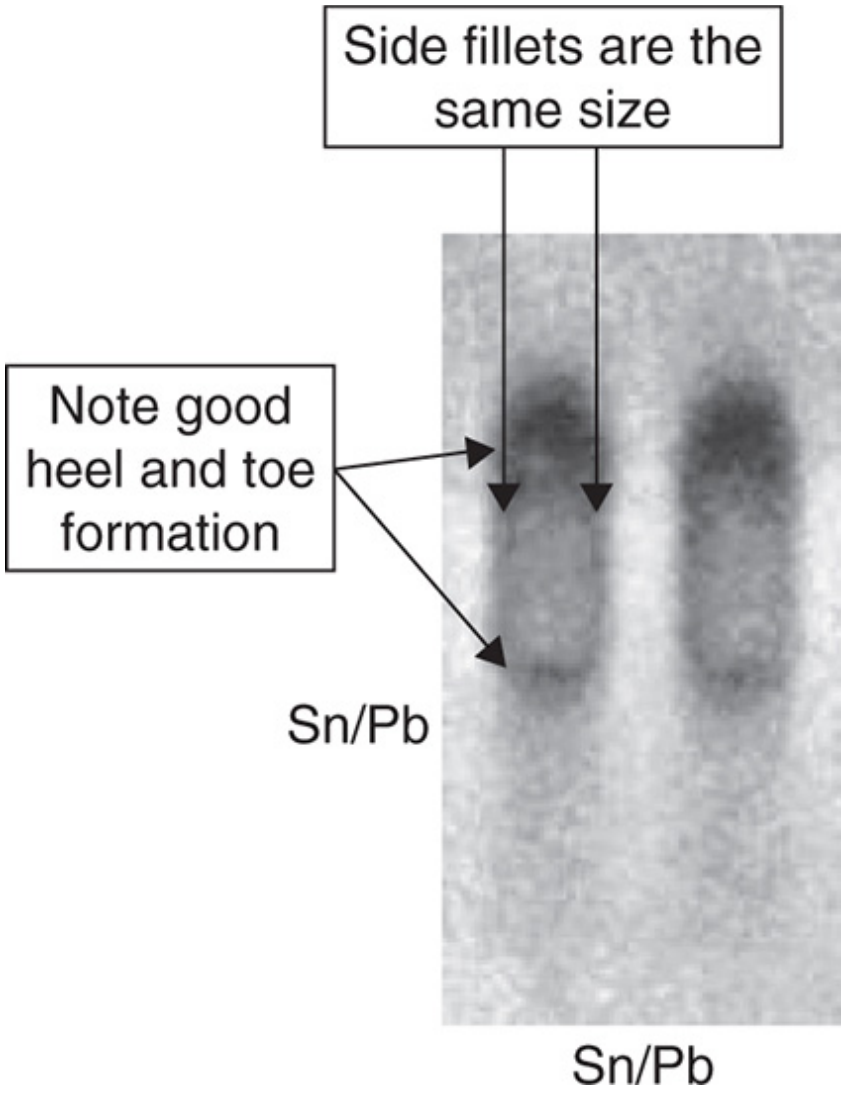

FIGURE 55.5 An x-ray image of a tin-lead example.

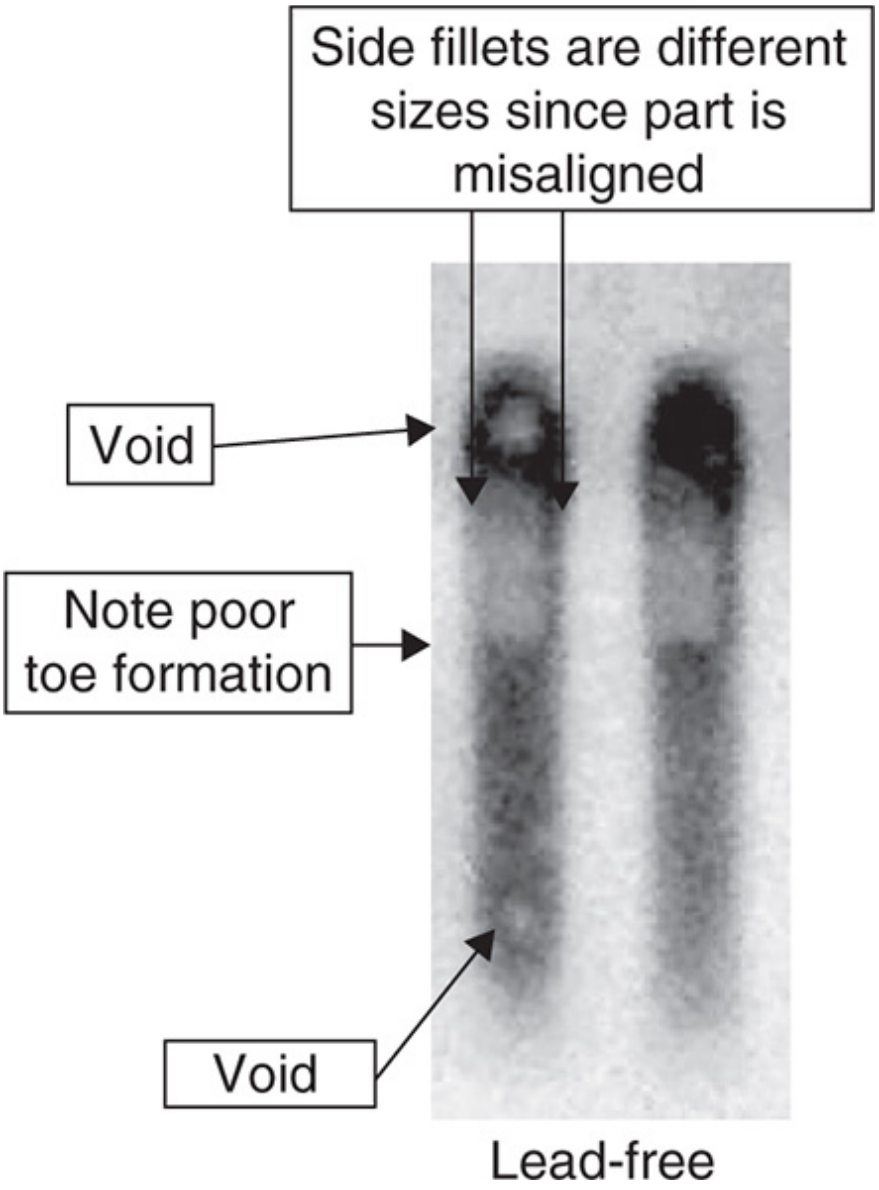

FIGURE 55.6 An x-ray image of a lead-free example.

A key issue for manufacturers is the lead-free alloy melting point of 217°C, higher than the 183°C for lead alloys. The higher melting point will have significant impact on manufacturing processes and potentially on component reliability.

During the transition to a lead-free process, it is important to understand all of the materials in use, as mixing lead-free and traditional tin-lead components will create many issues during the transition to a lead-free process. Ideally, all lead-

free components and materials will be utilized, but this is not always possible.

Figure 55.5 is an x-ray image of a tin-lead example. A good heel formation and toe formation can be seen. The side fillets are approximately the same, indicating that the component pins are centered on the pad. Note also that very little solder appears on the pad below the toe in the photo; all solder is around the component pins.

Figure 55.6 is an x-ray image of a lead-free example and reveals a couple of wetting issues. Solder is over the full pad. The pad sizes on both boards (Figs. 55.5 and 55.6) are approximately the same. Also, note that the side fillet to the right is stronger than to the left, indicating that the component is misaligned on the pad. The toe fillet is insignificant. The heel fillet has formed correctly; a void can be seen in one of them. A void is also visible on the same pin further down on the pad.

During the transition to a lead-free process, expect to see many of these types of defects. Defect levels are expected to increase. The following types of defects are typically noticeable during lead-free transitions: opens, bridges, misalignment, tombstones, and voids. Because of the higher reflow temperatures, component defects are also expected to increase. Large variations in defect levels should be expected. For some board types, small increases or no increase will be seen, whereas for others a significant (more than 10 times) increase in DPMO values will be seen. These defect levels will vary from one manufacturing site to another.

Inspection and especially automated inspection will be a significant help in addressing the tighter process window acceptable for a lead-free process. For process control, pre-reflow inspection will provide the biggest benefit. The obvious benefit is that solder paste inspection (SPI) and pre-reflow automated optical inspection (AOI) systems provide early defect and potential defect detection and prevention

specifically by identifying the defects that are expected to increase with the use of lead-free solder (opens, bridges, and so on, as previously mentioned in this chapter). An additional benefit—and perhaps the most valuable one—is the insight that the process engineer can gain by evaluating the results from SPI and AOI systems as lead-free materials are adopted. By integrating SPI and AOI systems in the manufacturing process as they move to lead-free materials, and then using the data for process optimization, the manufacturer can eliminate most of the process difficulties that a lead-free process creates. This implementation will in turn allow users to bring lead-free lines up to speed more quickly and efficiently, saving on labor, materials waste, and so on.

After reflow, the main objective is to identify defects so that repair action can take place. For this manual visual inspection, AOI post-reflow, or automated x-ray inspection, can be used. Even with good process control, defect levels are likely to increase, especially for higher-complexity boards. If defect levels are higher, then a good inspection strategy becomes more valuable.

55.5 MINIATURIZATION AND HIGHER COMPLEXITY

Printed circuit board real estate continues to be coveted. Boards are getting smaller and smaller as more and more capabilities are built on them. To keep up with this trend, complex packages and devices and miniature devices are cropping up. Many would argue that a 0402 chip component is small, but “small” becomes subjective when you consider 0201s and 01005s. The 01005 component’s sizes typically range from 0.10 mm (0.004 in.) × 0.304 mm (0.012 in.) to 0.20 mm (0.008 in.) × 0.40 mm (0.016 in.), depending on the supplier. Note that the 0201 typical is 0.60 mm (0.0236

in.) × 0.30 mm (0.0118 in.), thus it's quite a jump. With devices on this size order, the design considerations are large and the propensity for defects is higher. Inspection must catch the defects, but at these sizes, approaching the eye of a needle, it is not practical to conduct inspections visually, and thus such automated test and inspection become paramount. Automated test and inspection continues to spur the development of camera and algorithm technology to keep up with the throughput, coverage, and size requirements demanded by the industry. Miniaturization in itself is quite a driver for these technologies. Add this to the material changes that are going on with materials changes such as lead-free materials, and the need for automated test and inspection only increases. AOI systems including three-dimensional (3-D) and two-dimensional (2-D) solder paste and pre- and post-reflow component inspection are typically lead-free-ready, as are x-ray test systems, with a few minor programming updates.

The advancement of the miniaturization movement also drives technologies such as multichip modules (MCM), system-in-a-package (SIP), and so on. These devices or boards, depending on how one refers to them, have many interconnects among themselves in addition to the requirements that they pose when the entire MCM, SIP, etc., is adhered to a printed circuit board. The number of hidden joints increases, the types of hidden joints increase, and the complexity of the attachment to the SMT board in general increases. All of these are contributors to the ongoing need for increase defect containment and defect coverage that only automated inspection and testing bring.

55.6 VISUAL INSPECTION

Visual inspection is the visual comparison by a human of some attribute of the printed circuit assembly with specified standards that describe the acceptable range for that attribute. The inspector normally picks up the printed circuit assembly or places it under a microscope and carefully observes particular attributes, such as the condition or bend radius of component leads or the wetting of solder joints to a lead. Visual inspection always involves human judgment in comparing the attribute to its conditions of conformance to standards.

55.6.1 General Inspection Issues

As Fig. 55.1 indicates, visual inspection can occur after each of the several printed circuit assembly process steps. Visual inspection often has different purposes, depending on where in the assembly process it occurs. These purposes fall into the following major categories:

- Quick detection of an assembly process step that is not operating within its normal range
- Detection of process defects as specified by the customer or industry or internal standards

55.6.2 Solder Joint Inspection Issues

Visual inspection after the reflow and wave-soldering process steps can also be just a quick scan for obvious defects to detect a process condition outside of control limits. In this case, the operator visually inspects for solder bridges, large solder balls or solder splashes, lifted leads, and a number of other improper conditions. Often, however, visual inspection after the soldering process steps is aimed at finding solder joints that do not meet specifications.

Visual inspection of solder joints against specification can cover 100 percent of the visual solder joints on an assembly. Inspecting samples of solder joints in conjunction with a documented process control system is also done. Inspecting for this purpose can be a lengthy process, taking as long as a half-hour for assemblies with 4,000 solder joints being measured against military specifications. As a rule of thumb, this kind of visual inspection has a throughput of about 5 joints per sec. compared to automated inspection techniques, which have capabilities of over 100 joints per sec. Thus, inspection of solder joints against specifications normally requires visual inspectors dedicated to this function with no other responsibilities. Visual inspection may still provide a low-cost alternative to automated inspection in some low-cost regions, which is one major factor contributing to its continued usage.

The visual inspector must be very familiar with the specifications of the attributes for each solder joint type. Each solder joint can have as many as eight different criteria for defects such as insufficient solder, misalignment, etc. Each assembly typically has more than six different solder joint types such as BGAs and QFPs, corresponding to different component packages with individual requirements for each. As an example, Fig. 55.7 shows the specification attributes for one component type (rectangular passive chips). Table 55.1 gives the corresponding conformance criteria for each attribute for this component type. More importantly, the visual inspector must be highly trained to make an accurate judgment of conditions on the borderline between good and bad. For instance, accurately determining whether a fillet height is one-quarter of the way up a component side that is only 0.05 mm high to begin with takes a lot of practice. Visual inspectors typically do not use any tools to help make these judgments. Rulers or calipers are very difficult or impossible to use to measure solder joint dimensions or thicknesses. Using reticules in microscopes in

conjunction with coordinate-measuring machines is possible, but is usually much too time consuming to be done on a regular basis.

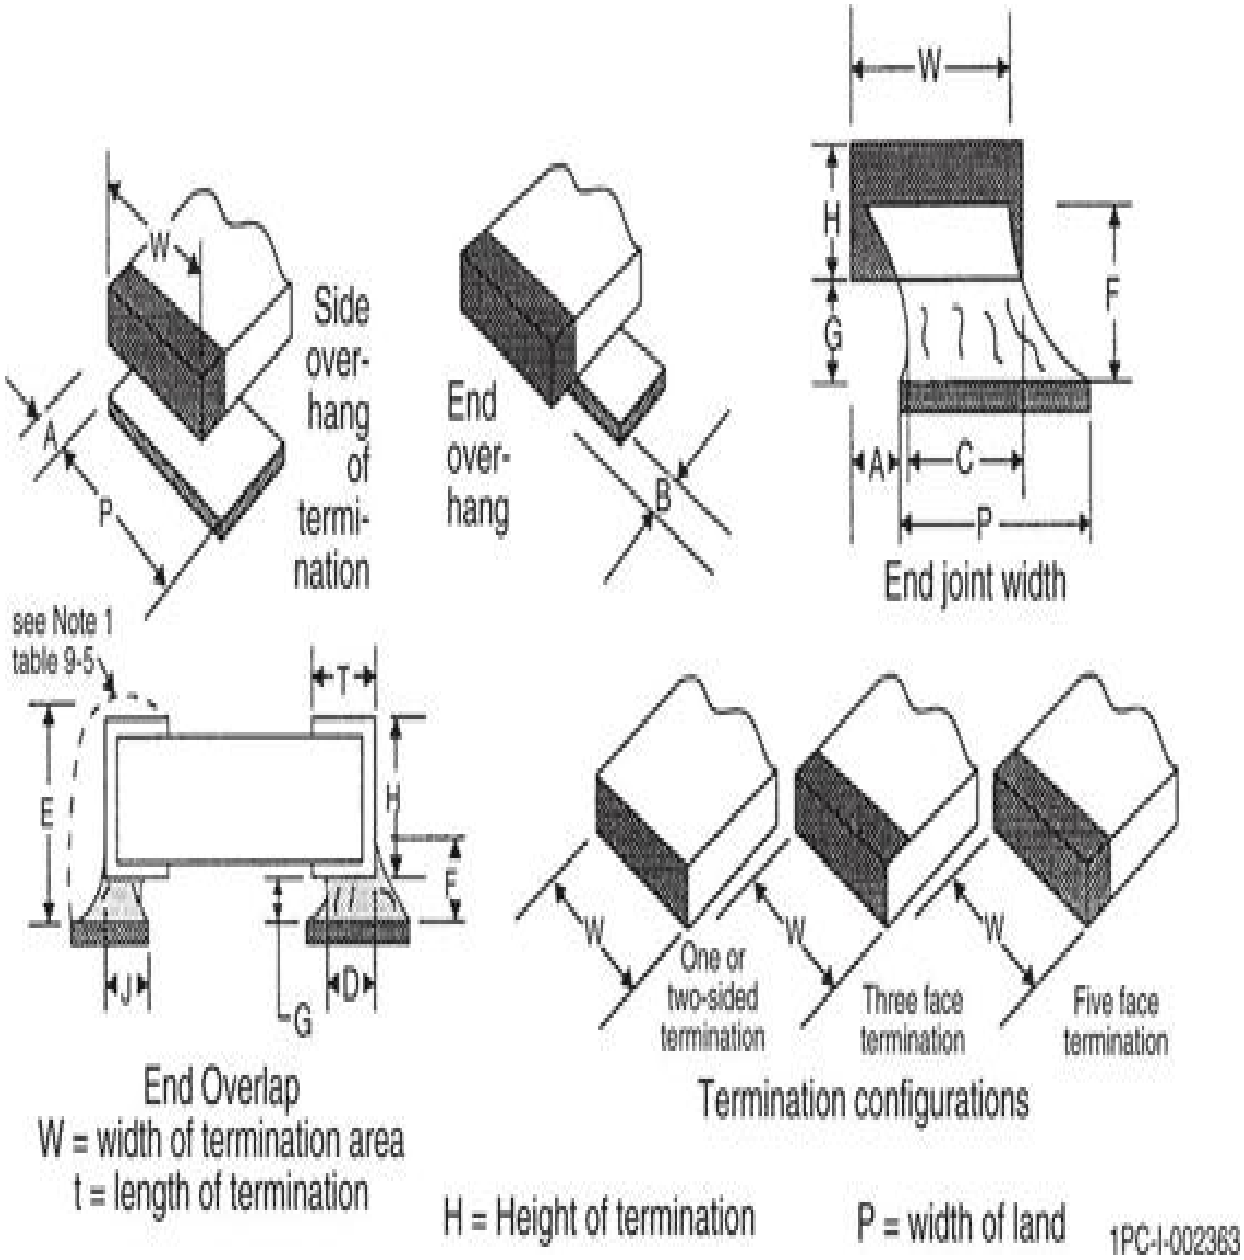

FIGURE 55.7 Inspection attributes for solder joints of surface-mounted rectangular passive chips.

TABLE 55.1 Dimensional Criteria: Rectangular or Square End Components (Dimensions in Millimeters)

Feature	Dim.	Class 1	Class 2	Class 3
Maximum side overhang	A	50% (W) or 50% (P), whichever is less; Note 1	50% (W) or 50% (P), whichever is less; Note 1	25% (W) or 25% (P), whichever is less; Note 1
Maximum end overhang	B	Not permitted	Not permitted	Not permitted
Minimum end joint width	C	50% (W) or 50% (P), whichever is less	50% (W) or 50% (P), whichever is less	75% (W) or 75% (P), whichever is less
Minimum side joint length	D	Note 3	Note 3	Note 3
Maximum fillet height	E	Note 4	Note 4	Note 4
Minimum fillet height	F	Note 3	Note 3	(G) + 25% (H) or (G) + 0.5 mm (0.02 in), whichever is less
Solder fillet thickness	G	Note 3	Note 3	Note 3
Height of termination	H	Note 2	Note 2	Note 2
Minimum end overlap	J	Required	Required	Required
Width of land	P	Note 2	Note 2	Note 2
Width of termination	W	Note 2	Note 2	Note 2

Note 1. Shall not violate minimum electrical clearance.

Note 2. Unspecified parameter or variable in size as determined by design.

Note 3. Properly wetted fillet shall be evident.

Note 4. The maximum fillet may overhang the land or extend onto the top of the end cap metallization; however, the solder shall not extend further onto the component body.

Visual inspection often occurs at the end of the assembly process or even after all of the electrical tests on the assembly have been completed. It is not possible, however, for invisible or hidden joints. The visual inspector looks for

scratches, partial delaminations, solder splashes or solder balls away from solder joints, and any other condition that does not affect assembly performance but does make the assembly look as though it might not be a high-quality product.

55.6.3 Standards for Visual Inspection

Many standards cover printed circuit board assemblies. Most major electronics manufacturers have their own internally developed workmanship standards. Several industry and military standards also exist. However, the joint industry standard IPC-A-610D, “Acceptability of Electronic Assemblies,” is the standard most often referenced for criteria defining reliable solder connections. This standard was developed by the Institute for Interconnecting and Packaging Electronic Circuits (IPC) (www.ipc.org).

The standard is a collection of visual quality acceptability requirements for electronic assemblies. It covers criteria for both pin through-hole and surface-mount technology solder connections. It also reflects requirements for three different classes of end products:

- *Class 1, general electronic products* These include consumer products and some computers and computer peripherals.
- *Class 2, dedicated service electronic products* This class includes communications equipment, critical business machines, and instruments where high performance is required and for which uninterrupted service is desirable.
- *Class 3, high-performance electronic products* These products include commercial and military equipment for which continued performance or performance on demand is imperative.

55.6.4 Capabilities of Visual Inspection

Visual inspection serves a number of important purposes well, but it also has several important limitations.

55.6.4.1 Advantages. Visual inspection can be an accurate and cost-effective method of defect detection for nonsubjective defects, such as larger missing components, larger misoriented or reversed components, or solder bridges. When low volume or lack of technical resources prevents the use of automation or more sophisticated tools, visual inspection is one alternative that finds many of the more subjective defects, such as solder joints with insufficient solder, lifted leads, or poor wetting. Finally, visual inspection can quickly detect when a process step has drifted significantly out of its control limits.

55.6.4.2 Disadvantages. Visual inspection also has many limitations, including the following:

- Low coverage of solder joint defect detection repeatability, particularly for fine-pitch parts, which results in high false accepts or defect escapes and high false reject rates
- Low coverage of component defect detection repeatability for smaller components such as 0402, 0201, or 01005 passive components
- Inability to see hidden solder joints in component types such as some connectors, PGAs, BGAs, chip-scale packages (CSPs), SIPs, or multichip modules (MCM)
- Inability to collect quantitative measurements in addition to defect data

55.6.4.3 Repeatability Limitations. Several studies have documented the low repeatability rate of visual

inspection of solder joints. One such study was conducted by AT&T at its Federal Systems Division.[1] This study showed that even the same inspector inspecting the same assembly twice had a defect call repeatability rate of only about 50 percent. Two different inspectors inspecting the same assembly had a defect call repeatability rate of only about 28 percent. This study did not include any very-fine-pitch SMT solder joints or 0603 passive components, which are more difficult to inspect visually.

To alleviate this severe limitation somewhat, manufacturers have implemented the use of microscopes with a magnification level of 10×. Often, stereoscopic microscopes are used to provide visual inspectors a better three-dimensional view. Not as frequently, manufacturers have implemented light sources and cameras to capture real-time magnified video images of the assembly being inspected. The lighting and high-resolution video images can make it easier for visual inspectors to see the acceptance criteria for which they are searching. These enhancements do improve the repeatability rate of visual inspection. But the requirement for subjective human calls and the tedium of carefully inspecting thousands of connections per hour still results in repeatability rates much lower than desired. Low repeatability means many missed defects that escape to final assembly or to customers, impacting reliability and wasting and possibly damaging rework of good connections.

55.6.4.4 Hidden Solder Joints. Several component types used in printed circuit assemblies do not provide visual access to solder joints. These components include packages with bump arrays where the solder joints are distributed in a matrix under the entire component body, such as ball grid arrays and chip-scale packages. For these components, all of the joints except those on the edges of the array are completely hidden from view. Other packages, such as J-leaded components, where the connections are under the

component body at the component edges, and 0.5 mm-pitch gull-wing components, where the solder joint heel is only 0.08 mm high and behind the component leads, also make visual inspection more difficult. Some manufacturers have attempted to solve this problem by using a penetrating imaging technique, such as x-ray, acoustics, or thermography, to acquire a live, magnified video image that the visual inspector can look at to make a defect call. However, the images resulting from these techniques are either less consistent or less well defined than a visual image, still requiring the inspector to make a difficult judgment call. Therefore, a low repeatability rate persists.

55.6.4.5 High-Complexity Boards. Many printed circuit boards today are entirely too complex to allow accurate visual inspection. Components as small as 0402, 0201, or even 01005 passive components are simply too small for accurate visual detection of missing parts and particularly misalignment defects. Add to this the fact that many printed circuit boards have hundreds of these component types per board, and the opportunity for the visual inspector to make a mistake becomes enormous. Further obstacles to accurate inspection are “families” of boards, where the basic layout of each board type is the same, but specific board types vary by purposely not mounting specific components. In these cases, a missing component can be completely acceptable even in places where the board layout may provide for a component to be mounted.

55.6.4.6 No Quantitative Measurements. Accurate quantitative measurements of dimensions ranging from 0.05 to 0.5 mm are not possible with visual inspection. Quantitative measurements provide much more information about a process step, allowing much tighter process control and providing insight into the causes of process variation, without which process improvement is a hit-or-miss

proposition. Some manufacturers have implemented semiautomatic measurement tools to allow operators to take quantitative measurements. Examples include optical-focusing microscopes and semiautomatic laser triangulation equipment. These tools do collect useful quantitative measurements, but are typically limited to sampling. Sampling is required because the tools are very slow. Measurement of solder paste height, volume, and registration with pads is possible because of easy visual access to solder paste depositions as well as their simple rectangular shape.

Automated inspection techniques using automated inspection equipment significantly overcome the repeatability and measurement limitations of visual inspection. It is for this reason that many manufacturers are implementing automated inspection.

55.7 AUTOMATED INSPECTION

The automation of inspection has evolved into systems that resemble the automated test equipment used to make electrical measurements and find electrical defects (faults).

Automated inspection systems generate images of the item to be inspected (normally solder paste, components, or solder joints), digitally analyze the image to locate and measure key features, and, based on these measurements, automatically decide whether a defect exists or not.

Just like visual inspection, automated inspection systems do not require physical contact with the printed circuit assembly to generate the desired images. Unlike visual inspection, however, automated inspection removes human subjectivity from defect detection, thereby increasing repeatability rates typically by an order of magnitude. Many of the automated inspection systems also provide accurate,

repeatable, quantitative measurements that directly correspond to process parameters, thus providing the means for process control and improvement.[2]

55.7.1 Measurements by Automated Inspection Systems

Figure 55.8 shows examples of measurements made by automated inspection systems.

55.7.1.1 Solder Paste Measurements. Typical solder paste measurements, shown in Fig. 55.8(a), are volume, area of pad covered, height, and misalignment with the pad. These quantitative measurements provide information about the paste viscosity, stencil registration, cleanliness, snap-off, and squeegee speed and pressure that can lead to improvement in the paste printing process.

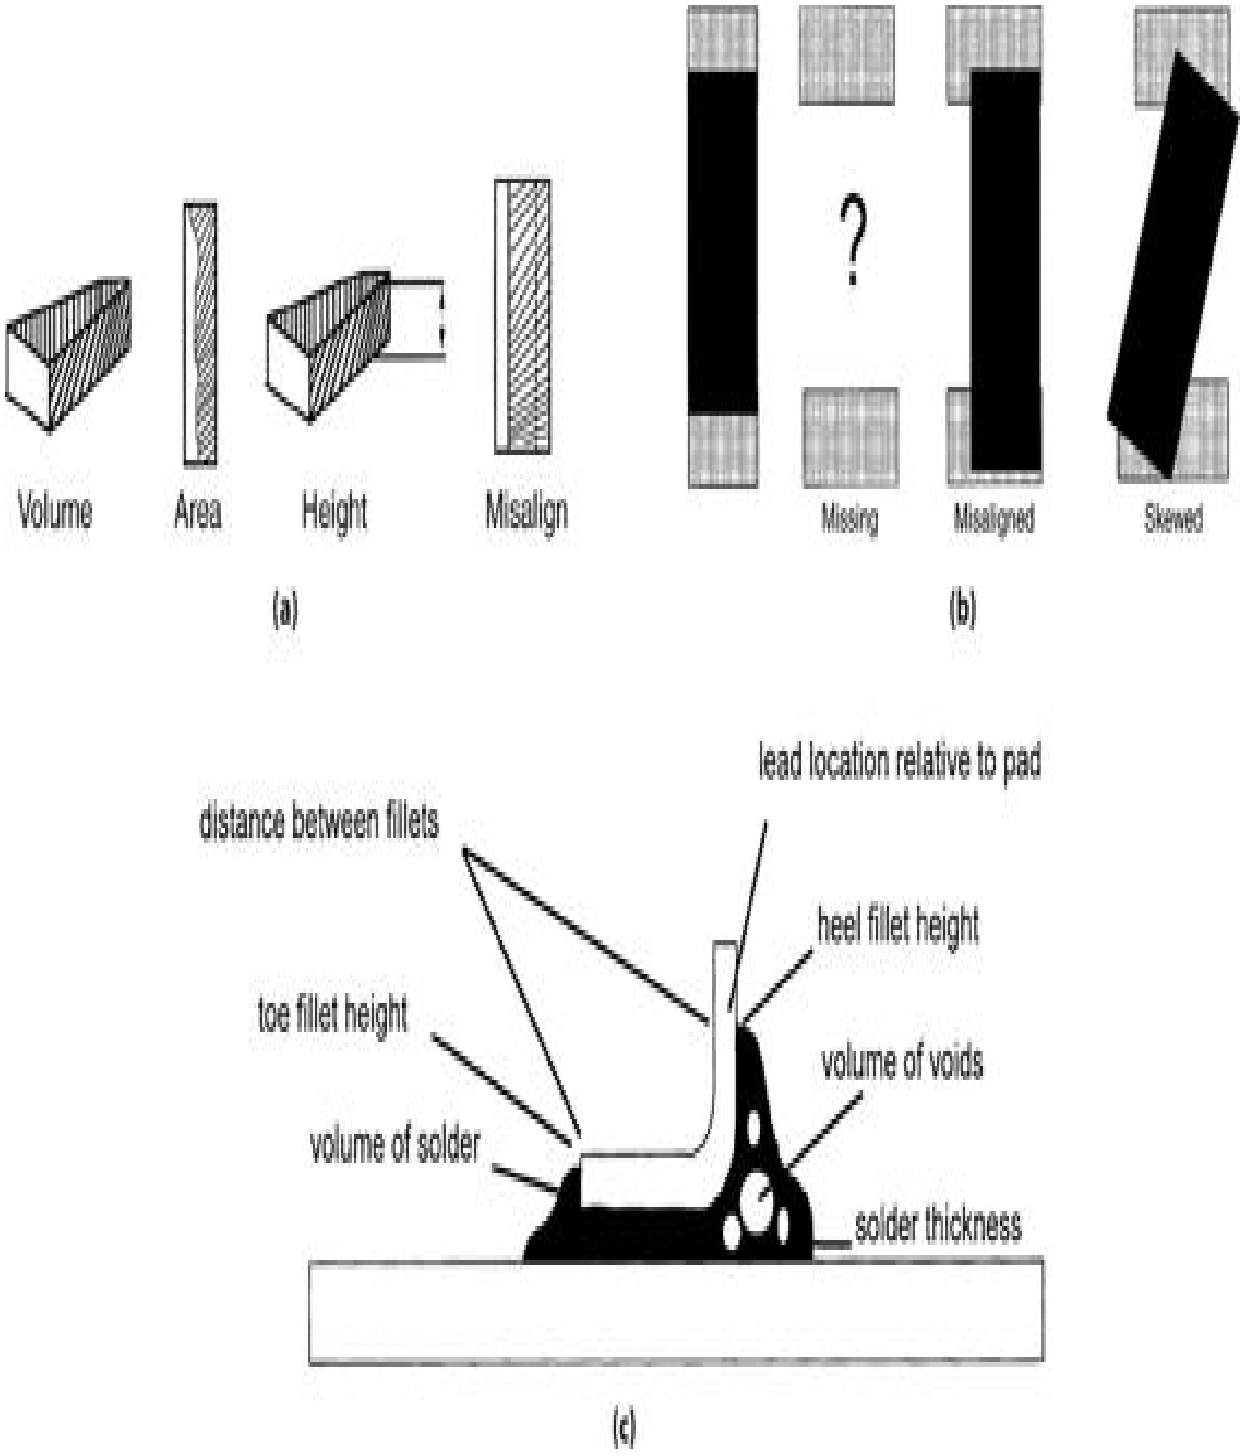

FIGURE 55.8 Measurements made by automated inspection systems: (a) Typical solder paste measurements made by automated inspection systems, including the volume of paste deposition, area of the pad covered by paste, height of the paste deposition, and offset of the paste from the pad; (b) typical component placement attributes inspected by automated inspection systems, including missing component, components misaligned along or across the pads, and skewed components; (c) typical solder joint measurements made by

automated inspection systems, including volume of solder, toe and heel fillet heights, distance between fillets, void volume, average solder thickness across the solder joint, and offset between the solder joint and pad.

55.7.1.2 Pre-Reflow Measurements. Typical pre-reflow component placement measurements, depicted in Fig. 55.8(b), include whether or not the component is missing, misaligned, or skewed. These measurements are usually attribute measurements, just separating good from bad. But quantitative dimensional measurement of the amount of misalignment, just after the placement process step, is also possible. Component placement measurements provide information about the rate of placement accuracy. Optical character recognition (OCR) and optical character verification (OCV) techniques allow for additional levels of verification, including correct part.

55.7.1.3 Post-Reflow Solder Joint Measurements. Solder joint measurements, such as fillet heights, average solder thickness across the pad, void volume, and pin-to-pad offsets, as shown in Fig. 55.8(c), provide information about the paste printing process, the component placement process, and the solder reflow process steps. Attribute measurements, such as solder bridges, opens, or insufficient solder, are most common. Quantitative measurements of solder joints are also possible and provide greater insight into process parameters. For instance, the variation of heel fillet heights and void volume across an assembly provides insight into the oven temperature profile and spatial distribution. The variation of average solder thickness provides insight into squeegee speed and pressure and stencil cleanliness. And the pin-to-pad offsets measure the component placement accuracy.

55.7.2 Types of Inspection Systems

Inspection systems normally are dedicated to one type of measurement capability: solder paste, pre-reflow, or post-reflow inspection. For example, systems for solder paste measurements do not normally also make component placement measurements. The cost of combining different measurement capabilities into one system would typically make that system prohibitively expensive. More importantly, to reduce manufacturing costs, manufacturers want to implement linear, sequential production lines where an assembly always flows in one direction and goes through each machine only once per assembly side. So automated inspection systems fall into three major categories:

- Those that make three-dimensional solder paste measurements
- Those that make quantitative pre-reflow two-dimensional solder paste and/or component placement measurements
- Those that make post-reflow solder joint measurements and attribute component measurements

For all three types, the automated inspection system compares the measurements taken against a specified conformance range to accept or reject automatically a solder paste brick, component placement, or solder joint as being within specification.

55.8 THREE-DIMENSIONAL AUTOMATED SOLDER PASTE INSPECTION

55.8.1 Operating Principles

Automated inspection systems designed for 3-D solder paste measurements use structured light sources and cameras or

digital light-emitting diode (LED) sensors to generate “three-dimensional images” of solder paste depositions. The structured light is normally some variation of a sheet of light or a laser line or spot. As Fig. 55.9 shows, the structured light sweeps across a solder paste brick, creating discontinuities and other features in the image that are calibrated to actual physical dimensions, such as height and area. In essence, the proportional nature of the deflection and height is turned into usable measurement results.

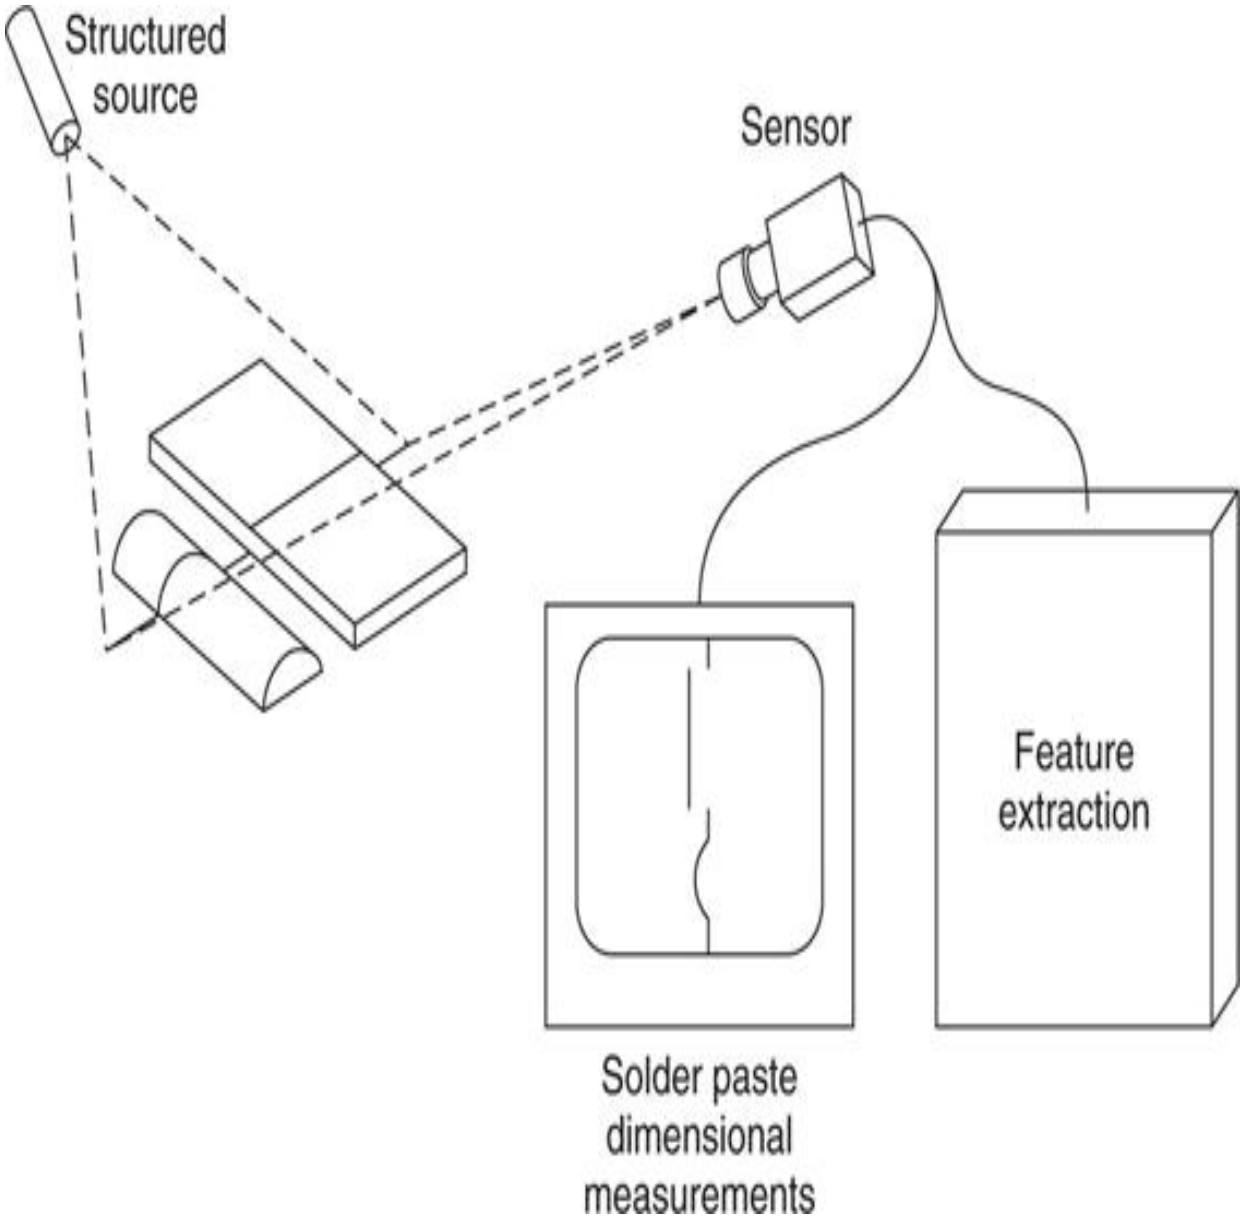

FIGURE 55.9 Schematic of automated inspection system for solder paste measurement. The camera or LED sensor obtains images with discontinuities in the laser line scan; the image-processing software finds these discontinuities, measures them, and calibrates them to real physical dimensions.

55.8.1.1 View Magnification. To achieve adequate accuracy, only a small portion of the assembly, called a *view*, is imaged at a single time. Magnification increases and digital quantization error decreases as the size of the view decreases. Views normally vary in size from 10 to 25 mm in diameter. So the automated inspection system may use more than 100 views to cover a typical assembly. The system moves the assembly or the image sensor on a positioning stage from view to view. The sum of move time plus image acquisition time normally makes up most of the total inspection time for a particular assembly.

55.8.1.2 System Throughput. The test speed for solder paste inspection systems varies anywhere from 2 to 22 cm^2/sec. The high end of this speed range can be fast enough to keep up with many automated printed circuit production lines. But for the slower systems, or even for the fastest systems on very-high-volume production lines, manufacturers inspect a specific subset of paste depositions on every assembly coming down the production line.

55.8.2 Applications

Automated solder paste inspection systems typically reside in the fastest speed ranges on the system throughput scale and therefore are utilized as process control tools in addition to defect detectors. Manufacturers typically use these systems to monitor the process by tracking the key quantitative solder paste measurements, normally height and volume, against control limits. The systems then alarm any condition where control limits are exceeded or definite

drifts are detected, allowing the manufacturer to assess the production line and monitor or choose to take action until appropriate adjustments have been made. (The alarm generated by the system is normally an obvious flashing message on a computer monitor.) Because the paste printing process step causes a large percentage of all production defects, tight production control of this process step using quantitative measurements can significantly lower the process defect rate. In fact, automated solder paste inspection systems have been linked through software to paste printing systems, allowing not only process control, but also closed-loop feedback for semiautomatic adjustment of paste printing parameters based on the paste measurements.

55.8.3 Advantages and Disadvantages

Automated 3-D inspection of solder paste depositions has the following major advantages:

- Real-time process control of paste printing to lower defect rates and rework costs
- Quantitative measurements, including volume, to help permanently eliminate the causes of paste defects
- Defect detection where rework is easiest, before component placement and solder reflow
- Process characterization during the lead-free conversion with minimal program tuning

Automated inspection of solder paste depositions has the following limitations:

- It is sometimes too slow to cover all paste depositions on an assembly.

- It does not measure or detect defects in component placement or solder reflow.

55.9 PRE-REFLOW AOI

55.9.1 Operating Principles

Automated inspection systems designed for 2-D component placement and solder paste quantitative measurements typically use optical techniques consisting of multi-angle light sources and charged-couple device (CCD) cameras to generate images. As Fig. 55.10 indicates, these systems extract specific features, such as edges of the components or solder paste deposits, in the images and then use these features to determine quantitative measurements of component and deposit misalignment or deposit area.

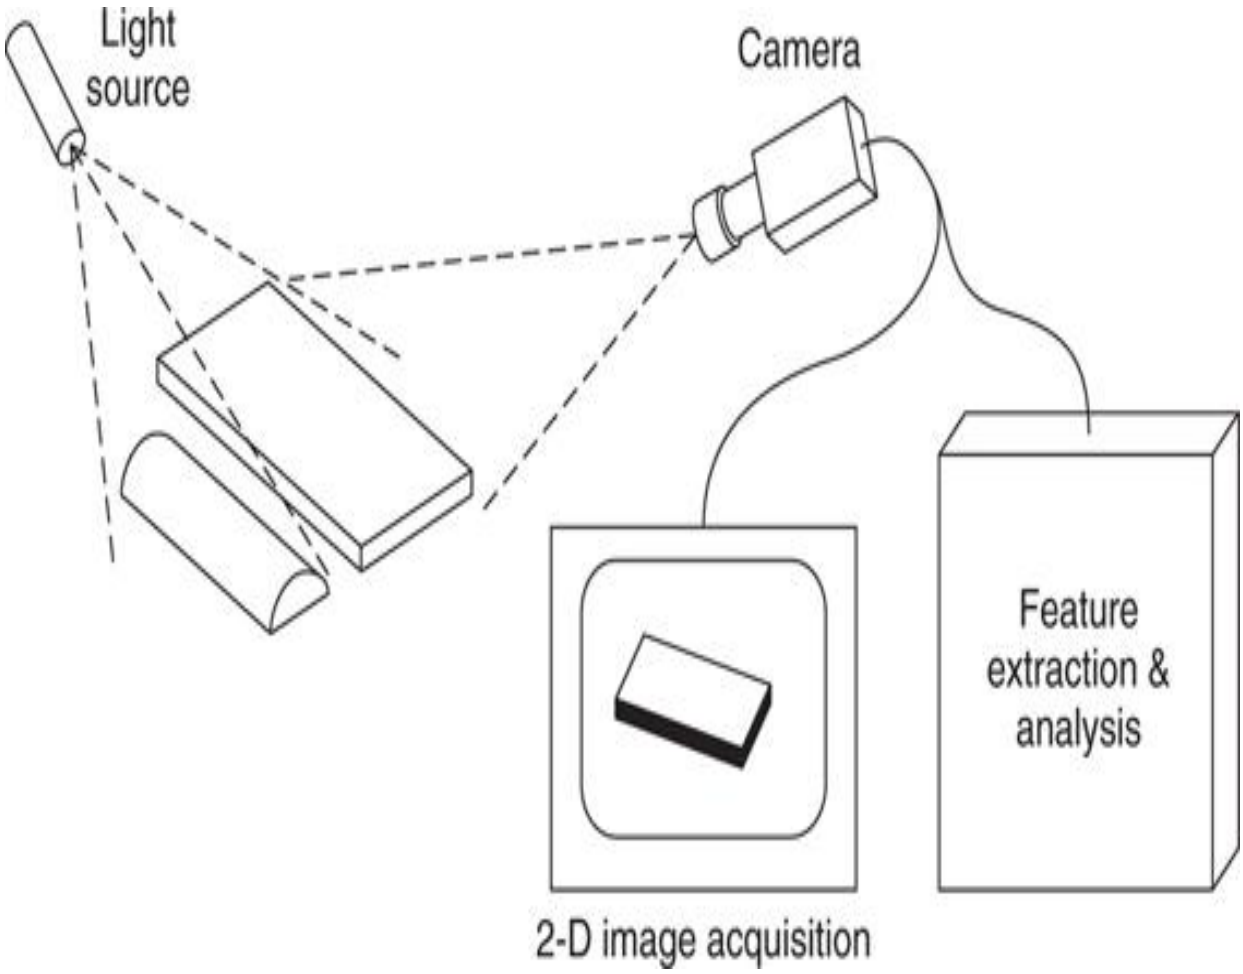

FIGURE 55.10 Schematic of automated inspection systems for component placement defect detection. The camera sensor obtains images of component positions relative to the printed circuit board. The image processing software extracts features from the image and compares them to present position limits to flag a placement as defective.

Automated optical inspection systems also image only a small portion, or *view*, of the assembly at a time. These systems normally can use somewhat bigger views than the 3-D solder paste systems because the features being extracted often do not require as much magnification as do measurements of solder paste depositions. However, inspection of components, such as 0402, 0201, and 01005 passive components, or very-fine-pitch deposits, can require the same level of magnification and therefore views as small as the 3-D solder paste inspection systems.

In general, pre-reflow AOI systems are typically two to three times faster than 3-D systems and range in inspection speed between 10 and 40 cm^2/sec. The prices of 2-D component and solder paste placement automated inspection systems are typically somewhat less than those of the 3-D solder paste systems with the fastest inspection speed capability.

55.9.2 Applications

The majority of pre-reflow AOI systems are placed directly following the pick-and-place process step in the production line. These systems therefore only measure the amount of misalignment of components and are generally fast enough to cover all components on a printed circuit board and keep up with the production line's cycle time. So manufacturers often use these systems to detect all misalignment defects as well as missing components. But the most important purpose of these systems is process control, just as it is for the 3-D solder paste inspection systems. The intent is to discover process drift early enough to prevent defects by tracking the key quantitative misalignment measurements against control limits. The systems then alarm any condition where control limits are exceeded or process drifts are detected, allowing the manufacturer to assess the production line and monitor or choose to take action until appropriate adjustments have been made. Some system suppliers in conjunction with pick-and-place equipment suppliers can develop closed-loop feedback software links allowing semiautomatic adjustment of the pick-and-place equipment.

Pre-reflow AOI systems also have the ability to inspect 2-D solder paste; however, this ability is utilized only to inspect a small percentage of the solder paste deposits combined with the component misalignment measurements. Component

misalignment measurements cover the passive components, whereas the solder paste measurements cover deposits for BGA, CSP, or fine-pitch QFP devices. Therefore, these systems are placed within production lines after the pick-and-place systems for passive devices but before the pick-and-place systems for the larger area-array and leaded devices. These systems serve the same purpose as those only meant for component placement measurement, both detecting defects and monitoring measurements within control limits to discover process drift as early as possible.

55.9.3 Advantages and Disadvantages

Pre-reflow AOI has the following major advantages:

- Real-time detection of systematic process defects where equipment is out of adjustment
- Detection of defects such as misalignment where rework is easier, before solder reflow
- Low-cost option for reasonable test coverage
- Process characterization during the lead-free conversion with minimal program tuning

Automated inspection of component placement has the following limitations:

- It does not measure or detect defects in solder reflow, and normally does not detect defects in solder printing.
- It does not measure 3-D for solder paste.

55.10 POST-REFLOW AUTOMATED INSPECTION

Solder joints have much more complex shapes than do solder paste depositions and components, so taking measurements of solder joints normally requires more complex imaging techniques than does measuring solder paste and components. Automated inspection systems for solder joints have used a variety of imaging technologies, including optical and x-ray imaging, thermography, cooling profiles of laser-heated solder joints, and ultrasonic imaging. But three technologies have dominated in these systems:

- Optical imaging using multiple light sources and cameras
- Transmission x-ray imaging
- Cross-sectional x-ray imaging

55.10.1 Post-Reflow AOI Systems

55.10.1.1 Operating Principles. Post-reflow AOI systems for solder joints are similar to, but more complex than, those for component placement. (Note that these systems also detect component defects such as missing, misaligned, or misoriented components, but their complex design is required for solder joint inspection.) Multicolor, multi-angled light sources are normally required to provide enough information in the images to allow sophisticated image-processing algorithms to detect the required features in the images accurately. If the light source is not multicolored or multi-angled, then many different cameras are usually used instead, each camera mounted at a different angle relative to the board being inspected.

The multiple light sources and cameras create and detect shadows from various angles to detect features of solder joints of all types oriented in different directions on the printed circuit assembly. These optical systems often use higher magnification, particularly for the smallest passive components and fine-pitch components, and therefore

capture a smaller portion of the assembly at any one time. The smaller views allow more image pixels per solder joint feature, allowing more accurate image processing and corresponding defect calls. The use of smaller views renders the throughput of these systems slower than that of component placement inspection systems. However, in general these systems are faster than 3-D solder paste measurement systems. Their throughput typically falls in the range of 10 to 40 cm^2/sec.

The systems' image-processing software uses sophisticated algorithms to extract specific features of solder joints, such as edges and areas of the solder joint in a specific range of angles relative to the board. Analysis of these extracted features then determines whether a defect exists or not. Defects detected include absence of solder, bridges, and grossly insufficient or excessive solder. These systems typically do not make quantitative measurements.

55.10.1.2 Application. These post-reflow AOI systems generate only attribute data. For instance, these systems detect the existence of a solder bridge between two joints or the absence or presence of a toe fillet on solder joints. But they do not measure the height of the heel fillet or the amount of solder in the solder joint. These systems typically do not measure how far a component is misaligned from its proper placement, but instead simply determine whether or not the component is misaligned more than a predetermined amount. These attribute data are not as useful for process control, and thus manufacturers use these systems strictly to detect defects. Normally these systems do, however, warn of a condition where the same defect has occurred several times consecutively or within a specific number of assemblies, indicating that some part of the process needs adjustment.

Post-reflow AOI systems cannot inspect hidden solder joints, such as those for ball grid arrays, pin grid arrays, and

in some cases J-leaded devices, and can have high false accept or reject rates for some component types, such as fine-pitch components at or below 0.5 mm pitch or small outline transistor (SOT) devices. If tall components are placed on the board very close to smaller components, post-reflow AOI systems can also have difficulty inspecting these smaller components.

55.10.1.3 Advantages and Disadvantages. Post-reflow AOI systems of solder joints have the following advantages:

- They eliminate visual inspection by automating solder joint defect detection, thereby also reducing unnecessary rework due to false reject calls.
- They reduce rework analysis time by pinpointing defects to the exact solder joint.
- They afford real-time process control of all three process steps—paste printing, component placement, and solder reflow—to lower defect rates and rework costs.
- They can be used during the lead-free conversion with minimal program tuning.
- They are a low-cost option for reasonable test coverage.
- Post-reflow AOI systems have the following limitations:
- Test throughput is not always fast enough to allow inspection of all solder joints within the manufacturing cycle time for the printed circuit assembly.
- A significant learning curve is required to become expert at developing solder joint tests with both low false accept and false reject rates.
- The ability to inspect hidden (or invisible) joints is not possible with post-reflow AOI.

55.10.2 Transmission X-Ray Systems

55.10.2.1 Operating Principles. Transmission x-ray systems radiate x-rays from a point source perpendicularly through the printed circuit assembly being inspected, as depicted in Fig. 55.11. An x-ray detector picks up a varying amount of x-rays depending on the thickness of metals that the x-rays are penetrating and converts the x-rays to light photons for a camera to create a grayscale image. The x-ray source is filtered so that metals of only a certain density range—lead, tin, gold, and silver—will absorb the x-rays. The copper leads and frames of components sitting on top of solder joints do not absorb the x-rays and are therefore practically invisible to the x-ray detector. Thus, x-ray systems can easily see the entire solder joint, no matter what component material may be on top of the joint blocking its optical or visual access. In other words, x-ray is the only automated inspection method equipped to inspect hidden joints such as those found in a BGA or CSP. The resulting x-ray image will be darker wherever the lead or tin solder or lead-free solder is thicker in the solder joint. The image processing capability of the system then searches for features, such as the heel and toe fillets, the sides of the solder joint, and even voids internal to the joint based on grayscale readings of the solder joint x-ray image. The system then uses predetermined decision rules to compare the grayscale readings to acceptance criteria to accept or reject a solder joint automatically. For example, the system might compare the relative grayscale reading for the heel fillet region, the center of the solder joint, and the toe fillet region. The acceptance criteria might state that the heel fillet reading should be twice that of the center and that the toe fillet reading should be 50 percent higher than that of the center. If the actual readings do not meet these criteria, then the solder joint is reported as being defective.

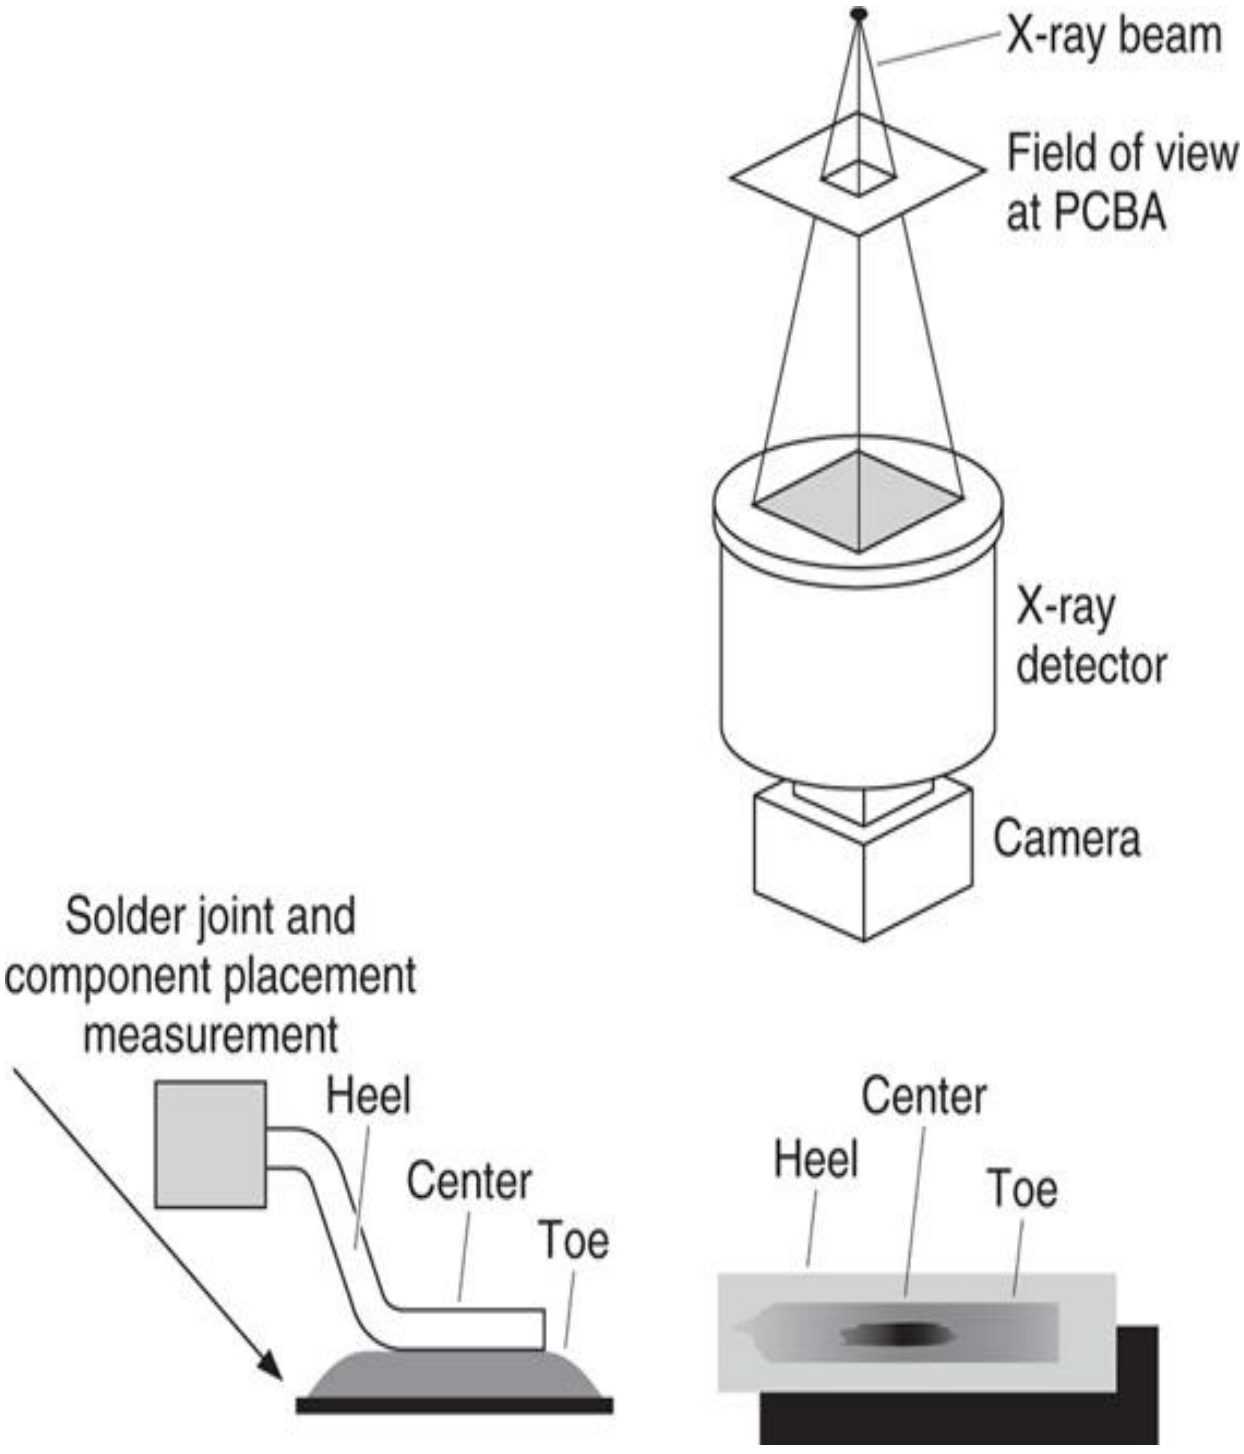

FIGURE 55.11 Schematic of transmission x-ray automated inspection system for solder joint defect detection. The x-ray detector converts a varying amount of x-rays to light, based on how much various parts of the solder joint absorb. The camera converts the light photons to an image, which is then processed to find solder joint features and flag defects accordingly.

The bottom of Fig. 55.11 shows an x-ray image of a gull-wing solder joint that shows the center of the joint as much darker than the heel fillet region. This solder joint is clearly defective, as the heel fillet region should always be darker and have a higher grayscale reading than the center of the joint, where the solder is thinnest for mechanically good solder joints. (The system's image processing capability is able to detect much more subtle changes in grayscales than can the human eye, allowing very accurate relative readings from one solder joint to the next.)

55.10.2.2 Application. Transmission x-ray technology works well for single-sided surface-mount assemblies. These automated inspection systems accurately detect solder joint defects such as opens, insufficient solder, excess solder, bridges, misalignment between pin and pad, and voids for most surface-mount solder joint types, including J-leads, gull-wings, passive chips, and small-outline transistors in hidden and nonhidden joints alike. These systems also detect missing components and reversed tantalum capacitors. Based on trends in grayscale reading, these systems also can accurately detect process drifts through real-time process control charting.

For double-sided assemblies, however, the transmission x-ray images of solder joints on the top side will overlap with the images of solder joints on the bottom side. The x-rays are absorbed by any solder in their path through the printed circuit assembly from the source to the detector. These overlapping images make accurate solder joint measurement impossible.

Transmission x-ray imaging also cannot easily distinguish between the top, bottom, and barrel of PTH solder joints or the bottom of BGA solder joints. So transmission x-ray systems cannot be used for accurate measurement of and defect detection in solder joints on double-sided assemblies or for PTH and BGA solder joints.

55.10.3 Cross-Sectional X-Ray Systems

55.10.3.1 Operating Principles. Cross-sectional x-ray systems radiate x-rays at an acute angle from vertical through the printed circuit assembly being inspected. As Fig. 55.12 indicates, images from all around the particular view being inspected are added together or integrated essentially to create an x-ray focal plane in space. This focal plane creates a cross-sectional image, approximately 0.2 to 0.4 mm thick, right at the focal plane, by blurring everything above and below the focal plane into the background, or *noise*, of the image. By moving the top side of an assembly into the focal plane, cross-sectional images of only the solder joints on the top side are created. By moving the bottom side of an assembly into the focal plane, cross-sectional images of only the solder joints on the bottom side are created. Separate images of top and bottom sides are always created, preventing any image overlap from the two sides.

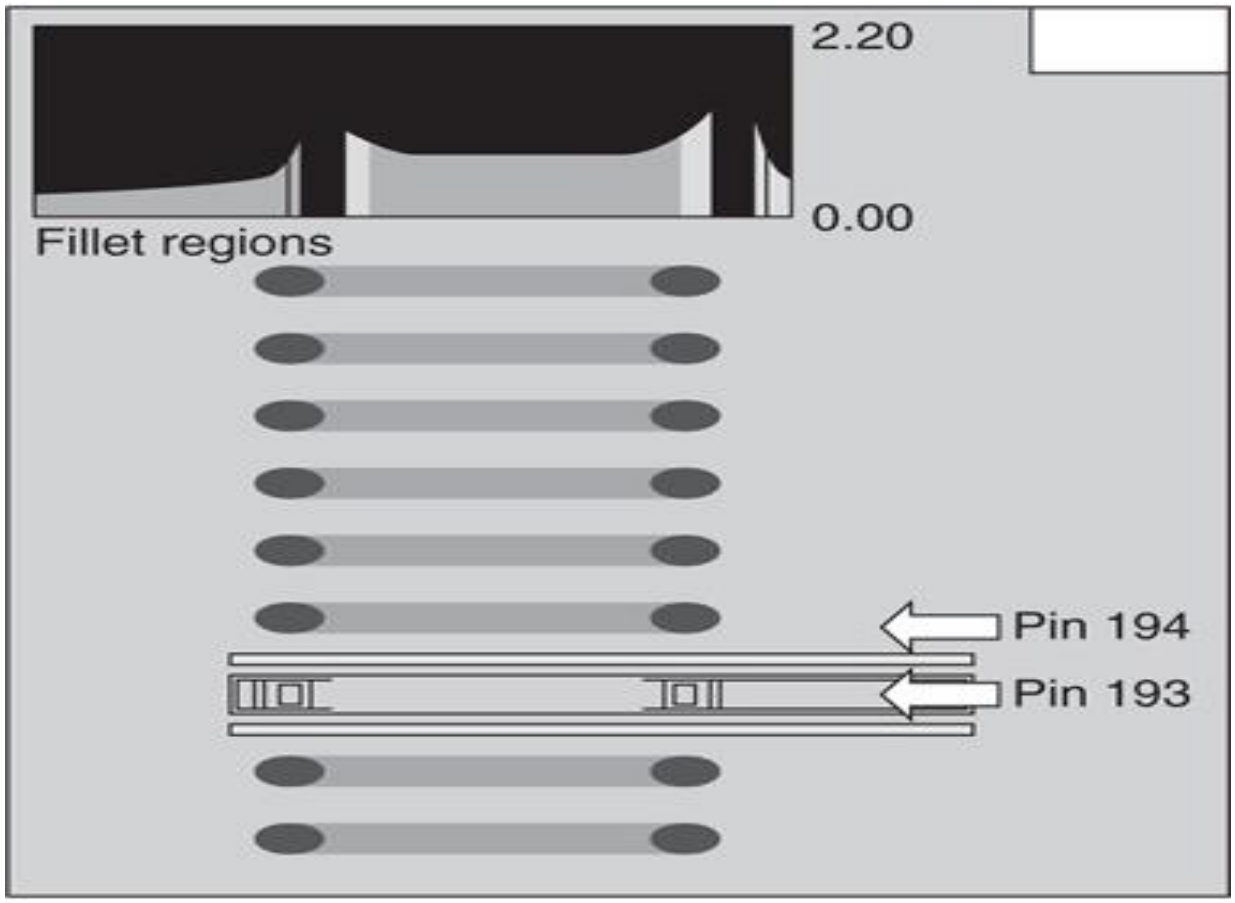
FIGURE 55.12 Schematic of cross-sectional x-ray automated inspection system for solder joint measurement. Adding images around a circle from a rotating x-ray beam and detector creates a focal plane that captures just the solder joints of interest and nothing else below or above.

55.10.3.2 Application. Cross-sectional x-ray automated inspection systems work well for all types of printed circuit assemblies, including single-sided and double-sided, surface-mount, through-hole, and mixed-technology assemblies. These systems accurately detect the same solder joint and component defects as do transmission x-ray systems, but, in addition, the cross-sectional x-ray systems accurately detect insufficient solder conditions for BGA and pin-through-hole solder joints.

Some cross-sectional x-ray automated inspection systems go beyond just grayscale readings of specific solder joint features. By carefully calibrating grayscale readings to actual solder thickness, it is possible to generate real-world measurements, in physical units rather than grayscale numbers, of fillet heights, solder and void volume, and average solder thickness for the entire joint. Figure 55.13 shows an example of these calibrated measurements. This figure includes the actual cross-sectional x-ray image of tape automated bonded (TAB) solder joints.

Tape-automated bond (TAB)



Good board (pin 6)

Reference designator	Inspection point	Thickness (in 0.001")
U1 pin 193	Pad	0.59
	Heel	1.18
	Center	0.69
	Toe	1.34
U1 pin 194	Pad	0.58
	Heel	1.20
	Center	0.68
	Toe	1.30

FIGURE 55.13 Cross-sectional x-ray image of TAB solder joints. Image-processing software converts the grayscale readings of the image for pin 193 into the side profile of solder thickness shown above the image. The actual calibrated measurements of average solder thickness across the pad, heel fillet height, center thickness, and toe fillet height processed from the images of pins 193 and 194 are shown in the table below the x-ray image. These measurements indicate that both of these solder joints are good.

The profile shown at the top of the x-ray image is generated by the system in physical dimensional units by interpreting and calibrating the grayscale readings of pin 193 in the x-ray image.

The table below the x-ray image includes example measurements for both pin 193 and pin 194.

Analysis of these physical thickness measurements of solder joints provides the information required for process characterization and improvement. For instance, variations in average solder thickness or volume for the solder joints across a single assembly or from assembly to assembly provide insight into the quality level of the paste printing process as well as sources of defects.

The image-processing software then finds and measures solder joint features and flags defects accordingly.

55.10.4 Advantages and Disadvantages of X-Ray Inspection

X-ray solder joint inspection systems can reach average inspection speeds of around 50 to 150 joints per second. X-ray solder joint inspection systems also have higher prices, typically about 50 to 100 percent more than the price of the optical solder joint systems with the fastest inspection speed capability.

Automated x-ray inspection of solder joints has the following major advantages:

- Its defect detection capability is extremely high.
- It eliminates visual inspection by automating solder joint defect detection, thereby also reducing unnecessary rework due to false reject calls.
- It reduces rework analysis time by pinpointing defects to the exact solder joint.
- It affords real-time process control of all three process steps—paste printing, component placement, and solder reflow—to lower defect rates and rework costs.
- It provides quantitative measurements to help permanently eliminate the causes of defects from all three process steps.
- It reduces failures at final assembly and in the field due to defective hidden solder joints and marginal solder joints due to insufficient solder or misalignment or excessive voids.
- During lead-free conversion, it can be used with minimal program tuning.

Automated inspection of solder joints has the following limitations:

- Test throughput is not always fast enough to inspect all solder joints within the manufacturing cycle time for the printed circuit assembly.
- A significant learning curve is required to become expert at developing solder joint tests with both low false accept and false reject rates.

55.11 IMPLEMENTATION OF INSPECTION SYSTEMS

Successful implementation of automated inspection systems into printed circuit assembly production lines requires a significant investment in training, process analysis, and system integration.

The implementation can be a lengthy process that requires concerted effort by engineers or skilled technicians. Listed here are highlights of what several manufacturers have learned are key aspects of successfully implementing automated inspection systems:

- *Assess requirements carefully* Start by carefully assessing the requirements for automated inspection in the particular production environment into which the system will be integrated. Determine exactly what kinds of defects are most important for the inspection system to detect, which measurements will most help with process improvement, and what benefits will generate the quickest financial return on investment.[3] This assessment must consider the testing and measurement capability that already has been implemented as well as new requirements arising from future printed circuit assembly designs.
- *Evaluate a select set of systems thoroughly* Select a small number of automated inspection systems to evaluate thoroughly and compare them against the system requirements. The evaluation should include a benchmark using printed circuit assemblies from production to determine the system's capabilities to detect accurately the important defect types within the required false reject rate, repeatedly make the required measurements, and not exceed the required test time. Elements of cost of ownership should be well understood, including test development time, maintenance skills and cost, expected system downtime, supplier support infrastructure, and supplier maintenance services and prices.

- *Plan for factory system interfaces* Consider and plan carefully for interfaces to other factory systems. These systems include board-handling equipment, bar code–reading systems, computer-aided design (CAD) systems for automatic download of board layout and component package information, and quality data management systems for SPC and historical quality tracking.
- *Focus on SPC measurements* Start with a focus on SPC measurements instead of defect detection. Until the process variation is reduced, most manufacturers will encounter either a false reject rate or a false accept rate that is higher than desired. Allowing one rate or the other to be too high while focusing on reducing the process variation first avoids time-consuming, unproductive tweaking of acceptance thresholds. Reducing process variation requires correlating measurements to the process parameters causing the variation and defects, and then properly adjusting these process parameters.[4]
- *Define defects carefully* With an understanding of the selected system's capability, carefully define the defects that must be detected for product quality and reliability. Many of the visual inspection criteria used in the past are not appropriate for automated inspection systems because the system takes objective and different measurements.
- *Invest enough resources* Do not underestimate the initial resource investment required to obtain optimum benefit from an automated inspection system. The implementation plan should include dedicated technical support for the first six months of operation and test development. Developing a thorough understanding of the measurement results and correlating the data to process parameters are key to successful use of the system. Implementation should also address the fact that production personnel will have to be convinced of the

accuracy of the system's test results before full benefit can be obtained from the system.

55.12 DESIGN IMPLICATIONS OF INSPECTION SYSTEMS

Automated inspection systems in general do not require many changes or limitations in the design of printed circuit assemblies. Because these systems use noncontact measurement techniques, fixturing requirements present very few design limitations, for instance. However, the following requirements will facilitate automated inspection if they are considered during printed circuit design.

55.12.1 Automated Board Handling Requirements

- Parallel edges of the assembly or panel must have adequate clearance (typically at least 3 mm), to allow board-handling clamps or belts to grab the assembly.
- Three corners of the assembly or panel must include alignment fiducials (or solder joints in post-reflow configurations).
- Bar code identification of assembly number and serial number must be present at a predefined location on each printed circuit assembly.
- The board must be adequately rigid without a fixture to prevent excessive board vibration during movement.

Panels with prerouted breakaway boards or bare boards less than 30 mil thick present the biggest challenge: Component, heat sink, or daughter-board height above or

below the bare board must not exceed the height clearance of the targeted automated inspection system.

55.12.2 Test Development Ease of Use Requirements

- There should be as few suppliers as possible (ideally one) for each component type. Variation in lead and component package dimensions from supplier to supplier for the same component forces longer and more difficult development of inspection programs for each printed circuit assembly type.
- Pad shapes and sizes must be uniform, particularly for each component package type. Variation in pad size and shape within a component package type forces longer and more difficult development of inspection programs for each printed circuit assembly type.
- Solder joints for optical and structured light automated inspection systems must be clearly visible.
- For transmission x-ray automated inspection systems, no components should be opposite or under dense structures, such as transformers, large capacitors, or thick steel heat sinks.
- There should be no silk-screened outlines around components. Although such outlines may be useful for visual inspection, they just confuse automated optical inspection systems.

CHAPTER 56
DESIGN FOR TESTING

Kenneth P. Parker
Agilent Technologies, Loveland, Colorado

56.1 INTRODUCTION

In the latter part of the 1970s, it became clear that forces of technology were causing an evolution in board complexity that was quickly outstripping testing technology. It is quite possible to design boards that essentially cannot be tested in an economical sense. This will doom projects and products to failure.

The author has personal experience here, having consulted in the mid-1970s with a Silicon Valley start-up company that had created one of the first dedicated word processors. This product was based on a customized processor that had been designed and sent into production with absolutely no thought about how it was to be produced in volume. There was no test strategy. When it was determined that volume production was impossible, the design team was brought onto the production floor in a last-ditch effort to produce shippable units. High-priced design engineers could only

produce one or two units a day, and they were no longer available for developing the next product. The company soon failed, a casualty of untestable design. The marketplace never got a chance to determine whether their product idea was a winner, because their design process was a loser!

In the 1970s and into the 1980s, it was very common for a design department to be physically and organizationally removed from the test department. The nature of product life cycles dictates that by the time a test department starts ramping up test program development for a board, the design team is off on the next project and finds it distracting to go back and help the test engineers with testing problems. Thus, in those years, the designers were unknowing contributors to difficult test problems. But what is different today, with the emphasis on outsourcing and contract manufacturing? Now, a design may be outsourced to one contractor, board layout to a second, test development to a third, and actual production to a fourth, all scattered about the globe.

Even if boards can be tested, the question bears asking, “Is there something a designer can do that will make testing easier, cheaper, more thorough, etc.?” The answer is that there is a great deal a designer can do (or fail to do) that will affect the testability of a board. The technology that addresses this problem is called design for testability (DFT).

By the middle of the 1980s, testing became a bottleneck in product development. The situation ultimately became severe enough that attention was paid to the effects that design has on testing. A landmark survey on DFT technology by Williams and Parker[1] brought DFT out of common lore and into the design lexicon of the electronics industry. That paper is still remarkably current[a] nearly 20 years later. In it were coined the terms *ad hoc testability* and *structured testability*. Before jumping into the DFT discussion, however, some definitions are crucial.

56.2 DEFINITIONS

These definitions are fully discussed in Chap. 55 and are repeated here in an abbreviated form for reference.

1. A *defect* is an unacceptable deviation from a norm.
2. A *fault* is a physical manifestation of a defect.
3. A *fault syndrome* is a collection of measured deviations from an expected good outcome.
4. A fault is *detected* when an operation with an expected outcome is conducted and this outcome is not observed.
5. A fault is *isolated* when an operation with an expected good outcome and one or more failing syndromes is conducted and the outcome matches a member of the set of failing syndromes.
6. A *test* is one or more experiments that are specifically constructed to detect (and possibly isolate) failures.
   - A *detection test* has an expected good outcome.
   - An *isolation test* has an enumeration of possible fault syndromes indexed to specific failures.

The technology of testing, as covered in Chap. 55, is highly influenced either positively or negatively by the design of boards being tested. If the preceding definitions are not clear, then the discussion of loaded board testing should be digested first.

56.3 AD HOC DESIGN FOR TESTABILITY

Ad hoc design for testability consists of a set of simple design rules of the form “Do this, don’t do that,” where “this” and “that” are often not motivated with reasons. For

example, when designing a board with ICs that have preset or clear pins, a rule might read as follows:

“Tie unused preset and clear pins off through a 100-Ω resistor to a power rail; do not tie them directly.”

The first-level reason for this is that a test engineer might want to access the preset/clear functions during testing, even though the designer did not use these functions. If these pins are tied through a resistor, a test engineer may still be able to manipulate them by applying a tester resource to them that can drive a signal in spite of the resistor. If these pins are tied directly to a power rail, the test engineer will never have that option. What might the difference be? Well, in a deeply sequential circuit, controlling the preset and clear functions might make the difference between a test that runs in milliseconds versus hours. Clearly, hours of testing (per board) are impractical, so the bottom line may be the difference between a thorough test and one that lacks significant fault coverage, affecting quality.

The real reason for the various ad hoc DFT rules is that, to effectively and economically test a circuit, one must be able to control and observe the circuit’s behavior. Most rules are related to controllability and/or observability of the circuit. The rule just cited is a controllability rule. Observability rules typically suggest ways one might be able to monitor signals that are deeply embedded in combinatorial circuitry, or that are activated only rarely by complex sequential events.

Ad hoc DFT is essentially the only way many products can have improved testability when those products are constructed with off-the-shelf merchant parts. Large, vertically integrated companies have the advantage of being able to customize testability into the heart of a design, including the very ICs themselves. Application-specific ICs (ASICs) allow more of this as well.

56.3.1 Physical Access

Testing is performed once the board to be tested is connected by some adaptor mechanism to the test system. This may be accomplished via the edge connector(s) of the board, where the tester is given the same access that the board gets in its end application. But far more common is “bed-of-nails” in-circuit test access, where the board to be tested is physically mounted on a platen and depressed into a field of precisely positioned spring-loaded probes (“nails”) that contact hundreds or perhaps thousands of internal board nodes. (See Sec. 55.4.2 in Chap. 55.) This can be a challenging mechanical proposition to implement, particularly when high-volume, reliable manufacturing is the goal.

Board designers must consider physical attributes of their boards early in the design process. They have a size target and then often find that there are density issues that may require fine-line geometries and two-sided component mounting to solve. The fact that in-circuit bed-of-nails access may be needed for testing should also be considered very early. See Ref. 2 for an excellent discussion of how test target pads need to be provided, and how artifacts of the board layout (particularly vias) may be used to satisfy some of these needs. However, due to the density revolution, full nodal access, which has been the holy grail of in-circuit testing, is often impractical. This leads to the question of what access is most important when full access is impossible. The answer to this question comes from the domain of circuit design.

56.3.2 Logical Access

Sometimes it is impractical to gain physical access to all nodes of a circuit. For example, Fig. 56.1(*a*) shows an IC

containing a large amount of complex logic, much of it deeply buried and effectively inaccessible from the I/O pins. Figure 56.1(*b*) shows the same IC with two additional gates added. The first is an exclusive OR gate that collects three buried signals, adds them together,[b] and brings the result to a spare I/O pin. This makes the states of those three signals much more observable. The second gate is an OR gate that allows us to insert a 1 from a spare input pin[c] into a deeply buried portion of the circuit. The assumption here is that the modified signal rarely reaches the 1 state in normal operation, so this extra controllability enhances our ability to manipulate the circuit for test purposes. Adding these extra gates can make it much easier to control and observe the performance of the IC. However, the downside is that we consumed a small amount of silicon area for the two gates, and, perhaps more importantly, we utilized two additional I/O pins. For many ICs, the extra cost of the pins could be a negative factor.

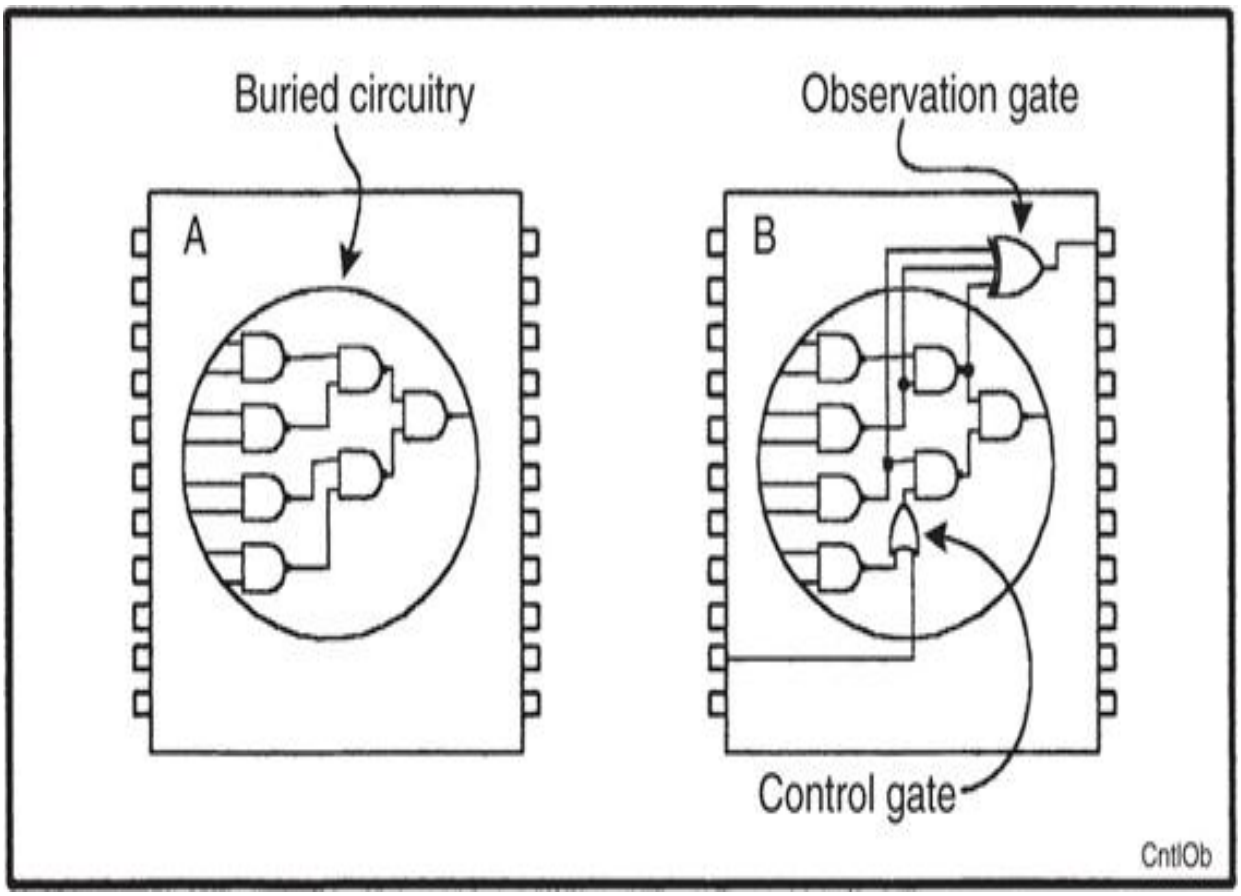

FIGURE 56.1 (*a*) An integrated circuit with deeply buried logic. (*b*) Same IC with controllability and observability logic added.

The choice of the optimal places to insert controllability and observability is not always clear, but rather is a trade-off of extra circuitry and pins vs. the difficulties that may be experienced in creating tests. There may be additional concerns as well with respect to circuit performance. For example, adding the controlling OR gate in Fig. 56.1 could add some signal propagation delay into the affected pathway, with detrimental results on system performance. When ad hoc circuit modifications are made for the sake of testability, it is likely that “seat-of-the-pants” decisions will be made rather than critical analysis. One person’s decisions might be remarkably different than another’s, with resulting great variability in testability improvements.

56.4 STRUCTURED DESIGN FOR TESTABILITY

Structured DFT was born inside companies that had vertical control over their designs, from custom ICs through systems. They also were well aware of their testing costs and realized that initial design decisions had a large impact on these downstream costs.

These companies studied the controllability and observability problems and instituted design rules into their design processes that, when followed, would guarantee that a circuit was testable. In the test department, where they also had complete control, they could utilize these added features with customized test development processes, gaining greatly enhanced levels of automation.

One of the earliest and most prominent structured DFT schemes was IBM's Level Sensitive Scan Design (LSSD), which was developed in the 1970s.[1] It is the precursor to what is called full internal scan technology now. In (greatly simplified) summary, LSSD design discipline requires every memory element (flip-flop or latch) to be constructed such that it obeys a testability protocol. This protocol allows two modes of operation: first, the normal operation of being a memory element in a design; and second, an operation for testing purposes, in which all memory elements can be connected into a serial shift register that can be loaded and unloaded by serial shifting. This makes every memory element a control point and an observation point within a circuit. No other memory elements are allowed in the design, e.g., no asynchronous feedback is allowed. This guarantees that circuitry between any control/observation point is combinatorial, not sequential (Fig. 56.2).

FIGURE 56.2 Circuitry made up of gates and flip-flops, redrawn to show that it can be represented as a bank of memory elements and a combinatorial circuit.

As might be imagined, these rules were looked upon by designers as restrictions of their creativity. Ed Eichelberger of IBM, a major proponent of LSSD, happens to stand about 5.5 feet tall. When asked in 1977 how designers received the LSSD rules, he quipped that, at the start, he was over 6 feet tall. Structured testability is not easy to implement. It requires commitment from the whole organization, starting with management.

The next piece of the puzzle was IBM's test generation software, which was able to automatically construct complete tests for combinatorial circuits (known as the D-algorithm and its derivatives). These tests could be shifted into the circuit and applied, and the results shifted out. This takes a lot of bookkeeping, but computers are good at that.

By using the LSSD discipline, IBM could verify that its designs would be completely testable, and those tests could be created by a computer program. Other companies such as Sperry Univac, Amdahl, Hitachi, etc., had similar proprietary structured approaches. Most smaller, nonintegrated companies were not able to participate in structured DFT—that is, until nonproprietary industry standards came into play.

56.5 STANDARDS-BASED TESTING

In the closing years of the 1980s, it became apparent that some sort of structured testability technology had to become accessible to the electronics industry at large. A small group of European companies led by Philips formed the Joint European Test Action Group (JETAG) and began work on a testability standard. The effort quickly attracted the notice of North American companies, giving rise to the JTAG standard.

As the proposal took shape, it was turned over to the IEEE, which ultimately produced IEEE Standard 1149.1-1990, Standard Test Access Port and Boundary-Scan Architecture,[3] in 1990.[d] Soon after 1149.1 came into being, a companion effort created IEEE Std 1149.4-1999, Standard for a Mixed-Signal Test Bus.[4] A complete coverage of these standards is beyond the scope of this chapter (see Ref. 5), so a brief summary is given here for an overview.

56.5.1 IEEE 1149.1, Boundary-Scan for Digital Circuits

The IEEE 1149.1 standard is a design discipline for digital ICs. It is a set of rules impressed primarily on the I/O structures of a device that allow two modes of operation, normal mode and test mode. In normal mode, the device performs its intended function. In test mode, the device obeys a protocol that has mandatory, optional, and customizable elements. The mandatory elements must exist, with the others being left as design options. The principle mandatory element of interest is a test mode dedicated to external test or EXTEST. When an 1149.1-compliant device is in EXTEST mode, its I/O pins are divorced from their normal operation and all internal functions of the device. Instead, the inputs become observation resources and the outputs become control resources[e] for test purposes. These resources are under control of the 1149.1 serial scan protocol. One can think of the I/O pins of the device being connected to shift register cells; states can be shifted in that will finally appear on all output pins (control) and the states of all input pins can be captured and shifted out (observe). This gives 1149.1-cognizant software a powerful tool for controlling and/or observing board-level node states. Figure 56.3 shows a simplified overview of the architecture.

FIGURE 56.3 General architecture of an 1149.1-compliant integrated circuit.

Boundary register cells interposed between the IC pins and the internal logic surround the normal content of the IC called the mission logic. A small state machine called the test access port (TAP) is used to control the test functions. Four mandatory test pins (test clock [TCK], test mode select [TMS], test data in [TDI], and test data out [TDO])[f] give standardized access to the test functions. All 1149.1 devices have a 1-bit BYPASS register used to bypass the (much longer) boundary register if it is not needed in a given testing activity. Figure 56.3 also shows an optional IDCODE register that can be shifted out to uniquely identify the IC, its manufacturer, and its revision.

It is intended that collections of ICs (called chains, as shown in Fig. 56.4) with 1149.1 be connected TDO-to-TDI so that they may form a long, shiftable register structure. The primary use for the 1149.1 EXTEST capability is to conduct board-level tests for shorts and opens. This is an example of how resources included in an IC design may be used to help with the testing problem at other levels in the manufacturing process.

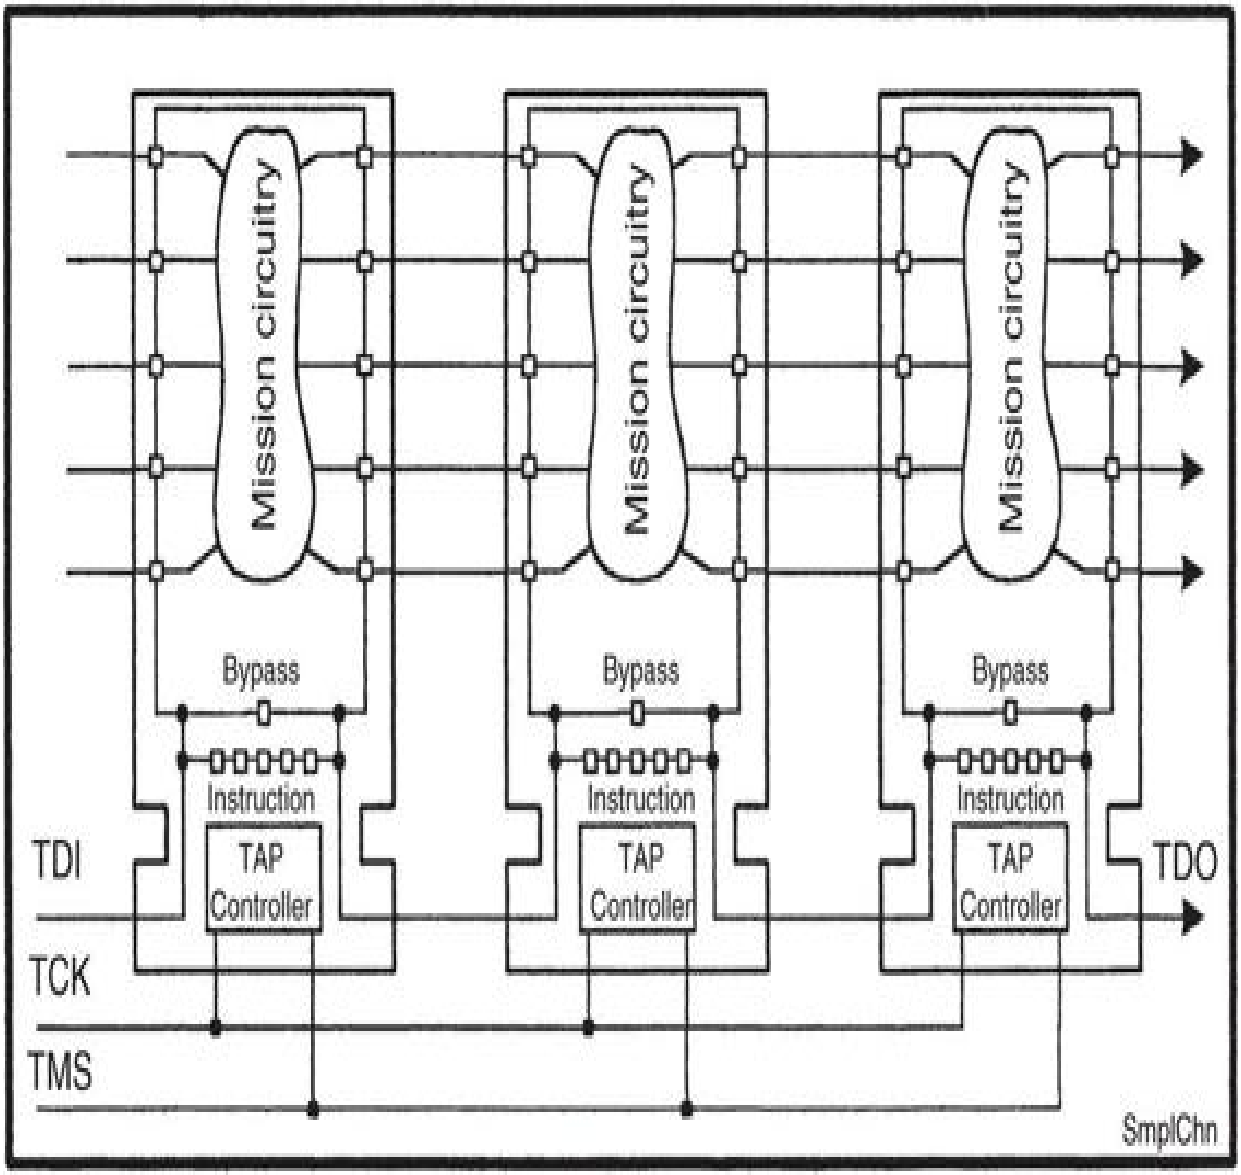

FIGURE 54.4 A collection (chain) of boundary scan devices can be used to test interconnections between ICs.

Briefly, interconnections between ICs are tested as follows. Consider the circuitry in Fig. 56.5. Some circuit nodes (also known as *nets* or *traces*) are accessible with a bed of nails and some are not. (To avoid clutter, the TCK and TMS signals are not shown.) Boundary scan can be used to test all the nodes; those with nails can be tested by coordinating nails with boundary scan resources and those without nails are tested solely with boundary scan.

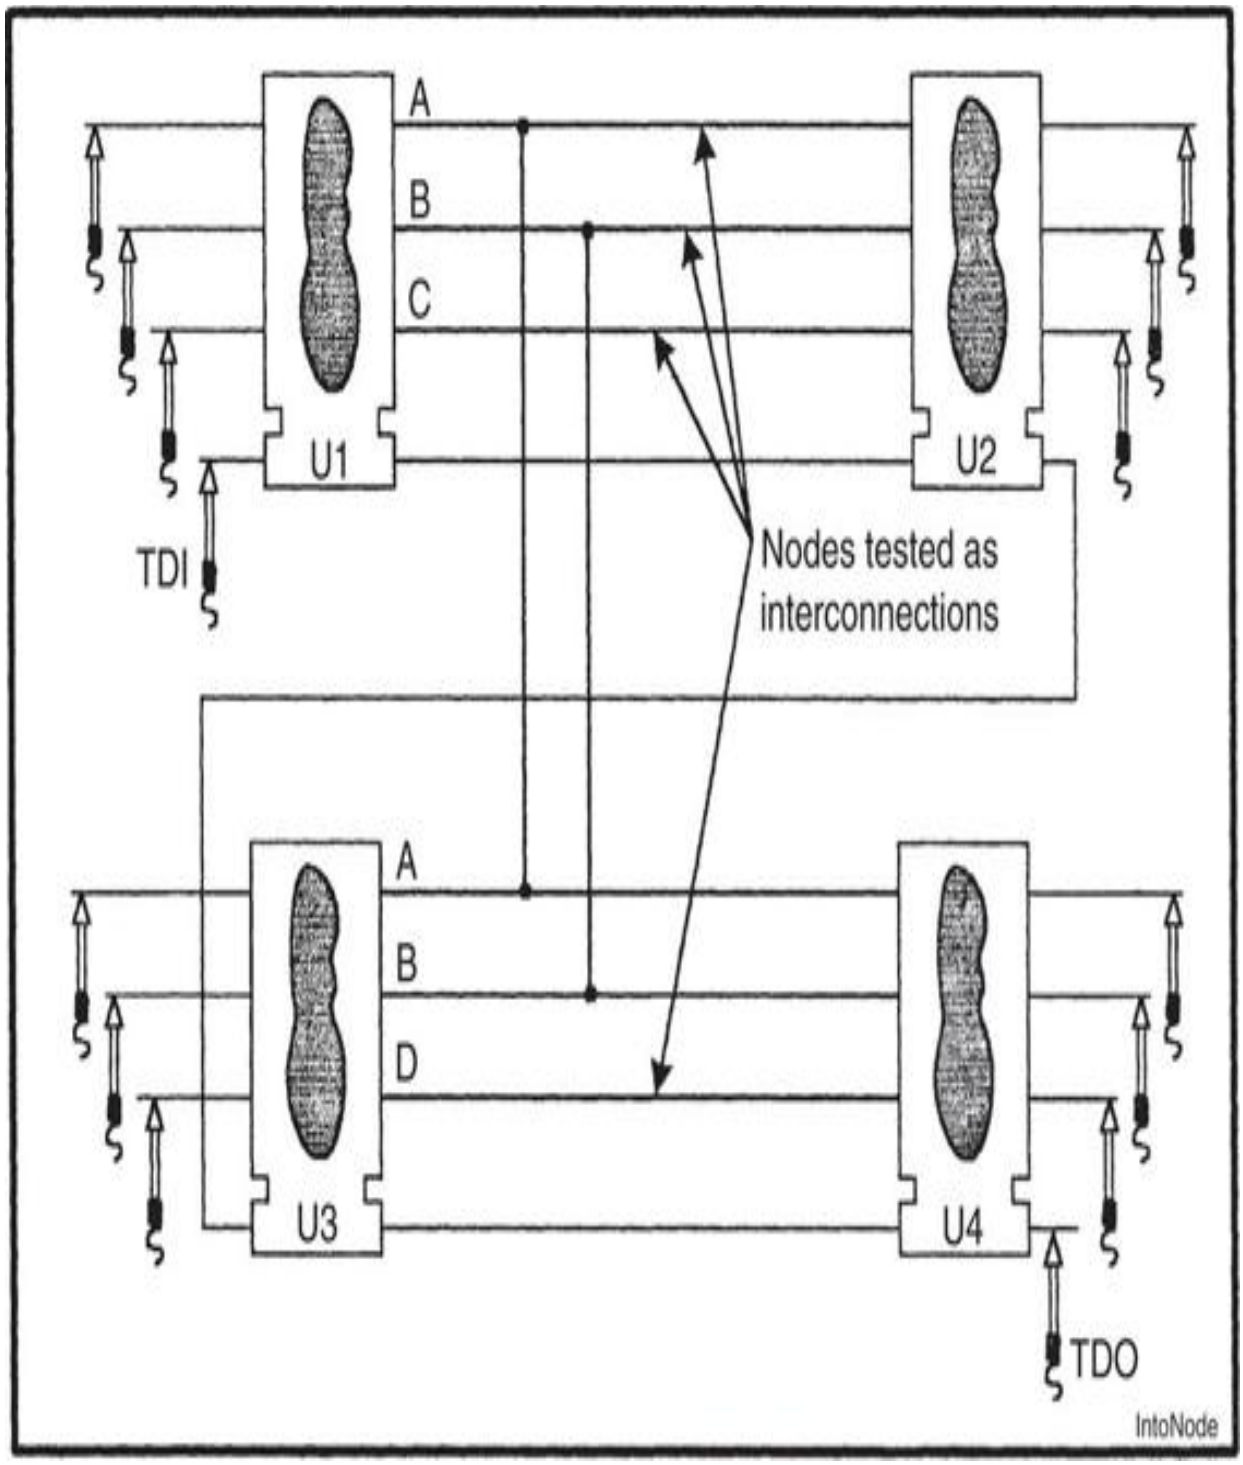

FIGURE 56.5 A set of boundary scan ICs with interconnections. Note that four nodes do not have bed-of-nail access.

As an example of this, boundary scan can be used to supply test patterns to nodes through a serialization process

that a human would find laborious, but that is simple for a computer. When a set of patterns has been delivered (to control) and monitored (to observe) by the appropriate boundary register cells, we have uniquely identified each node with a “signature.” A defect such as a short will cause two nodes to have deviant signatures, as shown in Fig. 56.6. Software can correlate observed deviations with the known boundary scan structure of each IC and the board netlist to yield a diagnostic message.

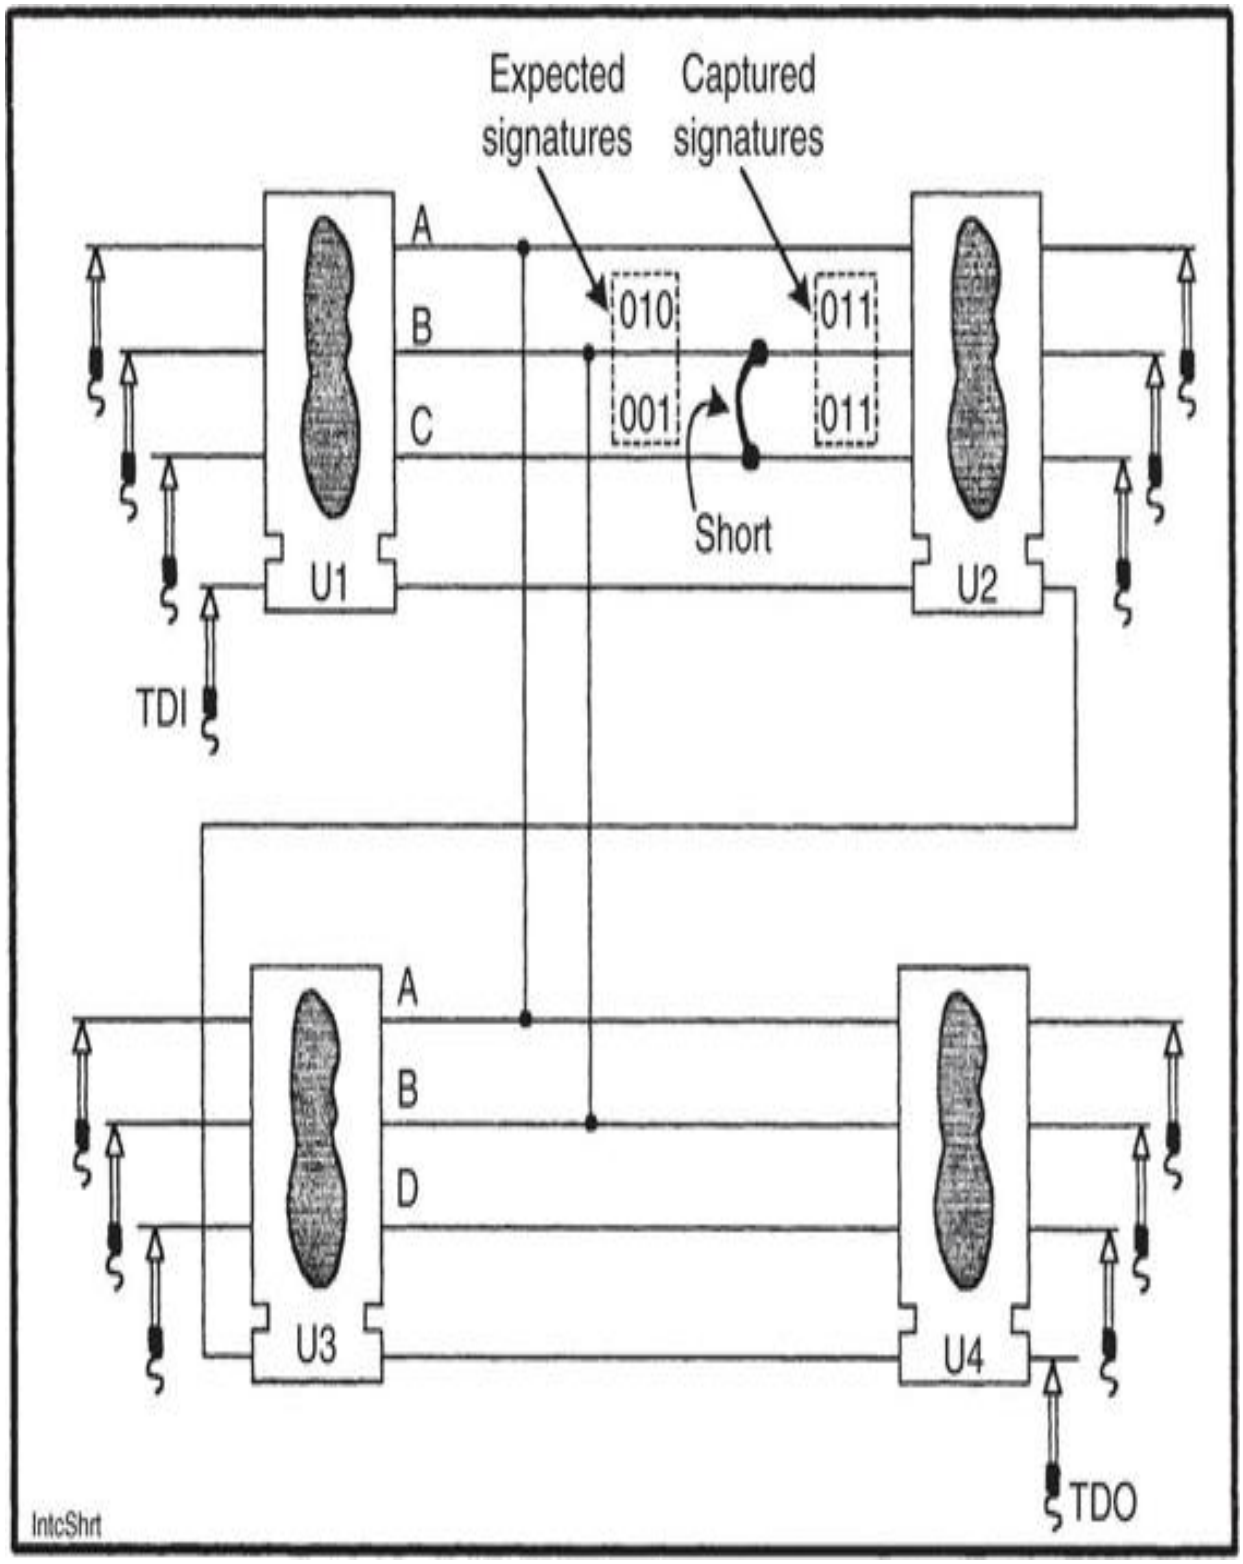

FIGURE 56.6 Interconnect testing drives unique patterns assigned to each node from drivers to receivers. In this case, a short is shown that creates a wire OR result.

The EXTEST capability can also be used during system testing to see if there are any system integration problems such as bad connections in backplanes and cabling. An IC designer may not see much attraction in EXTEST, but the 1149.1 standard offers other test modes that will allow a designer to access internal scan paths or built-in self-test functions. The 1149.1 standard's name has two parts, *Standard Test Access Port* being the first and crucially important one. It signifies that the standard anticipates being used as a standardized protocol for accessing any on-chip, board-level, or system-level testability scheme. In support of this, the standard is deliberately extensible, allowing clever designers to implement additional operational modes that can be used to solve unique testing problems.

The 1149.1 standard has proven itself to be quite useful and it has several contributions. First, it allows the creation of software that can automatically write tests for boards where in the past the same level of test effectiveness was nearly impossible to achieve, and then only with weeks or even months of skilled labor. It is not uncommon to see a boundary scan board test prepared in a single day that otherwise might have taken weeks. Second, 1149.1 ICs can "read" their input pins and scan out the result. This allows diagnostic software to pinpoint the location of open solder problems where in the past an IC might have been falsely indicted as faulty. Third, it allows tests to be performed on digital circuits without 100 percent accessibility to board nodes. With the trend toward miniaturization of components making it difficult to provide full nodal access, boundary scan is allowing the elimination of many access points. Of course, not all points may be eliminated, so one must understand which are still necessary. Finally, because many industry segments are affected by the test problem, a standard offers a way for everyone to benefit. One can find a large number of applications and tools available to solve testing problems that would not have been possible without a standard.

56.5.2 IEEE 1149.4, Boundary-Scan for Mixed-Signal Circuits

Boundary scan (1149.1) is a digital testability standard. However, there is also a trend in the superintegration of circuitry toward higher mixed-signal digital-analog content in our designs. The IEEE has developed a mixed-signal testability bus with a new standard 1149.4.[4–6] This standard is constructed as a superset of 1149.1 boundary scan, adding two additional analog test pins to the definition. The goal of the standard is to support opens and shorts testing of mixed-signal boards and to provide the capability of making analog value measurements of discrete analog components such as resistors, inductors, and capacitors without direct nodal accessibility, that is, a full bed of nails. (See Fig. 56.7.) It has been likened to in-circuit testing without a bed of nails, which is again not without caveats. (The elimination of test access points will still have to be done with thoughtful deliberation.)

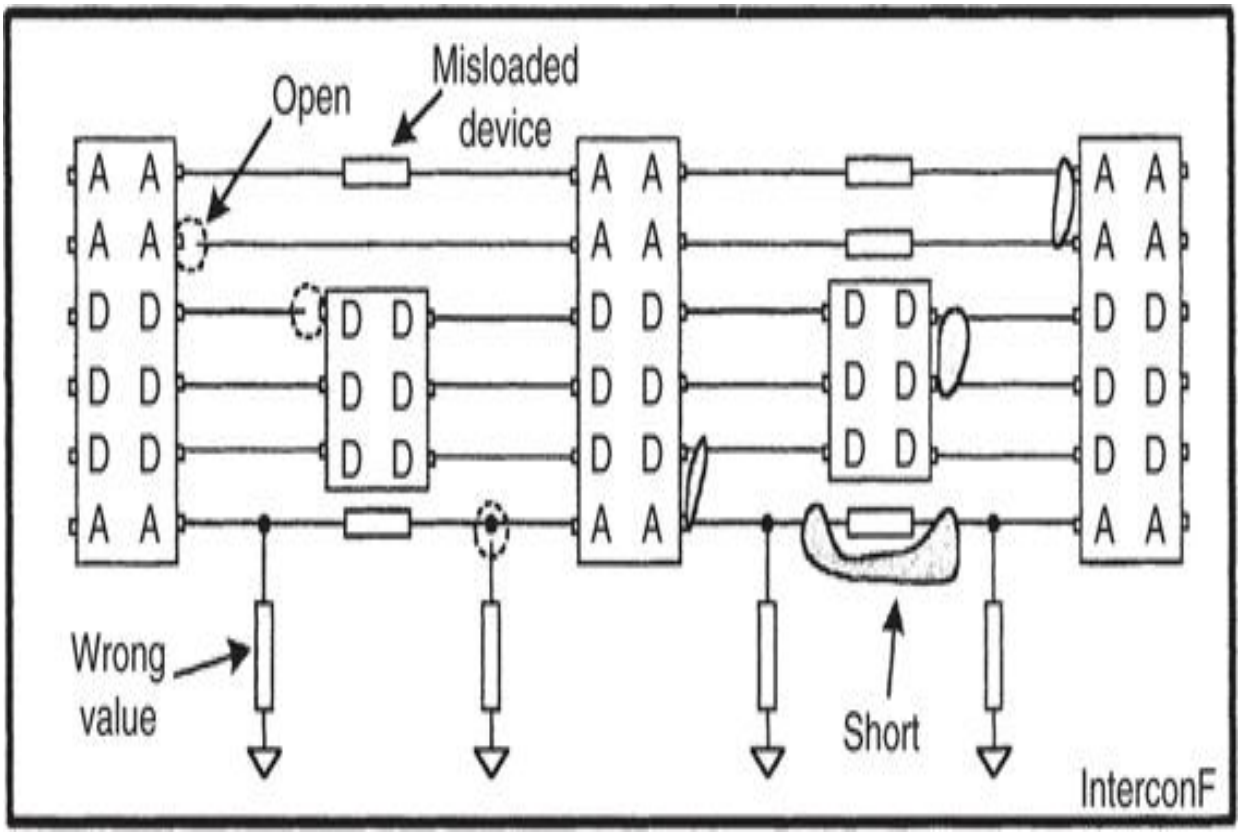

FIGURE 56.7 A mixed-signal circuit with some possible defects. IC pins marked A and D are analog and digital, respectively.

A mixed-signal device constructed with 1149.4 has the general architecture shown in Fig. 56.8. It is in many ways identical to an 1149.1 IC, but it has an additional analog test access port (ATAP) that is used to facilitate the control and observability of analog signals at device pins. The ATAP brings into the IC two additional analog signals that are used during testing.

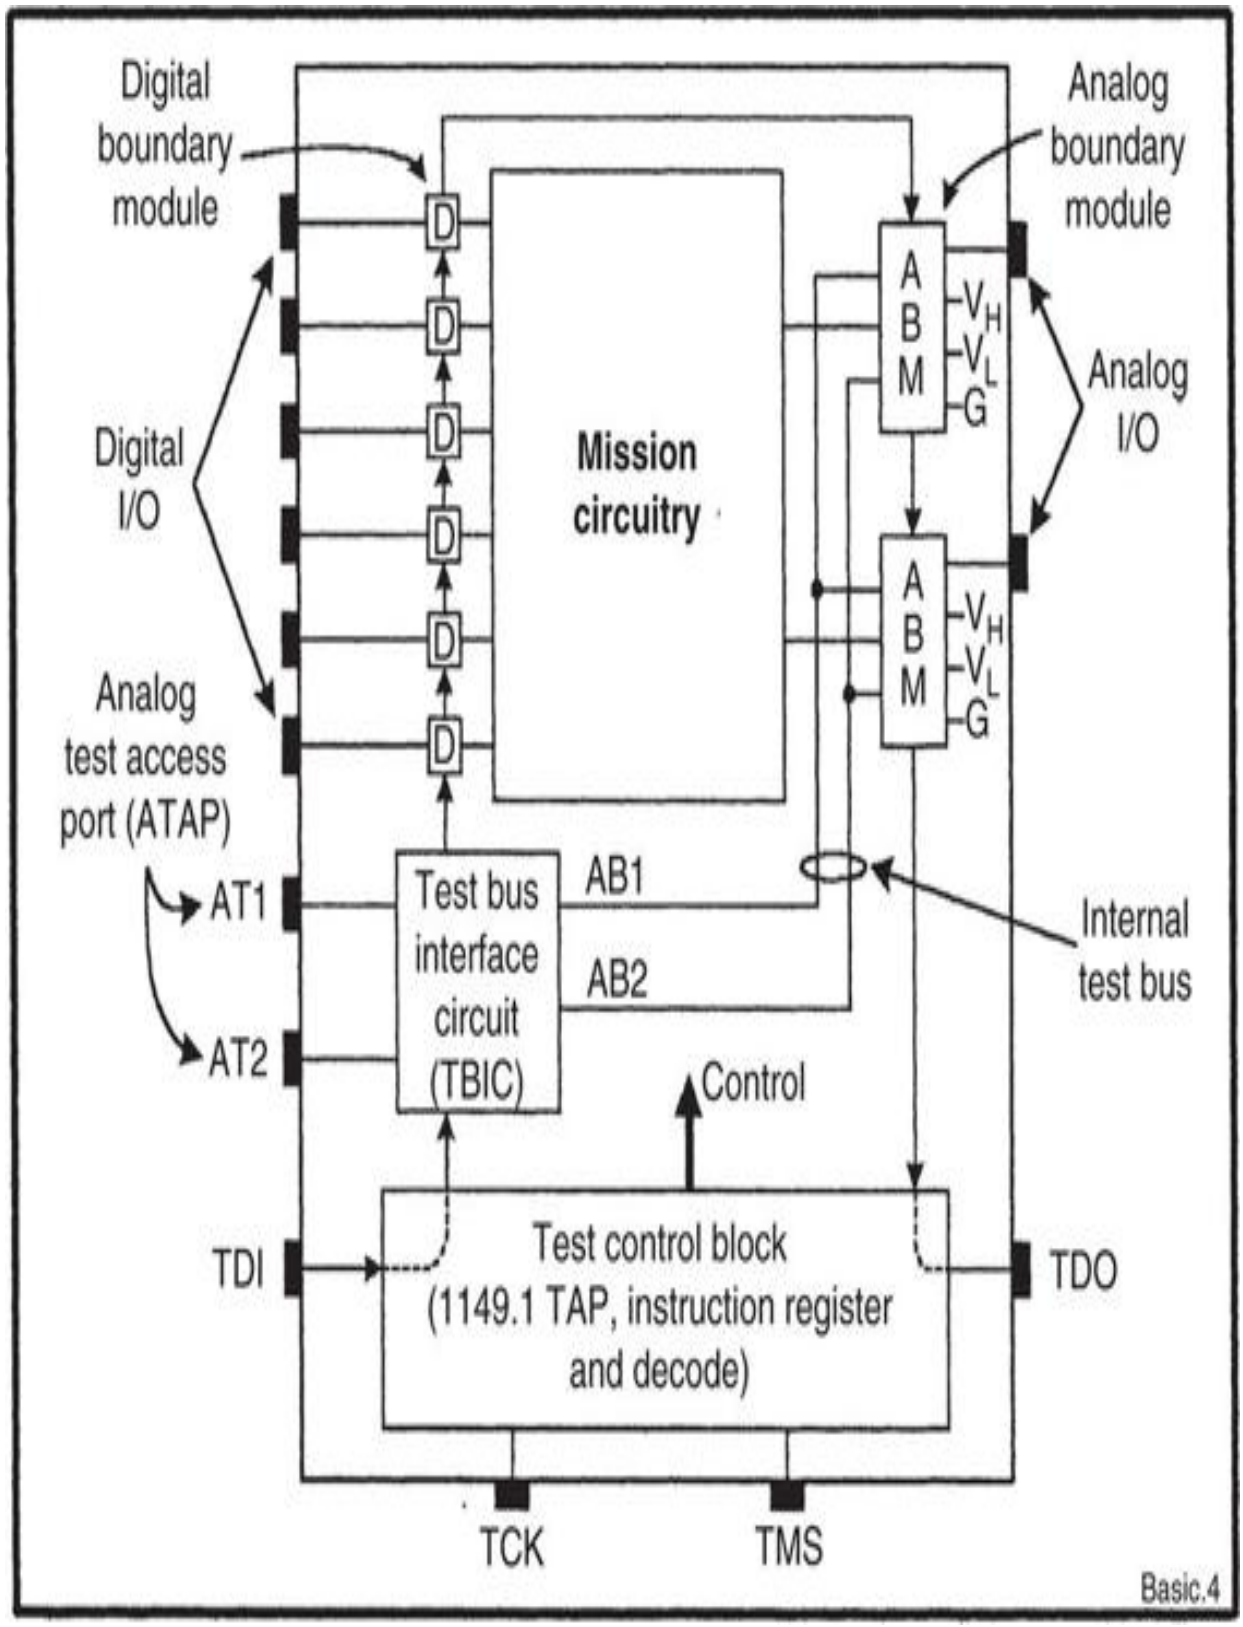

FIGURE 56.8 General architecture of an 1149.4-compliant IC.

With 1149.4, digital device pins are treated exactly as done with an 1149.1 boundary register. Analog pins have an augmented structure called an analog boundary module (ABM) as part of the boundary register. The ABM allows an analog pin to be tested for simple shorts and opens (this is called 1149.1 interconnect test emulation) as well as allowing the injection and/or observation of analog signals via the ATAP.

An ATE system can utilize the test resources in an 1149.4 IC as shown in Fig. 56.9. This requires the coordination of a digital test sequencer with analog test resources—in this case, a current source and voltmeter. Pathways from these resources and through the 1149.4 IC can be used to make measurements on discrete analog components on a board, even with no bed-of-nails access to the components.

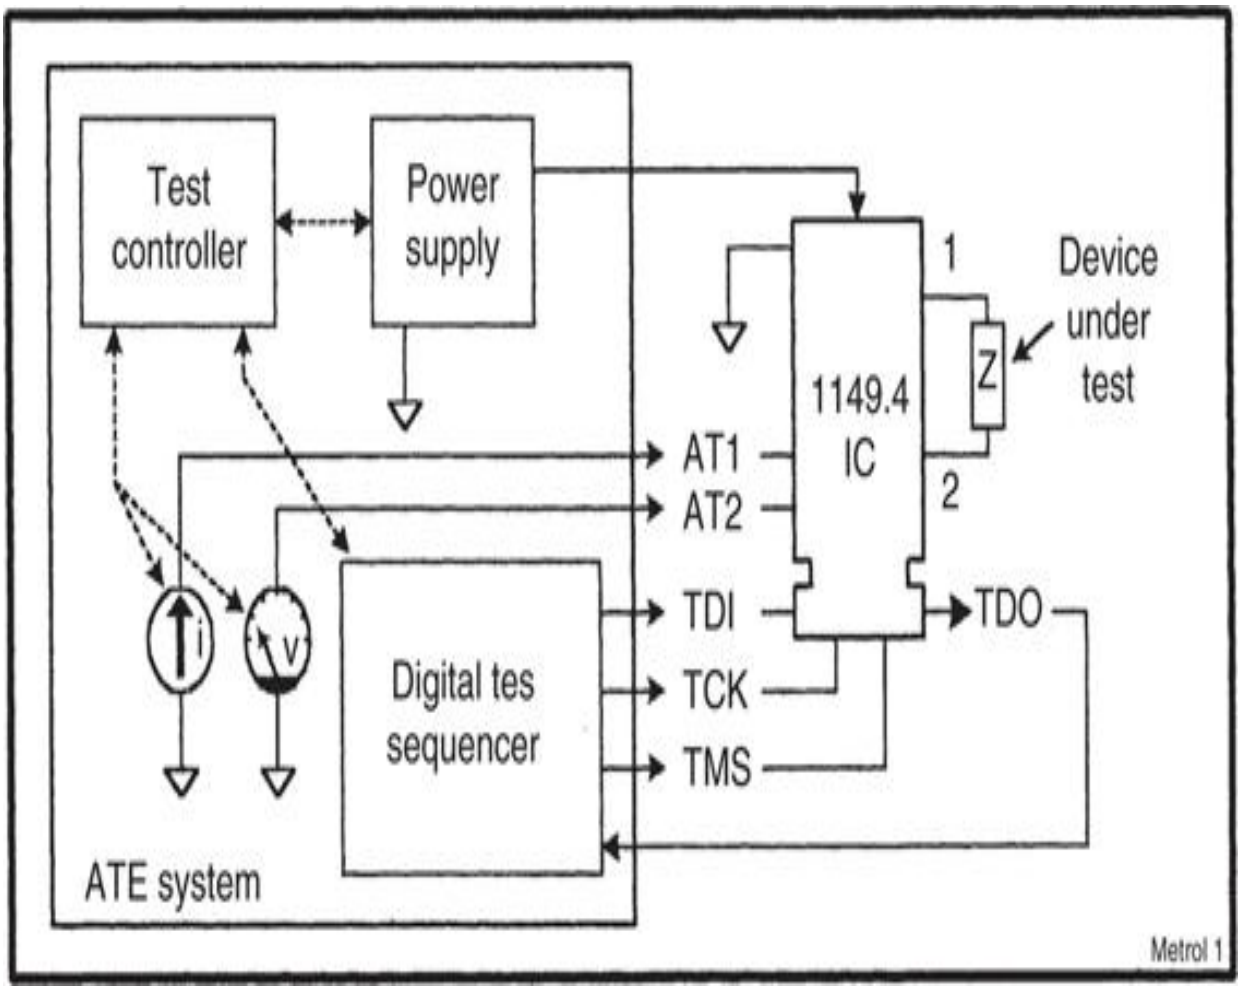

FIGURE 56.9 An ATE system can use 1149.4 resources to gain access to discrete analog components.

The pathways needed for a measurement are provided by silicon switches in the ABM. Because switches implemented this way have significant nonlinearity and nonnegligible impedances, these must be accounted for in the measurement processes. Figure 56.10 shows how an analog device can be tested with two measurements. First, the tester's current source is connected such that current can flow along AT1 into the IC. There it flows on the AB1 bus inside to the ABM connected to pin 1 of the IC. The current flows through Z and then into pin 2 of the IC. Pin 2's ABM directs the current to ground, completing the current path. In Fig. 56.10(*a*), the ATE system's voltmeter is connected via

the path AT2-AB2 to the ABM on pin 1, where it can observe the voltage at the top of Z. In Fig. 56.10(*b*), the voltmeter is switched to measure the voltage at pin 2, the bottom of Z. Subtracting the two voltage measurements gives the voltage drop across Z for a known current. Ohm's law gives us the value of Z, which we can check for the right value. This process works even with suboptimal silicon switches because we are using a current source to provide the known current and because the voltmeter pathway consumes a vanishingly small current and thus does not affect the accuracy of the measurement.

In the future, with these and other standards, test engineers may be able to do complex tests on superdense circuitry with far less nodal access than they were afforded in the past. This will be an enabling technology because without it the electronics industry may find it uneconomical to produce superdense designs except in very high-end applications.

[a] This survey does not cover the topic of standards-based testing (Sec. 56.5), because the testability standardization work promulgated by the IEEE began in the later 1980s.

[b] The addition is modulo-2 yielding a single bit. Any single-bit error delivered to the three inputs of the exclusive OR will cause the output to change from its expected state.

[c] This spare input pin should be held to a 0 value when the IC is performing its normal function. A pull-down resistor to ground could assure this, whereas during test, a tester signal could assert a 1 value when needed for testing.

[d] An IEEE standard has as a suffix the year of its creation or last update. A standard must be updated and/or reaffirmed every 5 years. Up to two supplements to a standard may be issued within the 5-year cycle. Users of a standard should keep up to date with it.

[e] Bidirectional signal pins can both observe and control the nodes to which they are connected.

[f] An optional fifth pin called Test Reset (TRST*) is an asynchronous active low reset for the 1149.1 circuitry. Because any TAP can be reset by five clock pulses to TCK while TMS is held high, TRST* is not actually needed for resetting an 1149.1 device. It is often included as a fail-safe measure with a board-level pull-down resistor providing a constant reset to the TAP. Many 1149.1-compliant ICs do not include the TRST* pin because the extra pin required may be too costly.

CHAPTER 57
LOADED BOARD TESTING

Kenneth P. Parker
Agilent Technologies, Loveland, Colorado

57.1 INTRODUCTION

Printed circuit boards, like everything else in the electronics industry, have been undergoing rapid technological evolution. This is only natural because everything, from the boards themselves, to the CAD systems that create them, to the components that populate them, to the assembly methodologies used to fabricate them, has been undergoing similar changes. These changes have common themes: greater functional density, better performance, improved reliability, and lower cost.

In the early 1990s, the move toward surface-mount technology (SMT) accelerated to the point that SMT designs became the rule. SMT supplanted, in large part, the familiar 100 mil centered through-hole package technology. The change came slowly, embraced by leading-edge applications that needed the density improvements that came with SMT. Many held back because they did not have a need for higher

densities and could not justify the risk of putting new processes in place to manufacture with SMT. The process of perfecting SMT brought to light a surprising fact—it was more efficient once the necessary automation was put in place and perfected. There are now applications that use SMT not because of the density improvements it affords, but rather because of the efficiency it provides. This is confirmed by the fact that many new devices can no longer be obtained in the old-style through-hole packages.

Along with SMT came increases in lead pitch density. First there was 50-mil pitch; soon came 25-mil pitch, then came 15-mil pitch, and so on. Other technologies such as tape automated bonding (TAB), chip-on-board (COB), multichip modules (MCM), and ball grid arrays (BGAs) are gaining acceptance. The industry has for some time been in the midst of a packaging revolution. This revolution has applied to boards as well. The average board, by virtue of high-density interconnect (HDI), now has more layers, finer lines and spaces, buried vias, devices mounted on both sides, and so forth. The net result is that loaded printed circuit boards are becoming incredibly densely packed with highly sophisticated components. We are in fact experiencing a density revolution. Figure 57.1 shows a range of common electronic devices superimposed on a penny to show scale.

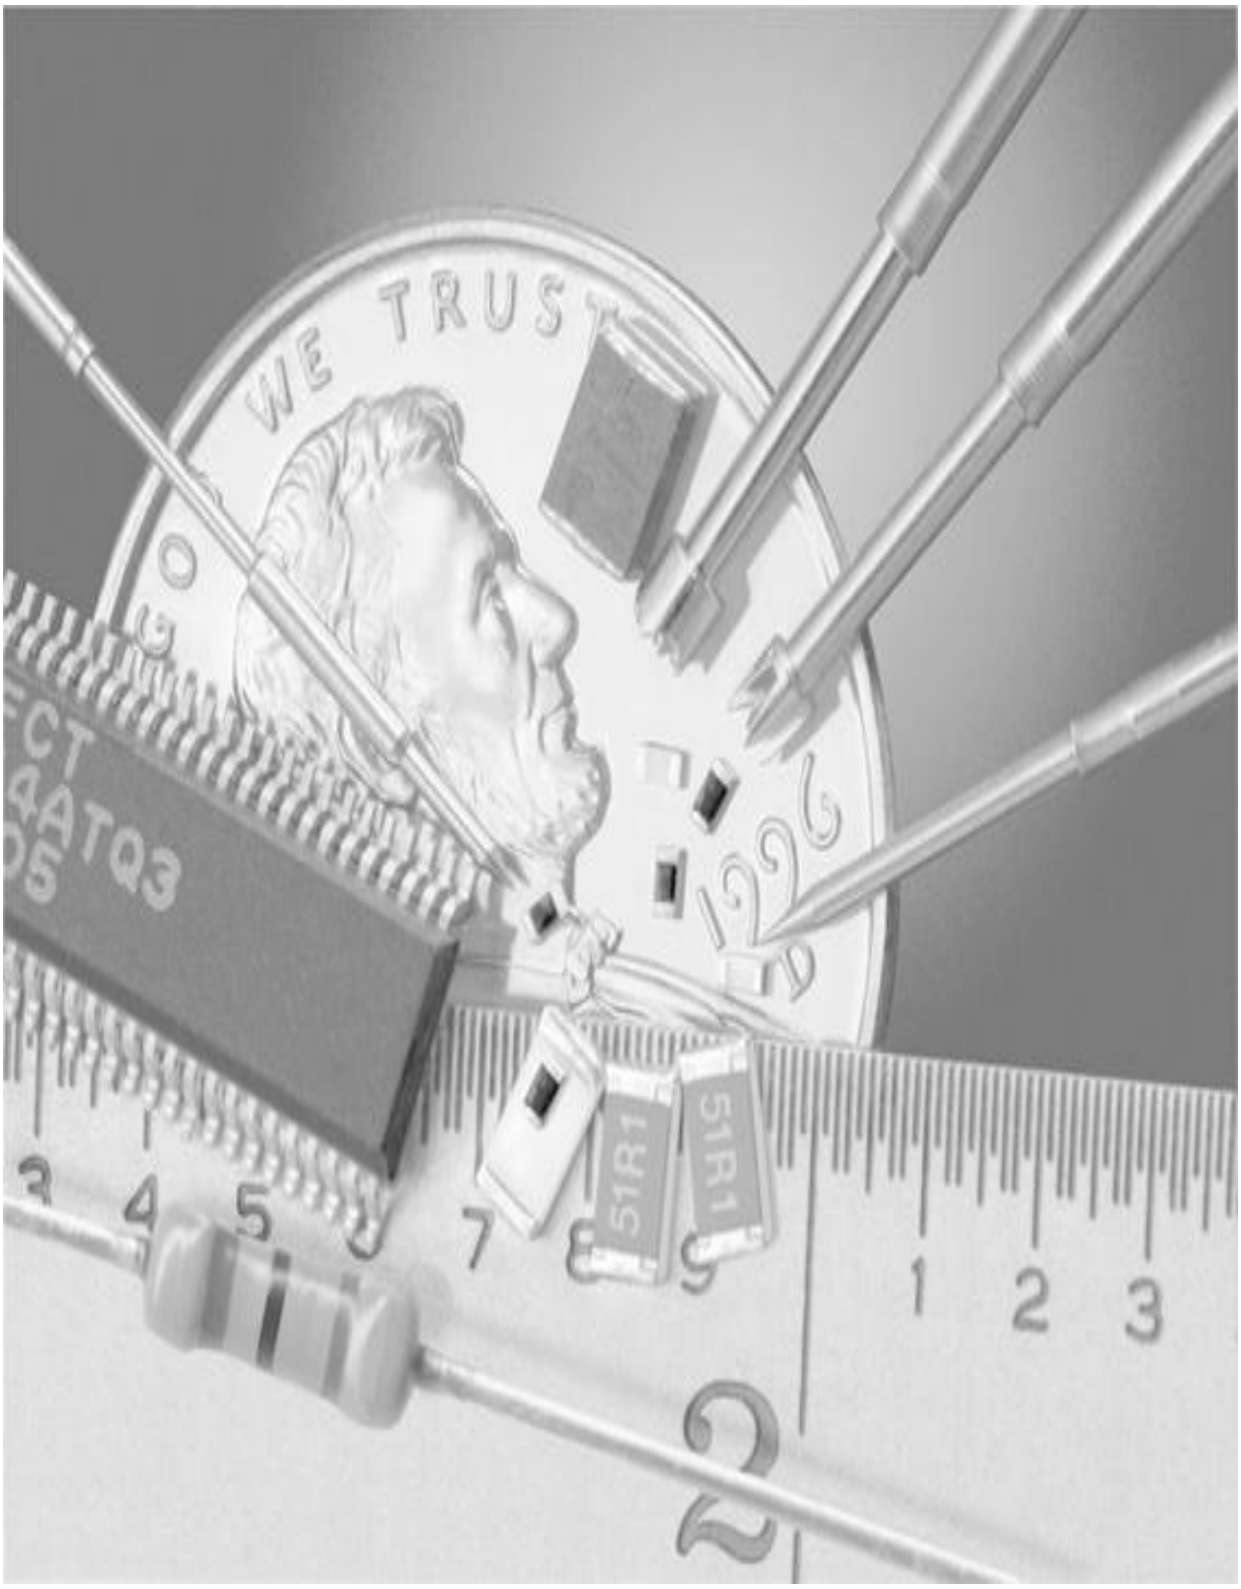

FIGURE 57.1 A US penny shows the size of some common PC board components, some older, some recent. The small black devices near Lincoln's bow tie are 04-02 (40 × 20 mils) surface-mount resistors. (Now 02-01 [20 × 10

mils] devices are being used.) Some 100-, 75-, and 50-mil test probes are shown for comparison. Note the lettering on the penny is done with 10-mil lines and the width of the circular part of the 9 is 35 mils, a common probe target size. *(Photograph courtesy of Agilent Technologies.)*

Testing has been impacted by all these changes. If perfect components were fed through perfect processes utilizing perfect machines run by perfect employees—testing would not be needed! Unfortunately, nearly perfect components are fed through processes that are subject to drift in many of the hundreds of variables that govern them, using machines that require careful calibration and preventive maintenance, operated by people who tire and err. For these reasons, testing is still an important part of loaded board manufacturing. However, as a result of the miniaturization brought on by the density revolution, our ability to gain the physical and electrical access needed for testing purposes is increasingly hampered. Because access to a circuit is crucial for testing, accessibility difficulties make testing steadily more difficult to accomplish. On top of this, the electronics industry is expected to provide continued improvements in cost, reliability, and quality. Testing plays a crucial role in these improvements, as will be seen.

57.2 THE PROCESS OF TEST

In the earliest years of the electronics industry—indeed, before anyone may have called it an industry—there was no concept of test. A product was put together and shipped, because inherent in the putting together was a basic appreciation for how the product was supposed to look and behave. This crafting quickly gave way to mass production[a] of somewhat more complicated items by workers who were not themselves experts in the craft. Of course, today, workers with little or no fathoming of what it is they are

producing turn out items of unbelievable complexity. If they had to know everything about the process, it would undoubtedly be too expensive to make the product.

It is also important to appreciate that boards are often themselves components of systems. Boards might have a respectable yield from a board test process of, say, 97 percent, which is to say, 3 of 100 still contain defects.[b] However, if 20 such boards are used in a system, the probability that the system will turn on is only 54 percent.[c] Because debugging a system is usually far costlier and more difficult than testing a board, there is much interest in higher post-test yields. This is why yields are being pushed into the 99 percent and higher levels.[d]

Test has gone through three stages of evolution during this time. It has been used as a sorting process, then as a repair driver, and finally as a process monitor.

57.2.1 Test as a Sorting Process

Test can be used to sort boards into two piles, good and bad. Essentially, such testing provides only one bit of information about a board. This one bit of information provides little clue as to what the problem is or how to repair it. If all we intend to do with a bad board is discard it, then one bit of information may be enough. In some applications, for example making $2 digital watches by the million, it may be economically impossible to attempt to repair bad units. However, as will be seen soon, discarding bad boards may also lead to discarding of valuable information about the health of our manufacturing process.

57.2.2 Test as a Repair Driver

It is very often economically justifiable to repair a bad board, if it can be done quickly and with little skilled analysis needed. This is where modern test systems begin to come into their own. More bits of information are needed per bad board; a diagnostic test is needed that accurately resolves failures into defect reports that can be acted upon to effect repairs. Because a freshly repaired board will need retesting to ensure it is now defect free, one also would like to find as many defects as feasible in each pass across a tester to avoid a glut of work in progress.

57.2.3 Test as a Process Monitor

When repairing boards, valuable information about the health of our board manufacturing process is at our fingertips. Indeed, the repair process may have the ultimate defect resolution because faults detected by a tester may still not be perfectly correlated with defects (see Sec. 57.3). If one views test as a process monitor, one can gain valuable insight into what is happening upstream in many of the subprocesses that come together to produce boards. For example, one may see solder opens as a chronic problem. Further examination may show that they are happening in one area of a board more than in any other. That may lead to the examination of the solder application process, which shows that a solder screen squeegee has an uneven amount of solder paste on it. The root cause of this uneven distribution of paste can then be sought and corrected.

It is quite important for the tester to do a good job of resolving faults into defects. Using an example of solder opens on digital devices, digital in-circuit test (detailed in Sec. 57.5.2) alone may indict devices as failing when it is really more of an open solder problem. The repair technician may notice this. However, it may well be overlooked because replacing the device “fixes” the problem. This pollutes the

information about our process, causing one to call the IC vendor with complaints when one should be examining the solder process. If tests are focused more closely on defects than on faults, then one may be able to better trust tester-derived process information. This requires test engineers to be students of their manufacturing process and available test technologies so that test techniques are kept in balance with the defects that are most important.

57.3 DEFINITIONS

Testing is a word often used in a vacuum. What are tests actually looking for? The answer to this question has a huge impact on how to go about testing effectively. It makes little sense to test meticulously for problems with low likelihood of occurring, just as it makes little sense to inadequately test for likely problems. However, many of the terms used in the testing industry are overloaded such that surprisingly little agreement on their definitions may be found. Worse, this confusion is often not realized, which complicates communications between process people, test people, and equipment vendors.

57.3.1 Defects, Faults, and Tests

57.3.1.1 Defects. A *defect* is an unacceptable deviation from a norm. As an example, a bond wire could be missing in an IC. This defect may in turn be due to a problem (the “root cause”) in a wire-bonding machine, such as it misfeeding wire. Other deviations may not be considered defects, but rather acceptable variations. For example, the plastic used to encapsulate a component may have significant variations in color that are still considered acceptable.

Defects require remedial action of some sort. Most often, defects lead to a repair operation that removes the defect and restores the product to acceptable status. In some cases, a defect may not be economically repairable and thus causes scrap. It is also possible that a defect will be overlooked and thus be delivered within a product to an end customer. In some cases, such as the manufacture of $2 wristwatches, some amount of defective product may be deemed acceptable. However, for many products, defects perceived by end customers can have grave economic consequences and are strenuously avoided.

57.3.1.2 Faults. A *fault* is a physical manifestation of a defect. (The word *fault* is often used synonymously with *failure*.) Thus a fault reveals the presence of a defect. A single defect may cause several faults (i.e., have several different manifestations), and a single fault could be the manifestation of several different defects.

A defect shows up as a fault. For example, the aforementioned missing bond wire on an input to a logic gate may cause it to see a permanent logic 1 rather than a time-varying signal. Several other defects can produce this same fault behavior. For example, missing solder between the input pin and the board, an electrostatically damaged input buffer within the IC, or a broken printed circuit trace between the upstream driver and the input will all exhibit the same faulty behavior. Similarly, one defect may cause several fault manifestations. For example, an open solder joint on an input pin (particularly a reset input) may cause an IC to show incorrect results, and these incorrect results vary in time.

An observed fault is not always a reliable pointer to a defect. For example, if an IC loaded onto a board has defective solder on one input pin causing an open circuit, this may appear to the IC to be a permanent, stuck-at-1 fault on that input. This faulty behavior may not be readily

apparent because the effect of the erroneous logic 1 must propagate through the internal workings of the IC before its effects (improper output behavior) are seen.[e] When this faulty output behavior is finally observed, it can be a highly challenging task to relate this observed behavior to the input stuck-at fault caused by the defective solder. This is illustrated in Fig. 57.2.

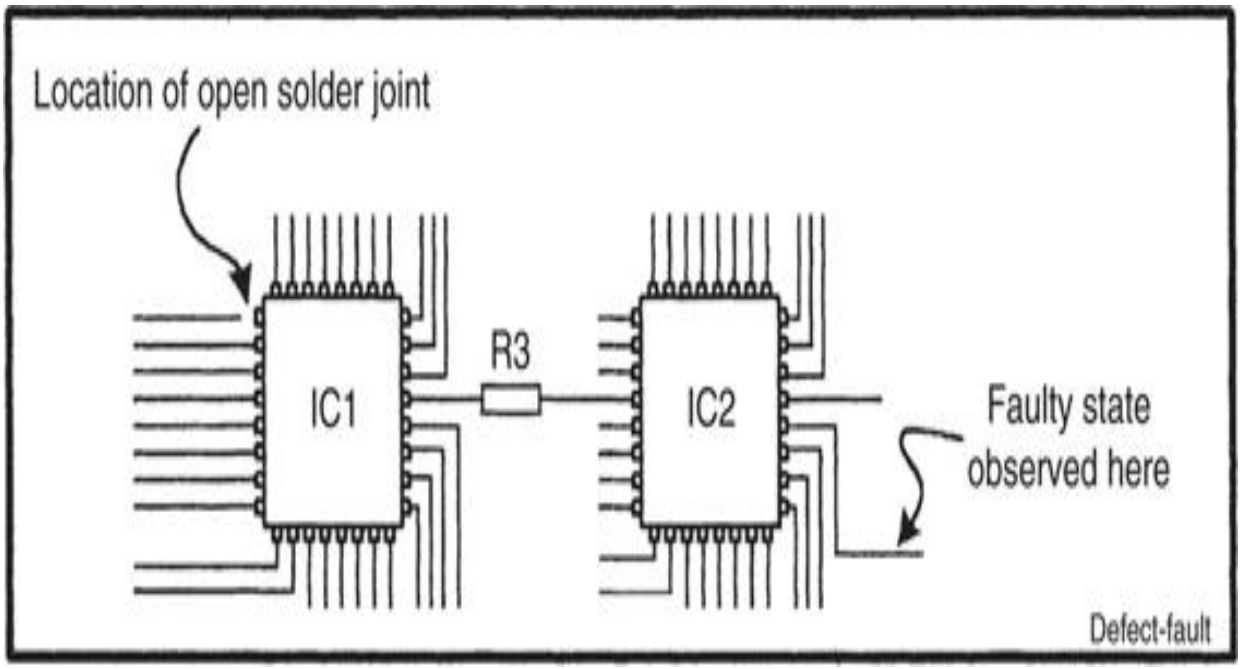

FIGURE 57.2 A defective solder joint on an input pin to IC1 causes a fault on an output of IC2. Note that IC1, R3, and IC2 are suspect, as well as six solder joints, two IC input buffers, two IC output buffers, and four IC bond wires.

57.3.1.3 Fault Syndromes. A *fault syndrome* is a collection of measured deviations from an expected good outcome. For example, a digital device may produce an incorrect response on several of its outputs when its inputs are stimulated in a certain sequence. The incorrect pins, their states at the point where they were incorrect, and the point in time where each failure was noted form a fault syndrome.

57.3.1.4 Fault Detection. A fault is *detected* when an operation with an expected outcome is conducted and this outcome is not observed. For example, when you turn on the power to a personal computer, you expect to see it boot up. If it doesn't, then you have detected a failure of some kind. There could be a plethora of reasons for this result, but you have little information to act upon. In other words, the underlying defect may not be easily resolvable.

57.3.1.5 Fault Isolation. A fault is *isolated* when an operation with an expected good outcome and one or more failing syndromes is conducted and the outcome belongs to the set of failing syndromes. For example, as your personal computer boots up, it may do a series of self-test operations. If any of these fail, a diagnostic message may appear on the screen that specifically identifies a failure. Again, the underlying defect may not be easily resolvable, but there is more information to act upon than you had when the fault was simply detected.

57.3.1.6 Tests. A *test* is one or more experiments that are specifically constructed to detect (and possibly isolate) failures. A *detection test* has an expected good outcome. An *isolation test* has an enumeration of possible fault syndromes indexed to specific failures. Thus, when a test fails, it provides us with information: a single bit of detection information, or a fault syndrome that may match an enumerated outcome, pointing to a fault.

A well-constructed detection test will detect a large number of potential failures. A well-constructed isolation test will accurately resolve a failure from a large list of potential failures. Note that an isolation test may encounter a failure that it was not constructed to isolate. If it fails (that is, if it detects the fault), it may not produce a syndrome that matches one from its list, or it may produce a match that is

erroneous. In either case, it has been reduced to a detection test.

Remember that an isolation test may point to a fault, but the fault may not be a good indicator of the actual defect that is present. For this reason, it is important to construct tests that target expected faults and that accurately resolve underlying defects. When defects are resolved correctly, it is then much easier to find and correct the causal problems.

There are, in general, three categories of faults being tested: performance faults, manufacturing defects, and specification failures.

57.3.2 Performance Faults

A *performance fault* is a fault in the performance of a system that occurs due to a mismatch of important parameters among the system's components. This mismatch is the defect. As a common example, the path delay seen by a digital signal as it passes through several components may exceed the intended design value, causing a malfunction. No single component in the path is defective, but the cumulative contributions of several components cause the performance fault. The repair for this defect is to replace one or more components in the path with new components specifically selected to give the proper delay.

There are several problems with testing for performance faults. First, the test developer must know about the circuit design in great detail. Second, it is difficult to set up a test that can resolve faults into specific defects (for example, the mismatch of parameters in several components). Third, it is difficult to avoid being confused by unanticipated defects that produce behaviors similar to the defects of interest.

Solving these problems implies great knowledge and understanding of a board design. Indeed, in some instances in a carefully designed board, the designer may have specific

knowledge of some critical parameter that has to be precisely managed and can alert those responsible for test. However, much of the testing for performance faults carried out in the past was not done with this knowledge, but rather because of a lack of this knowledge. In the past, tools that could help control the key parameters of a design were unavailable, or designers were using components that were incompletely specified, or perhaps they were too trusting of their “seat-of-the-pants” instincts. It was expected that performance testing would give adequate coverage of any problems that might occur. In effect, performance testing was used to validate a design after the fact.

The expectation that performance testing will somehow protect products from the effects of poor design is now obsolete. It amounts to wildly shooting in the dark against a well-hidden, stealthy enemy force of unknown size and distribution. Given the ever increasing complexities of boards, it is simply not reasonable to expect that test engineers could stumble at random across effective tests for all possible design problems, and certainly not within the lifetime of the design. With the increase in effectiveness of design tools, designers should no longer be relying on test for design validation. Testing for performance faults will still be important, but it must be used in its proper role—to verify that critical parameters identified in the design process are properly controlled.

57.3.3 Manufacturing Defects

A *manufacturing defect* is a defect resulting from a problem in the manufacturing process. Manufacturing defects tend to be fairly gross in nature. Table 57.1 gives a list of potential manufacturing defects.

TABLE 57.1 Examples of Manufacturing Defects Seen at the Board Level, Sources of the Problems and Causes

Defect	Source(s)	Cause(s)
Shorts between solder pins	Wave/reflow soldering	Too much solder, solder screen defect, pin misregistration, bent pins
Solder open	Solder application, wave/reflow soldering	Too little solder, solder screen defects, tombstoning, bent pins
Missing component	Placement, soldering	Shock, abrasion, too little glue
Wrong component	Placement setup, inventory, handling	Handling error, mismarked packages, operator error, wrong specifications
Misoriented component	Placement setup	Handling error, operator error
Dead component	Placement, soldering	Dead on arrival, handling damage, electrostatic damage

Manufacturing defects are the result of the havoc inherent in manufacturing processes. These defects result in faults that may be very easy to detect and to correlate with their root cause(s), but this is a function of the test approach. Some manufacturing defects can still be difficult to detect and resolve, as the example given of a solder open on a device input pin shows (Fig. 57.2).

57.3.4 Specification Failures

Specification failures are similar to performance faults. Performance specifications are checked against requirements for the full range of operating conditions expected, such as temperature, humidity, vibration, electronic noise, etc. Specification test is often a regulatory or contractual requirement. One may argue that these

specifications are largely unnecessary because, if a circuit design is robust, makes use quality components, is accurately assembled, and is thoroughly tested for manufacturing defects, one does not have to make it perform all of its functions to know that it works. This is the “proof by construction” argument, used by successful manufacturers of kitchen matches and bomb detonators. Full specification test may also be impossible in practical terms because there may be too many combinations of circuit functions versus operating ranges. If only a subset of combinations is to be checked, this begs the question of which subset.

If specification test is required nonetheless, such testing is usually carried out with custom-tailored test equipment that can simulate the range of operational environments of interest. Such testing may be quite time consuming, and the cost of the supporting test equipment may range from trivial to hyperexpensive. At one extreme, a manufacturer of I/O cards for personal computers may simply plug each one into a computer and see if it performs a simple loopback test. At the other extreme, a manufacturer of guidance computers for missiles may require a missile shot on a test range, full telemetry, and support from the Air Force and Navy. The bottom line is that you should seriously question the motivations for and expectations of testing for specification faults.

57.4 TESTING APPROACHES

We have seen a spectrum of faults, performance faults, manufacturing defects, and specification faults. Each has evolved a test technology.

57.4.1 Testing Boards for Performance Faults

Performance testers are often known as edge connector functional testers. They connect to the edge connectors of the board under test with mating connectors that are then adapted to the tester resources by a customized fixture called an adapter. In most cases, no other connections are made by the test fixturing to any internal nodes of the circuit. In essence, the board is tested in an environment that resembles its application environment to some degree.

Some performance testers have guided probe capability.[1,2] A guided probe is a manually positioned test probe with a measurement (and sometimes stimulus) capability and supporting software. It is used to temporarily gain access to internal nodes of a circuit, one at a time, where observations of internal circuit behavior during a test can be made and processed by software to provide enhanced fault resolution.

How does this software know what the nodes of a circuit are supposed to be doing during a test? One could enter all these data by hand if one knew the design of a circuit well, but this is impossible for any circuit that consists of more than a handful of gates. The most popular way to get these data is by logic simulation of the circuit.[f,2] Good circuit simulation is often used by designers to prove the circuit behaves the way they expect it to under various input conditions (input vectors) they are interested in. Fault simulation is used to study how a circuit behaves when that circuit is perturbed by a modeled fault. An example of a modeled fault is a stuck-at-0 on a gate output, meaning no matter what the gate's inputs are, the output is 0. The single stuck-at model is the most prevalent fault model in existence. It assumes that only one stuck-at (either 0 or 1) may exist in a circuit at any one time. A fault simulator can be used to predict, for a given modeled fault, how the circuit

will behave when stimulated with input (test) vectors. If the modeled fault causes one or more observation points (like circuit output pins) to deviate from normal behavior, we can declare the fault detected by that vector. In the common case of sequential circuits, it is more accurate to say all vectors detected the fault up to and including the one that caused the observable deviation.

Another technology used by some performance testers is the fault dictionary.[2] Fault dictionaries are prepared with fault simulators. A fault dictionary is a three-dimensional data structure of Boolean true/false bits (see Fig. 57.3). The first dimension is an enumeration of all test vectors. The second dimension is a list of modeled faults that are to be simulated. The third dimension is an enumeration of the circuit's output pins. A given bit in the fault dictionary is true if the corresponding output pin fails on the corresponding vector for a given fault.

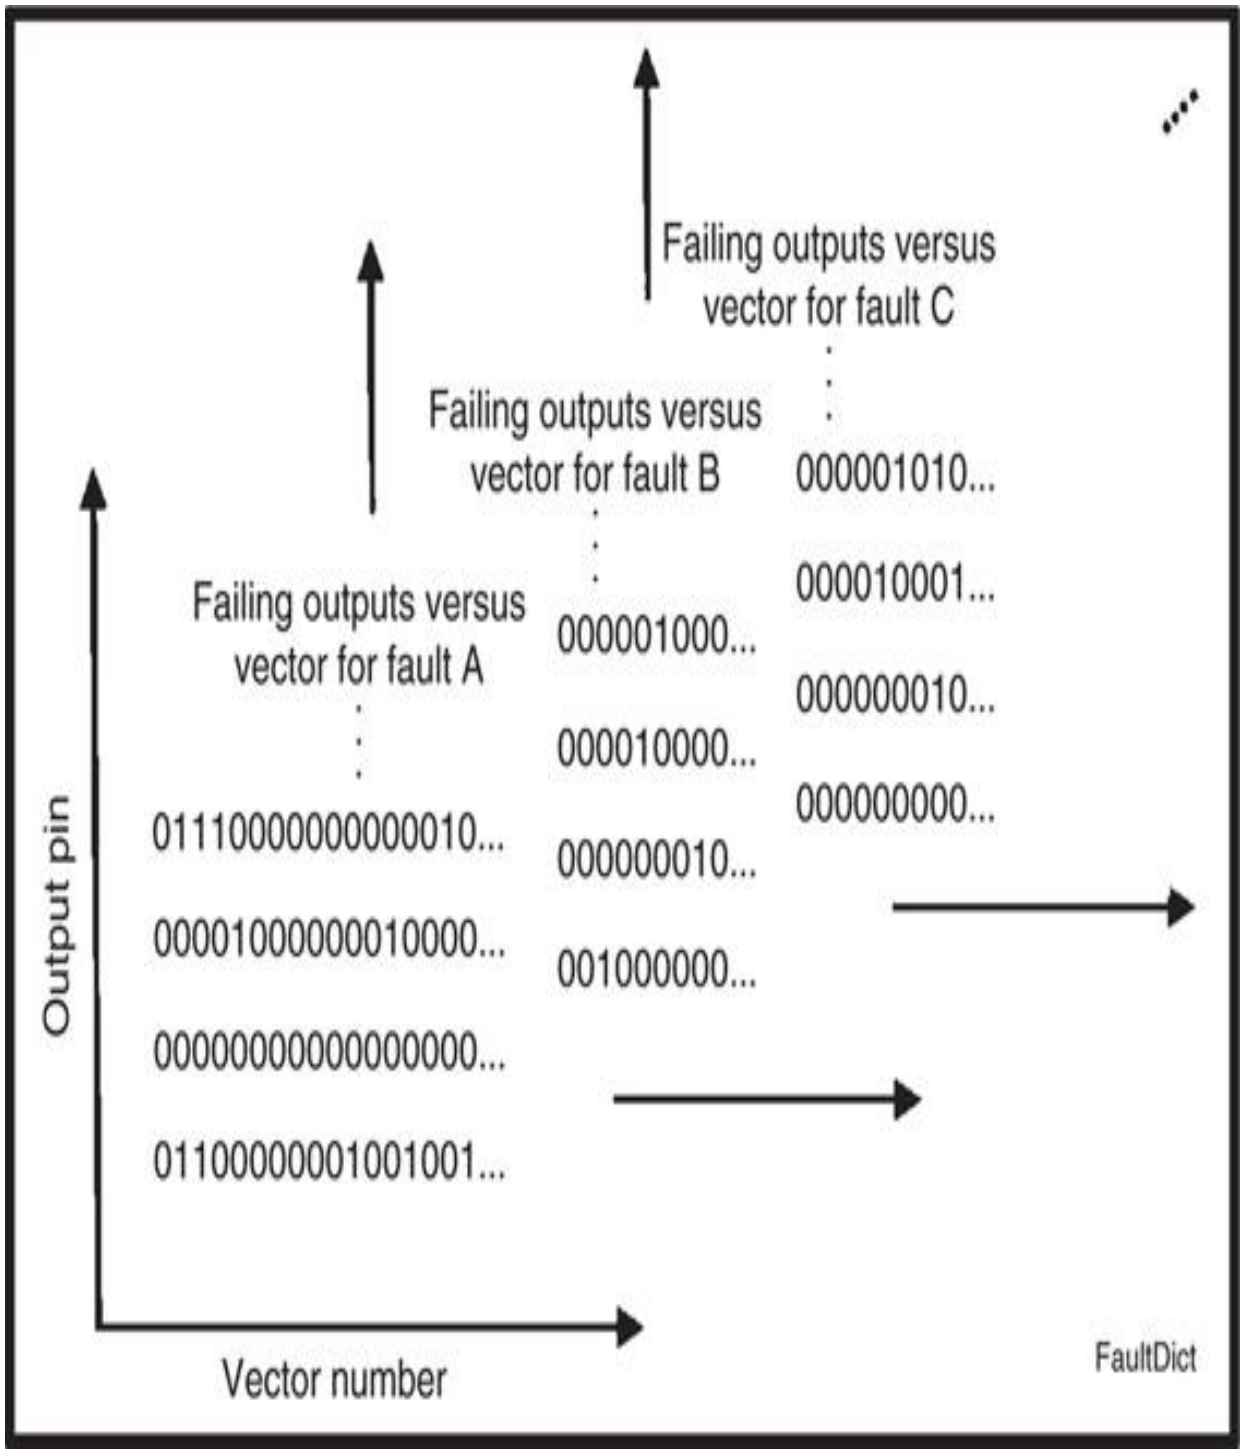

FIGURE 57.3 A fault dictionary. For each “page” corresponding to a modeled fault, bits set to 1 indicate that a given output pin fails for a given vector number. When testing is performed, the failing output(s) and failing vector number are noted and then each page is searched at those coordinates to look up a matching fault. (Note that more than one fault may produce a match.)

For a given vector and fault, the output pins that are expected to fail can be looked up in this dictionary. In a testing scenario, we take a failing test vector and list of failed output pins, and attempt to look up a fault (or faults) that match the failed pin behavior for that vector. Fault dictionaries work well when actual defects that cause a circuit to fail closely match the fault model. When defects occur that vary from the modeled faults, then a dictionary lookup may come up empty (no matching fault), or matches may be found but point to the wrong faults, or so many matches may be found that it is impractical to examine them all to see which (if any) are the actual problem. Dictionary generation is computationally intensive, dictionaries may consume huge amounts of storage space,[g] and dictionary lookups may not work. This technology was invented along with small-scale integrated bipolar technologies such as early TTL or ECL. The advent of large-scale integration and CMOS technology[h] has made fault dictionary technology nearly useless in board testing practice.

Performance testers are intended to emulate the environment the board would encounter in its native application. This means the tester itself needs to be carefully customized to supply this environment, or it must be a general-purpose tester with a great degree of flexibility. Flexibility brings cost, so commercial functional testers tend to be among the most expensive. Programming such machines is a complex task, due both to the flexibility of the tester and to the nature of the test requirements. It is difficult at best to get automated support for functional test programming. Typically, such programming takes extreme patience and a high level of skill—again, two more costs. To compound this, any last-minute design changes to the board may cause expensive and time-consuming test modifications or invalidate the tests altogether.

57.4.2 Testing Boards for Manufacturing Defects

Manufacturing defects can be detected by a functional test, but because functional testers are expensive and difficult to program, other techniques have arisen to test for them. These testers have one or more of the following advantages:

1. They are much easier to program, often requiring less than 10 percent of the time of functional test development.
2. Automatic test program generators that analyze the circuit design database do most of the work and relieve the skill required of the programmer.
3. Their programs are much less sensitive to design changes because they take a divide-and-conquer approach; the effects of design changes are localized, requiring that only a portion of the test be reprogrammed.
4. They offer much better defect resolution for many defects because localized portions of the circuit are being analyzed, reducing diagnostic complexity.

The principal technology is the in-circuit tester. This tester utilizes a high degree of nodal access—that is, connection to printed circuit traces—to perform its work. Nodal access is provided by a unique fixture called the bed of nails. (See Fig. 57.4.) This fixture is made up of a platen that supports the board under test. The platen is drilled with holes below each target point for nodal access. In the holes are spring-loaded “nails” that contact the target points on the board. (Special clamshell fixtures allow nail access to both sides of a board.) The platen with board forms the movable top layer of a vacuum chamber. When vacuum is actuated, the platen with board moves down, depressing the nail springs and causing nail contact with board nodes. (Sometimes mechanical

actuation is used in place of or to assist vacuum.) The nails are wired (typically with wire-wrap technology) to the stimulus/measurement resources of the tester. These resources contain mechanical relays that allow connection of various tester functions to a given nail.

FIGURE 57.4 Cutaway drawing of a board resting on top of an in-circuit vacuum-actuated fixture, the bed of nails. The interface pins (the mechanical interface to the ATE pin electronics) are placed very close to reduce path lengths.

Once a tester has access to the nodes of a board, it can perform in-circuit (also called in situ) tests. The idea is to test components as if they are standing alone, while they in fact are part of a board circuit. The actual electrical processes used in in-circuit testing are explained in Sec. 57.5.

57.4.3 Testing Boards for Specification Faults

There is not much to add here because often, testing for specification defects is very similar to testing for performance faults. However, if for (say) contractual reasons, you are required to show your boards working as specified, you may be required to construct “live” situations where they are performing in a realistic system setting. Again, the extreme case of a missile shot on a test range could be involved. The question must be, is there an easier way?

57.5 IN-CIRCUIT TEST TECHNIQUES

The problem of in-circuit testing can be subdivided into two main categories, analog in-circuit testing and digital in-circuit testing.

57.5.1 Analog In-Circuit Test

Analog in-circuit test addresses testing for shorts in the printed wire circuitry; analog components, passive devices such as resistors, inductors, and capacitors; and simple

semiconductor components such as diodes and transistors.[i] Analog in-circuit testing is conducted without applying power to a board; that is, it is an unpowered test methodology.

Shorts (unwanted connections between nodes) are tested for first because subsequent testing will profit from the assumption that shorts are not a factor, and subsequent testing may need to apply power to the board. Unpowered shorts testing may be accomplished by applying a small DC voltage [j] to a node while all others are connected to ground. If current flow is observed that is below a computed threshold, then the node cannot be shorted to any of the grounded nodes. If the current flow is above the programmed threshold, there may be an unexpected path to at least one of the grounded nodes. The destination node(s) can be determined by linearly searching the grounded nodes for the current flow (this is slow) or by using half-splitting techniques (which are fast[k]) to determine the other node(s) the current is flowing to. When the algorithm has finished stimulating all nodes sequentially, it can declare which nodes are shorted and use *x*-*y* position data to show where to look for the problems. Typically, shorts are repaired before continuing with other tests because they may confuse the resolution of defects and may cause physical damage when the power is later turned on.

Unpowered tests on analog components such as resistors, capacitors, inductors, etc., are performed next. Again, low stimulus voltages keep semiconductor junctions turned off. AC voltages are applied and phase-shifted currents are measured in order to deduce the values of reactive components (capacitors, inductors). For a simple measurement of a lone[l] impedance *R*, apply a voltage to one terminal of the component (through the bed of nails) and connect a current-measuring device (conceptually, an ammeter with zero impedance to ground) to the other component terminal. The current flow observed due to the

known stimulus voltage is related to R by Ohm's law ($R = V * I$). See Fig. 57.5(*b*).

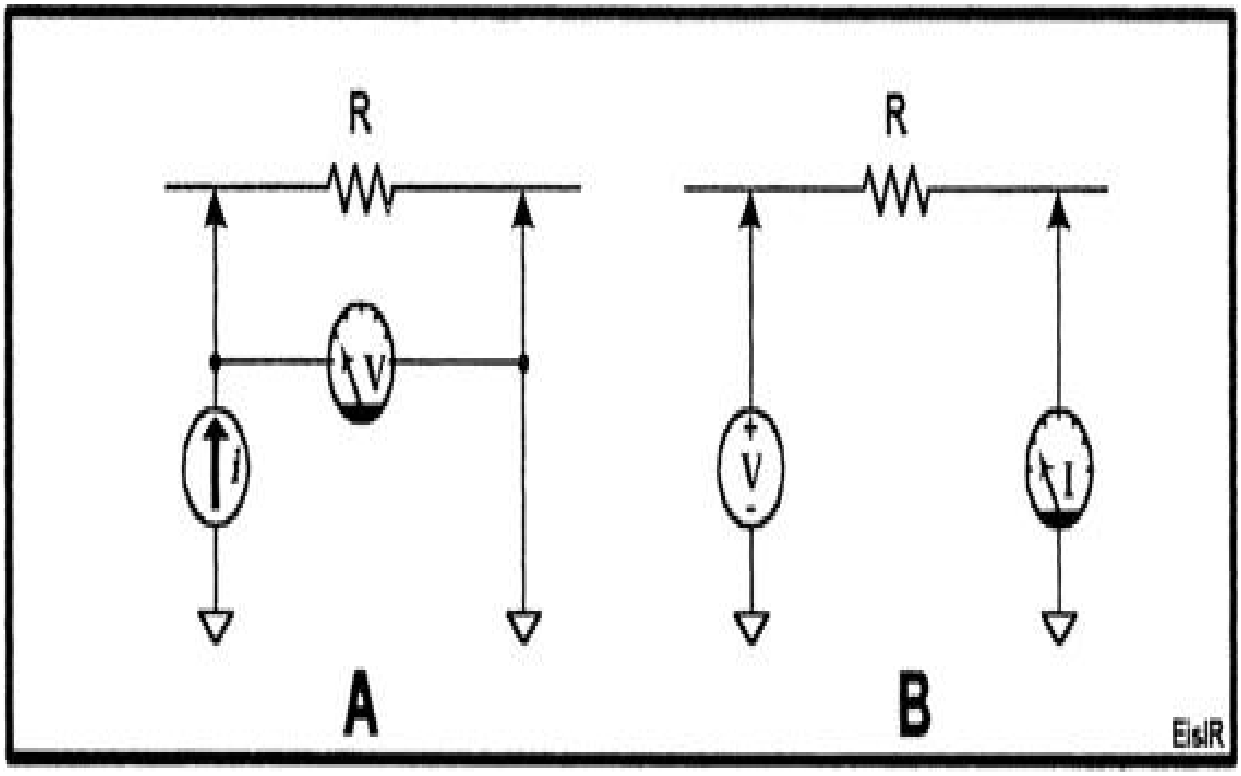

FIGURE 57.5 An analog component on a loaded board can be accessed by two in-circuit probes that connect its terminals with tester resources. There are two approaches: force a known current and measure a voltage (*a*) and force a known voltage and measure a current (*b*).

However, some discrete analog components may be connected to one another in ways that prevent simple measurement of the current flowing through the component due to parallel pathways that sidetrack some of the current. In Fig. 57.6, when applying a voltage to one terminal of R, a current also flows in a parallel path through R_a and R_b. The ammeter does not measure the true current through R because current from the parallel path also gets to the ammeter.

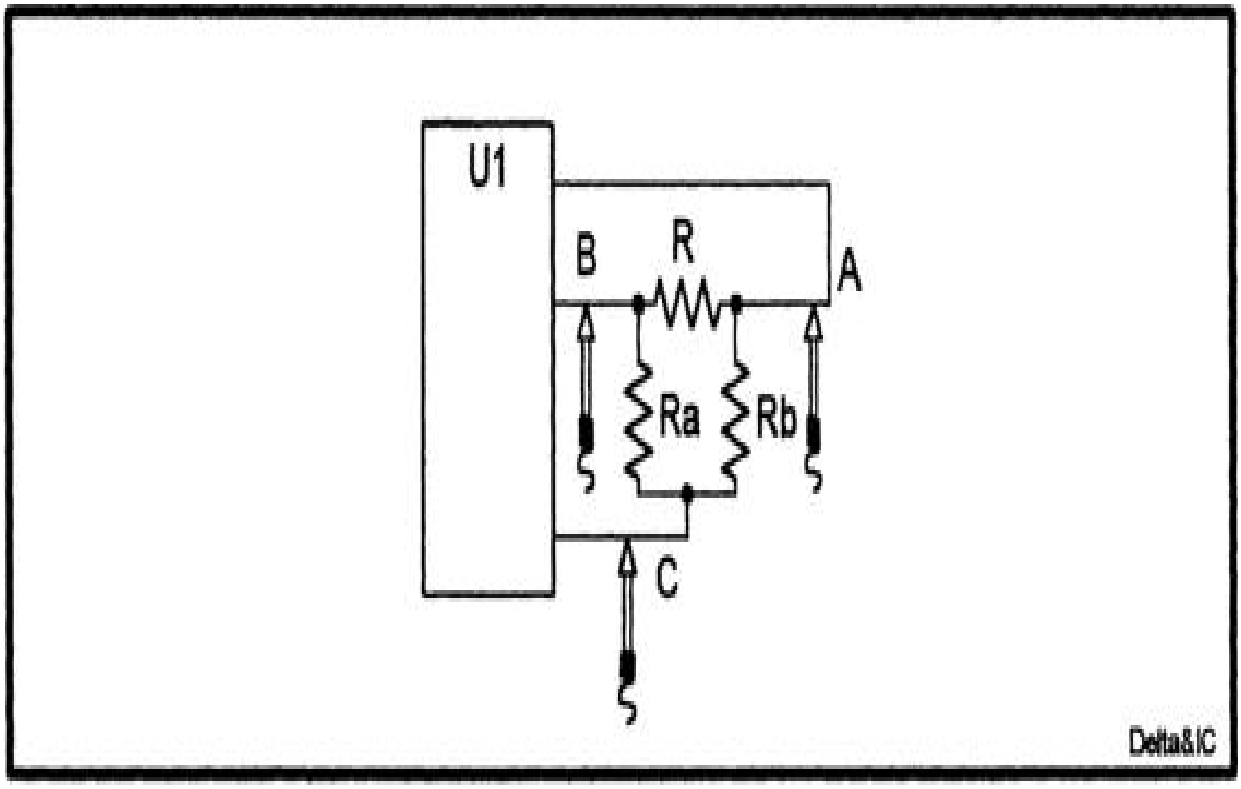

FIGURE 57.6 Three analog devices interconnected with an integrated circuit (U1).

The parallel path problem can be solved with a process called guarding. Guarding is accomplished by using a third nail to connect ground to the node marked *C* as shown in Fig. 57.7. When *C* is grounded, all the sidetracked current goes to ground because there is no voltage drop across R_b to attract current to or from the ammeter. All the current seen by the ammeter comes through *R*, so again Ohm's law gives the value of *R*. This is a classic three-wire measurement. It turns out that, for general component topologies, multiple guards (ground connections) may be required, but these are still considered three-wire measurements. In some cases where enhanced accuracies are needed or where there are extreme ratios of component values in a network, additional sense wires are used to eliminate errors that are due to small voltage drops in fixture nail, wire, relay, and trace

contributions. (See Fig. 57.8.) See Ref. 3 for a discussion of enhanced measurement accuracies.

57.5.2 Digital In-Circuit Test

Digital in-circuit test focuses on the digital components residing on a board, and requires that power be applied to activate the digital logic contained within the ICs. Just as analog components can be tested without removing them from a board, digital components can be tested the same way. The key technology is backdriving. When applying digital stimuli to a digital device's inputs (via the bed of nails), a tester's driver must overcome the voltage levels that connected upstream devices are producing. This is done by equipping the digital in-circuit tester with powerful, low-impedance drivers that can backdrive upstream drivers with enough current to create the desired signal voltage in spite of their state. With tester receivers connected by nails to the device's outputs, the tester can monitor these outputs for expected responses to the stimuli. (See Fig. 57.9.)

A problem with backdriving is that the tester drivers are abusing the upstream drivers in other devices[m] while testing the device of interest. Studies[4] have shown that this is a legitimate concern and that damage to upstream devices may occur. For example, overdriven silicon junctions or device bond wires may heat up enough to be damaged. Sometimes this damage may occur surprisingly fast (within milliseconds). This problem can be solved by careful application of tests with an eye toward their duration. If backdrive testing can be done quickly, and/or with appropriate cooling intervals, then damage can be successfully avoided.[5] This has allowed digital in-circuit testing to become the dominant testing technology.

A great advantage of digital in-circuit testing is that it is performed directly on the inputs and outputs of a targeted device. If the device should fail testing, this is seen directly, rather than having its identity masked by interactions with other devices. This is a major differentiation from functional testing. Faults typically can be resolved to two categories of defects: failed ICs or solder opens on I/O/power pins.

Another major differentiator is the ease—indeed, automation—of test programming that is possible with digital in-circuit testing. Tests for ICs can be prepared as if the ICs were standing alone,[n] stored in a library, and recalled from the library when needed. Modern digital in-circuit testers may have library tests for tens of thousands of devices. For custom, one-of-a-kind ICs for which a library test may not exist (e.g., ASICs), it is still substantially easier to create a test for just the one device than it is for a collection of ICs.

57.5.3 Manufacturing Defect Analyzer

A manufacturing defect analyzer (MDA) is essentially a very low-end analog in-circuit tester. One way it maintains low equipment cost is by not having power supplies to power up a board. Another cost savings comes by having only rudimentary programming and operating software. Some amount of test accuracy and yield must be traded for these savings.

57.5.4 General-Purpose In-Circuit Tester

The workhorse of the electronics industry is the general-purpose in-circuit tester that merges support for analog and digital in-circuit tests. An example of a widely used system is shown in Fig. 57.10. It contains power supplies for powering boards and often contains sophisticated analog in-circuit programming tools and extensive libraries of digital tests. The typical test and repair flow for this tester is shown in Fig. 57.11. Note the early exit to repair for boards that fail shorts testing. This avoids applying power to boards that contain shorts because these may present hazards to the board and human operator, plus they also confuse the diagnosis of faults later in testing.

57.5.5 Combinational Tester

In situations where a manufacturing line has a variety of technologies in production, a need may exist for both functional and in-circuit testing. Thus, hybrid functional/in-circuit testers (commonly called combinational testers) exist. These machines give test engineers a full complement of tools to address testing problems. They also allow “one-stop” testing, where manufacturing defects and functional performance faults can be detected at one site in the production flow.

A combinational tester utilizes a bed of nails to perform in-circuit analog and digital tests. It may also utilize edge connector access to perform functional tests. In some cases these approaches are hybridized by constructing a two-stage bed-of-nails fixture that has two lengths of nails used in the bed, and a platen that has two stations of depression during operation. The first station is full depression, which brings all nails into contact with the circuit board for standard in-circuit access. The second station is partial depression, where only the longer nails still contact the board, perhaps at the board edge, for functional testing. The removal of the shorter nails removes the electrical loading they present to internal circuit nodes and allows the board to operate in a more natural environment.

57.6 ALTERNATIVES TO CONVENTIONAL ELECTRICAL TESTS

Alternative tests use radically different approaches to specifically address the resolution of defects. These may be

needed to address blind spots in traditional electrical test methodologies. Two specific examples of defects that are difficult to resolve by conventional tests are given here.

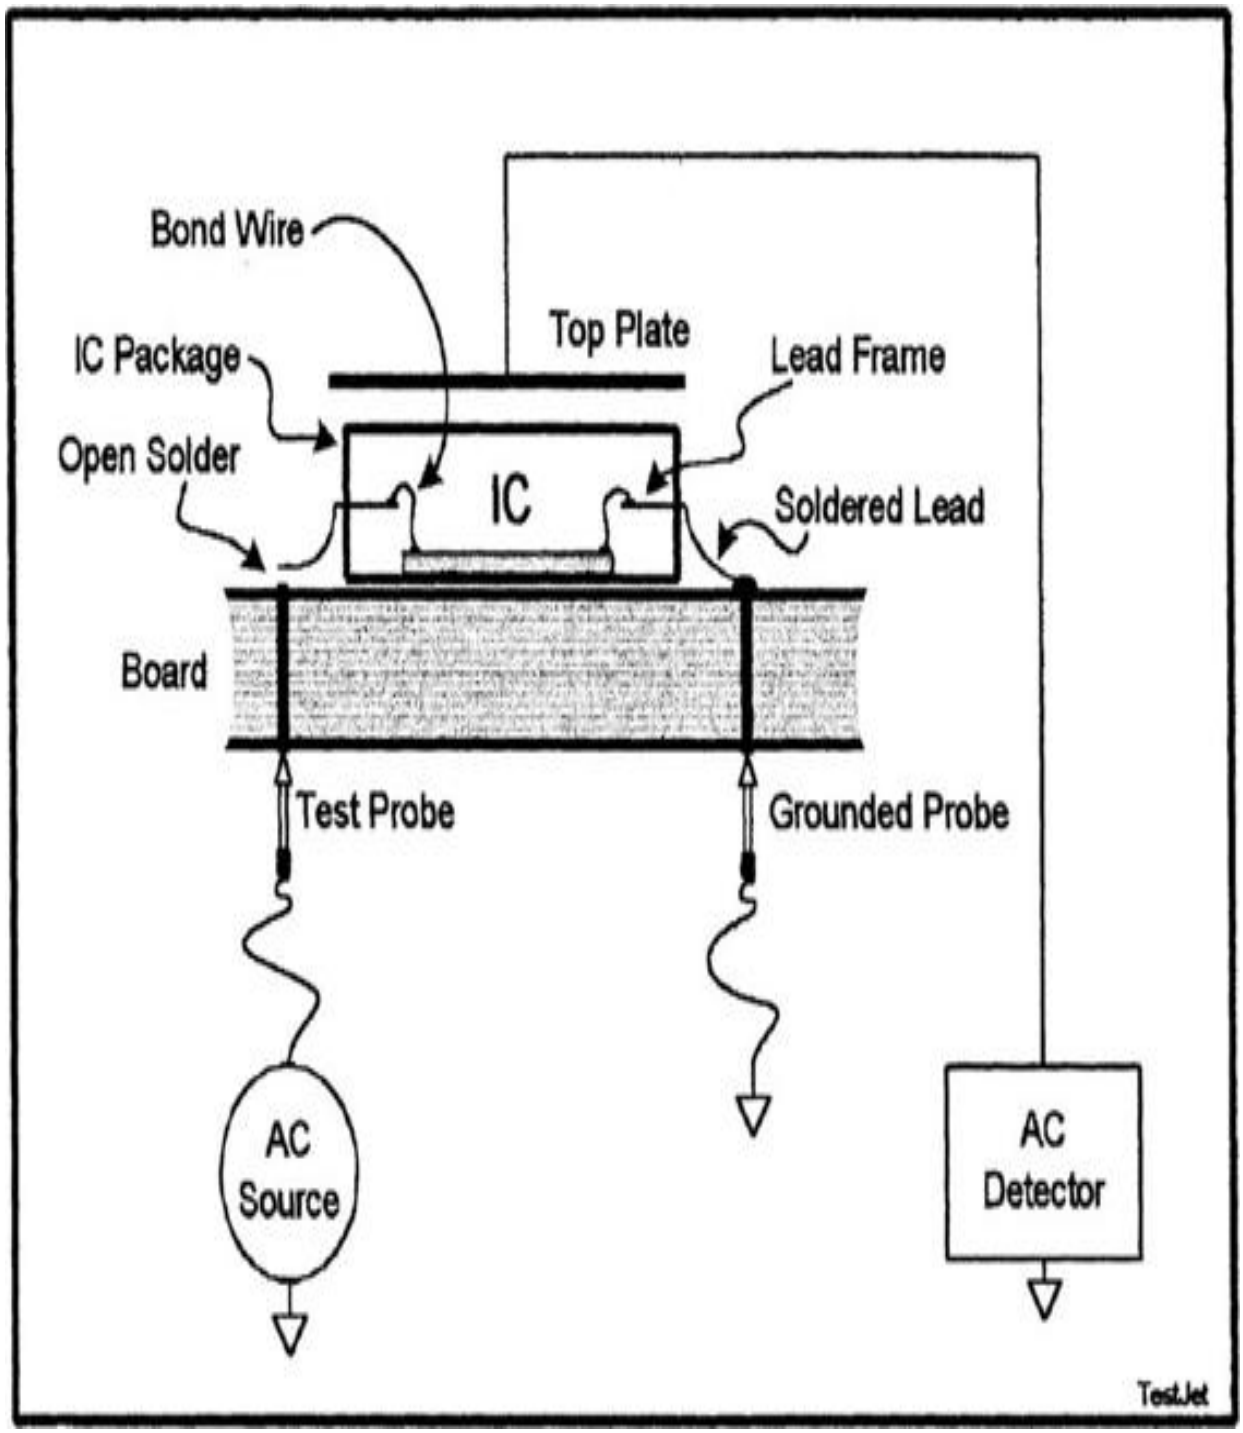

FIGURE 57.12 Capacitive leadframe testing used to find open solder joints.

First, consider a board with a large number of bypass capacitors. All of these capacitors are connected between power and ground so their parallel capacitances are summed. Using an analog in-circuit test, it is possible to test for this summed capacitance. However, if one capacitor is missing or tombstoned, the tester most likely will not notice because the resulting decrement in capacitance will likely fall well within the summed tolerances of the summed capacitances. The performance of the board at higher operating frequencies may be adversely affected, however, due to a loss of noise immunity. This could be detected (possibly) by a performance test. However, if this performance test failed, it could be very difficult to resolve which capacitor was missing. One non-traditional way to test for this problem is to use human visual inspection to look for missing capacitors. This may not find solder opens, however. Another approach would be to use an automated x-ray laminographic tester to check for the existence and solder integrity of each capacitor. Even the orientation of polarized capacitors can be verified. (See Chap. 55 for a discussion of x-ray inspection.)

Second, consider again the open solder problem on a digital device input. This defect may manifest itself as improper device behavior, but it would be wrong to replace the device (which would also fix the solder open) because the device is not at fault. Digital in-circuit testing has trouble resolving solder opens on input pins from bad devices.[o] Final resolution can be obtained either by visual inspection or by using a handheld probe to see if board signals reach IC legs, but this is becoming increasingly difficult as packaging dimensions continue to shrink (e.g., TAB) and newer attachment technologies (e.g., ball grid arrays) are used that prohibit visual inspection or probing altogether.

An alternative approach to the open solder problem uses a capacitive coupling technique to look for opens. The technique exploits the fact that many ICs have a leadframe

that forms the conductive path from the legs of the device to the die bond wire pads. Using the bed of nails, all but one node attached to the IC can be grounded (this is an unpowered technique) and a small AC signal can be applied to the node that remains. An insulated metal plate pressed against the top of the IC forms the top plate of a capacitor and the stimulated IC leg and lead frame conductor form the bottom plate.

Figure 57.13 shows an equivalent circuit for capacitive opens test for a properly soldered IC lead and for an open solder condition. The capacitance C1 may be on the order of 100 fF (100×10^{-15} F), which is small enough to require sophisticated detection electronics to measure in the face of environmental noise. Now, if the IC leg is soldered to the stimulated board node, the correct capacitance will be measured. If the solder joint is open, then a second small capacitance C2 now exists in series with the first. This reduces the measured capacitance by a factor of 2 to 10. Capacitive leadframe test allows testing of complex ICs for solder opens without knowing what the ICs actually do and without applying power. The technique requires no complicated programming, and gives accurate resolution of solder defects. The technique has been extended to allow testing of solder integrity for connectors and switches. A fixture for capacitive leadframe testing is shown Fig. 57.14.

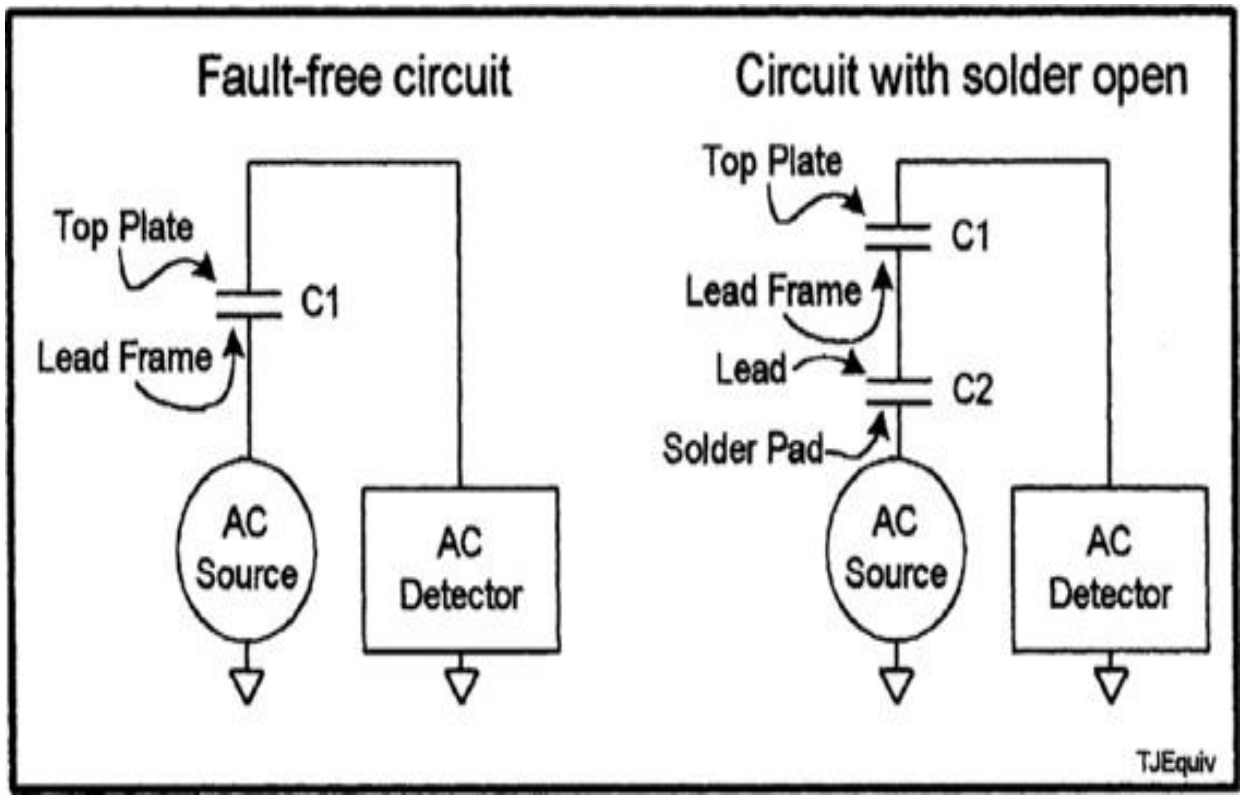

FIGURE 57.13 Equivalent circuits for fault-free and open solder conditions.

FIGURE 57.14 A test fixture with board on a bed of nails, with clamshell top fixture containing capacitive sensor plates. Notice eight closely spaced sensor plates (right) that test for opens in eight (white) connectors on the board.

57.7 TESTER COMPARISON

Table 57.2 summarizes the types of tester for comparative costs and capabilities. A majority of manufacturers value good diagnostic resolution and fault coverage, so it is not surprising that in-circuit and combinational testers are in widespread use. Next in prevalence are the MDA testers, which are typically used where coverage and diagnostic resolution may be sacrificed for ease and speed of programming, usually in low-cost, high-volume products. Functional and specification testers are becoming rare, and are often only justified by the existence of contractual or regulatory requirements.

TABLE 57.2 Costs and Capabilities of Various Testers

Tester Type	Typical Cost ($)	Programming Time	Diagnostic Resolution	Fault Cover	Comments
MDA	10^4–10^5	1–2 days	Fair	Poor	No digital coverage; requires known good board for programming.
In-Circuit	10^5–10^6	5–10 days	Best	Good	Fixturing is a major portion of preparation time.
Combo	10^5–10^6	10–30 days	Best	Best	Functional test programming is a major portion of preparation time.
Functional	10^5–10^6	1–4 months	Fair	Fair	Very high skill required for test preparation and interpreting results.
Specification	10^3–10^8	Weeks to years	Poor	?	Very high skill required for test preparation and interpreting results.

[a] Perhaps the reader remembers the TV ads for Zenith televisions from about 25 years ago. They showed individual axial lead components being hand-wired onto lug strips and then soldered. The voice-over mentioned "*hand-crafted*" quality as if to imply that automated manufacturing (being used by Japanese manufacturers like Sony) was suspect.

[b] It is important to differentiate test yield from defect coverage of a test. The yield of the manufacturing process before test might be (say) 50 percent, and the yield after test may be 97 percent. This may be accomplished with a test that detects (covers) 90 percent of the important defects.

[c] From basic probability theory, $(0.97)^{20} = 0.54$ is the chance that 20 independently manufactured boards with a probability of 0.97 of being fault free will all be fault free.

[d] Measuring yields in percentages is telling. In the IC industry, yields are measured in parts per million. One ppm corresponds to 99.9999 percent, and 250 ppm, a good IC yield, equals 99.975 percent yield. Will the board industry ever get into these ranges? Will it make sense to try?

[e] See Sec. 57.6 for a discussion of how a new testing methodology may pinpoint a defect that conventional methodologies have difficulty isolating.

[f] Logic simulation implies the treatment of the digital nature of the circuit, typically omitting any interaction with any analog portions of the circuit. Analog simulators do exist, but are implemented in a very different technology from digital simulators. Mixed-signal simulation is not anywhere near as viable as digital simulation, which presents a problem for test engineers.

[g] For example, say a circuit has 100,000 gates. The number of stuck-at faults to be simulated may easily be 200,000. A set of test vectors for these may easily exceed 500,000. If the circuit has a fairly normal complement of 250 outputs, then a fault dictionary for this example would consume the product of faults times vectors times outputs (2.5×10^{13} bits, or about 3.125 terabytes, give or take a gigabyte). Fault simulation times lasting months, even on very fast computers, have been reported. Of course, larger circuits will need more!

[h] CMOS VLSI circuits have several defect modes that are inconvenient to model in popular fault simulators, and thus fault models are more likely not to match defects. Two of the offending defect modes are bridging faults (intermetal shorts) and metallization opens that may actually introduce capacitive memory into a circuit. These are difficult to represent with traditional fault-modeling techniques.

[i] Complex analog devices such as analog or mixed-signal ICs are not very amenable to analog in-circuit testing because they require power to be applied to the board. Simple diodes and single transistors can be tested by in-circuit stimulus that essentially examines the characteristics of their semiconductor junctions.

[j] The reason for using a small stimulus voltage (typically less than 0.2 V) is to prevent current flow through semiconductor junctions that may exist between nodes. This voltage will not turn on a junction. These junctions may exist in parasitic form within ICs and are not always documented.

[k] A half-splitting technique (also called a binary chop) is a fundamental algorithm of computer science. It works by successively considering half of a set of items (grounded nodes that are receiving current in this case) while removing the other half from consideration. It recursively divides sets repeatedly until only one item is left to consider. It has a complexity related to the logarithm (base 2) of the size of the original set of items. By comparison, a linear process has a complexity linearly related to the size of the original set.

[l] This component may not be alone in a physical sense, but because low stimulus voltages are used, other connected devices such as ICs may be electrically quiescent so that the component is electrically alone.

[m] This abuse can be mitigated by “conditioning” upstream drivers. One method is to disable the upstream drivers by devoting additional tester drivers to driving states on disabling inputs (when they exist) such as output enable pins. Of course, the problem may simply be moved upstream, because the disabling inputs may also be connected to upstream drivers that are now being overdriven in place of the original drivers. This conditioning process may be carried out to several levels, if desired.

[n] This assumes that the IC does not have any topological constraints on its I/O pins, such as having an input pin connected directly to ground or an output pin fed back to an input pin. In such cases, the prepared test may be incompatible with these constraints and may only be used after incompatible segments of the test are deleted, reducing fault coverage.

[o] Ignore for the moment the possibility of using boundary scan to solve this problem, which is discussed in Chap. 56.

CHAPTER 58

FAILURE MODES AND EFFECTS ANALYSIS

Happy T. Holden
Co-Editor-in-Chief, Printed Circuits Handbook, *and PCB Technologist, Zeeland, Michigan*

58.1 PROGNOSTICS AND HEALTH MANAGEMENT

Reliability has many dimensions. One current popular focus in the safety and availability of systems or products through the use of *prognostics and health management* (PHM). Prognostics is the process of predicting the future reliability of a product by assessing the extent of deviation or degradation of a product from its expected normal operating conditions. Health management is the process of decision making and implementation of actions to use, maintain, repair, or replace the product based on the state of health and expected future use of the product.

58.1.1 Key Elements of Prognostics

- Failure modes and effects analysis (FMEA) (see Fig. 58.1)

- Physics of failure (PoF): (1) using expendable devices, such as fuses, (2) modeling of stress and damage utilizing knowledge of loading conditions and system properties (material, geometric, etc.)
- Data-driven approaches—monitoring and reasoning of parameters that are precursors to impending failure, such as shifts in performance parameters
- Synergistic techniques—combination of FMEA, PoF, and data driven methods

There exists a huge potential for product improvements using these methodologies, but it all starts with FMEA.

58.1.2 What Is FMEA?

58.1.2.1 Definition. FMEA is a systematic process to evaluate failure modes and causes associated with the design and manufacturing processes of a new product. [It is somewhat similar to the Potential Problem Analysis (PPA) phase of the Kepner-Tregoe program.] A list of (1) potential failure modes of each component or subassembly and causes associated with the designing and manufacturing of a product, (2) identify actions which could be eliminate or reduce the chance of a potential failure occurring, and (3) then document the process and give each mode a numeric rating for frequency of occurrence, criticality, and probability of detection. Finally, these three numbers are multiplied together to obtain the risk priority number (RPN), which is used to guide the design effort to the most critical problems first.

Two aspects of FMEA are particularly important: a team approach and timeliness. The team approach is vital because

the broader the expertise that is brought to bear on making and assigning values to the failure mode list, the more effective the FMEA will be.

Timeliness is important because FMEA is primarily a preventive tool, which can help steer design decisions between alternatives before failure modes are designed-in, rather than redesigning after the failure occurs. FMEA is equally applicable to hardware or software, to components or systems.

58.1.2.2 Comparison to FTA. Another similar process is fault tree analysis (FTA). While FMEA is a “bottom-up” approach, FTA is “top-down.” FTA starts with the assumption of a system failure mode, and then works down through the system block diagram to look for possible causes of that mode.

Thus, FTA requires fairly complete, detailed information about the system, and is most effective after the system is well-defined. (FTA could be performed, in a limited way, on alternative system concepts; this could be used to help decide the best of several alternatives.) A separate FTA must be performed for each system failure mode.

FTA and FMEA are complimentary. Whenever possible, both should be used. For practical reasons, FTA should be limited to the really serious system-level failure modes, such as those involving safety or permanent system damage. FMEA can be used at the component, subassembly, and module level, to help optimize those modules. There are excellent discussions and examples of FTA in the Further Reading section at the end of this chapter.

58.1.3 Benefits of FMEA

The RPN calculated by FMEA allows prioritization of the failure mode list, guiding design effort to the most critical

areas first. It also provides a documentary record of the failure prevention efforts of the design team, which is helpful to management in gauging the quality and extent of the effort, to production in solving problems which occur despite these efforts, and to future projects which can benefit from all the work and thinking which went into the failure mode and cause lists.

Eliminating potential failure modes has both short term and long term benefits. The short term benefit is most often recognized because it represents savings of the costs of repair, retest, and downtime, which are objectively accountable. The long term benefit is much more difficult to measure, since it relates to the customer's satisfaction or dissatisfaction with the product, and his perception of its quality.

58.1.3.1 FMEA Supports the Design Process

- Aiding in the objective evaluation of alternatives during design
- Increasing the probability that potential failure modes and their effects on system operation have been considered during design
- Providing additional information to aid in the planning of thorough and efficient test programs
- Developing a list of potential failure modes ranked according to their probable effect on the customer, thus establishing a priority system for design and test
- Providing an open, documented format for recommending and tracking risk-reducing actions
- Identifying known and potential failure modes which might otherwise be overlooked
- Exposing and documenting the ways a system can fail, and the effects of such failures
- Detecting primary but often minor failures which may cause serious secondary failures or consequent damage

- Detecting areas where “fail safe” or “fail soft” features are needed
- Providing a fresh viewpoint in understanding a system’s functions

58.1.3.2 FMEA Report Uses

- Formal record of the safety and reliability analysis and planning, to satisfy customers or regulatory agencies
- Evidence in litigation involving safety or reliability
- Design of diagnostic routines or built-in tests
- Basis for creating trouble-shooting procedures
- Means to consider and prevent manufacturing defects
- Problem follow-up and corrective action tracking
- Future reference to aid in analyzing field failures, evaluating design changes, or developing improved designs

58.2 THEORY

In simple terms, the FMEA process attempts to list every failure mode of each component of a system, and to predict its effect on system operation. Failure effects can be considered at more than one level, for example, effects at the subsystem or overall system levels.

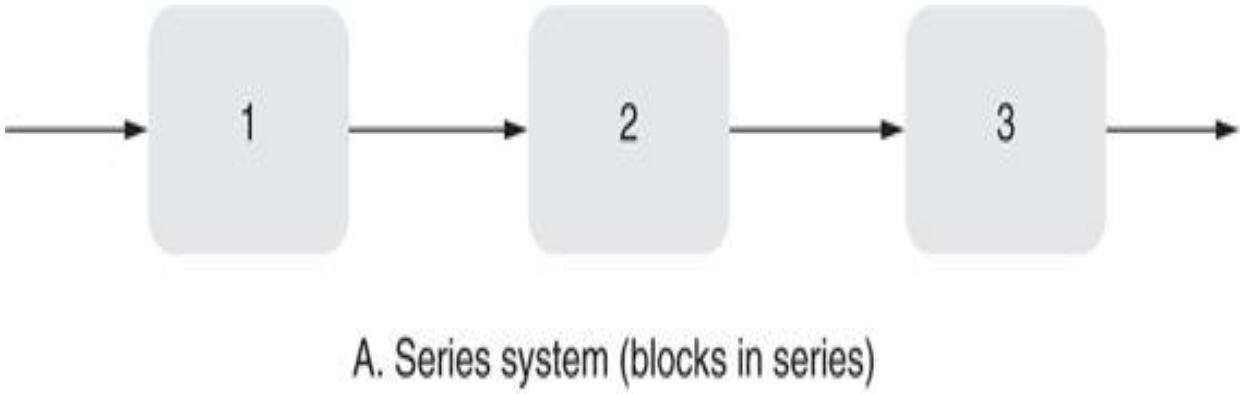
FMEA can be accomplished using either a component or functional approach. In the component approach, actual failure modes are listed (e.g., resistor open, bearing seizure). The functional approach is used when the details of the design are not yet fully defined. In this approach, function failures are considered (e.g., no feedback, memory lost). FMEA can also be performed using a combination of component and functional approaches. The failure mode is the symptom of the failure, as distinct from the cause of the

failure, which consists of the proved reasons for the existence of the symptoms. Reliability aspects of the components must be considered in this process. FMEA requires inputs from hardware, software, systems, customer service, and manufacturing in assessing component failures, effects at higher levels of the system, fault detection, and in evaluating failure compensating provisions in the design.

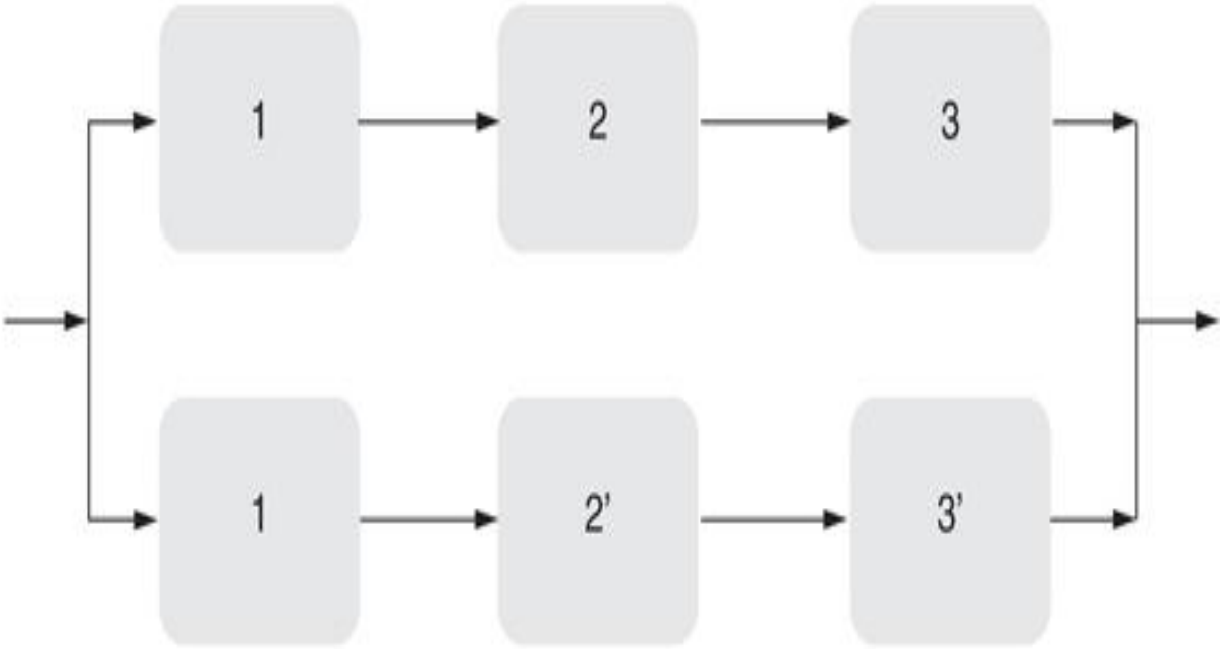
58.2.1 Procedure

FMEA should be performed by a team of people having broad knowledge of the system's design and application. All available information on the design should be obtained: external and internal reference specifications, schematics, computer-aided design (CAD) data, stress analysis, reliability prediction data, test results, etc.

A system functional block diagram and reliability block diagram (Fig. 58.2) should be prepared, as these are important for preparing the FMEA, and for understanding the completed analysis. All possible operating modes of the system and their functional relationships should be considered in the analysis. If the system has redundancy, it should also be considered by evaluating the effects of failure modes assuming the redundant system may or may not function.



A. Series system (blocks in series)



B. Redundant series system (series blocks in parallel)

FIGURE 58.2 Reliability block diagram examples.

FMEA can be performed from different points of view, such as failure detectability, safety, repair cost, availability, etc. The customer’s point of view should always be first, in order to improve customer satisfaction with the final product. The viewpoint being considered should be consistent throughout a particular analysis, in order to assign proper criticality

values. A hierarchical approach works well with systems, using a component approach at the lowest assembly level, and a functional approach to combine the effects of various subsystems. This also allows the FMEA to be performed even when some subsystems are not yet completely designed.

If CAD has been used on parts of the system, the FMEA can utilize that capability to simulate the effects of various failure modes. Such an analysis can greatly enhance the accuracy and objectivity of the FMEA process.

FMEA is an ongoing process which should be started as soon as initial design information is available. It should be updated and enhanced as the design evolves, so that the analysis can be used to improve the design. All possible design alternatives should be separately analyzed, so that the effect on system performance and reliability can be considered in deciding which option to implement. Test results should be used later to update the analysis.

58.2.1.1 Requirements to Perform FMEA. There are basically sixteen (16) steps to create a FMEA:

1. A team of people with a commitment to improve the ability of the design to meet the customer's needs
2. Schematics and block diagrams of each level of the system, from subassemblies to complete system
3. Component specifications, part lists, and design data
4. Functional specifications of modules, subassemblies, etc.
5. Design manuals
6. Manufacturing requirements and details of the processes to be used
7. FMEA forms and a list of any special considerations, such as safety or regulatory, applicable to this product

58.2.1.2 Steps in Performing FMEA (See Fig. 58.3)

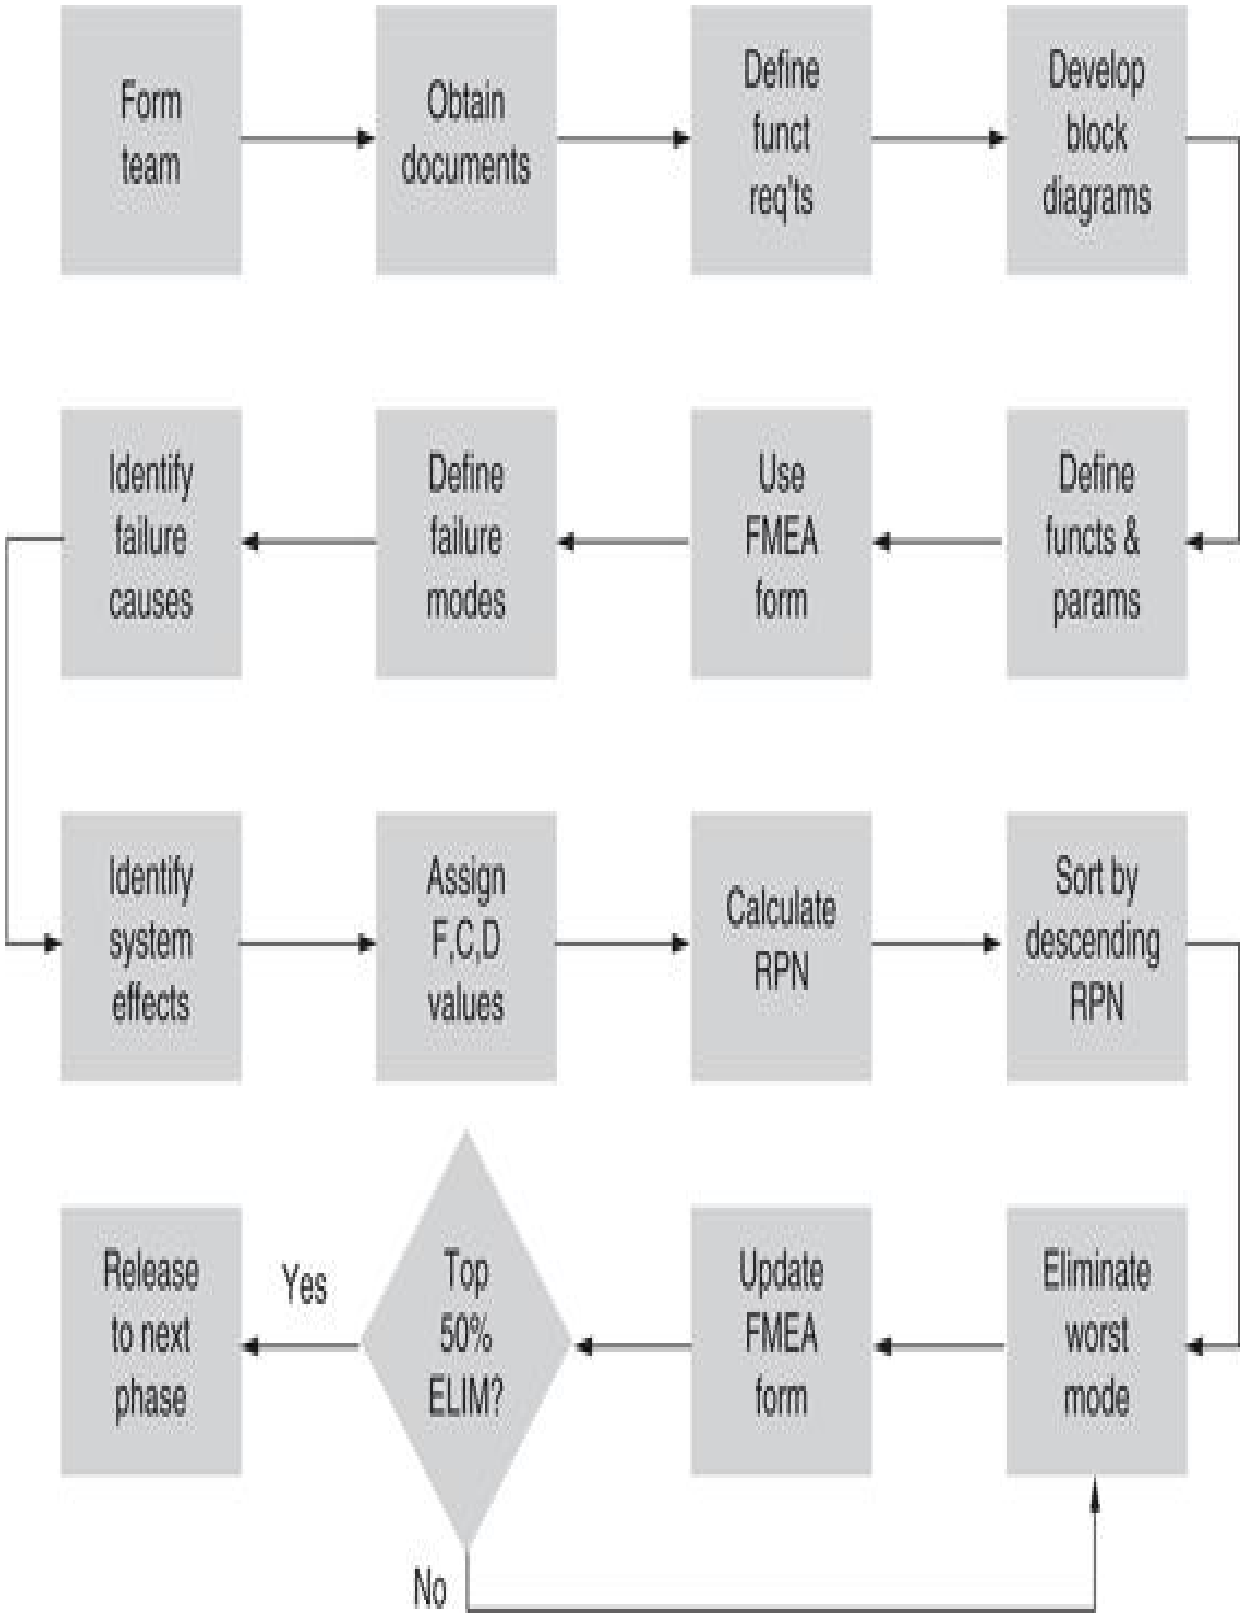


FIGURE 58.3 FMEA flow chart.

1. Discuss and define system functional requirements, including all modes of operation (list in order of decreasing importance).
2. Develop a functional block diagram and a reliability block diagram (Fig. 58.2) for each subassembly being analyzed.
3. Define parameters and functions of each functional block required for successful operation of the system.
4. Using the FMEA forms to document the further steps, identify potential failure modes for each of the functional blocks.
5. Analyze system or subassembly functions affected by factors such as those in the list of FMEA considerations.
6. Identify all possible causes for each failure mode of the functional block being analyzed. The causes must be detailed to the component level wherever possible.
7. Identify all possible ways the failure modes could affect the functions of the higher-level assemblies.
8. Assign the frequency, criticality, and detection values for each failure mode (see Tables 58.1, 58.2, and 58.3).

TABLE 58.1 Frequency Ranking

Criteria for Probability of Failure	Code
REMOTE probability of occurrence. Process capability shows at least X ± 4 SIGMA (99.99%) within spec.	1
LOW probability of occurrence, with process in statistical control. Capability shows at least X ± 3 SIGMA (99.87%) within spec.	2
MODERATE probability of occurrence for processes experiencing failures. Process in statistical control, with X ± 2.5 SIGMA (99.38%) within spec.	3
HIGH probability of occurrence, with frequent failures. Process is in statistical control, but capability shows X ± 2.5 SIGMA or less.	4
VERY HIGH probability of occurrence. Failure is almost certain to occur sooner or later.	5

TABLE 58.2 Criticality Ranking

Criteria	Code
MINOR nature of failure, no noticeable effect on performance, undetectable by customer.	1
LOW severity, causing only slight customer annoyance due to very minor subsystem performance degradation.	2
MODERATE failure causing some customer discomfort, dissatisfaction and annoyance due to subsystem or total performance degradation.	3
HIGH degree of customer dissatisfaction due to nature of the failure (inoperable subsystem or total system).	4
VERY HIGH severity ranking for failure mode involving potential safety problems and/or conformance to federal regulations. Nonregulated components with a 4 or 5 criticality code and frequency code >1 should be designated as control items.	5

TABLE 58.3 Detection Ranking

Criteria	Code
REMOTE likelihood that product would be shipped containing such an obvious defect, since it is detected by subsequent factory tests.	1
LOW likelihood for shipment with defect which is visually obvious or has 100% automatic checking.	2
MODERATE likelihood for shipment with defect since the defect is easily identifiable through automatic inspection or functional checking.	3
HIGH likelihood of shipping with subtle defect.	4
VERY HIGH likelihood that defect will not be detected prior to shipping (checks are impossible or defect is latent).	5

9. Obtain the risk priority number (RPN) by multiplying the three values assigned in step 8. This priority number will allow us to focus on the most important failure modes first.
10. Determine corrective actions for each failure mode, and update the design status as it progresses.
11. Summarize the failure modes and corrective actions in order of decreasing RPN.
12. Focus on eliminating at least the 50 percent of the failure modes with the highest RPN.

Two examples of a FMEA analysis are shown in Figs. 58.4 and 58.5.

58.3 WHAT IS PROCESS FMEA?

58.3.1 Definition

A process potential FMEA is an analytical technique utilized by manufacturing/process engineers as a means to assure that, to the extent possible, potential concerns have been considered and addressed. In its most rigorous form, a P-FMEA is a summary of the engineer's thoughts (including an analysis of items that could go wrong based on experience and past concerns) as a process is developed. This systematic approach parallels and formalizes the mental discipline that an engineer normally goes through in any manufacturing planning process.

The process potential FMEA identifies potential product related process failure modes, assesses the potential down-stream effects of the failures, identifies the potential manufacturing or assembly process causes and identifies failure modes ranking according to their effect on the "customer," thus establishing a priority system for corrective action considerations. The P-FMEA also documents the results of the manufacturing or assembly process.

A list of (1) potential concerns that might cause failure modes for each process or subassembly and causes associated with the designing and manufacturing of a product, (2) identify actions which could be eliminate or reduce the chance of a potential process failure occurring, (3) then document the process and give each mode a numeric rating for frequency of occurrence, criticality, and probability of detection. Finally, these three numbers are multiplied together to obtain the risk priority number (RPN), which is used to guide the design effort to the most critical problems first.

Two aspects of P-FMEA are particularly important: a team approach, and timeliness. The team approach is vital

because the broader the expertise that is brought to bear on making and assigning values to the failure mode list, the more effective the P-FMEA will be.

Timeliness is important because P-FMEA is primarily a preventive tool, which can help steer manufacturing development decisions between alternatives before failure modes are built-in, rather than reworking after the failure occurs. P-FMEA is equally applicable to hardware or software.

58.3.2 Steps in Performing P-FMEA

1. Discuss and define manufacturing and process functional requirements, including all modes of operation (list in order of decreasing importance).
2. Develop a functional block diagram and a reliability block diagram (Fig. 58.2) for each manufacturing/process being analyzed.
3. Define parameters and functions of each functional block required for successful operation of the process.
4. Using the FMEA forms to document the further steps, identify potential failure modes for each of the functional blocks.
5. Analyze process or subassembly functions affected by factors such as those in the list of FMEA considerations.
6. Identify all possible causes for each failure mode of the functional block being analyzed. The causes must be detailed to the component level wherever possible.
7. Identify all possible ways the failure modes could affect the functions of the higher-level manufacturing steps or processes or assemblies.
8. Assign the frequency, criticality, and detection values for each failure mode (see Tables 58.1, 58.2, and 58.3).
9. Obtain the RPN by multiplying the three values assigned in step 8. This priority number will allow us to focus on

the most important failure modes first.

10. Determine corrective actions for each failure mode, and update the manufacturing documentation as it progresses.
11. Summarize the failure modes and corrective actions in order of decreasing RPN.
12. Focus on eliminating at least the 50 percent of the failure modes with the highest RPN.

58.3.3 Summary

FMEA and P-FMEA are a continuing process which should be initiated at investigation/launch time of the design cycle and then be regularly updated as changes occur throughout the phases of product development. FMEA must be completed before the design is “frozen,” for its purpose is to affect the design and harden it against failures due to causes that can be anticipated. Potential manufacturing or assembly concerns known by the design engineer should be conveyed to the production engineers, using means such as the P-FMEA team meetings. Figure 58.6 provides a blank FMEA worksheet for your use.

RELIABILITY

CHAPTER 59

CONDUCTIVE ANODIC FILAMENT FORMATION

Laura J. Turbini
International Reliability Consultant, Waltham, Massachusetts

Antonio Caputo
Isola Group, Chandler, Arizona

59.1 INTRODUCTION

Electrochemical migration (ECM) is the movement of ionic species in the presence of moisture under the influence of a DC bias. There are several factors which affect the rate of electrochemical migration. These include the nature of the substrate and metallization, the presence of contaminants, the voltage gradient, and the presence of sufficient moisture. This last element is critical, for without sufficient monolayers of water on the surface, ion mobility is impossible.

One type of ECM involves the corrosion of copper. A quantitative test for this has been developed and applied to

some weak organic acid fluxes. The effect of varying the accelerating temperature and humidity was evaluated.

A second example of ECM is the failure mode known as conductive anodic filament (CAF) formation which was first observed in the mid-1970s by two different research groups, Bell Laboratories and Raytheon. Since then, further studies have led to an understanding of the factors that affect CAF formation. Water soluble flux constituents can affect the rate of CAF formation because they are absorbed by the epoxy substrate. SEM/EDS has been used to demonstrate that copper and halide ions are present in the CAF filament around the epoxy/glass interface as well as within the epoxy matrix. CAF has been identified as a copper hydroxy chloride salt that causes catastrophic failure when it bridges because it has semiconductor properties. Brominated CAF—copper hydroxy bromide—can form when a high bromide concentration exists in the flux. The chemistry of CAF formation is explained in detail. A CAF test method for multilayer boards has been developed by Sun Microsystems, and then introduced as an IPC test method. This chapter will explore these topics in more detail.

59.2 ELECTROCHEMICAL MIGRATION

Electrochemical migration (see Fig. 59.1) is the movement of an ionic species under the influence of a DC voltage. Moisture is essential for electrochemical migration to occur. In the presence of moisture, metal ions form at the anode and migrate toward the cathode, where they plate out to form dendrites. When a dendrite bridges the gap between the electrodes, a short occurs that may burn out quickly due to the high current within the fragile dendrite.

FIGURE 59.1 Electrochemical migration showing the movement of positive ions toward the cathode and negative ions toward the anode.

Electrochemical corrosion increases as circuit spacing decreases. This is due to the increase in the electric field, which is inversely proportional to the spacing between the conductors [see Eq. (59.1)].

$$E = \frac{V}{d} \tag{59.1}$$

where E = electric field
V = voltage
d = spacing between the conductors

Ohm's law [Eq. (59. 2)] describes the linear relationship between voltage, current, and resistance:

$$V = IR \tag{59.2}$$

where V = voltage drop
I = current in amps
R = resistance in ohms

Resistance is not an intrinsic property of a material. Rather, it depends on some geometric factors as well as the intrinsic resistivity of the substrate. For surface resistance, use Eq. (59.3):

$$R = \rho \frac{d}{A} \tag{59.3}$$

where ρ = resistivity of the material
d = the separation between the conductors traces
A = the cross-sectional area

Conductivity (σ) is the inverse of resistivity:

$$\sigma = \frac{1}{\rho} \tag{59.4}$$

Both resistivity and conductivity can be affected by processing chemicals. Electrochemical corrosion increases as circuit spacing decreases.

Ionic contaminants, which dissolve in the moisture on the surface, increase the conductance (lower the resistance) of the insulating layer between the anode and cathode. Their presence enhances electrochemical migration. How much the migration is enhanced depends on several factors: the solubility of the ion, the mobility of the ion, the effect of pH on solubility, the reactivity of the ion, temperature, and relative humidity.

The solubility of the ion and its mobility in water are important because conductivity depends on both of these factors [see Eq. (59.5)].

$$\sigma = \sum N_i q_i \mu_i \tag{59.5}$$

where N_i = the number of charge carriers of a particular type (e.g., Na^+ cations, or Cl^- anions)
q_i = the charge of the carrier
μ_i = the mobility of the charge carrier

The mobility of a given ion is dependent on temperature and its diffusion coefficient per Eq. (59.6):

$$\mu_{\text{ion}} = \frac{q}{kT} D_{\text{ion}} \tag{59.6}$$

where k = Boltzmann's constant
T = degrees kelvin
D_{ion} = diffusion constant for a particular ion

Tables of ionic conductance in aqueous solution as well as diffusion constants can be found in the *Handbook of Chemistry and Physics*.[1]

Most contaminants from processing do not exist in isolation from one another. Rather, there may be several ionic species present, some of which will interact with one another to create new ionic species.

Solubility of the contaminant salts also depends on the pH. Water ionizes under a bias voltage, creating an acidic medium at the anode and a basic medium at the cathode, as shown in the following reactions [Eq. (59.7)]:

$$\begin{aligned} &\text{Anode:} && \mathrm{H_2O = \tfrac{1}{2}O_2 + 2H^+ + 2e^-} \\ &\text{Cathode:} && \mathrm{2H_2O + 2e^- = 2OH + H_2} \\ & && \mathrm{O_2 + H_2O + 4e^- = 4(OH)} \end{aligned} \tag{59.7}$$

This creates a pH gradient from anode to cathode.

Temperature is another important factor to consider. An increase in temperature increases ion solubility, mobility, and reactivity.

In summary, several factors affect electrochemical migration. These include the nature of substrate and metallization, the presence of contaminants, the voltage gradient, and the presence of sufficient moisture. This last

element is critical, for without sufficient monolayers of water on the surface, ion mobility is impossible.

59.3 DEVELOPING A QUANTITATIVE COPPER CORROSION TEST

The IPC has a number of test methods to qualify substrates and soldering materials. Surface insulation resistance (SIR) is most commonly used to measure ECM susceptibility, but other common tests used over the years have been the copper mirror test (a qualitative measure of raw flux-induced corrosion), a flux corrosion test for assessment of flux residues on copper under harsh environments, qualitative and quantitative tests for individual halides, and for total ionics. At the present time a quantitative test for the corrosivity of flux residues on copper is needed—and this is important because copper is the base metal of almost all electronic circuits.

In 1989, Bono introduced the first quantitative test method.[2] The test coupon consisted of a consisted of a single-sided epoxy glass PWB with uncoated copper traces 9- to 10-μm-thick ~75 μm distance between points A and B (Fig. 59.2*a*). These traces constitute the anodes in an electrolytic cell with broad cathode tracks on either side of the thin copper traces. The separation between the anode and cathode was 2 mm. Each test piece contained five copper traces and a sixth electrolytic cell where the copper trace was replaced by a standard resistor approximately equal to the measured resistance of the printed traces. Figure 59.2*b* shows the anodic traces connected to a 12-V power supply (V_2) through a current-limiting resistor of 50 kΩ (R_2). The cathodic tracks were powered by a 250-V supply

(V_1) across a 5-kΩ resistor (R_1) used to monitor the SIR of the substrate.

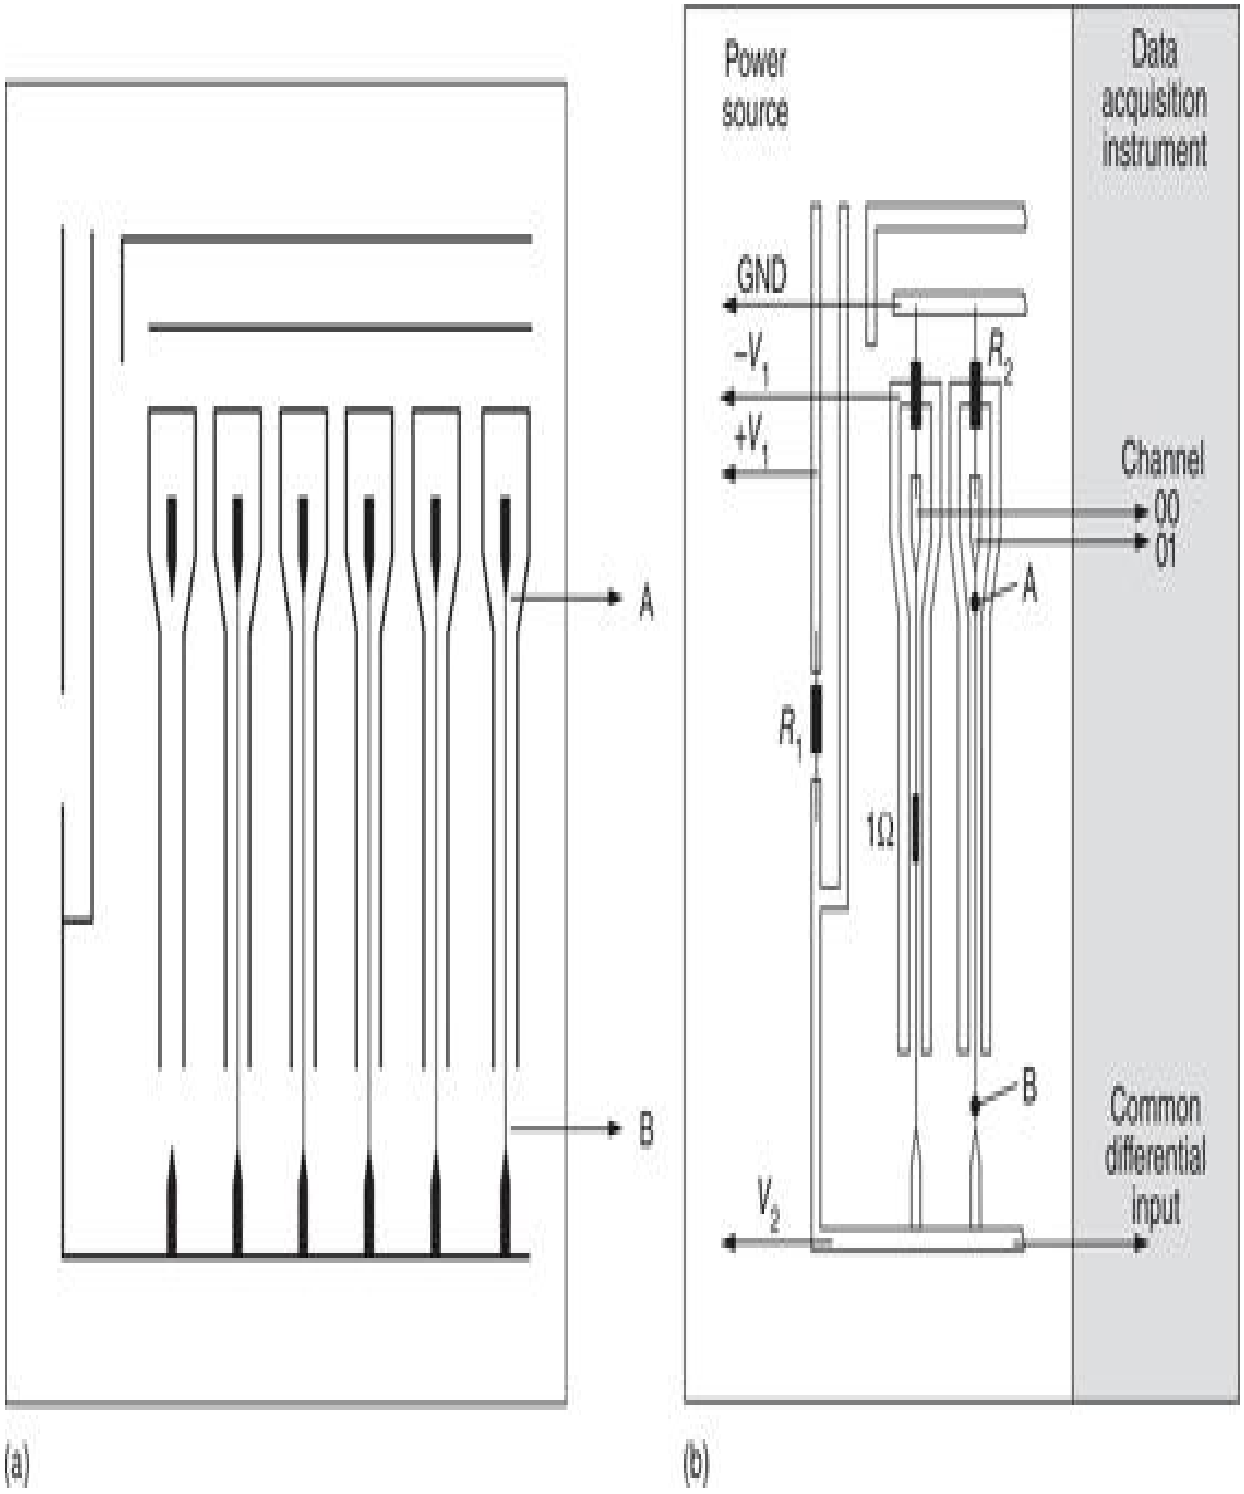

FIGURE 59.2 (*a*) Bono test coupon and (*b*) test configuration for corrosion test with V_1 = 250 V, V_2 = 12 V, R_1 = 5 kΩ and R_2 = 50 kΩ.[2]

The Bono test is designed to indicate the extent of corrosion by measuring the change in resistance of the copper trace over time while being exposed to controlled humidity and a bias voltage. The resistance R_{wire} of the copper trace is given by

$$R_{\text{wire}} = \rho \frac{L}{A} \tag{59.8}$$

where ρ is the resistivity of copper, L is the length of the trace and A is its cross-sectional area.

When corrosion occurs, the cross-sectional area of a trace decreases and R_{wire} increases. By measuring the resistance with respect to time, the extent of the corrosion can be assessed. A time dependent corrosion factor $CF(t)$ is defined as

$$CF(t) = \frac{R_{\text{wire}(t)} - R_{\text{wire}(0)}}{R_{\text{wire}(0)}} \times 100\% \tag{59.9}$$

where $R_{\text{wire}(0)}$ is the initial resistance of the trace and $R_{\text{wire}(t)}$ is its resistance at time t.

Liquid flux was initially used to evaluate the corrosion factor[2]; more recently, the method has been applied to flux-cored solder wire residues, although some parameters of the test coupon were changed.[3] For example, the spacing between anode and cathode in the first study was 2 mm, while it was reduced to 120 µm in the second. Also, the length of the anodic trace was changed from 80 to 145 mm. Other changes in the electrical parameters were even more significant; for example, the direct-current (DC) voltage V_1

applied to polarize the electrolytic cell was decreased from 250 to 20 V. Recently, this test was used to assess the corrosivity of solder paste residues.[4] However, no detailed parameters to define the test parameters were reported. To further develop this test method, it is necessary to precisely define all the parameters of the test method.

The Bono test was modified by Turbini et al.[5,6] to better characterize the effect of soldering flux residues on the metallic circuits of PWBs. Major changes shown in Fig. 59.3 were made to the test coupon. Each coupon consists of a single-sided epoxy glass printed circuit board with five electrolytic cells containing uncoated copper traces. See Figs. 59.2 and 59.3. The spacing between the anode and cathode was set to 0.5 mm to match the spacing on the IPC-B-24 test boards used for SIR testing of soldering fluxes. To enhance the sensitivity of the test, the length of a copper trace was increased by using U-shaped tracks, and its cross-sectional area was reduced through the use of a thinner, 8.6-μm copper film. Turbini et al.[6] also moved the resistors from the test board in the environmental chamber to an external terminal block to eliminate testing inaccuracies related to the high temperature and humidity inside the chamber. Another significant modification was the decrease of V_1 from 250 to 50 V to prevent formation of conductive anodic filaments (CAF), which had been the cause of failure in the original design of Bono, rather than reflecting the actual corrosion factor. Figure 59.4*a* and *b* show schematics of the electrical corrosion circuit of one electrolytic cell in Turbini's tests 1 and 2, respectively. In the case of the circuit for test 1 (Fig. 59.4*a*), breakdown of the insulation resistance of the substrate caused the current I_1 through the copper trace (R_{wire}) to become additive to the current I_2 from the power supply (V_2). Thus, a sensor was added to the circuit to determine whether such breakdown of insulation resistance was affecting the accuracy of the copper trace resistance

measurements shown in the circuit wiring (Fig. 59.4*b*). The direction of the current from the 10-V supply was changed so that any breakdown in the insulation resistance of the 50-V circuit would reduce the resistance value obtained and thereby signal a problem.

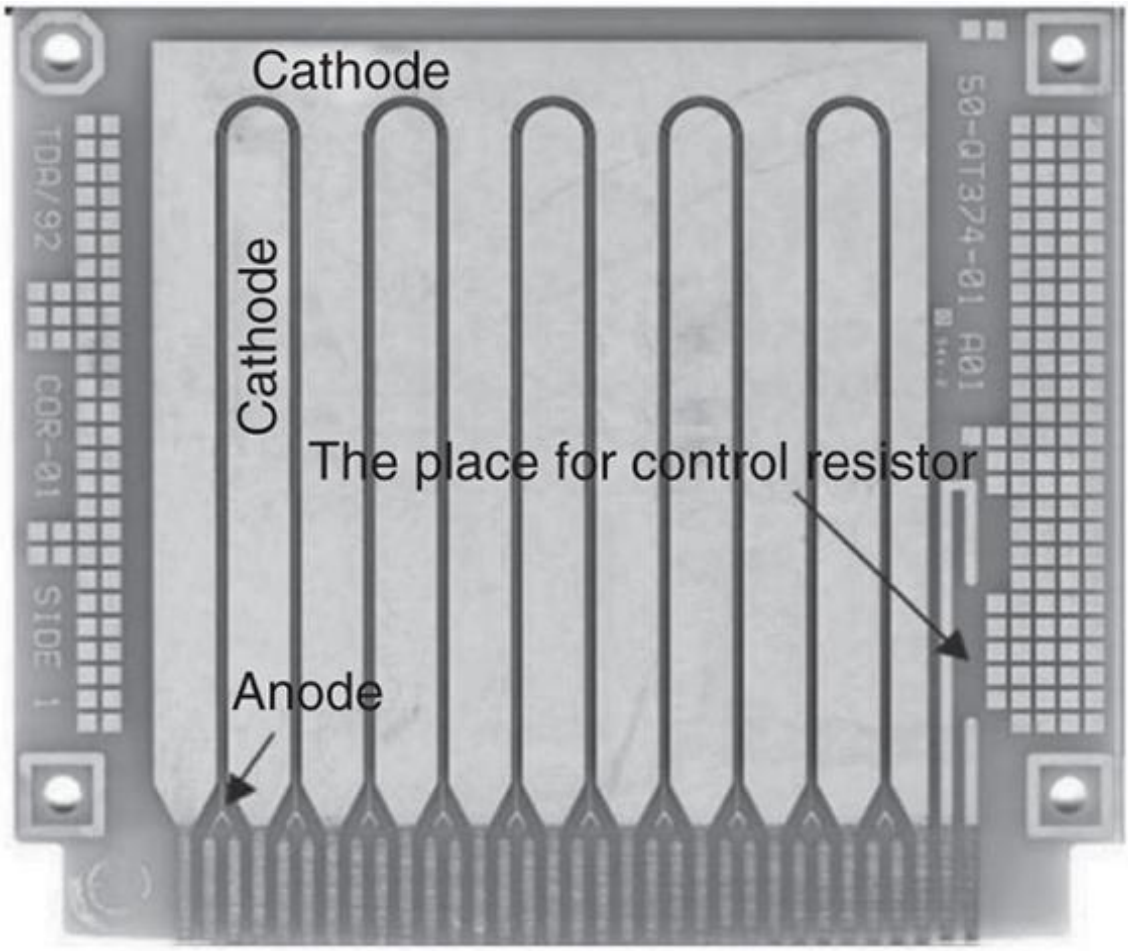

FIGURE 59.3 Schematic of test coupon used by Turbini et al.[6]

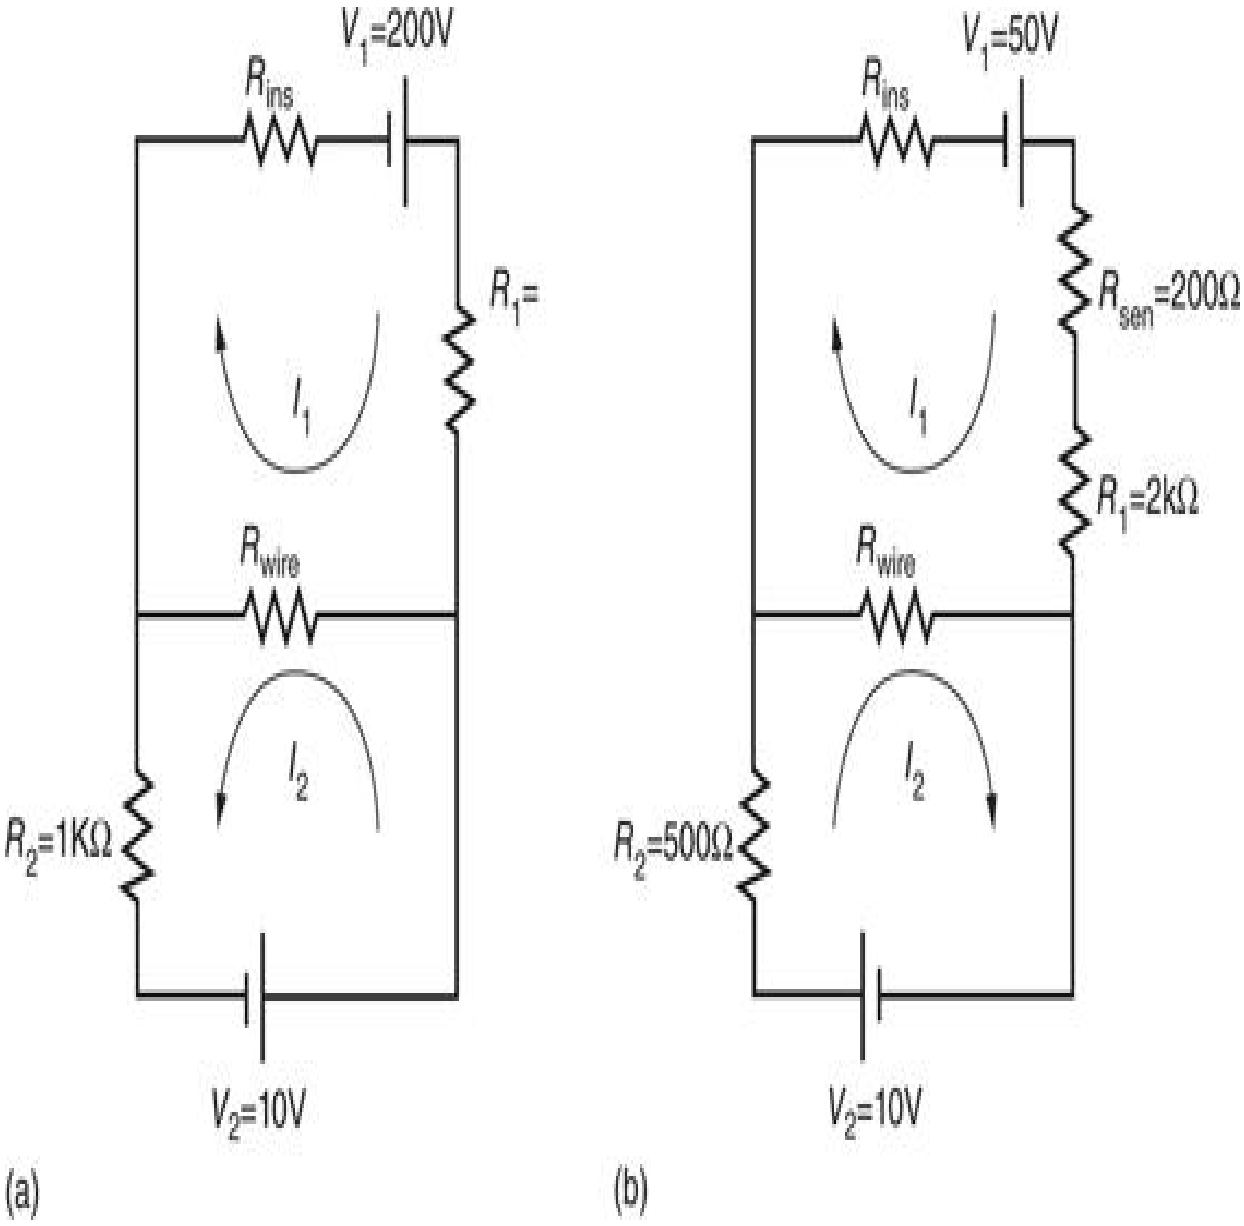

FIGURE 59.4 Electric circuit for an electrolytic cell in (*a*) Turbini test 1[5] and (*b*) Turbini test 2.[6]

Zhou et al.[7] developed a quantitative test method and used it to characterize the corrosion effects of five weak organic acid (WOA) fluxes (abietic acid, succinic acid, glutaric acid, adipic acid, and malic acid) on copper circuits. Experiments were performed under three temperature/humidity conditions (85°C/85 percent RH, 60°C/93 percent RH, and 40°C/93 percent RH) using two

WOA solution concentrations. The extent of corrosion under the various conditions was measured in terms of the %CF value.

Figure 59.5 presents a schematic of the electrical test system. An environmental chamber was used to provide different temperatures and humidities for accelerated aging. A Keithley 2420 source meter provided the precision voltages and currents to measure the resistance of the anodic copper wires. The test cables from the interface box were wired to the scanner box consisting of a Keithley 3706 switching system with a digital multimeter. The resistors (200 Ω and 2 kΩ) used for each test coupon were wired into the resistor interface box. The connectors in this box were standard serial connectors. The electrical wiring of each test coupon is shown in Fig. 59.6.

FIGURE 59.6 Schematic showing electrical wiring of each test coupon.[7]

Five sets of experiments were conducted with solutions containing each WOA at two different concentrations denoted as 1 and 2. In each case, concentration 2 was double concentration 1. The experimental conditions used for each of the five experiments are provided in Table 59.1. The test coupon used is shown in Fig. 59.3. It consisted of a single-sided epoxy glass PWB with five electrolytic cells. The thin uncoated copper traces act as anodes between two broad copper tracks acting as cathodes. The resistance of an anodic copper trace was measured to be approximately 5 Ω.

TABLE 59.1 Experimental Conditions in Tests for Each WOA

Test	Environment (°C, %RH)	Duration	Deposition (x 10^{-4} moles)
1	85°C/85%RH	7 days	4.5
2	40°C/93%RH	20 days	4.5
3	40°C/93%RH	20 days	9.0
4	60°C/93%RH	20 days	4.5
5	60°C/93%RH	20 days	9.0

The test coupons were fluxed and reflowed, allowed to cool and then a standard resistor was soldered to each board for reference. The board was inserted into a card edge connector and placed in an environmental chamber at the desired temperature and humidity conditions. Measurements of the resistance of the anodic traces were taken once equilibrium was reached, after 24 h for the 85°C/85 percent

RH tests and 40 h for the 60°C/93 percent RH and 40°C/93 percent RH tests. When the test had been completed, the coupons were removed from the chamber and examined with an optical microscope.

A summary of the final %CF values of each acid under the five test conditions is presented in Table 59.2. This table and subsequent plots present the average and standard deviation of the final CF values measured on the ten copper traces on two test coupons exposed to each acid. Figure 59.7*a* shows the evolution of %CF over the course of test 1 at the experimental conditions of 85°C/85 percent RH with the lower flux concentration. As shown in Table 59.2, all of the CF values remained below 0.2 percent, indicating no significant corrosion of the PWB copper traces. This result is expected because almost all the WOA depositions would have evaporated or decomposed at 85°C, as noted by Christian[8] and Tellefsen.[9] All the test boards were clean with no visible residues, except for a color change of the copper metal where the WOA had been applied. The results of test 2, conducted under conditions of 40°C/93 percent RH at low WOA concentration for 20 days, are shown in Fig. 59.7*b*. Clear evidence of corrosion which varied among the fluxes tested was observed in this case. Small amounts of unevenly distributed blue and green residues appeared on the anodic tracks on boards exposed to malic acid.

TABLE 59.2 Summary of Final CF Values for Each Acid in Tests 1 to 5

WOA	Test 1 85°C 85% RH 1x[a] (%)	Test 2 40°C 93% RH 1x (%)	Test 3 40°C 93% RH 2x[a] (%)	Test 4 60°C 93% RH 1x (%)	Test 5 60°C 93% RH 2x (%)

FIGURE 59.7 Evolution of %CF values during the course of (*a*) test 1, (*b*) test 2, (*c*) test 4, and (*d*) test 5.[7]

The WOA solution concentration during test 3 was double that used during tests 1 and 2, with the other accelerating conditions (40°C/93 percent RH) maintained the same. It was easy to observe dark-green residues on the copper traces of the malic acid flux at the end of the experiment, as well as long copper dendrites. It was observed that the %CF values obtained in test 3 compared with those measured in test 2 reveal the very strong effect of WOA concentration on copper corrosion. Test 4 was conducted under the condition of 60°C/93 percent RH at low WOA concentration for 20 days. Except for temperature, all other conditions were identical to those in test 2. As shown in Table 59.2 and Fig. 59.7*c*, the corrosion factors for each acid were greater than those obtained in test 2 but less than those measured in test 3; no dendrites were identified on any coupon at the end of test 4. Test 5 was conducted at high WOA concentration, intermediate temperature (60°C), and high RH (93 percent) for 20 days (Fig. 59.7*d*). The coupon exposed to malic acid showed excess green residues over most of its surface. The %CF values among the fluxes tested were easily distinguishable from one another under these test conditions and were also higher than those measured during any other test. The corrosivity of the WOAs was found to increase in the following order: abietic acid < succinic acid < adipic acid ~ glutaric acid < malic acid, which agrees with that of SIR measurements reported in the literature.[10]

The CF values at 60°C were greater than the values at 40°C, which were greater than the values at 85°C. This suggests that a temperature of 40°C is not high enough to enhance the rate of corrosion. At 60°C, corrosion likely occurs faster than the evaporation and/or thermal decomposition of the WOA. Thus, the results clearly show that this is the best temperature for distinguishing the

corrosion effects of the different WOAs. Consequently, T/H conditions of 60°C/93 percent RH are the recommended stress conditions for corrosion testing. Although the original tests at 60°C were conducted for 20 days, it is clear from the data that a testing duration of 10 days should be sufficient to easily distinguish between the %CF values obtained for the various WOAs.

59.4 UNDERSTANDING CAF FORMATION

In the mid-1970s, Bell Labs' researchers were concerned about potential failures of printed wiring boards intended for high-voltage switching applications. They reported[11,12] on accelerated life testing of flexible PWBs coated with ultraviolet (UV)-cured resin, and identified two new failure modes: conductive bridges between conductors on the surface, and conductive shorts through the substrate.

AT&T Bell Labs' test vehicle (see Fig. 59.8) was a flexible epoxy glass PWB, 0.005 to 0.007 in thick with comb patterns of 0.008 in lines and 0.009 in spaces. Some combs were biased on the surface and some were biased through the substrate. Processed boards, coated with conformal coating, were tested from 35 to 95°C, 25 to 95 percent relative humidity (RH), and direct current (DC) voltages up to 400 V. For accelerated testing at 85°C, 80 percent RH, and 78 V bias, failures occurred within 2 to 5 days.

Bell Labs identified two major failure modes that they described as causing "catastrophic loss of insulation resistance due to the formation of conductive bridges between conductors." The first failure mode—*through-substrate shorts*—only occurred above 75°C and 85 percent RH and thus was not considered to be a problem at use conditions (see Fig. 59.9).[11]

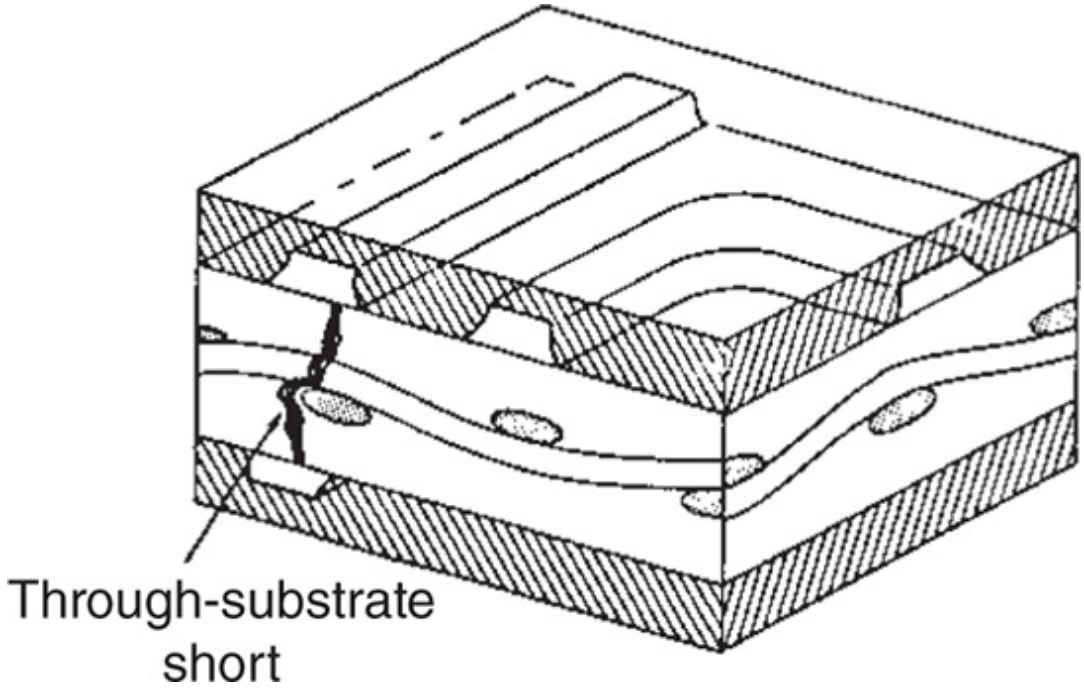

FIGURE 59.9 Through-substrate short.[11] (© 1976 IEEE.)

The second mode involved shorts between conductors on the same side of the board in which conductive material accumulates between the glass bundles and the epoxy (see Fig. 59.10). R. H. Delaney and J. N. Lahti[12] noted that the thicker the buttercoat, the less this failure was observed. They also detected a failure, which they termed *anodic eruption failure mode*, in which corrosion products emerged

from the anode to the covercoat surface, charring the surface, and then growing back through the covercoat to the cathode, where it shorted (see Fig. 59.11).

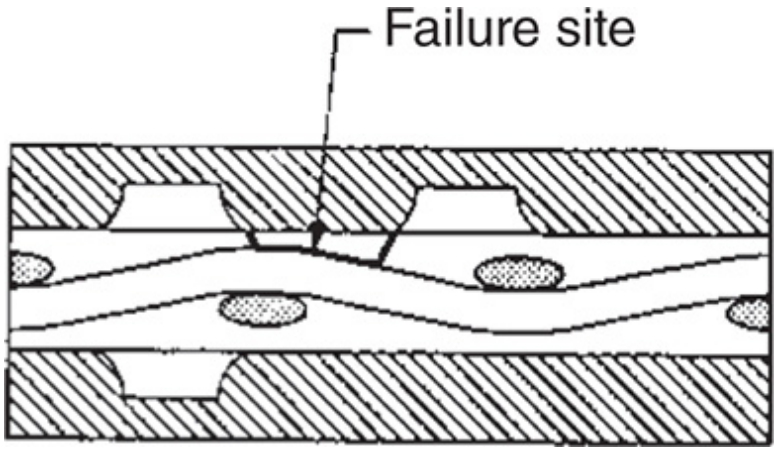

FIGURE 59.10 Subsurface substrate failure.[11] (© 1976 IEEE.)

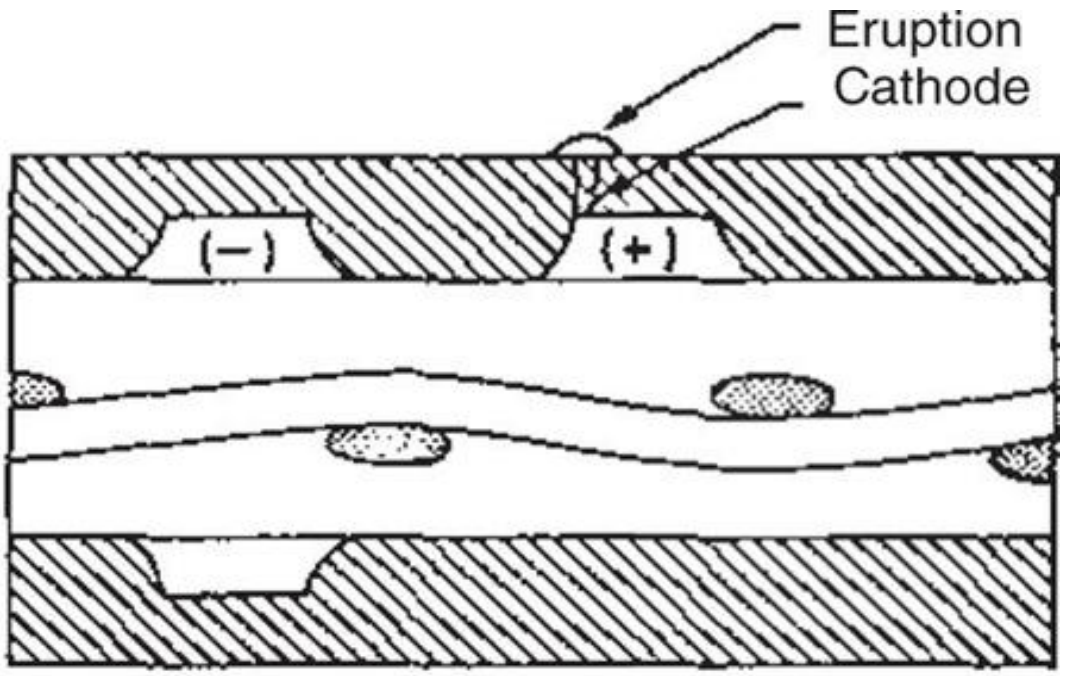
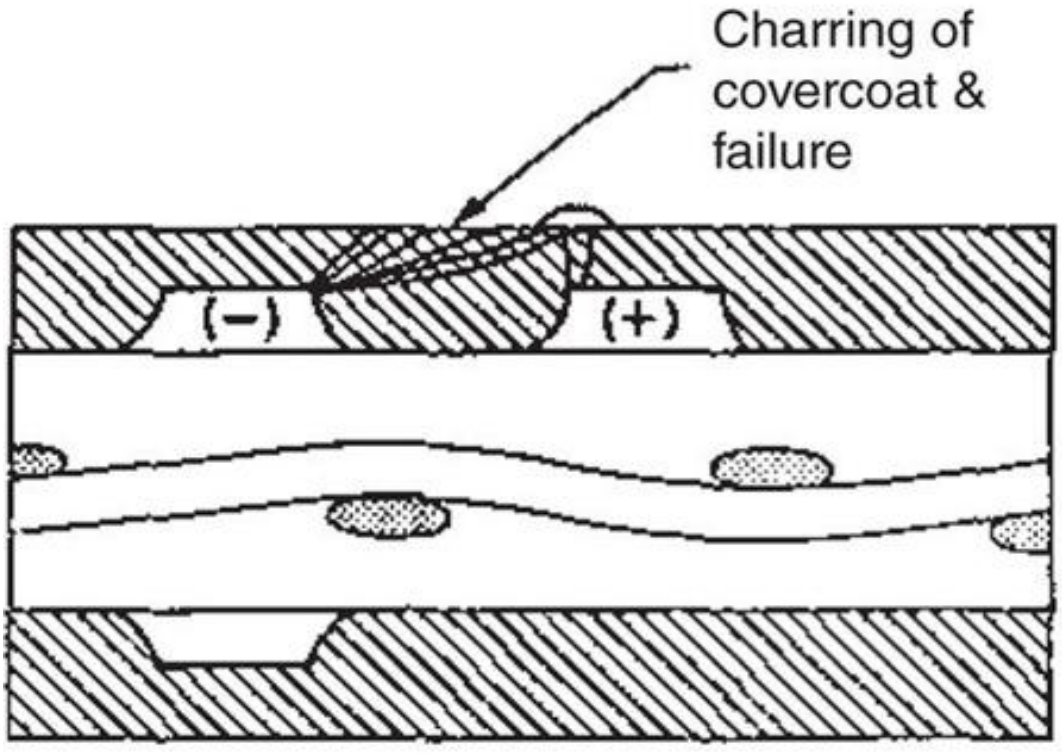


Early stage



Late stage

FIGURE 59.11 Anodic eruption failure mode.[11] (© 1976 IEEE.)

In 1976, Der Marderosian at Raytheon, while studying measling, crazing, and delamination, examined the reliability of multilayer PWBs by applying a DC voltage between ground planes and conductor traces (see Fig. 59.12).[13] Test coupons were biased at 100 V and aged at 65°C and 95 percent RH for 10 days. Based on the results, Der Marderosian reported a failure that he termed the “punch thru” phenomenon. This is similar to the “thru substrate shorts” reported by Delaney.[12] To study this failure further, Der Marderosian obtained test coupons from three different vendors biasing some at 100 V DC, others at 100 V AC, and a third group was unbiased. Since “punch thru” was observed only when DC bias was applied, Der Marderosian concluded that this failure was due to electrochemically initiated metal migration. He reported that the number of incidents of “punch thru” decreased as aging voltage was decreased. The addition of a urethane conformal coating appeared to accelerate, not suppress, the problem.

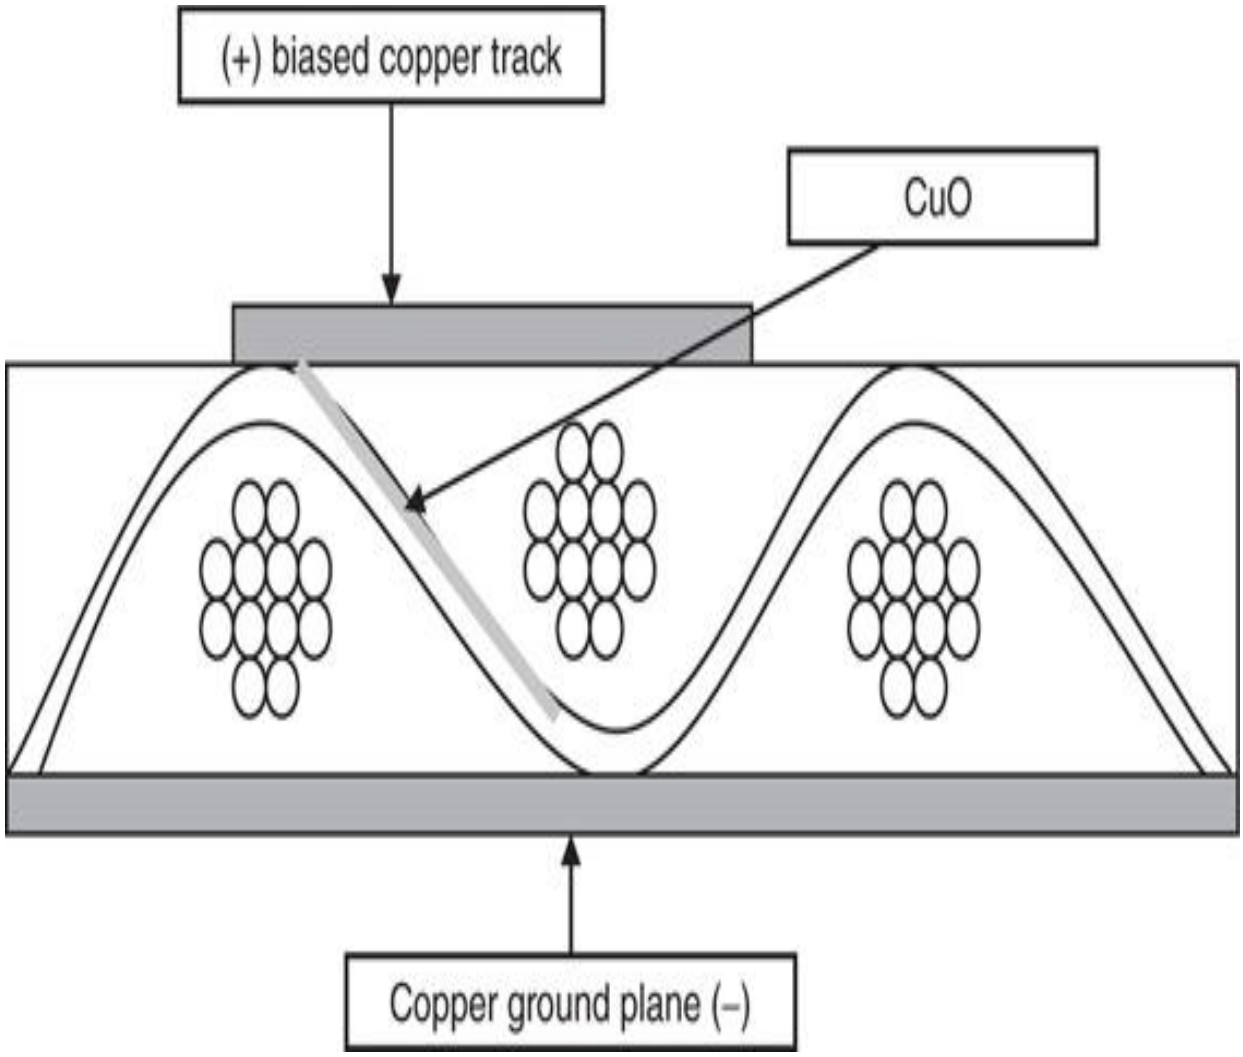


FIGURE 59.12 Raytheon test coupon with “punch thru” from anode trace to copper ground plane.[13]

“Punch thru” is an electrical failure that eventually manifests itself in a rupture of the insulation between two layers of copper metallization. In the early stages, Der Marderosian observed conductive copper-containing deposits that he assumed were CuO along the glass fibers. Eventually these deposits shorted to the cathode, carbonizing the epoxy causing it to be more conductive. Epoxy blowout then ruptured the glass fibers. In the later stages, Der Marderosian observed melting of the copper traces.

Equation (59.10) represents Der Marderosian's concept of the production of CuO and $Cu(OH)_2$ at the anode. At the cathode, reduction takes place yielding copper and hydrogen gas. He noted that copper hydroxide decomposes to copper oxide above 60°C.

$$3Cu + 3H_2O = CuO + Cu(OH)_2 + 2H_2 + Cu \qquad (59.10)$$

Lando et al.[14] first used the term conductive anodic filament (CAF) to describe this failure in 1979. They defined the mechanism of CAF formation as a two-step process: degradation of the epoxy/glass interface, followed by the electrochemical reaction [see Eq. (59.10)].

$$\begin{aligned} &\textit{Anode:} && Cu = Cu^{n+} + ne^- \\ & && H_2O = \tfrac{1}{2}O_2 + 2H + 2e^- \\ &\textit{Cathode:} && 2H_2O + 2e^- = H_2 + 2OH^- \\ & && H_2O + \tfrac{1}{2}O_2 + 2e^- = 2OH^- \\ & && Cu^{n+} + ne^- = Cu \end{aligned} \qquad (59.11)$$

In 1980, T. L. Welsher et al.[15] reported that CAF was potentially a serious reliability problem for closely spaced conductors and proposed a mean time to failure (MTTF) based on Eq. (59.11):

$$MTTF = a(H)^b \exp(E_a/RT) + d(L^2/V) \qquad (59.12)$$

where H = humidity
E_a = activation energy
R = gas constant
T = temperature in Kelvin
L = conductor spacing
V = voltage
a, b, Ea, d = material dependent

Welsher et al.[15] noted that additional work was needed to determine the exact dependence of CAF on conductor spacing and humidity. They also reported that glass-reinforced triazine is CAF-resistant.

In 1980, they expanded their view of the MTTF and reported it as shown in Eq. (59.13):

$$\mathrm{MTTF} = \alpha\left(1+\beta\frac{L^n}{V}\right)\cdot H^{\gamma}\exp\frac{E_a}{kT} \tag{59.13}$$

where α, β = material-dependent constants
γ = humidity-dependent constant
n = related to the orientation of the conductors
L = spacing
V = voltage
H = humidity
E_a = activation energy
k = Boltzmann's constant
T = temperature in kelvins

Ready and Turbini[13] studied the effect of voltage and spacing on CAF failures for a hole-to-hole test pattern (see Fig. 59.13). Using two different spacings (0.50 and 0.75 mm) and two different bias voltages (150 and 200 V), they were able to show the relation is L^4/V^2 [see Eq. (59.14)]:

$$\text{MTTF} = C \exp(E_a/kT) + d(L^4/V^2) \tag{59.14}$$

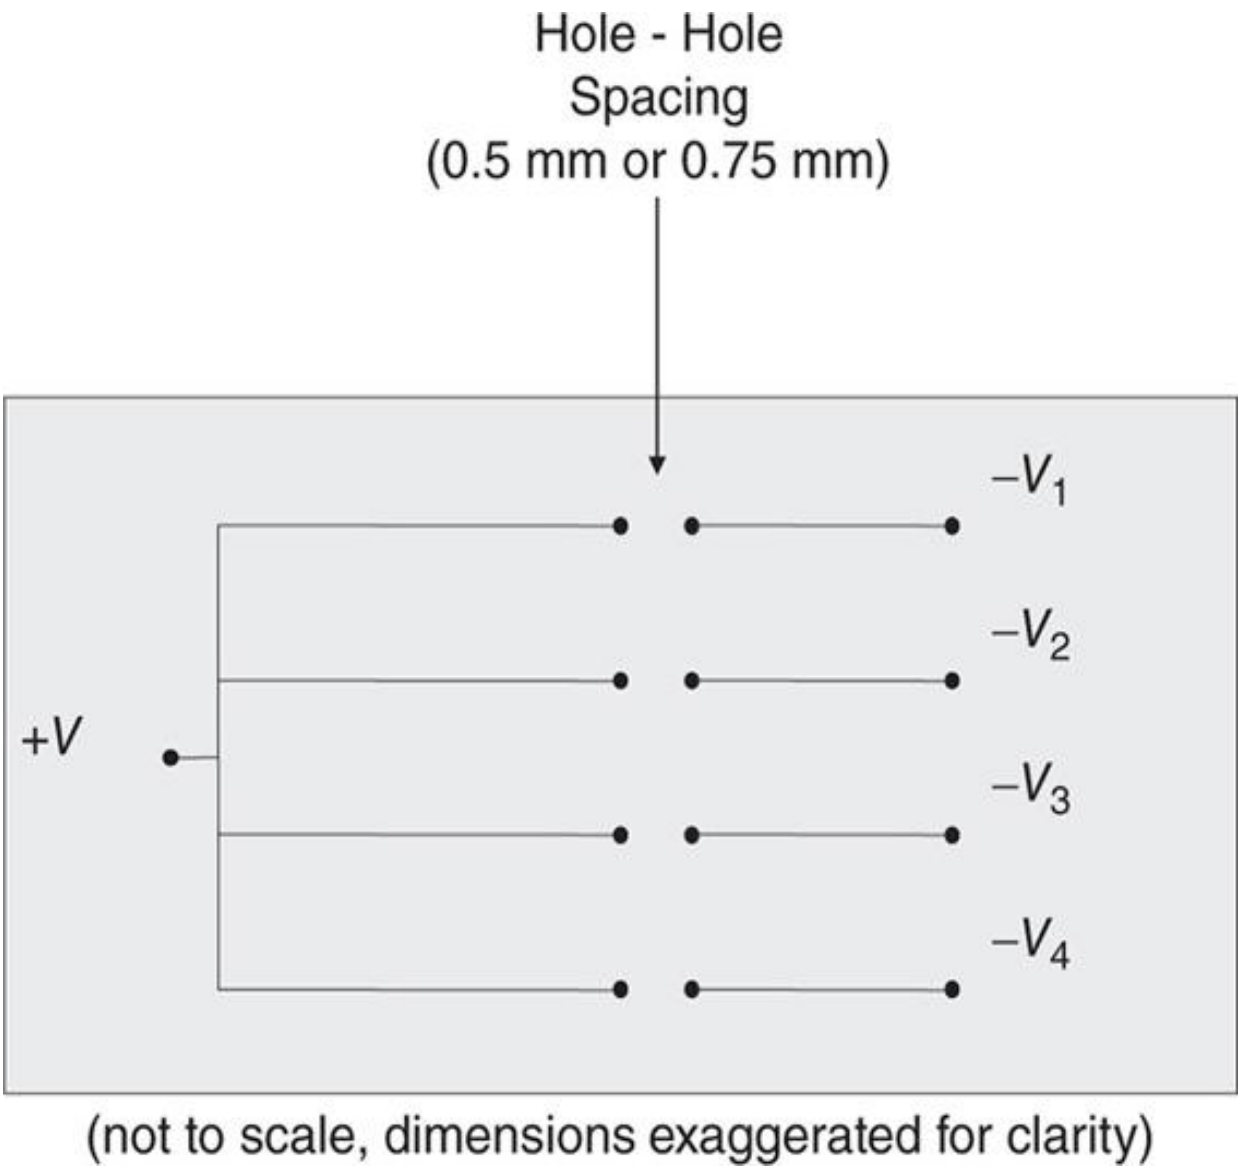

FIGURE 59.13 Hole-to-hole test vehicle used by Ready et al.[16]

59.4.1 CAF Formation

In the case of CAF formation, copper ions are created electrochemically at the anode. Residual chloride ions from the reaction of epichlorohydrin with Bisphenol A (forming a precursor to the epoxy) exist at low levels in the FR-4 substrate. These react with the copper ions and later water to produce the CAF[16]—$Cu_2(OH)_3Cl^-$, which grows from the anode since it is insoluble in acid. The favored path for this is at the epoxy glass interface.

Ready and Turbini[16] identified the chemical nature of CAF as atacamite: $Cu_2(OH)_3Cl$. An examination of the Pourbaix[17] diagram (see Fig. 59.14) for the copper-chlorine-water system reveals that copper hydroxy chloride is insoluble below pH4 and thus this salt will grow from the anode, which is acidic. They also explained that the high conductivity of this salt, which causes catastrophic failure when it bridges to the cathode, suggests that it conducts through electrons and holes, that is, it has semiconductor properties. CAF filaments are typically no larger than 50 μm in diameter and 0.2 mm in length.

59.5 FACTORS THAT AFFECT CAF FORMATION

A number of factors affect CAF formation. These include substrate material, conductor configuration, processing, voltage and spacing, soldering flux, and humidity in the storage and use environment.

59.5.1 Substrate Material

Lando et al.[14] compared FR-4 with several substrates: G-10 (a non-fire-retardant epoxy/woven glass material), polyimide/woven glass (PI), triazine/woven glass, epoxy/woven kevlar, and finally polyester/woven and chopped glass. Similarly, B. Rudra et al.[18] performed an extensive experimental comparison among the substrates: bismaleimide triazine (BT), cyanate esters (CE), and FR-4. In addition, Ready[19] compared the CAF susceptibilities of FR-4 with CEM-3 (a substrate similar to G-10 except with chopped glass) and MC-2 (a blended polyester and epoxy matrix with woven glass face sheets and a chopped glass core). Of all materials tested by these investigators, the BT material proved to be most resistant to CAF formation (due to its low moisture absorption characteristics). Conversely, the MC-2 substrate proved to have the least resistance to CAF formation. The susceptibility of the materials follows the trend below:

MC-2 > Epoxy/Kevlar > FR-4 ~ PI > G-10 > CEM-3 > CE > BT

To ensure immunity to CAF, the laminate of preference is BT. In recent years, laminate suppliers have developed other CAF-resistant substrate materials. However, there is a cost penalty to consider.

59.5.1.1 Conductor Configuration. Lando et al.[14] evaluated several different conductor configurations:

Hole-to-line (H-L)
Hole-to-hole (H-H)

This evaluation showed that susceptibility to CAF is H-H > H-L > L-L. Lahti et al.[20] demonstrated that the smaller the spacing between conductors and the greater the proximity of the glass fibers to the copper conductors, the faster the growth of CAF. They noted that for a multilayer board, failure initiated in the most deeply buried layers.

59.5.2 Processing

The epoxy glass bond can be weakened by the drilling or depaneling processes in PWB manufacture. It will also be weakened during the soldering process due to the difference in coefficient of thermal expansion (CTE) of the epoxy and glass. Data from Turbini et al.[21] demonstrated that the increased soldering temperature associated with lead-free alloys significantly increases the incidence of CAF.

Another processing factor is the diffusion of polyglycols from water-soluble flux into the PWB substrate that occurs during soldering. Since the diffusion rate is temperature-dependent, the length of time that the board is above the glass transition temperature will affect the amount of polyglycol absorbed into the epoxy, and that will in turn affect its electrical properties. J. A. Jachim et al.[22] reported on water-soluble flux-treated test coupons that were

prepared using two different thermal profiles. Those which experienced the higher thermal profile exhibited a surface insulation resistance (SIR) level that was an order of magnitude lower than those processed under less aggressive thermal conditions.

59.5.2.1 Voltage and Spacing. Two other critical factors used in determining CAF susceptibility are voltage and spacing. The CAF growth is fueled by the electric field (*V/d*), and failure occurs more quickly with smaller spacing between conductors.

59.5.3 Effect of Soldering Flux

It has been shown that polyglycols[22] (which are found in water-soluble fluxes) diffuse into the epoxy during soldering. This absorption has been shown to reduce electrical performance by increasing moisture uptake by the substrate.[23] Jachim et al.[24] were the first to link the use of polyglycols in soldering fluxes and fusing fluids to increased susceptibility to CAF formation.

Ready et al.[25] showed that the use of certain water-soluble fluxes or fusing [hot air solder level (HASL)] fluids could increase CAF formation. In examining a catastrophic field failure (see Fig. 59.15), they demonstrated the presence of a copper-bromide containing salt between an inner layer power plane and ground pin, separated by 0.005 in. Using a test coupon manufactured in the same lot as the failed product, they extracted the flux residues from an inner layer of the multilayer board and used ion chromatography to match the residues from the board's inner layer with the constituents of the flux.

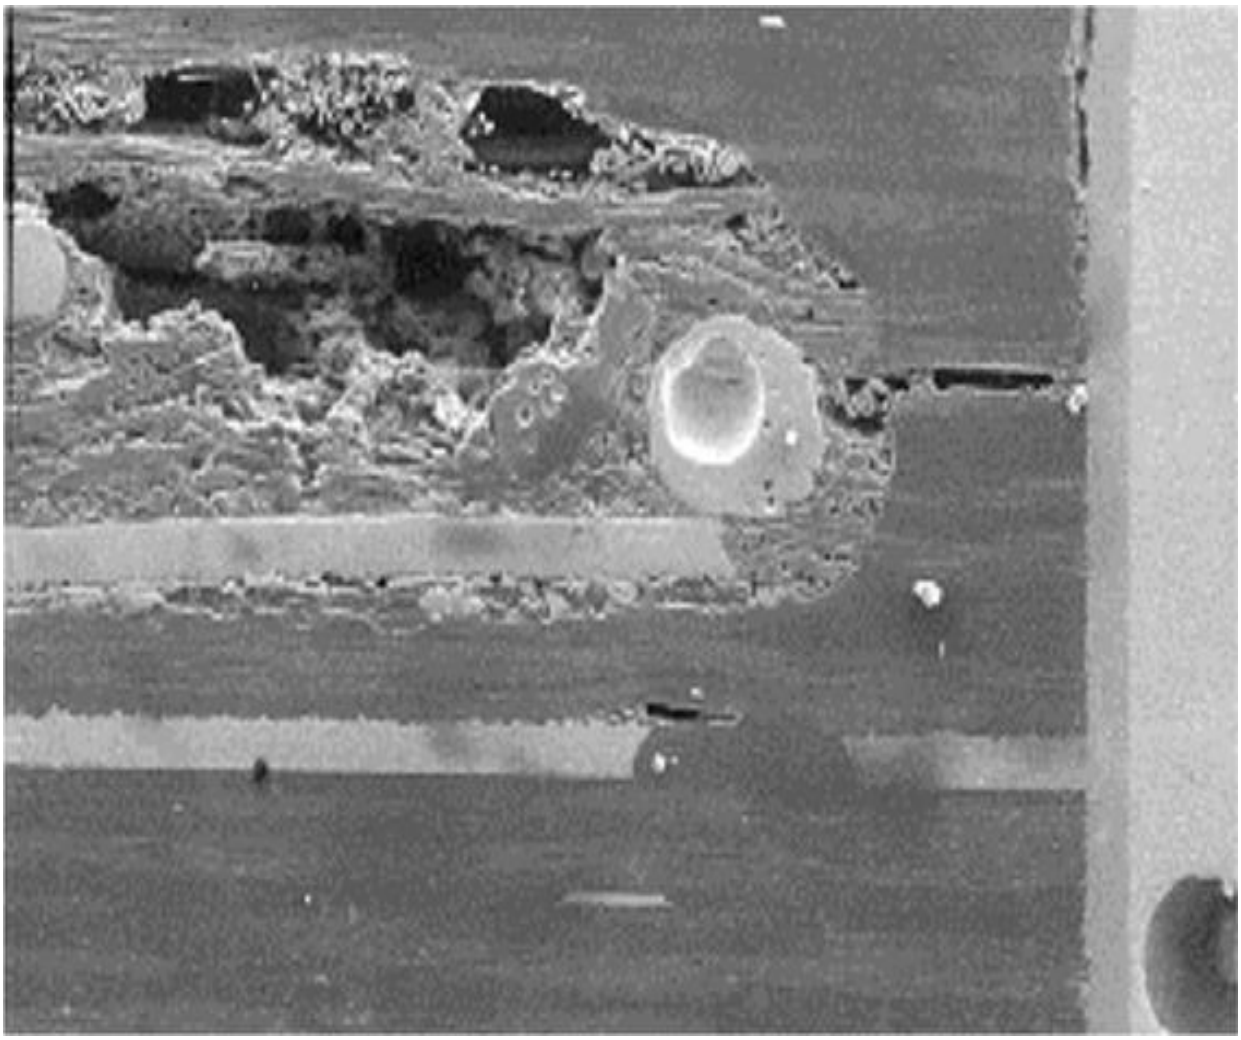

FIGURE 59.15 Catastrophic field failure of military hardware. The conductive filament grew from the +20 V ground plane to the −20 V ground pin. Flux residues enhanced this failure rate.[25]

59.5.4 Humidity in the PWB Storage and Use Environment

J. A. Augis et al.[26] determined that there is a humidity threshold below which CAF formation will not occur. They found that this relative humidity threshold depends on operating voltage and temperature. It is important to remember that this relative humidity need not be present in the operating environment. Moisture absorption can occur

during any part of the assembly's lifetime. This is particularly critical during transportation or storage, when the assembly may experience harsh environmental conditions.

59.5.4.1 Determining the Chemistry of CAF Formation. It was noted that the morphology of CAF appeared different when certain fluxes are used.[16] In Fig. 59.16*a*, when no flux is used, CAF forms only as a crystalline filament at the epoxy glass interface; in Fig. 59.16*b*, the flux contained polyethylene propylene glycol (1800) and there appears to be a copper-containing compound in stratified layers within the matrix in addition to the filament at the epoxy-glass interface; and in Fig. 59.16*c*, the flux contained a linear aliphatic polyether and one sees a copper-containing compound appearing in a striated morphology as well as the crystalline filament at the interface. The analysis of the copper containing compound in the epoxy matrix leads to a complete description of the chemistry of CAF formation in the works of Caputo, et al.[27–29]

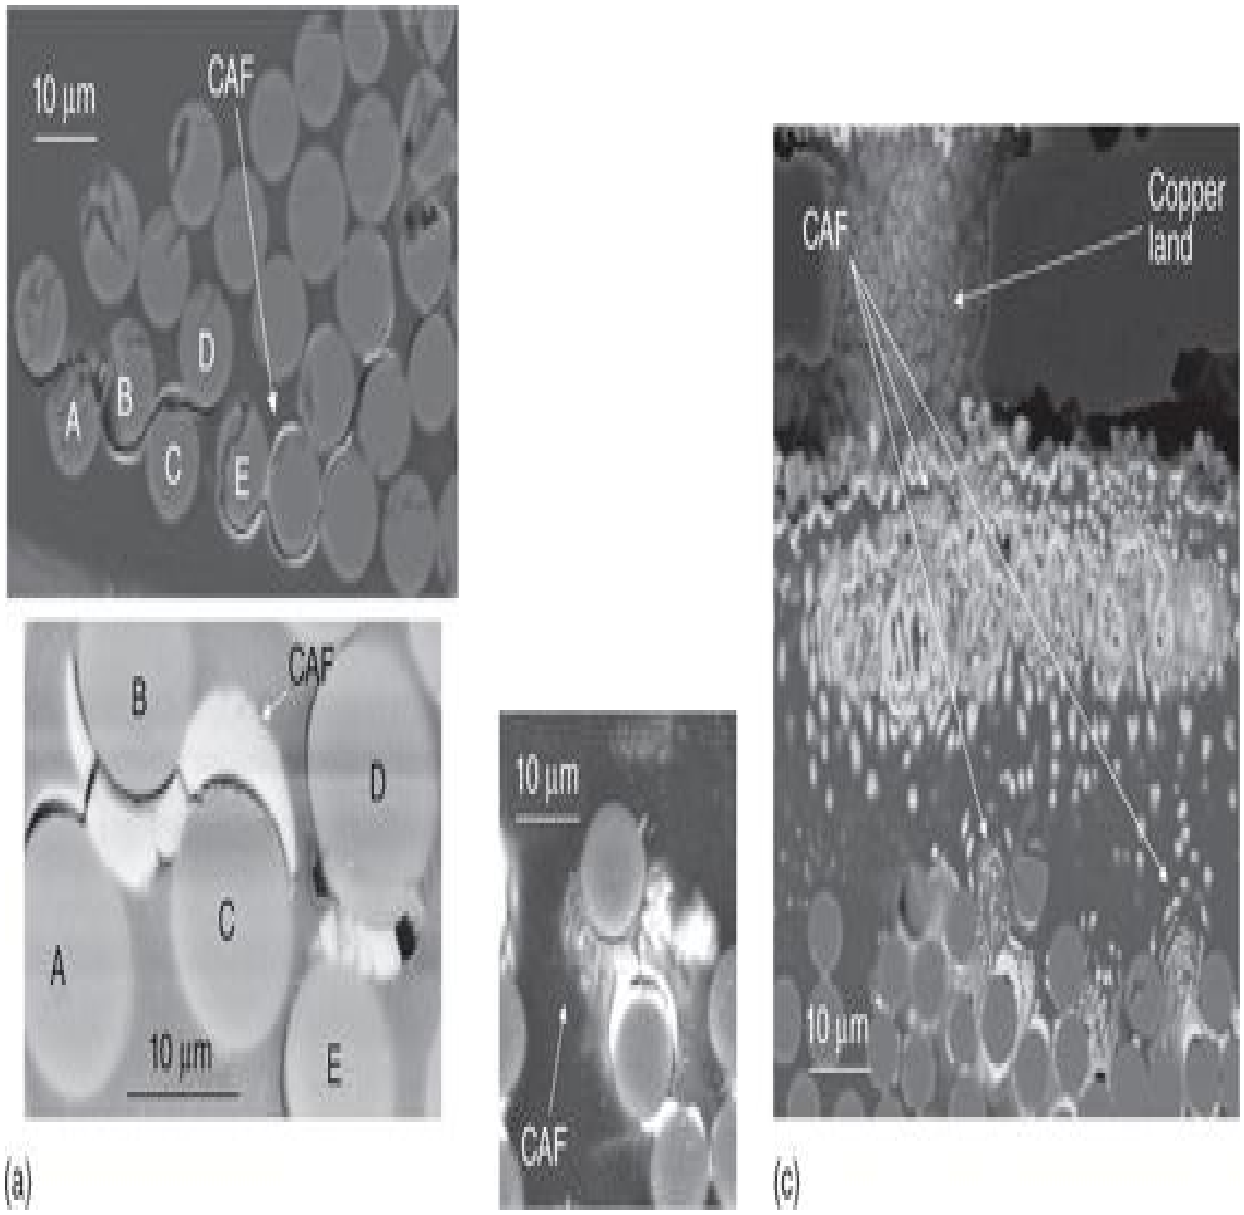

FIGURE 59.16 Morphology of CAF differs when different flux constituents are used: (*a*) CAF only at the glass epoxy interface, (*b*) copper-containing compound in stratified layer plus CAF.[16]

59.5.5 Chloride CAF

While CAF is normally found in the inner layers of multilayer boards, earlier work used single or double sided PWB in studying it since CAF can be visible as a shadow growing from the anode (Fig. 59.17).

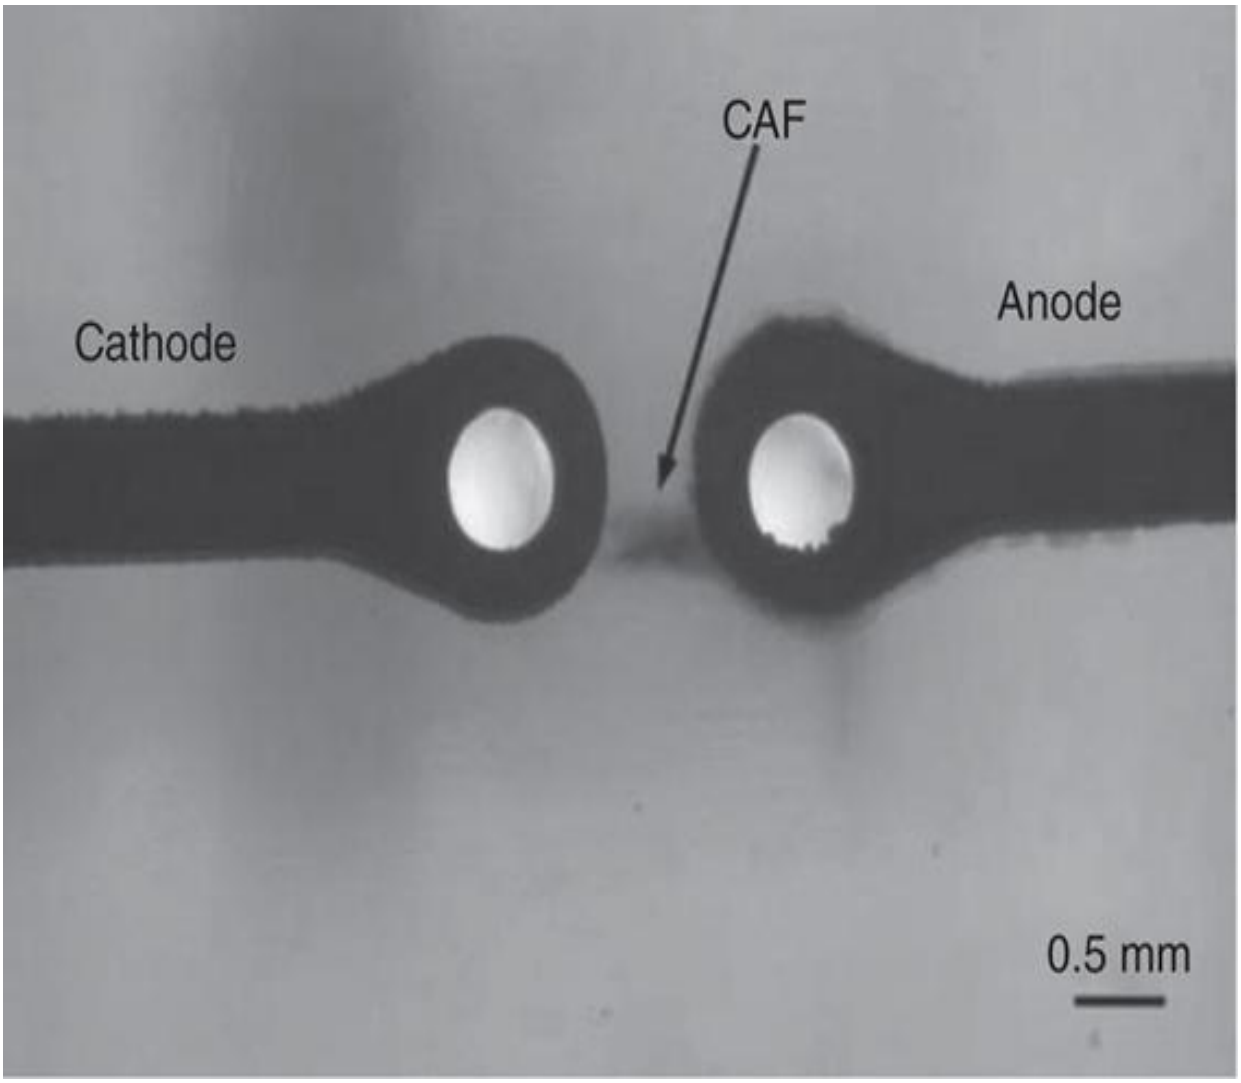

FIGURE 59.17 Typical backlighting image of CAF.[27]

In the case of CAF formation, copper ions are created electrochemically at the anode. Residual chloride ions from the reaction of epichlorohydrin with bisphenol A (forming a precursor to the epoxy) exist at low levels in the FR-4 substrate. These react with the copper ions and water to produce the CAF—$Cu_2(OH)_3Cl$—which grows from the anode since it is insoluble in acid. The favored path for this growth is at the epoxy glass interface. An SEM/EDS image of a cross-section of a board processed with polyethylene propylene glycol (PEPG) flux reveals that the compound within the polymer matrix contains copper and chlorine (Fig. 59.18).

XPS was used to identify the compound as Cu^{+1} and Cl^{-1} by matching the binding energies for the copper and the chloride. Based on CuCl being the copper compound in the polymer matrix, the following mechanism for CAF formation is proposed to occur at the anode (Eq. 59.15):

Attack of copper with chloride

$$Cu + Cl^- \leftrightarrow CuCl + 1e^-$$

Generation of oxygen and hydrogen ions

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^- \qquad (59.15)$$

CAF formation

$$12\ CuCl + 3O_2 + 6H_2O \rightarrow 4Cu_2(OH)_3Cl + 4Cu^{2+} + 8Cl^-$$

The Pourbaix diagram for the copper, chlorine, water system (Fig. 59.14) shows that $Cu_2(OH)_3Cl$ (CAF) is insoluble below pH4 and thus begins to grow from the anode.

59.5.6 Bromide CAF

Ready et al.[16,25] also demonstrated that the halide content affects the chemical nature of the CAF. When coupons are processed with either no flux or flux containing 2 wt.% chloride or 2 wt.% bromide, CAF contains both copper and chlorine. When flux containing 15 wt.% bromide was used, Ready et al.[25] found that bromide-containing CAF could be created. To verify this and to analyze the cause of the bromine-containing CAF, Caputo[29] processed test boards (Fig. 59.13) with the high bromide flux which caused the catastrophic field failure described above (see Table 59.3) The boards were reflowed between 240 and 245°C either 1 or 2 times and cleaned. After accelerated aging of the boards

at 85°C/85 percent RH using +200 V bias and +100 V test for 28 days, coupons were cross-sections. SEM/EDS analysis was used to show that the CAF contained Cu and Br (Fig. 59.19) and that the residues in the polymer matrix also contained Cu and Br (Fig. 59.20). TEM analysis of the CAF sample produced x-ray diffraction patterns matching $Cu_2(OH)_3Br$. The Pourbaix diagram[30] (Fig. 59.21) of the copper, bromide, water system shows that $Cu_2(OH)_3Br$ is insoluble below pH 7.

XPS was used to identify the copper bromide compound found in the polymer matrix as $Cu+^{1}$ and Br^{-1} by matching the binding energies for the copper and the bromide. Previous work shows that electrodissolution of copper in bromine behaves similarly to the chloride system[31,32] and thus the bromide CAF forms according to the following equation [Eq. (59.16)]:

$$4CuBr + O_2 + 4H_2O = 2Cu_2(OH)_3Br + 2Br^{-1} + 2H^{+1} \quad (59.16)$$

Extraction of ionic residues from the coupons was performed by placing the coupons in Kapak polyester bags and covering them with a measured volume of 50/50 v/v solution of isopropyl alcohol (IPA) and deionized (DI) water solution. The chloride and bromide ion levels are listed in Table 59.3, where the unprocessed control board is compared with others exposed to one or two reflows with the HASL flux. The data indicate that bromide ions are absorbed by the brominated epoxy coupon whereas the chloride ions from the HASL flux were not.

Meeker and LuValle[33] had suggested that there are two competing reaction products in CAF formation: a corrosive copper chloride compound and some innocuous trapped chlorine compounds. Caputo found no evidence of any "innocuous trapped chlorine compounds." Thus the physical evidence shows that Eq. (59.15), a nonreversible reaction catalyzed by H^+ ions, is the more appropriate explanation for CAF failure in PWBs.

59.6 TEST METHOD FOR CAF-RESISTANT MATERIALS

In the late 1990s, laminate suppliers began to develop new materials that they marketed as CAF-resistant. To evaluate these materials, K. Sauter[34–36] developed a CAF test vehicle, which consisted of a multilayer board with daisy-chained hole-to-hole spacing of 0.27, 0.38, 0.50, and 0.65 mm. The holes were either in line with the glass fiber direction or staggered. Accelerated aging was done at 65°C and 85 percent RH for 500 h. Sauter's results[36] show variations based on laminate material, manufacturer, and diagonal versus inline holes, with the former being more CAF-resistant. He also defined a "readily conductive region" around the plated-through holes, which must be considered in establishing design rules. This test vehicle and procedure has been developed as an IPC Test Method (IPC-TM-2.6.25A), "Conductive Anodic Filament (CAF) Resistance: X-Y Axis."[37]

59.7 MANUFACTURING TOLERANCE CONSIDERATIONS

Test board designs for performing statistical studies of CAF-resistant materials must take into account the limitations of the PWB manufacturing process.[38] As the hole-to-hole spacing becomes closer, the limits of the drilling process must be considered. Drill wander can be caused by splay when the drill enters the board at an angle. These two factors are exacerbated with smaller drill size. Sauter studied field data for production boards and recommended a minimum spacing of 0.65 mm hole-wall to hole-wall for telecommunication applications cycled 365 times per year. Using a high *Tg* dicyandiamide FR-4 laminate material and a specific PWB supplier he could achieve 20 years minimum expected product service life.

CAF-resistant substrates are frequently more expensive than traditional FR-4, and therefore they are reserved for

products that require high reliability, optimizing both cost and performance. Designs are multilayer rather than double-sided rigid boards. An important difference between a multilayer board and a double-sided rigid board is the glass-to-resin ratio. In drilling the holes, more damage will occur at the epoxy glass interface for boards with higher glass content.[39] Typical double-sided PWBs use eight sheets of 7628-glass cloth with a thickness of 0.175 mm to create a 1.5 mm thick board. The portion of resin in this board would be 30 to 40 percent. For a multilayer board, the glass cloth thickness may range from 0.035 to 0.10 mm per layer. In this case, the amount of resin in it ranges from 55 to 65 percent in the case of the 0.035 mm glass cloth thickness and from 45 to 50 percent in the case of the 0.10 mm glass cloth thickness. In the drilling process, the board with a higher resin content creates less hole damage than one with a lower resin content.

Microvias that are created by laser drilling can be located at a reduced pitch for CAF studies because one does not expect drill damage from a laser-ablated hole and it will not be subjected to the drill wander of a mechanically drilled hole.

The catastrophic failure presented earlier in this chapter (see Fig. 59.15) was caused by a power plane (anode), which created a CAF that shorted to the hole (cathode). In designing a test board, the power plane must always be the anode in order to reduce the current density for corrosion. A large cathode in contact with a small anode creates a high-current density at the anode and increases the corrosion rate.

CHAPTER 60

Reliability of Printed Circuit Boards

Reza Ghaffarian

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California

60.1 INTRODUCTION

This chapter describes the reliability of printed circuit boards (PCBs) in response to environmental stresses—that is, their reliability in service—and the influence of design, materials, and manufacturing decisions on this behavior. A variety of stresses may be present in the service environment of the PCB assemblies. Thermal stresses come from fluctuations in the ambient temperature in the service environment of the assembly or from power dissipation of high-power devices mounted on the PCB. There are also thermal stresses associated with assembly and rework. Mechanical stresses may be due to bending and flexing of the assembly during later assembly steps or in service, mechanical shock during transportation or use, or mechanical vibration, for example, from cooling fans. Chemical sources of environmental

stresses include atmospheric moisture, corrosive gases (e.g., smog or industrial process gases), and residual chemically active contaminants from the assembly processes (e.g., from flux).

These environmental stresses may act singly or in concert with one another and the electrical potential differences that exist when the assembly is functioning to cause electrical failures in the PCB and printed circuit assembly (PCA). This chapter will focus on the reliability of the PCB only. Reliability of the other elements of PCA including interconnections and components is beyond the scope of this chapter.

This chapter will focus on the delayed effects of PCB manufacturing defects and the wear-out mechanisms of properly manufactured product. Reliability of PCB with plated through holes (PTHs), plated through via (PTVs), and with microvias is discussed. PTV and microvia technology are required for implementation of high density and high I/O area array packaging assemblies. The remainder of this chapter is organized into three major technical sections:

60.2 PCB Trends and Reliability
60.3 PCB Fabrication and Failure Mechanisms
60.4 PTH Thermal Cycle Reliability and Projections Methods

60.2 PCB AND MICROELECTRONICS TRENDS AND RELIABILITY

This section first briefly presents the three elements that play key roles in defining reliability for a microelectronics system, that is, PCB, packaging, and global/local interconnections. The characteristics of these three elements are (1) PCB (e.g., polymer, Cu, plated through hole, and microvia), (2) packaging (e.g., die, substrate, solder joint, and underfill), and (3) solder joints (e.g., via balls or

columns). The section then focuses on the PCB manufacturing and via technologies and reliability under various environmental conditions. It specifically discusses reliability of PCBs with plated through holes (PTHs). The section also discusses in detail, the key failure mechanisms for PTH and analytical models developed for projection of accelerated environmental testing of PCBs with PTHs to field environmental requirement.

60.2.1 PCB/Microelectronic Packaging Trends

Figure 60.1 categorizes single-chip microelectronic packaging technologies into three key technologies: (1) plastic ball grid arrays (PBGAs), (2) ceramic column grid arrays (CGAs), and (3) and smaller foot print wafer level packages.[1–8]

FIGURE 60.1 Single-chip packaging technologies is divided into three categories to better address various technologies.

PBGAs, chip scale packages (CSPs), and wafer-level packages (WLPs) are now widely used for many commercial electronic applications, including portable and telecommunication products. Ball grid arrays (BGAs) with 0.8- to 1.27-mm (32- to 50-mil) pitches are implemented for high reliability applications, generally demanding more stringent thermal and mechanical cycling requirements. The plastic BGAs introduced in the late 1980s and implemented with great caution in the early 1990s, further evolved in the mid-1990s to the CSP, also known as fine-pitch BGA (FPGA), having a much finer pitch from 0.4 mm down to 0.3 mm (16 to 12 mil). Wafer-level packaging, protecting die at the wafer stage, is another option with CSPs.

To accommodate higher I/O single-chip die, the flip-chip BGA (FCBGA) is developed. FCBGA is similar to PBGA, except that internally a flip-chip die rather than a wire-bonded die is used. Because of these developments, it has become even more difficult to distinguish different area array packages by size and pitch; only now, its internal die attachment configuration also need to be considered. The ultimate size reduction can be achieved by protecting single die at the wafer level; hence, introduction of wafer level packages. WLPs also addresses the key issues of using single bare die; it improves ease of handling and functional testing.

Conventional PCBs with PTH vias with 150 μm (6 mil) or larger diameters are still the vias of choice used for conventional and area array packages with larger pitches. PTHs serve to electrically connect different conductor layers in multilayer PCBs. The denser packages with tighter pitches or higher I/O with fully populated arrays of balls/columns require use of high density interconnect (HDI) technology with microvias to meet miniaturization and performance requirements. Use of PCBs with microvia technology, also

known as sequential build-up (SBU), is a must when area array die are directly attached on a board to accommodate their finer (0.254-mm (10-mil) pitch and smaller).

Figure 60.2 compares PTH and microvia technologies used for conventional and fine pitch area array board assembly, respectively. The PTHs can be buried (providing interconnection between innerlayers), semi-buried (providing interconnection from one of the two outer layers to one of the internal layers), or through vias (providing interconnection between the outer two layers). Microvias are generally blind surface vias with sizes of 150 µm (6 mil) or smaller.

Figure 60.3 shows an x-ray of a PCB having both PTH vias, PTH via in pad (PTHViP) and microvias with either as plated or filled.[9,10] Note that dark columns represent filled vias since x-rays are absorbed by filling materials, and therefore, these are darker compared to unfilled versions. Microsections of microvias and filled via in pads are also shown in the figure.

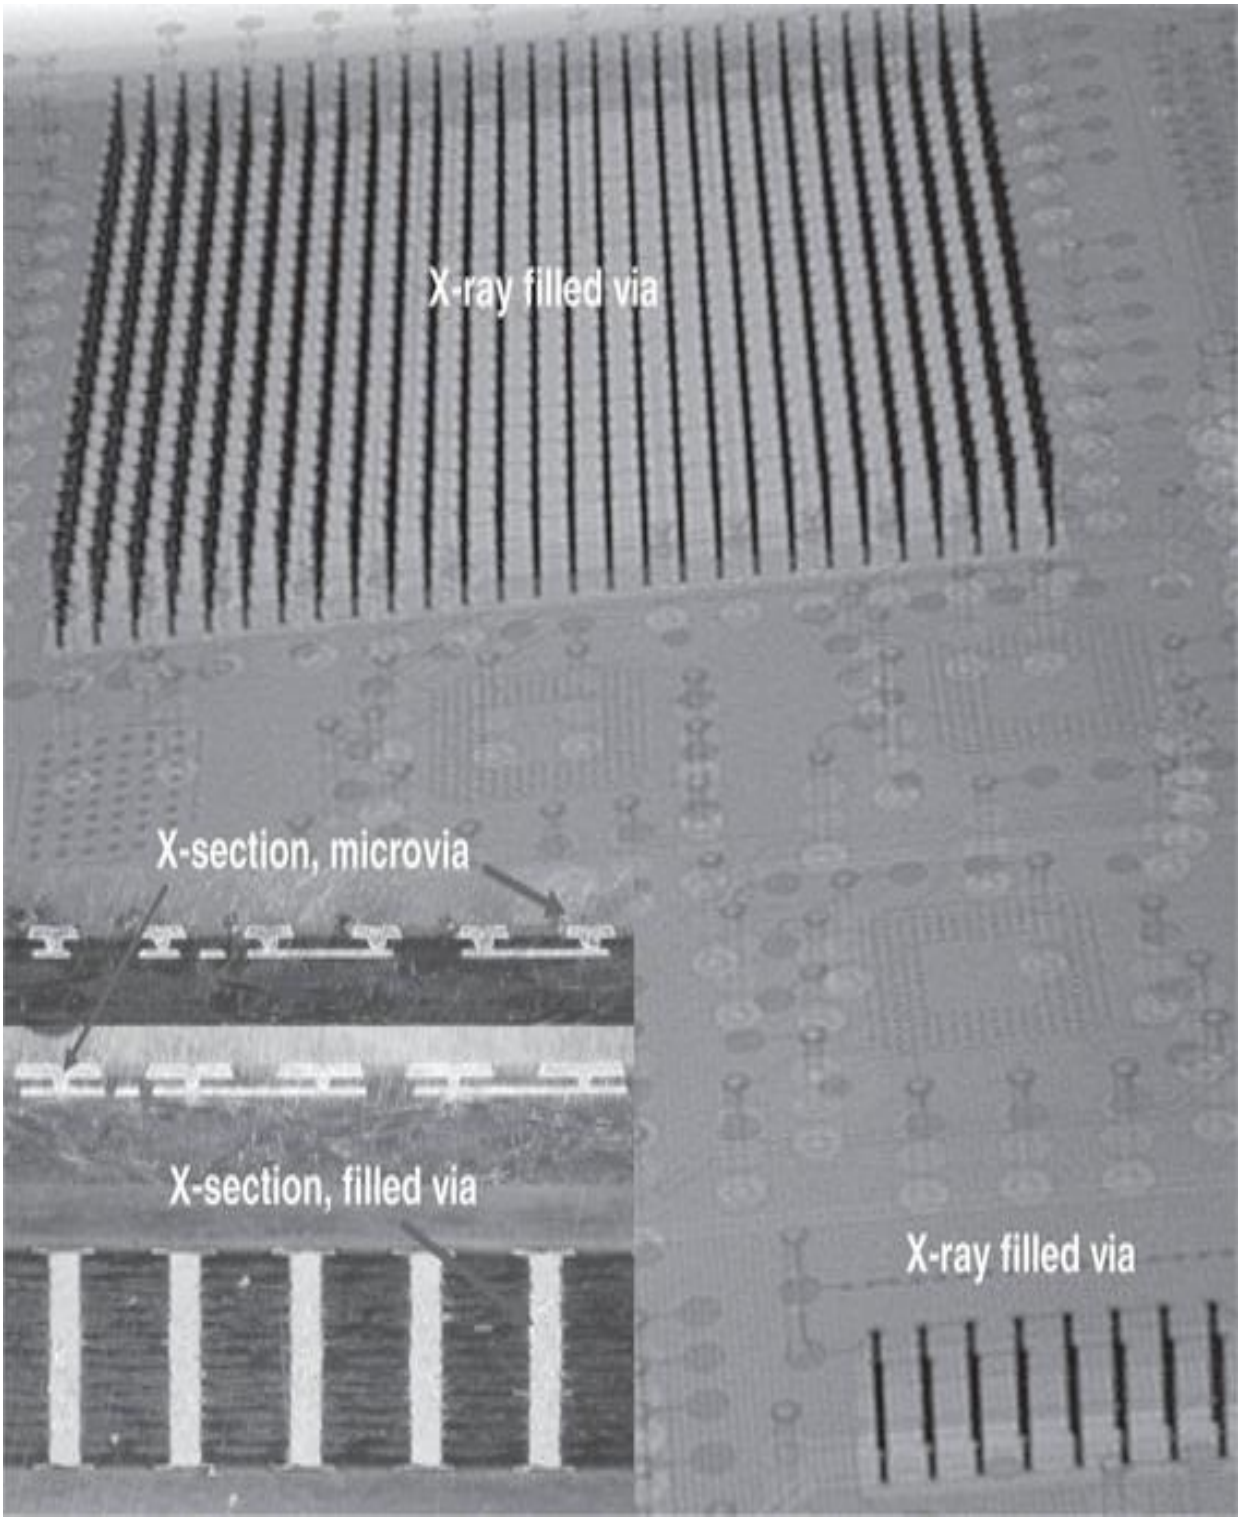

FIGURE 60.3 Microsection of microvia and filled via with x-ray of PCB with filled (dark) and unfilled microvias.[9]

IPC is an excellent resource for reviewing printed circuit board specifications and guidelines including IPC-TR-609,[11] Round Robin Reliability Evaluation of Small Diameter Plated Through Holes in PCBs, and high density interconnect (HDI), guideline documents, design rules, materials, and test specifications. A few key standards on PCB technologies are given below.[12]

- Figure 60.4 shows the hierarchy of IPC performance and qualifications including IPC-6012 for rigid PCBs and IPC-6016, which contains the general specification for high density substrates not already covered by other documents.

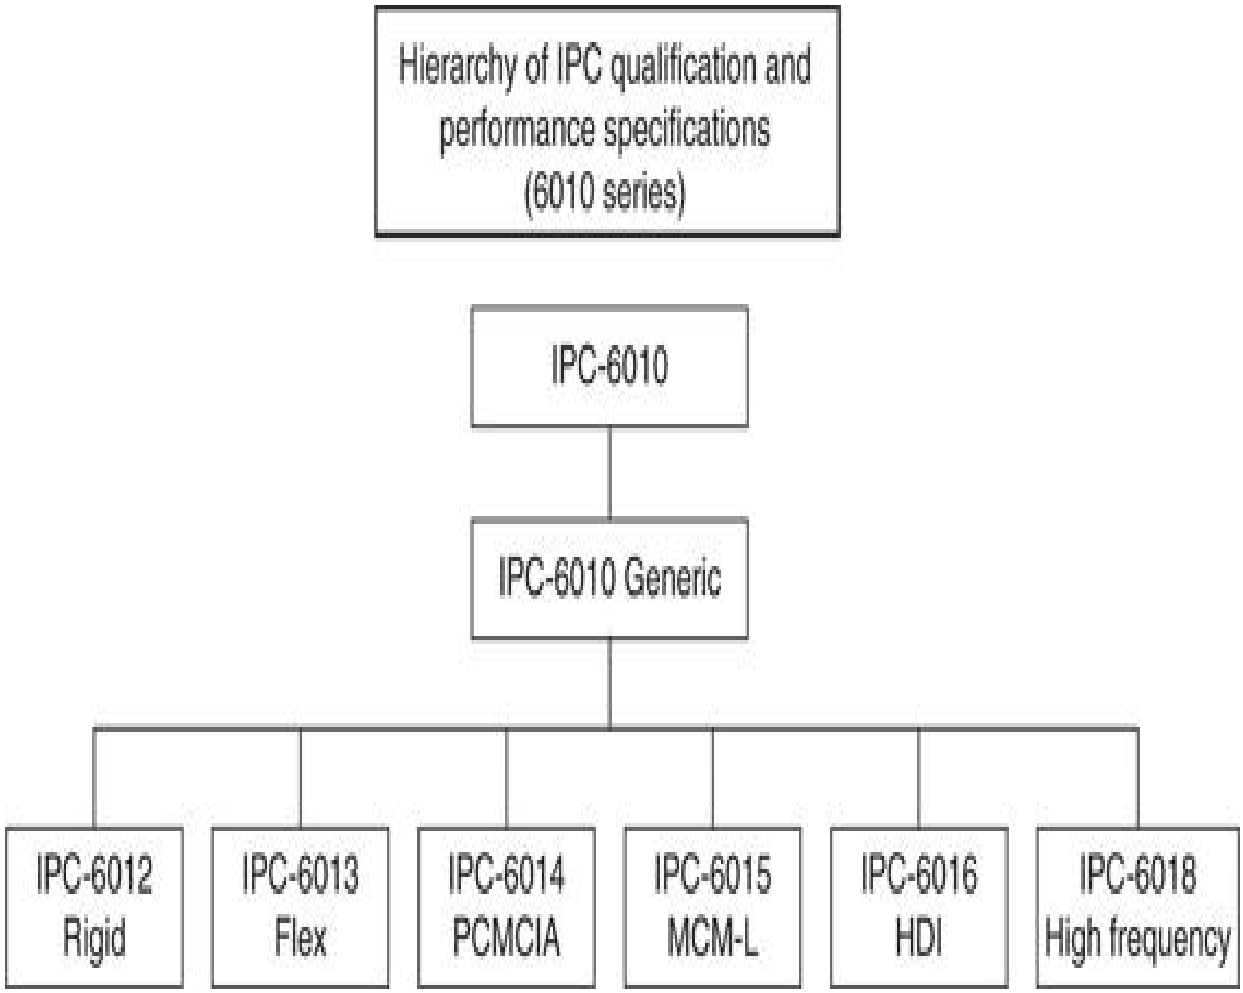

FIGURE 60.4 Hierarchy of IPC qualifications specifications for PCBs.[12]

- IPC-2315, the purpose of which is to provide guidelines for HDI technology, including educating users in microvia formation, selection of wiring density, selection of design rules, interconnecting structures, and materials characterization.
- IPC-4104, the purpose of which is to identify materials used for HDI structures. A series of specifications are defined for specific available materials, each outlines engineering and performance data that could be used for ordering.
- IPC-TM-650-2.6.26, in which the 2.6.26 test provides guidelines on changes in resistance measurements of a PTH/PTV when subjected to thermal cycling. IST coupons (designed by Interconnect Solution Inc.) are used to provide application of DC current through the interconnections. The number of cycles to failures provides a qualitative assessment of the performance of all interconnections. Test 2.6.8 provides the PTH/PTV interconnection resistance to thermal cycling effects of extreme heat due to heat exposed during the assembly, rework, and repair process.

60.2.2 Reliability of Microelectronic System

Reliability under thermal stress for package, PCB, and assembly depends on the reliability of constituent elements, for example, the PCB and its global/local interfaces (attachments). As schematically shown in Fig. 60.5, three elements play key roles in defining reliability for a system, global, local, and interconnections. The characteristics of these three elements—package (e.g., die, substrate, solder joint, and underfill), PCB [e.g., polymer, copper (Cu), plated

through hole, microvia], solder joints (e.g., via balls, columns)—together with the use conditions, the design life, and the acceptance failure probability for the electronic assembly determine the subsystem reliability.

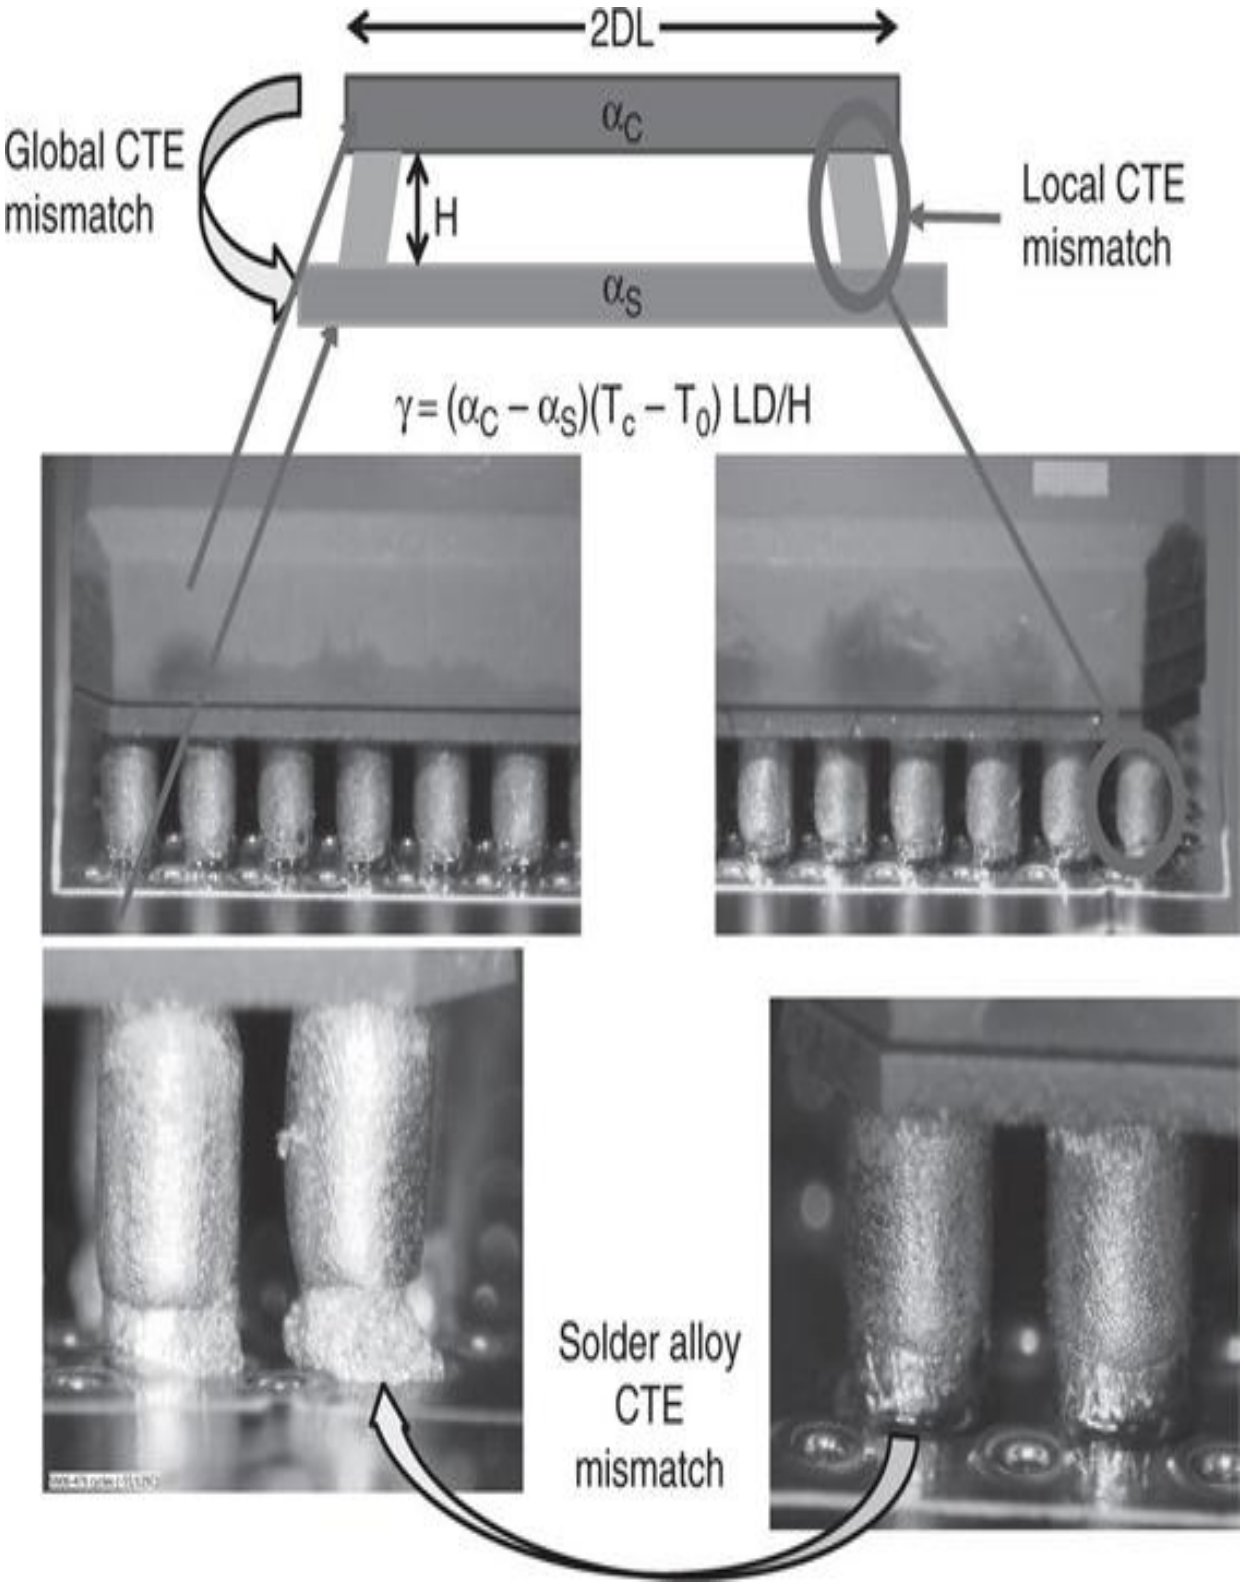

FIGURE 60.5 Three key elements defines reliability under thermal stress are due to global, local, and solder alloy coefficient of thermal (CTE) mismatches.

In other words, reliability is the ability of a system (here microelectronics) to function as expected under the expected operating conditions for an expected time period without exceeding the expected failure levels. However, reliability is susceptible to early failure by infant mortality due to workmanship defect, lack of sound manufacturing, and use of a design without reliability consideration. Design for manufacturability (DfM), design for assembly (DfA), design for testability (DfT), and so on, are prerequisite to ensure the reliability of the product. Only a design for reliability (DfR) can assure that a manufactured product with an acceptable quality will also be reliable in the product application. The elements of the system reliability are schematically shown in Fig. 60.6, and they are comprised of device/package/PCB and interconnections and also include consideration of design for reliability prior to assembly and subsequent manufacturing and quality assurance implementation.

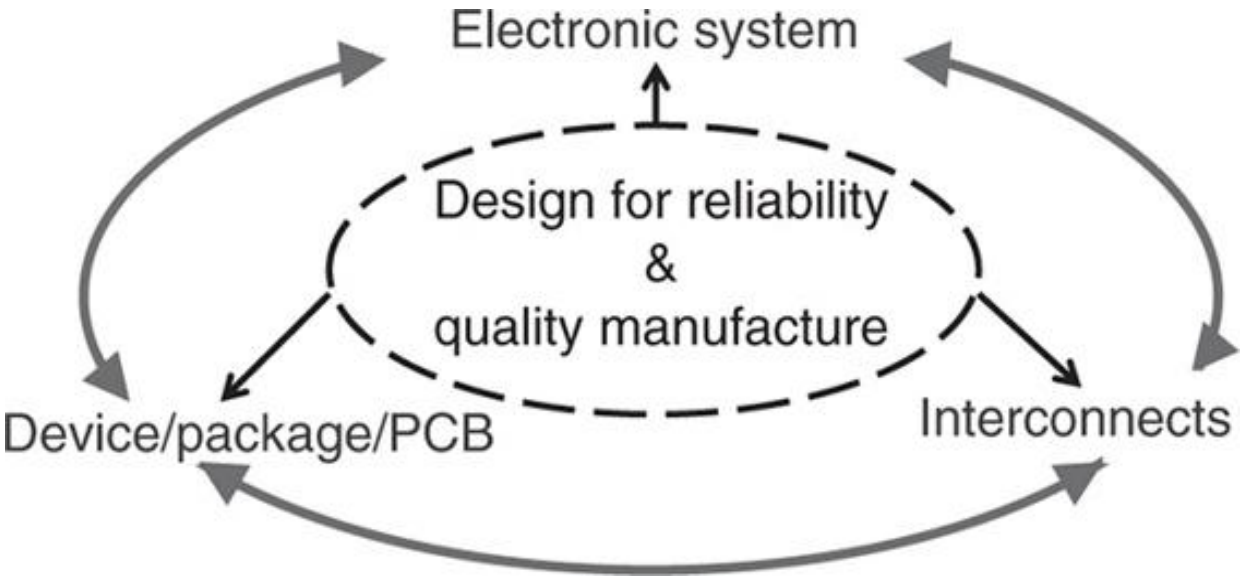

FIGURE 60.6 System reliability achieved through design for reliability (DfR), sound manufacturing, and quality to packaging/ device/PCB and interconnections.

In general, both statistical and probabilistic modeling approaches are considered in reliability methodology. Statistical approaches are employed after testing, whereas probabilistic predictive modeling is employed at the product design (DfR).

60.2.3 Reliability and Failure (Bathtub Curve)

Mathematically, the reliability of an object at time t can be stated as[13]

$$R(t) = 1 - F(t)$$

where $R(t)$ is the reliability at time t (i.e., the proportion of parts still functioning), and $F(t)$ is the fraction of the parts or systems that have failed at time t. Time may be measured in calendar units or some other measure of service time such as on/off cycles or thermal or mechanical vibration cycles. The unit of time that makes sense depends on the failure mechanism. When several failure modes are present, it is often helpful to think in terms of several time scales.

A plot of the failure rate of a product as a function of time typically takes the shape of a “bathtub” curve (see Fig. 60.7). This curve illustrates the three phases that occur during the lifespan of a product from a reliability perspective. In the first, infant mortality phase, there is an initially high but rapidly declining failure rate caused by infant mortality. Infant mortality is typically caused by manufacturing defects that went undetected during inspection and testing and lead to rapid failure in service. Burn-in can be used to remove these units before shipment. The second phase, the normal operating life of the product, is characterized by a period of stable, relatively low failure rates.

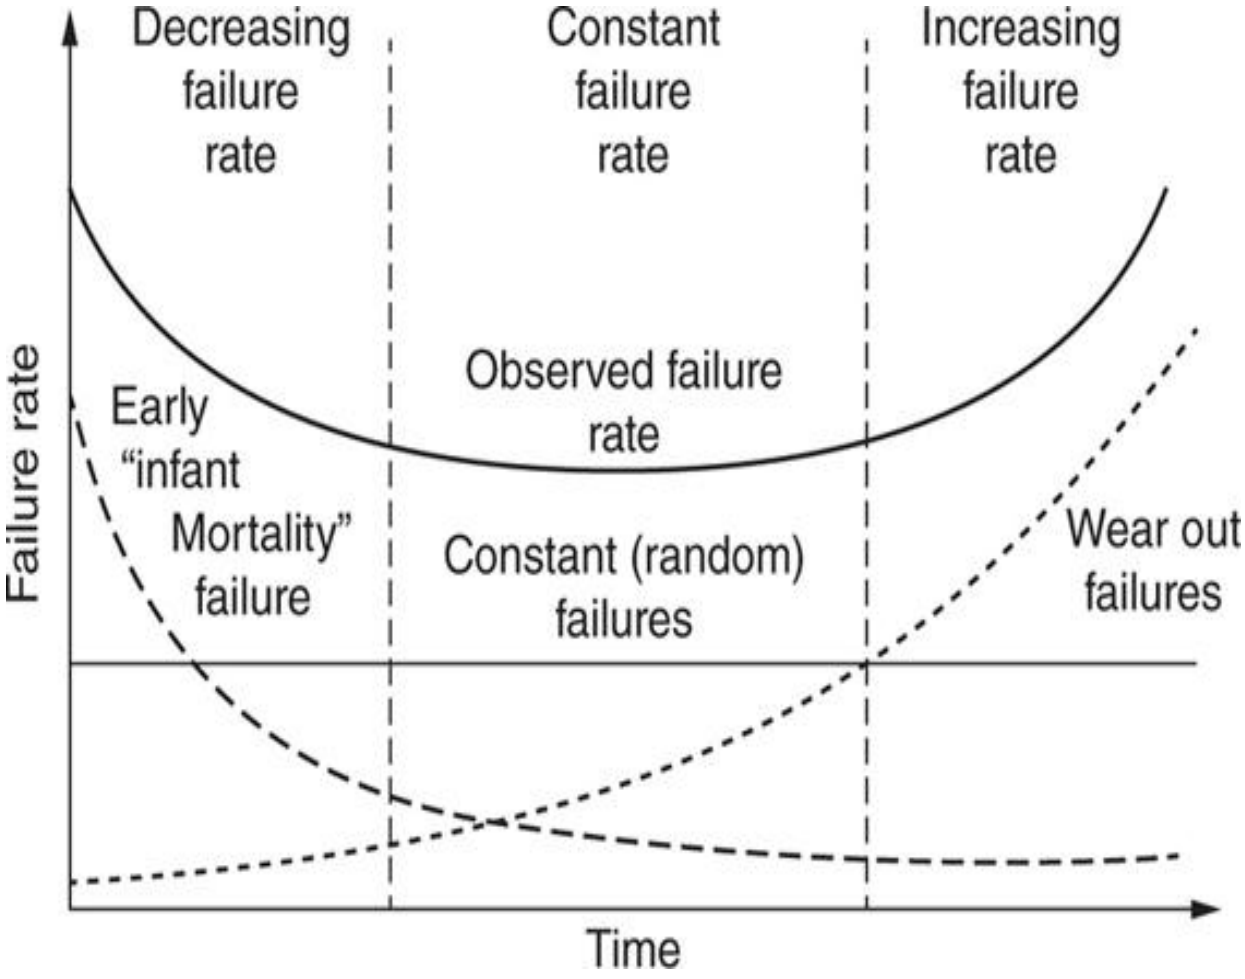

FIGURE 60.7 Classic bathtub reliability curve showing the three stages during the life of a product from a reliability perspective: infant mortality, steady-state, and wear-out.

During the operating life, failures occur apparently randomly, and the failure rate r is roughly constant with time. An exponential life distribution is often assumed to describe the behavior in this region. In that case,

$$r = (N_t / N_o)\left(\frac{1}{\Delta t}\right)$$

and

$$R(t) = e^{-rt} = e^{-1/MTBF}$$

where N_t = number of failures in time interval Δt

N_o = number of samples at the beginning of the interval

$MTBF$ = mean time between failures

During the third phase, the wear-out period, the failure rate increases gradually due to wear-out phenomena until 100 percent of the units have failed. For some systems, the second steady-state region may not exist; for PCB PTHs/microvias and solder joints, the wear-out region may extend over most of the life of the assembly. The key focus of this chapter is to understand and define specific wear-out phenomena, which manifest themselves in properly manufactured PCBs after a period of service, and to predict when they will significantly affect the failure rate.

Most wear-out phenomena can be characterized by cumulative failure distributions governed by either the Weibull or the log-normal distribution. Weibull distributions have been successfully used to describe solder-joint and plated-through-hole fatigue distributions, while log-normal distributions are generally associated with electrochemical failure mechanisms. While these distributions may be quite narrow in some cases, their use should serve as a reminder that even with nominally identical samples, failures will be statistically distributed over time.

A practical use of fitting a distribution to reliability data is to extrapolate to smaller failure rates or other environmental conditions. To simplify the equations, the expressions in the text refer to the mean life of the relevant portion of the assembly. If the constants that define the failure distribution are known, the time to reach a smaller proportion of failures may be readily calculated. For example, for failure modes that are described by a Weibull distribution, the time t to reach x percent failures is given by

$$t(x\%) = t\ (50\%)\left[\frac{Ln(1-.01x)}{Ln(0.5)}\right]^{1/\beta}$$

where β is the Weibull shape parameter, usually between 2 and 4 for solder-joint failures.

Recently, a complex three-step concept (TSC) reliability model was proposed for microelectronics.[14] The classical statistical Bayes' formula was suggested to be used first as a diagnostics tool. Its objective is to identify, on the probabilistic basis, the faulty (malfunctioning) device(s) from the signals ("symptoms of faults"). Then, physics-of-failure-based Boltzmann–Arrhenius-Zhurkov's (BAZ) model could be used to estimate the remaining useful life (RUL). If the RUL is not long-enough, further, corrective restoration of the faulty device becomes necessary. The restored device is then put back into operation (testing), provided its continuing failure-free probability of operation is found to be satisfactory. If the operational failure nonetheless occurs, the third, technical diagnostics step should be undertaken to update reliability. Statistical beta-distribution, in which the probability of failure is treated as a random variable, is suggested to be used at this step.

60.2.4 Reliability Testing Methods

Almost every reliability test program must solve the problem of determining whether an object is reliable in a time that is much shorter than the expected use period. Obviously, one cannot spend 3 to 5 years testing a personal computer that will be marketed for an even shorter time span or 20 years testing a military system. Depending on the failure mechanism, there are two approaches that may be combined: (1) accelerate the frequency of the occurrence that causes failure and test the ability of the object to

survive the expected number of events, or (2) increase the severity so that fewer occurrences are needed. Drop tests that simulate shock during transportation are an example of the first approach. Since the time between drops does not affect the amount of damage caused, a lifetime of drops can be conducted in rapid succession. However, the effect of temperature and humidity on corrosion over the lifetime of the product can be tested only by increasing the temperature, the humidity, the concentration of contaminants, or some combination of these factors. The difficulty is ensuring that the test reproduces and/or correlates to the failure mechanism in service.

To use this data for making true reliability predictions—that is, the probability of failures at a given time under given conditions—testing must be continued until enough parts fail that a life distribution can be estimated. Unfortunately, this process can be time consuming, so qualification tests are often substituted. Qualification test protocols specify a maximum number of failures that may be observed in a specified period in a sample of specified size. If few or no failures occur, a qualification test provides almost no information about the failure distribution; for example, the probability of failure during the next time interval is unknown. This limitation of qualification testing is minimized when the life distribution for properly manufactured samples is already known or can be estimated based on experience with similar designs.

Many reliability or qualification testing approaches do not follow either of these schemes. Instead, they test the ability of the product to survive a sequence of tests under extremely severe conditions for a short time or small number of exposures. Again, this type of testing may be adequate when it is supported by long experience with both the product type and its use environment; however, it is risky because it is not based on ensuring that probable failure modes will not occur in the life of the product. When new

technologies or geometries are introduced, the old tests may not always be conservative. By the same token, irrelevant failure modes that would not occur in service may be introduced by the harsh test conditions.

60.2.5 Design for Accelerated Reliability Testing

Accelerated reliability test design is summarized into seven key steps.

1. *Identify the service environment and the acceptable failure rate over a specified service life*.
2. *Identify actual environment of the PCA (modified service environment)*. The service environment should be translated into the ambient environment actually experienced by the PCA. For example, the temperature experienced by the PCA is influenced by both power dissipation and cooling. The mechanical environment is influenced by shock-absorbing material, resonances, and so on.
3. *Identify probable failure modes* (e.g., solder-joint fatigue, conductive anodic filament growth). Accelerated reliability tests are based on the premise that the frequency and/or severity of the environmental exposure can be increased to accelerate the incidence of the failure that occurs in service in a known way, that is, that the data can be used to predict the life distribution for the in-service PCA environment. This assumption makes sense only if the same failure modes occur in the test as in real life. It cannot be overemphasized that the accelerated tests must be designed around the real failure modes. Probable failure modes may be identified from past service experience, the literature, or preliminary testing or analysis.

4. *For each failure mode, construct an acceleration model*. An acceleration model that allows test data to be interpreted in terms of the expected service environment is crucial to life distribution estimation. It is also extremely helpful in designing good tests, so ideally the acceleration model should be developed before the accelerated reliability tests are carried out. As an example, for solder-joint reliability modeling, Coffin-Manson relationship relating cycles-to-failure to strain in solder joints to rigid components can be used. The relationship predicts that increasing strain will decrease the number of cycles to failure in a specific way. Within a certain temperature range, increasing the temperature cycling range is a way of increasing the strain.

In general, the acceleration model should be based on the rate-controlling step in the failure process. In some cases, the rate will be determined by an Arrhenius type equation; for example, if diffusion is the rate-controlling process:

$$D = D_o \exp(-E_a/KT)\; X \propto \sqrt{Dt}$$

$$t_2 = (D_1/D_2)t_1 = t_1 \exp[-E_a/K(1/T_1 - 1/T_2)]$$

where D = diffusion rate

D_o = diffusion constant

E_a = activation energy for the process

K = Boltzmann constant

and T_1 and T_2 and t_1 and t_2 are two temperatures and corresponding equivalent diffusion times.

Note that even when temperature is an important factor, *an Arrhenius relationship may not exist;* in the preceding thermal cycling example, the failure rate is roughly

proportional to $(\Delta T)^2$. Some acceleration models will be explored in the following sections.

The limits of applicability of an acceleration model are as important as the model itself. Increasing or decreasing the temperature too much may promote new failure modes that would not occur in service or invalidate the quantitative acceleration relationship. For example, if the temperature is elevated above the glass transition temperature, T_g, of the board, the *z*-axis CTE increases sharply, and the modulus decreases. This may actually lessen the strains imposed on solder joints, but it may also promote PTH failures.

Finite element modeling/analysis (FEM/FEA) can be invaluable in developing and/or applying acceleration models for thermal and mechanical tests. Two-dimensional nonlinear modeling capability will usually be required in order to get meaningful results. Models can be constructed to estimate the stresses and strains in the material (e.g., the Cu in a PTH barrel or the solder in a surface-mount or through-hole joint) under operating conditions as well as under test conditions. These estimates will be far more accurate than the simple models provided in this overview because they can account for the interactions between materials in a complex structure and both elastic and plastic deformation.

5. *Design tests based on the acceleration models and accepted sampling procedures*. Using the acceleration model and the service environment and life, select test conditions and test times that simulate the life of the product in a much shorter period of time. The sample size must be large enough that it is possible to determine whether the reliability goal (acceptable number of failures over the service life) has been met.[15] Ideally, the life distribution in the accelerated test should be determined, even when the test period must be extended to do so.

6. *Analyze failures to confirm failure mode predictions*. Since an accelerated test is based on the assumption that a particular failure mode in the accelerated test is the same one that occurs in service, it is important to confirm by failure analysis that this assumption is valid. If the failure mode in the accelerated test is different from the one expected, several possibilities should be considered. (1) The accelerated test is introducing a new failure mode different from the one that will occur in service. Usually this means that the acceleration of one parameter (e.g., frequency, temperature, humidity) was too severe. (2) The initial determination of the dominant failure mode was incorrect. In this case, to understand the significance of the test results, a new acceleration model must be developed for this failure mode. The new failure mode may be promoted more or less effectively by the test conditions than the mode originally assumed. (3) There may be several failure modes. In this case, the two failure distributions should be considered separately, so that life predictions will be meaningful. The difficulty in determining which of the above scenarios holds is that for genuinely new technologies or service environments, the failure mode in service may not be known. In these situations, it is desirable to conduct a parallel test with less aggressive acceleration for comparison.
7. *Determine life distribution from accelerated life distribution*. The accelerated life distribution should be determined by fitting the data with the appropriate statistical distribution, such as the Weibull or log-normal distribution. The life distribution in service can be determined by transforming the time axis of the life distribution using the acceleration model. This predicted life distribution in service can then be used to estimate the number of failures in the specified service life.

The following discussion of testing for some specific failures will provide examples of this methodology.

60.2.6 Printed Circuit Board Reliability Tests

60.2.6.1 Thermal. PTH failures are the predominant source of PCB failures in service, and predicting them is the primary goal of PCB testing at elevated temperatures. PTH reliability testing should simulate the thermal excursions of a PTH throughout its life. Generally, the most severe thermal cycles are experienced during assembly and rework. One of the older acceptable thermal stress test is MIL-P-55110 (also found in IPC-TM-650). Following baking at 120 to 150°C, the specimens are immersed in an RMA flux and floated in a eutectic (or near-eutectic) Sn-Pb solder bath at 288°C for 10 s. For lead-free, the bath temperature is at 260°C or higher. Following the test, the samples are cross-sectioned, and the PTHs are examined for cracks. This is a severe test that ensures that the sample will survive a single wave-soldering or solder pot rework cycle.

Most thermal cycling tests for PCBs cycle the PCB repeatedly over a wide temperature range; many are actually thermal shock tests using liquid-liquid cycling. The results of five accelerated tests with different temperature extremes, ramp rates, and dwell times have been compared by the IPC, which also provides a simplified analytical model to estimate PTH life.[11] The results of all tests suggest the same approaches for maximizing PTH reliability, but they do not all correlate well quantitatively.

Figure 60.8 shows a number of suitable test coupons for PCB PTH/microvia evaluation. These include (1) a test coupon that contains 3000 PTHs and varying annular ring sizes,[13] (2) an IST (interconnect stress testing) coupon with

hundreds of PTH and microvias with direct current induced thermal cycling,[16] (3) an HATS (highly accelerated thermal shock) coupon with 4 daisy-chain nets and up to 36 coupons per chamber and air-to-air cycling,[17] and (4) PCQR^2 (process capability, quality, and relative reliability) test panel for standard comparison of printed circuit board manufacturing processes.[18]

60.2.6.2 Mechanical. PCBs are rarely subjected to mechanical tests that could cause electrical failures; however, adhesion of both Cu and solder mask to the laminate is critical and is often tested. Loss of solder mask adhesion can provide a place for corrodents and moisture to accumulate, which can be the cause of electrical failures when the board is exposed to temperature and humidity.

Adhesion is commonly tested using the peel test described in IPC-TM-650, Method 2.4.28. The simplest version of this test is conducted by scribing the adherent and dividing it into small squares. If the Cu or solder mask pulls off with a piece of tape with strong adhesive, the adhesion is inadequate. More quantitative tests that measure the actual peel strength are performed primarily by laminate and solder mask suppliers.

60.2.6.3 Temperature, Humidity, Bias. These tests are designed to promote corrosion on the PCB surface and conductive anodic filament growth, either of which can cause insulation resistance failures. Surface insulation tests utilize two interleaved Cu combs with an imposed dc bias across the combs. These combs may be designed into existing boards or a coupon such as the IPC-B-25 test board (shown in Fig. 60.9) may be used. The measured resistance (ohms) from the comb pattern can be converted to surface resistivity (ohms per square) by multiplying the measured resistance by the square count of the pattern. The square count is determined geometrically by measuring the total length of the parallel traces between the anode and cathode and dividing by the separation distance. Special precautions are needed to make accurate measurements of insulation resistance.[19] Measurements of resistance above 10^{12} are

very difficult and require careful shielding. Measurements of resistance below 10^{12} can be conducted in most laboratory environments if certain precautions are taken.

FIGURE 60.9 Test coupons used to check moisture, insulation, and metal migration resistance: (*a*) the IPC-B-25 test board, used to qualify the process; and (*b*) the Y coupon, designed to be incorporated into production boards for statistical process control. (*From IPC-SM-840*.)

The actual tests are usually conducted at elevated temperature and humidity with an applied dc bias. A test for moisture and insulation resistance of bare printed circuit boards is included in IPC-SM-840A. The severity of the test depends on the intended use environment; for typical commercial products (Class 2), the test is conducted at 50°C, 90 percent RH, and 100 V_{dc} bias for 7 days. The minimum insulation resistance requirement is 10^8 Ω. The military test procedure for moisture and insulation resistance is specified in PCB military specification, MIL-P-55110.[20] The moisture resistance test should be conducted in accordance with military specification, MIL-STD-202, Method 106, with applied polarization voltage (100 V_{dc}) and Method 402, Test condition A. IPC-SM-840A also includes a test for electromigration resistance. The test is conducted at 85°C/90 percent RH at a 10 V_{dc} bias with a limiting current of 1 mA for 7 days. A significant change in current constitutes a failure. The samples are also microscopically inspected for evidence of electrolytic metal migration. A common test for dendritic growth due to flux residues is 85°C/85 percent RH/1000 h at a -20 V_{dc} bias. These tests are empirically based; however, several investigators have attempted to develop acceleration factors for these and similar tests.[21,22]

60.2.7 Accelerated Thermal Cycle/Shock Tests

Figure 60.10 shows a representation of thermal cycle and shock tests currently being used for PCB reliability evaluation. Thermal cycle qualification of PTHs has evolved

within the last decade to accommodate effectiveness and cost.[23,24] Thermal shock oven temperature cycling testing has a well-established history as an indicator of the long-term field life of PCB products. However, verified correlation with actual long-term field life has been difficult to achieve due to the long time required for testing and the associated expense. In the 1990s, interconnect stress testing (IST) was developed, and more recently highly accelerated thermal shock (HATS). Testing has been developed as a more practical indicator based upon the through-hole via and internal interconnect reliability of printed wiring boards

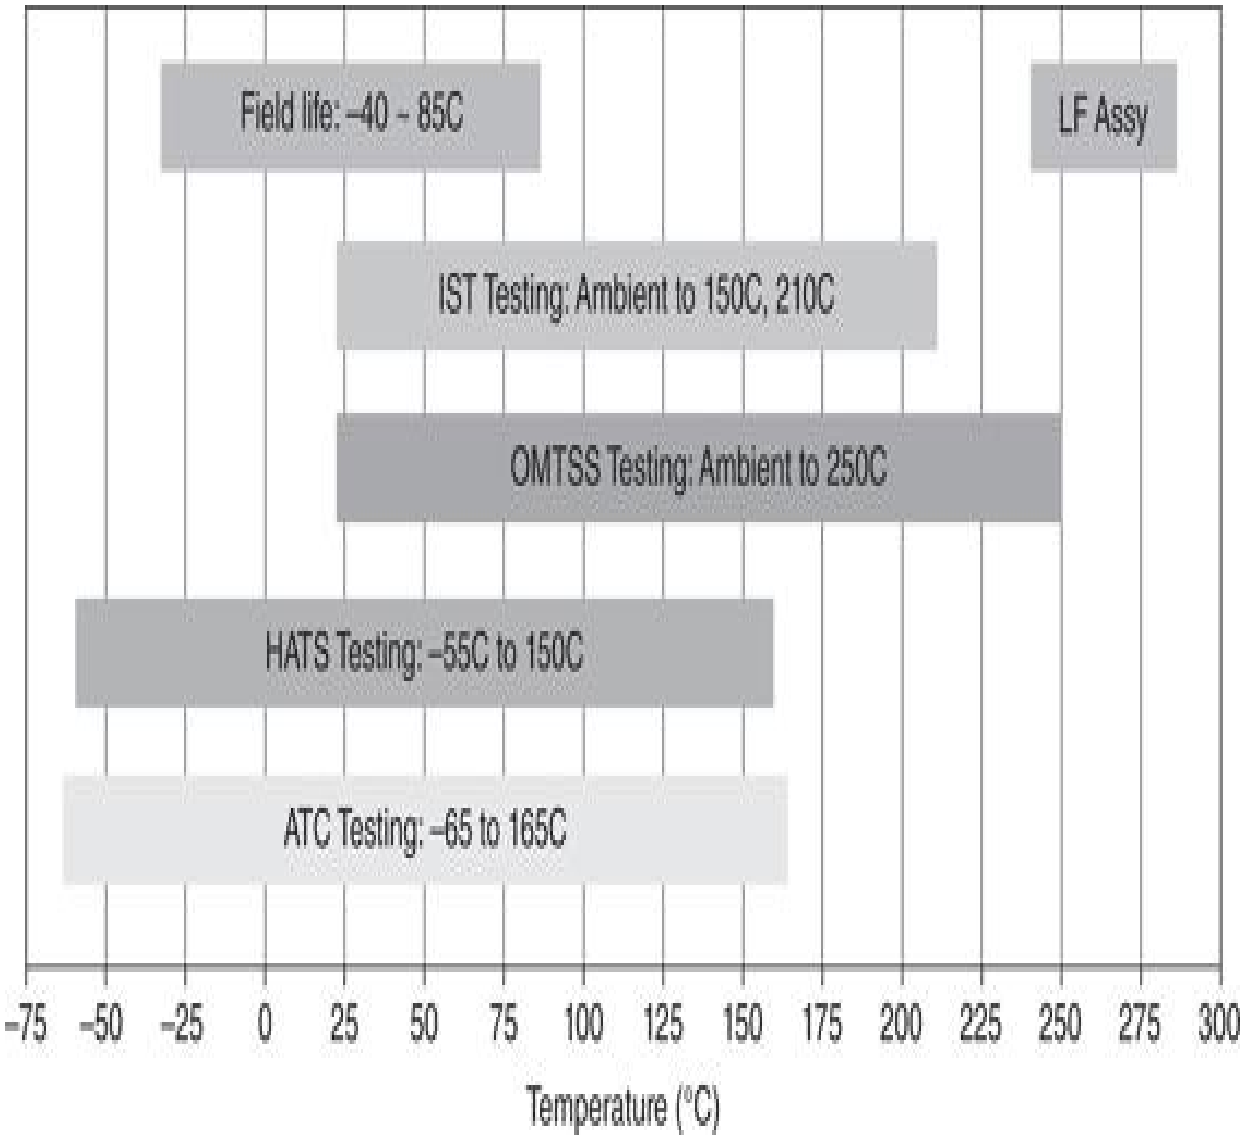

FIGURE 60.10 Representation of accelerated thermal cycling and shock currently practice for PTH/microvia PCB reliability characterization.[23,24]

60.2.7.1 Thermal Shock Oven Testing. This test method measures cycles to failures (CTFs) on actual functional production boards or appropriately designed test boards/coupons. The ovens are capable of air-air cycling over a potentially large temperature range (−40 to +145°C). Transition rates between 25 and 35°C/min are used for this testing, with a 20-s dwell at both high and low temperatures.

60.2.7.2 IST Testing. This test method measures CTFs on specially designed IST coupons that are thermally cycled using current flow through internally heated circuits that heat the coupon and the adjacent plated-through holes. Failure is defined as a 10 percent increase in the resistance of the plated-through hole. Reference: IPC-TM-650, 2.6.26.

60.2.7.3 HATS Testing. This test method measures CTFs on specially designed HATS coupons typically having 4 daisy chain nets each. There can be up to 36 coupons per chamber load that go through air-to-air cycling over a potentially large temperature range (−55 to +160°C). Transition rates for this testing are usually at least 25°C/min up to 50°C/min, depending upon the high and low temperature and the HATS equipment capability.

60.2.7.4 Thermal Shock Testing. The thermal shock test method (TSM, IPC-TM-650, Method 2.6.8) that uses conventional stress/microsectioning is long and more difficult to characterize and detect failure. The IST is now an accepted test method by the IPC and found to better detect ILS failure than conventional TSM. The IST (IPC-TM-650, Method 2.6.26) is a DC-current-induced thermal cycling test that can also be used to determine PTH barrel cracking based on industry round-robin testing. It was shown that (1) qualitative correlation exists between ILS and TSM for

“gross” innerlayer separation, (2) IST is more consistent and sensitive for “fine-line” innerlayer separation, and (3) IST testing shows that smaller diameter vias are less likely than larger-diameter vias to exhibit innerlayer separation on the same panel.

For example, recent studies have shown that microvias require testing above the resin T_g. It has been recently established that the IST testing of microvias should be thermal cycled to 190°C. Testing at 190°C allows enough thermal expansion to cause a compromised microvia to fail in less than 500 cycles and at the same time does not produce any artifacts in the failure mode. Testing at 150°C will produce mean time to failure well in excess of 1000 cycles. Testing at temperatures higher than 190°C produces faster time to results but, upon microscopic analysis, the failure mode may not reflect the same failure mechanisms that are experienced in assembly or the end-use environment.

The IPC process capability, quality, and relative reliability (PCQR^2) has been demonstrated by testing a reasonably good correlation of the HATS test results with the more established thermal shock oven temperature cycling testing over the same 185°C temperature range (−40 to +145°C). The test failure criterion was a 10 percent increase in resistance. The temperature ranges for these cycling/shock tests are listed in Table 60.1.

TABLE 60.1 Comparison of Thermal Profile for Various Thermal Cycle/Shock Conditions Uused to Qualify PCBs and Microvias

Test Type → Thermal Cycle ↓	Oven Standard	IST Standard	IST Microvia	HATS
Lower temp (°C)	−50	22	22	−40
Upper temp (°C)	125	128	190	145
Delta T (°C)	175	172	168	185
Dwell time (min)	10	3	3	0.25
Cycle time (min)	60	5	5	9.6
Cycle/day	24	288	288	150

60.3 PCB FABRICATION AND FAILURE MECHANISMS

Printed circuit boards can be divided into the following types:

- Rigid boards that are widely used as single-sided or double-sided boards, or multilayer boards
- Flexible and rigid-flex boards
- Others including metal-core boards and injection molded boards

PCBs evolved from single-sided (all interconnections on one side) to double-sided and multilayer boards to meet the demand of higher performance systems requiring higher packaging density and faster propagation speeds. Currently, PTHs provide connections between the PCB's top and bottom side allowing wires to cross over each other without the need for jumpers. Multilayer PCBs provide the routing requirements to meet the increased pin count of IC

packages. Only multilayers have power and ground planes that are a must for high-performance systems. The planes are needed to meet controlled impedance for the high-speed traces, the need for bypass capacitors, and the need for low inductance values for the power and ground distribution networks. In multilayer boards, the PTHs can be buried (providing interconnection between innerlayers), semi-buried (providing interconnection from one of the two outer layers to one of the internal layers), or through vias (providing interconnection between the two outer layers).

When choosing among PCB substrate materials their mechanical, electrical, chemical, and thermal properties must be considered. At present, the copper-clad laminates and the prepregs are made with a variety of different matrix resin systems and reinforcement materials, such as woven glass fibers. The most commonly used resin systems for commercial applications are fire resistant (FR-4) difunctional and polyfunctional epoxies. The glass transition temperatures, T_g, range from 125 to 170°C, which may not be sufficiently high for some applications. Polyimide resins with higher T_g (>200°C), long-term thermal resistance, lower coefficient of expansion (CTE), and long plated-through via (PTV) life and high reliability are used for high-performance multilayer PCBs with a large number of layers.

Most multilayer boards are made of glass-reinforced with one of these or other resin systems not discussed here. Rolls of glass cloth are coated with liquid resin (A-stage). Then the resin is partially cured to a semistable state (B-stage or prepreg). The internal circuits are made on single- or double-sided copper-clad laminates. Two approaches are used to pattern Cu conductors, either by removing or etching Cu (subtractive process) or adding (additive process) Cu as required. Conductive paste is now also an option to form layer pairs and to attach substrates together in multilayers. The innerlayers are stacked up with B-stage polymer. The

rolls are cut into large sheets, and several sheets are stacked to form the desired final thickness sheets separating the layers. Rigid pins are used to establish layer-to-layer orientation. The B-stage prepreg melts during lamination and reflows. When it is cured, it glues the entire package into a rigid assembly. An alternative approach to pin-parallel composite building is a sequential buildup of the layers, which allows buried vias.

60.3.1 PCB and Via Types

Typical hole-diameters for PTV to microvia ranges from 300 to 50 µm (12 to 2 mil). These vias are divided into three general categories:

1. PTV. The plated-through-hole vias are formed through the entire thickness of the PCB. If it is used for component mounting it is identified as a PTH (plated-through hole) to distinguish the case when is as used solely as an interconnect (PTV).
2. Blind via. Blind vias are located on the outer layers at the top or at the bottom of the PCB and formed such as to make contact with the innerlayers.
3. Buried Via. Buried vias are holes formed within the innerlayers of a PCB without access to the top or bottom surfaces. These via holes are formed before lamination and plated and filled depending on the PCB build-up technology.

High density interconnects (HDIs) constitute the newest layering connection approach for multilayer PCBs and substrates in electronic packaging that accommodate dense and fine pitch package and die requirements. The high density requirement is achieved by using much smaller via (microvia) structures. Microvias are vias of less than or equal

to 150 µm (6 mil) in diameter used as blind and buried vias to form interconnections through one dielectric layer within a PCB. Microvias are cost effective and more reliable when are used in outer layers in a blind via construction where the outer layers of a multilayer PCB are connected to the next adjacent signal layer.

Microvias offer several distinct advantages[25,26] over their mechanically produced counterparts) from both the aspect of physical features and electrical performance, including the following:

- Microvias within the pads (via-in-pad) allow significant reduction in fan out and routing and therefore increased packaging density for assembly with a reduced layer count, greater layout efficiency, and improved cost effectiveness for a given PCB.
- PCBs with microvias enable the designer to incorporate the newest high density packages and die into their system. The microvia is especially valuable or may even be required when using parts such as full array packages, CSPs, and flip chip direct attach (FCDA) designs. PCBs with conventional through-hole fabrication technology have physical size limitations that cannot support parts with fine-line geometry.
- PCBs with microvias show better electrical performance and signal integrity due to their physical structure. As the physical size of microvias become smaller and shorter, both the inductance and capacitance decrease, resulting in a reduction in switching noise.
- RFI/EMI/ESD (radio frequency interference/electromagnetic interference/electrostatic discharge) can be improved by effective grounding. Increased routability area combined with the microvias-in-pad implementation enable a designer to utilize more

ground plane around the component, thus reducing the ground return loop.

- Proven microvia technology yields higher reliability because of the significantly lower area aspect ratio (1:1) due to its fabrication in one dielectric layer when compared to a larger drilled through-hole via having a much high aspect ratio (>10:1).

60.3.2 PCB Failure Mechanisms

PCB failure mechanisms can be categorized into three key types:

- Thermally induced failures. The most common failures are due to PTH/PTV and HDI microvia failure. For this reason, these types of failures will be discussed in detail below.
- Mechanically induced failures can occur during mechanical loading into test fixtures or insertion into box/brackets, or when the assembly experiences mechanical shock or vibration in use. In general, a PCB is stronger than the packages and interconnections; therefore, this failure mechanism is less important for PCBs and will not be discussed further.
- Electrochemical failures generally cause reduction in surface insulation resistance (SIR) and if excessive SIR degradation occurs, unacceptable cross talk between circuit elements may occur, causing the circuit to cease functioning properly. Exposure to humidity, especially when ionic contaminants are present, is a common cause of insulation resistance failures that is accelerated by elevated temperatures and electrical bias. The impedance often decreases slowly over a long period of time. If the SIR value falls below the designed level, there will be cross talk between circuit elements that should be isolated, and the circuit may not function properly. Insulation resistance

deterioration is particularly harmful for analog measurement circuits. The medical products that use sensors attached to a patient also pose special concerns, because deterioration of insulation resistance has the potential to cause electrical shock. Electrochemical failures are usually accelerated by temperature, humidity, and applied bias. Even though this type of failures are critical, it is beyond the scope of this chapter.

- Conductive contaminant bridging of circuits by conductive salts may occur if plating, etching, or flux residues remain on the board. These ionic residues are good conductors of electricity in a moist environment. They tend to migrate across both metallic and insulating surfaces to form shorts. Corrosive byproducts, such as chlorides and sulfides formed in industrial environments, are chemically similar and can also cause shorting. An example of this type of failure is shown in Fig. 60.11.[27]

FIGURE 60.11 Migration of corrosion products across the surface of FR-4 bridging two conductors.[13, 27]

- Dendritic growth occurs by the electrolytic transfer of metal from one conductor to another; consequently, it is

also termed *electrolytic metal migration*. It is also referred to as *electromigration*, although it should not be confused with the process that occurs in aluminum conductors in integrated circuits, which has a different mechanism. It is significantly accelerated by the presence of hydrolyzable ionic contaminants (e.g., halides and acids from flux residues or extracted from polymers). Delaminations or voids that promote the accumulation of moisture or contaminants can promote dendritic growth. The dendrite resembles a tree, since it consists of a stalk with branches. When the growth touches the other conductor there is an abrupt rise in current, which sometimes destroys the dendrite but may also cause an electrical circuit to temporarily malfunction or damage a device. An example of this type of failure is shown in Fig. 60.12.

FIGURE 60.12 Transmitted light micrograph through a PCB that failed in the field. Dendritic growth has formed at the interface of a UV-cured screened solder mask and the FR-4 surface.[13]

- Galvanic corrosion occurs between dissimilar metals because they have differing affinities for electrons (i.e., they are more or less electronegative). Galvanic series have been compiled for many common metals and alloys. Metals near the top of the series (noble metals) do not

corrode; those near the bottom corrode easily. When these metals are near each other, the more noble metal becomes the cathode, the less noble the anode. Moisture is required to couple the two metals electrically. Applied bias is generally not required, but may accelerate the reaction if the polarity is correct. When the anode is very small compared to the cathode, its corrosion can be very rapid. Conversely, if the anode is much larger than the cathode, corrosion is unlikely to be serious, particularly if the difference in electronegativity is small.

- Conductive anodic filament growth. Conductive anodic filament growth (CAF) causes electrical shorts when a metal that dissolves anodically is redeposited at the interface between the glass (or other) fibers and the resin matrix of a printed circuit board. Conductive anodic filament growth is promoted by delamination at the glass-polymer interface, which may in turn be promoted by various environmental stresses including high temperatures (greater than about 260°C (500°F) for FR-4) and thermal cycling. Shorts seem to occur most rapidly when a single fiber bundle connects two pads. Once delamination has occurred, the metal migration that causes shorts to occur is promoted by increasing temperature, relative humidity, and applied voltage
- Whiskers. Whiskers are faceted filament-like structures that grow spontaneously on the surface of a plated metal and can cause shorts between closely spaced conductors. Whiskering can be differentiated from other causes of shorts such as dendritic growth, because neither an electrical field nor moisture is required for whiskers to form. Whiskering is a particular problem with pure tin. The whiskers grow in response to internal stresses in the plating or external loads. Sn whiskers are commonly 50 µm (2 mil) long and 1 to 2 µm (0.04 to 0.08 mil) in diameter.

60.3.3 PTH/PTV Failures under Thermal Stresses

Figure 60.13 shows schematically several common key failures and failure locations of the PTH that are frequently observed due to thermal cycling exposure of a PCB. Barrel cracking occurs due to high CTE mismatch between the organic resin matrix and the Cu in the Z direction since the embedded reinforcement material (for example, glass or aramid fibers) has minimum effect on lowering the CTE in this direction. The effective CTE in the X and Y directions in general is much lower due to the lower CTE of the reinforcement material. In addition, the resin CTE increases sharply above its glass transition temperature, causing further CTE mismatch strain induction on the Cu and the potential of PTH/PTV failure.

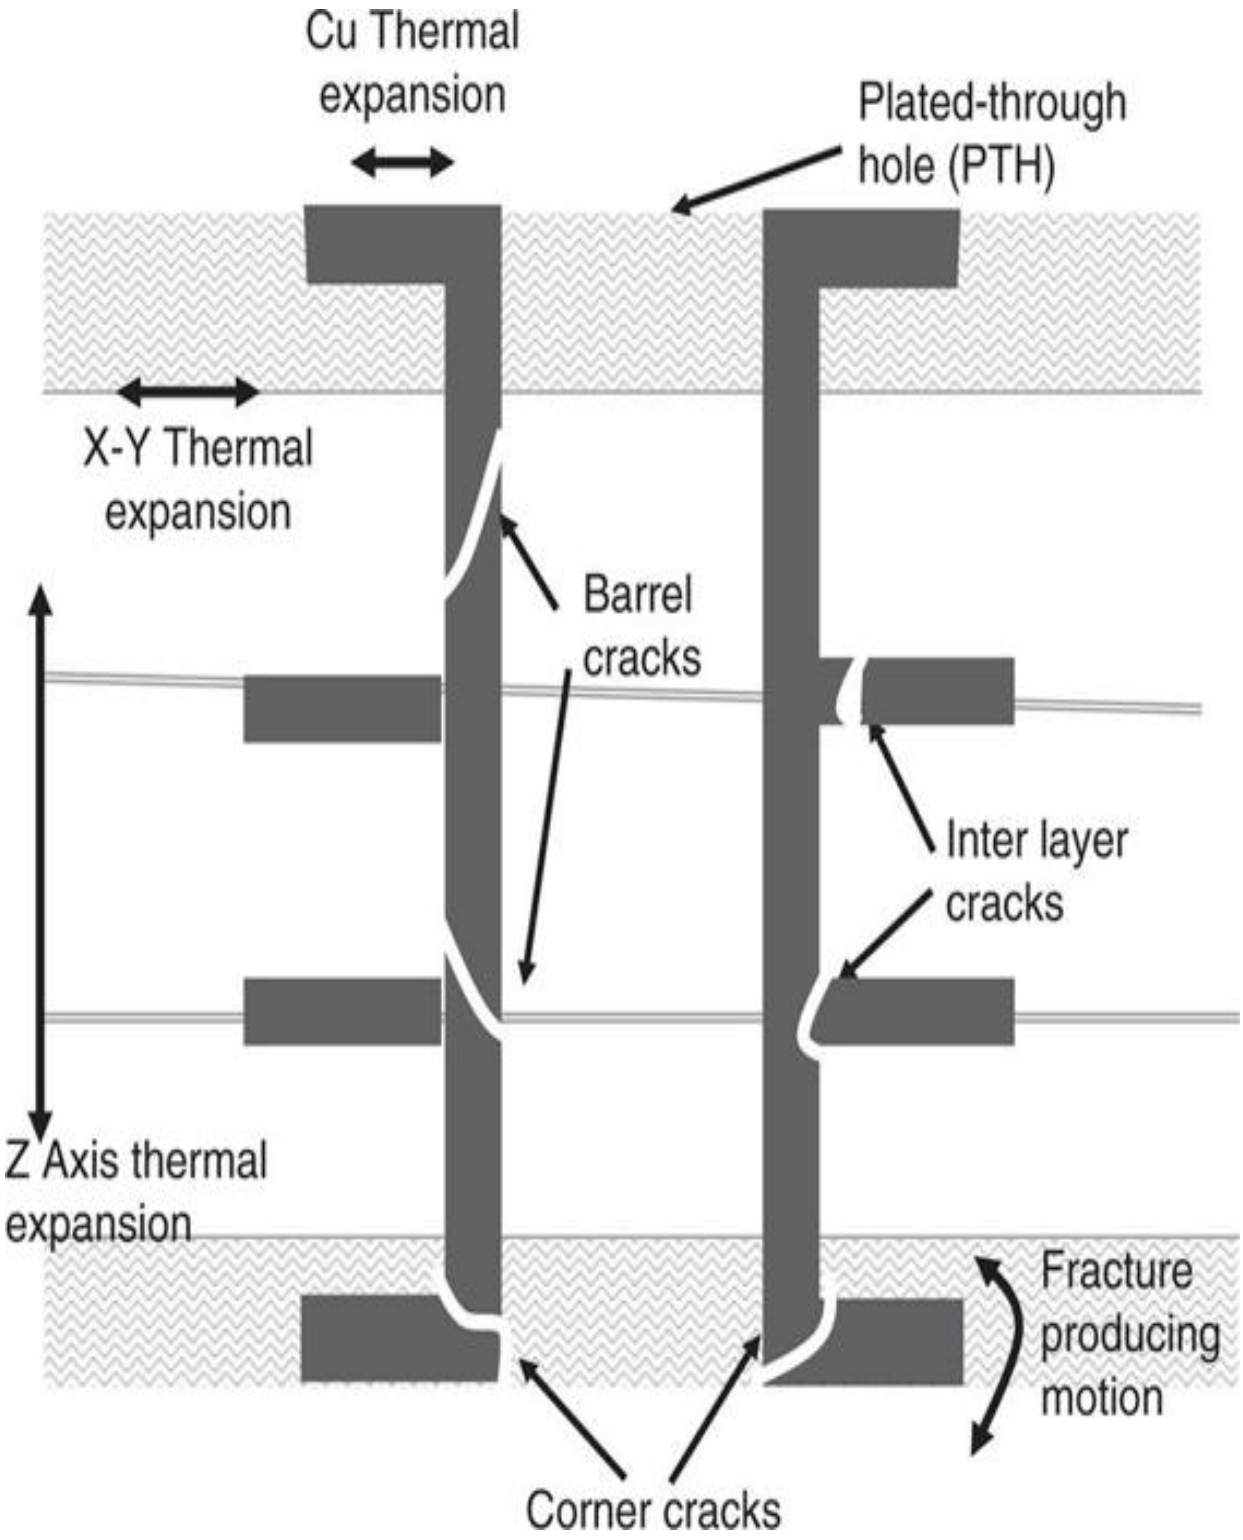

FIGURE 60.13 Common failure mechanisms for plated-through-hole vias.

Innerlayer separation (ILS) can be in the form of innerlayer Cu foil failure, separation of the foil and Cu flash, or

separation of the Cu flash and electrolytic Cu. Whereas barrel cracking and land rotation is caused by the *z*-axis CTE mismatch, ILS occurs in the *x* and *y* directions due to resin expansion into the free space of the PTH. If the Cu wall is thick enough to deform only elastically, then ILS typically does not result. However, if the barrel wall is thin and unsupported, the barrel will plastically deform inwards causing a large tensile stress at the PTH inner attachment points. A Cu foil with good quality can delay failure due to these stresses.

60.3.4 PTH Reliability and the Effects of PCB Fabrication Parameters

60.3.4.1 Laminate and Lamination. Delamination in PCBs may occur between the laminate materials or between the laminate material and the Cu foil. One cause of delamination is defective laminate material. Defects such as incomplete bonding at the resin/fiber interface can result in delamination due to formation of voids at these interfaces. Other common causes of delamination are excessive lamination pressure and/or temperature, contamination at interfaces, heavily oxidized Cu foil surfaces, and lack of oxide treatment to enhance adhesion between Cu innerlayers and prepreg. Debonding increases the risk of conductive anodic filament growth because it provides a place for moisture to accumulate. It can also result in increased stresses on the plated-through holes (PTHs) during thermal cycling.

Laminate voids and resin recessions are separations of the laminate material from the copper conductor that may occur during multilayer PCB lamination. Most acceptability specifications prohibit voids larger than 76 µm (3 mil); however, smaller voids are not generally considered to be detrimental to reliability. Some of the causes of laminate voids are entrapped air during lamination, improper flow of

resin, and improper epoxy cure, perhaps due to improper lamination pressure and/or temperature, inappropriate heating rate, or too little prepreg.

60.3.4.2 Cu Foil. The major cause of innerlayer foil cracks seems to be poor ductility of the Cu. Poor foil ductility can have a more significant effect on PTH reliability than such well-known culprits as insufficient plating thickness and excessive etchback. A minimum of 8 percent elongation is required for 1-oz foil to eliminate this problem. Foils plated in a Hull cell can be easily evaluated for room-temperature ductility using a 180° bend test.[28] Poor copper ductility can be correlated to the microstructure observed in metallographic cross sections.[29]

60.3.4.3 Drilling and Desmear. Poor drilling and desmear (etchback) can cause PTH failures by providing stress that contributes to conductive anodic filament growth. The following paragraphs describe the effects of poor desmear and some drilling defects that can cause poor plating, such as resin smear, rough walls, loose fibers, and burrs. Resin smear can cause weak connections between plated-through holes and innerlayer copper that fails under environmental stress. There is always some resin smear, which is removed by the desmear (etchback) process. If the desmear process is not effective, or if the resin smear is excessive, poor interconnection to the innerlayers can result. Possible causes of excessive smear are a dull drill or the wrong feed rate or drill speed, all of which can cause increased drill heating, resulting in more smear.

Similar errors in drilling setup can cause rough hole-walls, loose fibers, or burrs. These defects are not serious in and of themselves, but can lead to rough plating or copper nodules, which introduce stress concentrations. Rough walls are typically associated with an incorrect feed rate or drill speed, or insufficiently cured material. Loose fibers may be caused

by incorrect drilling parameters or improper cleaning. Burrs are usually associated with too fast a drill feed or a dull drill.

Poor drill registration can also decrease reliability of innerlayer via connections or the soldered connection to through-hole components. Poor registration can cause breakout on innerlayers; that is, the drill hole may fall outside the pad on the innerlayer it is intended to connect to. Breakout increases the probability of PTH barrel failures. Breakout on outer-layers means that the solder fillet for a through-hole component will be partially missing, resulting in decreased reliability for some critical components.

Whether caused by excessive resin smear or not, poor etchback can result in a weak connection between the plating in the hole and the innerlayer copper. Etchback (see Fig. 60.14) removes laminate resin and woven glass in the hole so that the internal copper projects slightly into the hole, permitting the plating to make contact with the innerlayer foil on three sides. This strength is important to prevent cracking at the interface under thermal shock conditions. A review of innerlayer cracking in or around the electroless copper at the junction between the innerlayer foil and the electroplated Cu in the hole suggests that *negative* etchback, in which the electroplated Cu projects into the laminate may also give good results. Zero etchback, when innerlayer foil is flush with the hole wall, is the most dangerous case because the bond line between the foil and the plated copper is located at the point of maximum stress.[30] However, flush etch back is considered the least dangerous and most reliable configuration by others.[31] Causes of insufficient etchback include improper lamination and curing, hardened epoxy smear, a depleted smear removal bath, or a host of process control issues, including improper bath temperature, agitation, or time exposure.

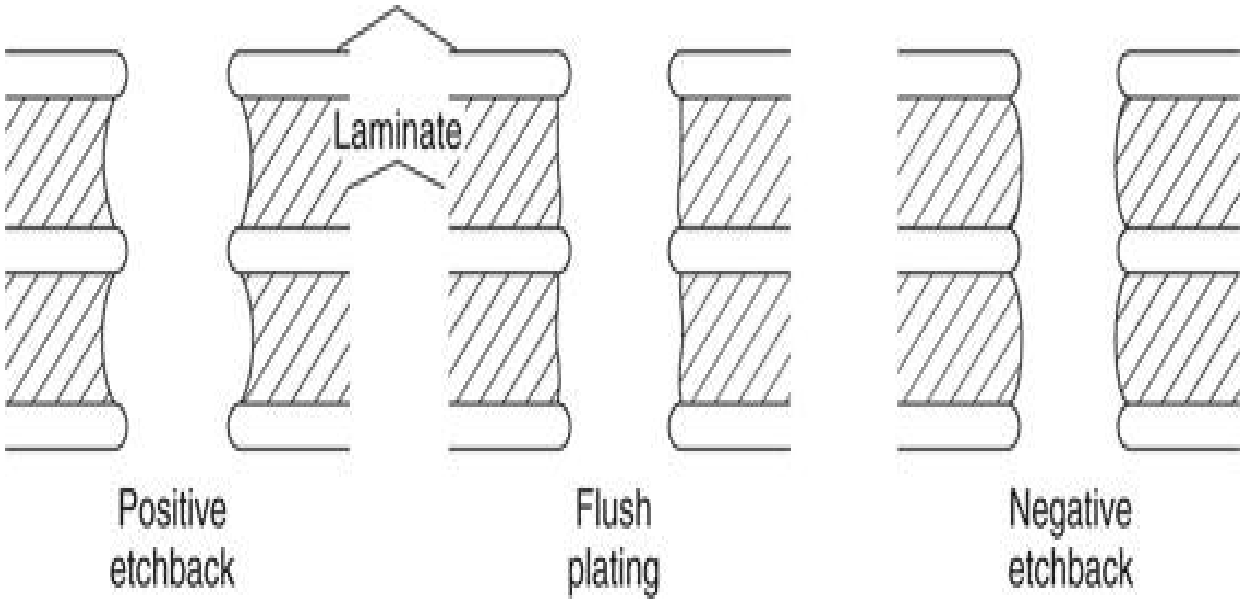

FIGURE 60.14 Schematic illustrations of positive, flush, and negative etchback. (*After M. W. Gray*.[30])

60.3.4.4 Plating. Defects from the plating process can be responsible for a variety of PTH reliability problems; in addition, as previously described, problems in earlier process steps such as drilling and desmear often show up as plating defects. Uniform coverage of the hole with electroless Cu is critical to the strength of the through hole and the adhesion of the metallization to the laminate. Oxidation of the innerlayer copper prior to electroless Cu plating is one source of poor plating adhesion. Poor control of bath composition can have the same effect.

The adhesion of the electroplated Cu to the electroless Cu and the ductility of the electroplated Cu also strongly affect PTH reliability. If the adhesion between the layers is poor, this interface may be the weak point, where failure initiates when the PTH is subjected to thermal stresses. Causes can include tarnished electroless copper that is insufficiently micro-etched, burning the electroless copper with too much current in electrolytic plating, and film contamination in the electrolytic copper.[30] Susceptibility to innerlayer cracks may be identified by looking for cracks in microsections after a

solder float test. The fatigue life of the Cu is directly related to its ductility. Plating process parameters and plating additives can strongly affect the plating ductility.

Insufficient plating thickness in the barrel also directly reduces PTH reliability because the stress and, consequently, the strain in the Cu are increased. Overall insufficient plating thickness can be caused by a depleted bath or insufficient plating time, among other things. Insufficient plating thickness in individual holes can also occur as a result of nonuniformities in plating current caused by nonuniform Cu feature density. It is particularly difficult to obtain adequate plating thickness in the center of high-aspect-ratio PTHs; good process control is important for aspect ratios greater than 3:1. Good coverage is difficult to obtain for aspect ratios greater than 5:1 by electroplating.

What constitutes “sufficient” plating thickness in PTHs is a subject of some controversy. Specifications range from 12 to 25 µm (0.5 to 1 mil) Cu thickness in the barrel. There are at least two reasons why there is no one right specification. First, different applications provide different levels of thermal stress and demand different levels of reliability. Second, design factors such as the aspect ratio of the plated holes determine the susceptibility of the PTHs to thermal fatigue. The IPC recommends an average minimum copper-plating thickness of 12 µm (0.5 mil) for consumer products (Class 1) and 25 µm (1.0 mil) for general industrial and high-reliability applications (Classes 2 and 3).

Poor coverage at the PTH knee can significantly accelerate PTH failures because it means the plating is thin at a point of high stress. It can be caused by excessive concentration of the organic leveling agents added to an electroplating bath.

60.3.4.5 Solder Mask Application. If it is properly applied, solder mask plays an important role in reducing the possibility of insulation resistance failures on PCBs. The solder mask protects the substrate from moisture and

contaminants, which would otherwise promote shorting under electrical bias. The ability of the solder mask to perform this function depends on good conformity and adhesion of the solder mask to a clean, dry substrate. If solder mask conformity or adhesion is poor, moisture and other contaminants may accumulate at crevices or delaminations between the solder mask and the substrate. Substrate cleanliness is particularly critical because, in addition to causing poor solder mask adhesion, it can also provide the ionic species needed for rapid electromigration. When the laminate material absorbs moisture readily (e.g., polyimide, aramids), baking before reflow may be required to prevent solder mask delamination (as well as reinforcement/resin delamination).

Other causes of poor adhesion or conformity include moisture on the board when the solder mask is applied, improper solder mask lamination or coating parameters, and improper solder mask cure parameters. Incomplete solder mask cure can create local soft pockets, which are common sites for delamination or contaminant entrapment. Solder mask over solder should also be avoided because delamination caused by reflow of the solder may allow contaminants to be entrapped.

60.3.4.6 Rework. Rework, whether repair of open or shorted solder joints or replacement of defective components, has a significant negative effect on component and PCB reliability. Rework of large through-hole components, such as pin grid arrays (PGAs) and large connectors, poses special problems. If it is improperly done it can result in PTH failures. Because the damage during these large thermal cycles is cumulative, the number of rework operations at a given site should be monitored and limited to a safe number. The number of cycles that will cause a fatigue crack to initiate in the copper in the barrel and propagate to failure depends on the aspect ratio of the PTH,

the type and thickness of plating in the hole, the substrate material, etc.

Due to the large number of joints that must be melted at once and the large thermal mass of the components, rework of large PTH components is often done with a solder pot. The thermal shock caused when the molten solder hits the board can cause PTH cracking due to *z*-axis expansion. A preheat step (to about 100°C for FR-4) helps to reduce the damage. The time the board is in contact with the solder fountain should also be minimized since dissolution of the copper plating inside the PTH occurs during this time. Thinning the plating in the PTH tends to increase the strain in the Cu during thermal cycling, further accelerating failure. If the total time for part removal and replacement is kept under 25 s, little dissolution is measured.[32] Weakening of the PTH by copper dissolution during PGA rework can be essentially eliminated by using NiAu plating. Although the thin Au coating that protects the Ni dissolves almost instantly during soldering, Ni dissolves quite slowly and effectively prevents thinning of the PTH metallization.

Rework temperatures also weaken the adhesive bond between the Cu conductors on the PCB and the laminate material; use of force to remove components when the solder is not completely molten can cause the pad to lift off the board. The latter can be a particular problem when using a soldering iron.[33,34]

60.3.5 PTH Reliability and the Effects of PCB Properties

60.3.5.1 Substrate. Difunctional FR-4 is the key material for high-reliability PCBs because its moderate *z*-axis expansion and moisture uptake characteristics are available at relatively low cost. Alternative substrate materials (see

Table 60.2) are generally selected for more favorable properties in one or more of the following three areas: thermal performance, including maximum operating temperature and glass transition temperature; thermal expansion coefficient; and electrical properties, such as dielectric constant. Thermal performance characteristics and thermal expansion coefficient can have a significant effect on PCB and solder joint reliability. Other characteristics of these materials, such as moisture absorption, can also affect reliability.

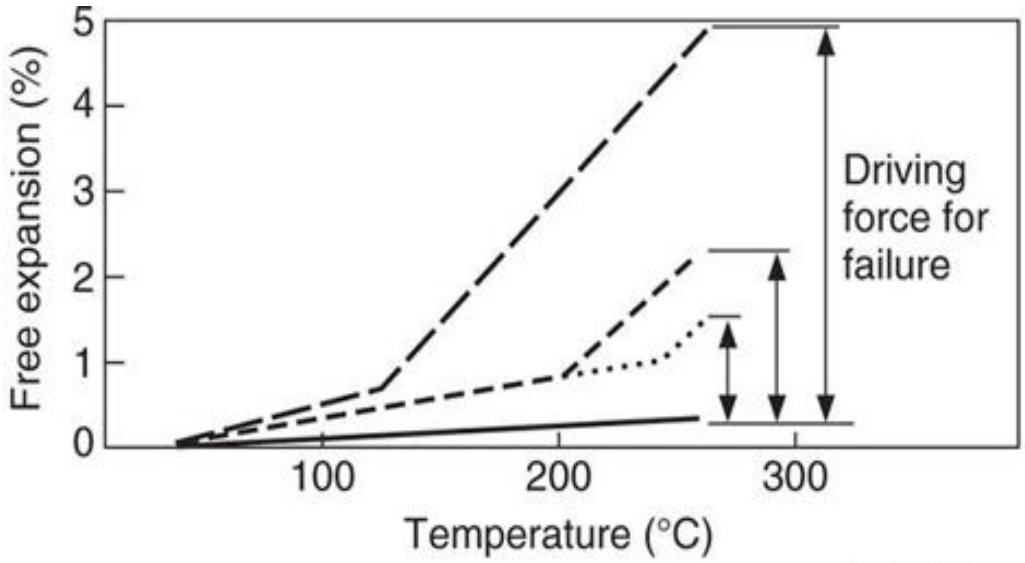
TABLE 60.2 Physical Properties of Some Printed Circuit Board Laminate Materials (IPC Dd-279)

Material	CTE, Y ppm/°C	CTE, Z ppm/°C	T_g, °C
Epoxy glass (FR-4, G-10)	14–18	180	125–135
Modified epoxy glass (polyfunctional FR-4)	14–16	170	140–150
Epoxy aramid	6–8	66	125
Polyimide quartz	6–12	35	188–250

PTH reliability can be improved by selecting a laminate with a lower *z*-axis CTE or a higher T_g. The damage caused to the PTH during a thermal cycle depends on the total *z*-axis expansion during the temperature change since the CTE is much lower below T_g than above.

The PTH strain can be reduced by increasing the T_g so that more or all of the cycle is below T_g (see Fig. 60.15*a*). Figure 60.15*b* shows that the increase in life can be quite significant. The strain imposed on the PTH can also be

reduced by decreasing the CTE at temperatures below T_g, but the effect on total z-axis expansion is much smaller.



Material	T_g, °C	z-axis CTE, ppm/°C
Copper	—	17
FR-4	125	73/300
FR-4/CE blend	200	50/230
CE	240	50/230

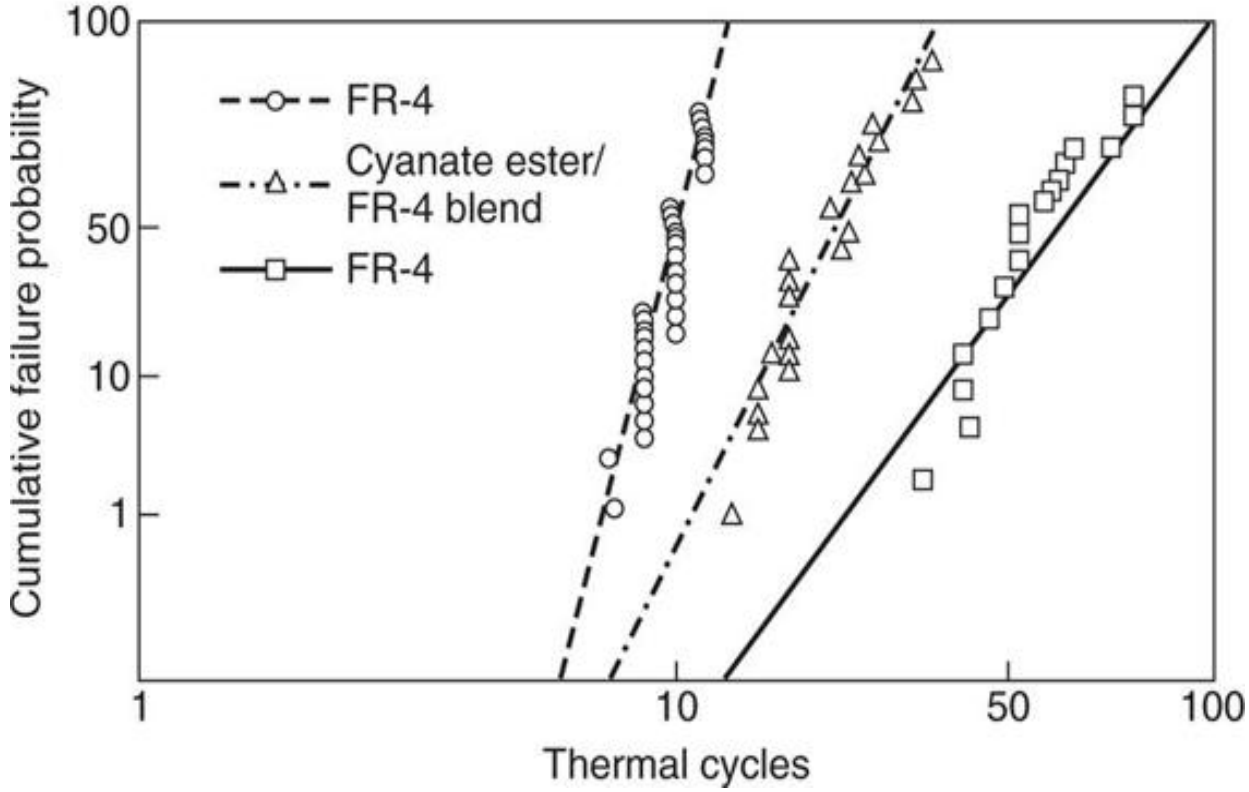


FIGURE 60.15 (*a*) Effect of differences in CTE below T_g and T_g on the free *z*-axis expansion of FR-4 (epoxy glass), cyanate ester (cyanate ester glass) and a cyanate ester/epoxy blend. T_g and CTE for each material below/above T_g are indicated. Cyanate ester is abbreviated CE in the figure. Cu is shown for comparison. (*b*) Weibull plot of PTH failures for these substrates during thermal shock cycling between 25 and 260°C. PTHs are 0.029-in diameter on 0.100-in grid on 0.125-in-thick laminate.[35]

Low-thermal-expansion metal cores or planes can also lower the overall substrate CTE because they constrain the expansion of the polymer material they are laminated to. Copper-invar-copper (CIC) is the most widely used material for constraining metal cores (also termed polymer-on-metal or POM construction), followed by copper-molybdenum-copper (CMC). The PCB and core are bonded with a rigid adhesive, usually in a balanced construction to minimize warping. Other special processing is also required. The CTE of the assembly can be estimated using a simple model for composite structures most often written as

$$\text{CTE(overall)} = \Sigma E\alpha t \,/\, \Sigma Et$$

where E, α, and t are the elastic modulus, coefficient of thermal expansion (CTE), and thickness, respectively, of the various layers. A more sophisticated model can be found in reference.[36] An example of the low overall CTE for a CIC core is shown in Fig. 60.16.

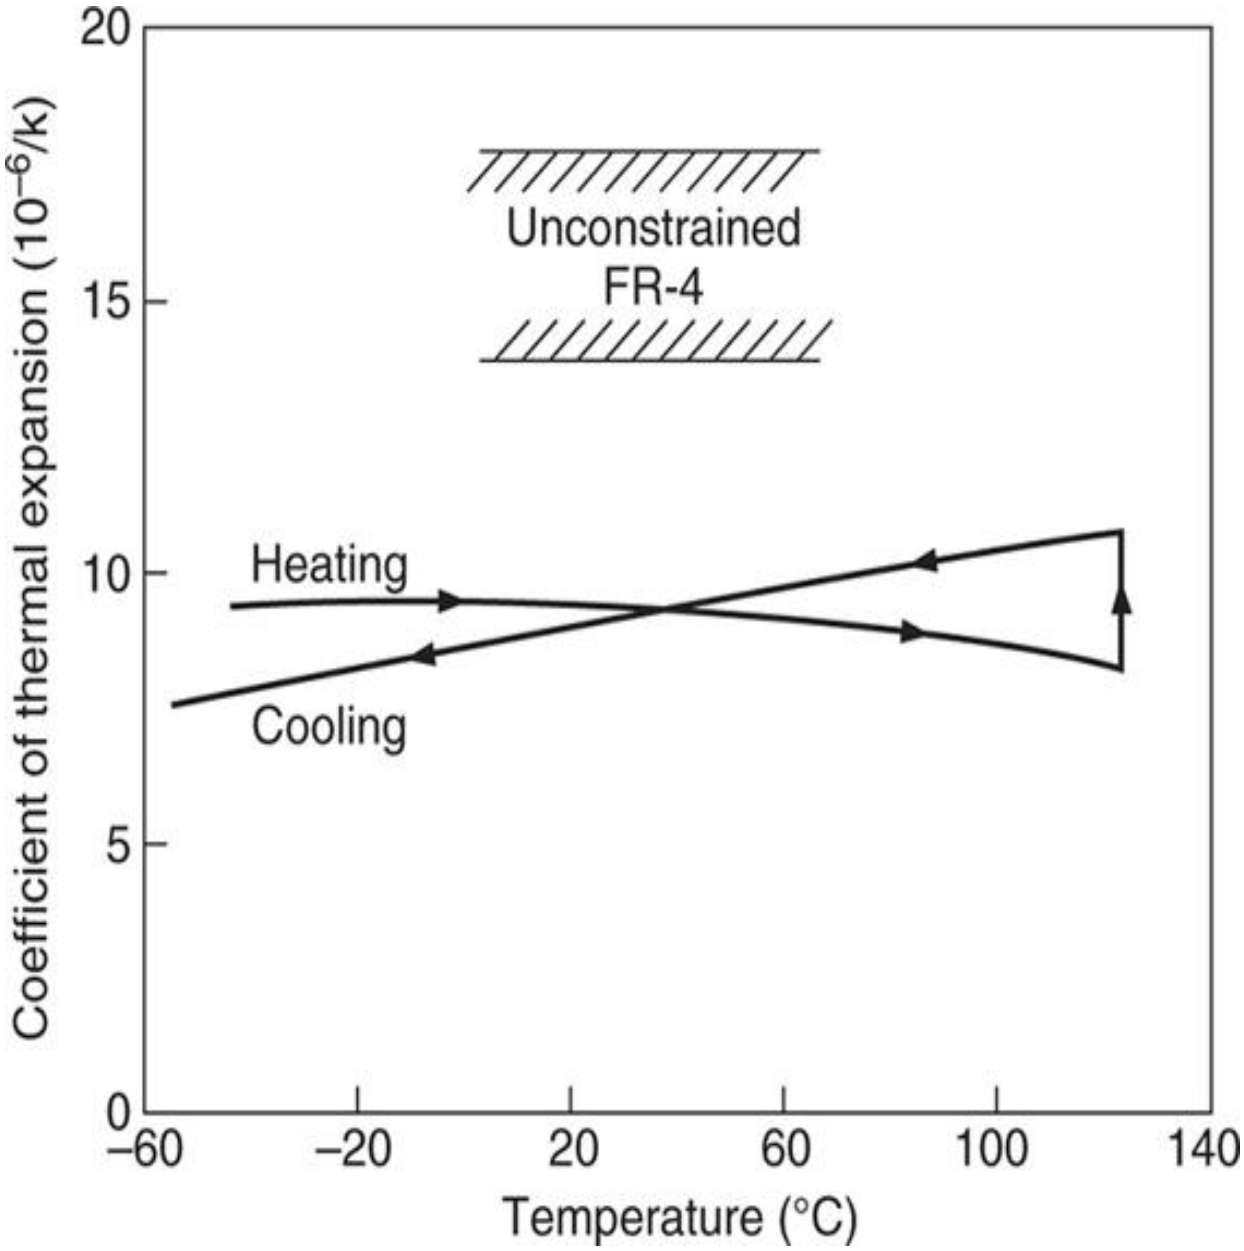

FIGURE 60.16 Example of the low overall CTE that can be achieved for a metal core construction. Two 1.4-mm-thick (0.055-in) multilayer FR-4 boards were bonded to a 2.2-mm-thick (0.085-in) copper-Invar-copper core.[13,30]

A variety of specialty resins with increased T_g is available, albeit at higher prices. Modified FR-4 materials with higher functionality offer the best combination of improved T_g at a reasonable price. Further improvements in T_g and other characteristics can be obtained with bismaleimide triazine

(BT), GETEK, cyanate ester, and polyimide, but at greater price penalties.

A lower *x*-*y* plane thermal expansion coefficient laminate can be obtained by replacing the continuous-filament E-glass used in most FR-4 PCBs with an alternative material. The CTE decreases as the fraction of silica dioxide (SiO_2) decreases and the level of quartz (as well as the cost) increases in the progression E-glass, S-glass, D-glass, and finally quartz, which has a CTE about one-tenth of E-glass. Aramid (Kevlar) actually has a negative CTE, but it is available in only a few glass styles. Some of the disadvantages of aramid fibers are higher *z*-axis expansion and higher moisture absorption relative to glass fibers that can result in decreased susceptibility to PTH failures and corrosion-related insulation resistance failures, respectively.

Because of its high T_g and low CTE below T_g, polyimide imposes much lower strains on the PTH for a given thermal cycle than other dielectrics. Resin material can affect fiber/resin delamination, one of the prerequisites for conductive anodic filament growth. Measling occurs at about 260°C for FR-4, but may occur at lower temperatures for boards with more hygroscopic resins.

60.3.5.2 Solder Mask. The three major types of solder mask—liquid screen-printed, dry film, and liquid photoimageable (LPI)—come with different benefits and concerns from a reliability perspective. The solder mask material should be selected for its compatibility with the heat and solvent characteristics of the assembly process, its capability to provide good conformity over surface features on the PCB, and its ability to tent vias if required. Since many of these characteristics are product-specific, only a few general guidelines can be provided here. Where tenting of vias is required to keep solder, moisture, or flux from wicking up under components, dry film solder mask should be used. However, excessively thick solder mask, particularly dry film

over closely spaced traces, can result in crevices. If the solder mask cannot flow enough to adhere closely to the board, the resulting crevices can entrap contaminants such as flux that can accelerate corrosion later. LPI solder mask provides excellent coverage, resolution, and alignment to other features, but it generally cannot be used to tent vias. IPC-SM-840 defines the performance and qualification requirements for solder mask.

60.3.5.3 Metal Finish. The metal finish on the SMT and TH pads can have an impact on PTH reliability and on the reliability of the solder joints made to these pads. Common metal finishes for solder-mask-over-bare-copper (SMOBC) boards include hot-air solder leveling (HASL or HAL), organic-coated copper (OCC), and electroless NiAu. Galvanically plated CuNiAu and CuNiSn made by another processing route are also available. These finishes provide a solderable finish for later printed circuit assembly. Of the common metal finishes, HASL is the only one that can directly reduce reliability of the board. In a typical HASL process, the board receives a severe thermal shock when it is dunked into a bath of molten eutectic Sn-Pb solder. The PTHs can survive only a certain number of solder shocks without failure; this process uses up one of these thermal cycles before the board leaves the fabricator.

CuNiAu boards fabricated either with the NiAu as the Cu etch resist or by the SMOBC process followed by electrolessly plating Ni and Au can confer improved PTH reliability. There are two mechanisms for the observed improvement: the enhanced rivet effect provided by the Ni and the elimination of Cu dissolution during solder shocks such as wave soldering or PGA rework. For high-aspect-ratio holes, electroless Ni confers an additional benefit because the plating thickness in the barrel is more consistent than for conventional electroplating.

In the simple picture of PTH failure shown in Fig. 60.17, the comparatively low CTE metal-plated PTH acts as a rivet that resists the *z*-axis expansion of the PCB. Because Ni has a higher elastic modulus than Cu, it strains less under the stress imposed by the expanding PCB. Consequently, adding Ni plating lowers the strain imposed on the Cu and lessens the amount of fatigue damage. In this model, the Ni protects the Cu, increasing PTH life.

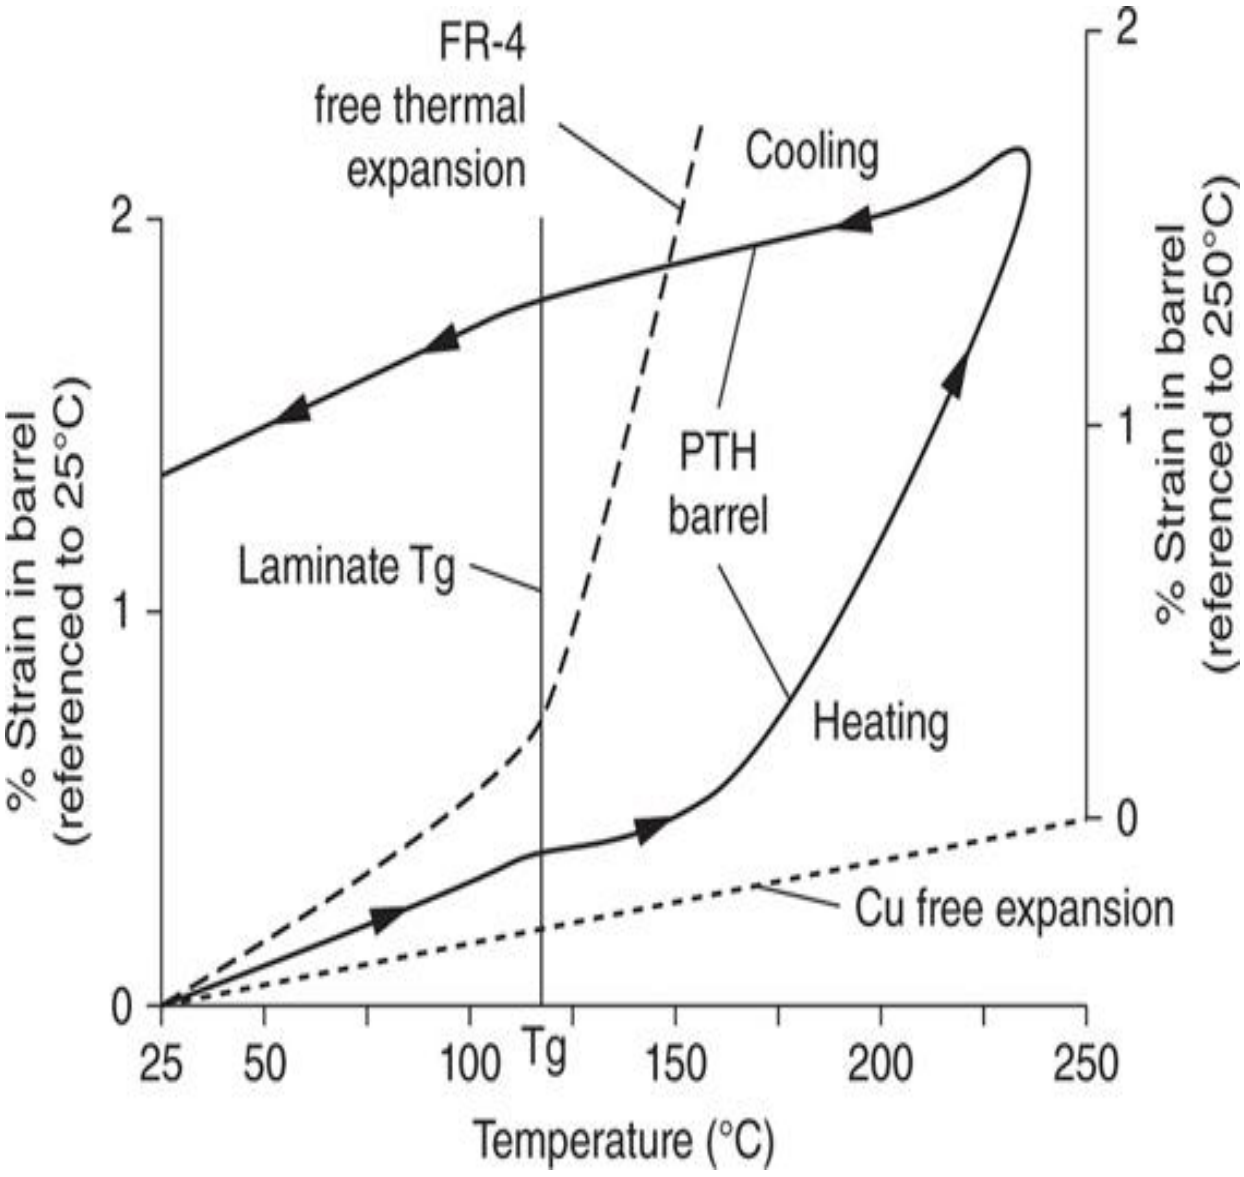

FIGURE 60.17 Strain versus temperature for FR-4 (epoxy glass), copper, and a PTH barrel in an FR-4 board during a single thermal cycle from 25 to 250 to 25°C.

While the thermal expansion of the individual materials is fully reversible, much of the strain in the Cu PTH barrel is plastic, so most of the strain is not reversed during cooling. Note that the rate of thermal expansion of the FR-4 increases sharply at T_g.[39]

The ability of the Cu to withstand the forces imposed on it by thermal expansion of the PCB is also dependent on the thickness of the Cu in the PTH. Unfortunately, in the SMOBC process all subsequent steps after pattern or panel plating reduce the Cu thickness from the plated amount. Nickel plating is resistant to the etches and developers used in later processing steps, so it protects the underlying copper from thinning due to dissolution. The HASL process and rework of large through-hole connectors or pin grid arrays (PGAs) can have particularly negative effects. Cu dissolves rapidly into molten eutectic Sn-Pb solder. During the HASL process or component removal and replacement with a solder fountain, large amounts of Cu can dissolve from the knee of the PTH. Nickel barrier plating minimizes this effect because Ni dissolves far more slowly in eutectic Sn-Pb solder than Cu does.

Use of Au plating can embrittle the eutectic Sn-Pb solder most commonly used in electronic assembly. Gold plating of various thicknesses is used for a variety of reasons, including as a solderability preservative over nickel plating, for connector contacts, and to provide wire-bondable pads. Reliability problems can arise because Au has a high solubility in eutectic Sn-Pb solders at reflow temperatures and dissolves extremely rapidly. In most cases, the Au finish on a PCB or component termination will be completely dissolved into the solder. In a wave-soldering process, the Au is washed into the bath, requiring monitoring and bath changes to maintain the Au concentration at a low level that does not affect the process. However, in a reflow process, this Au remains in the finished solder joint. To avoid embrittlement of the solder by the $AuSn_4$ and $AuSn_2$

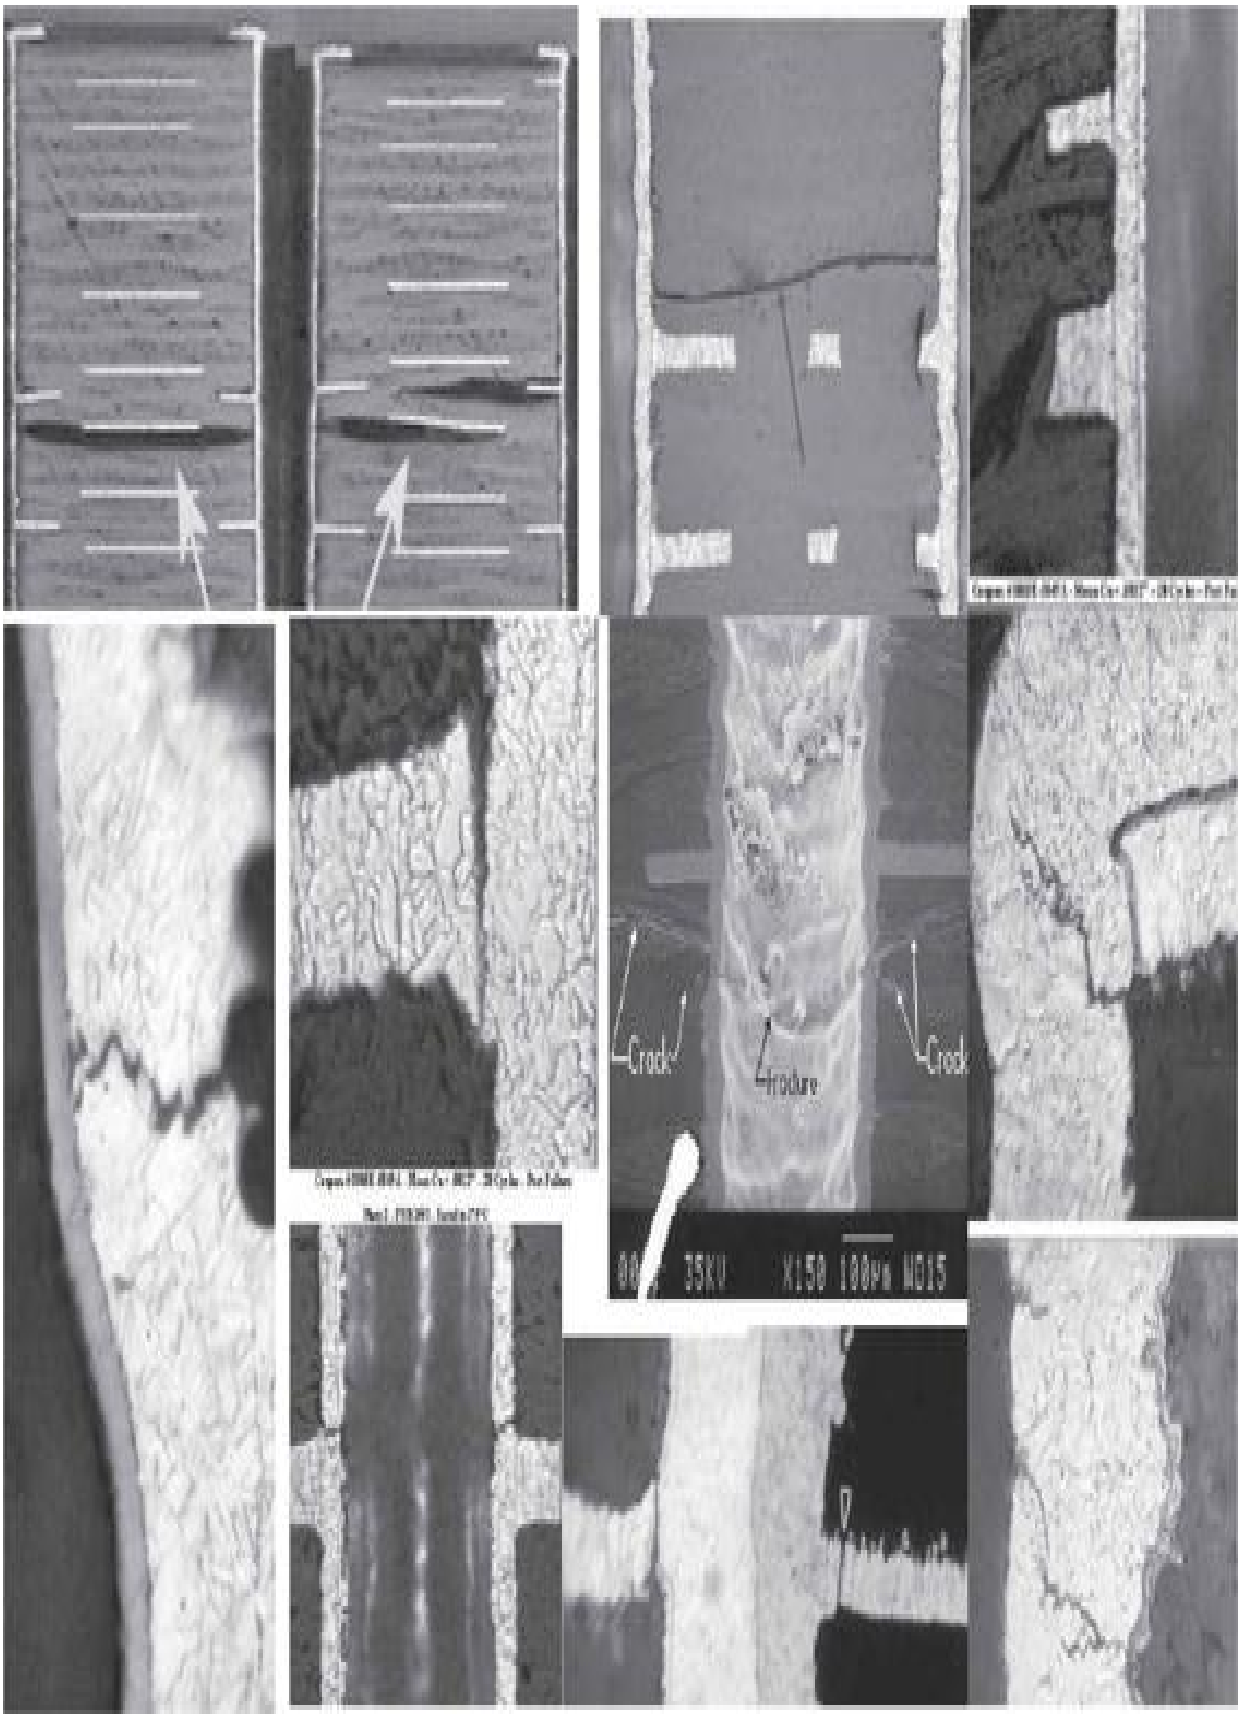
intermetallics that can form, the Au concentration should be kept below a critical level that most authors set at 3 to 5 percent by weight.[37,38]

60.4 PTH THERMAL CYCLE RELIABILITY AND PROJECTIONS METHODS

Plated-through holes (PTHs) and microvias are the most vulnerable features on PCBs to damage from thermal cycling and the most frequent cause of PCB failures in service. PTHs include holes for through-hole (TH) components and vias that make electrical connections between layers. Most organic resin-matrix substrate materials are highly anisotropic, with a much higher CTE above the glass transition temperature T_g in the through-thickness (z) direction than in the plane of the woven matrix cloth (the x-y plane of the board). Since above T_g the CTE climbs sharply, aggressive thermal cycles can result in large strains in the z direction and, consequently, on the PTHs. The PTH acts like a rivet, which resists this expansion, but the Cu barrel is stressed and may crack, causing electrical failure. Figure 60.17 illustrates the increasing strains on the barrel associated with low- to high-temperature excursions, especially excessive strains above the T_g excursion.

Failure may occur in a single cycle or may take place by initiation and growth of a fatigue crack over the course of a number of cycles. PTHs are subject to repeated thermal shocks from room temperature to solder reflow temperatures (220 to 250°C during board fabrication (e.g., hot-air solder leveling) and assembly (reflow, wave soldering, and rework). For high-aspect-ratio PTHs, these thermal cycles are severe and potentially could cause failures after 10 or even fewer of

these cycles. PTH fails in a number of ways depending on the stress condition and the weakest points. A representation of these failure mechanisms is shown in Fig. 60.18. In the following sections, models that have been developed to address each specific failure mechanism are addressed.



Crack
Fracture
Crack

FIGURE 60.18 Representation of Cu PTH failure mechanisms.

60.4.1 Coffin-Manson Relationship

On a physical level, the number of thermal cycles to failure is affected by the strain imposed on the Cu PTH in each cycle and the fatigue resistance of the copper.[40] These factors are, in turn, controlled by a number of environmental, material, and manufacturing parameters. Low-cycle metal fatigue, in which most of the strain is plastic strain, can be treated approximately with the Coffin-Manson relation:

$$N_f \propto \frac{1}{2}(\varepsilon_f/\Delta\varepsilon)^m$$

where N_f = number of cycles to failure
$\Delta\varepsilon$ = strain
ε_f = strain ductility factor, which correlates closely with tensile ductility
m = constant near 2

This relation significantly underestimates life for high cycle fatigue, which can occur after repeated thermal cycling in service. The strain $\Delta\varepsilon$ can be estimated by finite element modeling or analytically. If no other data are available, ε_f for electroplated Cu can be approximated as 0.3. The number of cycles to failure can be increased by increasing $\varepsilon_f/\Delta\varepsilon$, primarily by decreasing $\Delta\varepsilon$.

There are, however, issues with the use of the simplified Coffin-Manson relationship since real PTH behavior is confounded by a number factors[11] including (1) physical limitations such as

- Anisotropy of thermal expansion (x and y versus z)

- Lack of homogeneity between glass and resin layers (different CTEs)
- Microstructural features that have the same scale as the PTH structure itself (grain size = Cu thickness)
- Large variations in mechanical properties (i.e., ductility) from lot to lot and board to board (even in well-controlled conditions)
- Defect structures (i.e., glass fibers and Cu grain boundaries) interacting at geometric strain concentrations (barrel/pad junction)
- Cu dissolution in solder pot (or Pb-free HASL) repair processes
- The catastrophic nature of the failure

And (2) simplifying assumptions that do not meet reality including

- Steady-state temperature distribution
- Uniform metal thickness
- Room temperature properties of copper
- No strain rate effects on copper properties
- Perfect registration of hole to pattern

A semi-empirical relationship developed as part of IPC round-robin testing to better define key parameters affecting reliability of PTH under thermal cycling.[11] This and other models are discussed in the following sections.

60.4.2 Semi-empirical Relationship

A semi-empirical analytical relationship was proposed for low-cycle fatigue mechanisms under thermal cycling. Figure 60.19 shows this relationship and detailed parameters required to calculate the mean cycles to failure.

$$\overline{N}_f^{-0.6} D_f^{0.75} + 0.9 \frac{S_u}{E} \left[\frac{\exp(D_f)}{0.36} \right]^{0.1785 \log \frac{10^5}{N_f}} = \Delta\varepsilon_{max}(\text{eff})$$

Plastic Strain Low-Cycle Fatigue

Elastic Strain High-Cycle Fatigue

Effective Cyclic Strain Range

$\overline{N}_f$ = mean cycles to failure

D_f = fatigue ductility from IPC-TM-2.4.2.1

S_u = ultimate tensile strength

E = modulus of elasticity

$$\Delta\varepsilon_{avg} = \frac{(\alpha_E - \alpha_{Cu})\Delta T}{1+\gamma}, \quad \text{if } \sigma_{avg} \le S_y$$

where $\sigma_{avg} = \frac{(\alpha_E - \alpha_{Cu})\Delta T E_{Cu}}{1+\gamma}$ and $\gamma = \frac{E_{Cu} A_{Cu}}{E_E A_E}$

α_E, α_{Cu} = CTEs of epoxy, copper

S_y = yield strength of ED copper

E_{Cu}, E_E = modulus of elasticity of copper, epoxy

A_{Cu}, A_E = load-bearing area of copper, epoxy

$$A_{Cu} = \frac{\pi}{4}\left[d^2 - (d-2t)^2\right], \text{ load-bearing area of copper}$$

$$A_E = \frac{\pi}{4}\left[d_E^2 - d^2\right], \text{ load-bearing area of resin}$$

d = drilled hole diameter

t = thickness of barrel wall

d_E = diameter of area of influence of PWB (undefined)

h = thickness of PWB

$$\Delta\varepsilon_{avg} = \frac{(\alpha_E - \alpha_{Cu})\Delta T E'_{Cu} - \gamma' S_y (1 - E'_{Cu}/E_{Cu})}{(1+\gamma')E'_{Cu}}, \quad \text{if } \sigma_{avg} > S_y$$

where $\sigma_{avg} = \frac{(\alpha_E - \alpha_{Cu})\Delta T E'_{Cu} + S_y(1 - E'_{Cu}/E_{Cu})}{1+\gamma'}$

and $\gamma' = \frac{E'_{Cu} A_{Cu}}{E_E A_E}$

E'_{Cu} = modulus of plasticity of ED copper

FIGURE 60.19 Semi-empirical model for projection of cycles-to-failure for Cu PTH in PCB.[11]

Figure 60.20 shows the plot of this relationship showing the effective strain in percent versus the average number of thermal cycles. Assumptions made for the PTH properties are also shown. Figure 60.21 shows a similar plot, which also includes the range of cycle-to-failure and experimental test data from another source.[41]

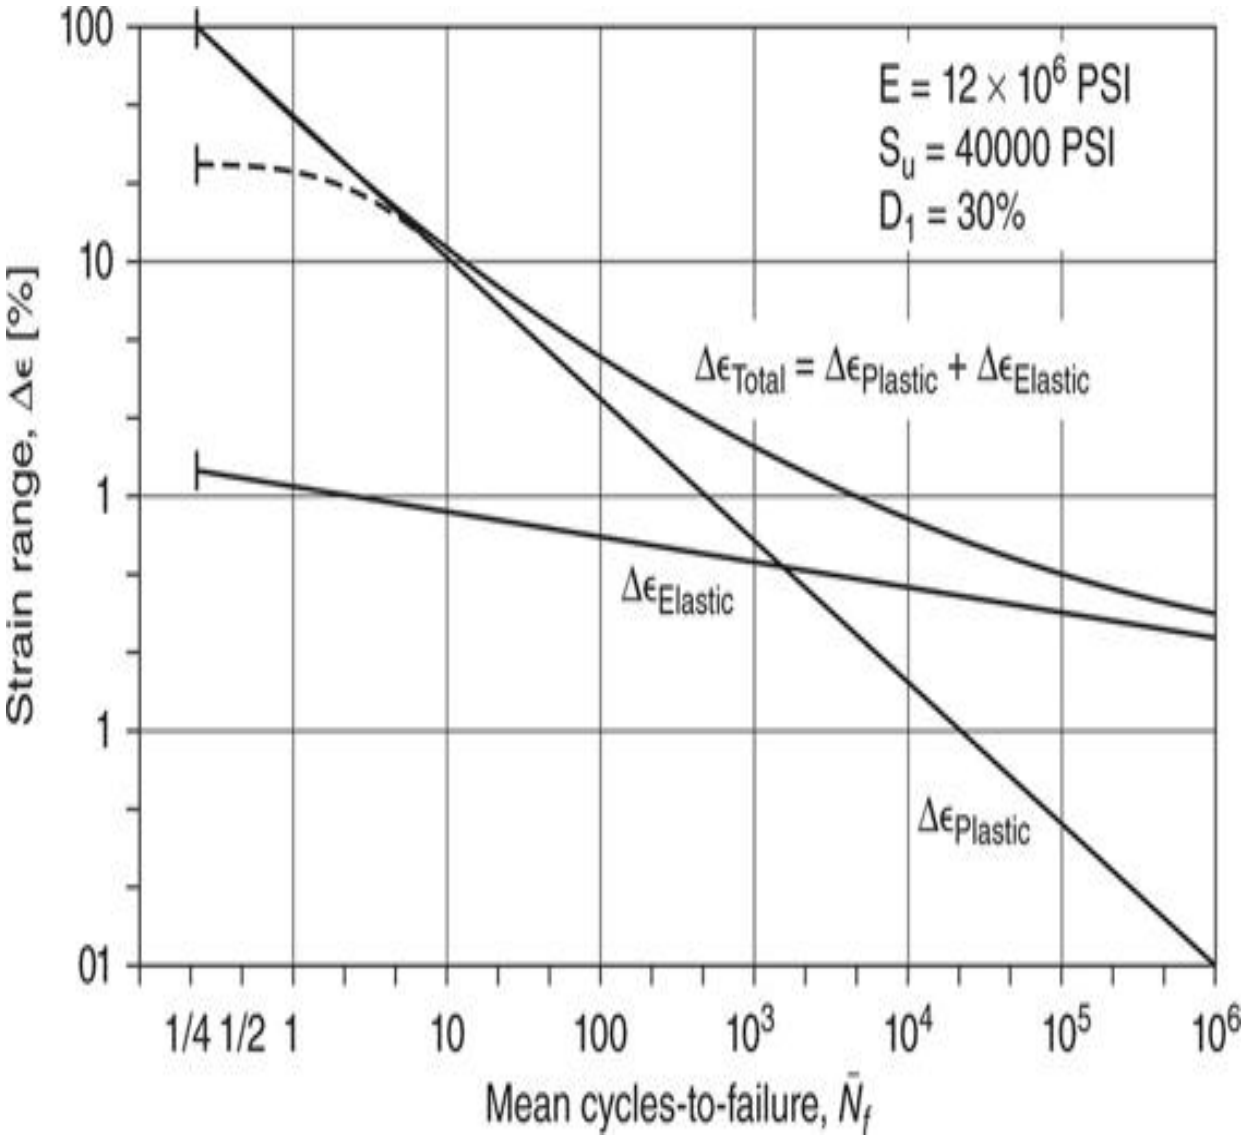

FIGURE 60.20 Semi-empirical relations (Coffin-Manson) strains versus fatigue life plot for electrodeposited copper.[11]

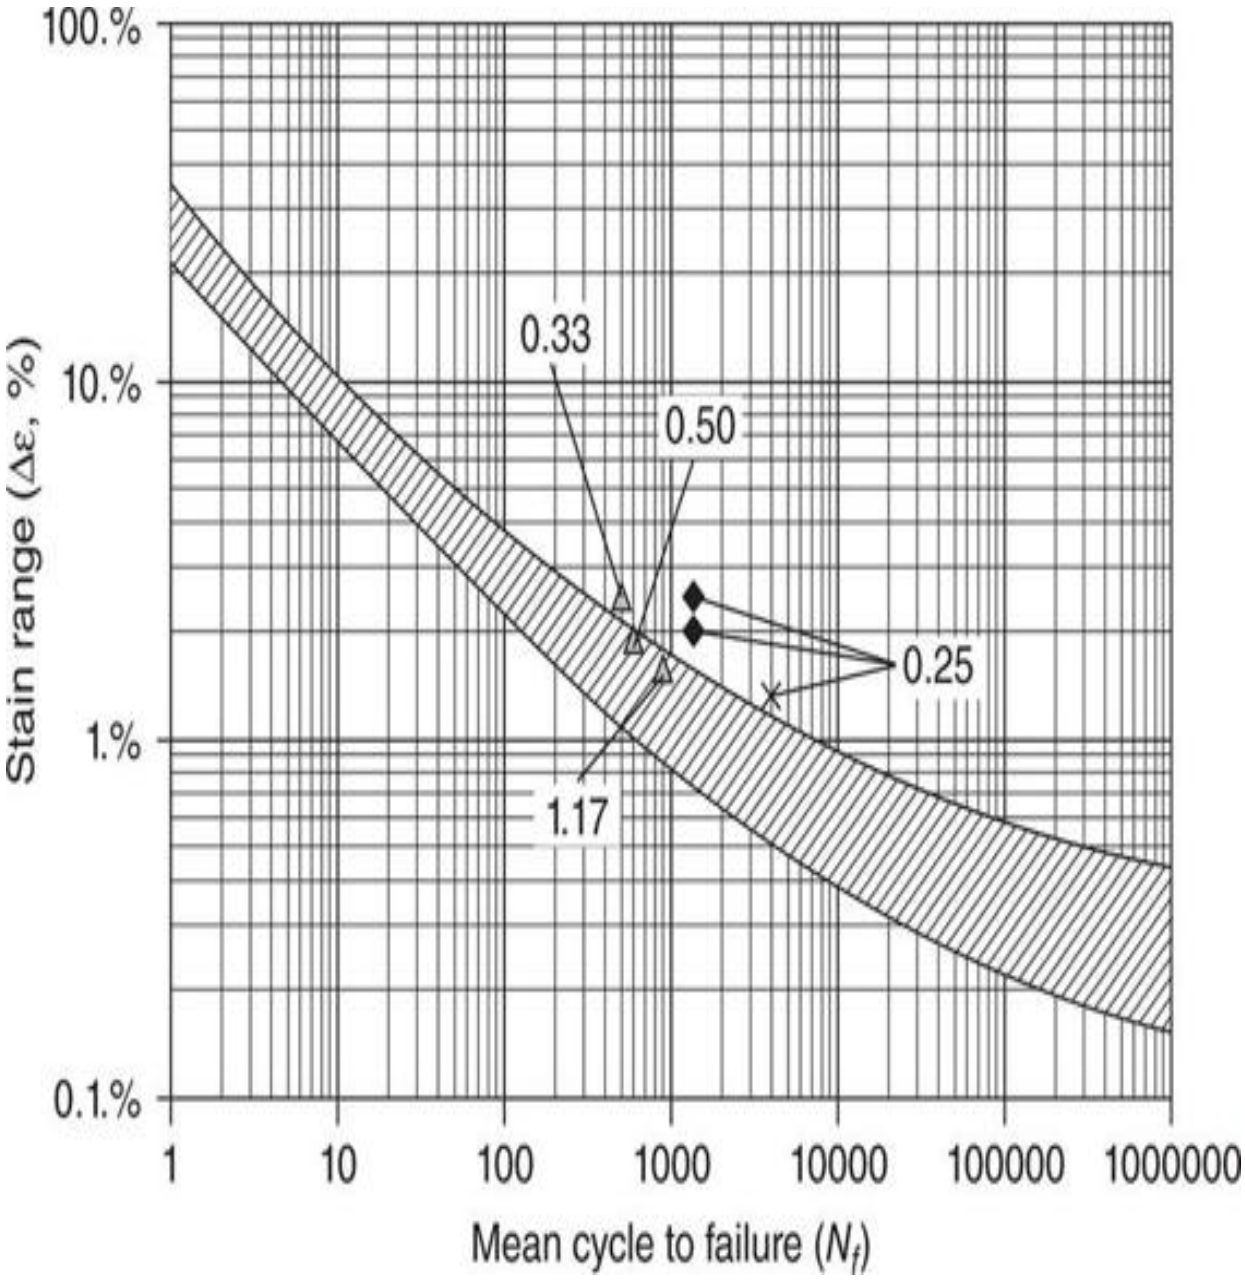

FIGURE 60.21 Shaded area is the life prediction from several copper fatigue models, triangles, diamonds, and one "X" are the experimental test data with strain ranges calculated by 3D the FE model.[41]

Life calculation for PTHs subjected to thermal cycling is a three-step process. The first step is to calculate the stress being experience by the Cu barrel of the PTH. Two simple formulas are assumed for calculation: (1) a linearly perfectly elastic behavior for below-yield strength, and (2) a linear

stress-strain relationship above the yield strength (see Fig. 60.22). It is further assumed that there are infinitely stiff outer lands and no inner lands. The PTH stresses are transferred to strains since strains are important to determining cyclic fatigue life to cyclic fatigue damage. The average cycles-to-failure, then, is calculated by iteratively solving the semi-empirical relationship.

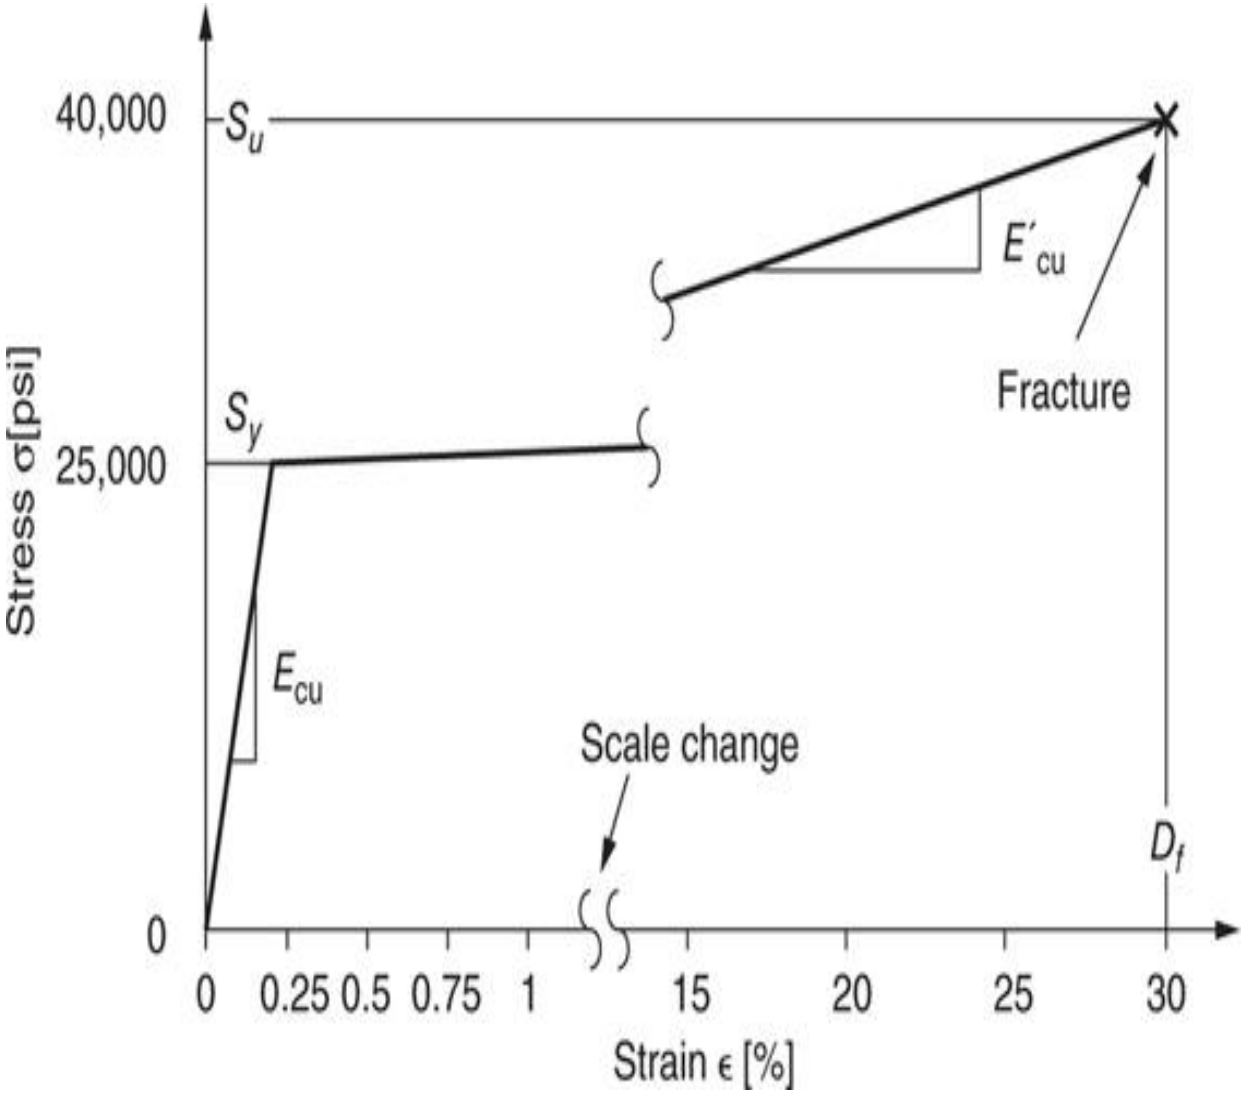

FIGURE 60.22 Linearized stress-strain diagram for electrodeposited copper (S_u = 40,000 psi, S_y = 25,000 psi, $E_{cu} = 12 \times 10^6$ psi, D_f = 30%).[11]

Round-robin test data indicated distribution cycles-to-failure due to severe strain concentration and PTH Cu nonuniformity properties. In addition, the assumption was made that properties are independent of temperature and time over the entire thermal cycle temperature range. In addition, the strains need to be adjusted by two other factors: a strain distribution factor, K_d and a PTH quality factor K_Q.

$$\Delta\varepsilon_{\text{eff}} = K_d\, \Delta\varepsilon\, (10/K_Q)$$

Table 60.3 lists cycles-to-failure test data from round robin[11] with predicted mean fatigue lives for various use environment using semi-empirical model for PTH. It includes CTF projections for marginal quality ($K_Q = 5$) and superior quality ($K_Q = 10$) of plated conditions.

TABLE 60.3 Predicted Mean Fatigue Lives for Marginal Quality ($K_Q = 5$) and Superior Quality ($K_Q = 10$) Plated-Through Hole Subjected to Ddifferent Tests/Cycles Environment[11]

* $S_u = 40{,}000$ psi, $D_f = 30\%$, $E_{cu} = 12 \times 10^6$ psi, $K_f = 2.5$

In summary, the designer and the PCB manufacturer have the following controls over the reliability of PTHs.

- Out-of-plane CTE of the printed board

- Plating thickness
- Aspect ratio (hole diameter over board thickness)
- Plating material properties (strength and ductility) and plating quality

One limitation of the semi-empirical model[42] is its dependence upon the quality of the PTH (i.e., the presence of defects such as voids, cracks, folds, etc.) whereas the strain distribution factor tends to be set to a value of 1.6. The quality factor, K_Q, can range from 0 to 10 with the following delineations

- Extraordinary (K_Q = 10)
- Superior (K_Q = 8.7)
- Good (K_Q = 6.7)
- Marginal (K_Q = 4.8)
- Poor (K_Q = 3.5)

For validation of a software that was developed for analytical PTH reliability prediction,[42] a quality factor was used to capture the sensitivity of the PTH to the quality of Cu plating. Quality factors were identified by two approaches: (1) by assuming a conservative quality factor, either good (K_Q = 6.7) or marginal (K_Q = 4.8) and (2) by calculating the quality factor from the IST or HATS test results.

The two-parameter Weibull probability distribution was used to describe the failure behavior of the PTHs. The Weibull distribution is generally accepted as a good distribution for reflecting low cycle fatigue behavior of ductile metals. Two key parameters in distribution are the characteristic life and the shape factor (slope). The slope typically describes the quality and the higher the slope the closer the time to failures are.

As stated, the PTH reliability prediction depends on a quality factor that may not be known in the design state. The quality factors were derived from published test data (see Table 60.4) to provide guidance on values that should be selected during design evaluation.[42]

Barker and Dasgupta[43] performed modeling studies to determine critical stresses in PTH and to determine qualitatively the effect of several geometric parameters. The parameters investigated included PTH spacing, inner-planes, nonfunctional internal pads, aspect ratio, plating thickness, solder filling with and without voids, and transient thermal

stresses due to the wave soldering process. The model was an idealization ignoring manufacturing flaws, such as plating thickness, variations, presence of stress concentrations, and interfacial delamination. The findings are summarized in the following:

- Decreasing PTH spacing improves mechanical reliability.
- Decreasing aspect ratio (thickness/radius) either by decreasing PCB thickness or by increasing PTH diameter is beneficial, with PCB thickness having a more pronounce effect.
- For FR-4 PCB materials, the effect of solid inner-planes, nonfunctional internal pads, and functional signal layers resulted in local stress relief in the vicinity of inner-planes/pads/layers. However, local stress increased for Kevlar-polyimide PCB materials.
- Solder filling with and without some voids did not significantly affect the critical PTH barrel stresses; which were also found to be independent of the PCB material.
- The PTH exposed to a wave soldering showed two opposing effects on the life of the PTH. The transient thermal stress consumed 33 percent of life whereas improved 25 percent of life due to compressive stresses upon cooling.

In another approach, the authors presented a simplified PTH analytical model to project the effect of various parameters, including influence of CTE and PTH, on cycles to failure (see Fig. 60.23).[44] In addition, the author performed experimental tests using IST coupon and subjection to thermal cycling in the range of RT to 150°C to determine the effect of PCB materials properties, surface finish, and drill diameter (see Table 60.5). As expected, material A with a lower T_g and a higher CTE showed the lowest CTF (~370 cycles) whereas material C with the lowest CTE and a lower

T_g showed the highest CTF (~2900 cycles). On the effect of PTH surface finish, the material with the highest Young's modulus and the lowest CTE (ENIG) yielded the highest CTF even though the thickness of ENIG was slightly lower than HASL. The test result on the effect of PTH surface finish is shown in Fig. 60.24.

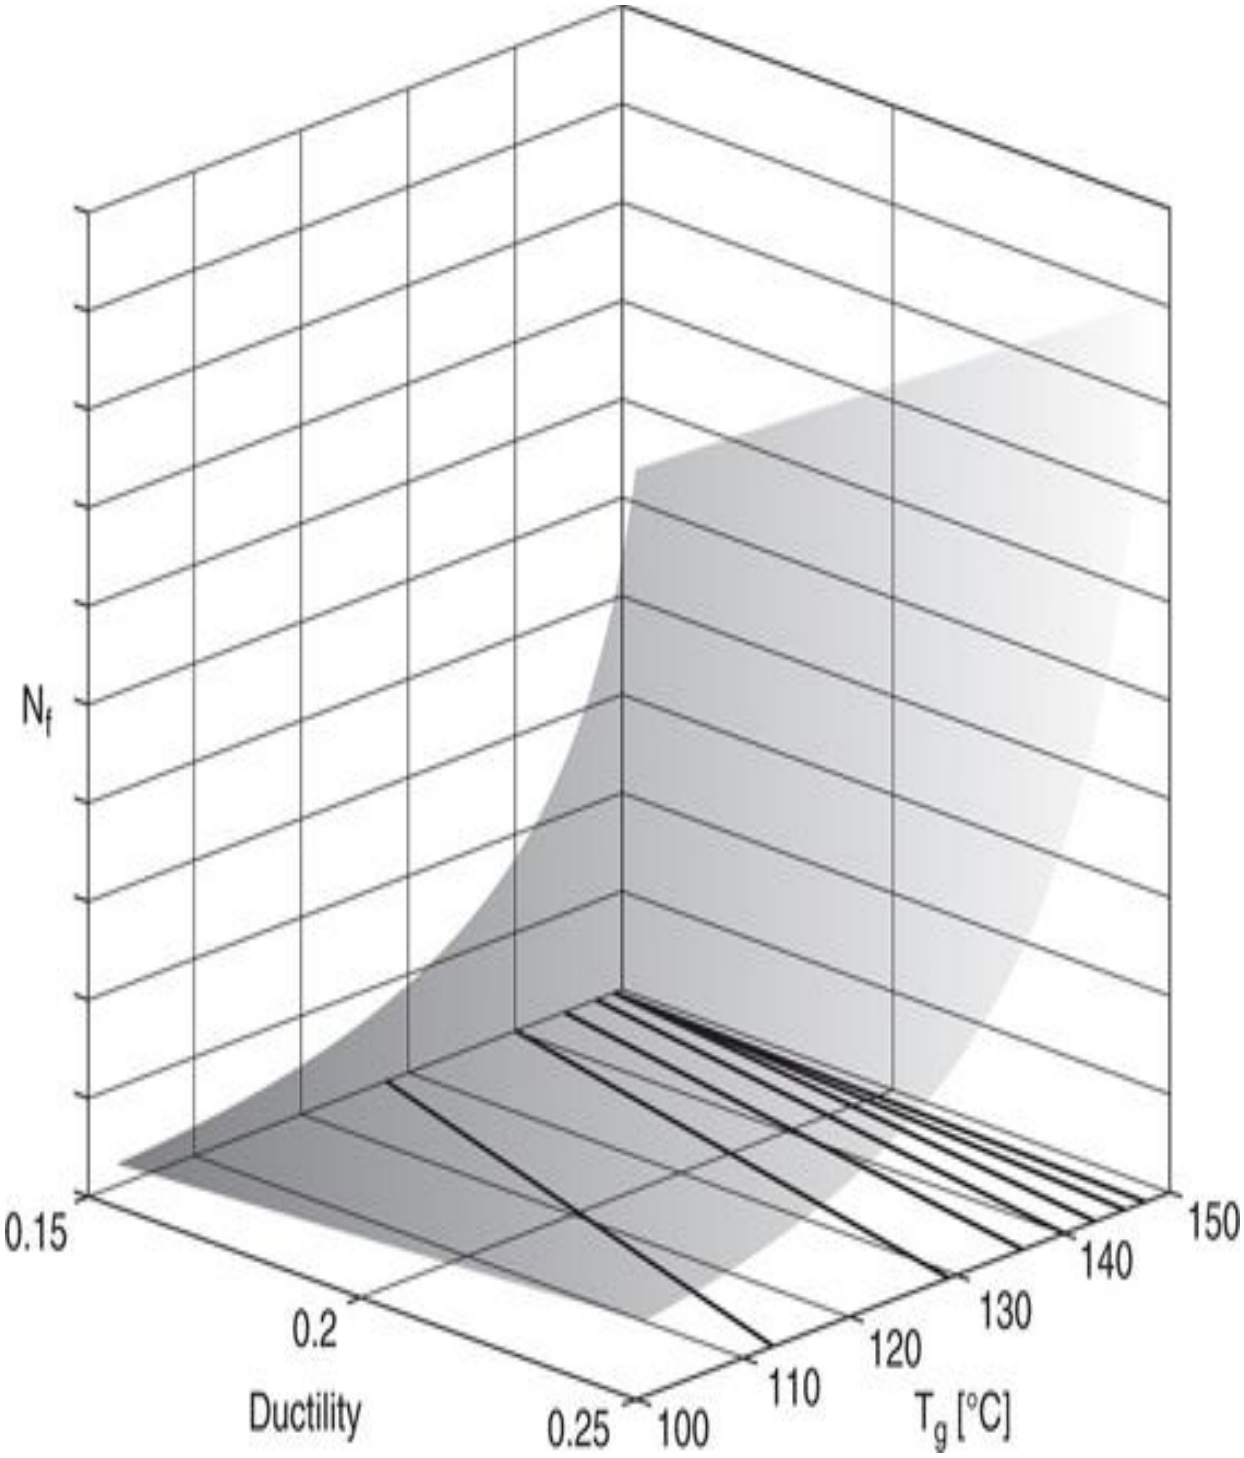

FIGURE 60.23 Projected Cu PTH cycles-to-failures versus Cu ductility and PCB glass transition (T_g) in the *z* direction.[44]

TABLE 60.5 Cycles-to-Failure from IST Coupon (RT/150ªC) and the Effects of (1) Z-CTE (α_{epoxy}), (2) Surface Finish, and (3) Effect of Ddrill Size[44]

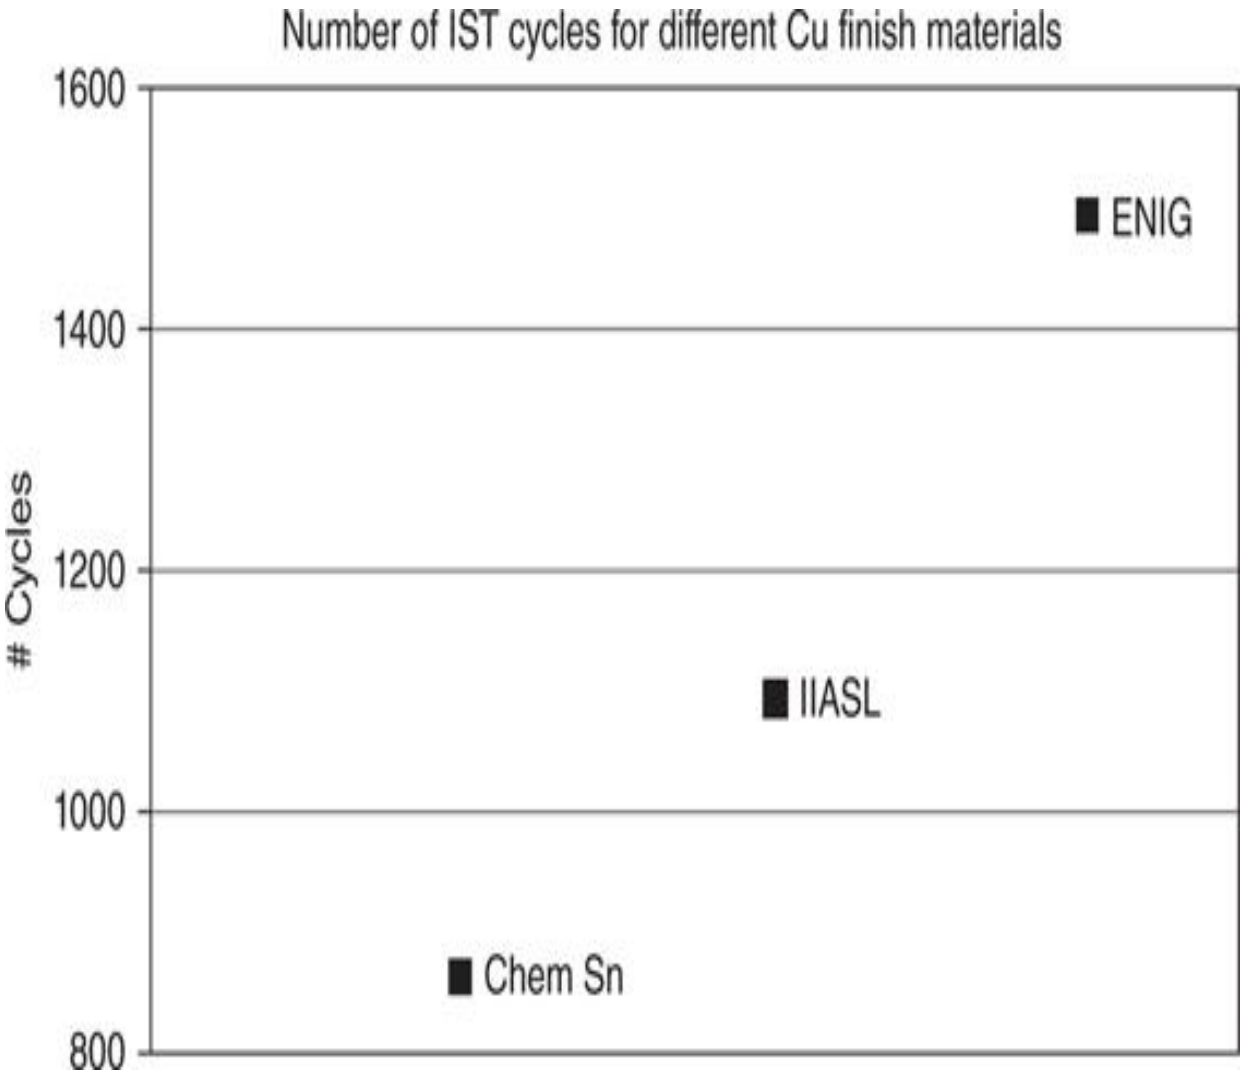

FIGURE 60.24 Effect of surface finish on cycles-to-failure.[44]

Goyal et al. performed both experimental and FEA analyses to determine the effect of various design and manufacturing parameters on reliability of high density PTH PCBs with and without solder fill.[45] The PTHs were subjected to 1000 thermal cycles in the range of −55 to 125°C (condition B) and −65 to 150°C (condition C). No failure of PTHs with solder fill via to 1000 cycles; however, the no-fill PTHs showed failures at various cycles that increased with increase in thermal cycling. The cumulative failures under condition B at 100, 200, 500, and 1000 cycles were 1, 3, 24, and 59 percent, respectively. The cumulative rates of failures

were higher under condition C and at 200, 500, and 1000 cycles were 10, 82, and 100 percent, respectively. Failures were due to PTH barrel necking and cracking with classical cup and cone features indicating ductile fracture of the plating. The fracture was found to occur near the center of the PCB thickness. The entire circumference showed cracking that initiated from the inside edge of the plating and propagated into the PCB material. The cracking of the PTH plating was also initiated from the regions of defects such as voids in the plating and/or at the plating to the PCB interface. The FEA analytical modeling showed the following key findings:

- The CTE mismatch (mainly along *z* direction) between Cu and organic laminate was the cause of excessive stress in the PTH barrel. The higher the CTE in the laminate structure, the larger the thermal fatigue damage at the barrel. Also, it was found that an increase in PCB thickness by 20 percent resulted in increases of 8 to 30 percent to the Cu layer stress.
- The increase in Cu plating thickness from 12 to 38 µm (0.5 to 1.5 mil) reduced its thermal stress by 25 to 70 percent while an increase in Ni plating thickness from 2.5 to 15 µm (0.1 to 0.6 mil) resulted in lowering the Cu plating layer stress by 30 to 70 percent. It was found that increasing the Ni plating thickness had a larger effect than increasing the Cu plating thickness in lowering Cu plating thermal stress. Also the results suggested use of a Cu layer with higher ductility and lower yield strength to minimize the PTH barrel fatigue damage generated in T/C stress.
- The use of solder-filled vias should reduce the thermal fatigue stress of the PTH barrel plate by 20 to 70 percent, depending on the plating material properties and the PCB layup. Different filling materials have varying impact on via thermal fatigue performance. However, the one with a

CTE value close to that of Cu would provide the most improvement in the reliability of the PTH.

In a more recent publication,[46] FEA simulation results calculated for total strains (elastic plastic strains) were compared to those presented by the IPC's semi-empirical model. A better correlation was found when failure was based on 20 percent changes in the daisy-chain resistance of vias. The FEA numerical results for the PCB/PTH specimen for the thermal cycle range of −30/150°C shown in Fig. 60.25*a* shows that the maximum von Mises stress occurs at the middle part of PTH during thermal cycle, it was 229.0 MPa at 150°C and 232.7 MPa at −30°C. The maximum residual strain at the center was 9613 μm (378 mil). The relevant simulation results are shown in Fig. 60.25*b*.

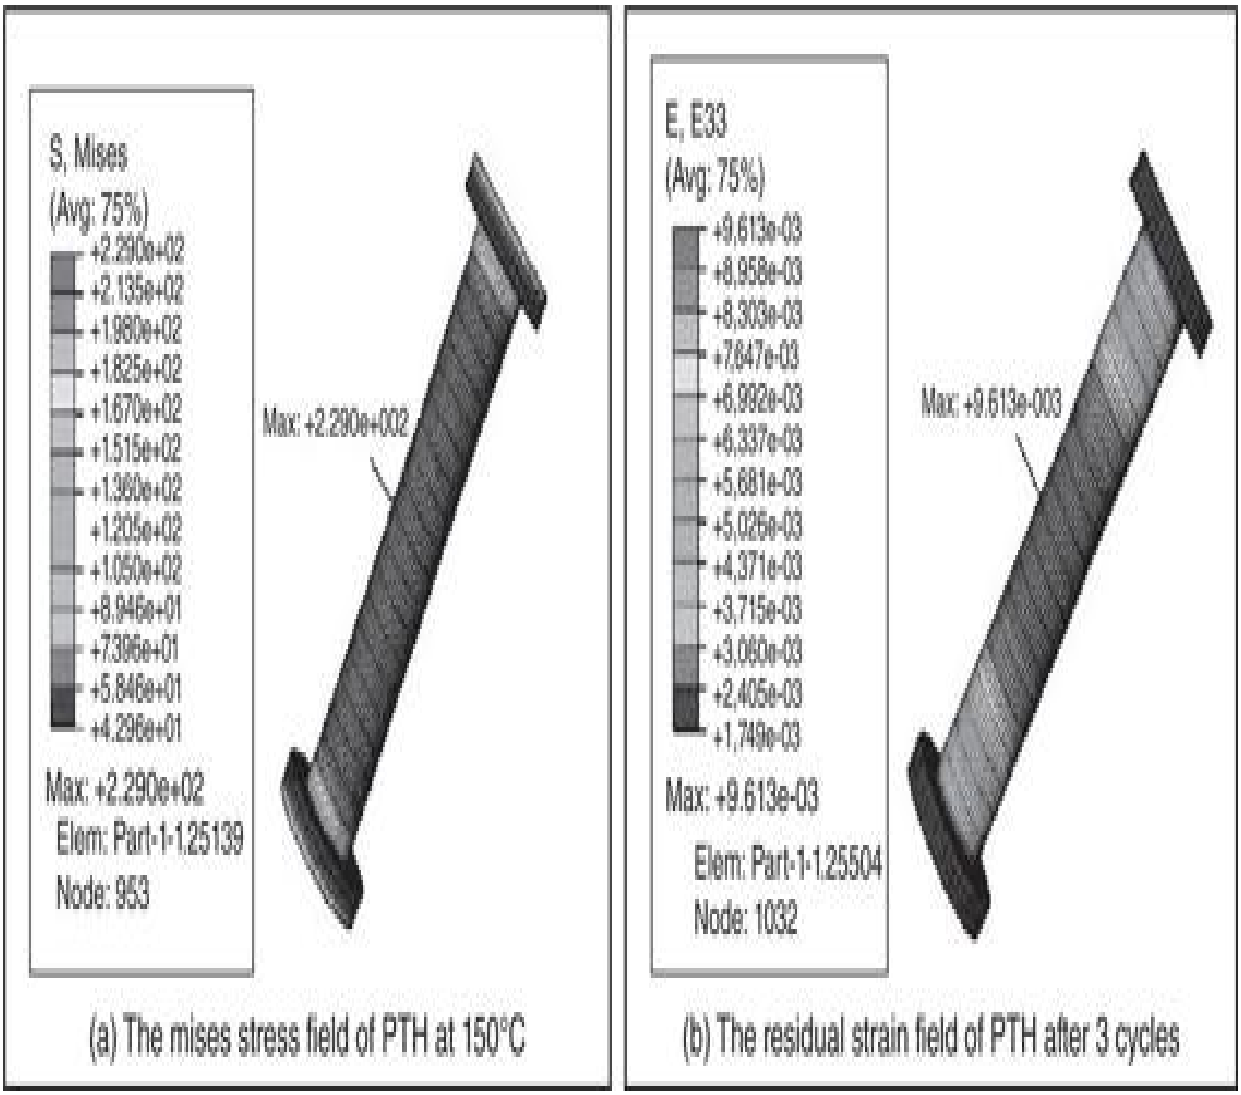

FIGURE 60.25 Finite element simulation of PTH for thermal cycle range of −30/150°C: (*a*) the maximum Von Mises stress is in the PTH center with 229.0 MPa at 150°C and (*b*) the maximum residual strain, 9613 μe.[46]

FEA with experimental thermal cycle (−65/125°C) tests were carried out to determine the key factors affecting the PTH thermal cycle reliability of rigid-flex printed circuit (RFPC), a laminate with mix of rigid and flexible substrates.[47] Both FEA and failures of RFPC test coupons revealed that the maximum barrel strain was not located at the center of PTH, but depended on the properties of bonding material, plating thickness, drill hole size, and board thickness. The use of

acrylic adhesive with a lower T_g resulted in a larger strain than the epoxy polyimide adhesives (see Fig. 60.26).

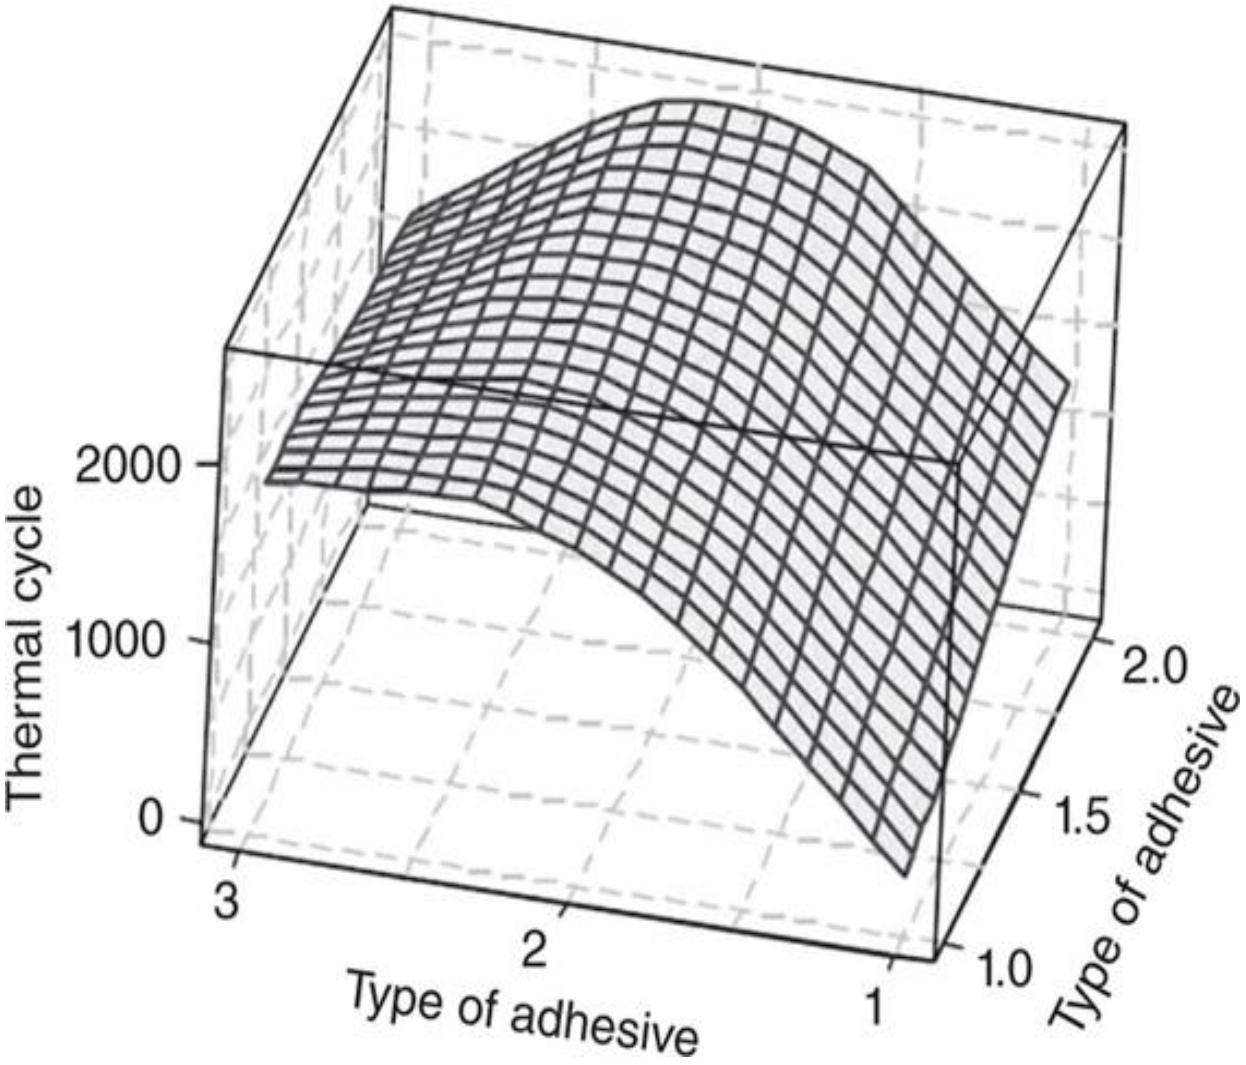

FIGURE 60.26 D surface plot of thermal cycle versus type of adhesive and plating thickness.

60.4.3 Inverse Power Law Relationship

Freda and Barker used the inverse power law (IPL) relationship for projection of PTH reliability under thermal cycling.[48] It was stated that IPL is widely used for nonferrous

metals such as Cu. Models such as those of Arrhenius or Eyring are not appropriate for the PTH since they deal with failure modes that are thermally induced. The authors applied the IPL relationship to project life or correspondent stress versus temperature cycles-to-failure.

The equation for the IPL relationship, after a logarithmic transformation, follows a conventional linear line. The relationship and log/log scale are

$$L(V) = 1/KV^{n}$$

$$\mathrm{Log}_{10}\, L(V) = -n \log_{10} V - \log_{10} K$$

where L = a quantifiable life measure; for this paper both mean life and T_1% percent life are used

V = the stress level

K = one of the model parameters to be determined, $K > 0$

n = another model parameter to be determined

To generate the IPL relationship, Freda and Barker[48] used the IST test coupons[16] to determine the effect of maximum temperature (RT is always starting temperature) on the PTH failure and changes in failure mechanisms. Four temperatures above T_g were chosen: 215, 235, 255, and 275°C. The rationale for the two extreme temperature were that the 215°C is about the lowest temperature that is still above the T_g, the CTE transition zone associated with a significant changes in laminate material properties. The rational for the 275°C exposure was to determine if there were changes in via failure modes at temperatures above the expected maximum Sn/Ag/Cu lead-free soldering temperature zone. Indeed, the IST coupons tested at 275°C did result in POST interconnect failures, two out of 12 coupons. POST interconnect defined as holes drilled at 0.85 mm (33.5 mil) diameter; a 3.3:1 aspect ratio, with daisy

chain connecting holes between 2nd and 3rd layers and between 25th and 24th layers. With the exception of these two coupons, the remaining 46 coupons from test above T_g were all PTH failures.

Figure 60.27 presents the raw data for the 48 IST test coupon failures characterized by Freda and Barker showing variations, especially below and above the T_g. An inflection point (or discontinuity) was assumed at the laminate T_g transition zone with data below T_g and data above T_g following a different trend line. However, selection of an inflection point can have a significant effect on the cycle-to-failure estimates at a 95°C field life temperature. The plot also includes the precondition data; it seems that the 10× precondition samples have a life close to 6× or if slightly longer. The authors were unable to provide an explanation for the life reversal with preconditioning; they stated that “a combination of a relatively small sample size and random chance may be a contributor.”

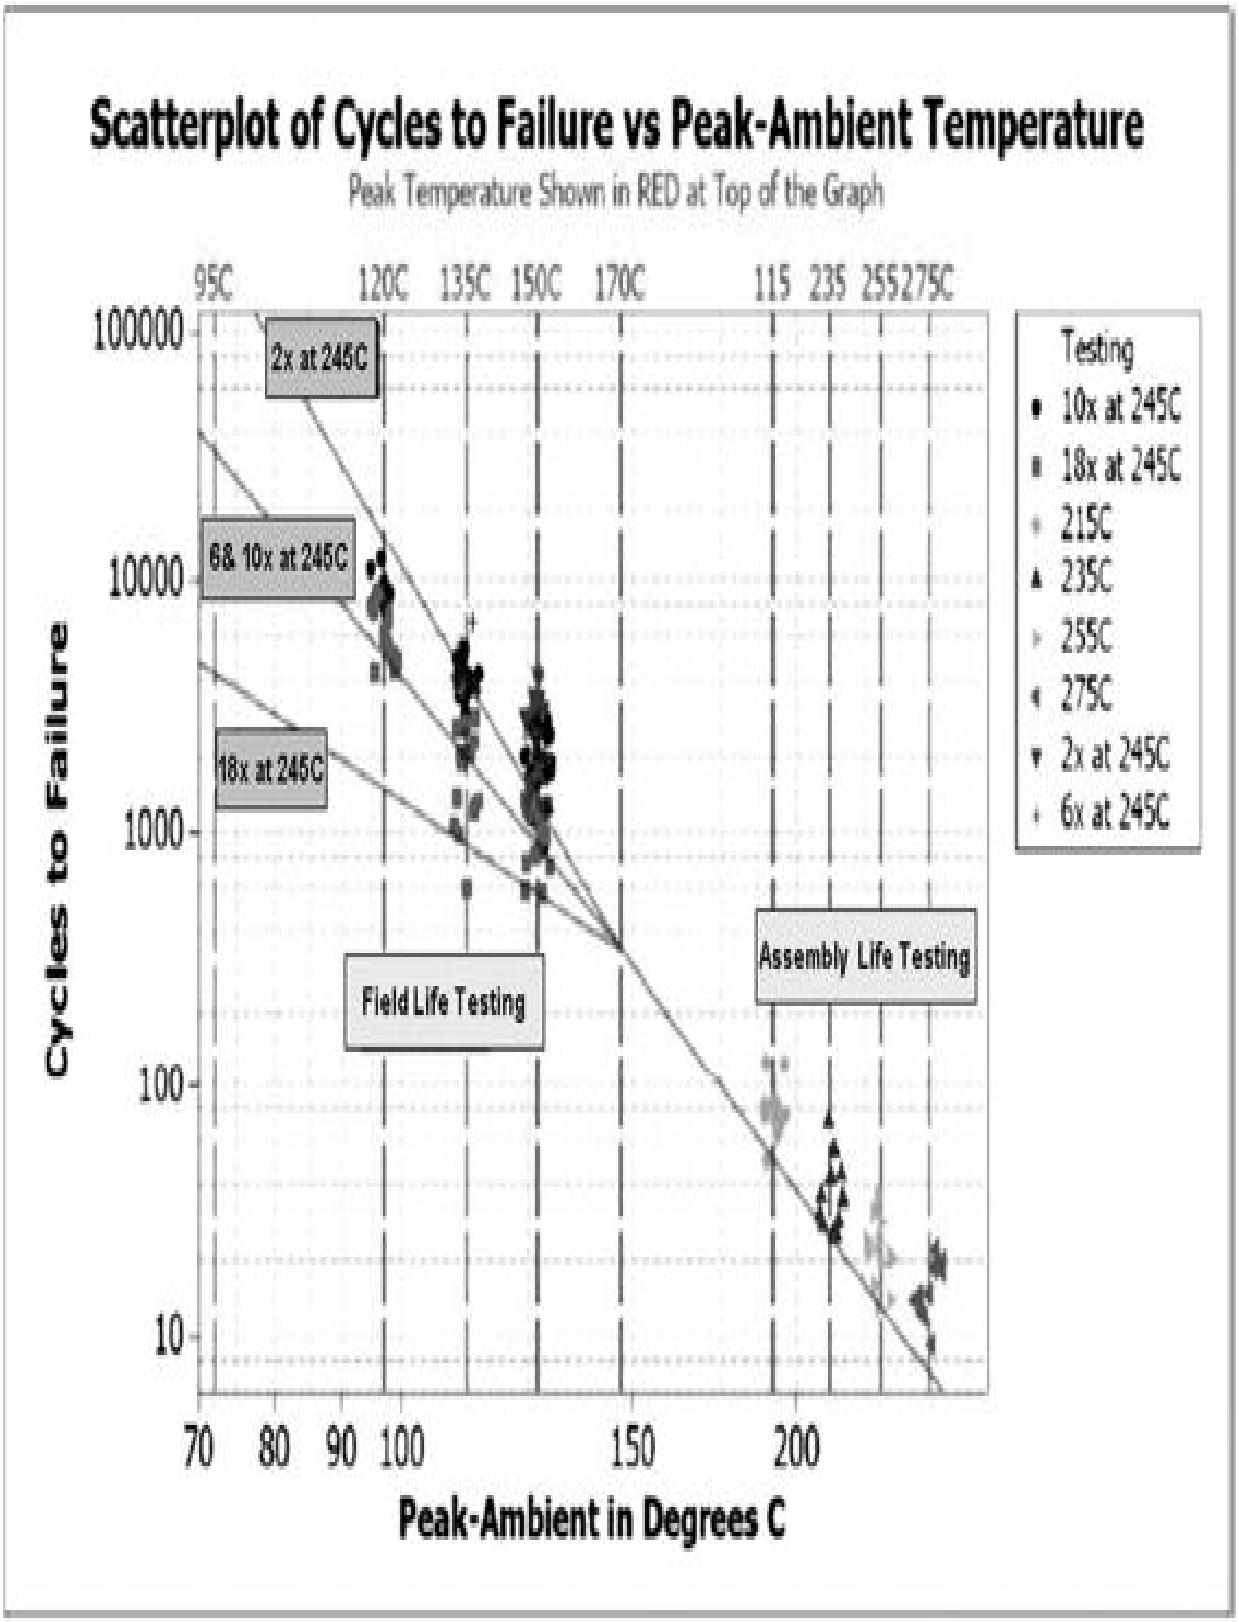

FIGURE 60.27 Log-log plot of all cycle to failure data versus temperature.[48]

Freda and Barker[48] also used Minor's rule to determine the average cycles-to-failure at temperature below T_g using CTFs for testing at 245°C and those at 120, 135, and 150°C with the same preconditioning. This allowed determination of the acceleration factor at each temperature relative to test data at 245°C. Monte Carlo simulation was used to determine failure variations from the average values. TMA and DMA testing methods were inventively used to address the large change in laminate material properties below and above T_g by generating the plot of temperature versus stress. TMA showed CTE increases from 28.9 ppm/°C below T_g to 128.7 ppm/°C above T_g; a 4.45 times increase. DMA showed a decrease in storage modulus) from 18,000 MPa below T_g to 2500 MPa above T_g, a 7.2 times decrease. Figure 60.28 shows log-log plot of scatter cycles-to-failure versus stress derived from the DMA stress/temperature relationship. These plots are now similar to classic S-N plots. The highest cycles-to-failure estimates of any of the analysis methods were listed, and it was shown that even with excessive preconditioning of 18× (> 2.5× is allowed on actual product with eutectic solder) at 245°C, the worst case estimate of cycles to failure is 3500 cycles, equivalent to >9 years in the field at one thermal cycle/day.

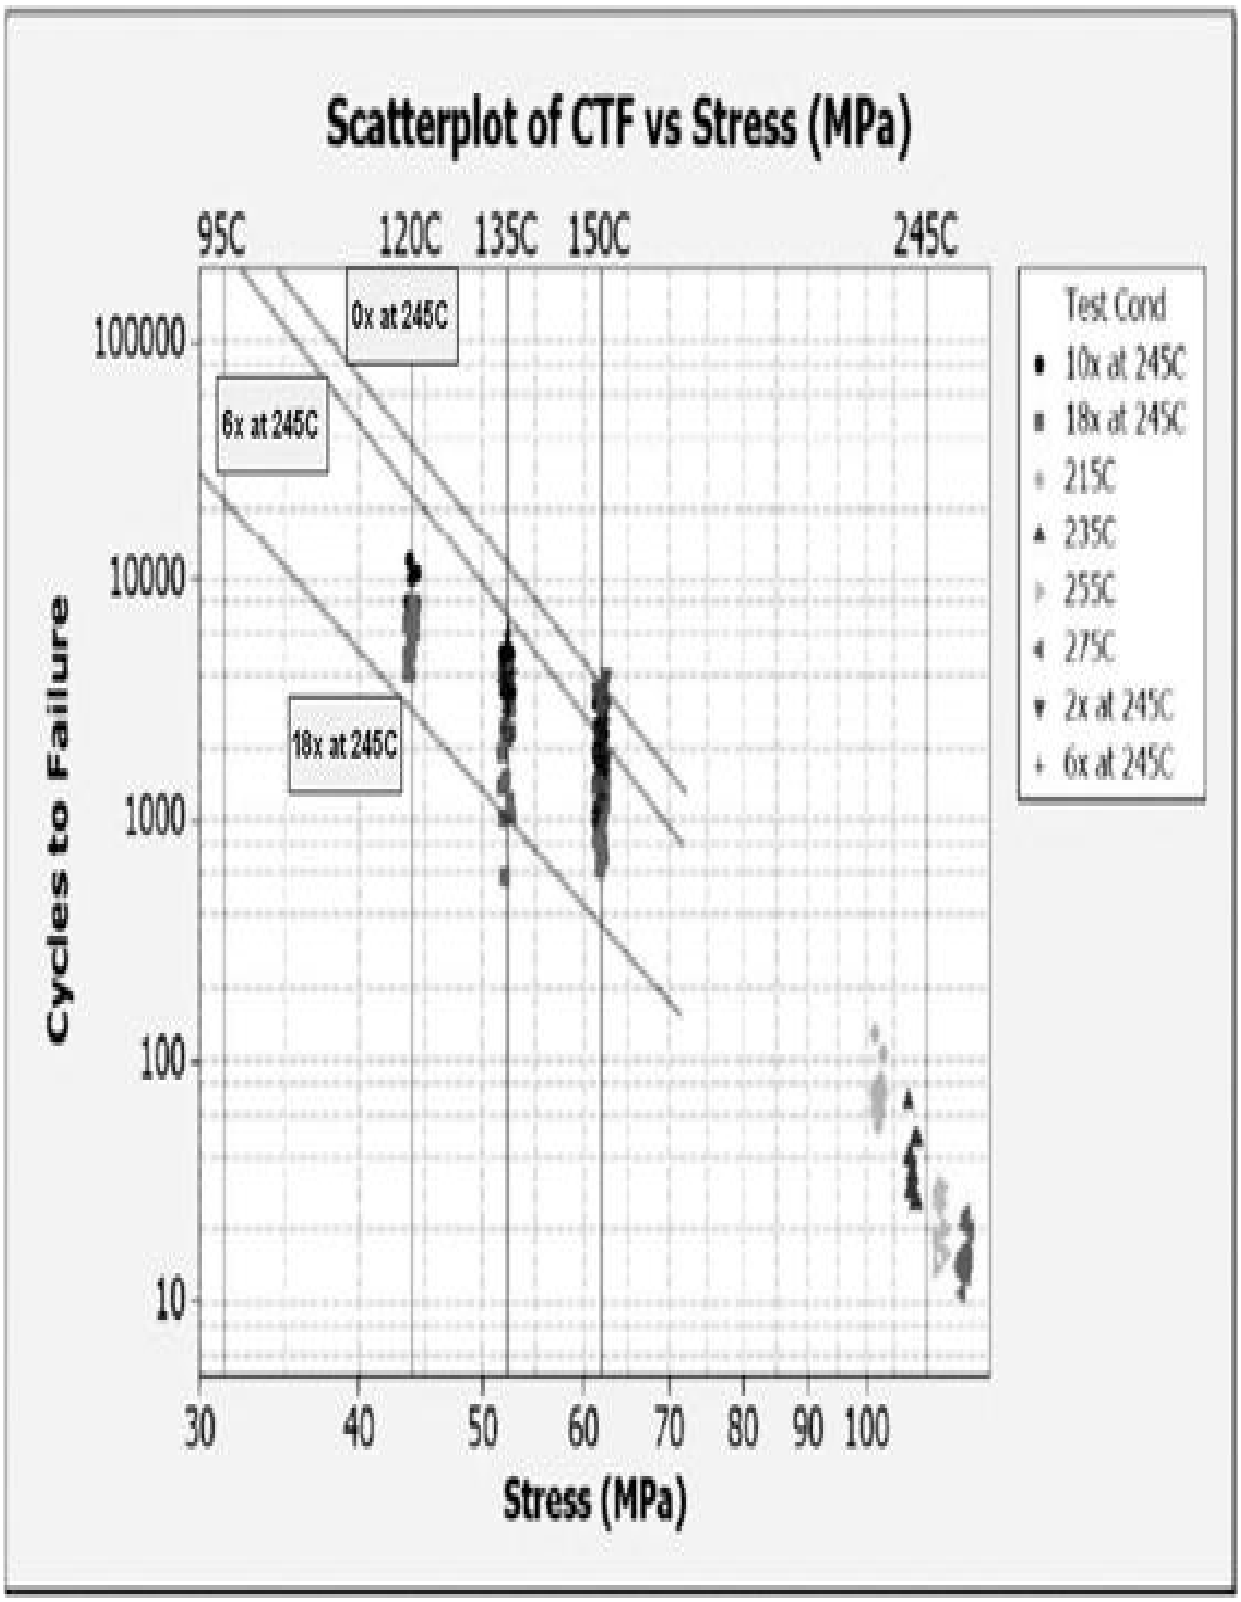

FIGURE 60.28 Cycle to failure versus stress scatter plot of all the raw data. The three parallel lines of cycles to failure versus stress were based upon Miner's

rule.[48]

A number of key findings:

- Material properties alone was inadequate to ensure high quality and reliably finished PCBs. Testing and evaluation of multilayer product was required. Internal damage was not detectable by surface visual inspection.
- The through-hole via pitch had a major impact on material survivability in Pb-free assembly with the tighter 0.8-mm (32-mil) pitch considerably more susceptible to damage compared to the 1-mm pitch.
- In the majority of cases, the 6× thermal shock at the 288°C test condition was more severe than the 6× reflow cycles at 260°C. Considering the complexity of the product (20 layers, 2.92-mm (0.115-in) thick, 11.5:1 aspect ratio) it is accepted that the requirement for six solder float thermal excursions is a very challenging. Hole wall separation was caused much more often after 6× reflow at 260°C than after 6× thermal shock at 288°C. This is believed to be a function of the longer time at temperature associated with the reflow oven compared to the very short duration of the thermal stress test.
- Hole wall separation was noted more often in the CAF sections compared to the 1-mm and 0.8-mm (40-mil and 32-mil) pitch IST and air-to-air (AtA) test vehicles.
- In both AtA and IST thermal cycling, while plating partially affected reliability, the *z*-axis CTE was the key contributor. Materials with lower CTE-Z below T_g (α1) provided the highest plated-through-hole reliability. Lower resin content constructions, which also have lower *z*-axis coefficients of thermal expansion, lasted considerably longer in thermal cycling without failure compared to the same materials used in the higher resin content constructions.

- When the material T_g, specifically as measured by DMA storage modulus, was below the testing temperature of both IST and ATC, then IST and ATC correlated very closely, and IST could be used to as an alternative to AtA thermal cycling for field life predictions.
- Supplier advertised data on *z*-axis CTE below T_g (α1) did not correlate with measured data on actual multilayer constructions, and hence, cannot be considered valid.

Park et al. also used an IPL relationship to determine relationship between cycles-to-failure and ΔT.[49] PCB test coupons with PTHs were subjected to two thermal cycle conditions in the range of -35/125°C and -55/125°C. The authors confirmed that the failure mode of PTH is copper barrel crack. From the Weibull plots of CTFs, the B10 (bearing at 10 percent, cycle-to-failure at 10 percent) values were estimated to be 606 cycles for Δ*T* of 180°C and 1065 cycles for delta of 160°C. Based on the IPL projection, it was shown that the acceleration factor was 49 and 28 relative to the field with a Δ*T* of 80°C (−40 to 40°C).

60.4.4 Corner Cracking Failure and Reliability

A majority of failures reported by industry indicate PTH failures at the center of barrel, but finite element analysis shows that the largest stresses occur not only at the center, but also at the shoulder of PTH as well as at the surface pad (see Fig. 60.29). Fehrer and Haddick reported corner cracking in FR-4 PCB when subjected to an extreme temperature cycling, immersion in hot oil at 240°C followed by cooling to room temperature by forced air.[35] The exposure was stated to be representative of solder and repair processes (tin-lead), particularly for high-pin-count through-hole devices. Both FR-

4 PCBs and cyanate ester PCBs were used. The average number of cycles-to-failure was 10 for FR-4 PCBs and 50 for cyanate ester PCBs. The primary failure mechanism was corner cracking in FR-4 PCBs and a combination of corner cracking and barrel cracking in the cyanate ester materials.

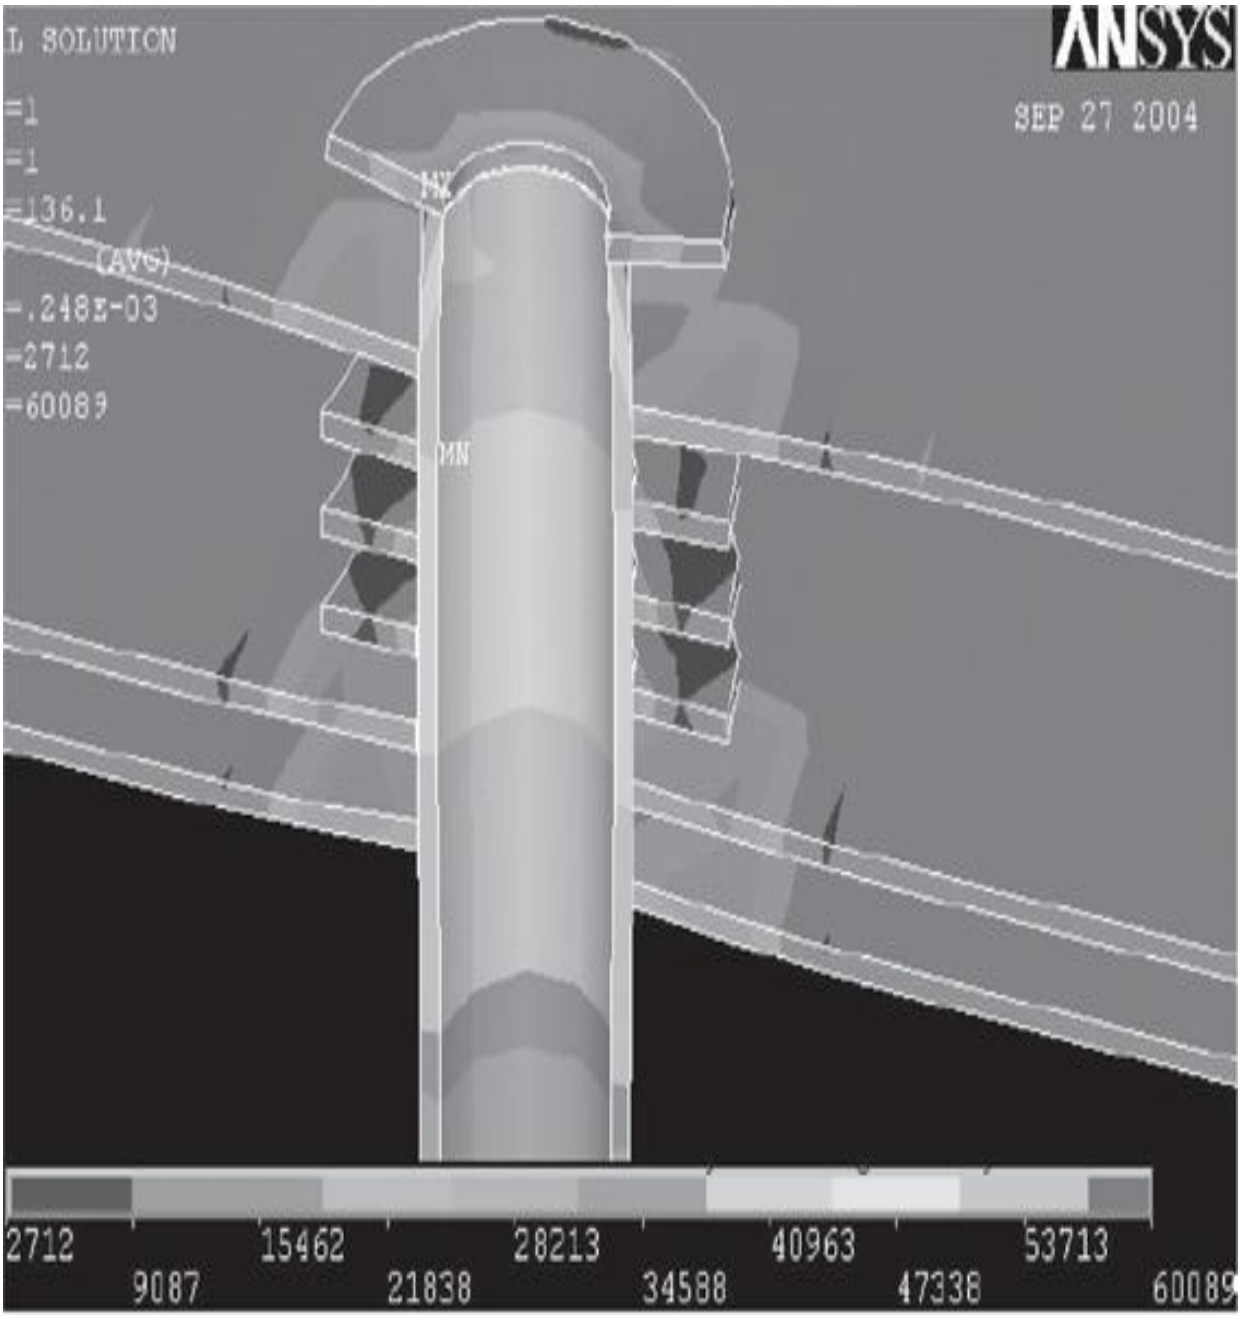

FIGURE 60.29 Finite element modeling of Cu PTH showing location of high stresses at the corner of surface pad and at the center of the PTH barrel.

The modeling, using modified pad tilt geometry in combination with the Coffin-Manson relationship, also projected low-cycle fatigue failures. For the pad tilt case, strain was assumed to be the same as the maximum strain acting at the support end of a cantilever beam, and this is shown in the following:

$$\varepsilon_f = Mc/EI = PL\ c/EI = 3EI\ \text{del}\ Lc/L^3\ EI = 3\ \text{del}\ L\ c/L^2$$

where ε_f = strain ductility
S = stress
E = Young's modulus
I = moment of inertia
C = distance from neutral axis
b = pad thickness
M = moment
L = pad annular ring
P = load
del = deflection

Now: c = pad thickness/2 = b/2, and del = free expansion of laminate = t CTE T = td, where t is half of the board thickness and d = thermal expansion of the laminate, substituting for c and del in equation, the strain in the pad-to-barrel joint:

$$\varepsilon_f = 3\ drb/(2L^2)$$

Misalignment of drilled-hole location to etched pattern should be taken into account. Therefore, in the graph of strain versus pad annular ring (Fig. 60.30), the dimensions will be representative of "minimum remaining annular ring." For reference, calculated barrel strain versus pad annular ring for an FR-4 PCB is also plotted in the figure.

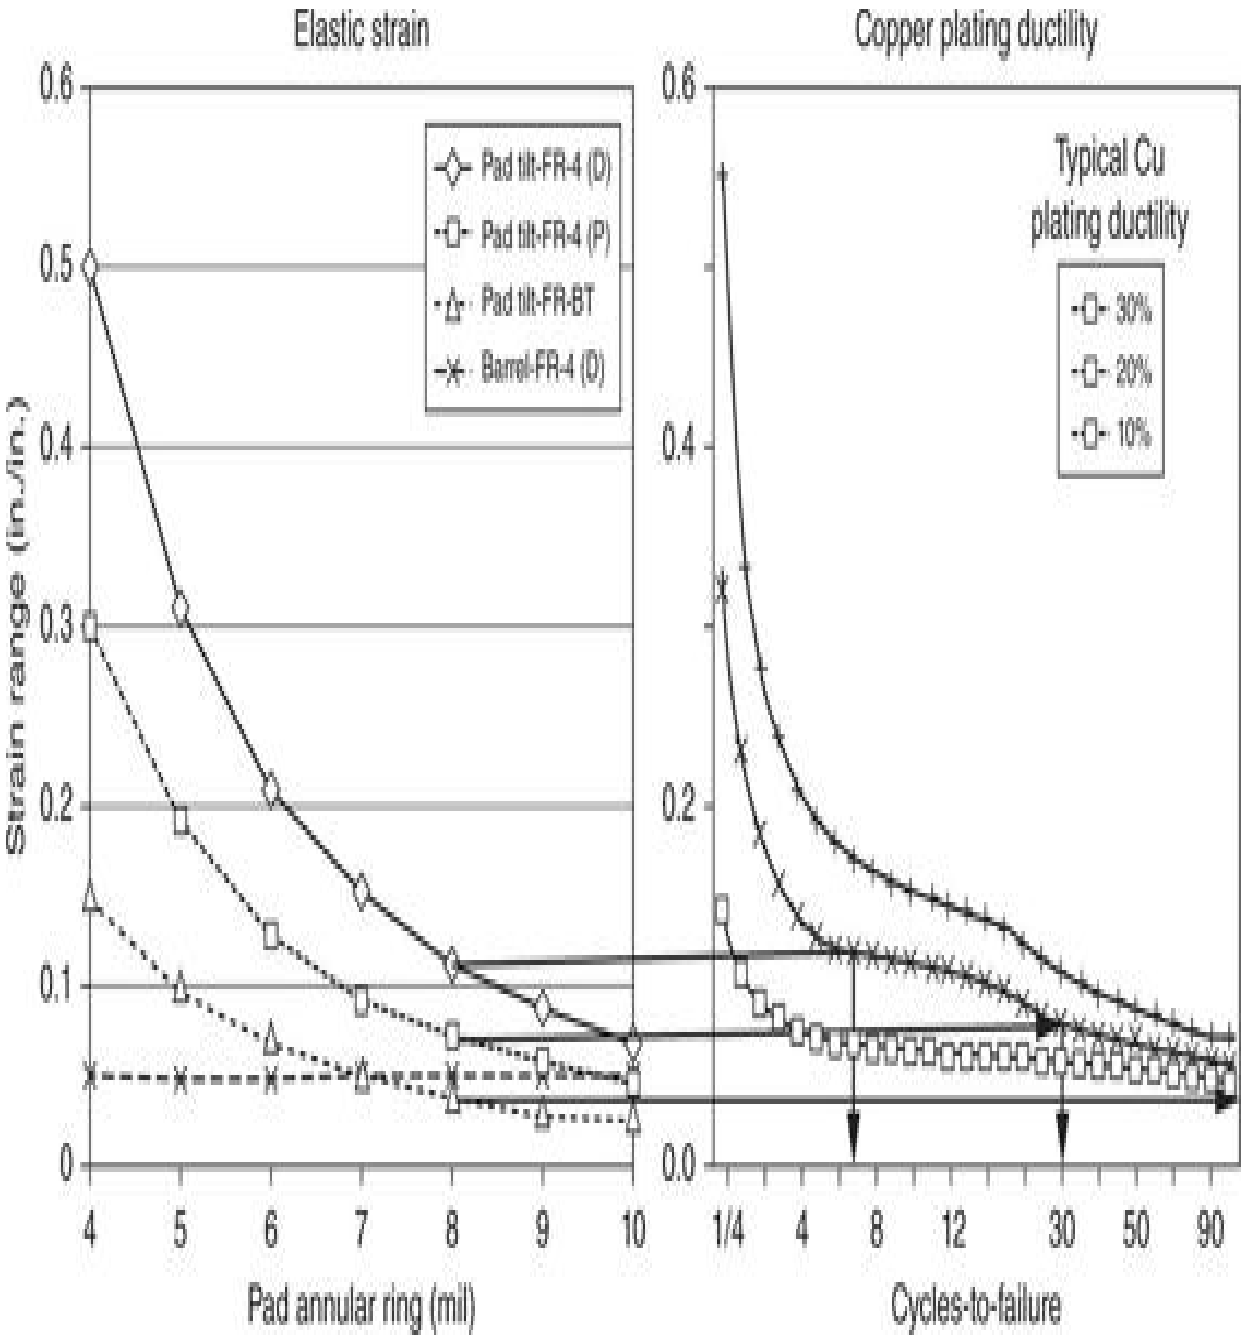

FIGURE 60.30 (*a*) Pad tilt strain versus pad annular ring and (*b*) cycles-to-failure.[35]

Tanaka et al.[50] was reported corner cracking for the case when PTH were filled with solder and then subjected to thermal and shock cycling, even though the PTH-filled solder showed longer life (see Fig. 60.31). The authors showed experimentally that the condition of solder fill affects crack

initiation in solder such that induces cracking through corner PTH and its failure after 500 cycles. Microsectional samples shown in Fig. 60.32 clearly show that cracks are first initiated in solder followed by the corner cracking of the PTH. Crack initiation in solder was prevented by forming a solder dome over the PTH copper ring. This condition did not show both formation of solder cracking as well as Cu PTH cracking. So, the Tanaka et al. concluded that there is a strong relationship between solder cracking and PTH solder-fill condition.[50]

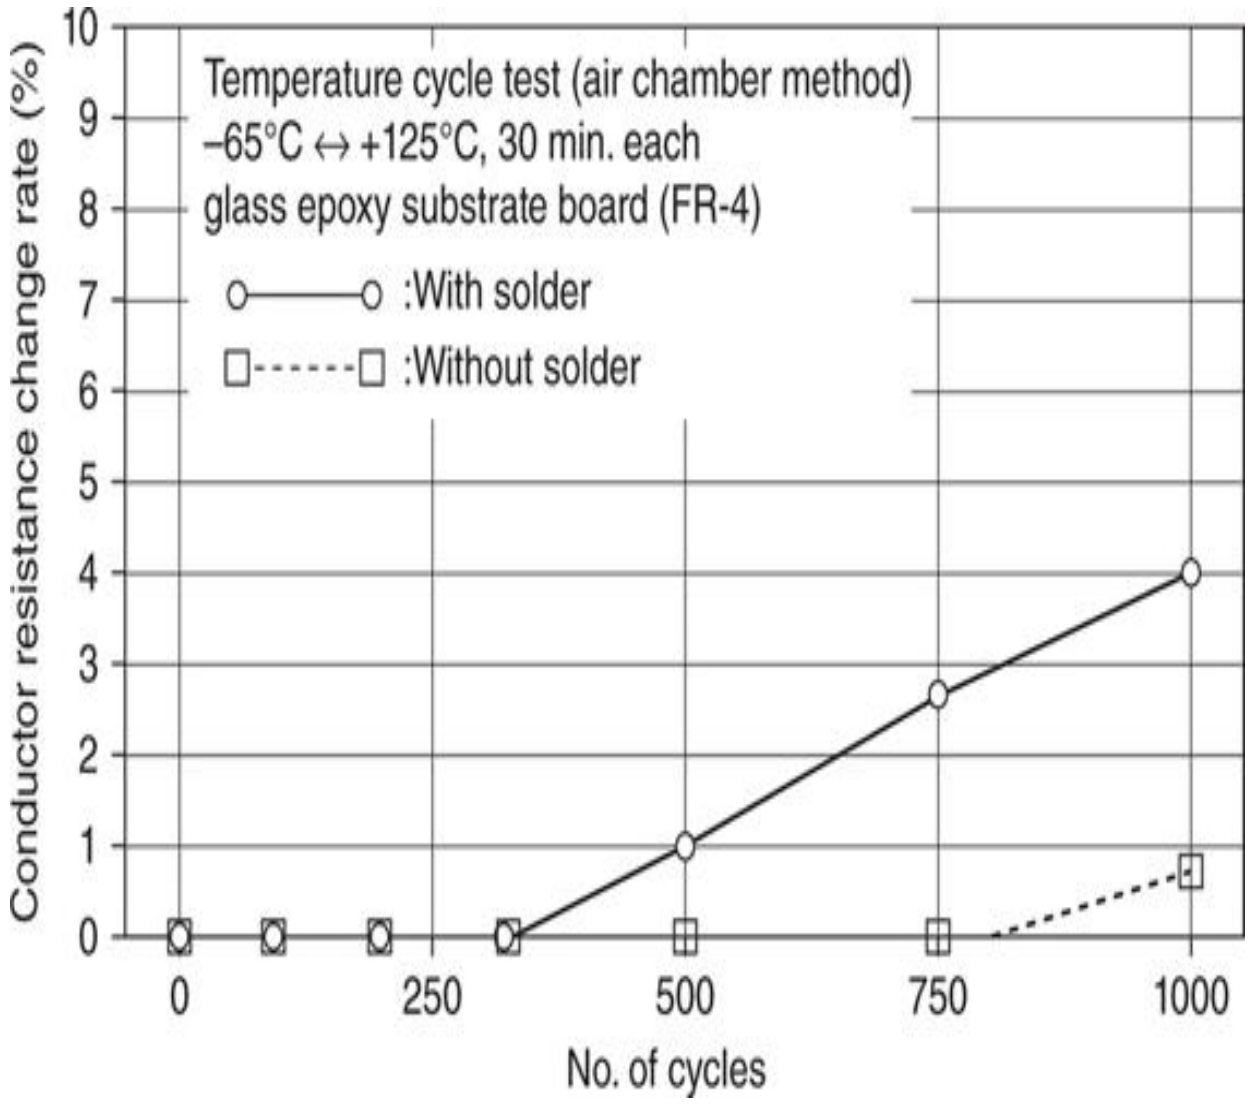

FIGURE 60.31 Cycles-to-failure for PTH with no-fill and solder fill.[50]

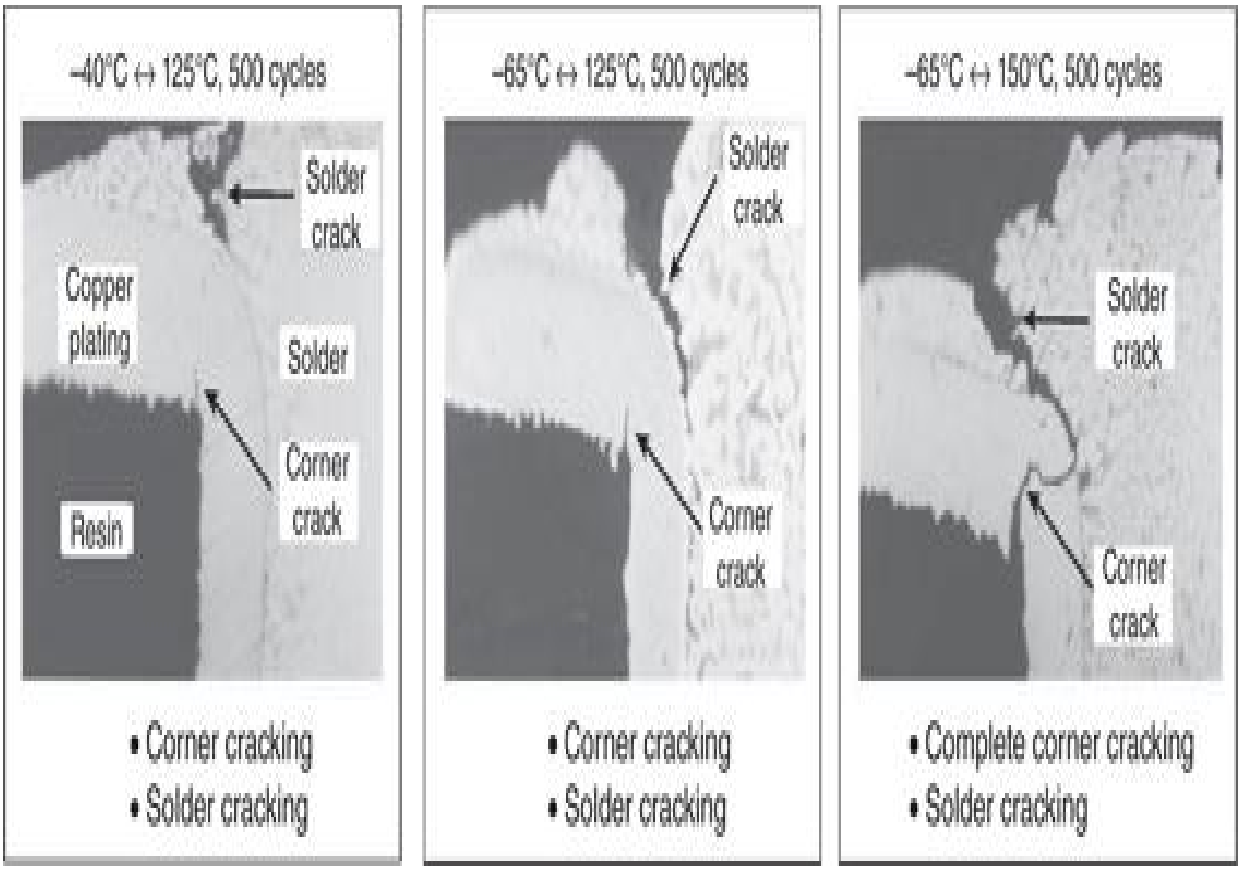

FIGURE 60.32 Corner crack initiation and failure for three thermal cycles at 500 cycles. Cracking is seen to be associated with solder fill cracking.[50]

60.4.5 PCB Properties and PTH Fill and Reliability

Wua et al. tested reliability of small PTH diameter and their failure phenomena using 0.25- to 1.5-mm (10- to 60-mil) diameters on the multilayer PCBs with 96 mil thicknesses.[51] The test boards were subjected to thermal cycle testing for 6000 cycles: from 0 to 100°C with 10°C per minute ramp rate (IPC 9701).[12] No failure was found for any PTH with a diameter larger than 18 mil or an aspect ratio less than 5.3 in this study. The first failures for 0.25-, 0.3-, 0.4-mm (10-, 12-, and 16-mil) PTH diameters were 2518, 1830, and 3985, respectively. The Weibull scale and characteristics values

were 4.92 and 3932 cycles for 10-mil diameter, 5.70 and 4439 for 0.4-mm (12-mil) diameter, and 11.89 and 5037 cycles for 0.4-mm (16-mil) diameters. The failures were dominated by wearout mode. The cross-section results show PTH failures were due to fracture at the barrel of the through hole (see Fig. 60.33) with a no-electrical-open caused by intermittent contact at the PTH shoulder.

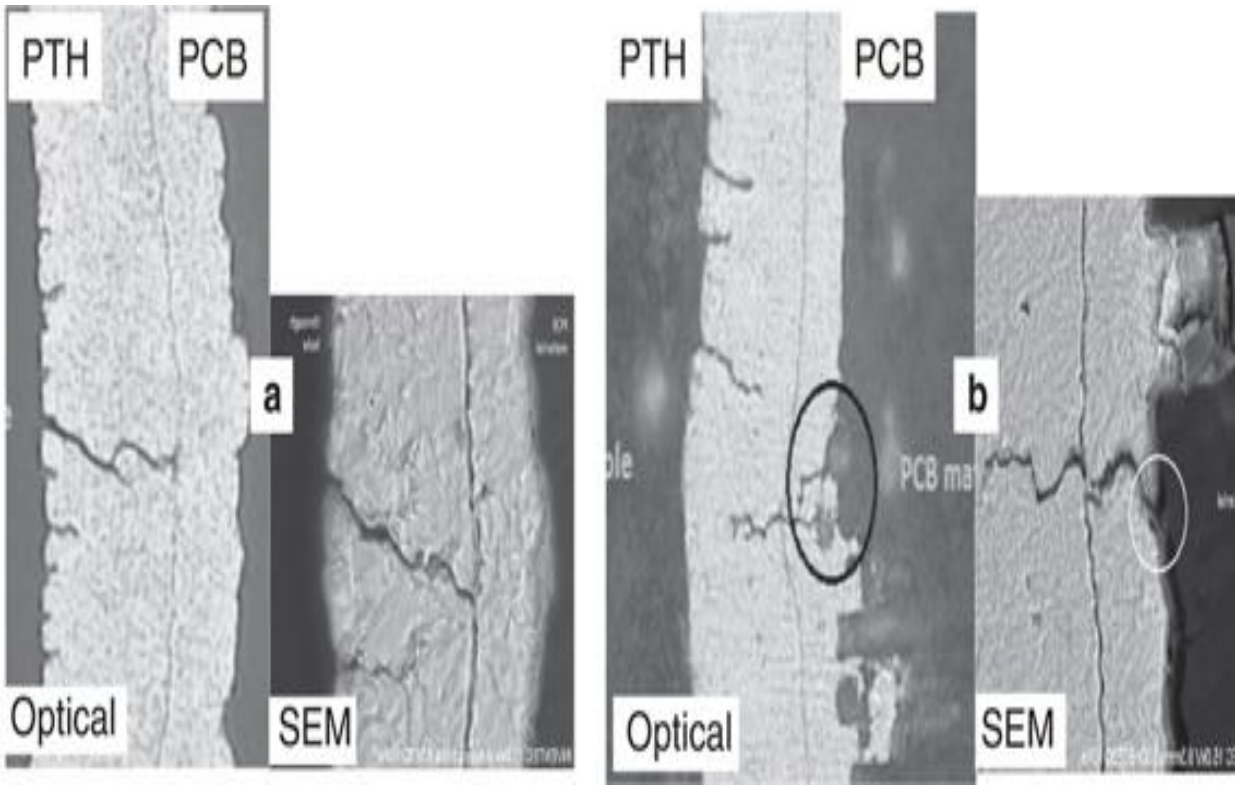

FIGURE 60.33 Optical and SEM photomicrographs showing the failure phenomena resulted from two physical mechanisms. (*a*) The crack originates from the inside edge of the plated copper and then propagates to PCB material. (*b*) Crack starts from weakness of plated copper or defect at the plated copper-PCB material interface.[51]

Based on Wua et al.,[51] the smaller the hole size, the less robust the hole reliability. The large heavily plated holes tend to have interconnection problems while small holes fail for barrel cracks. Another author, Reid, states that test data show that the hole size as small as 114 μm (4.5 mil) are robust with one key drawback.[31] The problem with such

small holes in a grid size of 0.5 mm (20 mil) is their tendency for crazing damage (generating a network of fine cracks). Crazing tends to be a path for conductive anodic filament (CAF) growth. So, the applications for the small hole and grid sizes are limited to the control environment with no humidity exposure.

Figure 60.34 shows PTH mean life cycles-to-failure for four different resin systems using 4 to 12 coupons tested from room temperature (23°C) to *T* (high) temperatures.[52] The curves reveal significant characteristics of the base resins, in particular, other than polyimide, which has a T_g above that of the temperature range tested, the approximate T_g of the materials is evident as the point of distinct change in slope of its curve. FEA revealed (see Fig. 60.35) that the difference in fatigue life of the plated through hole does not change significantly when the diameter of the plated through hole changes from 203 to 305 µm (8 to 12 mil), at least on a 0.48-mm-thick (190-mil) board.

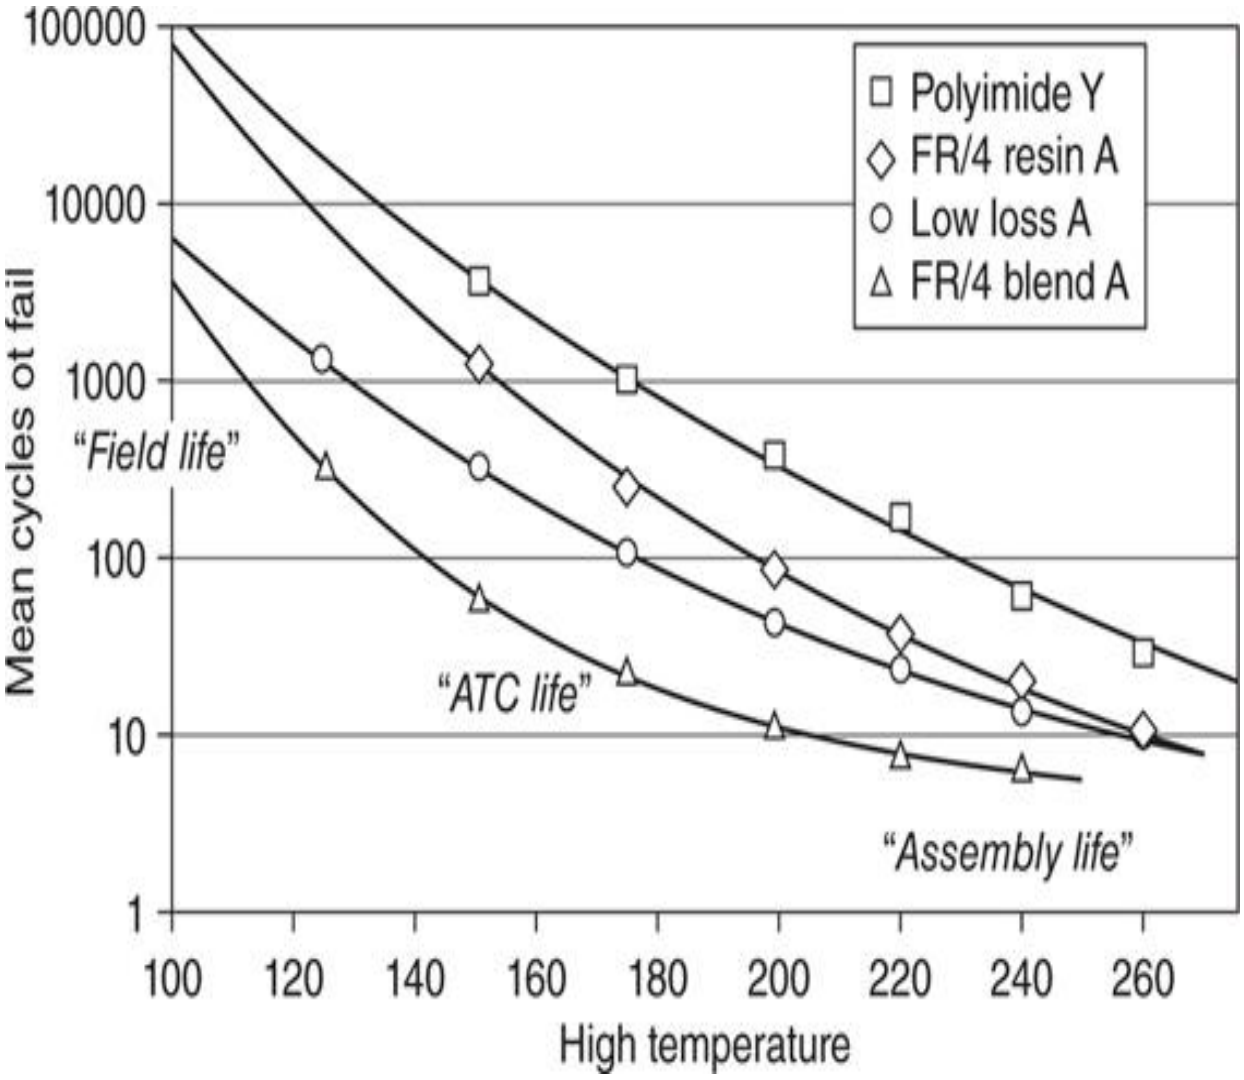

FIGURE 60.34 "PTH life curves" for 4 resin systems with CITC 23°C to *T* (high). Coupons 3.0 mm (0.120 in) thick, 0.25 mm (0.010 in) vias.[52]

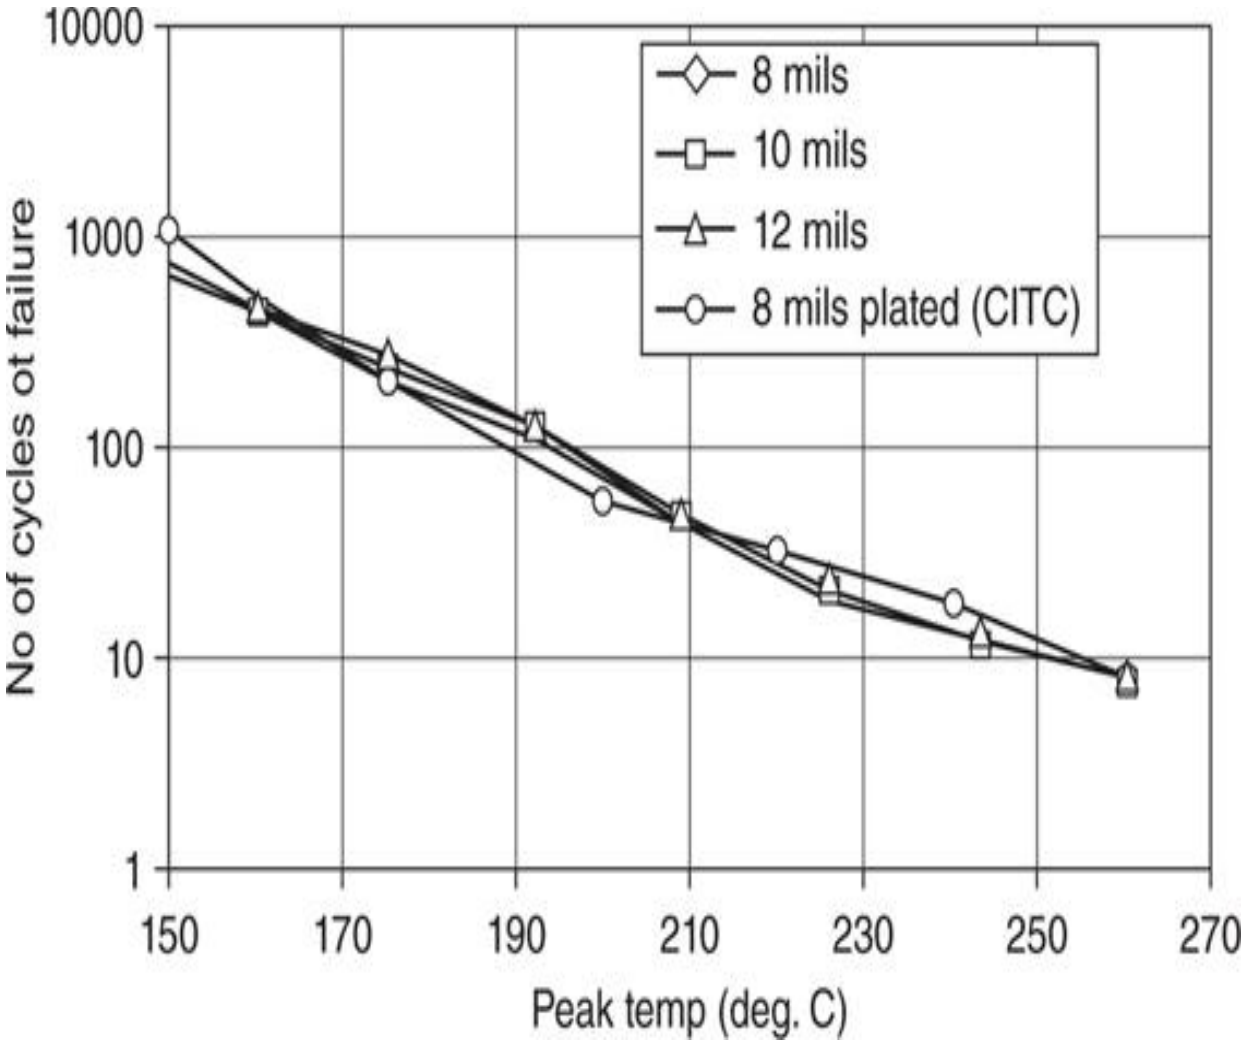

FIGURE 60.35 FEA fatigue life predictions vs. cycles-to-failure (CITC) life data.[52]

Recent data generated based on the HATS testing (−55/145°C)[24] for via sizes from 203 to 355 μm (8 to 14 mil) showed only slight differences with no clear trend (see Fig. 60.36). There was a significant increase in the stresses and strains in the PTH structure with an increase in the CTE of the hole-fill material. Figure 60.37 shows a plot of the vertical sidewall stress versus CTE.[53] Similar trends were shown for the von Mises stress and strain within the PTH. The location of the maximum displacement shifts from within the via to the center of the composite as the CTE of the hole fill is increased. In general, a low CTE hole-fill material is preferred

for a lower stress level in the PTH. The effect of hole-fill modulus was also studied. A similar trend was observed in that the stresses in the system increased with an increase in hole-fill modulus. A lower hole-fill modulus resulted in lower stresses in the PTH system.

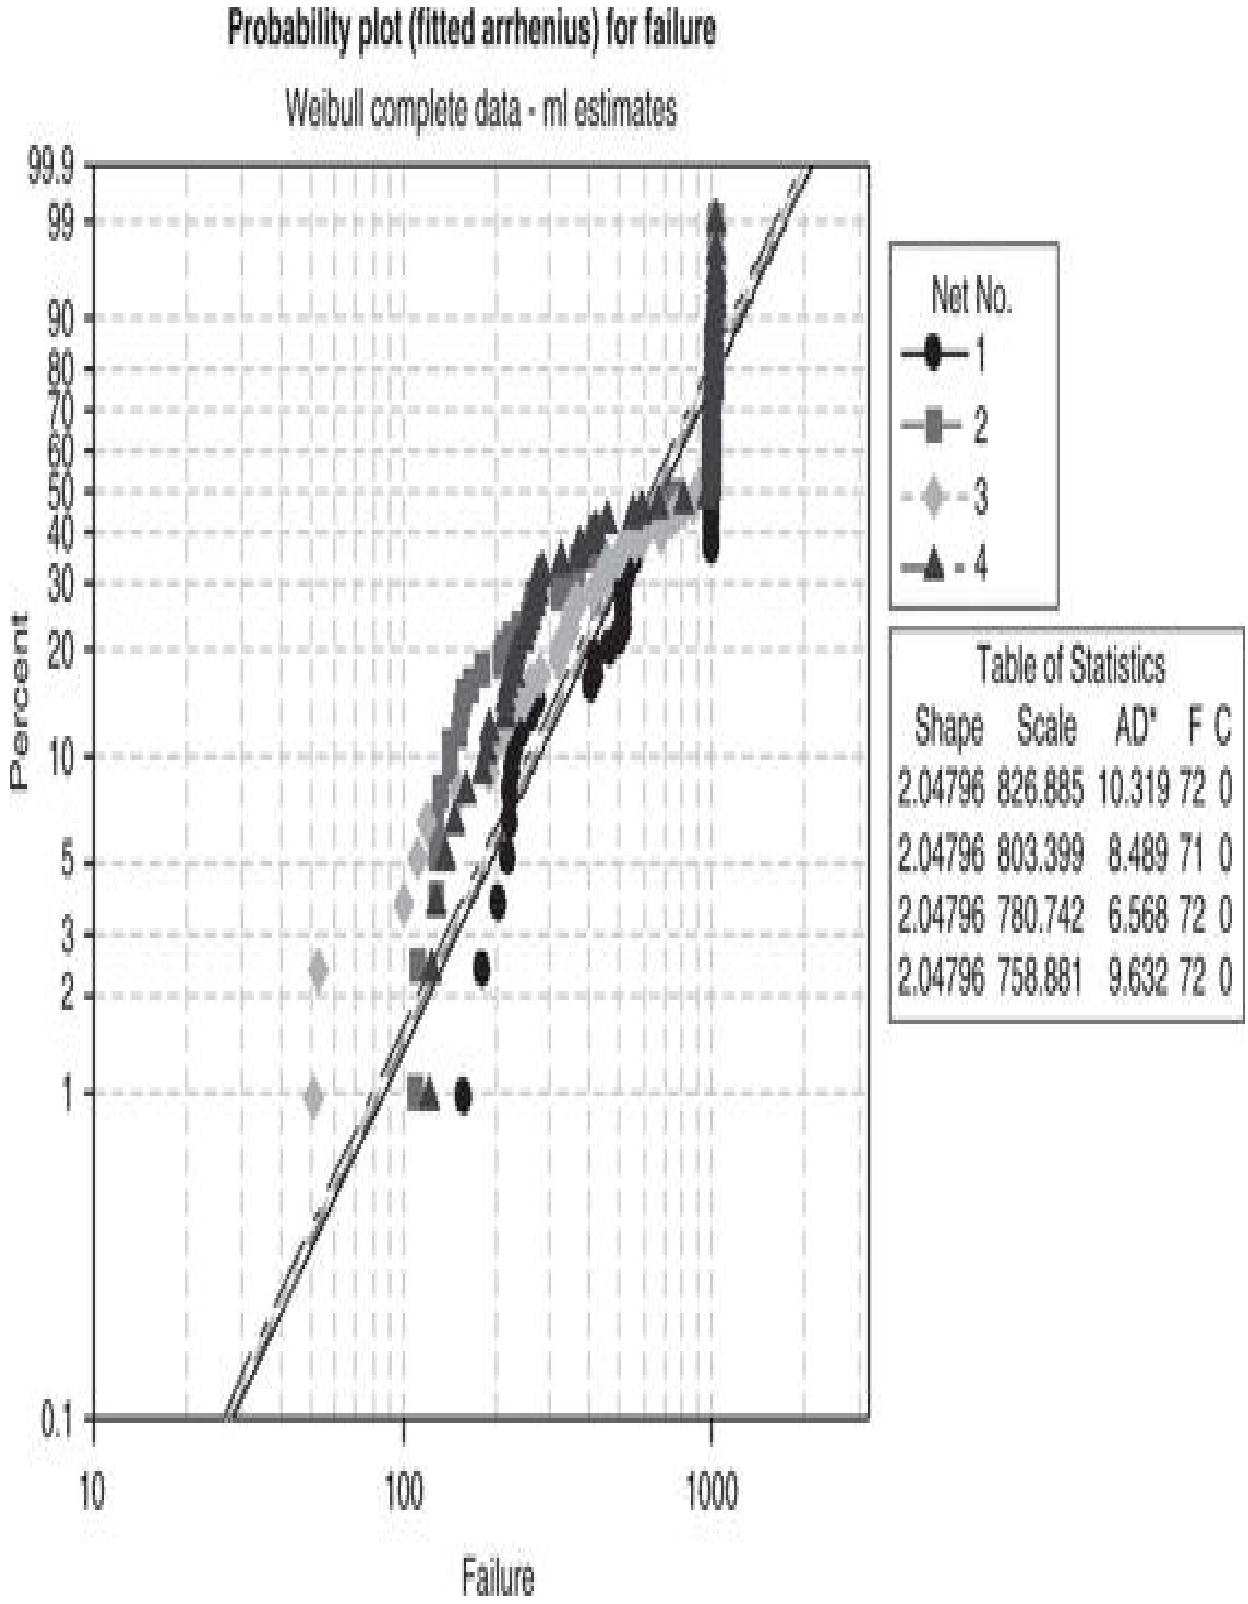

FIGURE 60.36 HATS cycles to failure of PCB with various PTH sizes [1 = 355 µm (14 mil), 2 = 305 µm (12 mil), 3 = 254 µm (10 mil), 4 = 203 µm (8 mil)].[24]

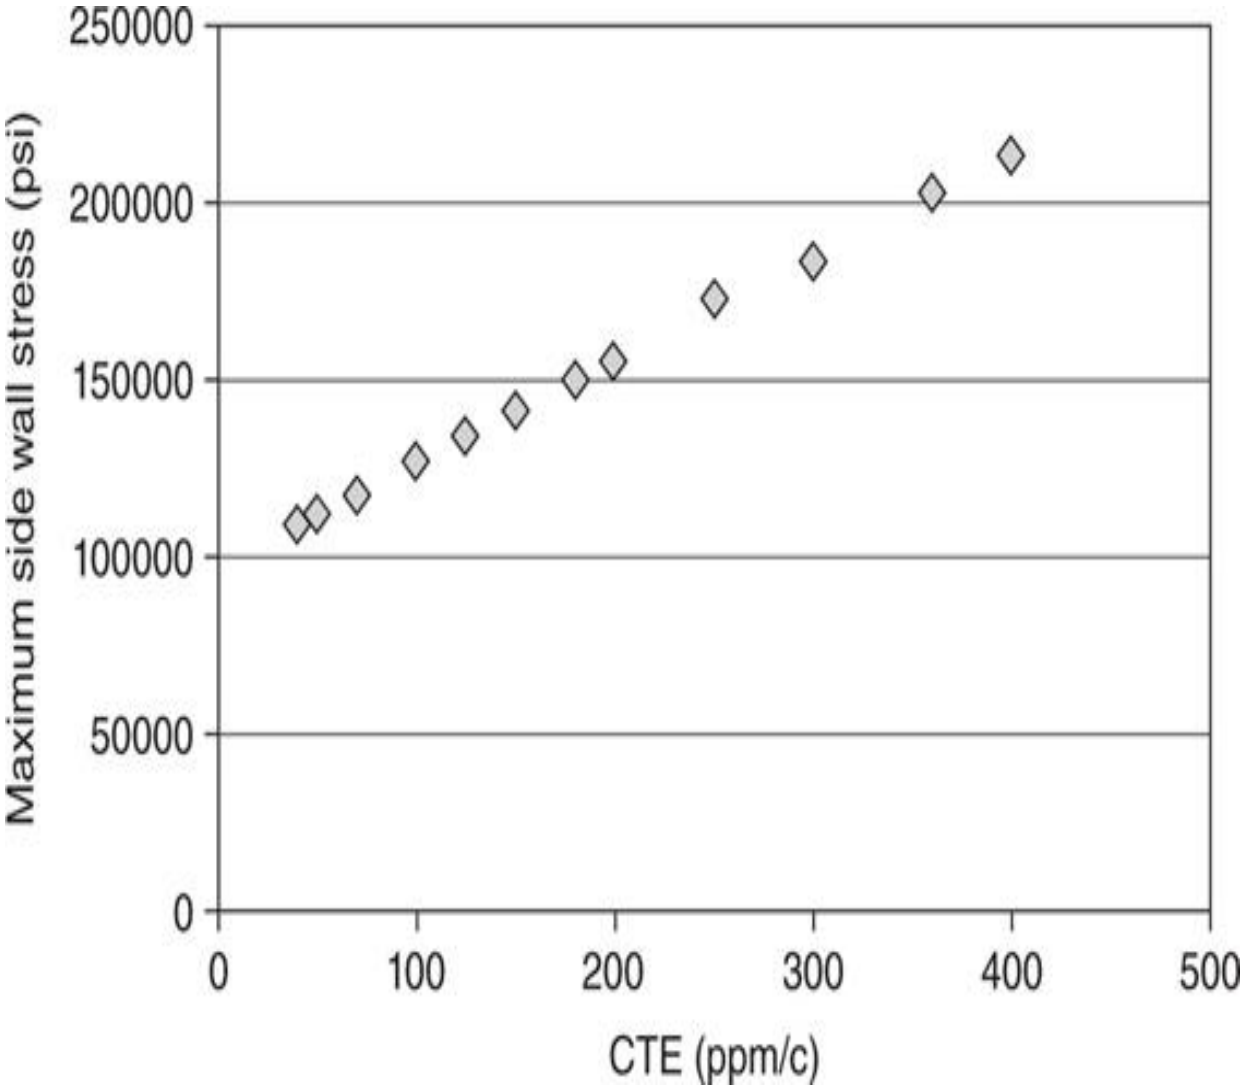

FIGURE 60.37 Vertical sidewall stress versus hole-fill CTE.[53]

However, under all hole-fill CTE and modulus conditions (keeping the rest of the material properties of the PTH build up constant), the stress in the via sidewalls did not fall below the yield stress of copper. This indicates that the necking of the copper barrels cannot be prevented by modifying the hole-fill material alone. The results of the study show that lowering the modulus of copper and the out-of-plane CTE of the FR-4 material can significantly reduce the stresses in the PTH and the via walls. Hence, modification of the PTH geometry such as the copper plating thickness and via size

may become necessary to prevent the failure of the PTHs during the assembly processes.

In another investigation on the effect of via-in-pad (ViP),[54] it was experimentally shown that thermal cycle reliability for a Pb-free SAC alloy depends on the particular device package type. For a BGA, reliability decreased with the use of ViP (see Fig. 60.38). For the BGA192, where the presence of ViP has a significant impact on the thermal cycle performance, the average void percent in diameter and area on the corner and adjacent solder balls is roughly four times greater for the ViP construction than the non-ViP construction. Authors believed that the voiding associated with the conformal microvia to be the cause of the reduced solder joint life, however, the failure analysis results, were not conclusive. The impact and size of the void associated with a microvia in a pad is a function of the component type, solder ball size, microvia drill size, and laminate thickness. However, the void location is more important than its size having a greater potential impact on solder-joint failure when voids are located in the fatigue crack path. Based upon this, it has been hypothesized that microvias in pad construction should result in poorer fatigue life performance for Pb-free than SnPb solder joints since the former exhibited a somewhat higher incidence of failure due to cracking in the board side of the solder ball where microvia related voids can influence fatigue-crack propagation.

FIGURE 60.38 Weibull plots of the BGA192 failure data with ViP and No ViP.

Through hole via pitches of 0.8 mm (32 mil) are more susceptible to internal material damage during Pb-free reflow or other thermal stresses than 1 mm (40 mil) or greater via pitch. Because of the closer pitch of the vias at 0.8 mm (32 mil), the stresses built up during Pb-free assembly resulting from the CTE differences between the copper plated through holes and the laminates, plus any vapor pressure generated during reflow, are less able to be distributed across the material between the vias. In the worst case this results in severe internal delamination of the materials.

60.4.6 Reliability of PCB under Pb-Free Assembly

Regarding the high temperature Pb-free reflow process, the primarily threat to the reliability of printed circuit boards (PCBs) comes from one source, the temperatures required during the soldering processes for the assembly of the components onto the PCB.[55] The PCB reaches temperatures higher than most components in the assembly. These temperatures can be between 230 and 245°C for soldering with SnPb-solders, and 265°C and 280°C when soldering with Pb-free solders. The FR-4 materials currently standard for PCBs are inadequate in their capability to survive the higher soldering temperatures required for most LF-solders. The effect of two and three reflow soldering preconditioning at 250°C, representative of lead-free solder reflow, is shown in Fig. 60.39.[24] Subsequent to preconditioning, the PCB test vehicles were subjected to highly accelerated thermal stress (HATs) testing in the range of −55/145°C (air to air). Even though the Weibull plots are not linear indication of a stress free region, it clearly shows significant reduction due to one additional soldering reflow. The 63 percent cycles-to-failure

decreased from 422 cycles to 292, about 30 percent reduction.

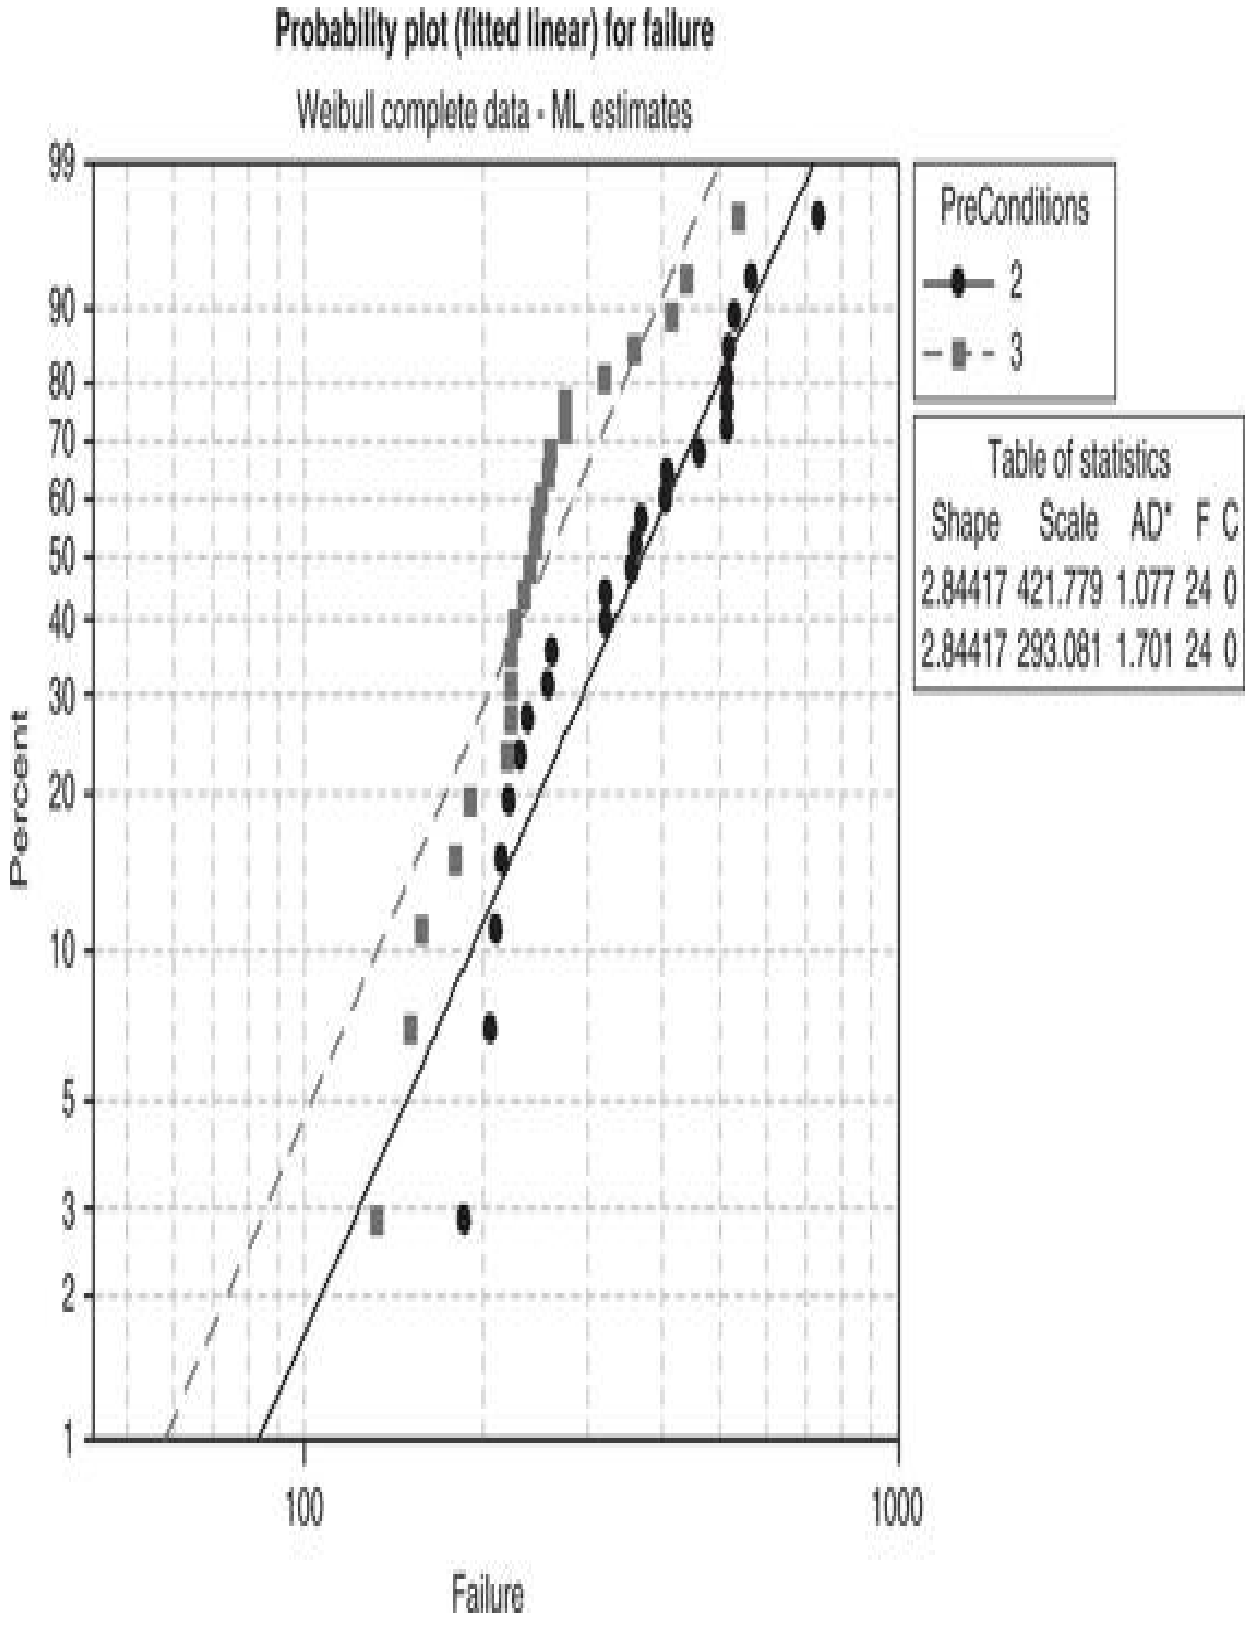

FIGURE 60.39 Effect of two- and three-cycle preconditioning at 250°C on subsequent number of cycles to failure (−55/145°C, air to air). It reduced the

average CTF from 422 to 294 cycles.[24]

The standard FR-4 materials for PCBs may be inadequate in their capability to survive the higher soldering temperatures required for most Pb-free solders. While today's FR-4s are significantly improved over the materials which were available previously, the improvement has occurred primarily with the glass transition temperature, T_g. Increases in T_g as well as possibly decreases in coefficients of thermal expansion (CTE) and increases in decomposition temperature, T_d, are also necessary. The improvements in T_g and CTE are required to ensure the integrity of the PCB interconnect structures (i.e., PTV copper barrels and barrel/innerlayer interconnects), whereas the improvements in T_g and T_d are necessary for the thermal stability of the PCB resin to mitigate barrel fractures as well as innerlayer separations (ILS). Smaller diameter PTVs tend toward barrel fractures, while larger diameter through-holes tend toward ILS. Resin degradation and decomposition occur at temperatures too high for that particular resin system. Werner Engelmaier proposed that three resin properties are needed to be improved to assure the survival and reliability of PCBs during the high soldering temperatures for Pb-free solders.[55]

- Glass transition temperature, T_g
- Decomposition temperature, T_d
- Coefficient of thermal expansion, CTE

The soldering temperature impact index (STII) was proposed to capture these three properties. The relationship is given as

$$\text{STII} = (T_g + T_d)/2 - [\%\ \text{thermal expansion 50 to 260°}] \times 10$$

The effect of STII for a large number of FR-4 PCB test vehicles was investigated under HATs (−55/145°C) thermal cycling.[24] The results are shown in Fig. 60.40. The STII varied from 181 to 247.

Failure

FIGURE 60.40 The effect of PTH diameter and STII on the number of cycles to failure (−55/145°C, air to air). As the STII increases, the CTF increases.[24]

The higher soldering of Pb-free temperatures, together with the very high Sn-contents of solders, leads to a significant increase in the rates of copper dissolved during soldering processes. Reductions in copper thickness by as much as 12 μm (0.5 mil) have been reported. Therefore, the minimum copper plating thickness needs to be increased to accommodate decreased plating during high temperature Pb-free soldering. In addition, the copper plating absorbs moisture that generates damage during PCB soldering processes due to high internal vapor pressure. The higher the moisture content and the higher the temperature, the higher the vapor pressure and resulting greater damage. Thus, for Pb-free soldering, the amount of moisture absorption should be reduced by a more rigorous moisture bake-out prior to soldering to assure the survival and reliability of PCBs.

In addition, when a PCB is exposed to elevated temperatures for long periods, the adhesion between the Cu and the laminate decreases, and the flexural strength of the laminate gradually degrades. Discoloration is usually an early symptom of such degradation. Cu adhesion is measured using a peel test. Adhesion at elevated temperatures or after elevated temperature exposure gives some insight into the ability of the material to withstand rework and other high-temperature processes. Flexural strength stability is compared by measuring the times at 200°C before the flexural strength decreases to 50 percent of its original value. The quality of the bond between the resin and reinforcement is compared by measuring the time it takes for copper-clad laminate to blister during a solder float test at 290°C.

An industry consortium investigated the PTH reliability of 20 different Pb-free capable PCB materials test vehicles with

27 different layer constructions built by three manufacturers all having Pb-free capable materials (Smetana et al.)[56] The materials were tested using both air-to-air (AtA) thermal cycling and interconnect stress testing (IST) methodologies. Both as built and after 6× Pb-free (260°C) reflow were evaluated.

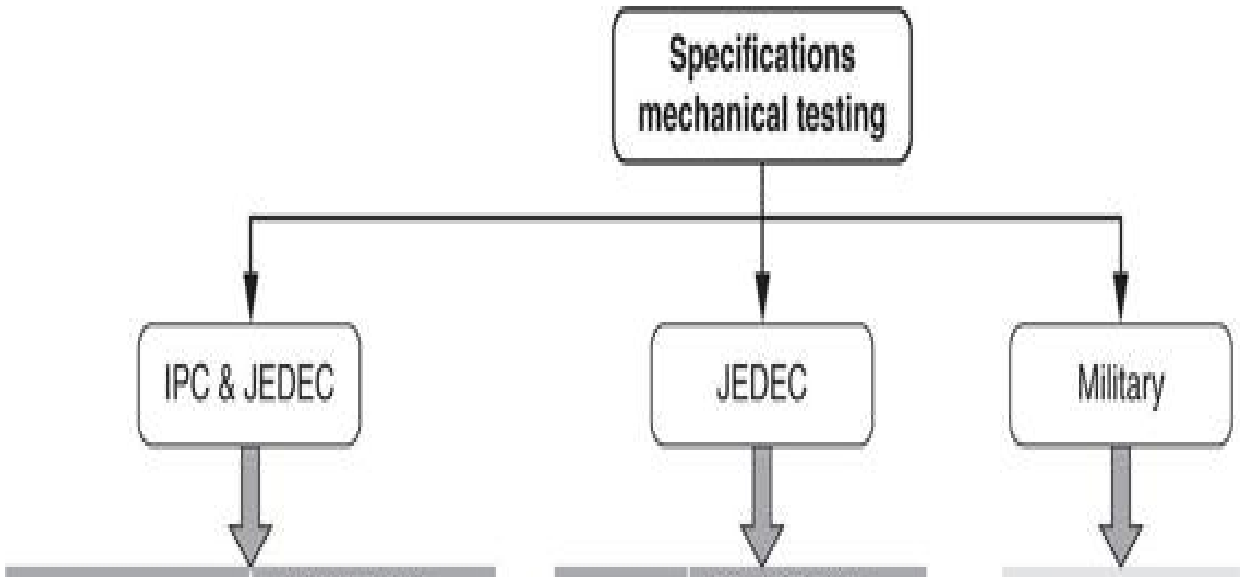
After 6× reflow, both AtA cycling from −40 to +135°C with 10 min dwell and ramp times and IST testing from ambient (23°C) to 150°C with 3-min heating ramps, 2-min cooling ramps, and no dwell at either temperature extreme. Testing was initially continued to a maximum of 3000 cycles, and then extended to 6000 cycles on certain materials that proved to be very robust. The Smetana et al. reference significant other evaluations, including the conductive anodic filament (CAF) tests, moisture sensitivity testing, stress versus temperature relationships, electrically quantifying the consistency of product construction, dielectric thickness, and material damage through assembly and characterization of the electrical characteristics of each laminate.

When evaluating Pb-free survivability, in the majority of cases, the 6× thermal stress at 288°C test condition was more severe than the 6× reflow cycles at 260°C. The 288°C thermal stress methodology is both easy to implement at the PCB fabricator and a valuable tool for looking at the first article, or as a production check on an actual design. It is recommended to use both the combination of reflow cycling and solder float testing when material and product qualification is important.

As a general observation, the laminate integrity of the Pb-free materials after 6× reflow cycles at 260°C was significantly better than earlier evaluation, showing that the materials industry is learning and maturing relative to materials ability to survive multiple cycles through Pb-free assembly.

60.4.7 Specifications for Field Life Requirements

Before field life projection, desired lifetime and product performance metrics need to be identified and documented. The desired lifetime might be defined as the warranty period or by the expectations of the customer. A meaningful reliability prediction must take into account the environment in which the product is used. There are several common approaches to identifying the environment. One approach is to identify the environment involves the use of industry/military specifications. Recent specifications on mechanical testing are summarized in Fig. 60.41. These have been generated in recent years by commercial industry, particularly by the Association Connecting Electronics Industries (IPC) and the Joint Electron Device Engineering Council (JEDEC) in response to increasing demands on area array packages and their miniaturized versions and stack technologies. It also includes the key military specification (Mil-STD-810F) (that was updated in 2008). The key specifications for evaluation under mechanical testing are as follows:



IPC/JEDEC-9702	Monotonic bend characterization of board-lavel interconnects
IPC/JEDEC-9703	Mechanical shock test guidelines for solder joint reliability
IPC/JEDEC-9704	Printed wiring board strain gage test guidelines
IPC/JEDEC-9707	Spherical bend test method for characterization of board level interconnects
IPC-9708	Test methods for characterization of printed board assembly pad cratering

JESD22-B111	Board level drop test method of components for hand held electronic products
JESD22-B110A	Subassembly mechanical shock

Mil-STD-810F Vibration/shock methods 514/516

FIGURE 60.41 Key Commercial and military specifications for mechanical testing, including those that define bending, drop, vibration, and shock for behavior of microelectronics.[2]

1. Joint IPC/JEDEC 9702 covers basic mechanical bend testing characterization and strains to failures using four points, a bend test method commonly used by industry. Specific strain gage attachment requirements are delineated in IPC-JEDEC-9704.
2. Joint IPC/JEDEC 9707 covers a new test method that is more applicable for area array packages. It uses spherical loading at points rather than loading through cylindrical rod as was used in four-point bend testing defined in IPC 9702. This standard supplements existing standards for mechanical shock during shipping, handling, or field operation, as well as filling the gap for IPC/JEDEC 9702 to better characterize maximum strain levels. The two specifications provide a common method of establishing the fracture resistance of board-level package interconnects to flexural/point loading during PCB assembly and test operations. No pass/fail qualification requirements are provided, since each package/assembly is considered unique.
3. IPC 9703 covers generic guidelines for mechanical drop and shock testing. These are only guidelines because of requirements differences between industries. The document scope includes: (a) methods for defining mechanical shock use conditions, (b) methods to define system-level and system-board-level component testing that correlates to the use conditions, and (c) guidance on the use of experimental metrologies for mechanical shock tests.
4. IPC 9708 was generated in response to newly observed board failures (pad cratering) resulting from the move to implement Pb-free solder alloys. Pb-free solders are generally stiffer than tin-lead solders; they can transfer

more of the applied global strain to the assembly. The Pb-free approach requires higher reflow temperatures that induce higher residual stress/strains in the assembly. Pb-free is typically assembled with phenolic-cured PCB materials that are more brittle than conventional dicyandiamide-cured (dicy-cured) FR-4 materials. These strains could eventually relax over time, but if mechanical strain is applied shortly after reflow, pad cratering could occur at lower mechanical strain levels.

5. JEDEC JESD-B111 was developed for portable electronics in response to the need to define resistance to repeated drops, which is required for mobile applications. The shock pulse requirement for a PCB assembly is defined based on JESD22-B110, condition B, Table 60.6 (or JESD22-B104-B, Table 1) with 1500 Gs, 0.5 ms duration, and half-sine pulse. This specification is widely used by industry, and data are valuable for high-reliability applications. JESD-B210A defines resistance to mechanical shock.

6. Mil-STD-810F covers many aspects of environmental testing (including mechanical vibration and shock), and it is well established for conventional microelectronics for high-reliability applications.

Other specifications are MIL-HDBK-310, SAE J1211, Telcordia GR3108, and IEC 60721-3. IPC-SM-785, and IPC 9701.

For example, for accelerated thermal cycle reliability testing of solder attachment, IPC-SM785, Guidelines for Accelerated Reliability Testing of Surface Mount Solder Attachments, has been in use for more than a decade. Only recently industry has agreed to release an industry-wide specification, IPC-9701, in response to BGA and CSP technology implementation.[57] The IPC-SM785 guideline, although very valuable and still valid, did not answer the key question of what the data means in terms of product application and data comparison. As has been well established by industry, many variables could be manipulated to either favor or disfavor test results. Considerable resources and time could be wasted to generate failure data not related to solder attachment. An example is the use of a surface finish having the potential of inducing intermetallic rather than solder joint failure. This is especially likely for a novice user/supplier.

The IPC 9701 specification addresses how thermal expansion mismatch between the package and the PCB affects solder joint reliability. In order to be able to compare solder joint reliability for different package technologies, numerous materials and process parameters were specified.

The newest revision, IPC-9701A (released in 2006) includes guidelines for Pb-free solder alloys.[58] The appendix added to the specification requirement establishes guidelines for modifications required for lead-free solder joints. Its Appendix A provides examples of test data and modeling approaches that are considered to better define the effects of various thermal cycle parameters on accelerated test

results and projection for product reliability. Lack of extensive field reliability data for Pb-free electronic products in 2006 made reliability comparison with tin-lead based on accelerated laboratory test data even more difficult.

For the SAC (SnAgCu) Pb-free solder alloys, dwell (soak) time might be required to be increased in order to accommodate their slower creep rates. A requirement for increased dwell is specified as another condition when experimental comparison between tin-lead and Pb-free solder alloys are deemed to be necessary. The thermal cycle (TC) test ranges, test profile, and the number of test cycles (NTC) reported were also standardized. These include the reference cycle in the range of 0 to 100°C (TC1) and the severe military cycle condition of −55 to 125°C (TC4). Three out of five total TC conditions are identical to the test conditions recommended by JEDEC 22 Method A104, Revision A. The NTC varied from a minimum value of 200 cycles to a reference value of 6000 cycles.

The advantages of using a specification for projecting field reliability include the low cost of the standards, their comprehensive nature, and agreement throughout the industry. If information is missing from a given industry, a user may simply choose standards from other industries. The disadvantages include the age of the standards (some are relevant to an older technology) and the lack of validation against current usage. The standards both overestimate and underestimate reliability by an unknown margin.

Table 60.6 provides for end use thermal testing.[59] Not all electronic systems experience the same environmental/operational requirements over their lifetime because of their different operating conditions. The traditional test methods are still in use, even with the advent of new materials and new processes. It is advisable to always question the methods that were used to establish field reliability predictions. No doubt, thermal stress, thermal shock, and thermal cycling will still be around for many

years; however, the limits of the testing range and time of testing may come under question. So, thermal modeling is still needed to project field reliability for PTHs and assemblies.

60.4.8 Field-Life Projection for PTH Reliability

Another approach to identifying the field environment is based on actual measurements of similar products in similar environments. This gives the ability to determine both average and realistic worst-case scenarios. All failure-inducing loads can be identified, and all environments, manufacturing, transportation, storage, and field, can be included. Such field information with appropriate modeling approaches, the field life can be more realistically projected.

So, the goal in modeling PTH reliability is to be able to estimate the available lifetime of a product after it has been subjected to all the manufacturing processes and burn-in testing.[60] The available PTH filed life are estimated by using the Pad/Barrel concentration model, semi-empirical relationship and fatigue Minor's rule. The damage accumulation rule (minor rule) is as follows:

$$A n_i/Ni = n_1/N_1 + n_2/N_2 + n_i/N_i = C$$

n_1, n_2, … n_i is the number of thermal cycles applied to the test or field coupon at a specific temperature or stress level

N_1, N_2, … N_i is the known number of cycles to failure, that is, the life at a specific temperature or stress level

C is a constant determined by experimentation and is usually found in the range of $0.7 \leq C \leq 2.2$

If $C = 1$, then Miner's rule becomes a simple equation of what proportion of life is used at each temperature

Table 60.7 shows calculation of cycle to failure for various manufacturing and effective strains, here specified as total strain range (TSR). The assumptions were for a typical PTH with the following parameters:

TABLE 60.7 Typical Small Hole Predicted Reliability[60]

			Nf (Cycles-to-failure)				
			TSR (in./in)		15% (Ductility)		
Thermal Cycle	Max Temp (°F/°C)	Failure Site	Min	Max	Min	Mean	Max
Generic	450/232	Barrel	0.044	0.106	5	17	29
		Knee	0.042	0.050	23	27	32
		Interconnect	0.029	0.030	64	66	69
Power On/Off	200/93	Barrel		0.003	19400		
		Knee		0.004	8780		
		Interconnect		0.002	30000		

- Drilled hole diameter = 0.0135 in
- Minimum plating thickness = 0.0010 in
- Maximum plating thickness = 0.0015 in
- Laminate material = FR-4 (difunctional)

Using both the barrel and the knee as the weakest members, the mean life fraction consumed during assembly (assuming 7 generic thermal cycles for manufacturing) as, Barrel:

$$n/N = 7/27 = 0.41 \text{ and Knee: } n/N = 7/17 = 0.26$$

Thus, 41 percent of the PTH barrel and 26 percent of the knee life will be consumed at the completion of the seven

assembly process steps. The remaining 59 and 74 percent of the PTH life, respectively, will be consumed by some fraction of the 19,400 operational cycles for the barrel and 8780 operational cycles for the knee (see Table 60.7), i.e.:

$$\text{Barrel: } n/N = n_b/19{,}400 = 0.59 \text{ or } n_b = 11{,}446 \text{ cycles}$$

$$\text{Knee: } n/N = n_k/8780 = 0.74 \text{ or } n_k = 6497 \text{ cycles}$$

For this case, the knee will wear out first after approximately 6500 field cycles. Based on the above, each additional assembly cycle is equivalent in the amount of damage induced to 1175 field cycles at the barrel and 318 field cycles at the knee.

60.4.9 PTH Reliability Improvement Approaches

Numerous publications and industry joint efforts covered the key PCB fabrication and properties and Cu PTH parameters that affect thermal cycle reliability. The strain accumulation on Cu PTH depends on strain level induced at each thermal cycle excursion. To increase the useful life cycle, the following approaches can be implemented:

- The PTH reliability can be increase by increasing the ratio of $\varepsilon_f/\Delta\varepsilon$ since the number of cycles-to-failure (N_f) is proportional to ½ $(\varepsilon_f/\Delta\varepsilon)^m$. This ratio can be increased by increasing the Cu ductility (increases ε_f) and yield strength (decreases $\Delta\varepsilon$). Cu strength and ductility are often inversely related, so these two factors must be balanced against one another.
- The number of cycles to failure can be dramatically decreased by defects in the hole wall or Cu plating in the

hole or PTH knee that act as stress concentrations (increasing the local stresses and strains) and/or facilitate crack initiation.

- Decreasing or eliminating thermal shocks by preheating the PCB before hot-air leveling, wave soldering, rework with a solder pot, etc.
- Decreasing the range of the thermal cycle (see Fig. 60.42). Decreasing the range of the thermal cycle is the single most effective measure for increasing the life of the PTH, especially if the thermal cycle exceeds the T_g of PCB.

FIGURE 60.42 Peak temperature versus number of cycles to failure by PTH barrel (solid bars) or corner (dashed bars) cracking in three different tests. Calculated lines are shown for comparison. Results are for acid-sulfate copper and FR-4. Other parameters are total strain energy required to cause fracture, 50 J/cm^3; hole radius, 0.45 mm; distance from hole center to free end, 0.8 mm; plating thickness, 0.02 mm; distance from hole center to pad edge, 0.8 mm; board thickness, 2 mm.[57]

- Decreasing the free thermal expansion of the laminate over the thermal cycle. The free thermal expansion can be reduced primarily by choosing a laminate material with a higher T_g, but also by choosing a laminate material (e.g., with Aramid fibers) with a low CTE below T_g (see Fig. 60.43).

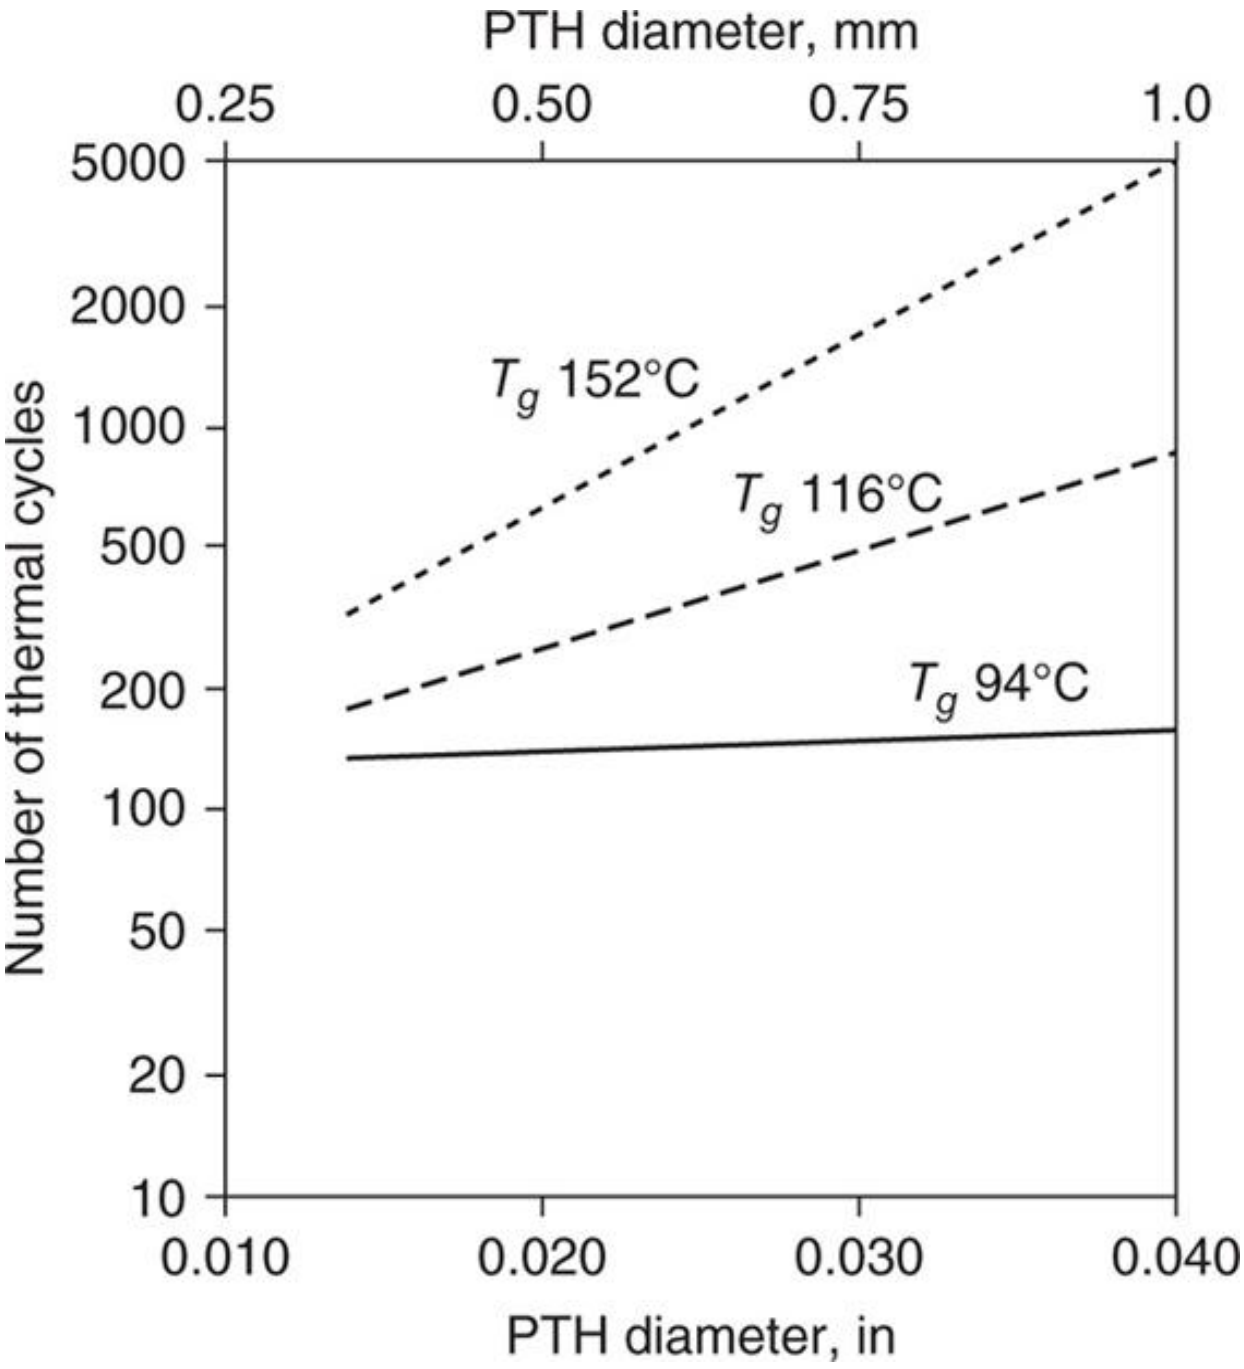

FIGURE 60.43 Effects of substrate T_g and PTH diameter on mean number of cycles to failure. The thermal cycle was 2 h with extremes at −62 and −125°C. Multilayer printed circuit board thickness 2.5 mm (0.10 in); Cu in unfilled PTH is 30 μm (1.2 mil) thick.[60]

- Decreasing the PTH aspect ratio (usually quoted as board thickness divided by finished hole size) by decreasing the board thickness or increasing the hole diameter (see Fig.

60.44). Aspect ratios tend to be higher in boards with eight or more layers because of their thickness and via density; aspect ratios greater than 3:1 require good-quality plating and aspect ratios higher than 5:1 are not recommended, in part because of the difficulty of achieving adequate plating thickness in the center of the barrel.

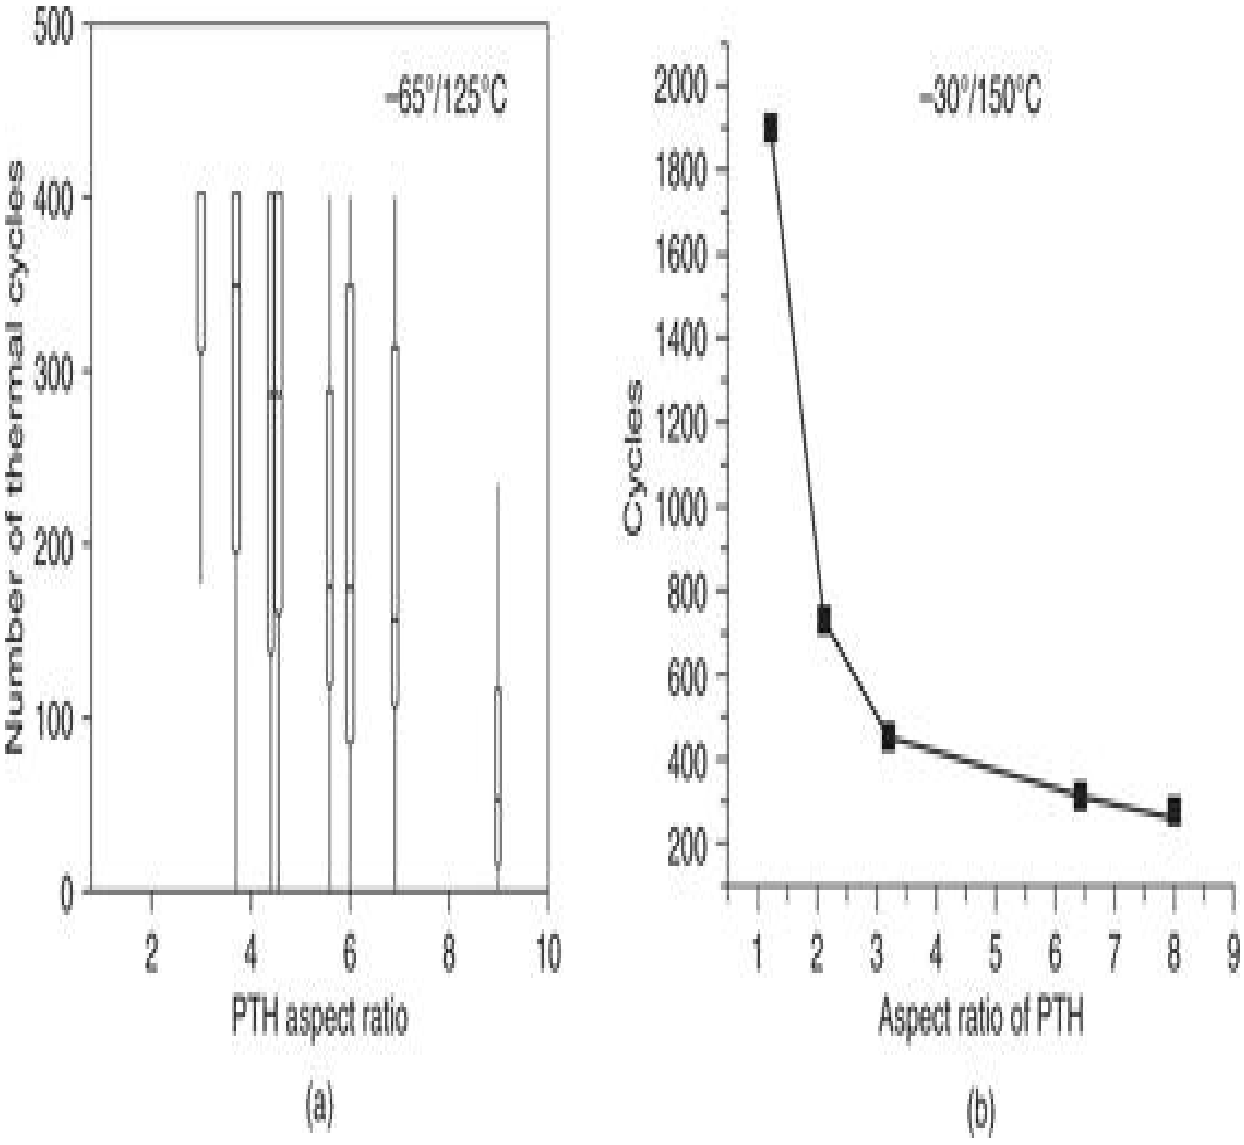

FIGURE 60.44 Cycles to failure versus PTH aspect ratio (*a*) for −65 to 125°C thermal shock cycles. Various hole diameters, board thicknesses, and board constructions[11] and (*b*) for −30 to 150°C thermal cycles modeled for two-layer PCB at a thickness 1.6 mm and plated copper thickness of 32 μm.[46]

- Increasing the Cu plating thickness (see Fig. 60.45). Increasing the plating thickness also increases the distance a fatigue crack must propagate to cause an electrical failure.

- Using Ni plating over the Cu. Nickel as one of the layers of a surface finish is either good, or, detrimental in PCB reliability. Normally well applied nickel extends the life of circuit boards by a factor of three or more.[31] Usually, the nickel interconnect structure survives 1000 cycles. The nickel stops the crack and performs well in thermal cycle testing. The crack forms after many thermal excursions but stops when it hits the nickel. However, coupons with nicks, bubbles, or breaks in the nickel finish will fail early. They tend to fail in a third the time of the same coupons without nickel. It appears that a defect in the nickel will force a crack that will crack from the nickel layer into the hole. This is called nickel acceleration. It is a rare condition but is common enough that it should be taken seriously.
- Decrease the number of PCB layers and increase PTH density (see Fig. 60.46). In the multilayer PCB, the quantity of stack up and copper foil layers may vary dramatically, from one to dozens. Based on a fixed PCB thickness of 1.6 mm (63 mil), a PTH diameter of 0.25 mm (10 mil), and a plated copper thickness of 32 μm (1.26 mil), the fatigue life of PTH in PCB with two, four, six, and eight layers of copper foil were modeled.[46] The predicted results are shown in Fig. 60.46. It can be seen that the fatigue life of PTH decreases with the increase of PCB layer quantity. The effect of PTH density on fatigue life also indicates that the board with more populated PTH (higher density), the higher the number of cycles-to-failure.

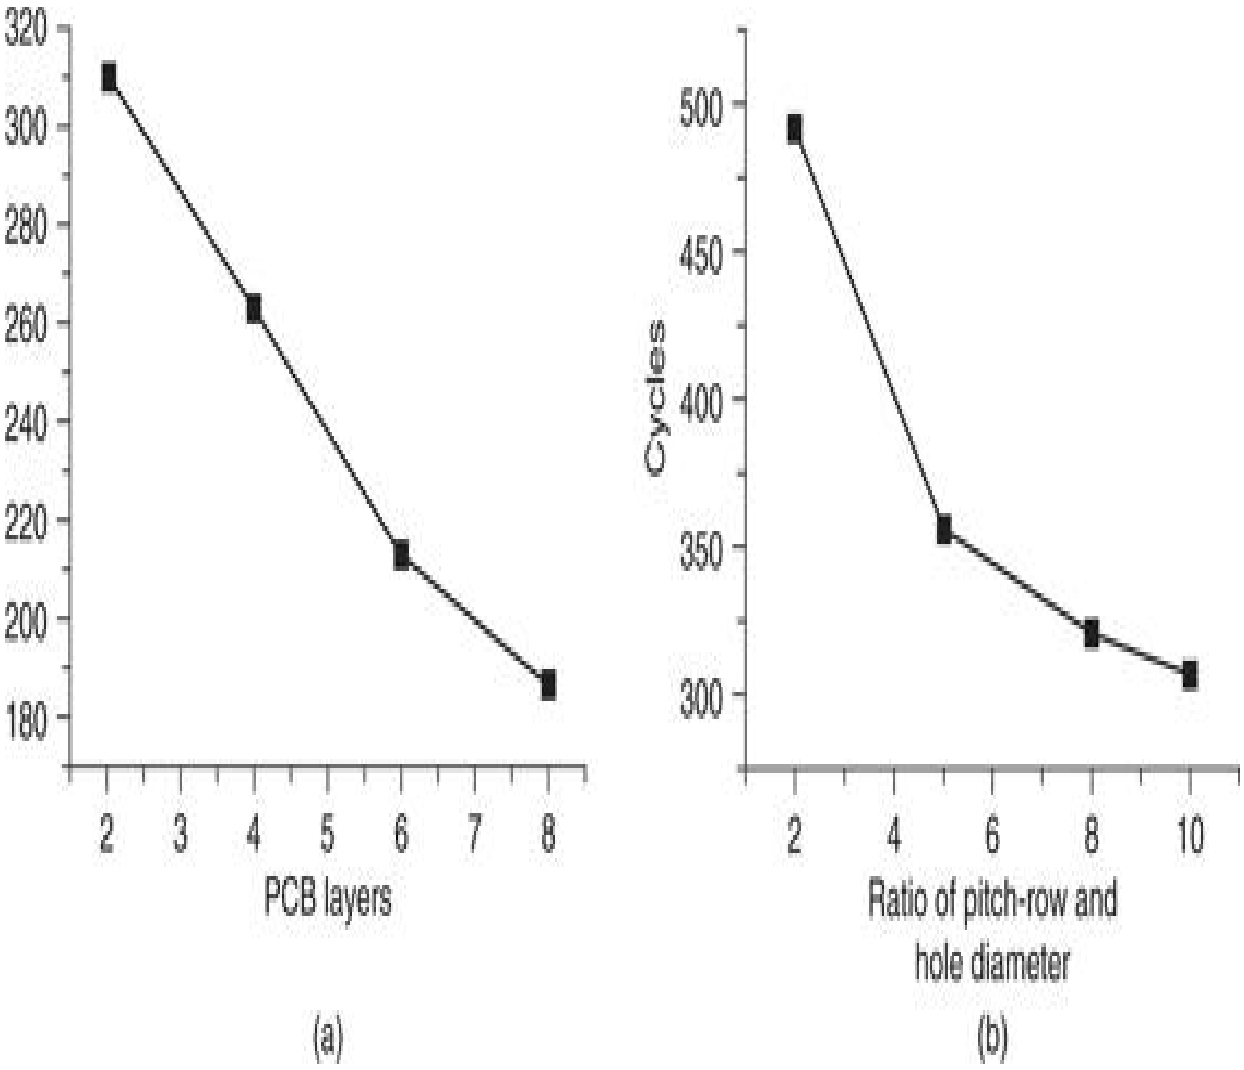

FIGURE 60.46 Prediction showing the effect of PCB geometry on PTH cycles-to-failure: (*left*) number of layers and (*right*) number of PTH (density).[46]

- The effect of types of internal copper interconnections on PCB reliability are yet to be fully characterized, but must be taken into account. Basically there are three types of internal interconnection formats, flush interconnections, etch back interconnections, and “three point” contact interconnections (see Fig. 60.47).

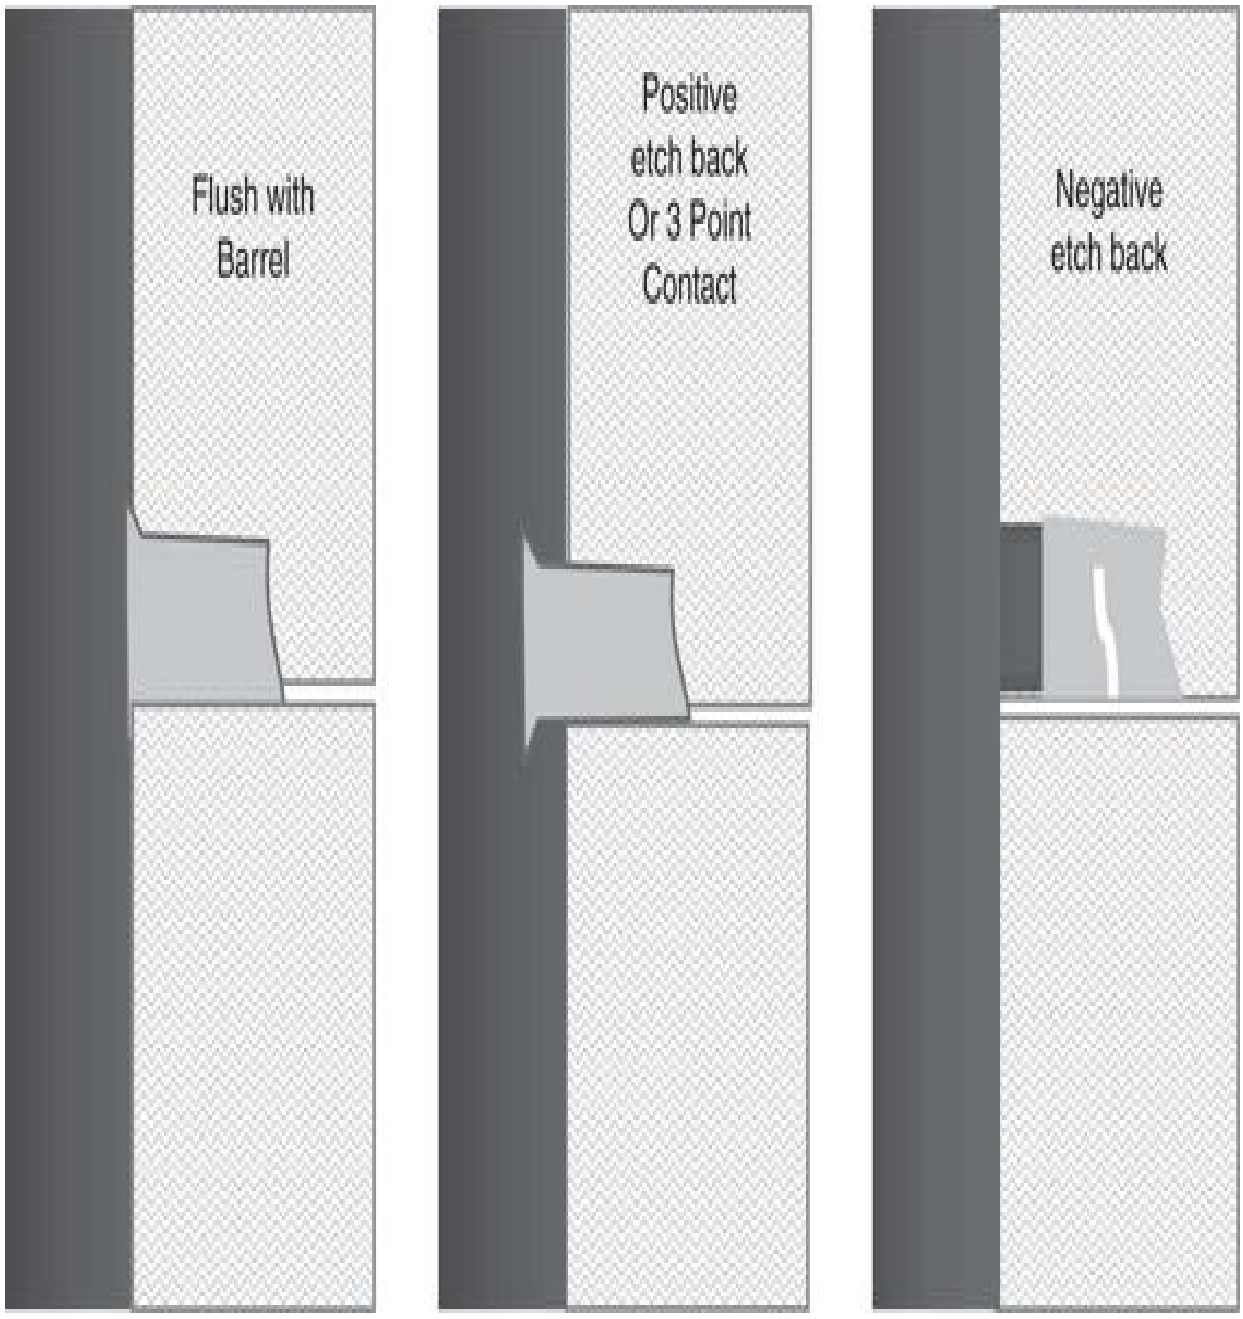

FIGURE 60.47 Three types of internal interconnections with decreasing reliability from flush to negative etch back.

Reid states,[31] although negative etchback is about as robust as flush it appears that the three-point contact has a tendency to cause foil cracks.[31] Furthermore, Reid states that “it is counter intuitive but three point contact is the least reliable” of the copper layer interconnections.[31] This is

due to potential foil cracks of the copper at the internal layer. Thus, the reliability ranking would be; flush, negative etch back, and the least reliable would be the three-point contact.

Also, numerous task groups from the IPC have performed round-robin tests to address PTH reliability including the following.

- PTH barrel cracking has been studied and the results reported in IPC-TR-609: “Round Robin Reliability Evaluation of Small Diameter Plated Through Holes in Printed Wiring Boards.”[17]
- Cu foil characteristics have been reported in IPC-TR-484: “Results of IPC Copper Foil Ductility Round Robin Study.”
- For “gross” failure, thermal stress with microsectioning is performed per IPC-TM-650, “Thermal Stress of Plated-Through-Hole.”
- For “finer” failure, monitoring of a larger number of PTH samples, and objective results with numerical value, the IST test can be use which is documented in IPC-TM-650, Method 2.6.26.

CHAPTER 61

RELIABILITY OF MICROVIA PRINTED CIRCUIT BOARDS

Reza Ghaffarian

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California

61.1 MICROVIA FABRICATION

Vias are formed by many methods, plated through holes (PTHs) are normally made by mechanical drilling followed by plating, whereas microvias are often made by other processes, including chemical means and ablation even though for larger microvias, advanced drilling techniques may be used.[1-6] Because of chemical and ablation limitations, the microvia layers generally do not have glass reinforcement that provides the rigidity needed for handling and end use structural requirement. With advancement in ablation techniques and materials, new procedures are being developed to address this limitation. The key methods of fabricating vias are as the following:

- Advanced mechanical drilling

- Laser drilling with UV-YAG, CO_2 or UV excimer
- Photo definition processing with unsupported photosensitive dielectric
- Plasma etching using a microwave-induced gas plasma

Fabrication of nondrilled microvias may have additional conductive materials replacing either the copper foil or copper metallization.

Mechanical drilling has traditionally been the most widely practiced method of hole creation. However, for creating microvias its use is limited. It cannot be used to generate microvias, and even if it could, its isotropic drilling feature is undesirable. The vertical walls of mechanically drilled holes are straight up and down, making them less desirable for the subsequent plating operations. Other fabrication methods generate anisotropic walls with a larger opening at the top, allowing for a better subsequent wall metallization. The process steps for three major methods of fabricating nonmechanically drilled microvias are shown schematically in Fig. 61.1.

61.1.1 Processes Involved for Fabricating Nonmechanically Drilled Holes

- *Laser ablation:* The laser-ablated formation of vias currently requires the use of nonglass reinforced laminate, such as aramid or resin-coated copper (RCC), for the dielectric. Three different drilling options for forming microvias in use are (1) transverse excitation in atmospheric pressure, (2) excimer laser, and (3) Nd:YAG (neodymium:yttrium-aluminum-garnet). The industry is making major strides to improve the throughput with lasers to make the cost more competitive with mass generation techniques such as photo and plasma vias.
- *Photovia technology:* The photovia approach is based on a photoimaged dielectric, usually a resin, and pattern plating to form the via and circuitry connections. The different photovia approaches can be broken down into three categories determined by the metallization process: (1) panel plate, (2) pattern plate, and (3) full-build pattern plate.
- *Plasma etching:* Plasma-etched vias rely on the use of copper clad nonglass reinforced laminate, such as polyimide or epoxy resin–coated copper (RCC) for the dielectric. The copper foil is used as a conformal mask to define the via openings in the process.

Paste via technology is another category that is widely used to produce via interconnections for commercial applications. Two common technologies in this category are ALIVH™ (Any-Layer Interstitial Via Hole), which is a

trademark[1,2] and B^{2}it^{TM} (Buried Bump Interconnection Technology, another trademark).

Table 61.1 and show the compatibility of via formation by the three techniques: laser, photo, and plasma, on four basic surface dielectric structures.[1,3] Laser vias can be produced in all four structures, whereas use of the other two techniques are limited. This is one reason why laser vias are more widely used. Table 61.2 shows a number of HDI design rules presented in IPC-2315 [1].

TABLE 61.1 Compatibility of Via Formation by Various Techniques

	Standard Configuration	RCC	Thermally Curable Resin	Photoimageable Resin
				Photo via	No	No	No	Yes
Laser via, CO_2	Yes?	Yes?	Yes	Yes
Laser via, YAG	Yes	Yes	Yes	Yes
Plasma via	No	Yes?	No	No

TABLE 61.2 Example of HDI Design Rules Illustrated in IPC-2315[1]

Feature	High Yield/Low Cost, µm (mil)	Common, µm (mil)	Top-Level Fabricator, µm (mil)	Exotic Fabricator, µm (mil)
Microvia hole diameter at target land, no plating	125–200 (5–8)	100–200 (4–8)	75–250 (3–10)	35 (1.5) min
Microvia diameter at capture land	350 (14)	300 (12)	250 (10)	150 (6)
Trace spacing on rigid outer layer	125 (5)	100 (4)	87 (3.5)	5 (2)
Minimum HDI dielectric thickness	75 (3)	62.5 (2.5)	50 (2)	25 (10)
Minimum aspect ratio	< 1.0	1.0	1.0	1.3 min
Minimum plated thickness	25 (1)	25 (1)	30 (1.2)	(1.20)

61.1.2 Microvia Failure Mechanisms

Figure 61.2 shows schematically a microvia with several common key failures and locations. The most common failure modes are a separation between the microvia base and the target pad, followed by a barrel crack and a corner crack. Occasionally, a pull-out failure occurs due to a circumferential crack around the via base.[4] The buildup interconnects are stacked microvias or stacked microvias on buried vias, where they are also copper capped as part of the electronic circuit. Stack microvias show additional failure modes and a greater tendency for corner cracks, particularly with the copper filled version. The extra failure modes require a mature process that is in balance in order to produce robust buildup structures.

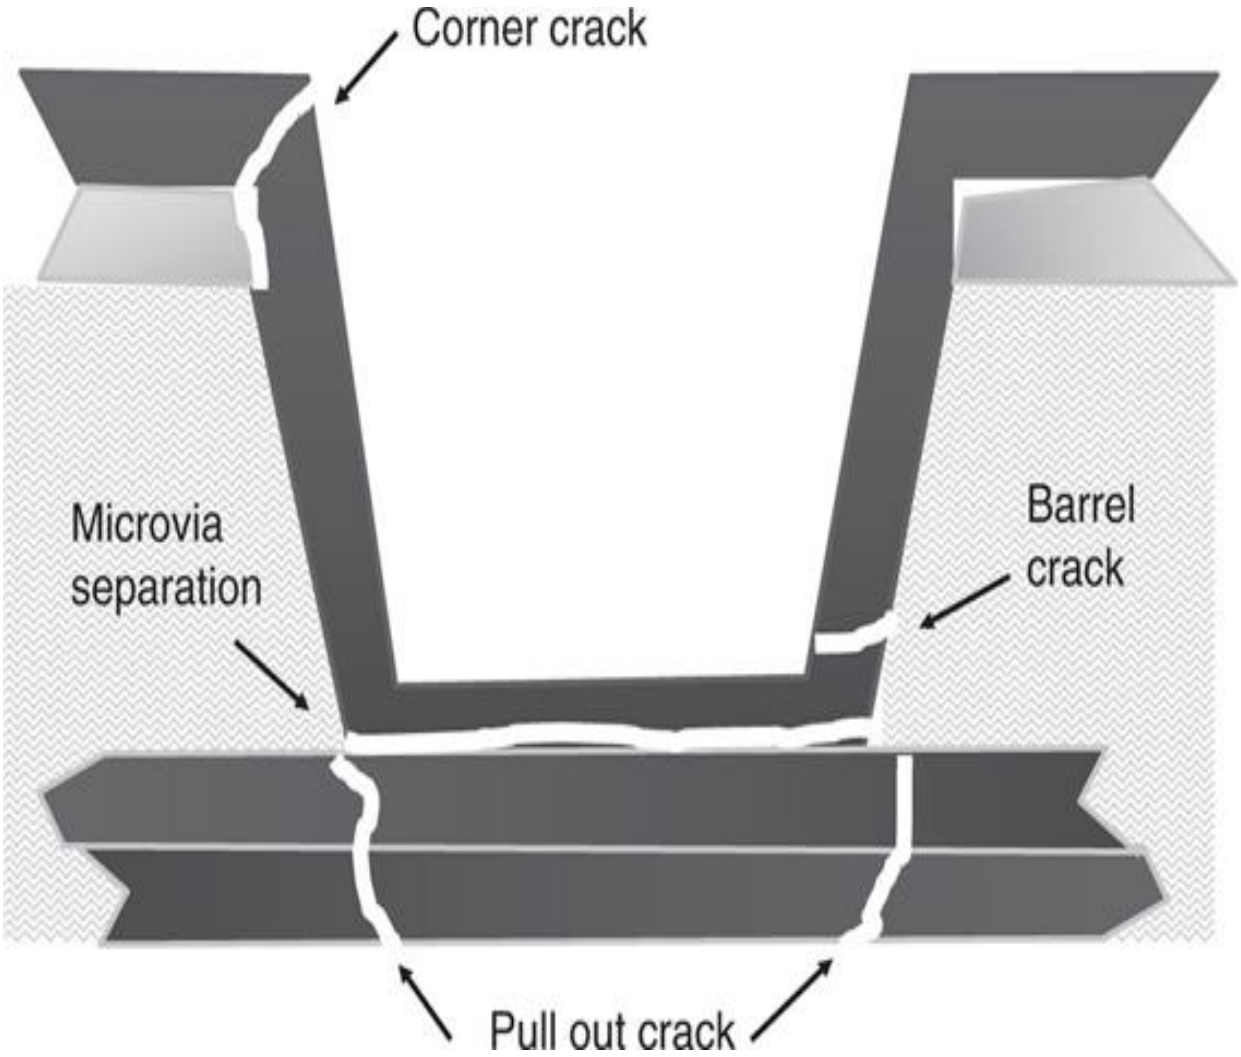

FIGURE 61.2 Common failure mechanisms for plated-through hole vias.

61.1.3 Microvia Reliability under Thermal Cycling

Microvia reliability covers two key areas: (1) the reliability of the printed circuit board (PCB) with microvias as formed and its resistance to normal assembly processes and subsequent user applications, and (2) after assembly, the effects of via-in-pad microvias on solder voids and the effect of the via structure on use conditions, including exposures to thermal and mechanical exposures. In late 1990, ITRI (the former

R&D division of the IPC) established limitations in size fabrication and relative reliability of various microvias. Further, more recent investigations on this subject are first discussed followed by the results of an internal thermal cycle testing.[5,6] Reliability modeling approaches and projections are also presented.

61.1.4 Microvia Voiding

One of the main assembly issues for the via-in-pad (ViP) microvias is the formation of voids in solder joints. Blind ViP is the most efficient routing to accommodate high-density interconnects, especially for area array packages with pitches lower than 0.8 mm (32 mils). Voids could result when gases trapped in microvias do not escape during reflow. A number of authors[7,8] investigated the effects of package pitch size, board design (including microvia sizes and surface finish), and assembly process parameters on the formation of voids. Their findings for tin-lead solder are summarized as follows:

- With the exception of 1.27 mm (50 mil) BGAs, as the pitch decreased so did the occurrence of voids.
- The smaller the microvia size, the smaller the void size. The centered and off-design microvias had the most voids, whereas the copper-filled and inverted microvias showed virtually no voids.
- Electroless nickel immersion gold (ENIG) surface finish PCBs tend to generate more voids compared to IAg (immersion silver) and organic solder preservative (OSP) finish; ENIG with 25 percent higher voids than IAg. In addition, with ENIG, voids were present at the component site after the first reflow and moved to the PCB site after the second reflow.

- A reflow profile with extended soak above 150°C, a lower peak reflow temperature, and a shorter reflow time were all effective to some extent in reducing voids. Conversely, solder paste type, solder particle size, and double-pass paste printing had a minimum effect on voiding. The addition of silver to tin-lead eutectic solder paste decreased void size.
- The 4-mil ViP accounted only for 6 percent of the total voids, whereas the 150- and 200-µm (6- and 8-mil) ViPs had equally high void percentages with 40 and 46 percent, respectively. Microvias with one layer of depth accounted only for 12 percent of the total voids, whereas those with three layers of depth (layer 1 to layer 3) accounted for 56 percent of the total voids.
- The thinner the PCB, the more voids produced.

For SnAgCu (SAC) solders, the voiding rate arising from microvias was studied by simulation.[9] It was shown that the lowest voiding was for Sn95.5Ag3.8Cu0.7 and Sn95.5Ag3.5Cu1.5. The voiding rate increased with decreasing Ag content from Ag3.5, mainly due to increasing surface tension. Voiding arising from microvias was governed by via filling and exclusion of fluxes. The voiding rate decreased with decreasing surface tension and increasing wetting force, which in turn was dictated by the solder wetting or spreading. Both low surface tension and greater solder wetting prevented the flux from being entrapped within the microvias. A fast wetting speed might also facilitate reducing voiding. However, this factor is considered not as important as the final solder coverage area.

61.1.5 Microvia and PTV Failures

Microvias as part of the PCB design are exposed to thermal stresses during manufacturing and applications. These

exposures may be either prolonged at an elevated temperature or isolated with repeated temperature cycles. These exposures could lead to PCB and microvia failures. The most important sources of thermal stresses are

- Thermal shocks and thermal cycles during PCB manufacturing. The thermal shock occurs when an assembly is exposed to rapid changes of temperature causing transient temperature gradients, warpage, and stresses within the part and/or assembly. The rate of temperature change for thermal shock is usually greater than 20°C/min (see, e.g., IPC-9701A).[10] Processes that can induce this rate of temperature change are solder mask cure and HASL (hot-air solder leveling).
- Thermal shocks and cycles occurring during assembling the PCB. Examples are glue cure, solder reflow, wave soldering, and rework using soldering irons, hot air, or molten solder in a pot.
- Thermal cycles in service. Depending on the application, these can be severe or mild, but include temperature changes from inside to outside the electronic box and component local temperature rises due to functioning internal electronics.

Two key issues are important in reliability of microvias. These are (1) the continuity of plated microvias providing interlayer connections and (2) the insulation among different nets. Similar to the PTH, but to a lesser extent, microvia failures occur due to thermal strains induced due to CTE mismatch between the plated microvia and the resin.

Manufacturing issues and board-level reliability were studied for a 0.4-mm (16-mil) pitch FPBGA, where microvias exist both in the package substrate and the PCB.[11] Results were compared after thermal cycling, drop testing, and mechanical bending. ViP package substrates showed better resistance to thermal cycling by 20 percent relative to non-

ViP (NViP) package substrates. Failures were both microvia and solder-joint cracking (see Fig. 61.3). ViP/NViP combination showed excellent drop performance with the first failure after 148 drops whereas ViP-ViP combination showed poor performance with failure after seven drops. In contrast, the best bend cycling results were for the ViP-ViP followed by the NViP-ViP combinations.

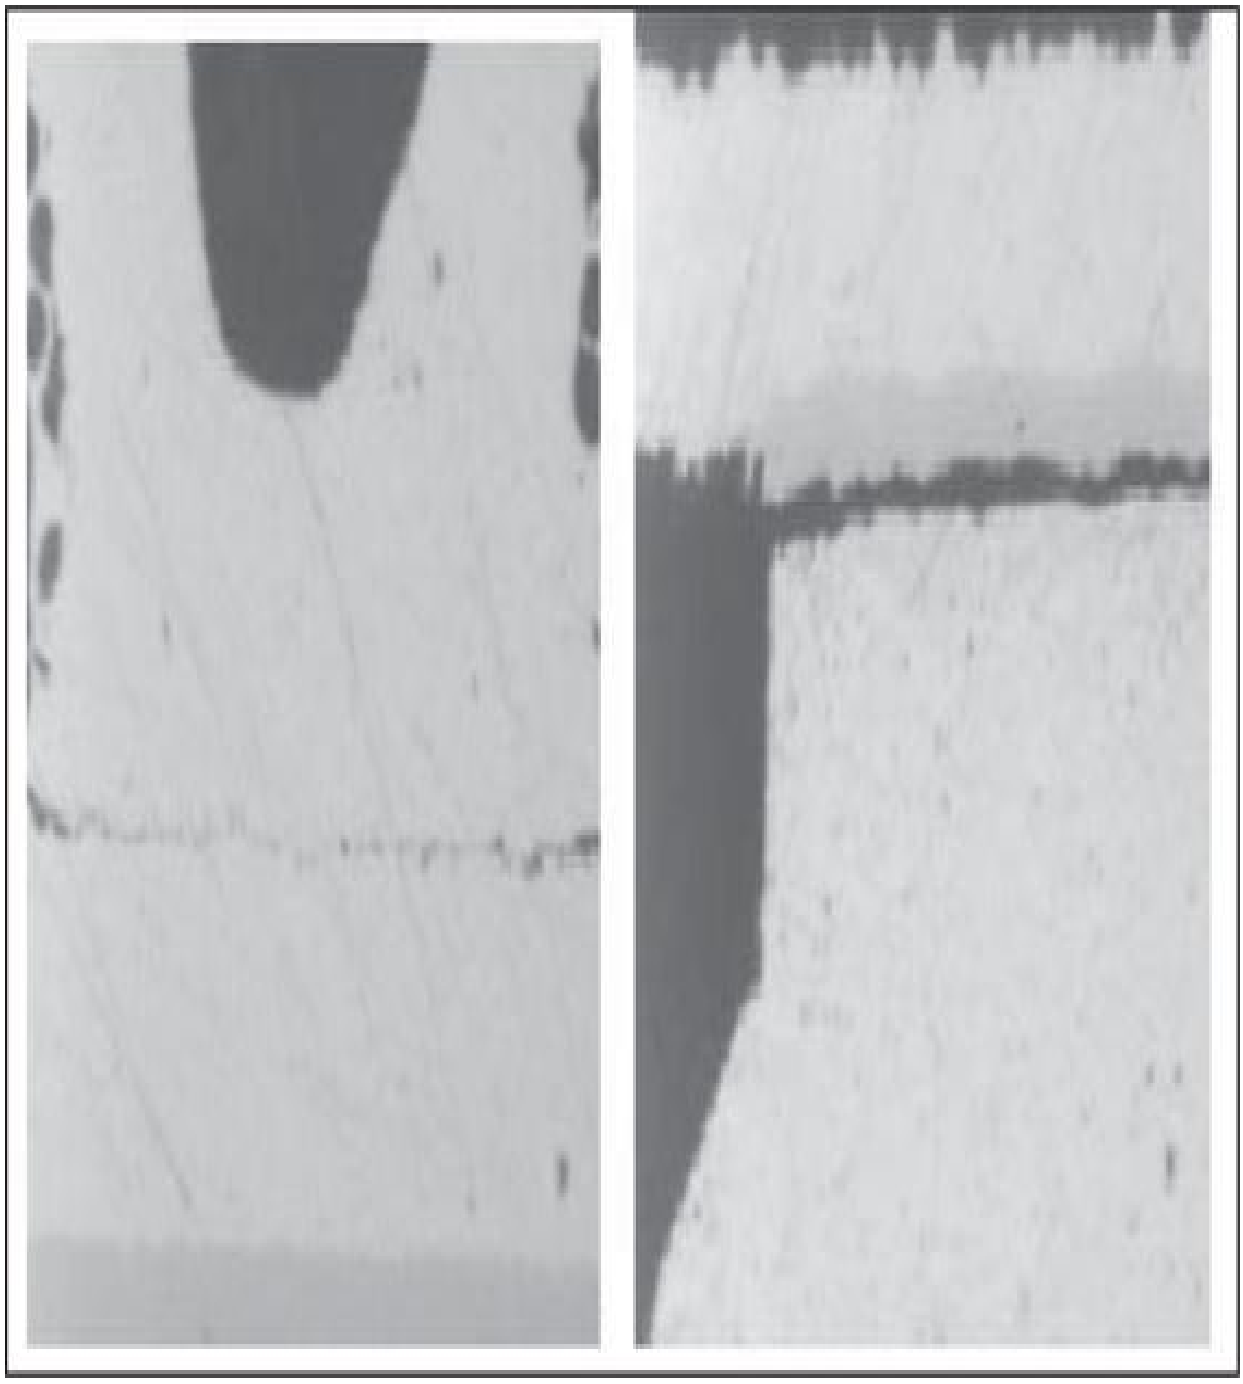

FIGURE 61.3 Package-via crack and solder-joint crack during drop test.[11]

The effect of ViP on the mechanical cycle bending behavior was investigated for 196 I/O Globtop PBGA packages with 1-mm (40-mil) pitch that were assembled onto PCBs with ViP structure.[12] Test results in conjunction with finite element

analysis indicated that the ViP structure by itself does not pose a reliability risk. However, increased applied loads could induce dielectric cracking that in turn could lead to trace and via failures.

The proximity of microvias to PTHs and its effect on the reliability of microvias was evaluated[13] under exposure to liquid-liquid thermal shock (LLTS) in the range of −55/125°C with 10 s in transition. Results indicated (see Table 61.3) that the maximum failures were from the vias at a distance of 1 mm (40 mils) [1.5 mm (60 mils) center-to-center distance from 0.5 mm (20 mils) PTH] from the PTHs. In addition, few failures were found in the vias at the distance of 125 µm (5 mils) from the PTH. The first failure was after 1100 LLTS cycles.

TABLE 61.3 Thermal Cycle Resistances of Microvias for Various Via Formation Technologies[1]

Via Hole Formation Technology	Dielectric Material	Failure Mechanism
YAG laser	Glass reinforced	No failure to 2000 LLTS (−55/125°C, 10 s transition)
YAG laser	Nonreinforced	Crack at the via pad interface
YAG + CO_2 laser	Glass reinforced	Improper cleaning of the glass fibers crack through the via
Photodefined	Nonreinforced	Crack at the via pad interface

Andrews, Parry, and Reid found that double-sided, PCB SMT assemblies for high-end use showed intermittent opens during electrical testing.[14] Using an IR technique, they were able to narrow failures to microvias. Cross-sectioning revealed a target pad to copper plating separation at the bottom of microvia. Further investigation showed that a

small percentage of microvias exhibited barrel cracks, and sometimes, knee corner cracks.

Having marginal microvia coupons, an IST study was conducted to determine the most effective testing parameters. After five cycles of preconditioning of coupons at 230°C, the coupons were tested to maximum temperatures of 150, 170, 190, 210, and 220°C. The mean cycles to failures were 1000, 789, 464, 76, and 44 cycles, respectively. For the 190°C maximum temperature dwell, the mean cycles to failure was less than 500 cycles; therefore, this temperature was selected for subsequent thermal cycling for a Pb-free board process assembly. Failures for 210°C and above included those of knee crack, material delamination/break down, and barrel cracks that are considered to be testing artifacts; and therefore, these temperatures are unacceptable for qualification to represent realistic environment.

Phenolic-based FR-4 coupons with microvias passed 1000 IST thermal cycles at 190°C after five times at 230°C. The effect of the lead-free reflow profile at 260°C conditioning on microvia degradation was severe. The coupons that were able to achieve 788 cycles at 150°C were reduced to a mean of 443 after 6 times at 230°C cycle and only four cycles after lead-free preconditioning, six times at 260°C.

Bora evaluated ALVIH-G board technology used for cell phones having a double stack of microvias on the outer layers.[15] The microvias were laser drilled, and the interconnection was conductive copper paste. The typical design rule was 100/100 microns line/space and 200/400 via/land. Reliability of a double-sided surface-mount assembly through two reflow operations and one rework using an eight-layer thin board [0.8-mm (32-mil) thick] epoxy glass with low moisture absorption instead of aramid that has a higher moisture absorption. Assemblies with BGA passed 500 thermal shocks in the range of −25 to 125°C and a 1000-h humidity test at 85°C/85 percent. Cross-sectioning

revealed graininess of solder after thermal shock with no separation of the microvia connection to the capture pad. In addition, no layer-to-layer separation was observed when the phone level drop test was performed at 1.5 m on a hard vinyl surface.

The effects of voids on reliability of filled microvias were investigated.[16] It was shown that void shape and void size are the two important parameters affecting the degradation of microvias. Voids with a larger size, but rounded corners, were less susceptible to cracking than voids with a smaller size, but sharp corners (see Fig. 61.4). The failure mechanism was identified as low cycle fatigue, where plastic deformation occurred at locations with a stress concentration. Two (out of 65) of the nonvoided samples degraded sooner than 22 (out of 29) of the voided ones. This indicates that voiding could be beneficial to microvias in some cases by relieving stresses.

In another investigation on the effect of via-in-pad (ViP), it was demonstrated that thermal cycle reliability for Pb-free SAC alloy depends on the particular device package type.[17] For BGA, reliability decreased with the use of ViP (see Fig. 61.5). Specifically, for the BGA192, it was found that the average void percent, including undercorner solder balls, was roughly four times greater for the VIP construction than the non-VIP construction.

FIGURE 61.5 Weibull plots of the BGA192 failure data with ViP and no ViP.[17]

The authors believed that voiding associated with the conformal microvias to be the cause of the reduced solder-joint life even though the failure analysis results were not conclusive. The impact and size of the void is a function of the component type, solder ball size, microvia drill size, and laminate thickness. The voids in the fatigue crack path have a greater potential impact on solder-joint reliability than their sizes. Therefore, a greater number of voids in microvias for Pb-free than for SnPb indicates a lower life performance for Pb-free solder-joint assemblies.

In a comprehensive study,[18] both x-ray and visual inspection were utilized to characterize behavior of fine to standard microvias and nonfilled and filled vias. Figure 61.6 shows optical photomicrographs of acceptable (top) and unacceptable (bottom) microvias chosen from the two PCB lots. A number of microvias were designed with a daisy-chain configuration to monitor their integrity during environmental testing. Figure 61.7 shows representative daisy-chaining in three photomicrographs taken by optical microscopy and x-ray. Apparent in the figure are two of the daisy-chain microvias (filled) with 3- and 4-mil diameters showing darker images by x-ray, whereas the 2-mil microvias are unfilled (top row daisy chain).

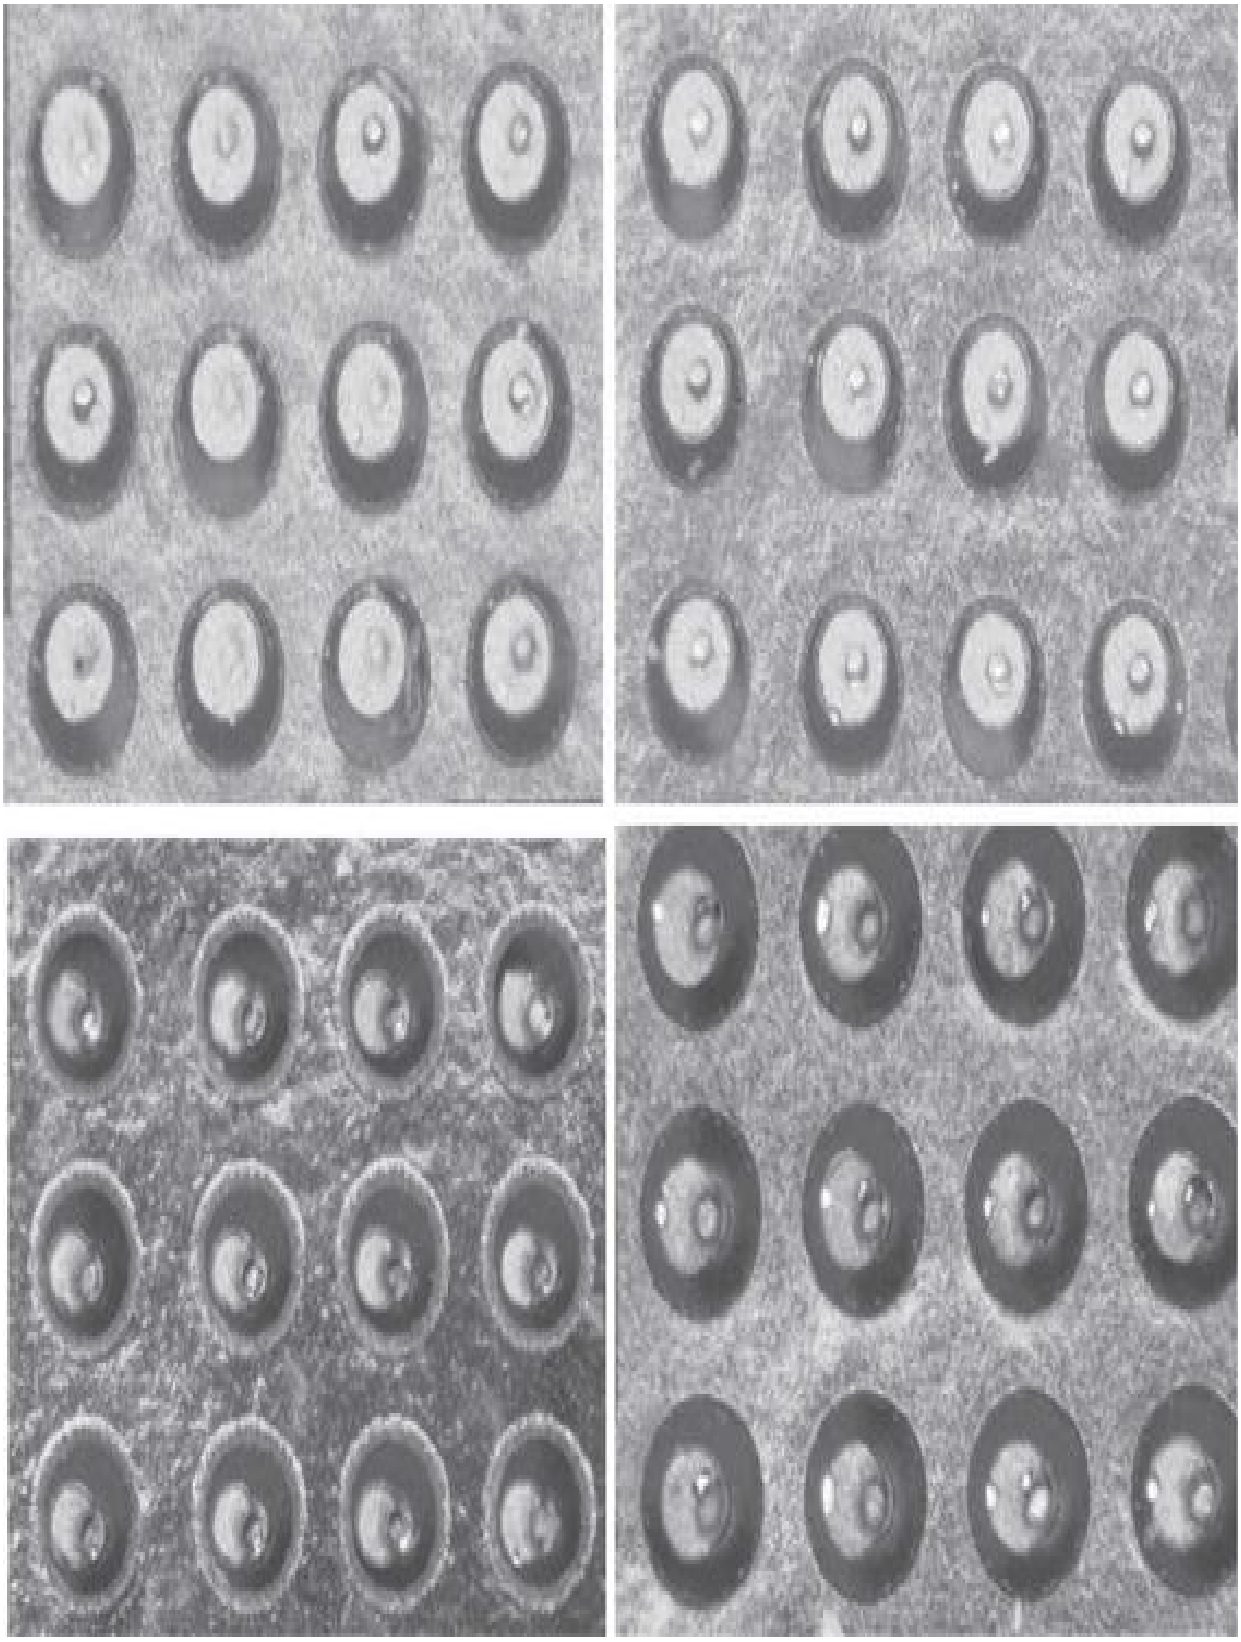

FIGURE 61.6 Optical photomicrographs of acceptable (top) and unacceptable microvias.[5]

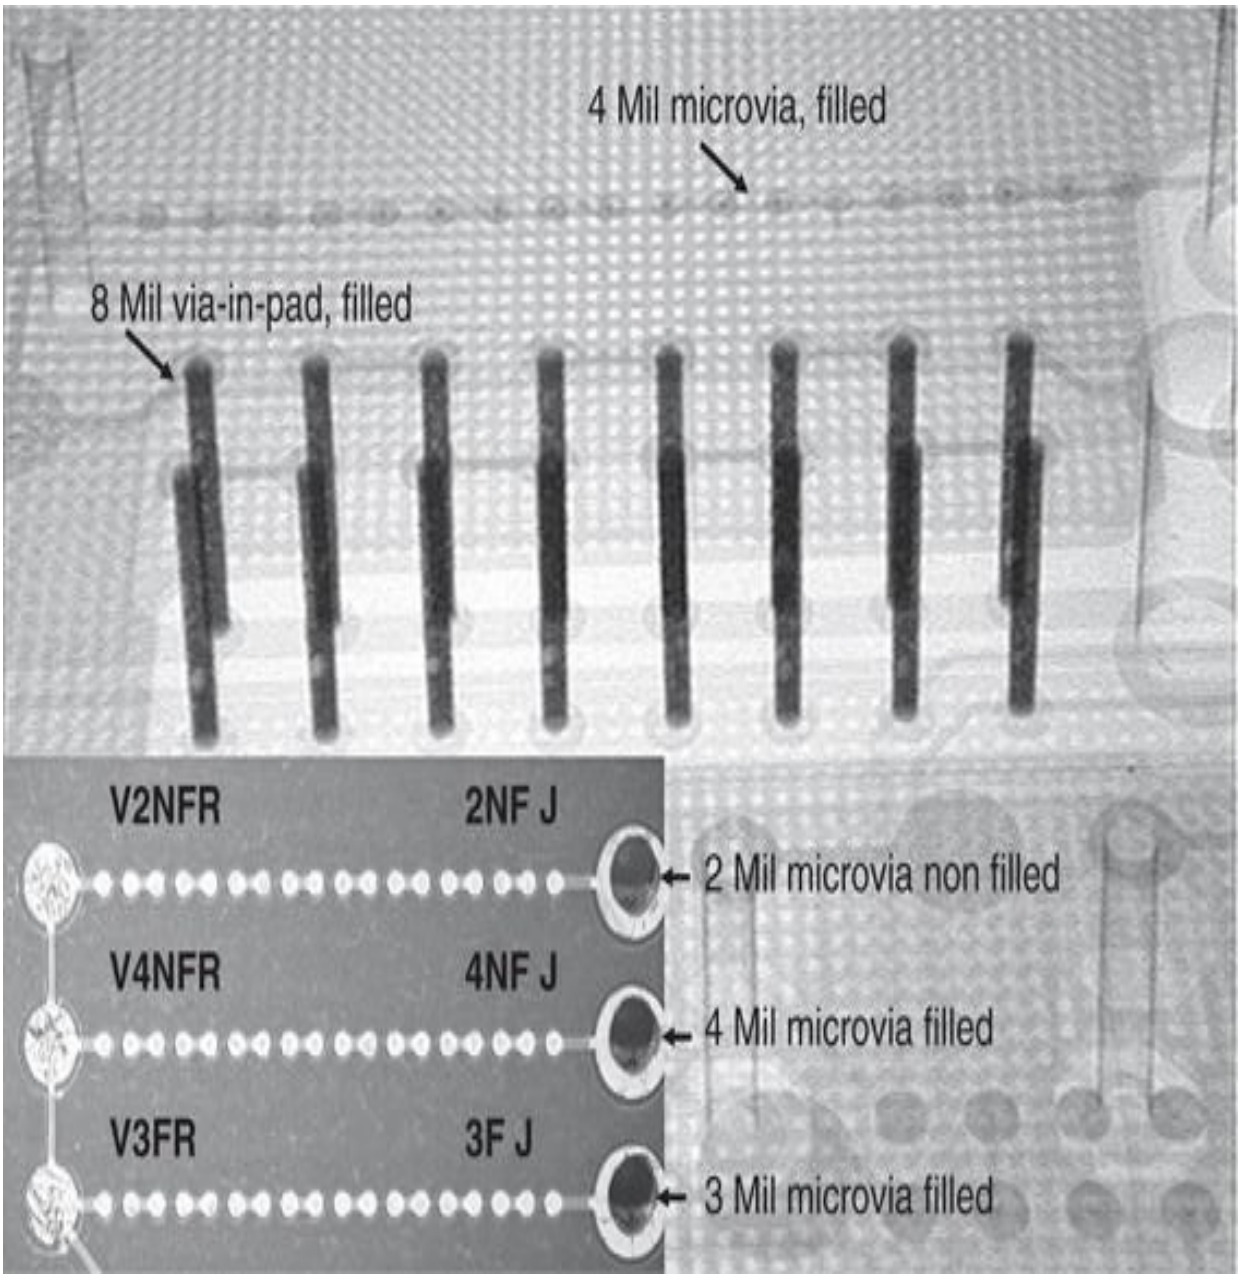

FIGURE 61.7 X-ray and optical photographs of daisy-chain microvias, filled (dark) and unfilled vias.[5]

Even though optical inspection and photomicrographs can provide some insight as to the quality of microvias, because of their fine sizes, other more power techniques (such as

SEM) are required to be performed to better characterize failure mechanisms and failure. A representative SEM photomicrograph showing failure is included in Fig. 61.8.

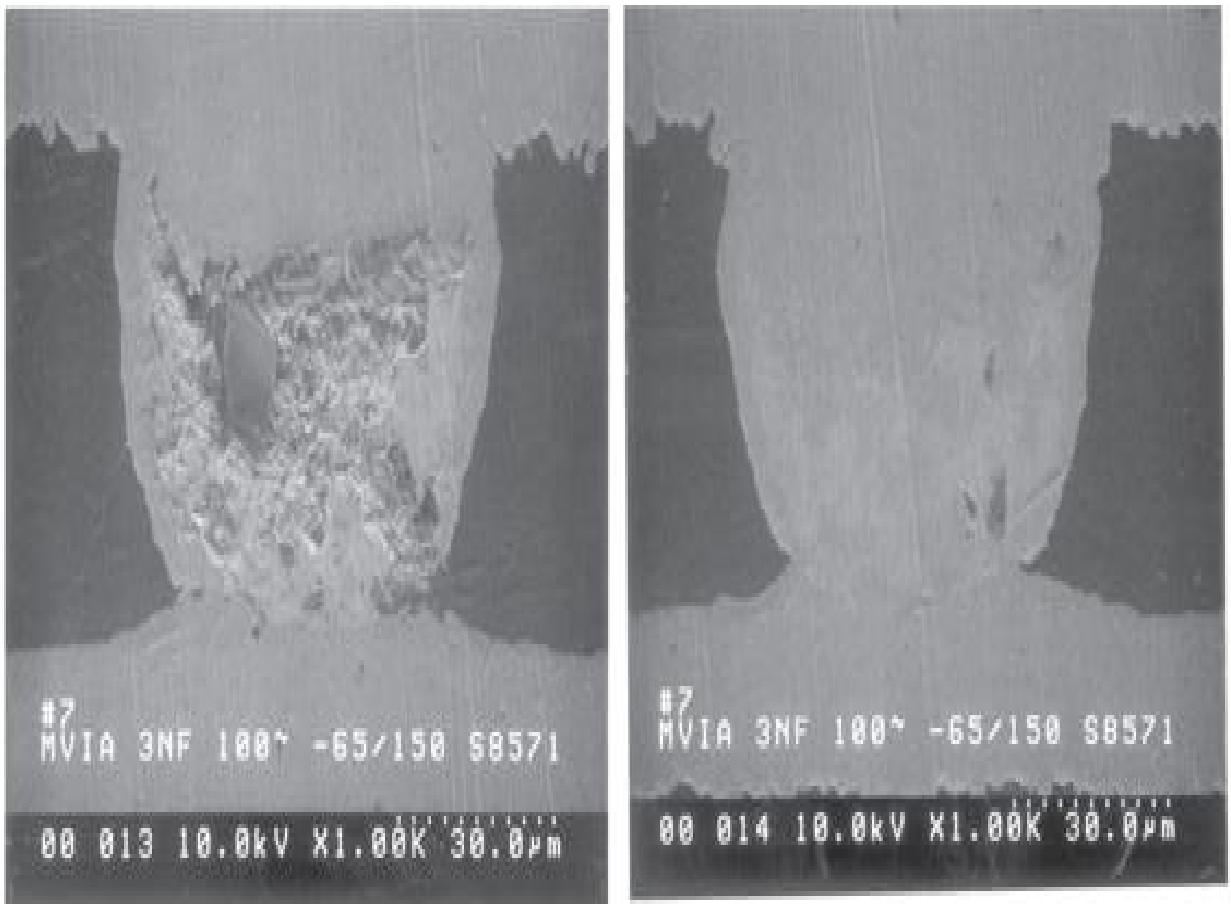

FIGURE 61.8 SEM photomicrogrphs showing cross-sections of a 3-mil, nonfill microvia after 100 thermal cycles (−65/150°C). Note, both microvias are filled even though a nonfill condition set.[5]

Figure 61.9 shows thermal expansion (CTE) for the *z, x*, and *y* directions, respectively. The CTE for the *z* direction is 43.21 ppm, which is about three times that of the *y* and *x* directions having values of 14.62 and 12.83 ppm, respectively. Above the T_g, the CTE in the *z* direction significantly increases and become 297.7 ppm. The T_g of the PCB is about 145°C (146.71°C). The T_g experiences significant changes detected about 260°C. After exposure to

this temperature, the sample was cooled to RT, and it was noticed that the PCB had delaminated. It was presumed that at lower temperatures—even with repetitive exposure—delamination would not occur.

61.1.6 Microvia and Stack Reliability Modeling

Microvias and stack microvias are currently used for package substrates and PCB package assemblies. Readers should refer to other publications[19,20] for high-density interconnect (HDI) and through silicon via (TSV) 3D packaging technologies. For microvias used in PCBs, they are usually the most robust interconnections when considered on their own.[4] There are three types of microvias: (1) surface-mount microvias, (2) stacked microvias, and (3) buried vias (see Fig. 61.10). The most robust microvia is a surface microvia without a fill material followed by a buried microvia filled at "b-stage." The least robust are microvias with a third fill material and copper-filled microvias. It appears that copper-filled microvias are just too new and have a tendency to have corner cracks. It should be noted that stand-alone microvias with caps or without caps have no advantage, or detrimental effect, if the process is robust.

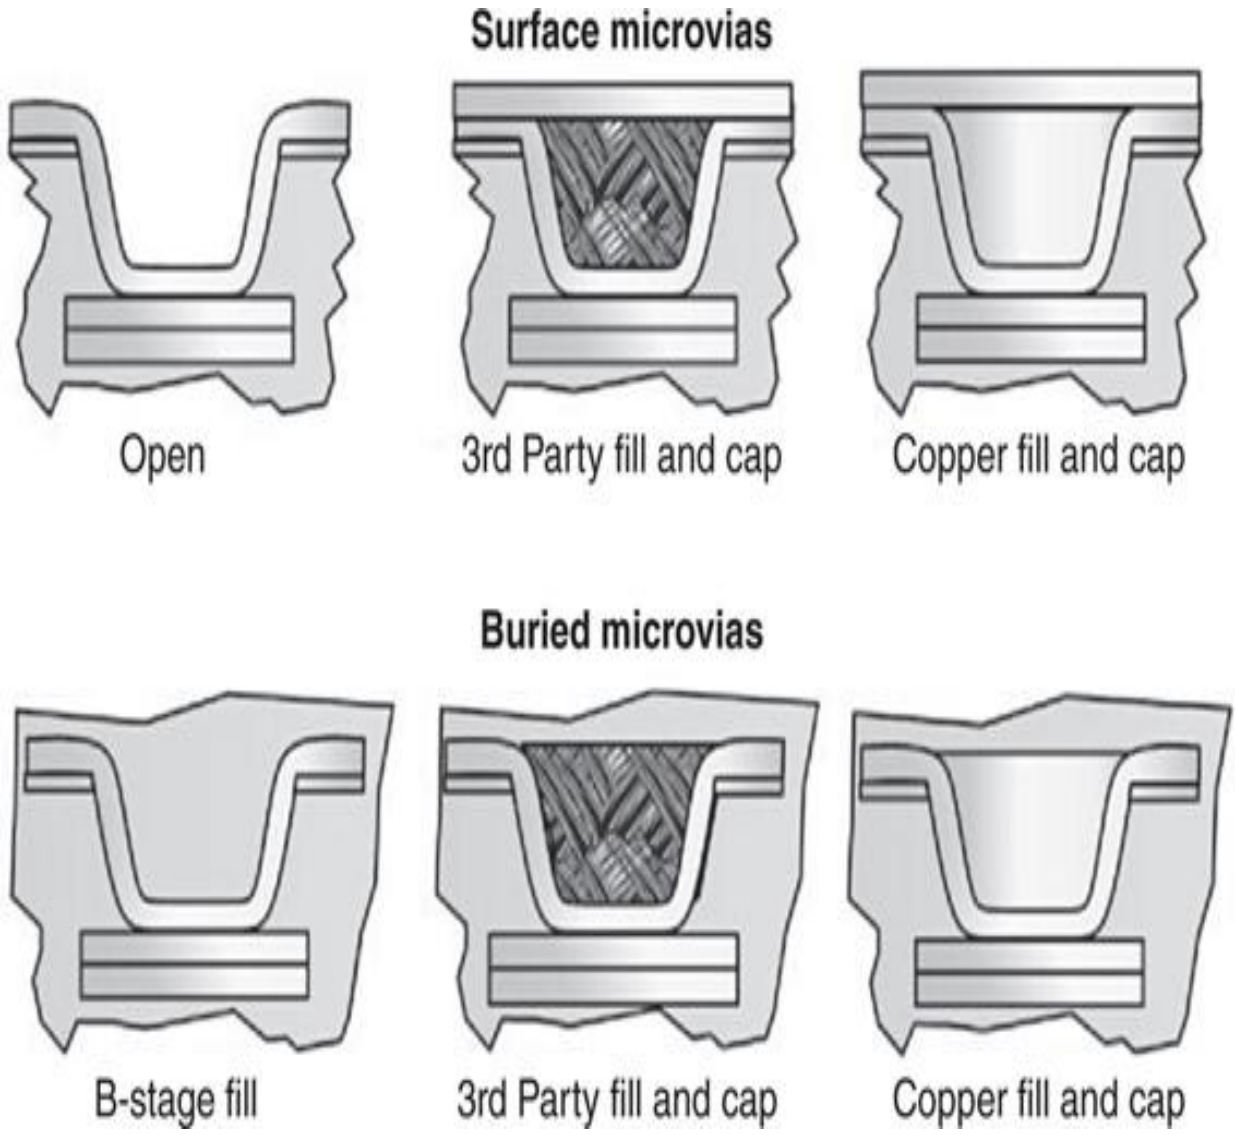

FIGURE 61.10 Three types of via fills—external and internal microvias.[4]

Improvement and control of copper plating processes was found out be a key factor for improving yield and reliability of microvias.[21] A finite element model was developed to perform a systematic analysis of the various geometric parameters of the microvias. Figure 61.11 shows the variation of TSR as a function of the diameter of the microvia. As the microvia size decreases, the TSR increases. Therefore, this leads to a lower fatigue life for the smaller microvias. It should be noted that the above study was carried out for a given dielectric thickness of 70 μm (2.75

mils). It was shown also that increasing the wall thickness of the microvia reduces the value of TSR. For 20 μm (0.78 mils) thickness, the microvia has hardly any plastic strains; therefore, they will fail due to high cyclic fatigue.

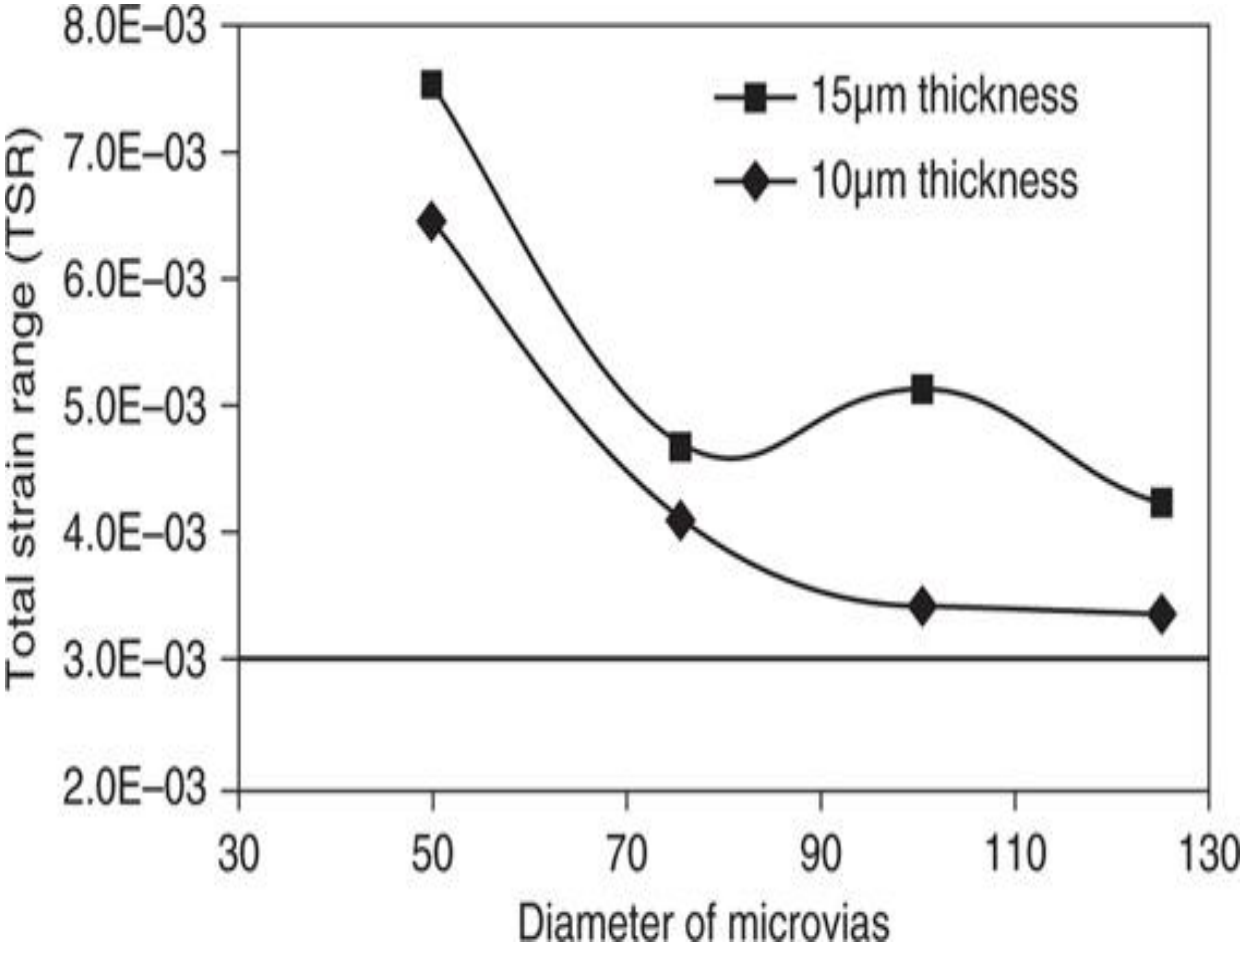

FIGURE 61.11 The variation of TSR as a function of diameter of the microvia.[22]

Analytical modeling was carried out to determine the effects of microvia buildup PCB on the wafer level chip scale packaging assembly (WLCSP). The diameters of the microvias were varied from 0.1 mm (4 mils) to 0.15 mm (6 mils) (see Fig. 61.12). Solder-joint reliability was modeled using time–temperature-dependent nonlinear analyses for Pb-free (96.5Sn–3.5Ag) and tin-lead solders (62Sn–2Ag–

36Pb). Modeling analyses showed the following effects of microvias in a WLCSP assembled onto a PCB.

FIGURE 61.12 Detailed geometry of two-dimensional (2D) finite element mesh for WLCSP assembly.[21]

- A microvia reduces the global deflection of the assemblies and increases the local displacement of the solder joints.
- A microvia increases the shear stress range, shear creep strain range, and creep strain energy density range in the solder joints. These parameters were slightly larger for 96.5Sn–3.5Ag than 62Sn–2Ag–36Pb.
- A microvia reduces the thermal fatigue life of the solder joints.
- The maximum stress in the microvia under thermal loading was less than the ultimate strength of the electroplated copper. Also, the maximum strain in the microvia was rather small.

Wong et al. performed an experimental study to design, fabricate, and test various configurations of microvias over the military thermal environmental range.[23] The parameters were solder mask on printed wiring board, microvia pitch, and microvia size, with each having either two or four levels of variation. The test vehicles were subjected to temperature cycling from −55 to 125°C with continuous monitoring of microvia integrity using a daisy chain configuration. The destructive physical analysis (DPA) results showed that (1) the smaller the microvia sizes, the higher the occurrence of manufacturing defects; (2) the microvias, having electrical continuities before the test, can survive 1000 temperature cycles; and (3) there is no influence or inclusive observation of the microvia pitch variation on the microvia fatigue damage. In addition, a thermomechanical analysis with nonlinear finite element computer code applied in a 100-μm-diameter (40-mil) microvia was performed to illustrate this microvia integrity when subjected to thermal cycling.

The model consists of 1333 elements and 1413 nodes. In the FEA, the effective strain of the copper barrier was calculated using an isothermal model, which started at 25°C

(strain-free temperature) and cycled from –55 to 125°C. The contour plots of the effective strains at −55 and 125°C are shown in Fig. 61.13. The fatigue life prediction model was based on the semiempirical model, IPC-TR-579, which relates the amount of copper strain range developed to the number of cycles needed to induce copper failure. The microvia thermal fatigue life was predicted to be 2607 cycles. The author stated that this, “agrees with the test observation that the microvia survived 1000 cycles without failure.”[23]

Modeling analysis was carried out to determine the reliability effects of single and stack microvias under thermal cycle conditions of −40 to 150°C.[24] Stack microvias were assumed to be either vertically stacked on resin filled PTH (RFP) or were offset to the side of RFP. Analysis showed that as the number of stack microvias increased, the stress on the bottom microvia's corner increased (see Table 61.4). Figure 61.14 shows plots of stress versus strain for increasing microvias. The offset stack microvia showed a lower stress, it decreased from 37 kgf/mm^2 [~53 ksi (1000 lb/in^2)] to 30 kgf/mm^2 (~43 ksi).

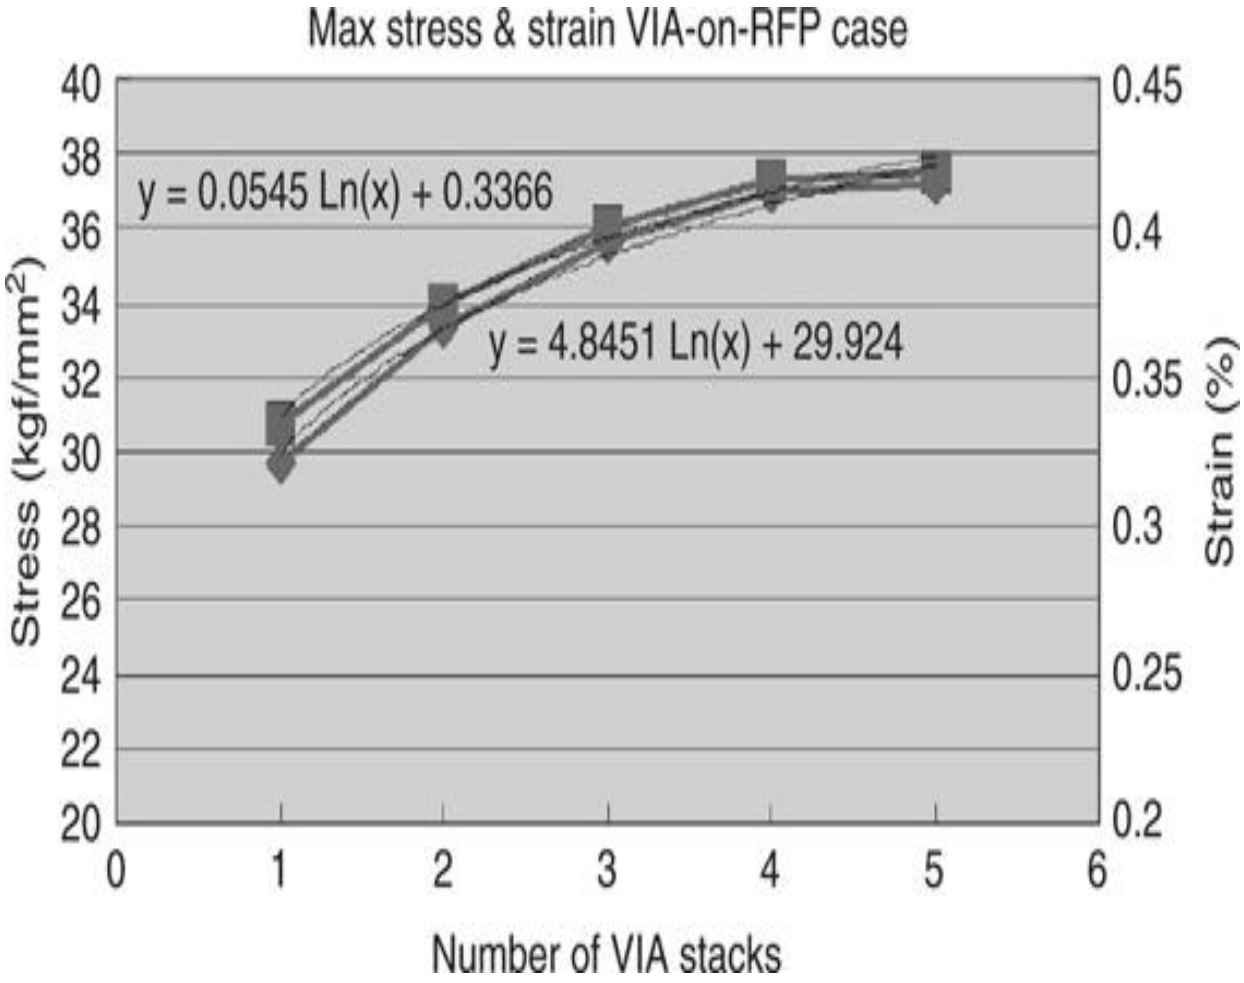

FIGURE 61.14 Maximum stresses and strains versus number of stack vias.[24]

Stack microvias show complex behavior under thermal stresses. For the stacks of three or more microvias, the microvia pad rotation was reversed on the stacks of three or more microvias.[4] The pad rotation was downward for the individual or staggered microvias (see Fig. 61.15); however, the pad rotation became upward for the stacked microvias. The stacked microvias, especially copper-filled ones, show greater tendency for corner cracks. It was shown experimentally that the stacked microvias were two orders of magnitude less robust than the staggered microvias.

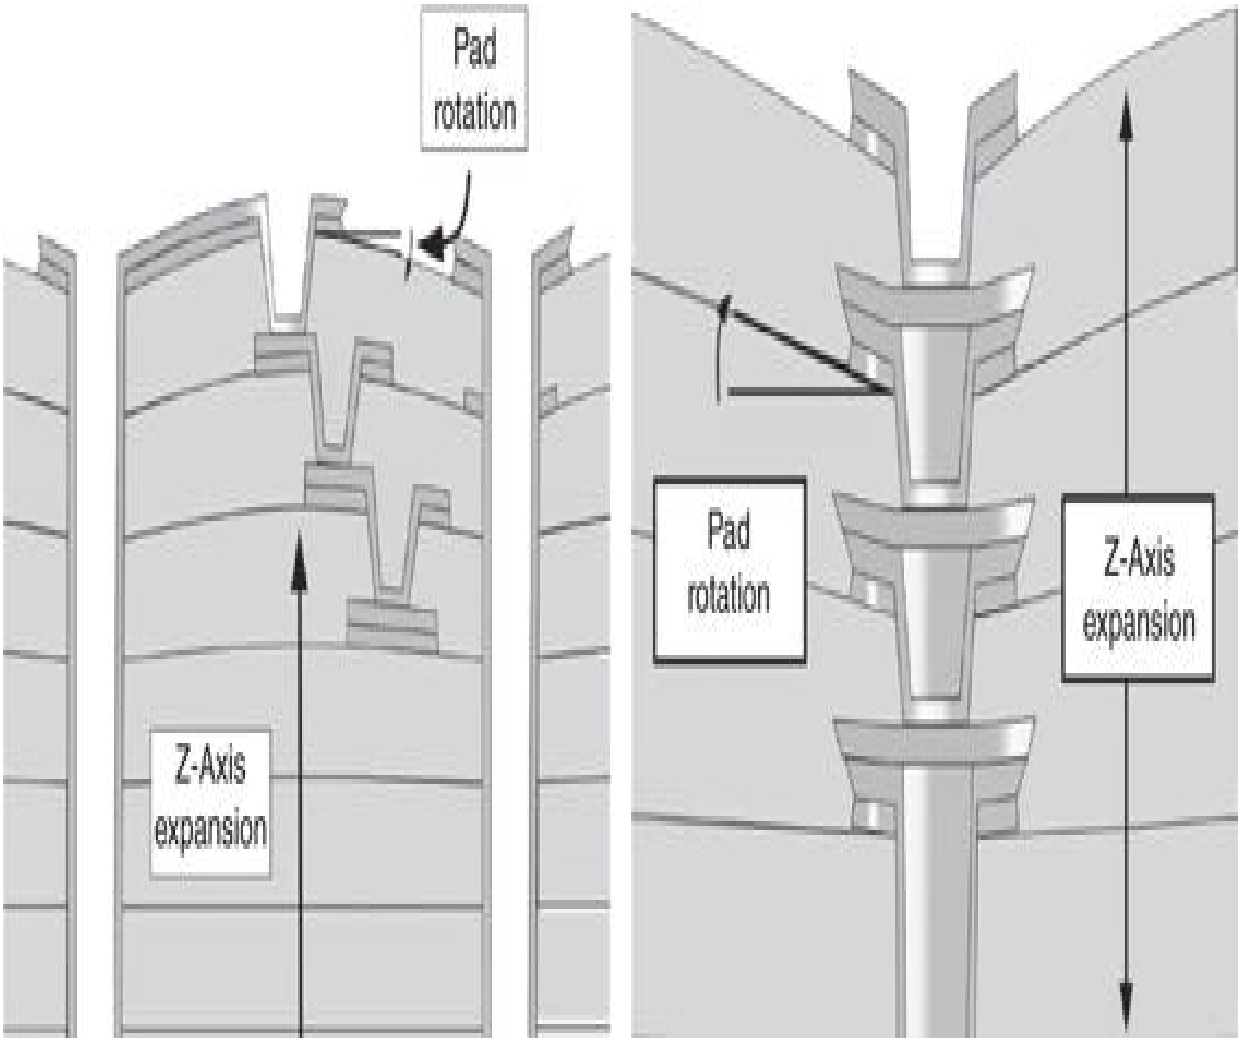

FIGURE 61.15 Pad rotation in stacked versus staggered microvias.[4]

61.1.7 Key Findings on Microvia

Key findings on microvia and plated via are summarized below. These include

- Microvia reliability involves two aspects: (1) failures due to routine PCB microvia formation and subsequent assembly processes and (2) failures due to void formation in the solder with subsequent failure during field thermal and mechanical exposures.

- Regarding microvia reliability, in the late 1990s ITRI (once part of IPC but now dissolved) with industry-wide participation performed a microvia fabrication feasibility and reliability investigation. This was an important activity with a wide-industry participation.
- Regarding microvia reliability and modeling, only limited work is available in the literature. Presentations included characterization of the effects of various PCBs and manufacturing parameters on ViP void formation at board sites, the combination of ViP/NViP in package substrates and ViP/NViP on PCBs, and the effect of distance of microvias to PTHs.
- Regarding voids in microvias, void shape and void size are the two important parameters affecting reliability. Voids with a larger size but rounded corners were less susceptible to cracking than voids with a smaller size but sharp corners.
- Limited test data indicate that reliability of conformal microvia-in-pad construction is not only device dependent, but it also depends on the solder-joint alloy used. Assemblies showed poorer fatigue life performance for Pb-free solder joints than for SnPb solder joints.
- In early 2000, a consortium successfully built test vehicles having ViP microvias from 50 to 100 μm (2 to 4 mils). Some microvias were filled, and others were nonfilled. These, as well as 200-μm (8-mil) THViPs, were first characterized visually and by x-ray before environmental testing.
- Visual inspection by optical microscopy was more effective in determining the condition of the microvias than x-ray radiography. X-ray radiography clearly identified filled vias, but it was of limited value for detecting other conditions.
- Microvia thermal cycling characterization revealed failure for 50-μm (2-mil) microvias after 100 cycles in the range of

−65/150°C. No failures were observed for larger vias.

- TMA characterization of cycled PCBs revealed that the T_g of the test boards was about 150°C with delamination starting at 260°C. TMA was also used to thermal cycle specimens between −100 and 245°C. The latter temperature is representative of a lower reflow temperature for a Pb-free assembly. After three cycles, no delamination was observed. The samples that were exposed to 260°C; however, did exhibit delamination.
- Microvia fatigue life was predicted to be 2607 cycles using the Cu PTH semiempirical relationship (IPC-TR-579). This agreed with the test observation that microvias showed no failure until 1000 cycles (−55 to 125°C).
- Single and stacked microvias showed a greater tendency for corner cracks, particularly with copper-filled stacked microvias. Staggered microvias were two orders of magnitude more robust than the stacked versions.

61.2 SUMMARY

Reliability of electronic systems is a complex subject. This chapter has touched on only one aspect of the problem: understanding the primary failure mechanisms of printed circuit boards. This approach provides the basis for analyzing the impact of design, materials choices, and manufacturing processes on printed circuit reliability, specifically plated-through-hole and microvia interconnections in tin-lead and Pb-free soldering environment. It also provides the foundation for developing accelerated testing schemes to determine reliability of PTH and microvia. It is hoped that the fundamental approach will enable the reader to apply this methodology to new problems not yet addressed in mainstream literature.

61.3 LIST OF ACRONYMS

ALIVH	Any-layer interstitial via hole
AtA	Air to air
ATC	Acceleration thermal cycle
B_{10}	Bearing at 10 percent, cycles-to-failure at 10 percent
B^2it	Buried bump interconnection technology
BGA	Ball grid array
BT	Bismaleimide triazing
CAF	Conductive anodic filament
CBGA	Ceramic ball grid array
CCGA	Ceramic column grid array
CGA	Column grid array
CIC	Copper invar copper
CMC	Copper molybdenum copper
CSP	Chip scale (size) package
CTE	Coefficient of thermal expansion
CTF	Cycles to failure
Cu	Copper
DfA	Design for assembly
DfM	Design for manufacturability
DfR	Design for reliability
DfT	Design for test
DMA	Dynamic mechanical analysis
DPA	Destructive failure analysis

EMI	Electromagnetic interference
ENIG	Electroless nickel immersion gold
ESD	Electro static discharge
FCDCA	Flip-chip direct chip attach
FCBGA	Flip chip ball grid array
FEA	Finite element analysis
FEM	Finite element analysis
FPBGA	Fine pitch BGA, a.k.a. chip scale package (CSP)
HASL	Hot-air solder leveling
HATS	Highly accelerated thermal shock
HDI	High-density interconnect
I/O	Input/output
IAg	Immersion silver
ILS	Innerlayer separation
IPC	Association connecting electronics industries
IR	Infrared
IST	Interconnect stress test
LASER	Light amplification by stimulated emission of radiation
LGA	Land grid array
LLTS	Liquid-liquid thermal shock
LPI	Liquid photoimageable
MLF	Micro lead frame
MTBF	Mean time between failures
Nd:YAG	Neodymium-doped:yttrium-aluminum-garnet

Nd:YLF	Neodymium-doped:yttrium-lithium-fluorine
Ni	Nickel
NViP	Non-via-in-pad
OSP	Organic solder preservative
PBGA	Plastic ball grid array
PCA	Printed circuit assembly
PCB	Printed circuit board
$PCQR^2$	Process capability, quality, and relative reliability
PGA	Pin grid array
PTH	Plated-through hole
PTHV	Plated-through hole via
PTHViP	Plated-through hole via-in-pad
PTV	Plated through via
PWA	Printed wiring assembly
PWB	Printed wiring board
QFN	Quad flat no-lead
RCC	Resin-coated copper
RFI	Radio frequency interference
RFPC	Rigid flex printed circuit
RH	Relative humidity
RMA	Rosin mildly active
RT	Room temperature
SBU	Sequential buildup
SEM	Scanning electron microscopy
SIR	Surface insulation resistance
SMT	Surface-mount technology

STII	Soldering temperature impact index
TCE	Also CTE, thermal coefficient of expansion
Td	Decomposition temperature
T_g	Glass transition temperature
TH	Through hole
THViP	See PTHViP
TMA	Thermal mechanical analysis
TSM	Thermal shock method
TSR	Total strain range
UV	Ultraviolet
ViP	Via-in-pad
WLP	Wafer level package

61.4 ACKNOWLEDGMENTS

Part of the research described in this chapter was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration. CHAPTER 62

COMPONENT-TO-PWB RELIABILITY: THE IMPACT OF DESIGN VARIABLES AND LEAD FREE

Mudasir Ahmad
Cisco Systems, San Jose, California

Mark Brillhart
Palo Alto, California

62.1 INTRODUCTION

The mandated conversion to lead-free assemblies has led to the convergence of several critical issues in the microelectronics industry. The conversion has further compounded several other factors that have been pushing the envelope in Component to Printed Wiring Board (PWB) reliability, including

- Radical increases in package-to-board input/output (I/O)

- Rapid reduction in interconnect pitch
- Overall rise in surface-mount component density
- Higher speeds and correspondingly higher heat dissipation

All of these factors pose tremendous challenges with respect to reliability, and they cause complex design trade-offs that must be considered while maintaining product reliability at required levels. Time to market and aggressive product life cycle pressures also require PWB designers to consider the impact that alternate designs and material sets may have on reliability, in a rapid fashion.

The PWB designer is faced with myriad packaged device types, field use environments, connectors, PWB materials, cost considerations, and real estate restrictions, which all must be optimized without degrading system reliability. Designers need tools to assess experimental reliability data, transform laboratory results into actual field loading conditions, and rapidly assess the reliability of different PWB layouts, material sets, and package types. Engineers must also have the capability for addressing complex loading conditions such as mini- and power-cycles and the knowledge of how they impact interconnect performance.

This chapter focuses on the design variables that impact the reliability of PWB-to-package interconnect (second- and third-level interconnect) of grid array devices and the impact of lead-free conversion on these design variables.

Some of the critical variables discussed in depth include

- Double-sided construction
- PWB stiffness effect
- Multiple packages in a small area
- Package and PWB warpage; assembly and reliability challenges
- Solder joint geometry; assembly and reliability challenges

- Package and PWB pad size
- Heatsink design and attachment
- Package and PWB surface finish; Black Pad, Brittle Failure, and Kirkendall voiding
- PWB electrical test architecture
- Carrier chassis design
- Package design parameters such as overall size, silicon technology, ball array, ball size/pitch, heat spreader/stiffener, material selection, die/package aspect ratio, substrate material, low-k dielectrics, and so on

The chapter is broken up into the following sections. Section 62.2, “Packaging Challenges,” outlines several of the performance challenges faced by next generation packages, and the key technical drivers behind these challenges.

Section 62.3, “Variables That Impact Reliability,” contains a discussion of the common design variables that could impact the reliability of a product; ranging from PWB design rules to package design parameters. The failure modes relating to the choice of different package design parameters are outlined, along with recommendations on ways to mitigate different manufacturing and test-related failure mechanisms.

62.2 PACKAGING CHALLENGES

The reliability of many types of leadframe components (see Figs. 62.1 and 62.2) has been assessed in great detail.[1] Figure 62.3 shows the typical definitions of interconnect levels in assemblies. While leadframe devices are by no means infinitely reliable at the first- and second-level interconnects, they have historically posed a lesser risk than grid-array packaged components, such as ceramic ball grid arrays (CBGAs), plastic ball grid arrays (PBGAs), ceramic

solder column carriers (CSCCs), flip-chip ball grid arrays (FCBGAs), and chip scale packages (CSPs). This is because the compliant leadframe in leadframe packages can absorb the differential strain induced in the solder joints, due to the mismatch in thermal expansivity between the silicon chip and the PWB. Ball grid array packages, on the other hand, rely entirely on the discrete solder balls absorbing the differential strain. Depending on the package construction, the solder joints at critical high strain locations could fail early, resulting in lower long-term reliability of the assembly. Figure 62.4 shows various grid array packaged devices.

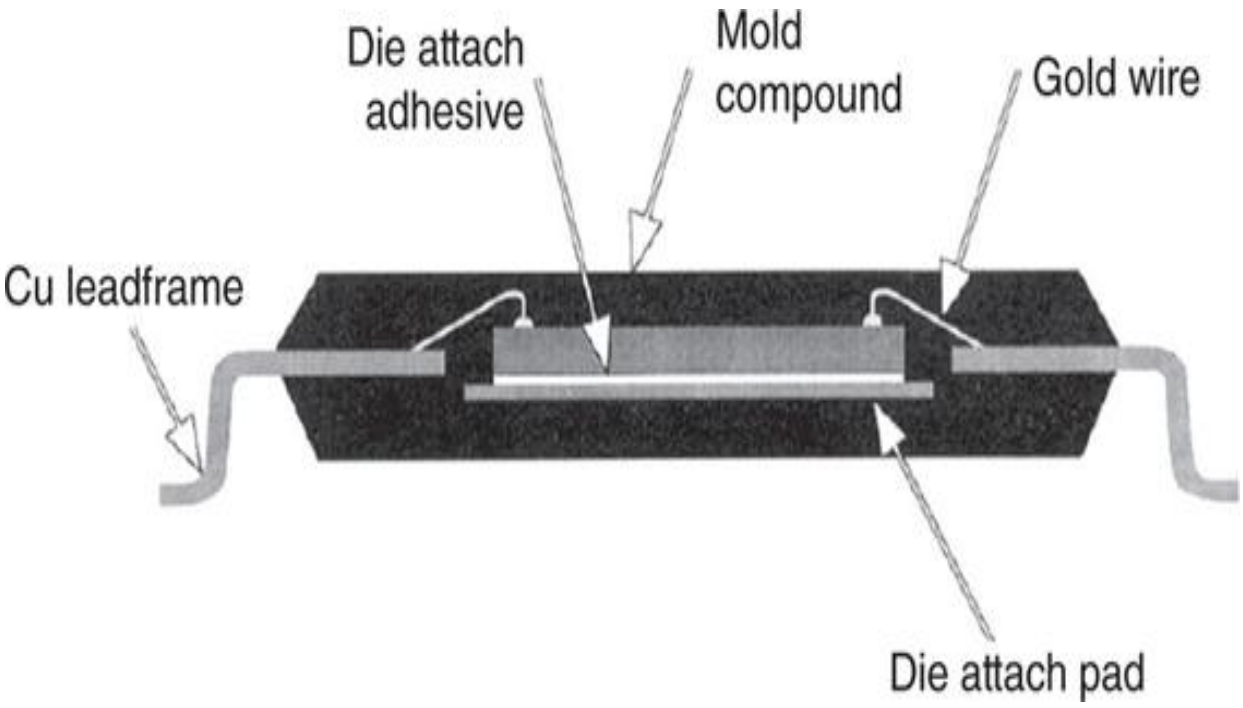

FIGURE 62.1 Diagram of a quad flat pack. Note the copper (Cu) leads that are attached by gold wire bonds to the die. This is the primary (or first-level interconnect) between the die and the package. The second-level interconnect will be created when the Cu leadframe is soldered to a motherboard via some type of surface-mount attach process. (*Courtesy of Amkor Technology, Inc*.)

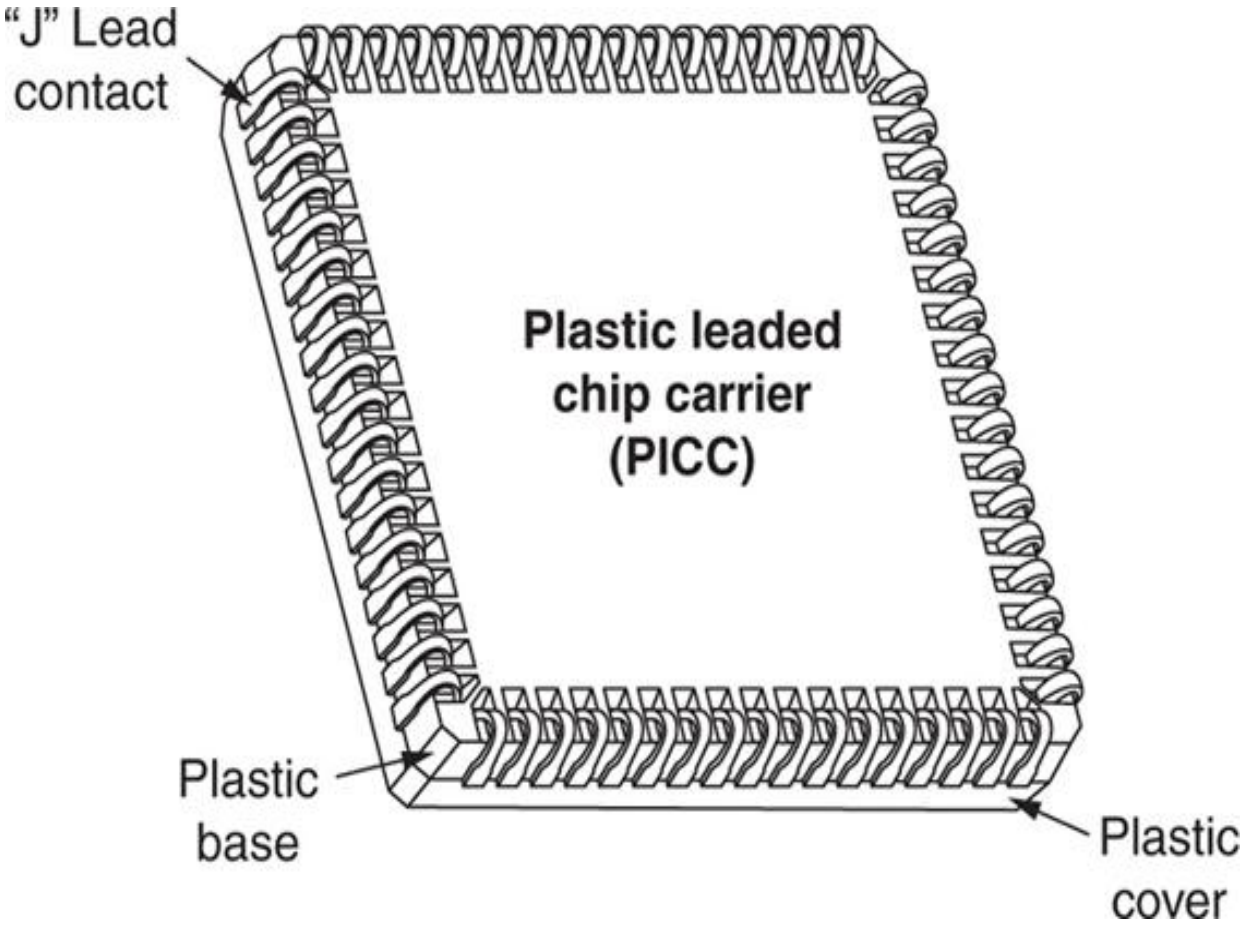

FIGURE 62.2 J-leaded device oriented bottom side up. (*Reprinted with permission from J. Lau, Ball Grid Array Technology, McGraw-Hill, New York, 1995, p. 20.*)

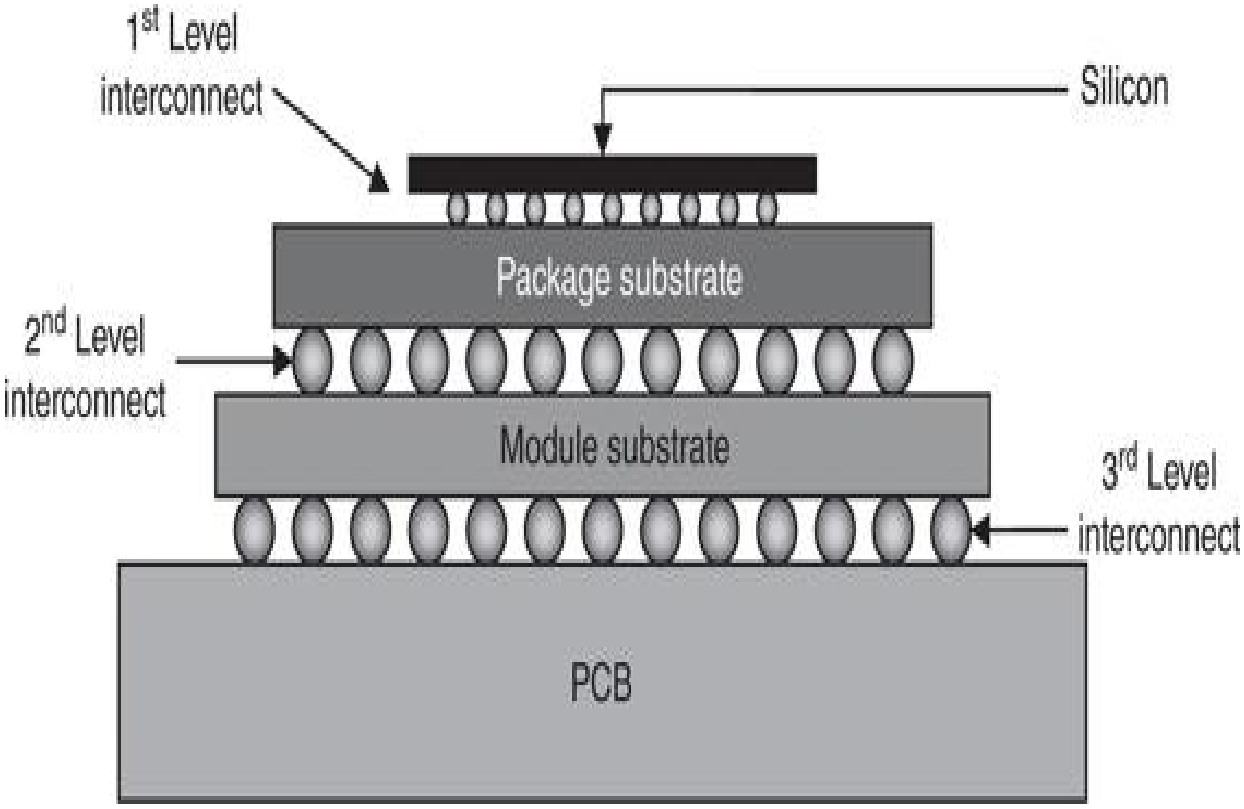

FIGURE 62.3 First-, second-, and third-level interconnects defined, employing a flip-chip assembly as an example. The first-level interconnect is the primary connection between the silicon die and the package substrate. In this example it is created by the solder bumps between the die and the package. The second-level interconnect in this example is the “next” level of connection between the package substrate and the module substrate. The third-level interconnect in this example is created when the solder balls on the bottom side of the module substrate are attached via SMT to the PWB.

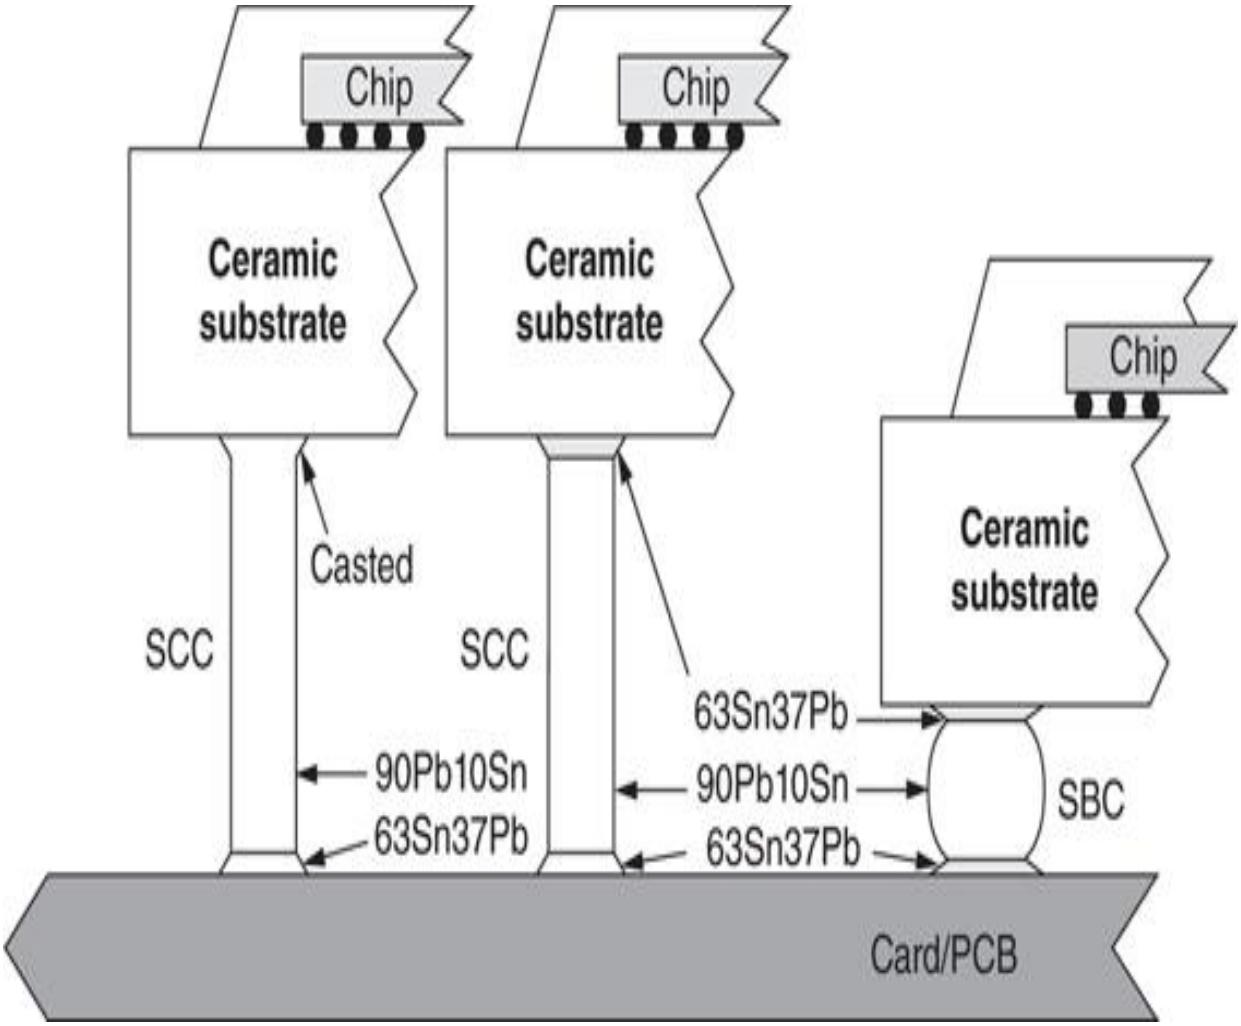

FIGURE 62.4 Cross-section of a ceramic solder column carrier and ceramic ball grid array (CBGA). Solder column carriers (SCC) and a solder ball carrier (SBC) are shown. The SBC is often referred to as a CBGA package due to the fact that it is a ceramic package substrate that employs solder balls to create a second-level interconnect between the package substrate and the PWB. The solder column carrier employs a column of high-lead solder (which is either casted onto the ceramic package substrate or attached by a layer of eutectic 63Sn/37Pb solder paste) to create a second-level interconnect between the ceramic package substrate and the PWB. A lead-free version of the SCC, made of copper columns is also being developed.[2] Typical ceramic ball grid array packages cannot achieve required reliability when body sizes exceed 32 mm per side. Ceramic packages having larger body sizes either employ SCC-type technology or connectors to create a second-level interconnect. (*Reprinted with permission from J. Lau, Ball Grid Array Technology, McGraw-Hill, New York, 1995, p. 27*.)

To meet increasing I/O density requirements, many of these types of packages are either increasing in body size,

decreasing in pitch, or both, to a point where the standard reliability envelope is being pushed to extreme levels. Additionally, most grid array packaged devices are high in cost (in many instances the grid array packaged devices are the most costly component on a printed circuit assembly) and thus cannot be deployed in a redundant design. Lack of redundancy creates critical path single points of failure (SPOFs). Failure of one of these devices can lead to catastrophic system-level failures. The proliferation of high-I/O, small-pitch grid array packaged devices throughout the electronics industry impacts almost all PWB engineers because any design has a high probability of containing one or more of these types of components.

Moreover, at higher speeds, there is an ever increasing need for reduction in signal delay between processors and the memories they communicate with. These processors could be microprocessors, network processors, programmable logic devices (PLDs), and application-specific integrated circuits (ASICs). This has given rise to the prominence of System-in-Package (SiP) modules, which significantly reduce the delay between on-PWB memory and ASICs (Fig. 62.5). SiP modules can have more than eight memories communicating with a single ASIC. The ASIC package is typically a flip chip, whereas the memories could be CSPs, stacked packages or PBGAs.

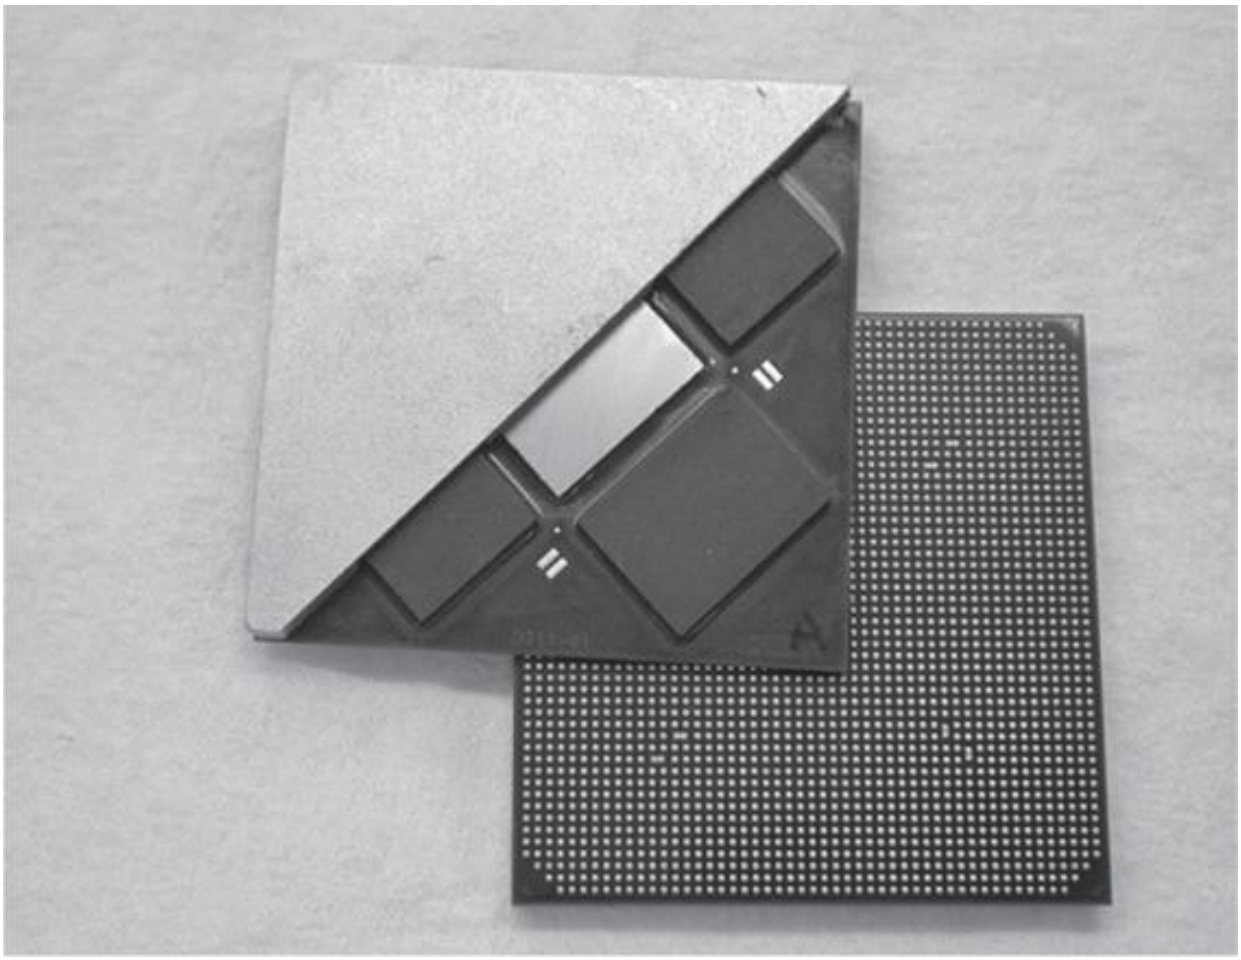

FIGURE 62.5 System-in-Package (SiP) module. SiP modules help reduce signal delay between a processor and the memory devices it communicates with. This SiP has one processor in the middle, surrounded by four discrete memory packages, all on one module. The module is soldered to the PWB via the solder balls on the back side of the module substrate.

Stacked die and stacked package memories have also become more prevalent in applications where space is a constraint (Fig. 62.6). Stacking helps compact more memory within the same foot print and in applications where height is not a critical constraint, they help conserve valuable PWB real estate while at the same time providing greater integration and performance. But stacking technology raises its own unique set of reliability challenges. These challenges include heat dissipation from the multiple dies, reworkability and the reliability of the interconnects between the individual stacked dies or stacked packages.

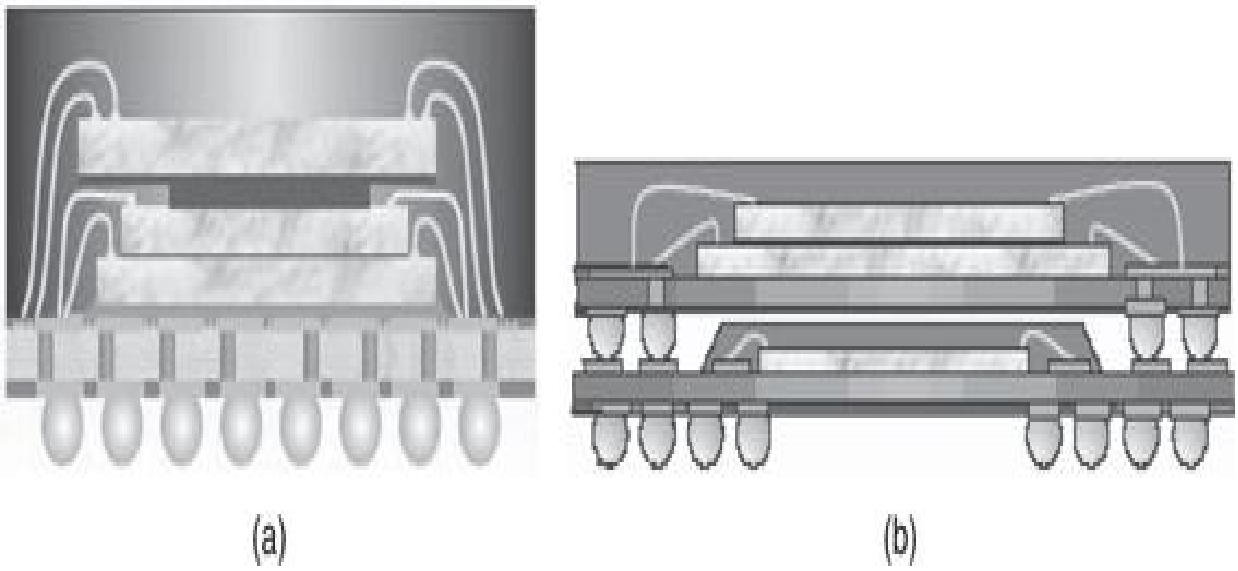

FIGURE 62.6 (*a*) Stacked-die package. Several dies are stacked within a single package and wirebonded to a single substrate. (*b*) Stacked package. Several wirebonded packages are stacked on top of each other with solder balls. (*Courtesy of Amkor Technology, Inc*.)

62.3 VARIABLES THAT IMPACT RELIABILITY

Electronic packages are composed of complex materials that are assembled via intricate processes and then subjected to a wide range of service environments. It is crucial to note that both the die-packaging processes and surface-mount technologies can impart stresses and create residual stresses in the final packaged assembly that impacts its interconnect reliability. Assessing the reliability of package devices requires that all variables that can hinder or enhance reliability be considered.

62.3.1 Actual Product Environment

The actual product environment is what drives the reliability of the assembly. Printed circuit assemblies are deployed in a

wide range of environments. Packages can be subjected to extreme temperatures and humidity. Automotive applications, for example, can see temperature ranges from −55°C to well over 95°C[3] along with up to 100 percent humidity. The rate at which temperature and humidity changes occur can be quite severe under the hood, causing components to transition from extreme cold to heat in a matter of minutes. This creates a very difficult environment to model, as the rate of occurrence of thermal and humidity cycles must be thoroughly understood. Severe shock and vibration can also be imparted to assemblies in this type of service environment, which adds to the complexity of reliability assessment. Great care must be taken when assessing these types of aggressive environments and their impact on packaging reliability. A thorough experimental analysis that employs thermocouples (to assess temperature conditions) and accelerometers (to assess shock and vibration loading conditions) should be employed to determine the actual end-use environmental conditions. These stressful environments are the primary driver for automotive applications employing extreme protection measures such as full encapsulation/potting for electronic devices placed under the hood.

Computer room environments represent the other extreme, with temperatures and humidity controlled to very tight tolerances. While servers, switches, hubs, routers, and other devices are housed in a controlled environment, their extremely large packages, coupled with power and mini cycles (discussed in the next chapter), create a set of loading conditions that are different from those found in automotive applications, but that are equally challenging. Worst-case loading conditions for a variety of end-use environments can be found in Table 62.1. Note the broad variation in temperature extremes, frequency of thermal cycles, and expected service life.

TABLE 62.1 Examples of Worst-Case Environments for Different Use Categories[3]

Use Category	T_{min}, °C	T_{max}, °C	t_D, h	Cycles per Year	Typical Years of Service	Approximated Acceptable Failure Risk, %
Consumer	0	+60	35	12	1–3	1
Computers	+15	+60	2	1460	5	0.1
Telecom	−40	+85	12	365	7–20	0.01
Commercial aircraft	−55	+95	12	365	20	0.001
Industrial and automotive passenger compartment	−55	+95	12	20–185	10	0.1
Military ground and ship	−55	+95	12	100–265	10	0.1
Space	−55	+95	1–12	365–8760	5–30	0.001
Military avionics	−55	+95	1–2	365	10	0.01
Automotive under hood	−55	+125	1–2	40–1000	5	0.1

T_{min}, minimum temperature; T_{max}, maximum temperature; t_D, dwell time at the operating temperature.

Prior to initiating any reliability assessment, it is crucial to understand the thermal, humidity, and mechanical loading conditions that a packaged device will be exposed to throughout its expected life time. Temperature maximums and minimums as well as the frequencies and rates at which the component cycles between extremes must be thoroughly understood. Complex thermal cycles (such as an outdoor product experiencing daily temperature changes coupled with a more local effect such as under-the-hood heating and cooling due to engine usage) must also be considered.

Humidity and vibration loading conditions must also be evaluated as part of an overall package qualification process.

End-use conditions can be estimated by attaching thermocouples, humidity, and shock/vibration sensors in the final product because it is used in field operating conditions. This data needs to be analyzed over time and different expected field conditions to get useful estimates of the end-use environment as illustrated in Table 62.1.

Once this data is generated, it can be used in typical acceleration factor models relating accelerated stress tests to field data. For example, if it is determined that it takes *x* hours or cycles for an assembled package to fail in a laboratory test, the acceleration factor model can be used to extrapolate expected life of the device in typical field operating conditions. Details on acceleration factor models and sample calculations are provided in the next chapter.

Although environmental impact has a large effect on interconnect reliability, there are some basic design variables that can have a positive or negative impact on solder joint reliability. These critical design variables and their impact on reliability are discussed in the following sections.

62.3.2 Double-Sided (Mirrored BGA)

The high-density revolution has forced PWB designers to place increasingly complex surface-mount devices in smaller and smaller spaces. This PWB density increase (where density refers to the number of components per unit area of PWB) may force designers to consider mirror BGA placement (see Figs. 62.7 and 62.8) or to place multiple devices on one side of a PWB.

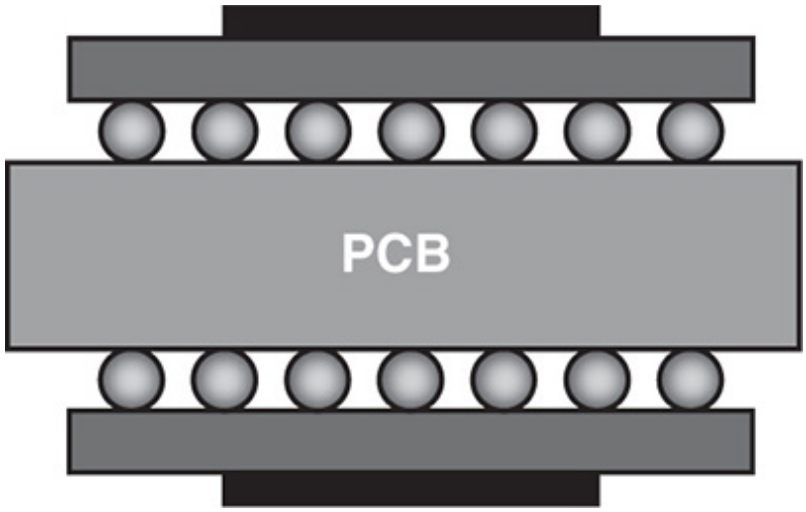

FIGURE 62.7 Double-sided BGA in mirror configuration. Note that the PCA is an exact mirror about the center line of the PWB. In some instances the top- and bottom-side packages share common vias.

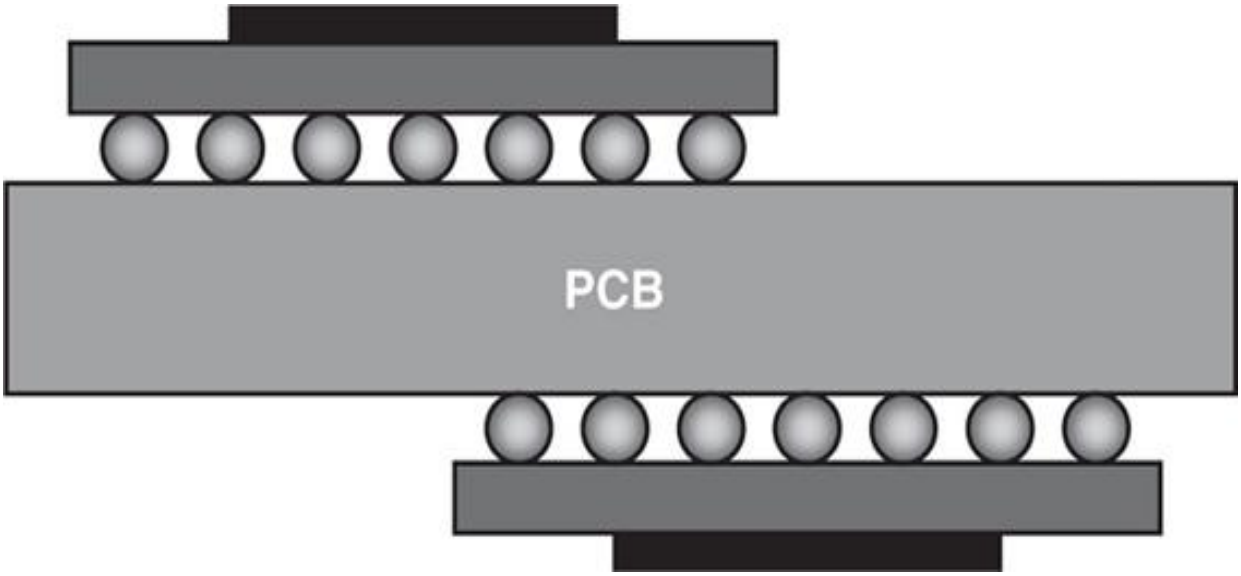

FIGURE 62.8 Double-sided BGA in quasi-mirror configuration. Note that although the packages are not right over each other, there is some overlap when looking from the top down or from the bottom up.

The beginning of the density revolution occurred when designers began implementing double-sided technologies to allow for the placement of surface-mount components on both sides of a PWB. The continued push toward device density has resulted in placement of BGA components in

mirror and quasi-mirror configurations, shown in Figs. 62.7 and 62.8.

While the double-sided configuration certainly reduces signal delay, the primary disadvantage is a significant reduction in the thermomechanical reliability of the solder joint interconnects between the packages and PWB. Placing BGA packages in mirror or quasi-mirror configurations tends to rigidize the PWB assembly such that it does not bend as much during temperature cycling. The increased stiffness of the PWB due to double-sided mounting means the solder joints have to absorb more differential strain between the packages and PWB, resulting in as much as a 50 percent reduction in solder joint fatigue life (Figs. 62.9 and 62.10).[4] In terms of solder joint strain, the effect is the same as having a thicker or stiffer PWB. The primary failure mode is cracking in the solder joints near the package/joint interface.

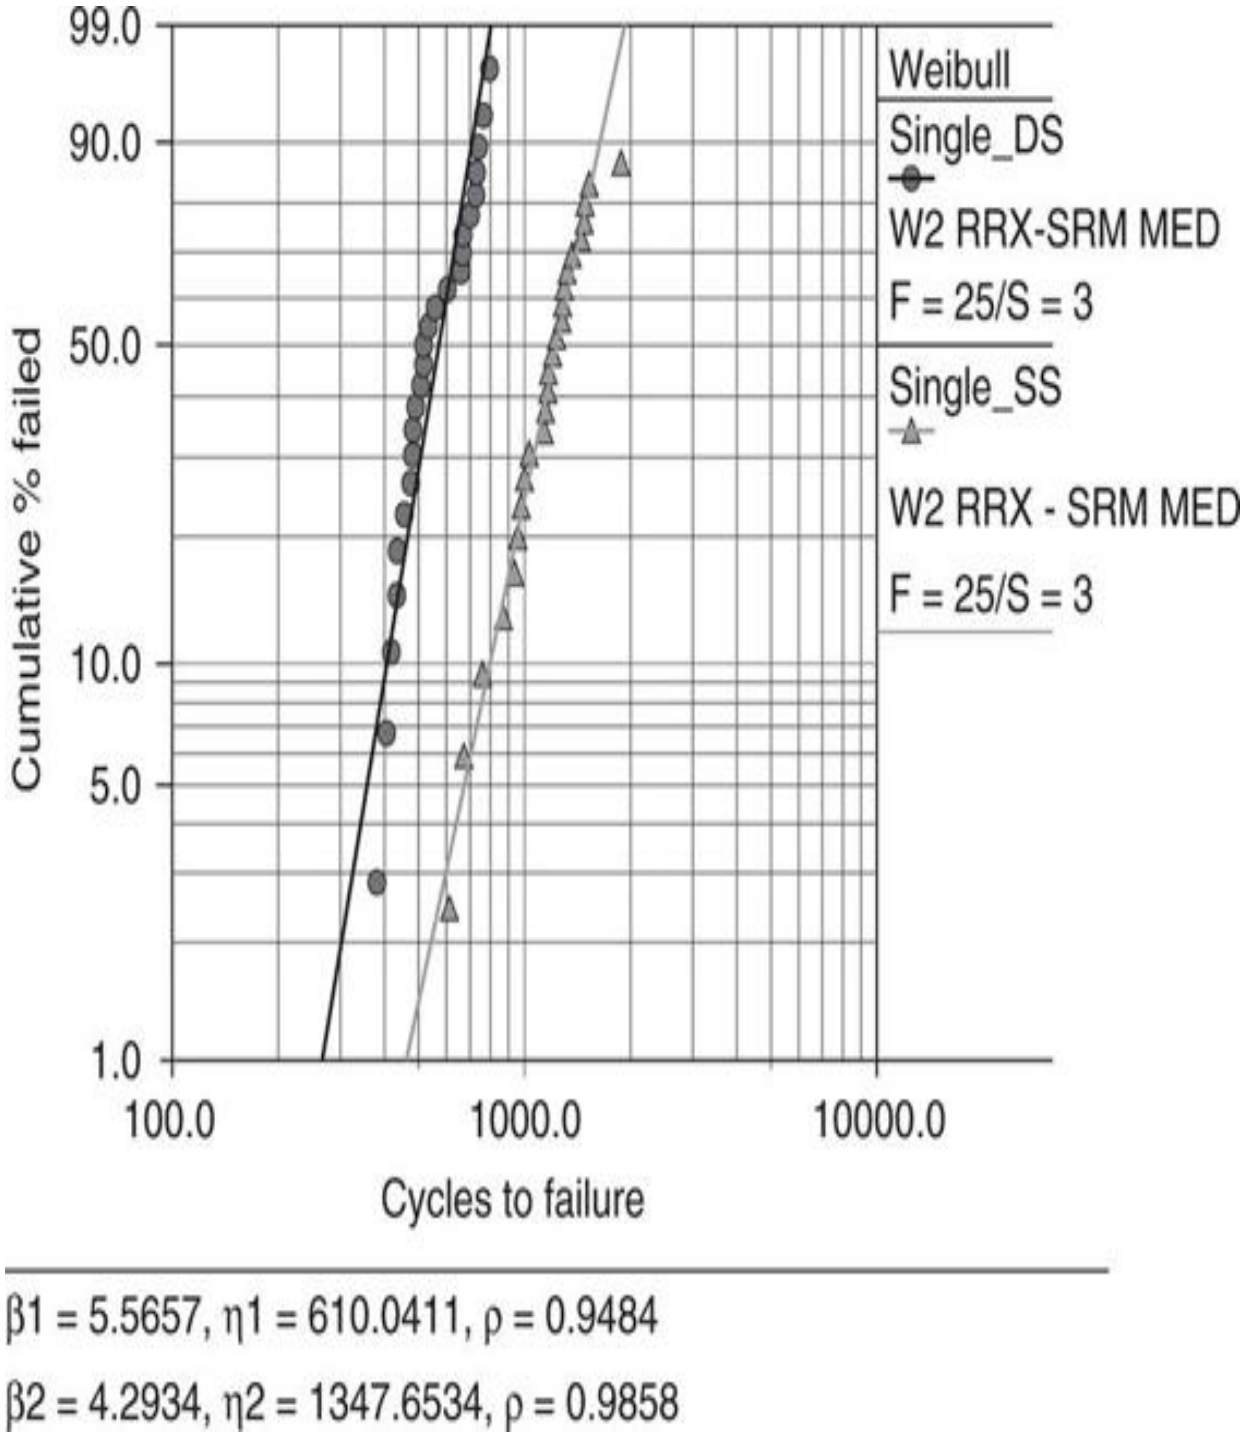

FIGURE 62.9 Weibull plot of single and double-sided mounting of single lead-free extremely thin chip scale package (PS-etCSP®). (*Reprinted with permission from Amkor Technology, Inc./© [2004] IEEE ECTC*.[4])

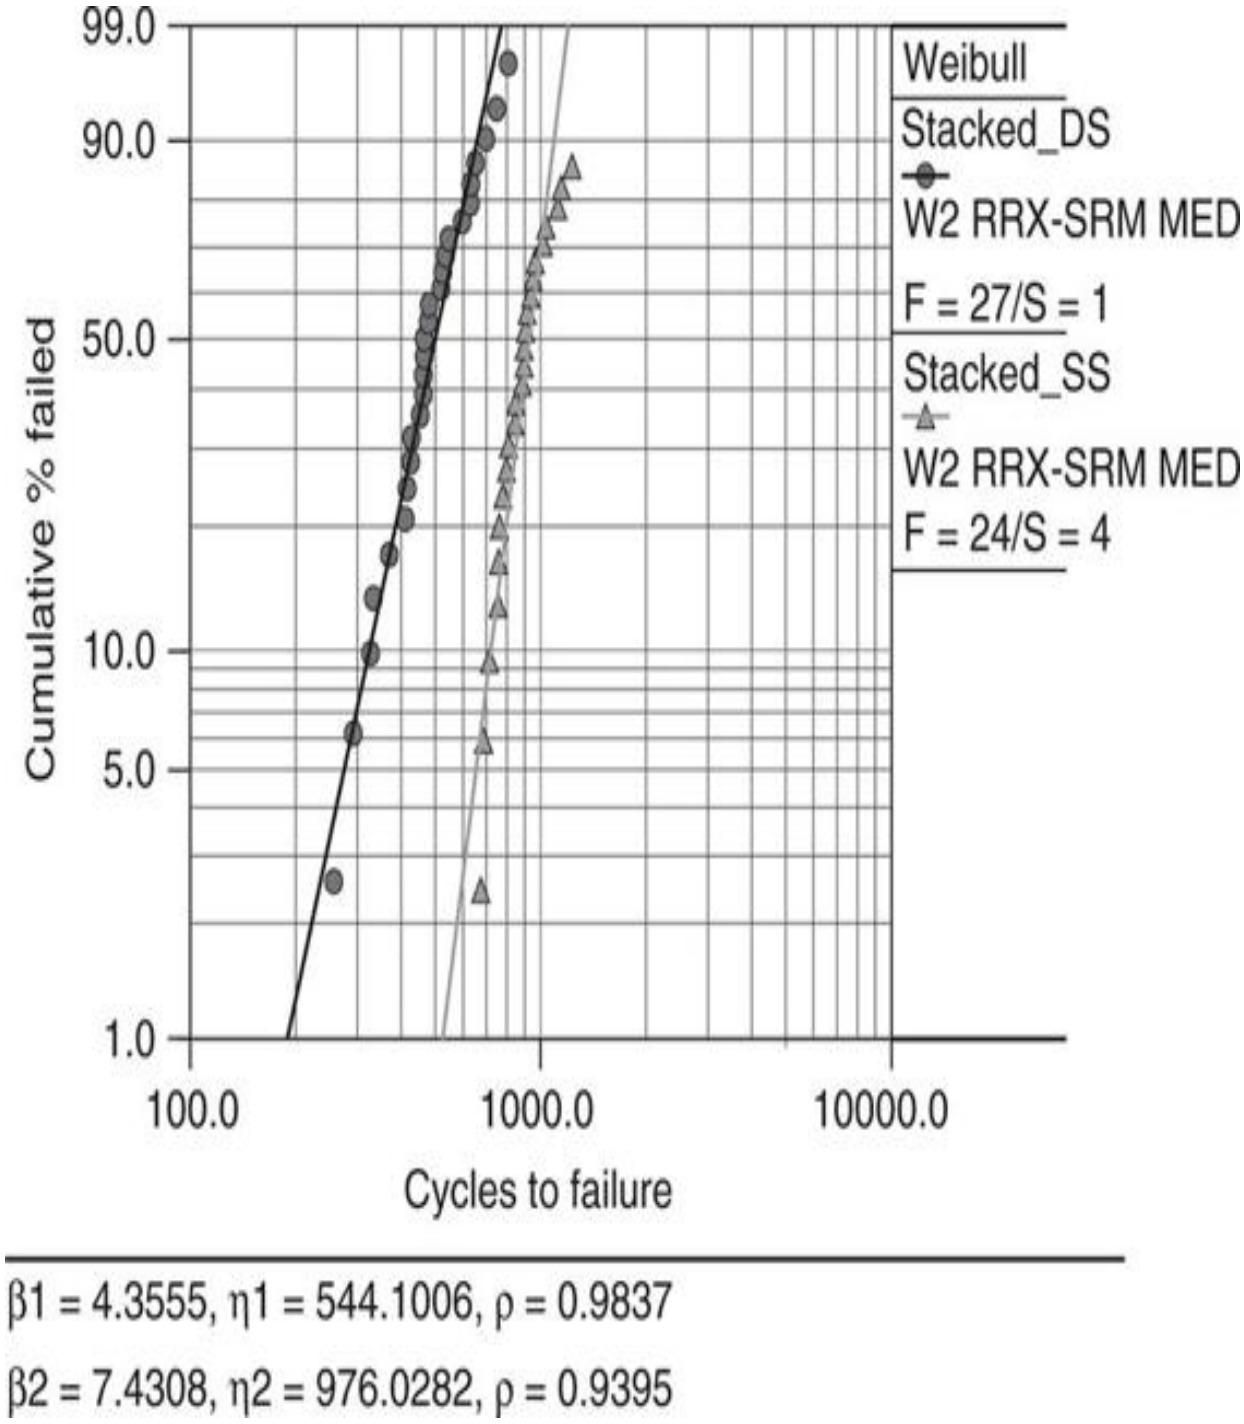

FIGURE 62.10 Weibull plot of single and double-sided mounting of stacked lead-free extremely thin chip scale package (PS-etCSP®). (*Reprinted with permission from Amkor Technology, Inc./© [2004] IEEE ECT.*[4])

Due to the dramatic decrease in assembly reliability when attempting mirrored configurations, these types of

configurations should be avoided whenever possible. When it is impossible to avoid a mirror configuration, a quasi-mirror configuration without common through-hole vias is recommended (see Fig. 62.8). Common through-hole vias in this configuration tend to rigidize the assembly and contribute to further reduction in solder fatigue life. A standard rule of 50 percent reduction in fatigue life when employing a mirror configuration may be taken as a first-pass approximation. Thermal cycle testing should be performed to ensure that the reliability degradation will still keep service life at an acceptable level when either a mirror or quasi-mirror configuration is considered.

62.3.2.1 Effect of Lead-Free Conversion. The reduction in lead-free package reliability when employing a mirrored double-sided configuration has been experimentally assessed.[4] Figures 62.9 and 62.10 show failure rates for single and stacked packages in single-sided and double-sided mirror positions.[4] Note the almost 50 percent reduction in fatigue performance when a single device is placed in a mirror configuration. The reduction is slightly less for the stacked packages, but the baseline reliability of the stacked package is 10 percent lower than that of the single package. The same trends have been shown with tin-lead eutectic assemblies, so it appears that the conversion to lead free would not mitigate this reduction in solder joint fatigue life due to double-sided mounting.

For details on Weibull distributions and failure life analysis, please refer to Sec. 59.2.2 in Chap. 59.

62.3.3 Board Stiffness Effect

As with the double-sided case described earlier, solder joint reliability generally decreases with PWB thickness. The thicker the PWB, the higher its stiffness, and the higher the

differential strain that the solder joints have to absorb. However, the percent reduction in solder joint fatigue life due to board thickness varies for different package constructions (e.g., CCGA, CSP, FCBGA, and PBGA).[5] The reduction is more pronounced in ceramic packages as compared to organic packages because of the higher mismatch in the coefficient of thermal expansion (CTE) between the package and PWB. Both thickness and number of layers of copper contribute to the stiffness of a PWB. As a result, the PWB thickness and layer count used to perform qualification testing should be representative of the end-use conditions in which the package would be used.

62.3.3.1 Effect of Lead-Free Conversion. The negative effect of PWB stiffness on solder joint reliability also applies to lead-free assemblies, as evidenced in Fig. 62.11. However, the amount of degradation could be different depending on the package type. Best practice recommendation is to use two different board thicknesses to perform temperature cycling qualification. This helps generate data for a specific package type over a range of board thicknesses. This recommendation is in line with the guidelines in the industry standard IPC 9701.[6]

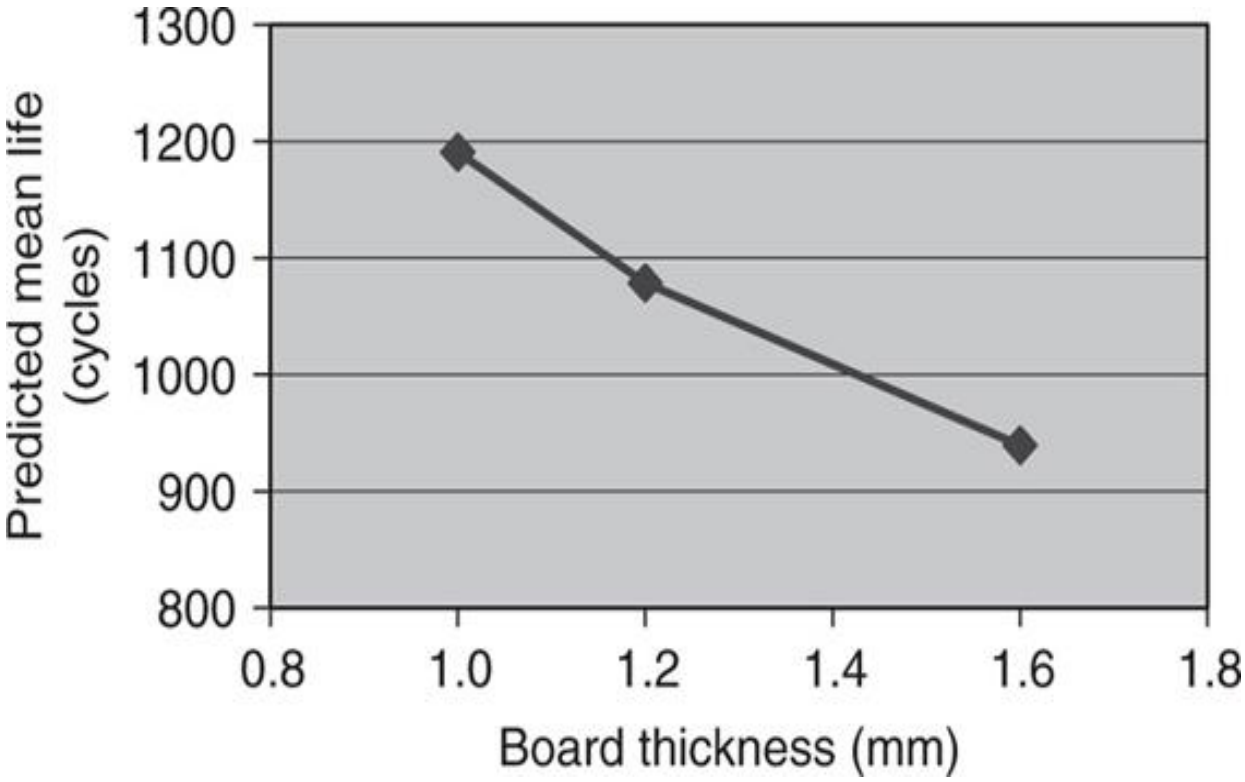

FIGURE 62.11 Effect of board thickness on solder joint reliability of stacked lead-free extremely thin CSP (PS-etCSP). (*Reprinted with permission from Amkor Technology, Inc./© [2004] IEEE ECT.*[4])

62.3.4 High Density due to Multiple Packages in a Small Area

A second source of reliability degradation due to density increase can be observed when a designer attempts to place many BGA packages in a small area on a thin PWB (see Fig. 62.12). The effective CTE of the packaged die or module tends to be much lower than that of the actual PWB. During reflow, the PWB and packages are in a stress-free state. Upon cooling, however, the packaged die contracts at a reduced rate (due to the lower effective CTE) than the underside of the PWB, causing a convex-type curvature to be imparted to the PWB. Moreover, if the thermal mass of the packages on the top side is higher than that on the bottom

side, this can lead to a skew in the temperature distribution across the assembly, which in turn exacerbates the warpage of the assembly. Thus, care should be taken to distribute the packages as uniformly as possible across the PWB on both sides, and also to balance the copper in the PWB itself.

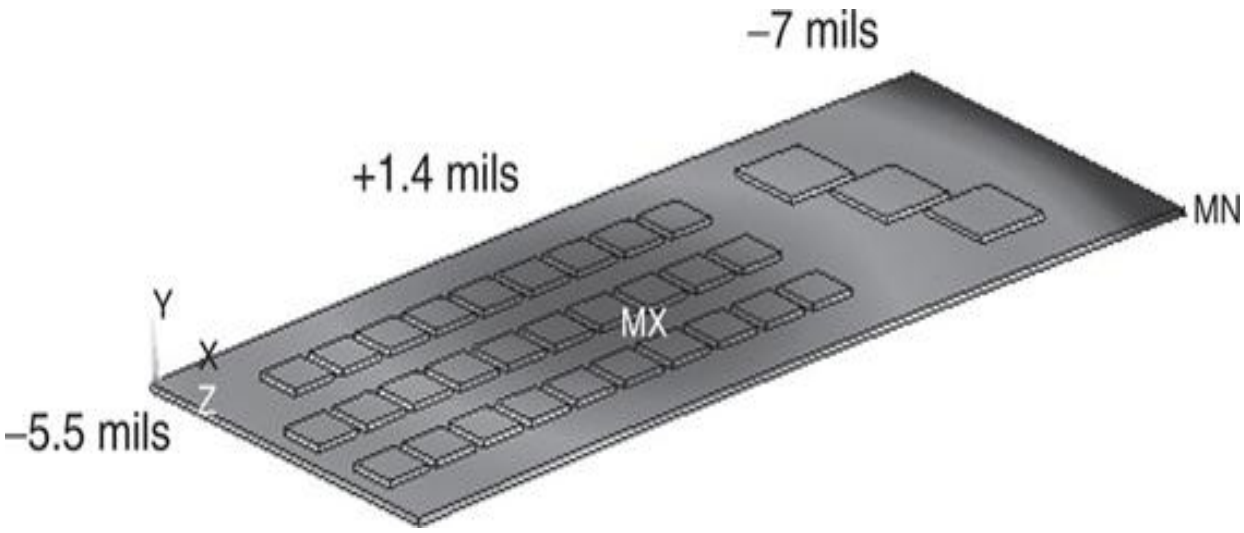

FIGURE 62.12 High-density placement of BGAs on top side of a PWB. This diagram illustrates the convex-type curvature of a PWB assembly where multiple BGA devices are all placed on one side of a board.

62.3.4.1 Effect of Lead-Free Conversion. Typical lead-free reflow temperatures (235 to 260°C) are higher than tin-lead reflow temperatures (220°C). As a result, the residual stresses built into the assembly after reflow could be higher in lead-free assemblies. These higher residual stresses are also a function of the cooling rate. Thus, it is important to not only control the heating side of the reflow profile, but the cooling side as well. The use of multiple zones for cooling is preferable, as it ensures better control. Moreover, forced convection ovens would be preferable over IR ovens for better control. Due to significant variations in the thermal mass of typical boards, it is difficult to provide universally applicable recommendations on reflow profiles.

62.3.5 Warpage Issues

The impact of warpage on a PWB assembly is multifaceted. First, warpage must typically be overcome when a PWB is placed in a card cage. Card cage placement of warped boards results in a rapid change in the loading of the solder joints that may lead to micro-crack formation or, in severe instances, solder joint fracture. Severe PWB warpage may create a card that physically cannot be placed in a card cage, resulting in a non-manufacturable product. Warped boards should be clamped in a controlled fashion to reduce the stress imparted to solder joints upon installation in a card cage.

62.3.5.1 Effect of Lead-Free Conversion. With the conversion to lead free, it is imperative to ensure that the base material used in the PWB is compatible with the higher reflow temperatures. While more industry wide research is needed, the use of materials such as Dicyandiamide (DICY) cured FR-4 appears to be limited to applications with less than 240°C peak reflow temperature, whereas Phenolic cured PWBs are preferred for applications higher than 240°C. This is because of the better resistance to delamination observed for the phenolics after multiple reflows.[7,8] The thermal mass of the components and the amount of copper in large panel boards could make it difficult to maintain temperatures below 240°C. Detailed temperature measurements and reflow profiling should be performed on large boards to ensure that the temperature rise across the PWB is compatible with the PWB material.

62.3.6 Die and Package Stress Issues

A second issue associated with board warpage is die and package stress. The package experiences an amount of stress as it constrains the PWB from contracting during cooling after reflow. If this stress is severe enough, the silicon may crack. Also, severe stress may create multiple types of package delamination and/or cracking. The extreme danger here is that a device could pass full first-level qualification (first-level qualification typically consists of thermal cycling, humidity and temperature exposure, extreme-temperature storage, and shock and vibration experiments performed on packaged devices not attached to a PWB) yet suffer from delamination/die cracking due to stresses imparted by a warped PWB. This is one of the primary reasons that many packaged IC suppliers and consumers require that second-level qualification test vehicles include daisy chains at the first-level interconnect. Inclusion of first-level joints or wire bonds allows for the impact of second-level attach on first-level reliability to be assessed simultaneously with second-level solder joint reliability during a second-level qualification.[9]

62.3.6.1 Effect of Lead-Free Conversion. Lead-free conversion exacerbates these potential silicon-level failures. Since the assembly is subjected to a higher temperature range than with tin-lead assemblies, there is a higher propensity for early failures due to residual stresses during cool down. In addition, there are potential concerns over the effect on low dielectric constant (k) materials in the silicon during second-level temperature cycling. This is discussed in more detail in Sec. 62.3.13.9. The effect of mold compound and underfill material selection on first-level interconnects is also discussed in more detail in Secs. 62.3.13.5 and 62.3.13.6, respectively.

62.3.7 Back-Side Component Issues

A third challenge related to warped PWBs concerns the back-side components in double-sided designs. During cool down after reflow, the top of the PWB is restrained from contraction due to the smaller effective CTE of the packaged device. This results in the bottom side of the PWB over contracting during cool down. The state of stress on the bottom solder joints due to warpage may be severe enough to fail solder joints or crack the die in bottom-side components. Additionally, the back-side components may be subject to residual stresses imparted after the second reflow (when the top-side components are attached via SMT) that may impact the long-term reliability of the devices on both sides and their second-level interconnects. As a result, it is important to characterize the thermomechanical reliability of the components that are mounted on the back side by performing temperature cycling qualification.

62.3.8 Solder Joint Geometry Issues

Another consequence of severe warpage is the shape of the post-assembly solder joints. Joints can become excessively deformed, such that the cross-section is too small to withstand fatigue. Joints can also become compressed or elongated, causing shorts or opens in some cases.

Moreover, with significant increases in body sizes of packages, there is a higher propensity for opens or bridges during reflow. For example, a 20-mm body-size package (1 mm pitch) would be easier to assemble on a relatively thin PWB, but with a 50-mm organic package, warpage is much more difficult to control, and it is a challenge to assemble it on a thick (≥125 mil, 20 + layer) PWB.

Tolerances are also difficult to control on large-panel, thick PWBs. Typical tolerances on high end PWBs are ±4 mils over the package site. Ensuring tolerances less than this is cost prohibitive. Current JEDEC guidelines[10] require ±8 mil

coplanarity across the package. However, there are no specifications on the maximum acceptable warpage of the package at or above the reflow temperature. The typical relationship between maximum diameter and warpage is shown in Figs. 62.13 and 62.13.

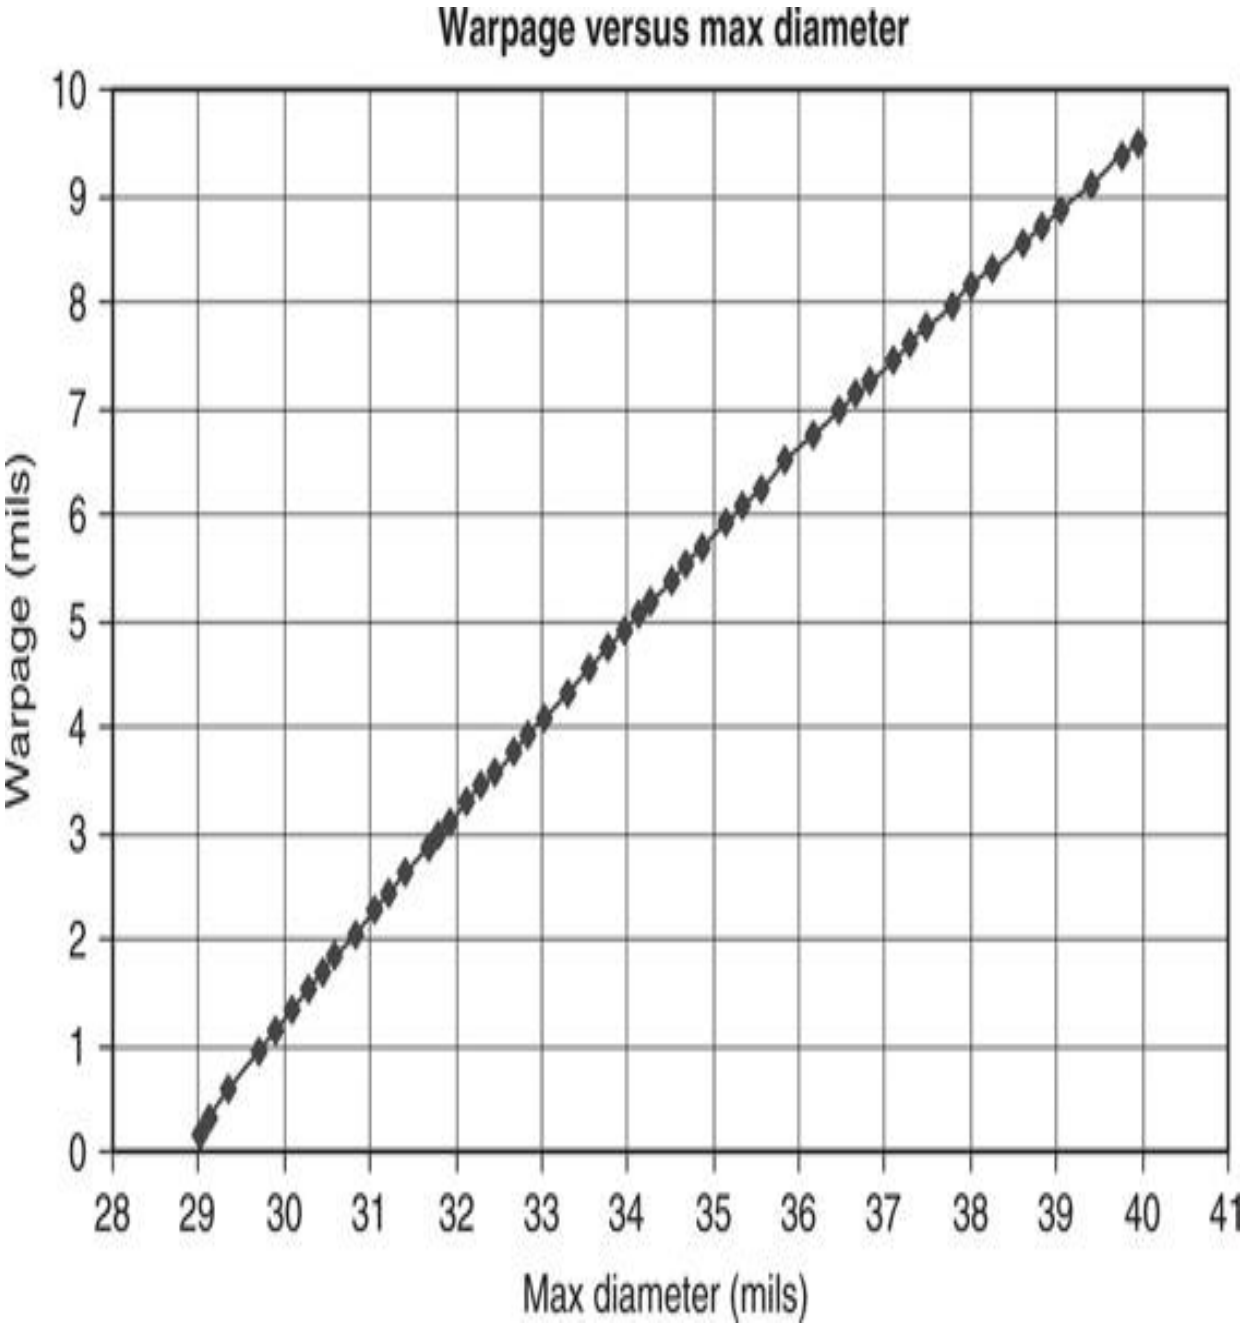

FIGURE 62.13 Warpage versus max diameter for solder joint bridging. (© *ASME, 2005*.)[11]

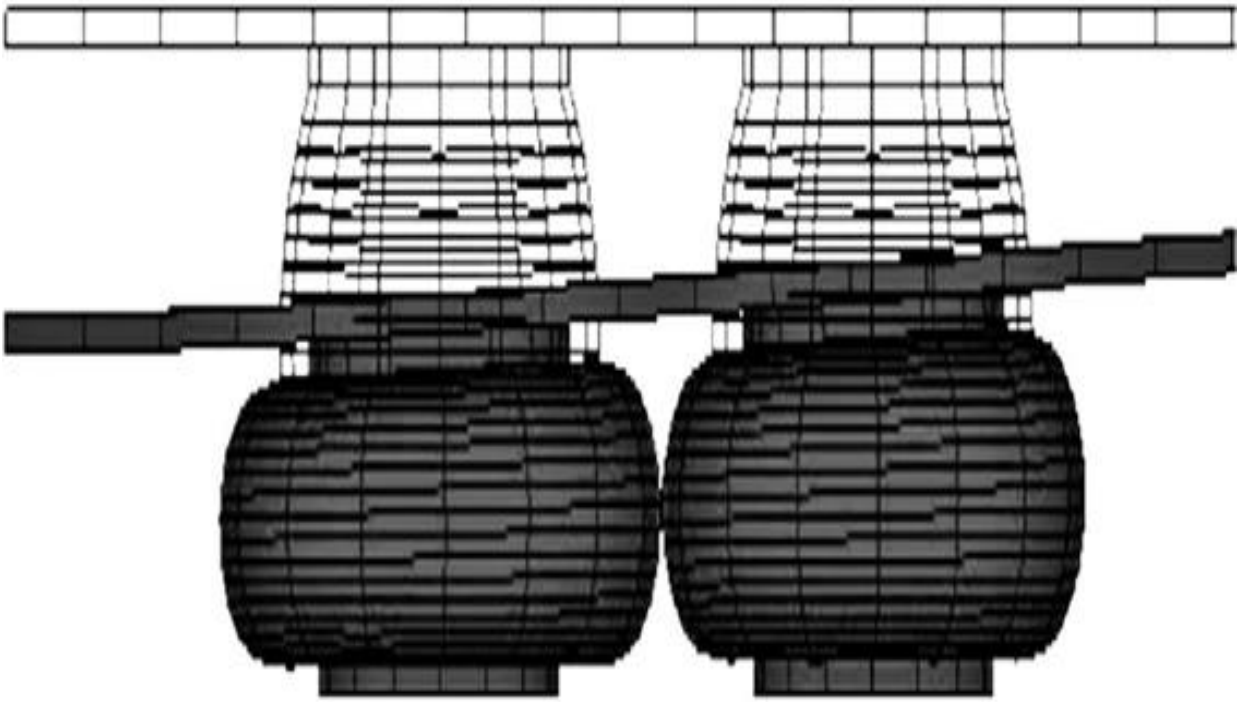

FIGURE 62.14 Bridging of solder joints—wireframe (unwarped), contour (warped). (© *ASME, 2005*.)

The joint parameters used in the analysis are

Paste volume (m^3)	4.909576e-011
Solder ball volume (m^3)	1.130972e-010
Upper pad diameter (mm)	0.60
Lower pad diameter (mm)	0.55
Viscosity of solder (Pa-sec)	2e-3
Surface tension (Nm^{-1}) (Tin-lead)	0.386

For a 1-mm pitch joint array, if the maximum diameter exceeds 40 mils (1.016 mm), bridging will occur. Based on the analysis results, if the effective warpage exceeds ~9 mils (0.23 mm) over a 7-mm distance along the package, the joints will bridge (Figs. 62.13 and 62.14). Due to

misregistration, bridging could occur at lower warpage levels. But, for the sake of clarity, the base of the solder joints has been assumed to have no warpage. Thus the predicted value (9 mils) is the *effective* warpage of the assembly. In practice, if the board has a concave warpage of 5 mils and the package has a convex warpage of 4 mils over 7 mm (above solder melting temperature), it could result in bridging.[11]

Given these values, there are a few critical points to note:

a. Simply maintaining the JEDEC recommended 8 mils coplanarity could be insufficient in some applications (e.g., large body size packages on thick PWBs).

b. It is important to characterize the *effective* warpage between the package and PWB in addition to the warpage of the free standing package alone.

c. This warpage characterization should be performed over the entire reflow temperature range, as opposed to at room temperature. Of critical value is the warpage at or above the melting temperature. The data should be recorded in accordance with the JEDEC high temperature package warpage measurement specification.[12]

d. Where possible, the characterization should be performed on PWBs that are representative of actual PWBs used in volume production.

One useful way to mitigate solder bridging is to depopulate the corner-most balls of the package. In large body-size organic packages, a significant amount of warpage occurs at package corners, so depopulating the 6 corner-most balls at each corner could help absorb about 2 mils of effective warpage (Fig. 62.15). This helps minimize the likelihood of solder bridging/opens. Many package suppliers already depopulate the four corner balls to improve long-term reliability of the solder joints.

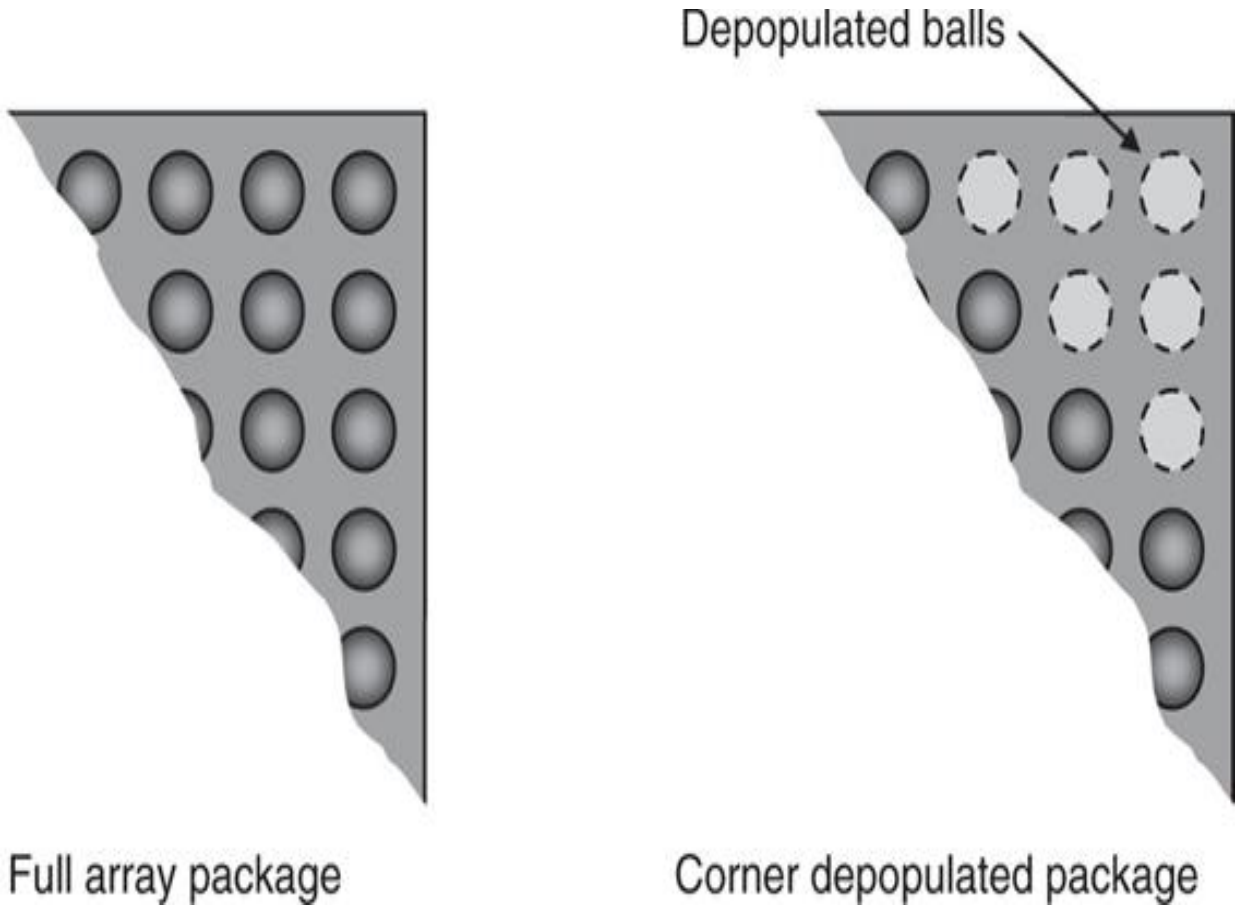

FIGURE 62.15 Depopulated corners to improve warpage-related assembly yield.

62.3.8.1 Effect of Lead-Free Conversion. It is important to note that the data presented in Figs. 62.13 and 62.14 is based on the surface tension of tin-lead solder. The surface tension[13] and contact angle of lead-free solders is higher than for tin-lead solders, but analytically, for the solder joint parameters analyzed, the warpage versus ball diameter curve is not significantly different from the data presented in Figs. 62.13 and 62.14. This is because the wetting area is presumed to be fixed in the analysis. For other solder geometries (gullwing, J-lead, QFN, and so on), the behavior of lead-free solders can be different.

62.3.9 PWB Pad Design

The size and shape of the pad used on the PWB has a significant impact on the reliability of BGA solder joints. In general, the reliability is optimal when the pad size/opening on the package side is the same size as that on the PWB side. Deviation from the same pad size could result in a reduction of up to 25 percent in solder joint fatigue life.[14] The side with the smaller pad size tends to fail earlier because the stress concentration is higher near the smaller pad. Generally, non-solder mask defined (NSMD) pads are used on the PWB for packages with solder pitches in the range 1.27 to 0.8 mm. As opposed to solder mask defined (SMD) pads, NSMD pads do not have a localized stress concentration around the solder joint, which tends to degrade the thermomechanical fatigue life of solder joints (Fig. 62.16).

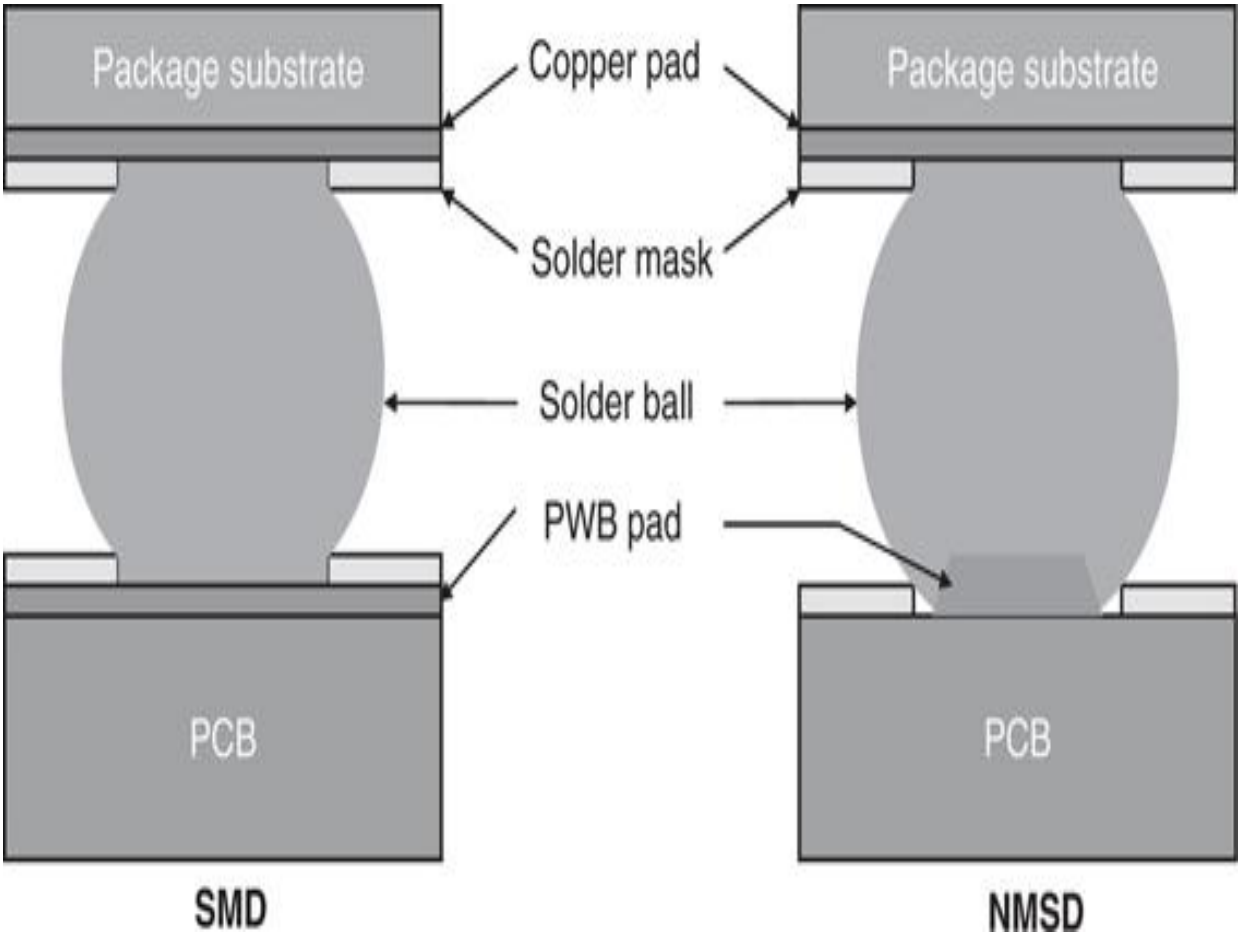

FIGURE 62.16 Solder-mask defined (SMD) and non-solder mask defined (NSMD) pad construction. For optimum reliability, the pad size on the PWB should be kept within 80 to 100 percent of the wetted pad area on the package side. This allows the stresses to be vectored equally between both ends of the solder joint, and if the PWB pad is slightly smaller, it allows a slightly higher stand-off height, which also tends to enhance solder joint reliability.

For packages with solder joint pitches less than 0.8 mm, a mix of NSMD and SMD pads is sometimes inevitable. At small pitches, it is difficult to route the traces from the pads in the typical “dog bone” fashion. Thus, to allow routability, the common, power and ground pads are “bussed” together to form one large pad. The connected pads are SMD, whereas the individual signal pads are kept NSMD.

In general, it appears that while SMD pads tend to improve the resistance of solder joints to mechanical shock loading conditions, they also tend to degrade the thermomechanical fatigue life of the joints. Therefore, when the choice of pad construction is made, the impact on both thermomechanical fatigue and shock conditions should be characterized. (Details of typical shock testing conditions are outlined in Chap. 59.)

It is important to note that the pad size specified in the fabrication drawings is not always the pad size that actually comes on all the fabricated PWBs. Actual measurements of pads specified at 12 mils NSMD could range anywhere from 9 to 15 mils. This is particularly critical for small pitch packages, because the solder volume is smaller and such variations in pad sizes could significantly alter the shape and reliability of the solder joints. A tolerance analysis such as worst case (WC) or root sum squares (RSS) should be conducted and a pad size specified such that it would not significantly exceed the pad size specified on the package side. Refer to the IPC-7351 specification for details of such tolerance analysis.[15]

Finally, it is clear that one common theme in the foregoing recommendations is that the PWB pad size should be pegged

to the package side solder wetted area. Across the industry, the challenge with this recommendation is that the package pad size/opening is not always provided by package suppliers in relevant datasheets and mechanical drawings. To address this issue, JEDEC revised the JEDEC Publication 95[10] in 2004 to include nomenclature showing the pad size and construction on the package mechanical drawings. Adoption of this JEDEC nomenclature by package suppliers would go a long way in ensuring that the PWB design used by end users does not deleteriously impact the reliability of the package.

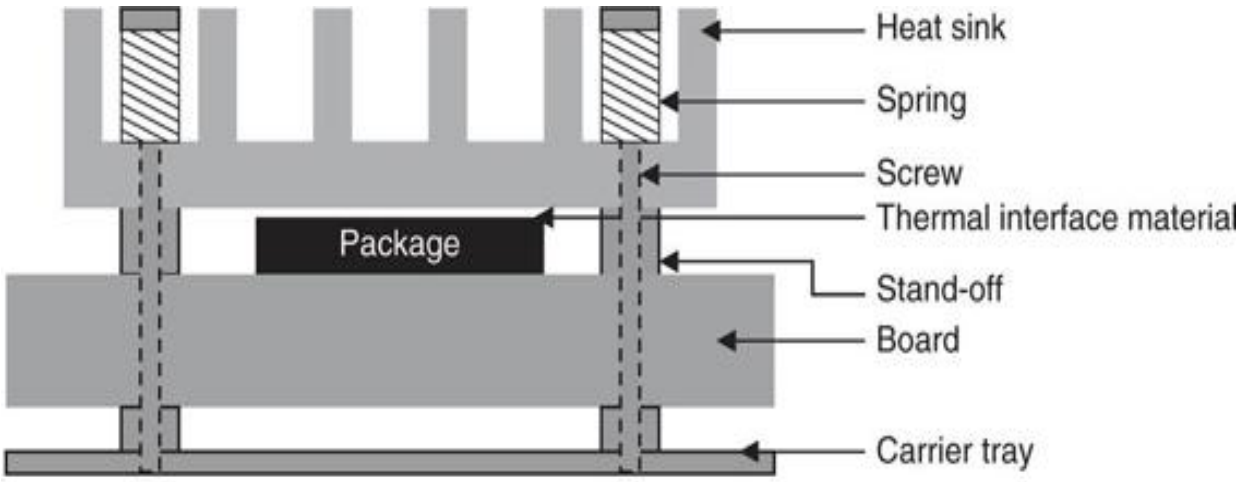
62.3.9.1 Effect of Lead-free Conversion. The impact of un-optimized pad size selection is detrimental to both tin-lead and lead-free assemblies. Fine pitch components (<0.8 mm pitch), regardless of solder metallurgy are much more prone to pad size-related failures.

62.3.10 Heatsink Design Issues

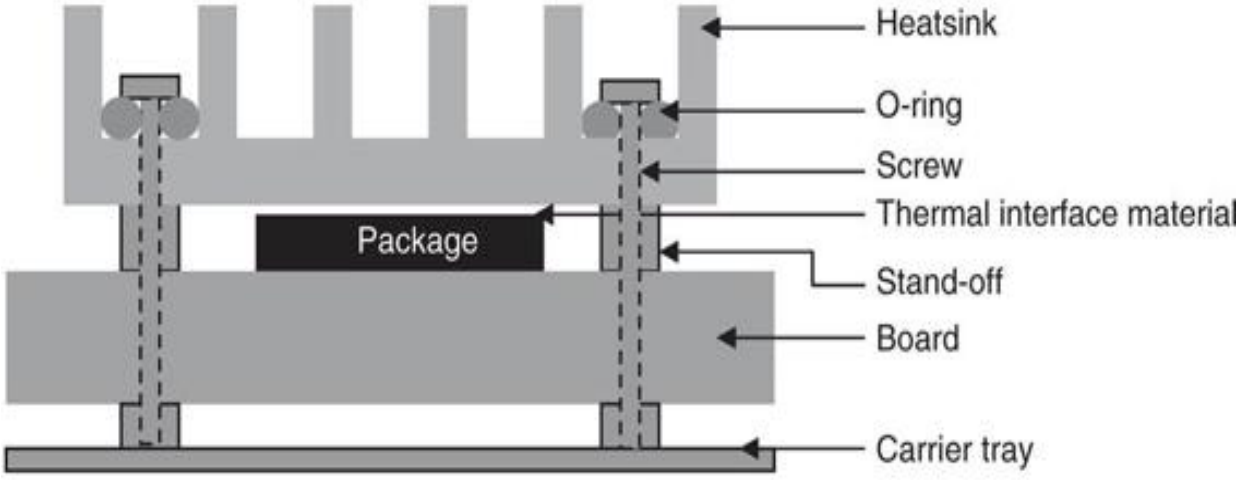
As PWB designs get more complex and more densely populated, the power dissipation from single cards can be on the order of 1000 W. A lot of heat needs to be transferred from individual cards, and from the chassis as a whole. Consequently, heatsinks are becoming larger and heavier. Heatsinks as large as 10 sq. in, weighing more than 1 lb are not unheard of. If not designed correctly, large heatsinks could transfer a significant amount of compressive load to the packages they are meant to cool. This compressive load could result in cracks in the package/ silicon, or cause the solder joints to deform and bridge.[16] On the other hand, smaller heatsinks that are anchored to the package substrate could impart additional bending moments on the substrate that could negatively impact the reliability of the package.[17]

For bolt-down heatsinks, a significant amount of the compressive load comes not from the heatsink weight but from the bolt down mechanism itself. Tolerance variations in package height, warpage, heatsink stand-offs, and so on only make the applied load worse. The attachment mechanism should be such that it can accommodate these variations in tolerance without transferring excessive load to the package.

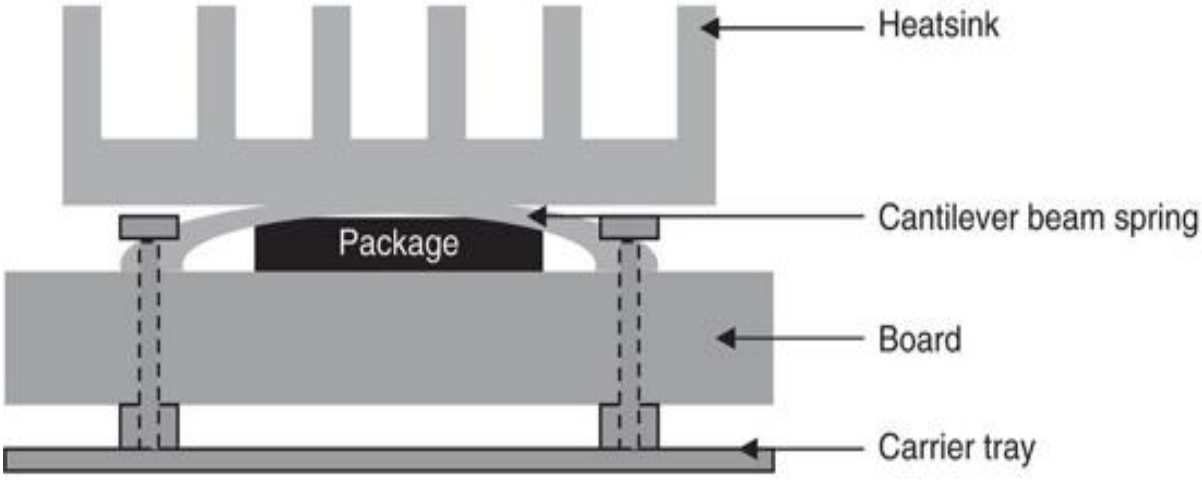
Some of the attachment methods that could help accommodate tolerance variations and minimize the amount of loading imparted on to the package are shown in Fig. 62.17. The trade-offs of using each method are summarized in Table 62.2.



Spring-loaded solution.



O-Ring solution.



Integrated cantilever spring solution.

FIGURE 62.17 Heatsink attachment methods.

TABLE 62.2 Comparison of Different Heatsink Attachment Methods

Attachment Method	Advantage	Disadvantage
Spring-loaded solution	Useful for absorbing significant tolerance variations by varying spring constants.	Relatively expensive. Bulky
O-ring solution	Less expensive. Less bulky.	Marginal control in tolerance stack-up induced pressure.
Integrated cantilever spring solution	More versatile. Could be range of expected loads.	Requires custom heatsink design. Could be more cumbersome to install.

Pressure-indicating film can be used to verify the amount of load applied on the package. The film contains tiny microcapsules of colored dye. These microcapsules rupture depending on the amount of pressure applied on the film, producing a pressure footprint. The results are not extremely precise, but can be used to estimate the amount of load applied, as a first pass approximation.

To verify the impact of heatsink loading on package solder joint reliability, temperature cycling can be performed on packages with heatsinks and compared with control samples. However, there are two caveats:

1. The heatsinks tend to cool the packages during temperature cycling, thus producing improved reliability data. The improvement may simply be because the solder joints are cycled over a lower temperature range. Thus it is important to either thermally shield the heatsink fins or calibrate the thermal cycling chamber such that the solder joints run at the same temperature range as control samples; in spite of the heatsinks.

2. Packages thermal cycled under compressive load could undergo two failure mechanisms: cyclic loading (fatigue induced opens) and static compressive loading (bridges due to solder collapse). Temperature cycling can accelerate the cyclic loading portion, but not the static loading portion. Thus, simply performing temperature cycling and comparing with control samples may not suffice. The static-loading component should also be accelerated, for instance, by dwelling at a high static temperature.

62.3.11 Surface Finish Issues

In recent years, the role of package surface finish in the robustness of BGA packages has gained more prominence. Several different surface finishes are used across the industry, and there are trade-offs with the use of each one. The surface finish used could impact intermetallics formed in the solder joints, which in turn can impact the thermomechanical and mechanical reliability of the package.

In recent years, a number of surface finishes have become more prevalent. The surface finishes with which the effect on package reliability is relatively well known, are outlined in this section.

62.3.11.1 Electroless Nickel Immersion Gold. This has been the surface finish of choice for most high-end, flip-chip BGA packages. It enables the routability of fine pitch traces in high pin count packages. Historically, Electroless Nickel Immersion Gold (ENIG) produces excellent board-level solder joint reliability.

However, there are two primary concerns with ENiG:

1. *Brittle fracture* This failure mode is seen in high strain/strain rate conditions, such as shipping, testing, and handling. A typical signature of this failure mode is a clean

separation in the intermetallic between the pad and the solder joint. This failure typically has a low defect rate in production, but the ensuing line stops, customer returns, and root-cause analyses are quite expensive. Moreover, the unpredictability of the failure and the susceptibility to mechanical handling/testing/shipping conditions makes it quite undesirable.

There are a few failure mechanism theories proposed to explain brittle fracture,[18] but no conclusive failure mechanism has been agreed upon in the industry. The predominant theory is based on the formation of Kirkendall voids during reflow, in the phosphorus-rich Ni layer and Sn-Ni intermetallic interface. Kirkendall voids are voids that form at the interface of two dissimilar materials. They form because the two materials diffuse into each other at different rates. Other factors such as the concentration of P in the Ni-P+ layer and the density of mudflat cracks in the Ni-P+ layer have also been shown to have an influence on the propensity of brittle fracture. The intermetallics formed in the joint during the assembly process are shown in Fig. 62.18.

(b) After the ball is attached, a number of intermetallics are formed between the copper pad and the SnPb solder joint. Kirkendall voids are known to form at the phosphorus-rich Ni layer and Sn-Ni intermetallic interface. (c) After board-level reflow, the interface region thickens and several more intermetallics are formed.[19] (*Reprinted with permission from Renesas Technology Corp./© [2003] IEEE ECTC*.)

The presence of pervasive Kirkendall voids could reduce the strength of the solder joint. A mechanically applied strain could result in the sort of brittle solder joint failure shown in Figs. 62.19 and 62.20.

- *Ni-Cu-Sn intermetallic* Another phenomenon reported to cause a similar failure is based on the formation of a Ni-Cu-Sn ternary intermetallic in the solder joint.[20] The Ni-Sn intermetallic forms on the component side during ball attach. When the part is mounted on the board, copper migrates from the board pad side, across the BGA ball, to form a Ni-Cu-Sn intermetallic on the component side. The thickness of this ternary intermetallic, typically 3 to 5 mm thick, could grow with additional reflows.[20] Clearly, an important factor contributing to this phenomenon is the surface finish on the PWB side. If the surface finish has a barrier like Ni to prevent copper from migrating across the BGA ball, this ternary intermetallic is less likely to form on the component side.
- *Strain/strain rate* It has also been observed that the strain to failure of solder joints is a strong function of the strain rate. The higher the strain rate, the lower the strain-to-failure. One theory to explain this strain rate dependency is that the stiffness of bulk solder itself is strain rate dependent: at low strain rates, solder tends to deform and absorb some of the applied strain. Thus, less strain is actually transferred to the Kirkendall void-rich region. At high strain rate levels (typically above 5000 uε/s), bulk solder behaves more like a linear elastic material and transfers more of the applied strain to the voids, causing brittle solder joint fracture. A graph illustrating the relationship between strain and strain rate for solder joint failure is given in Chap. 59.

  It is important to note that brittle solder fracture does not always occur exclusively. Frequently, it can be accompanied with pad lift, substrate cracking, or other intermetallic-related failure.

2. *“Black pad” corrosion phenomenon*[21] This is a discoloration phenomenon caused by excessive oxidation of the Ni. This leads to increased contact resistance, which causes intermittent opens during electrical testing. It is believed that the “black pad” phenomenon is caused by impurities in the plating bath during the ENIG plating process. The impurities create pores in the gold plating, thus exposing the Ni to moisture and other contaminants. Consequently, the Ni oxidizes and manifests in varying extremes as a discoloration in the pad. Tighter process controls during the plating process and regular purging of the plating bath can significantly mitigate this corrosion phenomenon. Failures stemming from black pad can be distinguished from brittle fracture by the following features: visible discoloration of the pads and a lot-to-lot dependency in failures due to impure plating baths.

62.3.11.1.1 Effect of Lead-Free Conversion. Given these known issues with ENIG, many package suppliers have moved away from it for lead-free applications. However, several package suppliers still use ENIG with standard tin-lead and lead-free solder. There isn’t enough data to show the effect of ENIG on lead-free solder, but preliminary results indicate that the failure modes seen with tin-lead solder would also be seen with lead-free solder. In general, since lead-free solders are stiffer than tin-lead solders, they have higher strain/strain rate strength than tin-lead solders. More detail on tests to evaluate failure strength and failure modes is provided in the next chapter.

62.3.11.2 Solder-On-Pad. This is also known as “pre-applied solder” because it involves pre-applying a small amount of solder on the package substrate pad before the ball-attach process. Care must be taken to ensure that the height of solder applied on the pad does not exceed the thickness of the solder mask (Fig. 62.21).

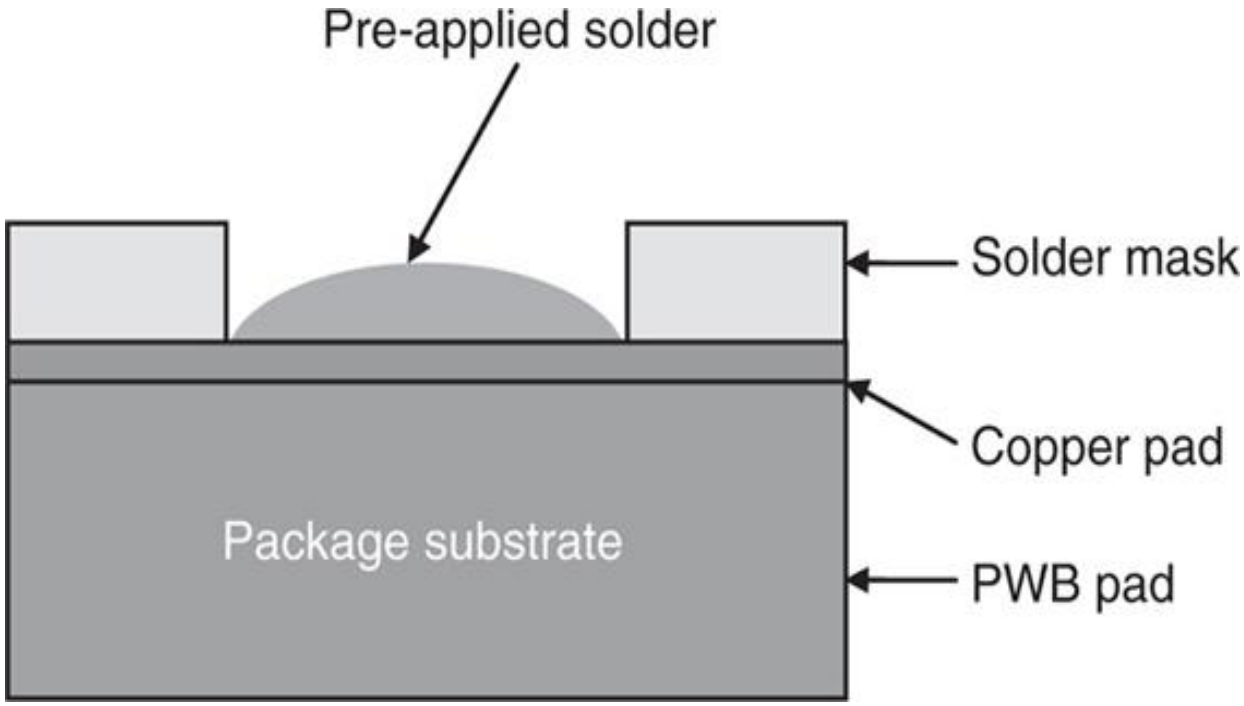

FIGURE 62.21 Solder-on-pad schematic.

Exceeding the height of the solder mask would result in alignment/registration issues during the assembly process. As with ENiG, there are concerns with the mechanical robustness of solder-on-pad (SoP) solder joints. The Ni in ENIG serves as a diffusion barrier for the copper metallization. In the absence of Ni, copper diffusion occurs much faster and two intermetallics are known to form in SOP solder joints: Cu_6Sn_5 and Cu_3Sn. Under high temperature aging conditions, these intermetallics are known to grow in thickness. Thus, if tin-lead or lead-free parts with SOP are aged at high temperature (either in lab testing or in field conditions), they could have a higher propensity for brittle fracture.[22,23] By extension, one concern is that if solder joints can become brittle when aged over time, what would happen if the product has been operating in the field at high nominal operating temperatures, and it is subjected to shock conditions? Would it fail early? For instance, what if the product is a cell phone with an SOP based BGA used in it? If the user drops the cell phone after sustained usage, is there

a propensity for brittle fracture? According to some publications on shock testing of lead-free assemblies (Cheng et al.),[22] aged SOP joints subjected to shock conditions tend to fail relatively early. However, this has not been universally demonstrated. Moreover, the shock conditions to which hand held products are tested (~1500 G max), are much more aggressive than typical shock conditions for server environments (~500 G max). In tests performed on aged tin lead SOP samples subjected to lower shock conditions, the parts were not shown to fail due to brittle fracture, even though the presence of some Kirkendall voiding was observed (Mei et al.).[24] However, the amount of Kirkendall voiding observed was not as pervasive as that reported by Cheng et al.[22] (Fig. 62.22).

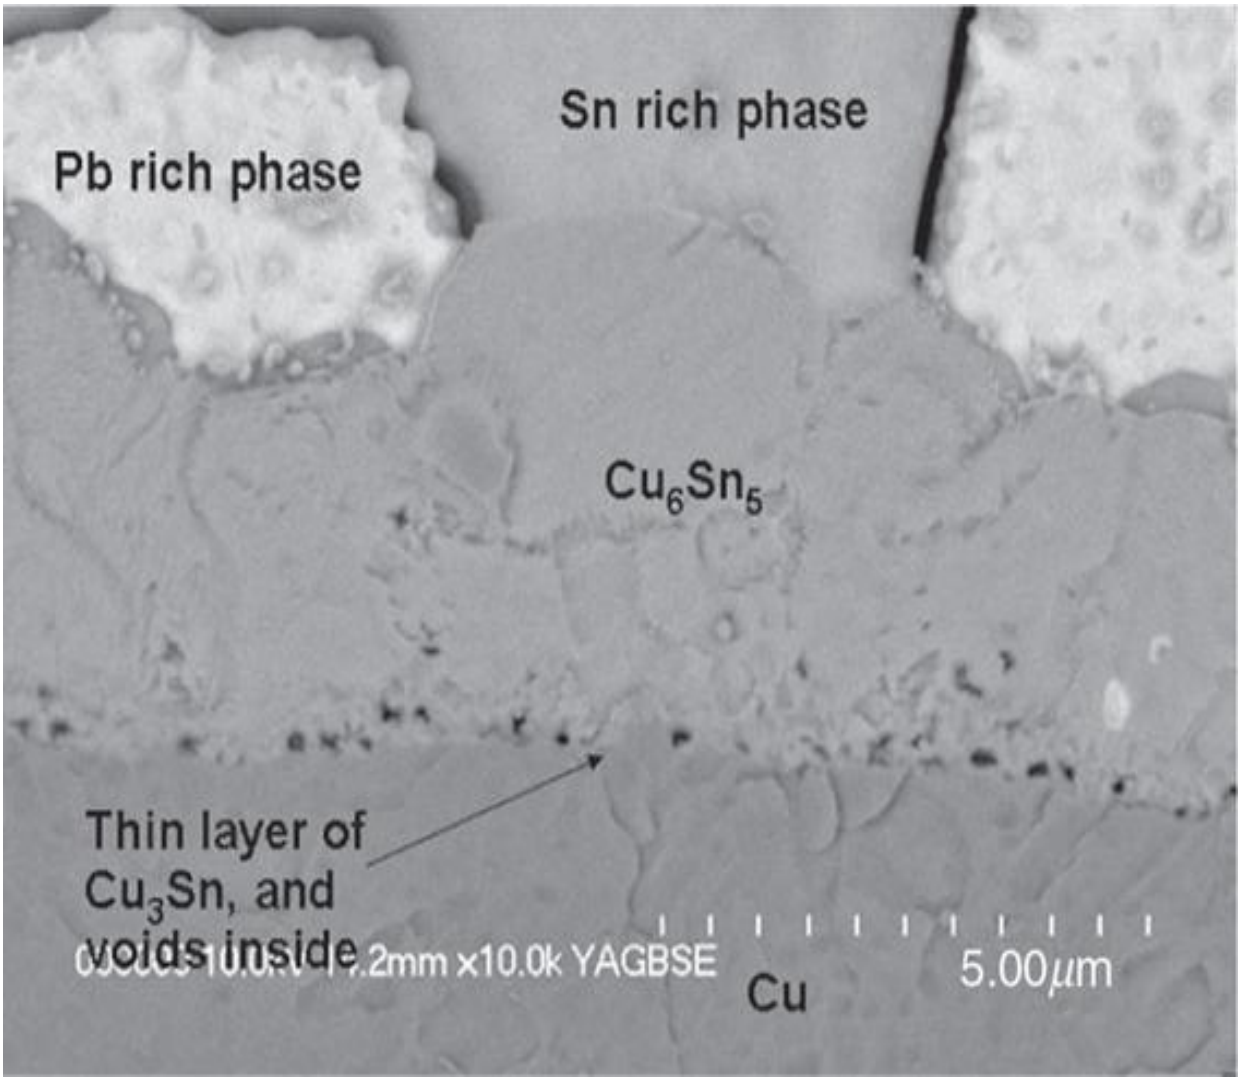

FIGURE 62.22 SEM backscattering electron image of tested sample with solder-on-pad surface finish—package/ball interface. The image shows the intermetallics formed at the joint/package interface. These intermetallics include a thick layer of Cu_6Sn_5 and a thinner layer of Cu_3Sn. Small voids are seen at the Cu_6Sn_5 and Cu_3Sn interface.[24] (*Reprinted with premission from IEEE © [2005].*)

A curve fit of the data by Cheng et al.[22] reported by Mei et al.[24] as a function of void area and aging time for different temperatures is shown in Fig. 62.23.

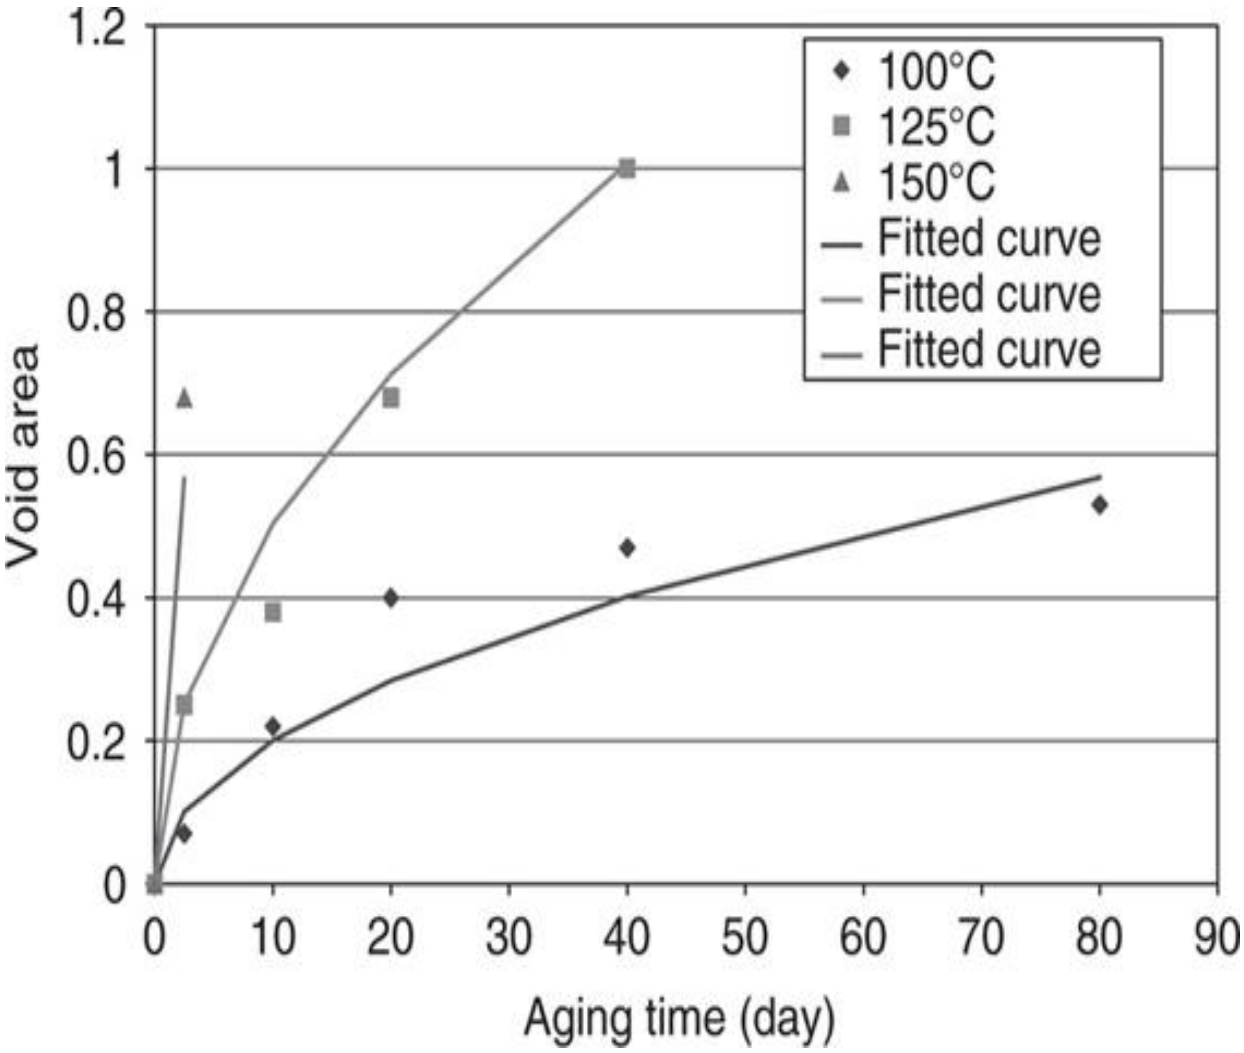

FIGURE 62.23 Curve fit of data at three different temperatures based on the data generated by Cheng et al.[24] The values are based on experimental measurements of void area versus time for different temperatures. (*Reprinted with premission from IEEE © [2005]*.)

The fit equation from the Cheng et al.[22] data is given as[24]:

$$A = Ct^{0.5} \exp\left(\frac{-Q}{RT}\right) \tag{62.1}$$

where A = ratio of voided area to the joint interface area
t = time in days
Q = activation energy
T = absolute temperature in K
R = gas constant.
$C = 145590\ (\text{day}^{-0.5})$
$Q = 45413\ \text{J/mol}\ (0.47\ \text{eV})$

With this approximate curve fit, extrapolating to end-use conditions can give an estimate of the time it would take for the voiding to reach 50 percent of the interface area. For instance, at 50°C nominal operating temperature, it would take 6000 days (16.5 years) to reach 50 percent of the interface area. It is important to note that the mechanisms that control the propensity and pervasiveness of Kirkendall voiding are not clearly known at this time. There isn't enough experimental data in the industry at this time to conclusively validate the aforementioned relations.

The occurrence of Kirkendall voids is not limited to the package/solder joint interface. If OSP is used as the PWB surface finish, the same phenomenon is observed to occur on the PWB side.[24]

In terms of strain/strain rate strength, un-aged, SOP-based joints have been shown to have as much as twice the strength of ENiG joints. More details on comparison tests are outlined in the next chapter.

There are a number of other surface finishes used in the industry, such as Electroless Nickel Electroless Palladium Immersion Gold (NiPdAu), Immersion Silver, Immersion Gold, Immersion Tin, OSP and Electrolytic Nickel Gold. There are reliability and process trade-offs with each surface finish. That is why it is recommended that strain/strain rate characterization and thermal cycling be performed for each

set of surface finish before it is selected for the specific end-use conditions in which it will be used. The industry test methods used to evaluate different surface finishes are outlined in detail in the next chapter.

62.3.12 Final Electrical Test Architecture

During in-circuit testing (ICT), assemblies are subjected to high strains due to the number and distribution of test points applied underneath BGAs. Assemblies are also subjected to high strain rates in ICT because the speed of engagement of test points helps reduce the electrical contact resistance between the test probes and probe pads. Thus, from an electrical test perspective, high strain rates are desirable during ICT. However, there is a strain/strain rate range beyond which the likelihood of solder joint failure increases.

The actual strains induced in a printed circuit board assembly (PCBA) is a function not only of the number and layout of test points, but also the fixture design, package and PWB warpage, the surface finish used on the package and PWB, and the fixture actuation rate. During final test, it is very difficult, if not impossible to reduce the number of test points. Thus, if they are correctly designed-in early in the design process, it would minimize the likelihood of strain-induced failures in final testing.

A schematic showing the forces applied in the immediate vicinity of a BGA package in an ICT fixture is shown in Fig. 62.24. The distribution of test points underneath a BGA should be made as uniform as possible. Several ICT fixtures have push fingers on the top side, which push down on the board, countering the force of the test probes. The use of “push-pins” or “push-fingers” on the top side of the board is not recommended. Push fingers induce localized stress concentrations, resulting in high strain in their immediate

vicinity. If used, push fingers should not be placed close to package corners. For some generic recommendations on ICT test point layout, refer to IPC7351.[15] An alternative to push fingers is the use of a Milled City or zero-flex top plate on the top side.

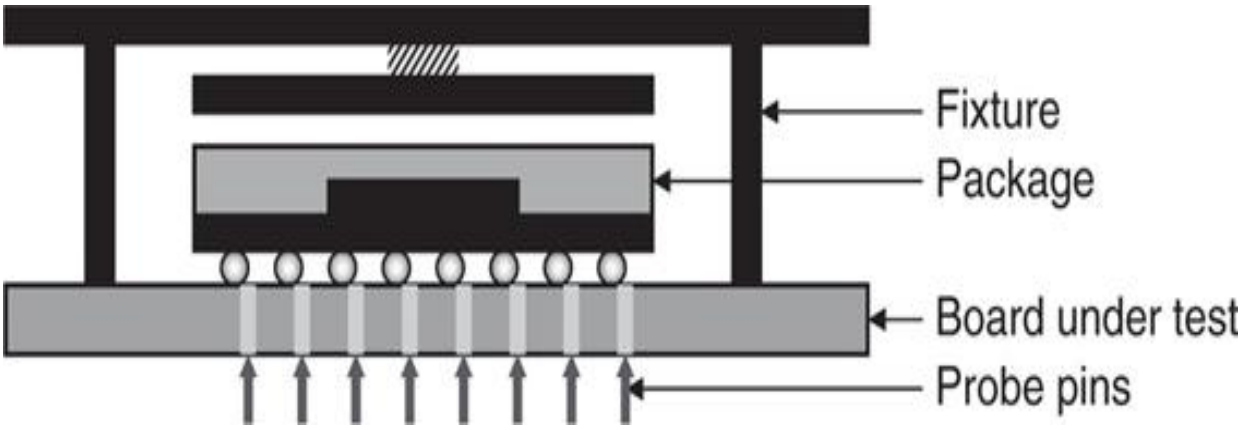

FIGURE 62.24 Schematic of ICT loading conditions.

This is basically a rigid metal plate which has a negative image of the entire board milled out. Thus, as opposed to having several push fingers, the entire board is pressed against the Milled City plate. This significantly reduces local stress concentration, and could potentially be used to enable PCBAs to withstand more test points. Milled City plates are expensive, but considering the cost of line stops and customer-related issues due to strain-induced failures in ICT, the nonrecurring cost of the Milled City is a worthwhile investment.

62.3.12.1 Effect of Lead-Free Conversion. The conversion to lead-free solder has given even more prominence to this issue. With lead-free solders, a higher temperature organic solderability preservative (OSP) could be used. As a result, it could take more force to establish contact with the test pads. This translates to higher force applied to the PCBA. Moreover, the effect of mechanical bending on lead-free solders is yet to be fully characterized.

Thus, there is a greater need to characterize the mechanical force applied on lead-free assemblies.

For the same applied force, the strain on thinner PWBs is higher than that on thick PWBs. Thus, this is more critical on assemblies with relatively thin boards (<93 mils thick). However, depending on the package, warpage, surface finish, and number of test points, it could also be seen on thick boards.

Strain gage characterization should be performed on fixtures with actual boards, in order to verify that excessive strains are not applied on critical components. In an effort to standardize strain characterization, the JEDEC/IPC 9704[25] test method was published in June 2005. This test method outlines the procedures and best practices relating to strain measurement in a manufacturing environment.

62.3.13 Package Design Parameters

A key factor that impacts second-level interconnect reliability is the package itself. Although the primary function of the package is to pass signals, power, and ground from the silicon device to the PWB, the package also provides protection for the silicon and enables a more robust interconnect than a direct chip attach. The critical package design parameters which can have a significant impact on the reliability of the solder joints are discussed in this section.

62.3.13.1 Overall Dimensions and Distance from Neutral Point. Package size continues to grow as the number of I/Os increase to meet the demands of ever increasing IC functionality. As IC complexity increases, memory is embedded in devices, while as silicon feature sizes decrease, I/O counts continue to be driven upward. Package dimensions have surpassed 50 mm. Package layer

counts for both ceramic and plastic material sets continue to increase rapidly.

In addition to the solder joint geometry issues outlined in Sec. 62.3.8, increases in overall size tend to coincide with increases in the distance from the center of the package to the outer ball (see Fig. 62.25). This dimension is referred to as the distance from the neutral point (DNP). As DNP increases, the amount of stress and subsequent damage inflicted on solder joints increases, especially during thermal cycles encountered in field environments. Thus packages with larger DNPs (and with all other material and design parameters equivalent) will have lower interconnect reliability. This is crucial when assessing second-level reliability data.

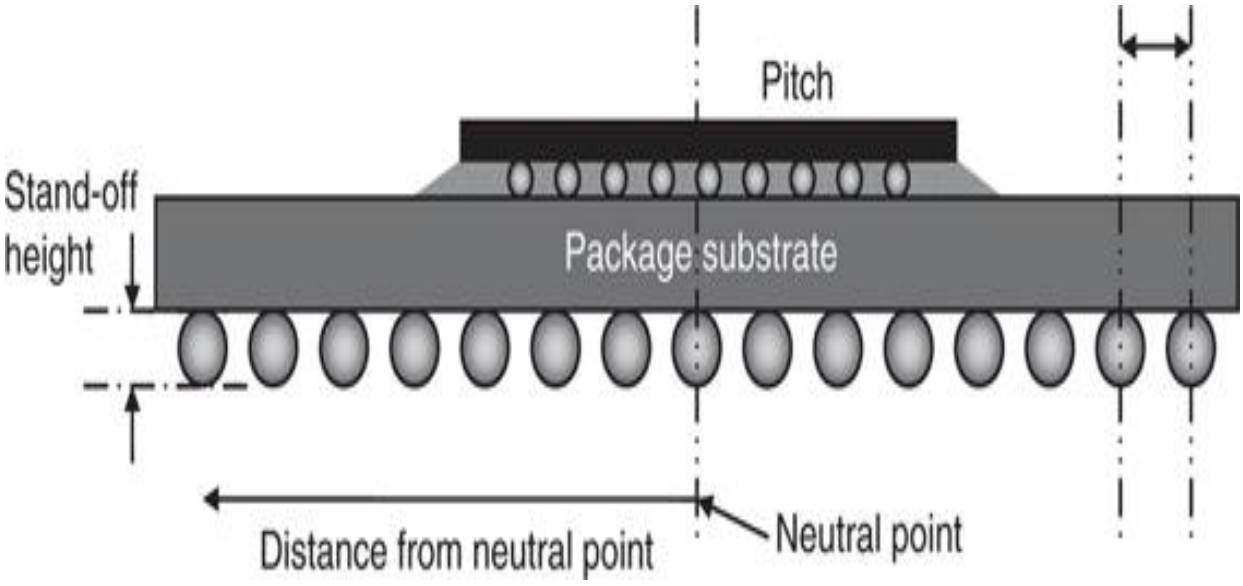

FIGURE 62.25 Distance from neutral point (DNP) for a BGA-type package. The DNP increases when moving away from the center (center line) of the package. Pitch is also indicated in this diagram. Pitch is defined as the center-to-center distance between two adjacent interconnects (in this example, between two adjacent solder balls).

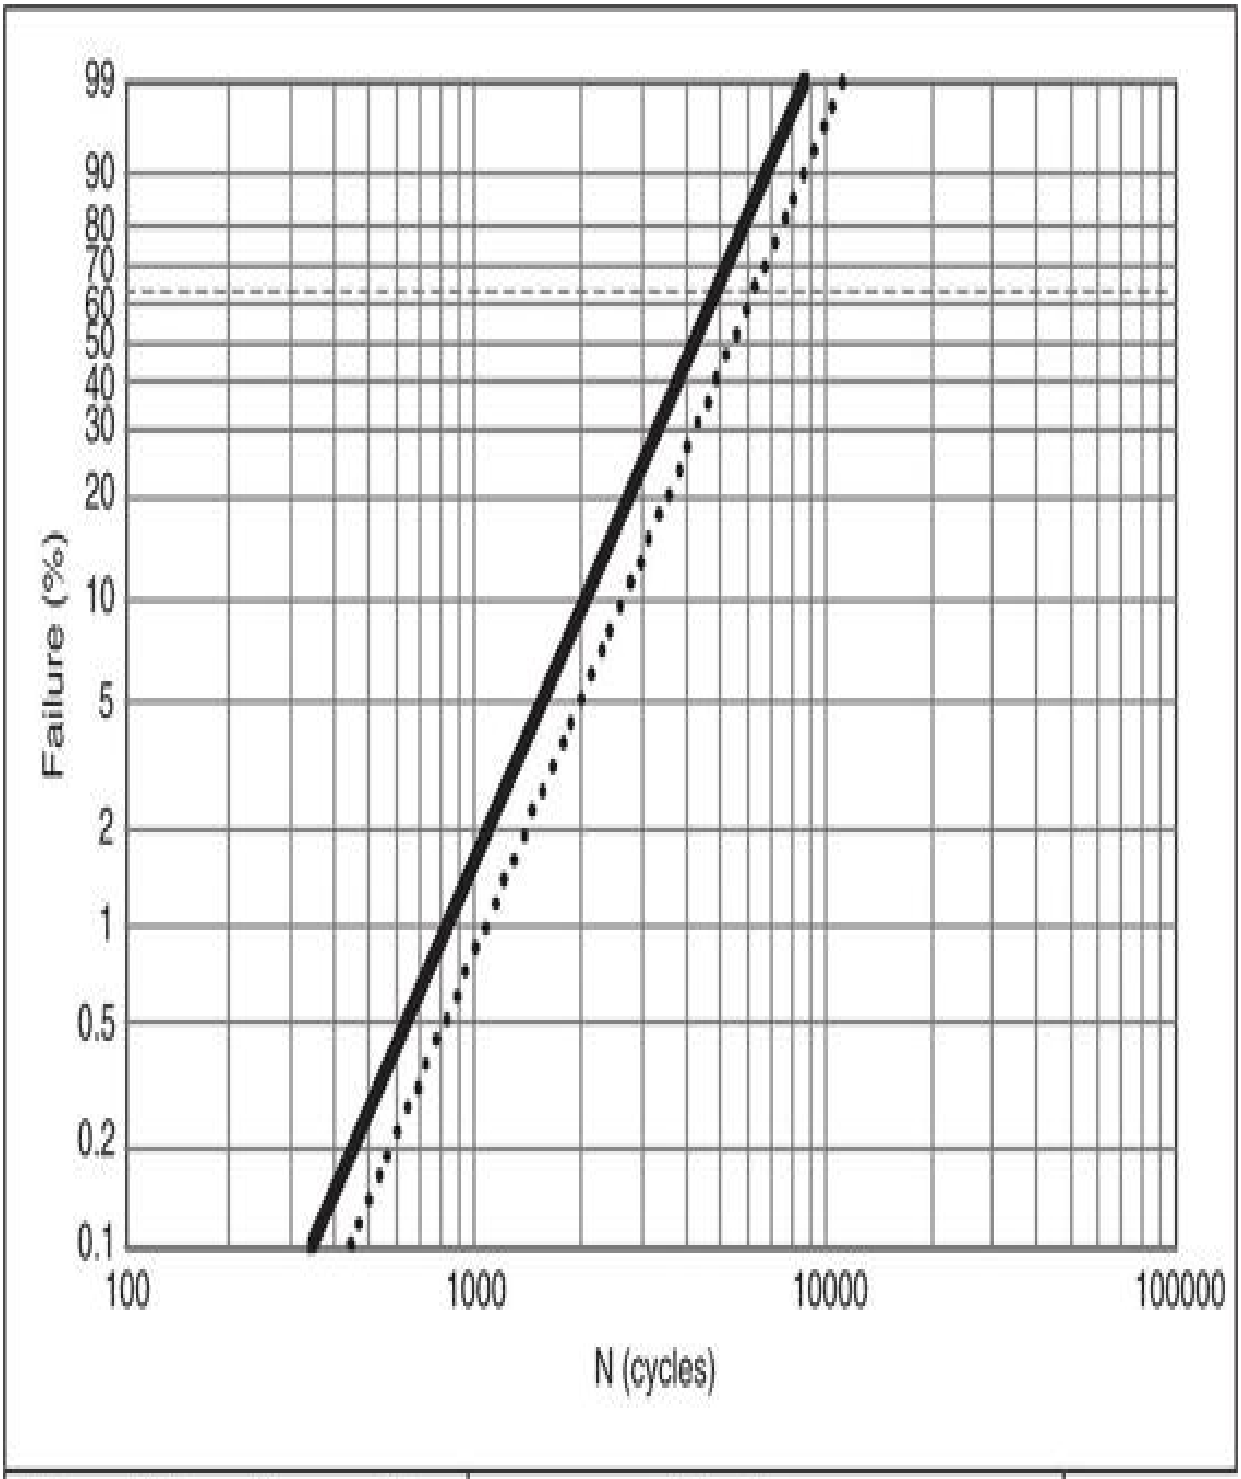
Most packaged IC suppliers qualify their products by thermal cycle experiments. The most common board-level temperature cycling methodology used across the industry is

outlined in IPC 9701.[6] The resistance in each solder joint is typically monitored in real time by incorporating a daisy-chain package and some type of data acquisition system. The end results of these experiments are failure distributions typically presented as Weibull plots (for details on Weibull distributions and failure life analysis, refer to Sec. 64.2.2 in Chap. 64) that show failure percentage as a function of time.[26] Note that if a package with a larger DNP than was qualified is considered, then there could be severe degradation in reliability and a full assessment should be conducted. However, if a package with a smaller DNP (10 to 20 percent smaller) than the package qualified (with all other material and design parameters being equal) is considered, then the proposed package should be at least as reliable as the qualified package.

62.3.13.2 Ball Pitch and Ball Size. Ball pitch is the center-to-center distance between two adjacent solder balls (see Fig. 62.25). In theory one could change the ball pitch and keep the same solder joint size. In practical applications though, decreases in ball pitch also require a reduction in solder ball diameter and pad size for physically accommodating the decrease in distance between adjacent balls. This decrease in ball size, with decreasing pitch, results in the formation of smaller balls with smaller stand-off between the package and the PWB. Smaller solder balls and decreased stand-off have been shown to decrease solder joint reliability (see Fig. 62.26).



Eta	Beta	r^2	n/s
4806	2.6	---	-/-
6231	2.6	---	-/-

	Data set	
▬	1	S3 30 Mil ball 1.5 mm
⋯	2	S3 35 Mil ball 1.5 mm

FIGURE 62.26 Weibull plots for two different ball size/stand-off heights. The solid line indicates the finite element analysis (FEA) predicted failure distribution for an interconnect based on a 30-mil stand-off height. The dashed line indicates the FEA predicted failure distribution for an interconnect based on a 35-mil stand-off height. Note that a reduction in stand-off height correlates with a decrease in fatigue life.

The dashed line in Fig. 62.26 represents the finite element analysis results for a 0.889-mm (35-mil) ball. The solid line represents finite element analysis results for a 0.762-mm (30-mil) ball. Note that the 0.889-mm ball is 1.3 times more reliable than the 0.762-mm ball. Thus reduction in pitch can result in decreases in reliability due to the subsequent decreases in solder ball size necessary to accommodate adjacent balls and the reduced stand-off heights due to smaller solder balls.

The PWB designer is therefore faced with a dilemma when considering a reduction in ball pitch. Not only is there a risk of reduced assembly reliability, but there is also a design challenge. A direct consequence of decreased pitch is added complexity in the ability to route all traces out from the package to the PWB. Designers are also sometimes forced to add additional layers to PWBs in order to accommodate reduced-pitch parts. This layer increase results in increased price and in some instances, drastic reductions in capacity due to the increased complexity associated with fabricating high-layer-count PWBs.

62.3.13.3 Ball Array (Full or Depopulated). Ball array is another variable that has an indirect impact on solder joint reliability. There is a coupled effect between the location of the edge of the packaged die, the solder ball array, and the state of stress in the solder joints. The silicon has a much lower CTE than plastic substrates. Thus the die can create a state of overconstraint, producing excessive stress in the solder joints under and near its edge. This overconstraint tends to be worst in joints near the edge of the die.

Figure 62.27 contains schematics of one configuration where a full array is employed and the edge of the die falls over the solder joints. Figure 62.28 illustrates an alternative design, where a region near the perimeter of the die is depopulated of all solder balls (the depopulated configuration). Many plastic (laminate) package suppliers offer a depopulated option to enhance reliability by not placing solder joints in the worst-case regions under the perimeter of the die. Additionally, many package designers further reduce risk of CTE-induced joint failure by only placing redundant power and ground or nonfunctional thermal balls under the core. If redundant balls or thermal balls do crack, the impact on device performance is negligible. Finally, in large laminate packages, the corner-most balls could also fail early. As a result, many package suppliers depopulate the corner balls of the package to enhance solder fatigue life.

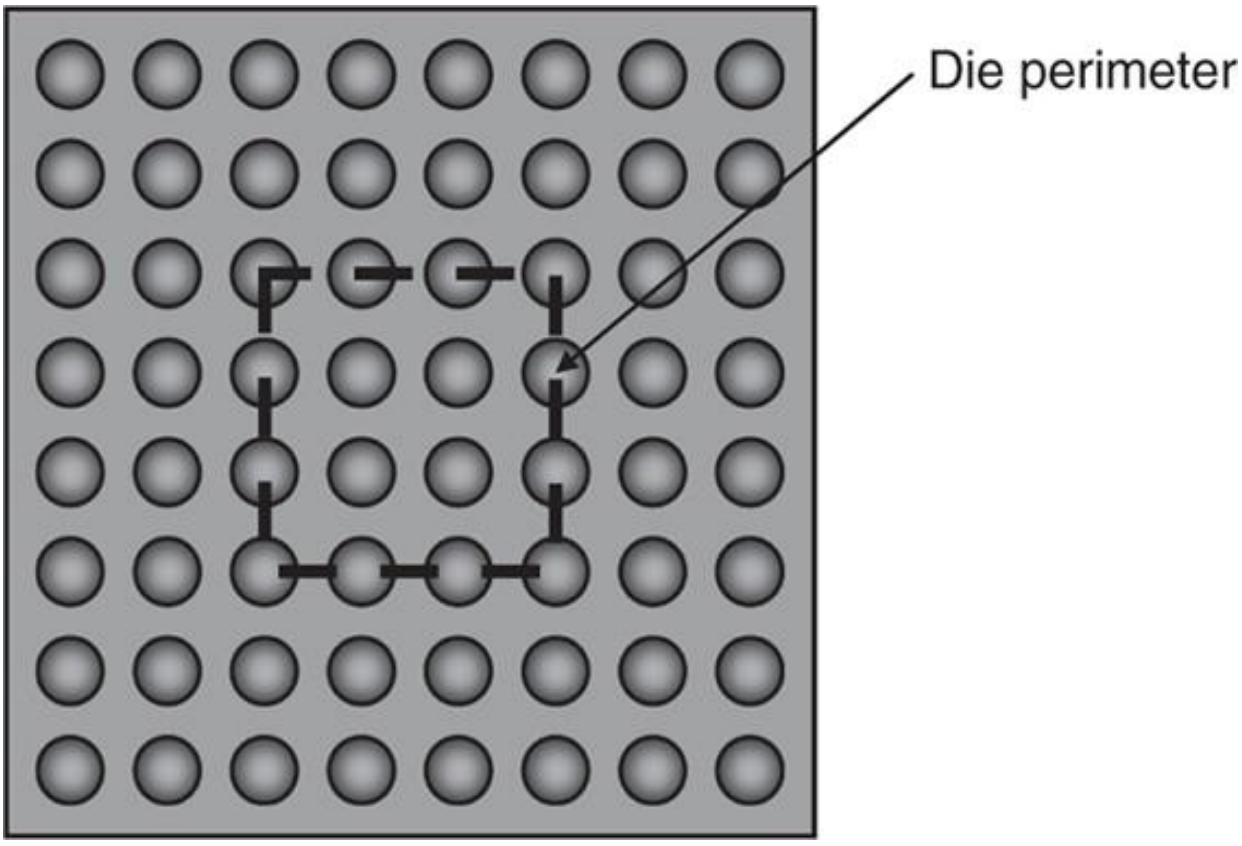


FIGURE 62.27 Full array with solder joints under the die perimeter. Solder ball locations are indicated by the array of circles. The die perimeter is indicated by the black dashed rectangular outline. Note that the die edge falls directly over solder joints.

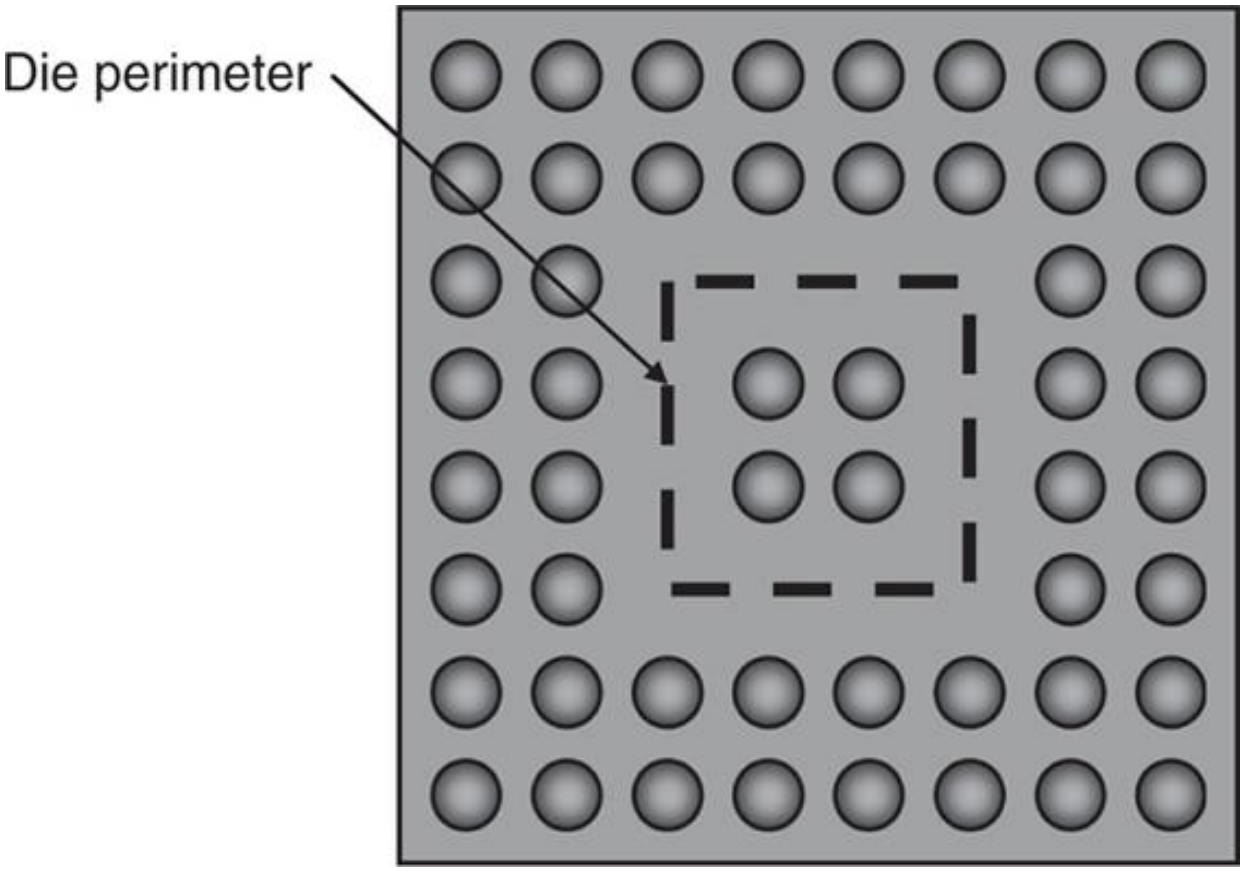

FIGURE 62.28 Depopulated array with no joints under the perimeter of the die. Solder ball locations are indicated by the array of circles. The die perimeter is indicated by the dashed rectangular outline. Note that the die edge falls in an area of depopulated solder balls.

62.3.13.4 Heat Spreader/Stiffener. A cross-sectional schematic of a flip-chip assembly, with a heat slug and stiffener, is shown in Fig. 62.29. The primary reason for employing a heat spreader lid is for thermal management. A secondary benefit is that the stiffener and heat slug reduce the potential for out-of-plane warpage occurring during reflow and thermal cycling. An additional benefit of incorporating a heat slug and stiffener into a laminate

package design is improved ability to handle the package due to increased robustness of the packaged die.

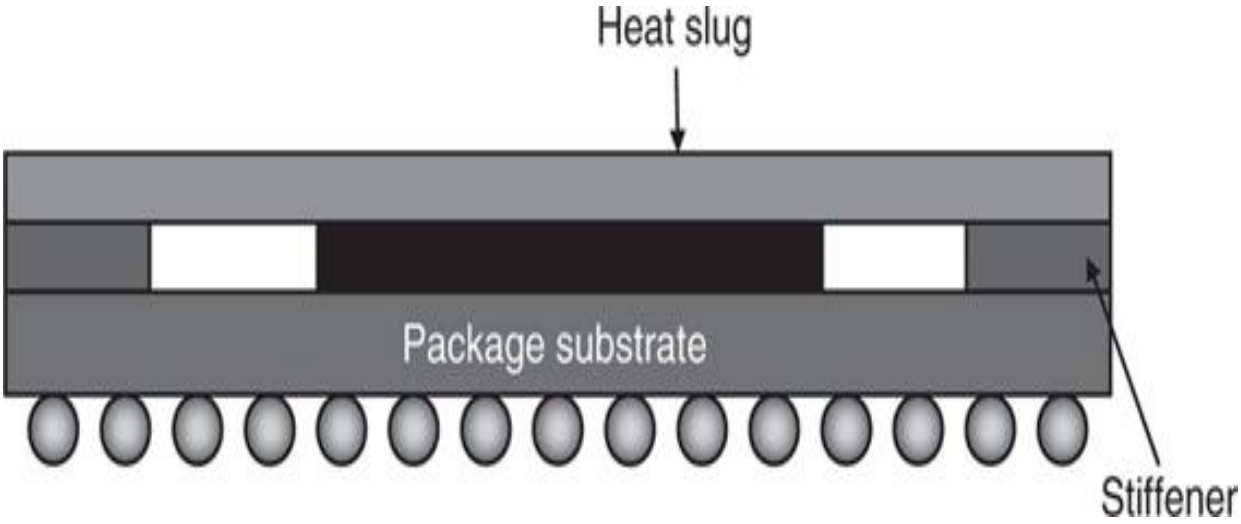

FIGURE 62.29 Flip-chip BGA with stiffener and heat slug. The stiffener provides added rigidity to the package and also provides mechanical support for the heatsink.

A variety of heat spreader materials have been used: copper, aluminum, steel, and aluminum silicon carbide (AlSiC). Copper provides the best thermal conductivity, but it has a high CTE. AlSiC has a slightly higher modulus than copper, but it has a lower CTE. As a result, in several applications, AlSiC is gaining more prevalence. Its thermal conductivity is lower than copper and comparable to aluminum (180 to 200 Wm^{-1} K).

For cost reasons, several package suppliers also use an alternative to the heat spreader/stiffener design, namely, a single piece lid design to act as a rigid support and provide heat transfer at the same time. This design is easier to manufacture and also reduces assembly steps (see Fig. 62.30 for more details).

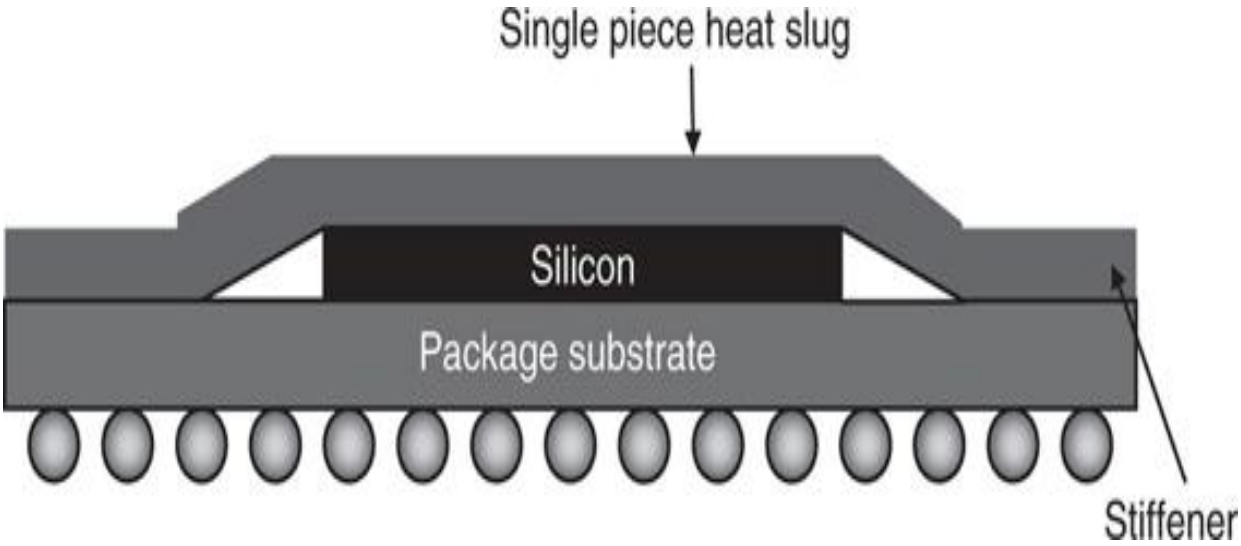

FIGURE 62.30 Single piece lid design.

The thickness of a single piece lid is typically less than that of the heat spreader/stiffener combination. Changing the stiffness of the package could alter its out-of-plane warpage, which in turn could impact the reliability of the solder joints. Therefore the effect on the overall stiffness should be characterized when using a single piece lid. One characterization method is to perform Moiré measurements on the free standing package, as a function of temperature.

Another variation of the standard heat spreader/stiffener design is the use of just a stiffener alone. This is usually for bare die applications where the wattage of the chip is so high that the thermal resistance between the chip and the heat spreader is unacceptable. In such cases, the stiffener is retained for stiffness and robustness, but the heat spreader is removed.

62.3.13.5 Mold Compound Selection. The overmold compound used in plastic ball grid array (PBGA) packages could significantly impact the assembly yield and reliability of solder joints. If the glass transition temperature (T_g) of the mold compound is significantly below the peak reflow temperature and if its modulus and CTE drastically change

above its T_g, the package could warp significantly as it is heated. As a result, when the package reaches liquidus, the effective warpage between the package and PWB could be such that solder joint opens/bridges could occur. In large PBGA packages (>40 mm), it would be more effective to use an integrated heat spreader in the molded package to rigidize it and minimize excessive warpage. Integrated heat spreaders are primarily used to improve thermal performance, but they also help rigidize the package for improved assembly yield.

With the conversion to lead-free materials, the mold compound selected needs to be such that it can withstand the higher reflow temperatures of lead-free assembly. If the mechanical material properties of the mold compound (elastic modulus, CTE, and T_g) are not appropriately selected, the package could warp significantly at reflow temperatures and result in solder joint opens.

62.3.13.6 Underfill Material Selection. The underfill material selected in flip chip BGA (FCBGA) packages could significantly impact the reliability of the board mounted package. If the underfill material is too stiff, it would rigidize the assembly and thus transfer more strain to the silicon die. This could result in delamination at any of the critical interfaces: underfill/ passivation, passivation/die, underfill/substrate, or within low-k layers.

On the other hand, if the underfill material is too soft, it could result in first-level interconnect failure. A less stiff underfill could also help reduce board-level assembly warpage, which in turn helps the second-level interconnects. Thus, the stiffness of the underfill selected should be optimized such that it does not lead to delamination or first-level interconnect failures.[9] In addition to stiffness, CTE, and T_g, there are several other factors that dictate the underfill

material selected, such as thixotropy, viscosity, shrinkage, curing temperature, and curing time.

The choice of underfill material is also influenced by the conversion to lead free. For lead-free packages, even though there is a European exemption on the first-level interconnects,[27] many package suppliers are looking at using lead-free first-level interconnects. As a result, the underfill material selected has to be such that it can withstand the higher reflow temperatures, and has low shrinkage for the increased temperature range.

62.3.13.7 Die/Package Aspect Ratio. The size of the silicon die relative to the package body size could significantly impact the reliability of the package. This is especially applicable to PBGA packages. The larger the die relative to the package, the higher the CTE mismatch-driven strains imparted to the second-level solder joints.[28] The degree of impact varies with package body size and absolute die size.

62.3.13.8 Package Substrate Material. The choice of package substrate material can have a large impact on solder joint reliability. Some substrates require employing solder ball alternatives (such as the ceramic solder column carriers shown in Fig. 62.4) or even the elimination of a soldered solution due to interconnect reliability considerations. A wealth of information regarding ceramic and plastic substrates can be found in the literature.[26,29,30] This section focuses on the impact of those materials on solder joint reliability.

The two key material properties of a substrate that impact interconnect reliability are modulus of elasticity (E) and coefficient of thermal expansion (CTE). Modulus of elasticity is defined as the ratio of stress to strain and can be used to describe a material's ability to resist deformation when subjected to an applied load. CTE relates the change in

length of material when heated or cooled and can be used to describe a material's deformation when subjected to temperature changes. Reference 31 contains detailed discussions of modulus of elasticity and coefficient of thermal expansion. A tremendous amount of material property data can be found in the literature.[26,29,30] Figure 62.31 contains a sketch of a simplified solder joint interconnect. Note that the driving force for solder joint fatigue during field use is the coefficient of thermal expansion mismatch between the assembled package and the PWB. Additionally, the modulus of elasticity of the substrate can impact the fatigue life of solder joints by increasing (or decreasing) the driving force that is imparted to the solder interconnect.

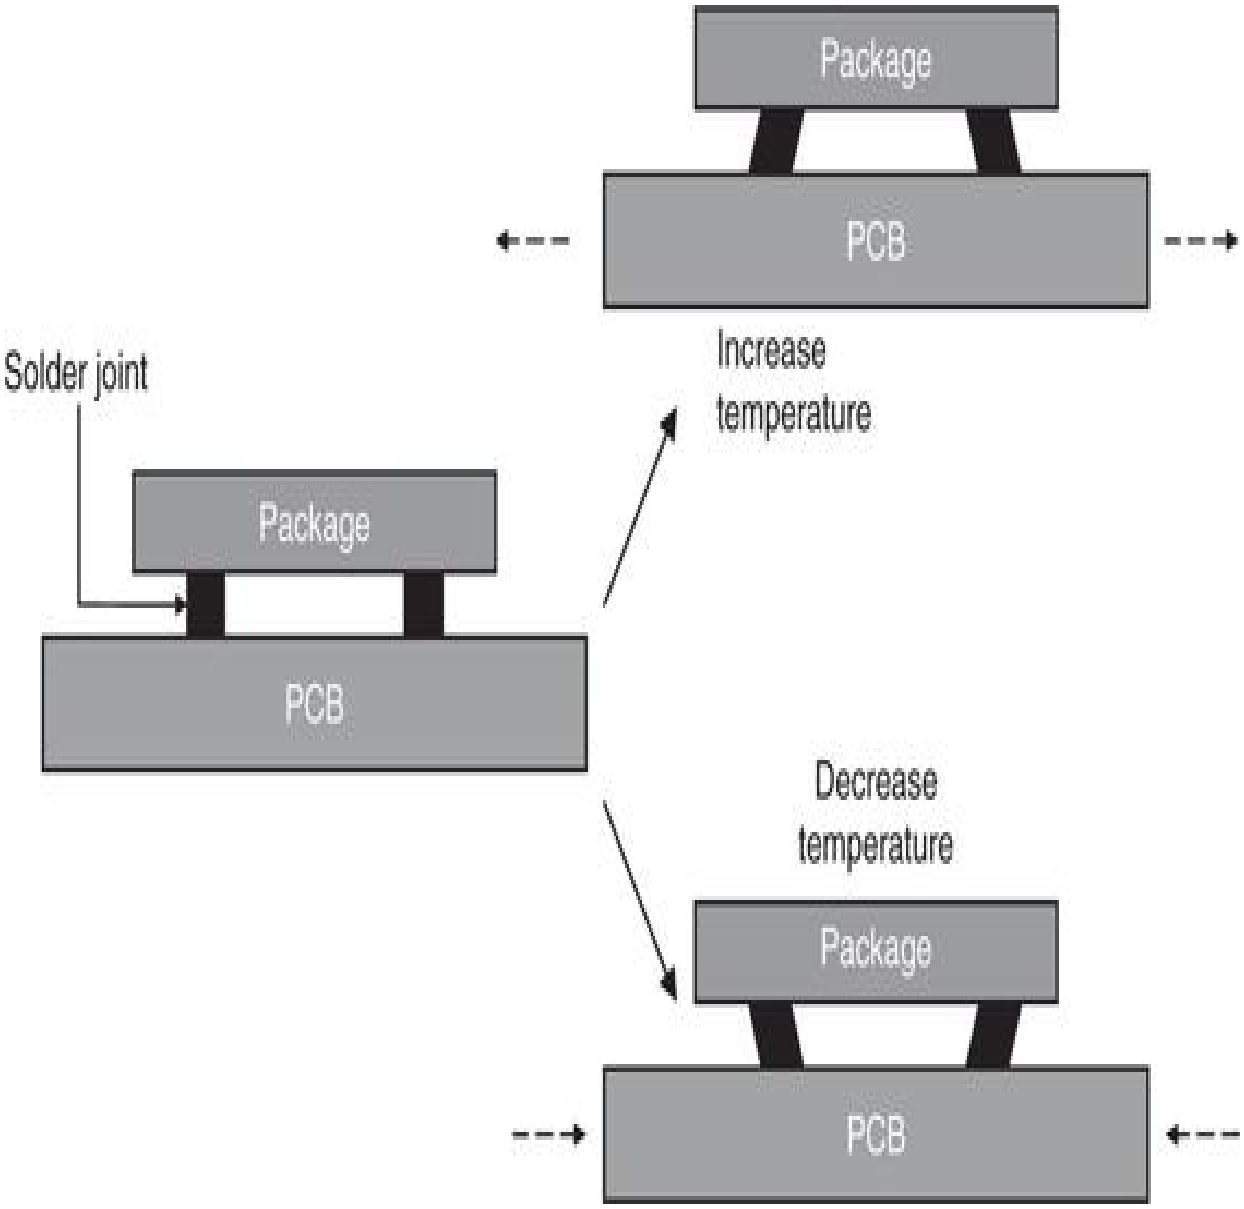

FIGURE 62.31 Simplified CTE mismatch effects. As the temperature increases, the PWB expands at a higher rate than the package due to the package having a lower effective CTE. As the temperature decreases, the opposite effect is observed.

Ceramic materials provide excellent CTE match between the die and package, which then reduces the risk of first-level solder bump failure in flip-chip applications. Unfortunately, this superb CTE match between the ceramic and the silicon die creates a large CTE mismatch between the ceramic package and the PWB. This CTE mismatch

creates severe stress on the second-level interconnects (see Fig. 62.31). This CTE mismatch, combined with DNP issues (previously discussed), limits ceramic BGA body sizes to approximately 32 × 32 mm. Ceramics with larger body sizes typically employ solder columns (Fig. 62.4) or compression-type sockets for second-level interconnect.

The CTEs of plastic packages tend to match the CTEs of PWBs fairly well. This CTE match allows for larger package body sizes to be employed when using a laminate-based BGA than with a ceramic package. It is crucial to note that many other variables independent of second-level reliability must be taken into consideration when selecting a package. Power requirements, signal integrity, first-level reliability (interconnect between the die and package), and cost must all be balanced when selecting the correct package for a specific application.

62.3.13.9 Impact of Low-k Dielectrics. Continued miniaturization and integration has led to the need for a multilevel interconnect layout to minimize the time delay due to parasitic resistance (R) and capacitance (C). The improvement in gate-level device speed is negated by the propagation delay at the metal interconnects because of the increased RC time constant.[32] For instance, the RC delay of long interconnections contributes up to 50 percent of the time delay in devices with a gate length of 250 nm or less.[33] A reduction in the RC time constant requires the use of low resistivity interconnect materials and low capacitance interlayer films. The capacitance is a function of the material dielectric permittivity (ε_i), area (A), and thickness (d). ($C = \varepsilon_i A/d$). Increasing the area would require increased interconnect lengths, which in turn would result in high resistance. The thickness can also not be increased because it also increases resistance and poses manufacturing challenges in consistently filling the interlayer layers. Consequently, the dielectric constant (k) needs to be

reduced. Hence the need for low-*k* materials. In addition to having a low dielectric constant, ideal low-*k* materials need to have low residual stress, high planarization capability, high gap-filling capability, low deposition temperature, and ease of process integration.[32] A list of possible candidates for low-*k* materials is outlined in Table 62.3.[33]

TABLE 62.3 Typical Low-k Materials[33]

Determinant	Materials	Dielectric Constant
Vapor-phase deposition polymers	Fluorosilicate glass (FSG)	3.5–4.0
	Parylene N	2.6
	Parylene F	2.4–2.5
	Black diamond (C-doped oxide)	2.7–3.0
	Fluorinated hydrocarbon	2.0–2.4
	Teflon-AF	1.93
Spin-on polymers	HSQ/MSQ	2.8–3.0
	Polyimide	2.7–2.9
	SiLK (aromatic hydrocarbon polymer)	2.7
	PAE [poly(arylene ethers)]	2.6
	Fluorinated amorphous carbon	2.1
	Xerogels (porous silica)	1.1–2.0

However, several of the new low-*k* materials are porous and structurally weak. This poses several challenges in the back-end assembly process: poor adhesion, residual stresses in the inner layer dielectric (ILD) films, and so on. In addition

to optimizing and better monitoring the wafer-sawing process, the effect of chip-to-package interactions also needs to be characterized. The choice of material set, underfill, substrate, lid material, and so on could impact the reliability of the low-*k* dielectric.

In flip-chip BGA (FCBGA) packages, the choice of underfill material in particular has been the subject of considerable interest.[34–36] In addition to a new material set and design rules, several packaging assembly manufacturers have evaluated the use of low glass transition temperature (T_g) underfills to reduce the stresses imparted to the silicon. However, while using a low T_g underfill may minimize the stresses on the low-*k*, it could in turn transfer the stresses elsewhere, such as in the first-level interconnect.[37] Moreover, the effect of the material set on ILD delamination and solder joint reliability may be different when the free standing package is stressed, as opposed to when it is mounted on a printed circuit board and then stressed.

In wirebond BGA packages, the effect of the wirebonding process on the low-*k* dielectric needs to be characterized.[38] In addition, the choice of mold compound material (modulus and CTE) could also impact the long term reliability of the low-*k* dielectric in the fully assembled package. The package with the selected material set should be subjected to component-level and second-level temperature cycling, followed by scanning acoustic microscopy (SAM) to ensure that there are no delamination-induced failures in the low-*k* dielectric or other critical interfaces.

CHAPTER 63

LEAD-FREE SOLDER JOINT RELIABILITY: FUNDAMENTALS AND DESIGN-FOR-RELIABILITY RULES

Jean-Paul Clech
EPSI Inc., Montclair, New Jersey

63.1 INTRODUCTION

Solder joints provide mechanical and electrical connections between components and the board or the substrate to which they are attached. Their integrity over the product design life is critical to the electrical performance of the system. Solder joints that crack due to thermal and/or mechanical loads lead to intermittent opens or completely open electrical interconnections. Solder joint failure rates are expected to remain below the components failure rates (often given in FITs, where 1 FIT is defined as 1 failure in 10^9 device hours) throughout the intended design life of the system. In practical terms, this means that components

should fail first and that solder joints should be designed to survive past the functional life of the system.

Over the last 30 years, solder joint performance has been influenced by technology trends:

- The demand for smaller parts and systems has led to finer pitch and smaller size solder joints, which may experience higher stresses than joints of conventional through-hole and first generation surface-mount assemblies.
- Integrated circuit (IC) packages have seen their silicon contents increase, reducing the effective coefficient of thermal expansion of packages and exacerbating the thermal expansion mismatch between board or substrate and components.
- The advent of portable electronics has called for improved drop performance while high-power ICs have raised thermal loads in computationally intensive applications and harsh environments. An example of more demanding use conditions is that of automotive on-engine assemblies that experience temperatures as high as 150 to 175°C.
- The transition from tin-lead to lead-free assemblies, with solder alloys having higher melting points than conventional eutectic tin-lead, has led to the introduction of new package and board materials whose impact on assembly reliability is not well established. Mixed alloys (lead-free paste mixed with lead-free balls of a different composition) have led to an infinity of possible solder alloy compositions, very few of which are characterized as well as tin-lead was.

Safety margins have been greatly reduced since the days of all through-hole assemblies. A proactive approach is thus needed to ensure that soldered assemblies meet product reliability goals. Once reliability goals are agreed upon by interested parties throughout the supply chain,

demonstrating the reliability of a circuit board assembly necessitates that proper resources be allocated to conduct adequate reliability testing and modeling.

Solder joint field failures fall into two grand categories or a combination of both:

- Infant mortality failures—these are often due to poor soldering quality such as insufficient solder, poor wetting or excessive offset of components with respect to mounting pads. Meeting workmanship requirements does not imply that field reliability goals are met. For example, Class III, “high-reliability” products that meet the most demanding workmanship requirements have failed in the field. Workmanship standards set criteria to achieve a certain level of soldering quality. They are not based on reliability test data.
- Wear-out failures that occur prematurely due to excessive stresses that could have been anticipated had design-for-reliability studies been performed. For example, leaded packages with a low expansion lead-frame (e.g., Alloy 42 instead of copper) add local stresses due to the local thermal expansion mismatch between solder and the lead foot. These stresses, combined with shear stresses due to the global in-plane expansion mismatch between the board and the component, can be detrimental to solder joint reliability and need to be considered when assessing product reliability. Another example is that of pure creep failures that occur under constant load, a violation of an old rule-of-thumb—learned from experienced engineers from the through-hole assembly era—which states that solder joints should not be subjected to static mechanical loads.

Soldering quality remains a prerequisite to long-term reliability and is best achieved by following industry standards and best soldering practices. This is addressed in

other chapters of this handbook and IPC standards (e.g., J-STD-001). The present chapter focuses on design-for-reliability rules that help build-in reliability at the design stage. Established rules-of-thumb and simple algebraic equations are given that enable physical designers to make quick decisions and rational choices in the early stages of board design. These rules and guidelines apply to both tin-lead and lead-free assemblies. Lead-free failures that have been brought to the author's attention occurred on similar components and under similar circumstances as for field failures of tin-lead assemblies. Chapters 62 and 64 cover test and modeling techniques that are of use to quantify and prove in the reliability of soldered circuit boards and packages.

63.2 RELIABILITY DEFINITION AND GOALS

The standard definition of reliability, as applied to solder joints, is that of industry associations (e.g., IPC-SM785, IPC/JEDEC 9701):

> "Reliability is the ability of a product to function under given conditions and for a specified period of time without exceeding acceptable failure levels."

The above definition is well accepted in courts of law during litigation proceedings involving solder joint failures in electronic products that have ceased performing properly. Three items are highlighted in the above definition:

- "*Given conditions*" refers to the spectrum of loads—thermal, mechanical and/or electrical—that the product is expected to sustain in use. This includes one-time or

cumulative stresses that the products will experience during shipping and handling and under field use conditions.

- The "*specified period of time*" is the target design life, for example, a 3- to 5-year life for laptop or desktop computers, 100,000 miles or 10 years of life for an automobile.
- "*Acceptable failure levels*" refers to the fraction-failed or percentage of failures that should not be exceeded at the end of life, for example, no failures at 40 years in some aerospace, medical, or solar panel applications, less than 0.01 percent cumulative failures at 15 to 20 years in telecommunication network applications, etc.

Reliability goals are set based on end-user requirements or customers' expectations. Design-for-reliability requires an upfront investment of time and resources, and a commitment to meet reliability goals. How to achieve these goals is the responsibility of the product management team, preferably with buy-in and input from the entire supply chain. Solder joints being the interface between board and components, both board and component characteristics have an impact on solder joint life. Reliability is best achieved through a team effort involving equipment manufacturers, suppliers, and assemblers.

63.3 WHY DO SOLDER JOINTS FAIL?

Both standard SnPb and lead-free solder joints have failed in the field. Unfortunately, field failures are not talked about much in the public domain and the history of SnPb failures is bound to repeat itself with lead-free or mixed assemblies. Most failures can be attributed to poor initial solder joint quality and/or an oversight of use conditions or basic design-

for-reliability practices. A few examples of failures investigated by the author and some of his consulting colleagues are discussed briefly in this section.

Through-hole solder joints have failed under numerous circumstances, especially under harsh conditions such as in automotive under-the-hood or on-engine units. Some of these failures, which are easily observed on the solder side of through-hole assemblies, are illustrated by photographs posted by repair shops on the World Wide Web (e.g., under automotive forums). However, very little to no failure mode analysis is available. This author participated in a field failure investigation, where through-hole solder joint failures occurred within a short period of time (less than 1 year) in a consumer, video system subassembly. Fatigue failures occurred in substandard solder fillets that were subject to thermomechanical cyclic loads.

SnPb solder joints of Leadless Ceramic Chip Carriers (LCCC) have failed in medical implants (Engelmaier, ca. 2000), even though the LCCC parts were small, solder joints met workmanship standards and use conditions were very mild (constant, internal body temperature around 37°C). The failures were attributed to excessive thermal cycling cumulative damage that occurred in the LCCC solder joints when “traveling salesmen” carried and delivered medical implants to health-care facilities up and down the East Coast of the United States, subject to diurnal and seasonal temperature cycles in their vehicles. The lesson learned in this case is the need to account for all thermo-mechanical cycles that circuit boards may experience from the end of the assembly line to the end of the design life.

Both SnPb and lead-free leaded components with Alloy 42 lead-frames have experienced solder joint failures. Alloy 42 small outline transistor (SOT) and small outline diodes (SOD) have failed under harsh automotive conditions. Alloy 42 TSOPs have failed in use in desktop computer applications (Engelmaier, ca. 1992–2000). In addition to the global CTE

mismatch between the component body and the circuit boards, the solder joints of these devices experience large stresses and strains due the local CTE mismatch along the interface between the foot of Alloy 42 leads (CTE around 4 ppm/°C) and the solder joint alloy (CTE around 24 ppm/°C). In several of these cases, failures could have been prevented by exceeding workmanship standards. As demonstrated by Reichelt (1998), even IPC Class III requirements may not be sufficient for components with Alloy 42 leads. Instead, assembly standards may need to be tightened for some harsh environment applications, requiring zero offset and no rotation of component leads with respect to the mounting pads on circuit boards.

SnPb solder joints have also failed in the case of leaded components with copper lead-frames. Here, the local CTE mismatch is much less of a concern since copper has a CTE of about 17 ppm/°C, close enough to the CTE of tin-based solders. SnPb solder joints of low profile Small Outline Integrated Circuit (SOIC) failed in a computer application within 1 year of use. Failure analysis showed coarsening of the SnPb microstructure, a strong indication of thermal cycling creep-fatigue failures. While the lead-frames were made of copper, the low-profile components had rather short leads that may not have been compliant enough to absorb cyclic shear strains driven by the board-to-component global CTE mismatch. Lesson learned: in the case of low-profile leaded components, estimate or measure leads stiffness as well as board and component in-plane CTEs to make sure that the leads are compliant enough to handle solder joint cyclic strains due to global CTE mismatches (Kotlowitz, 1989).

SnPb failures have occurred by pure creep rupture in through-hole assemblies with insufficient solder filling—in spite of meeting workmanship requirements—or due to excessive static loads. The rule-of-thumb (original source unknown) still holds that soft solder joints are not load-

carrying members. Thus, they should not be subjected to constant, static loads, especially by design.

No component is immune to solder joint failures when reliability is not built-in at the design stage or when use conditions are not accounted for properly. Assembly standards may provide an agreed upon level of quality but do not warranty that solder joint reliability requirements are met. The latter are application dependent and are unique to each and every product. Exceeding industry's standard workmanship requirements may be needed in some applications.

63.4 MAIN EFFECTS AND BASIC RULES-OF-THUMB

63.4.1 Under Thermal or Power Cycling Conditions

Under thermal cycling conditions, the in-plane thermal expansion between board and components results in cyclic shear deformations of the joints. Referring to Fig. 63.1, the outermost critical joints are sheared by an angle γ. If the board and component are infinitely stiff, or if stress relaxation in the soft solder joints is complete, the maximum cyclic shear angle (or strain) is approximated as

$$\Delta\gamma_{MAX} = \frac{L \cdot \left|\alpha_B - \alpha_C\right| \cdot \Delta T}{h_S} \qquad (63.1a)$$

where L is the distance to neutral point (DNP) or distance from the component center to the most critical joint, h_S is the component stand-off height or solder joint thickness

between the board and component pads, a_C and a_B are the in-plane coefficients of thermal expansion (CTEs) on the component bottom side and on the top side of the board, respectively. D*T* is the temperature swing between the cold and hot sides of the thermal cycle.

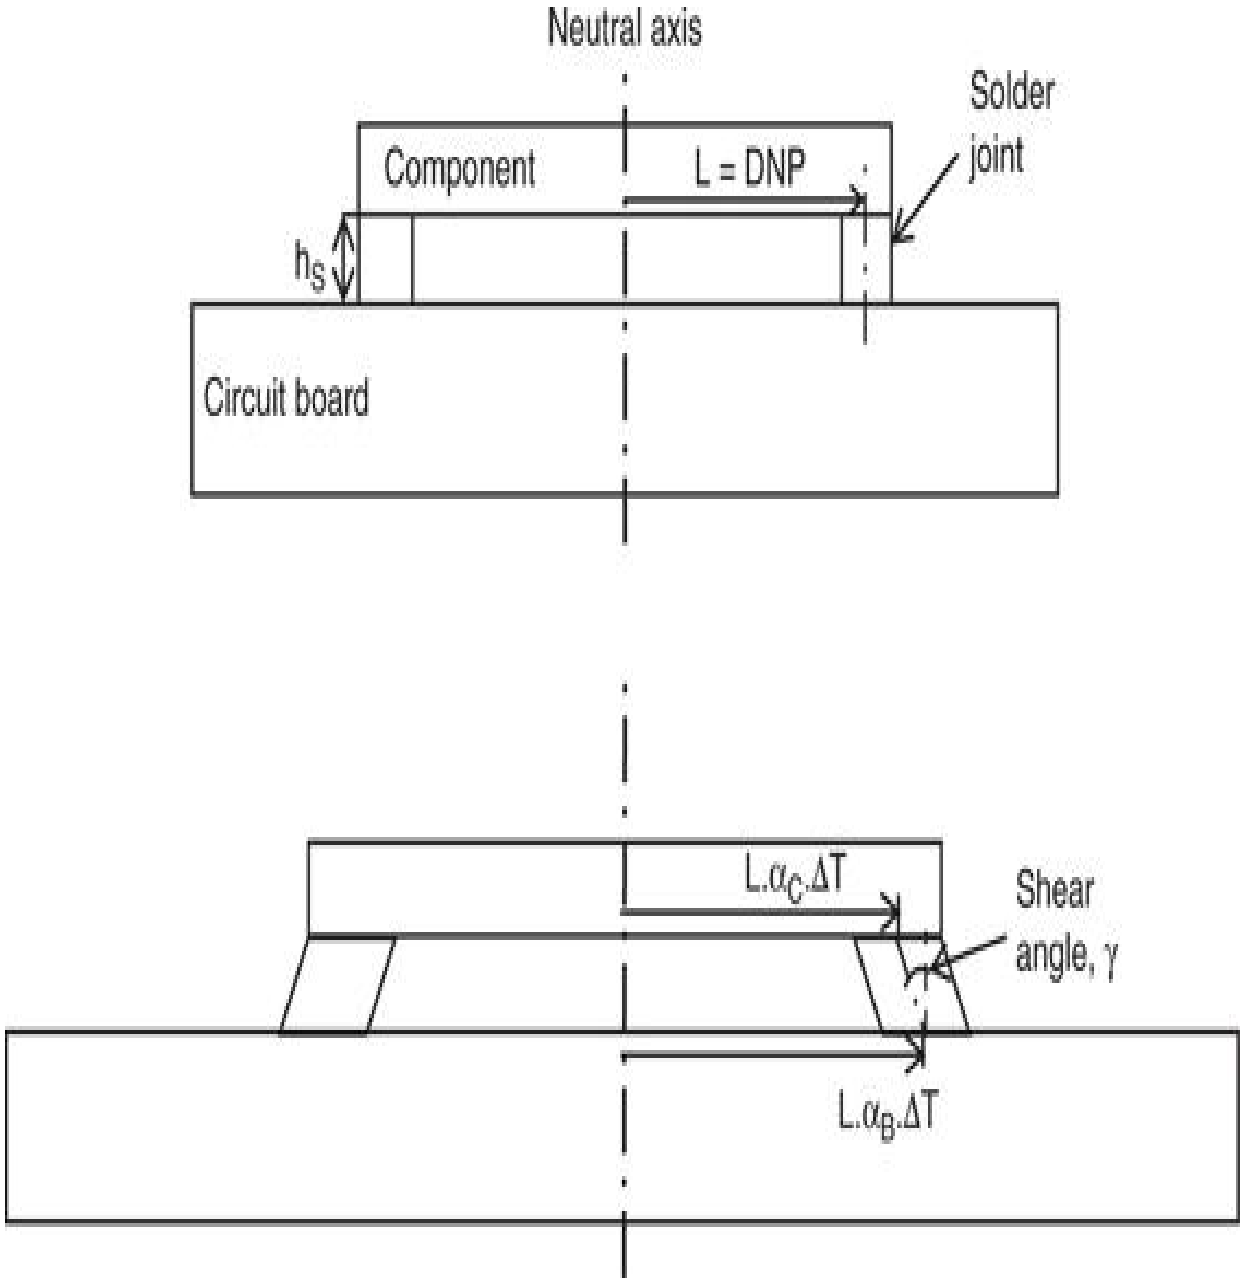

FIGURE 63.1 Solder joints under shear due to the difference in the in-plane thermal expansion of the board and component during thermal or power cycling. The amount of shear is given by the shear angle γ.

Example: Consider a ceramic ball grid array (CBGA) with a CTE of 6 ppm/°C and a 20 × 20 array of solder joints (1 mm pitch) mounted on a circuit board with an in-plane CTE of 18 ppm/°C. The component stand-off height is 20 mils or 0.508 mm.

The maximum DNP at a corner joint is L = 10 * 1 mm * √2 = 14.142 mm. For a temperature swing DT = 30°C, the maximum cyclic shear strain is

$$\Delta\gamma_{MAX} = \frac{14.142 \cdot (18 \cdot 10^{-6} - 6 \cdot 10^{-6}) \cdot 30}{0.508} = 0.01 = 1\% \qquad (63.1b)$$

Shear strains or angles, as given by Eq. (63.1a), are dimensionless or in angular radians. The 1 percent shear strain in the above example corresponds to a shear angle of 180° * 0.01/p = 0.57°. This may seem like a small angle of shear but, under repeated cyclic loading, these small angles of deformation have a cumulative effect due to the permanent set that is induced in the solder joints by plastic flow and creep of the soft solder alloy. The 1 percent shear strain is considered high and would raise a flag about the long-term reliability of these corner joints. The 1 percent level is not an absolute threshold, it simply suggests that the reliability of those solder joints has to be investigated more in depth. For example, if the solder attach or pad area is large enough, then the solder joints have a sufficiently large load bearing area to reduce shear stresses and to provide for extended crack propagation times.

Solder joints that are subjected to thermal cycling fail in low cycle fatigue, that is, they fail in a few hundred to a few thousand cycles. The actual failure mechanism is a combination of creep and cyclic fatigue. As a first order approximation, the number of cycles to failure, N_f, follows a Coffin-Manson relationship with an exponent m in the approximate range 1 to 2:

$$N_f \propto 1/\left(\Delta\gamma_{MAX}\right)^m \qquad (63.2)$$

Equations (63.1a) and (63.2) suggest four different ways to increase the life of solder joint attachments under thermal cycling conditions:

- Keep the component and/or die size as small as can be.
- Minimize the board to component CTE mismatch, $\Delta\alpha = |\alpha_B - \alpha_C|$.
- Increase the component stand-off height, h_S.
- Reduce the maximum allowed temperature swing, ΔT, and do not allow it to increase over time using reliable cooling techniques.

The above rules-of-thumb apply regardless of the solder alloy composition, tin-lead or lead free. The CTE mismatch effect is very strong as can be seen in Fig. 63.2 for two different types of component, a leadless ceramic chip carrier (LCCC) with a CTE of 5.4 ppm/°C (Sherry and Hall, 1986) and a chip scale package (CSP) with a CTE of 8.6 ppm/°C (Choi et al., 1998). LCCCs were mounted on circuit boards with in-plane CTEs in the range 9 to 21 ppm/°C. The CSPs were assembled on circuit boards with in-plane CTEs in the range 13.4 to 17.3 ppm/°C. In the latter case, when the board CTE increases from 13.4 to 17.3 ppm/°C (a change of about 4 ppm/°C), solder joint life decreases from 2000 to 500 cycles, that is, by a multiplicative factor of four times. Clearly, solder joint life is highly impacted by the board-to-component CTE mismatch and it is of utmost importance to control, measure and/or predict board and component CTEs accurately.

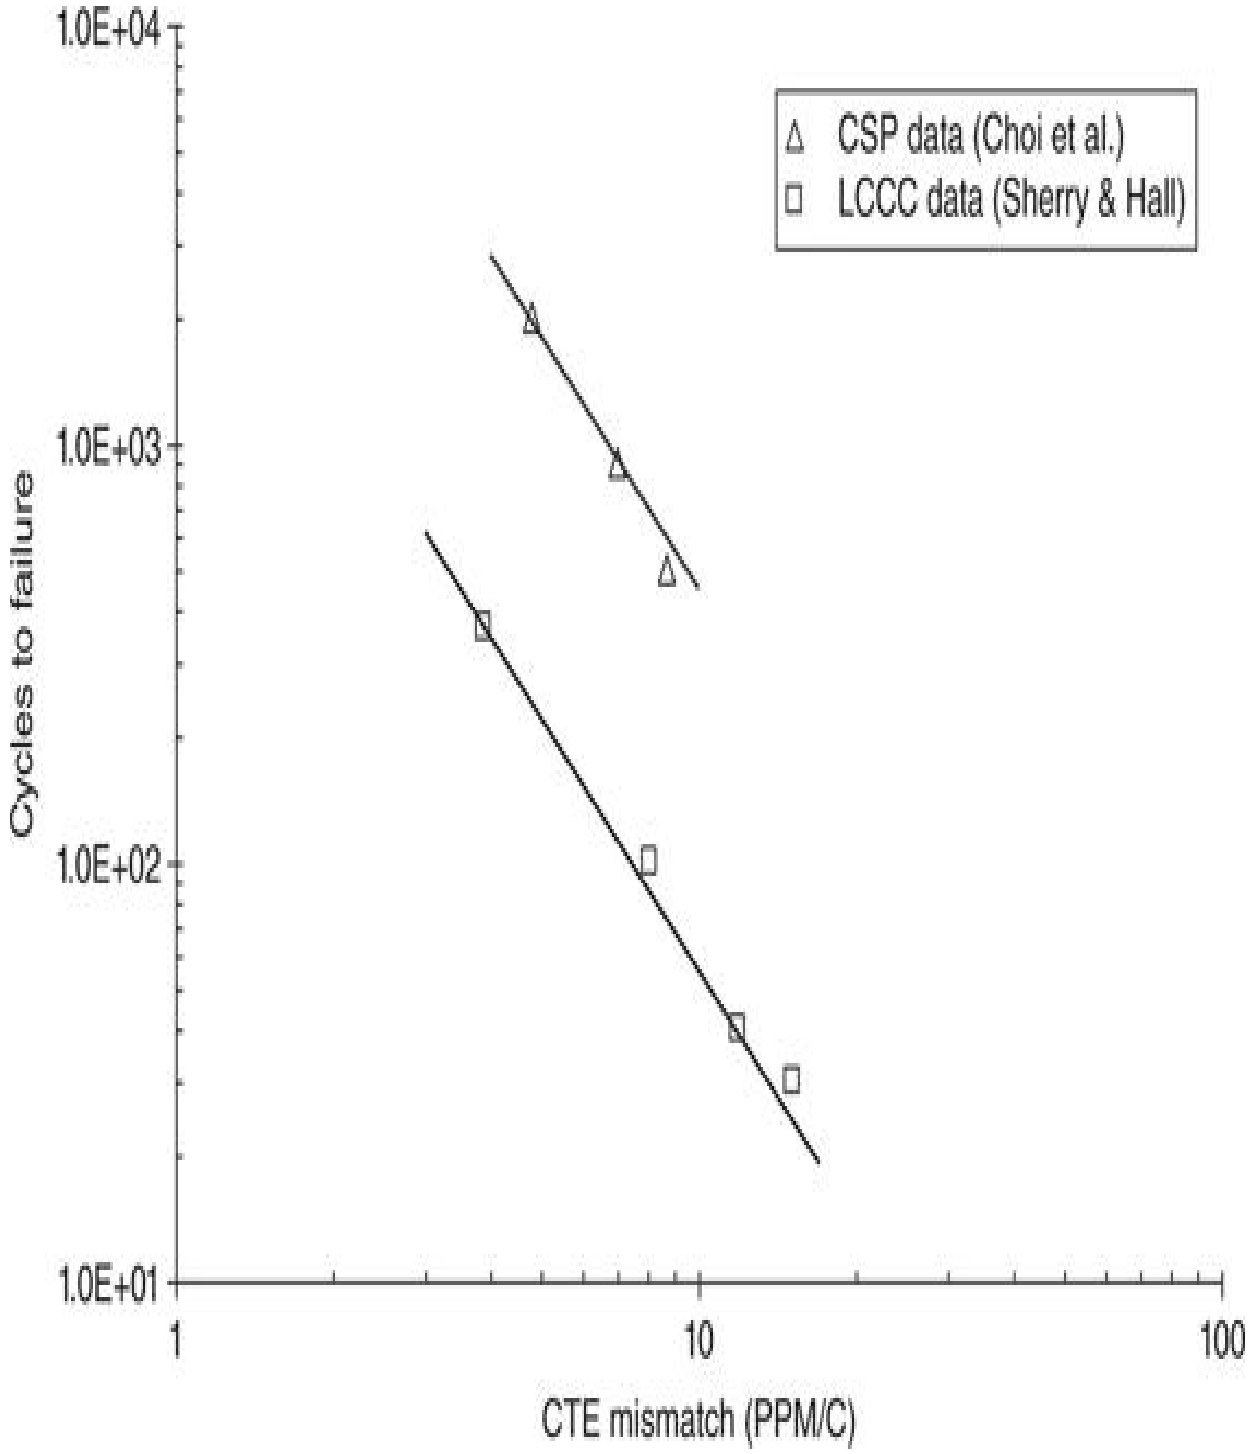

FIGURE 63.2 Log-log plot of cycles-to-failure (median or characteristic life) versus CTE mismatch for two component types mounted on double-sided rigid boards. The slope of the best-fit lines that have been forced through each dataset is exactly −2. The goodness of fit suggests that the Coffin-Manson relationship [Eq. (63.2)] captures the CTE mismatch effect well.

Another significant loading mechanism takes place in single-sided assemblies whereby the assembly bends due to the bimetallic strip effect (Fig. 63.3). The solder joints resist the expansion mismatch between the board and component, creating shear forces and moments at the board and component interfaces with the solder joints. These forces and moments force the assembly to bend as illustrated in Fig. 63.3. Thus, the shear strain in solder joints has two components: ϕ due to simple, in-plane shear, as previously discussed, and θ due to bending of the assembly. These two changes in the corner angle of the idealized solder joint of Figs. 63.1 and 63.3 ($\angle ABC = 90°$) go in opposite directions. Thus, bending of the assembly by bimetallic strip effect relieves stresses and strains in the solder joints. The bending of single-sided assemblies during thermal cycling was first characterized experimentally by Hall (1984). This stress relief mechanism is the main reason why single-sided, thinner board assemblies lead to longer solder joint life than thicker board assemblies. Any other means of reducing the flexural stiffness of boards, such as the use of more compliant laminate materials, will enhance the ability of the board to flex and improve solder joint reliability under thermal cycling conditions. Opposite requirements apply under mechanical loading conditions. Last, the ability of the assembly to flex in the component area is suppressed in mirrored, double-sided assemblies with components mounted back to back or with a slight offset of components on the top and bottom side of the board. The resulting decrease in solder joint life can be by a multiplicative factor of two to three times.

FIGURE 63.3 Under thermal cycling conditions, bending relieves shear stresses and strains in solder joints of single-sided assemblies. In addition to in-plane shear (angle ϕ in drawing to the left), the solder joint is sheared due to bending of the assembly (angle θ in drawing to the right) by bimetallic strip effect. The resulting shear strain, or angle, is $\gamma = \phi - \theta$.

Industry standards for reliability assessment of surface-mount assemblies under thermal or power cycling conditions include IPC-SM-785 and IPC-9701.

63.4.2 Under Mechanical Loading Conditions

Under out-of-plane mechanical loading conditions (bend, drop, shock, vibration), solder joints are stretched (or compressed) in the *z* direction, perpendicular to the mid-plane of the board (Fig. 63.4). In a bend test or under vibration, the board flexes up or down at a rapid rate and the solder joints fail in high cycle fatigue (i.e., in tens of thousands to millions of cycles).

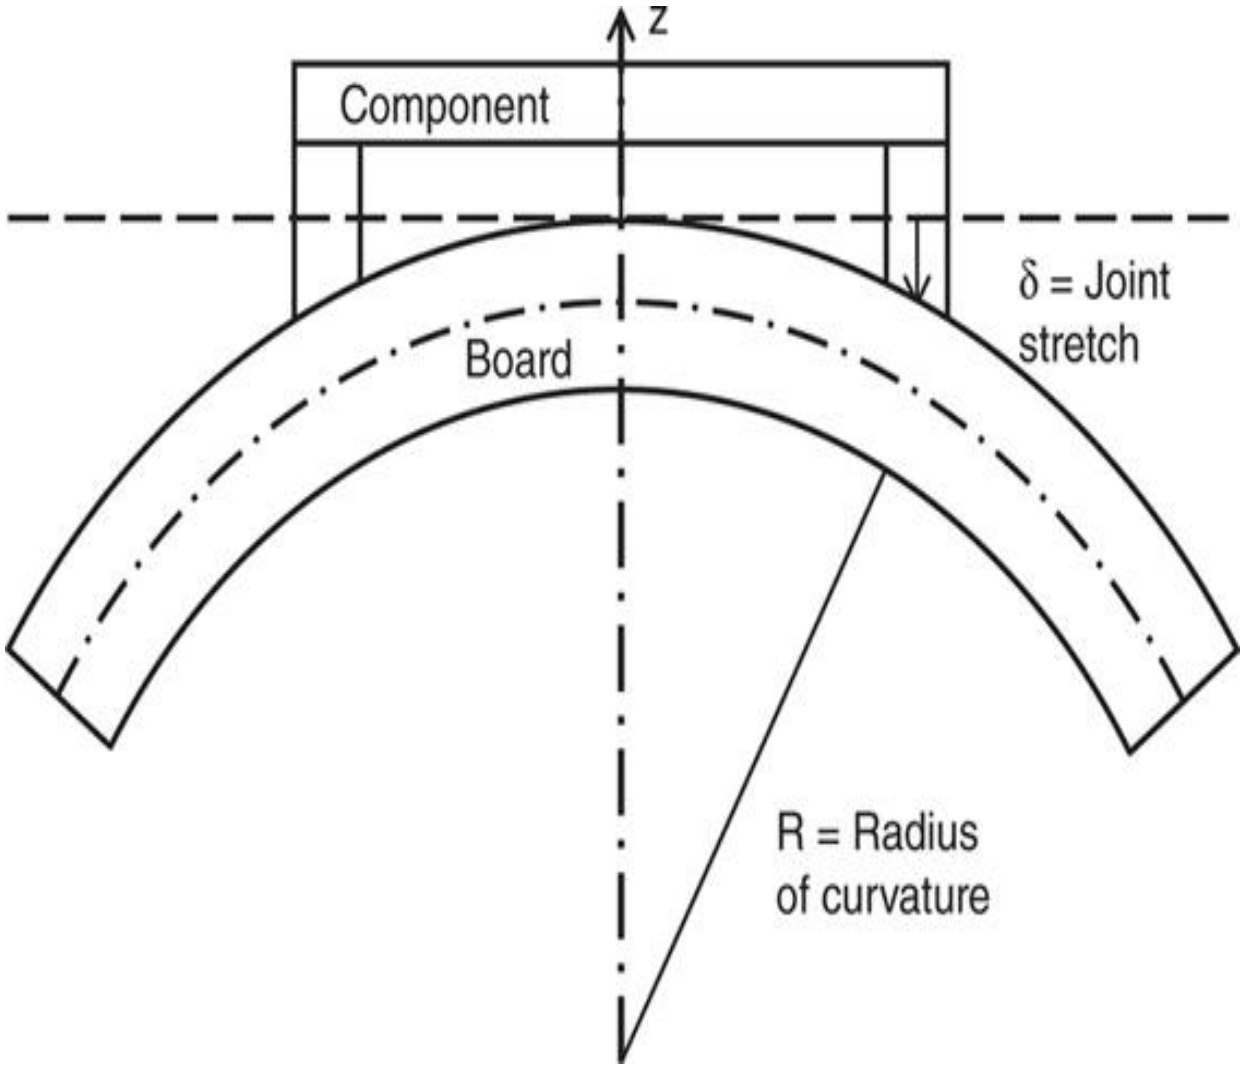

FIGURE 63.4 Under bend, drop, or vibration loading in a direction perpendicular to the board, out-of-plane flexure is the main deformation mode of the board. Outer-row solder joints are stretched (or compressed) due to board curvature. The amount of tensile stretch in the joints is given by the relative deflection of the board, δ.

Out-of-plane flexure can be minimized by “clamping” or stiffening the board. “Clamping” can be achieved by securing the board to the product’s chassis, frame, or housing using wedge-clamps or other fixation means such as screws. Stiffening of the board is by means of rigid, stiffening ribs that are bonded, bolted down or riveted to the board in the direction that is at the intersection of the mid-plane of the board with the plane of maximum bending or curvature

(*x* axis in Fig. 63.5*a*). In the example of Fig. 63.5*a* (board with two free edges and two clamped edges), out-of-plane deformations can be further reduced by using stiffening ribs that go from one clamped edge to the other. Ribs that would be mounted parallel to the *y* direction of the board would be ineffective and make things worse because the added mass of the rib(s) would lower the resonance frequency of the board and amplify out-of-plane deflections.

FIGURE 63.5 (*a*) Example of boundary conditions for a circuit board subjected to out-of-plane vibrations. The left and right edges are clamped, the two other edges are free. Components are shown as squares. (*b*) First mode shape (thick solid line) and curvature (thin solid line) of board in Fig. 63.5*a*.

Figure 63.5*b* shows the board deflection profile [first mode shape, $Z(X)$] as well as the curvature plot for the board in Fig. 63.5*a*.

The first mode shape is approximated as

$$Z(X) = Z_{MAX} \cdot \left[1 - \cos\left(2\pi \frac{X}{B}\right)\right] \tag{63.3a}$$

where B is the length of the board in between the two opposite clamps. The corresponding curvature is

$$Z''(X) = Z_{MAX} \cdot \left(\frac{2\pi}{B}\right)^2 \cdot \cos\left(2\pi \frac{X}{B}\right) \tag{63.3b}$$

The maximum out-of-plane deflection is in the center area of the board. As importantly, curvature is the largest, in absolute values, at the center of the board but also near the clamped edges of the board. Since curvature of the board is what stretches (or compresses) solder joints, first solder joint failures are as likely to occur in the center area of the board as near the clamped edges (left- or right-side components in Fig. 63.5*a*). This has been verified experimentally in the NASA-JGPP lead-free solder project (Woodrow, 2005). Thus, large critical components should not be mounted near the center of the board or near clamped edges. As can be seen in Fig. 63.5*b*, the ideal location where to mount critical components is one-fourth of the way along the length of the board (at positions $X = B/4$ or $X = 3B/4$) since, at these locations, the board curvature is nil.

The resonance or natural frequency, f_n, of a flat board goes as

$$f_n \propto \sqrt{\frac{D_B}{\rho_B}} \tag{63.4}$$

where ρ_B is the mass per unit area of the assembled board and D_B is its flexural rigidity:

$$D_B = \frac{E_B \cdot h_B^3}{12(1-\upsilon_B^2)} \tag{63.5}$$

E_B is the effective Young's modulus of the board, n_B is its Poisson's ratio and h_B is the board thickness.

Since dynamic displacements at the center of the board go as G_{out}/f_n^2 (Steinberg, 2000), where G_{out} is the output acceleration ($G_{out} = Q.G_{in}$, where G_{in} is the input acceleration and $Q \sim \sqrt{f_n}$ is the board transmissibility), board and solder joint strains can be reduced by increasing the minimum resonance frequency of the board. Equations (63.4) and (63.5) thus suggest several ways to improve solder joint life under shock and vibration conditions, namely, by increasing the board stiffness—using a thicker board or stiffer laminate materials—or by reducing the board mass per unit area. Steinberg (2000) offers a wider spectrum of design guidelines to improve board assembly reliability under shock, drop, and vibration conditions. The majority of these generic guidelines apply regardless of solder composition, tin-lead or lead free.

Industry standards for reliability testing under mechanical loading conditions include JEDEC/JESD22-B111 (drop test),

JEDEC/JESD22-B113 (bend test), IPC-JEDEC-9707 (spherical bend test), MIL-STD-810G (environmental/vibration testing).

63.4.3 Process and Intermetallic Thickness Effect

While design parameters and material properties have a significant impact on solder joint reliability, process deviations from standard reflow temperature profiles also affect solder joint life. Figure 63.6*a*, *b* shows solder joint life in terms of characteristic life under thermal cycling conditions and life in hours under vibration testing versus the initial intermetallic compound (IMC) thickness for two different components (1206 resistor in Fig. 63.6*a*, mBGA component in Fig. 63.6*b*). The data has been plotted from tabulated test results by Tu et al., 1997 and 2001. The initial IMC thickness depends on the soldering temperature profile and the time above liquidus. The trends are device specific and should not be applied to other devices without caution. Nevertheless, the test data from Tu et al. clearly indicate that the effect of intermetallic thickness is significant. The life trend in Fig. 63.6*a* is an inverse relationship with the characteristic life decreasing by more than two times when the initial IMC thickness changes from 1 to 2.5 μm. The vibration data in Fig. 63.6*b* does not follow a monotonous trend and suggests a possible, optimal IMC thickness for improved reliability under mechanical loading conditions.

(*b*) Effect of initial intermetallic thickness on vibration life of BGA solder joints on FR-4 board (SnPb assembly). Data points are from Tables I and II in Tu et al., 2001.

Soldering or reflow profiles are standardized for yield purposes. The data of Fig. 63.6*a*, *b* suggest that the product management team should monitor assembly profiles closely since deviations from standard conditions can have a large impact on IMC thickness and, thus, on solder joint reliability. This should not be an issue when communication channels are established whereby assemblers at a given site or at a different manufacturing location keep interested parties updated on current assembly conditions.

63.5 PARAMETERS THAT AFFECT SOLDER JOINT RELIABILITY UNDER THERMAL CYCLING CONDITIONS

A large number of solder joint failures occur under thermal or power cycling conditions. Figure 63.7 gives a list of 14 parameters that affect solder joint life under such conditions. Not shown in Fig. 63.7, but also significant, are the pitch of the assembly, P, and the board pad and component terminal finishes. Besides in-plane CTEs of boards and components, other properties that matter are Young's moduli in flexure and in tension as well as Poisson's ratios. Important geometric parameters that affect solder joint life, other than the critical DNP of the component and the solder joint thickness, include board and component thickness and the solder joint load bearing or crack area, A. The latter is typically determined by the component solder attach area or the diameter of the solderable pad area on the component side. For multilayer components such as BGA type

components with a substrate, die attach layer and a molding compound cap, the thickness, and basic mechanical properties (CTEs, moduli and Poisson's ratio) of each material layer also affect solder joint reliability. The reasons why all of these parameters matter and affect solder joint life are discussed below.

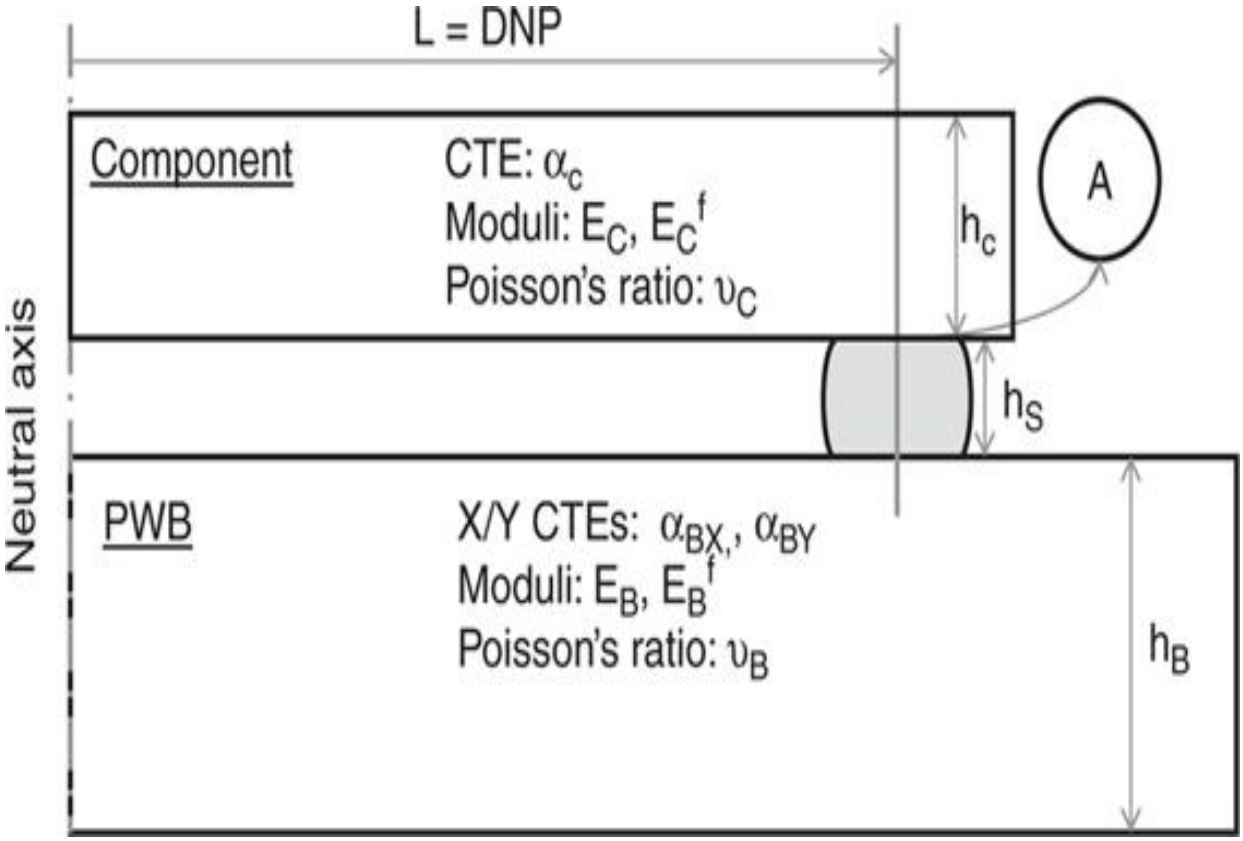

FIGURE 63.7 Schematic of assembly cross-section showing 14 parameters that affect solder joint reliability: nine board and component material properties plus five geometric parameters (assembly pitch, *P*, not included).

The above 15 parameters (pitch included) are required entries in the simulation of solder joint stress/strain hysteresis loops during thermal cycling. Examples of measured hysteresis loop data (symbols) and simulations are shown in Fig 63.8*a* for a SnPb assembly and 63.8*b* for a SnAgCu assembly (Hall, 1984, Shirazi, 2011, Clech, 2007, 2013). The solder joint stress/strain loops lay between

isothermal stress reduction lines of slope k at the temperature extremes T_{min} and T_{max}. The slope or stiffness parameter κ is given as

$$\kappa = Kh_S/A \tag{63.6}$$

where K is the stiffness or spring constant of the assembly. In the case of leaded packages, K is the lead flexural stiffness in the diagonal direction of the package. For leadless assemblies, K is the equivalent spring constant of three springs in series [Eqs. (18) to (23) in Clech, 1996] that account for elastic deformations of the board and component in tension and in bending as in a bimetallic strip (Hall, 1984).

FIGURE 63.8 (*a*) (after Fig. 1 in Clech, 2013): Example of measured and simulated stress/strain hysteresis loop for corner joints of SnPb LCCC assembly on FR-4. Temperature cycle is between −25 and 125°C, with 0.5°C/min ramp rates and 2 h dwell times at the temperature extremes. (*b*) SAC305 stress/strain hysteresis loops during thermal cycling. Data points (circles) are from Shirazi, 2011, and simulation (solid line) is from Fig. 12 in Clech, 2013.

For example, for single-sided leadless assemblies, the assembly stiffness K is the equivalent stiffness of three springs in series:

$$\frac{1}{K}=\frac{1}{K_1}+\frac{1}{K_2}+\frac{1}{K_3} \tag{63.7a}$$

where the spring constants are K_1 for mechanical stretching of the component, K_2 for mechanical stretching of the substrate, K_3 for bending of the assembly. The spring constants are estimated from strength of materials (Hall, 1984; Clech, 1996):

$$K_1=\frac{\mathrm{E}_C^{\iota}h_C P}{L(1-\nu_C)} \tag{63.7b}$$

$$K_2=\frac{2\mathrm{E}_B^{\iota}h_B P}{L(1-\nu_B^2)} \tag{63.7c}$$

$$K_3=(D_C+D_B)\frac{P}{LH^2} \tag{63.7d}$$

where $H=\frac{h_C}{2}+h_S+\frac{h_B}{2}$, and D_C and D_B are component and board flexural rigidity factors:

$$D_C = \frac{E_C^f h_C^3}{12(1-\nu_C)}, \; D_B = \frac{E_B^f h_B^3}{6(1-\nu_B^2)} \tag{63.7e}$$

In the above, subscripts "*C*" and "*B*" are for component and board, respectively. *P* is the assembly pitch, h_C is the component thickness, h_B is the board thickness, n_i's are Poisson's ratios, E_i^t 's are Young's moduli in tension (superscript "*t*") and E_i^f 's are Young's moduli in flexure (superscript "f"). Equations (63.7c) to (63.7e) show that the board parameters of Fig. 63.5 have a significant effect on the assembly stiffness *K* and, thus, on solder joint reliability. A different formulation of stiffness parameters applies to double-sided, mirrored assemblies (Clech, 1996), where identical components are mounted back to back on the bottom and top side of the board. Because of symmetry with respect to the mid-plane of the board, the ability of the board to bend in the component mounting area is suppressed in mirrored assemblies. This stiffens the assembly considerably and reduces solder joint life during thermal cycling.

The hysteresis loop areas give the strain energy density per cycle and represent the amount of work (per unit volume) exerted by the assembly on the solder joints. Cycles to failure, N_f, scaled for the solder joint crack area, *A*, have been found to be in an inverse relationship with strain energy density for SnPb (Clech, 1996) and SAC387/396 assemblies (Clech, 2005):

$$N_f/A = C/\Delta W \tag{63.8}$$

where *C* is a solder-dependent fatigue constant.

Thus, strain energy density is an engineering measure of solder joint damage during thermal cycling. Life predictive

correlations as were just mentioned are not widely available for newer or exotic lead-free solder compositions. However, a simplified stress/strain loop model (Clech et al., 2009) provides guidelines for designers to minimize strain energy density, that is, to maximize solder joint life based on design parameters alone, regardless of the solder joint composition. For a given assembly and thermal cycle, and assuming that stress relaxation in solder joints is complete, the strain energy density takes on a maximum value [Eq. (3) in Clech et al., 2009]:

$$\Delta W_{\max} = \kappa \cdot g_0^2 \cdot \Delta T^2 \tag{63.9}$$

where $g_0 = \dfrac{L \cdot \left|\alpha_B - \alpha_C\right|}{h_S}$ is the shear strain per degree of temperature rise.

An example application illustrating how to use the above design equations to predict the effect of board thickness—and that of the concurrent change in board CTE and Young's modulus—on solder joint reliability is given in the next section.

63.6 SIGNIFICANCE OF BOARD PARAMETER EFFECTS

63.6.1 Board Properties: T_g, CTEs, Young's Modulus

Epoxy-fiberglass boards exhibit a glass transition temperature, T_g, beyond which its moduli of elasticity drop by orders of magnitude. Typical T_g's for commercial grade FR-4 boards are in the range 110 to 150°C. As a rule,

assembled circuit boards should not operate above their glass transition temperature. This rule applies under accelerated thermal cycling conditions as well since reliability test results are more difficult, if not impossible, to interpret when test vehicles go over the glass transition temperature of the board.

Below the T_g of the board, the modulus of elasticity decreases slightly as temperature increases. At a minimum, board properties should be measured at room temperature. As discussed in the previous section, board moduli and CTEs have a strong impact on solder joint reliability. Good estimates of these properties for the product boards of interest are thus critical to solder joint reliability assessment and/or predictions. A common mistake is to use Young's modulus and CTEs provided by suppliers for thin prepregs or laminates. These prepreg or laminate properties are provided for information purposes and are not representative of product board properties. Board properties depend on glass-cloth style, epoxy contents, layer stack-up (core, prepreg, solder mask; power, ground, signals), and other board contents (filled or unfilled vias, pads) that are unique to each product board. It is thus important to measure or model board properties accurately based on the construction of representative test or product boards. For critical components, for example, a large BGAs with a large number of mounting pads and vias under the component, a component-area board coupon is preferred since in-plane CTEs can be 1 to 2 ppm/°C higher in that area compared to an area of the board that does not carry components.

Note also that, for most epoxy-fiberglass boards, CTEs may differ by a couple of ppm/°C (up to almost 5 ppm/°C) in the *x* and *y* (in-plane) directions of the board. Figure 63.9*a* shows measured *x* and *y* CTEs (horizontal axis) for a variety of test boards from the literature and the corresponding difference in *x* and *y* CTEs on the vertical axis. For a given board, *x* and *y* CTEs are represented by a pair of symbols ("×" and "□"),

some of which are connected by a dashed, double-arrowed line for illustration purposes. For example, for the pair of symbols near the top of the chart, the *x* direction CTE is close to 16 ppm/°C, whereas the *y* direction CTE on the same board is near 21 ppm/°C. The difference in *x* and *y* CTEs on the same board coupon is 4.7 ppm/°C. This may have a significant effect on the attachment reliability of rectangular components. To maximize solder joint reliability, these components should be mounted with their long axis in the direction of the board that has the lowest in-plane CTE. This simple rule applies, for example, to chip resistor and capacitors, or resistor network assemblies.

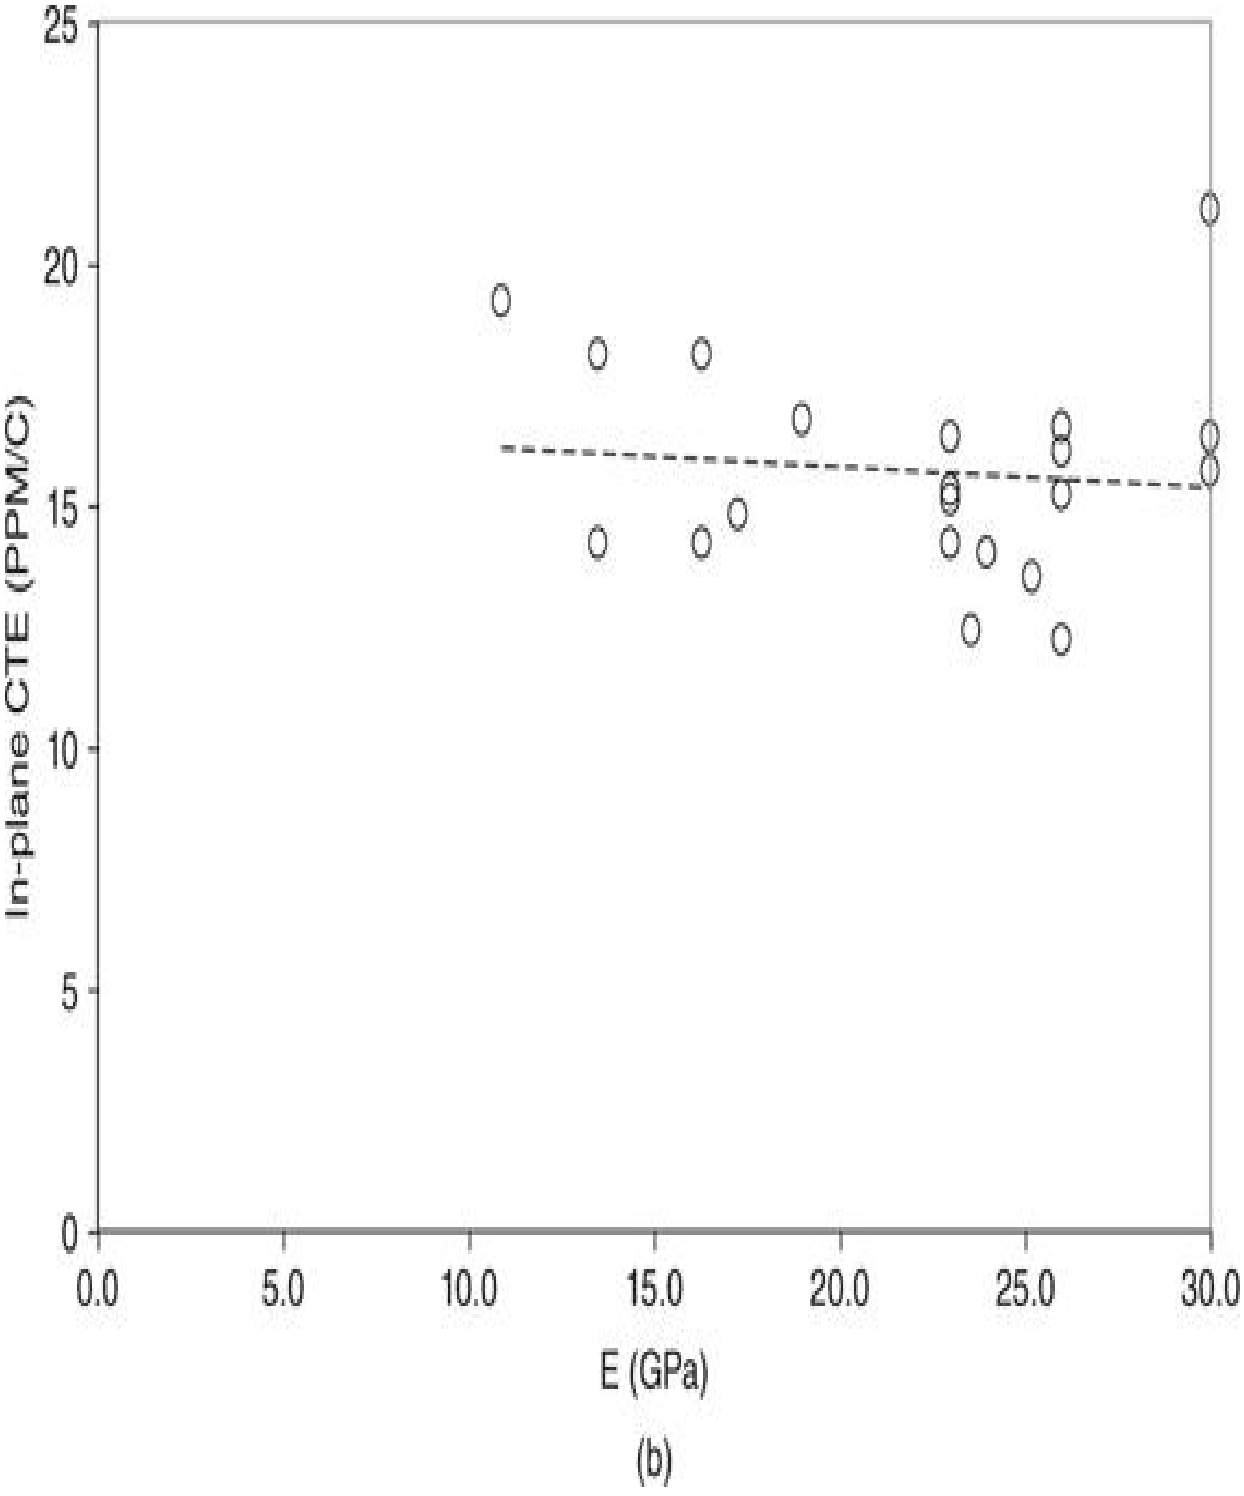

FIGURE 63.9 (*a*) Updated survey of *x* and *y* CTEs of FR-4 type test boards. *X* and *y* CTEs are represented by a pair of symbols ("×" and "□") parallel to the horizontal axis and the corresponding difference, for a given board, is along the vertical axis. (*b*) Updated survey of FR-4 test board properties: in-plane CTEs versus Young's modulus. CTEs cover the range 12 to 21 ppm/°C, Young's modulus varies from about 10 to 30 GPa.

Board CTEs and moduli are not measured in a systematic manner or it is often assumed that they follow “handbook” values. A shown in Fig. 63.9*b*, in-plane CTEs and moduli that were measured on FR-4 type boards cover a wide range of values: 12 to 21 ppm/°C for CTEs and 10 to 30 GPa for Young’s modulus. Figure 63.9*b* is an update of a survey of measured properties from throughout the literature (see Fig. 3 in Clech, 2013). Clearly, there are no “typical” values of epoxy-fiberglass board properties and the use of “handbook” or so-called “standard” values should be avoided. This is consistent with the conclusions of Ratanawilai et al. (2003) who found that in-plane CTEs measured on a variety of memory boards from one company varied from 12 to 22 ppm/ºC. The wide range of modulus and in-plane CTEs in Fig. 63.9*b* also suggests that board constructions can be tailored upfront to give them optimum properties (moduli and CTEs) that will help improve solder joint reliability.

In-plane board CTEs can be measured by means of strain gauges, thermo-mechanical analysis (TMA) or laser moiré interferometry (Han et al., 1996). Board modulus can be measured by dynamic mechanical analysis (DMA), or by use of a tensile or a three or four-point bend test specimen. Relevant industry standards include IPC-TM-650 for T_g and *x*/*y* CTEs, and ASTM-D-3039, ASTM-D-790 and ASTM-D-6272 for board moduli.

63.6.2 Board Thickness Effect

The effect of board thickness on attachment reliability under thermal cycling conditions can be large. Primavera (1999), for example, reports a life reduction of two times for chip scale packages (CSPs) on 1.575-mm-thick boards compared to identical CSPs on 0.4-mm-thin boards. It is important to keep in mind that board properties (moduli and CTEs) change with board thickness because these properties

depend on the board layer count and the relative board contents (epoxy fiberglass and copper) and their respective properties. The impact of “board thickness” on attachment reliability is the result of the synergistic effect of the board thickness itself and that of concurrent changes in board moduli and CTEs.

By combining and expanding Eqs. (63.6) to (63.9), and keeping only the terms where board thickness and properties appear, the dependence of cycles to failure, N_f, on board thickness, in-plane CTE and board moduli, as well as component properties, is given by simple design equations (Clech, 2015):

$$N_f \propto 1/(\kappa \cdot g_0^2) \propto 1/[K \cdot (\alpha_B - \alpha_C)^2] \tag{63.10a}$$

$$N_f = C_1 \cdot \frac{\left[\dfrac{1-\upsilon_C}{E_C h_C} + \dfrac{1-\upsilon_B^2}{2E_B h_B} + \dfrac{\left(\dfrac{h_B}{2} + h + \dfrac{h_C}{2}\right)^2}{\dfrac{E_{C,f} h_C^3}{12(1-\upsilon_C)} + \dfrac{E_{B,f} h_B^3}{6(1-\upsilon_B^2)}}\right]}{(\alpha_B - \alpha_C)^2} \tag{63.10b}$$

where C_1 is a constant that accounts for non-board-related factors in Eqs. (63.6) to (63.9) such as component size, stand-off height, assembly pitch and thermal conditions.

When cycles-to-failure are available for different board thickness, C_1 is obtained by plotting N_f versus the calculated ratio of algebraic terms on the right-hand side of Eq. (63.10b) (large bracket and parenthesis squared) and fitting a linear trendline with zero intercept through the data. Regardless of the constant C_1, Eq. (68.10b) is a simple algebraic equation that gives the shape of design curves for

cyclic lives versus board thickness, given known entries for the board modulus and CTE. No assumption is being made on the shape of these design curves. Instead, the board thickness dependence, and the effect of the board modulus, come straight out of the strength-of-materials formulation of the assembly stiffness, *K*.

Example: Figure 63.10 shows the fit of Eq. (63.10b) to thermal cycling characteristic lives (Shih et al., 2004) for a "hiCTE" ceramic ball grid array (CBGA) package mounted on boards of thickness 62, 93, and 130 mils. The test boards of different thickness had different in-plane CTEs and moduli as measured by Shih et al. (2004) and as indicated in the legend of Fig. 63.10. The three curves of Fig. 63.10 correspond to the graphs of Eq. (63.10b) for the different values or pairs of modulus and CTE of the test boards. For the 62- and 93-mil boards, the in-plane CTEs are very close, 15.9 ppm/°C and 15.85 ppm/°C, respectively. Their moduli are 26 and 23 GPa, respectively. Thus, the vertical shift between the two top curves of Fig. 63.10 is essentially due to the change in the board modulus. The shift between the middle and lower curves is much larger. Part of it is due to the change in modulus from 26 to 30 GPa, but that shift should not much larger than the shift between the two top curves when the board modulus changed from 23 to 26 GPa. Instead, a greater fraction of the shift between the two lower curves is due to the larger change in board CTE, from 15.9 to 18.75 ppm/°C. The board properties and the model [Eq. (63.10b)] explain why the life reduction is much larger when the board thickness goes from 93 to 130 mils compared to going from 62 to 93 mils. In the latter case, the CTEs are about the same and the modulus decreases, thus the life reduction is small. In the former case (93 to 130 mils), the board modulus increases and the CTE mismatch between the board and component increases significantly, leading to a large reduction in solder joint life.

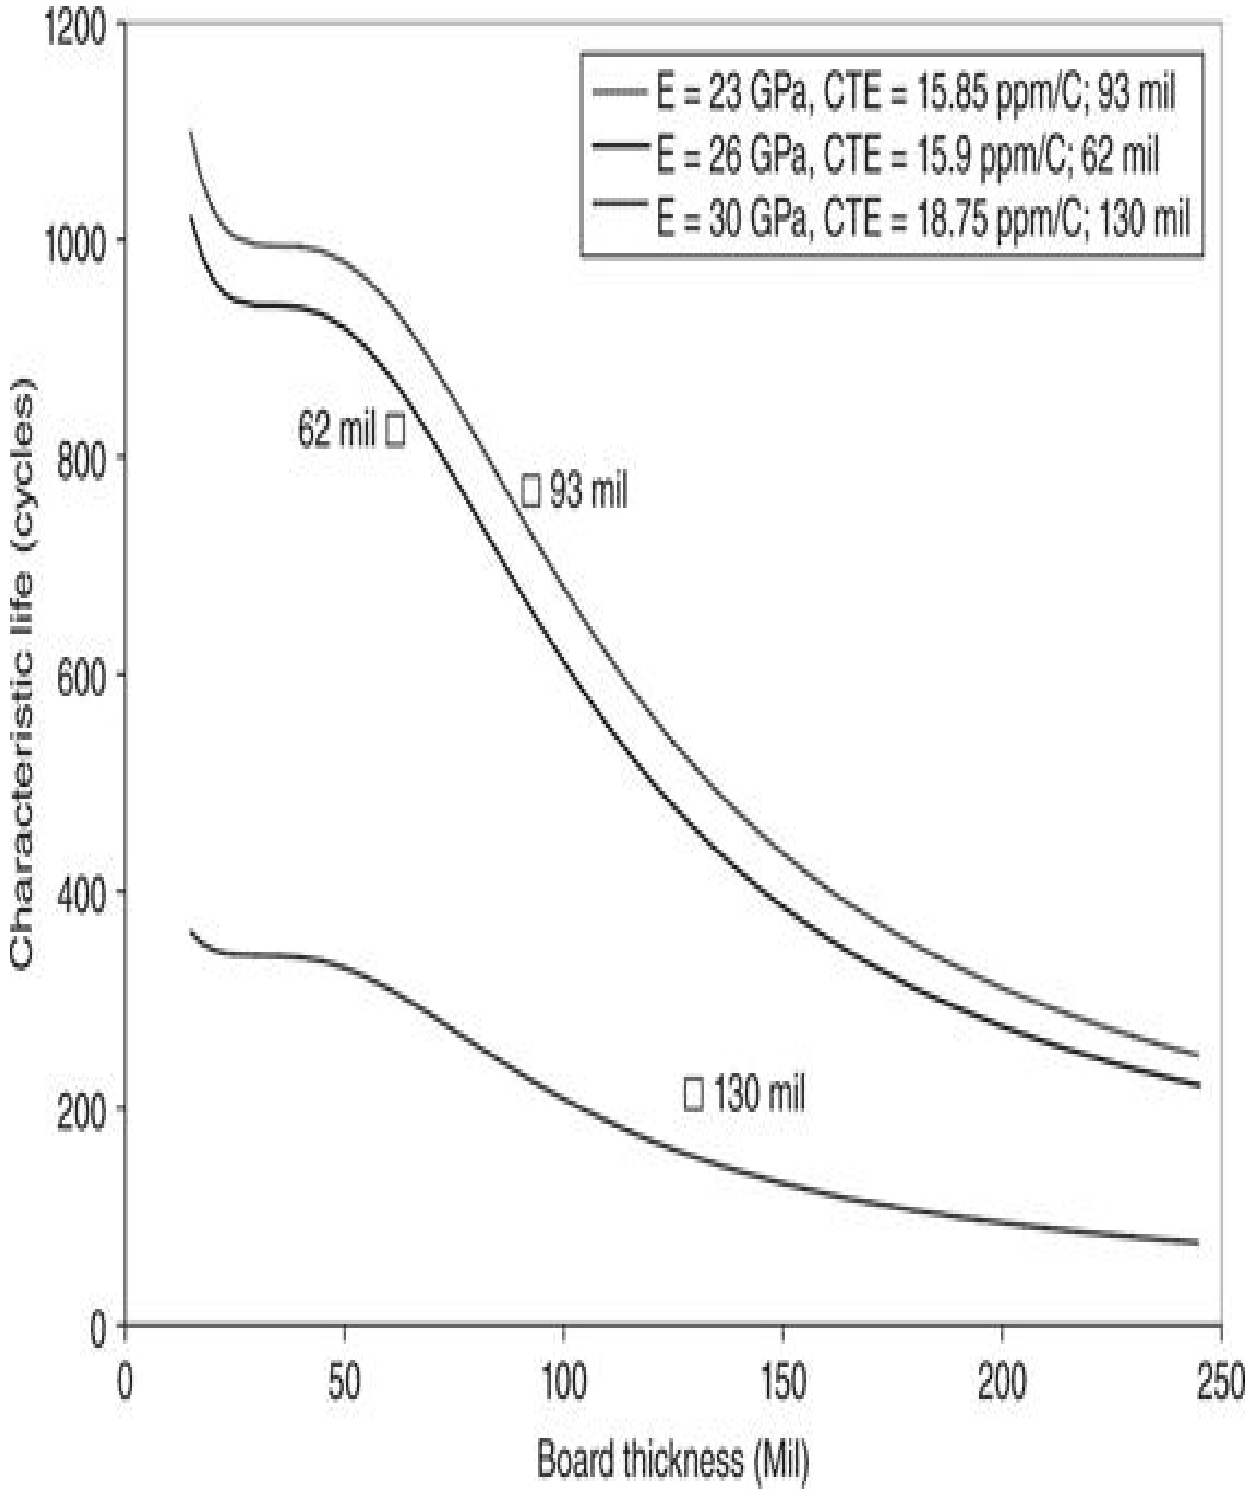

FIGURE 63.10 Solder joint life is plotted versus board thickness. Model lines are after Eq. (63.10) for given values of board's modulus E and in-plane CTE in diagonal direction of package. Data points for the same pairs of E and CTE values are test results for hiCTE CBGAs on 62-, 93-, and 130-mil-thick boards after R. Shih, 2004.

The board thickness model [Eq. (63.10b)] and the test results are in very good agreement. Shih et al. (2004) also reported that their test results were confirmed by finite-element analysis. The usefulness of Eq. (63.10b) is that it allows quantifying how much of the change in life is due to CTE effects and how much is due to the board modulus. Further validation of the use of Eq. (63.10a, b) is given in Clech (2015), including its application to the effect of component thickness effects as in the case of thick CBGA substrates and bare die assemblies.

The above example clearly illustrates that board thickness effects cannot be considered separately from board effective properties. The change in board properties with board thickness also points to the need to measure or model the effective properties of circuit boards, CTEs and moduli, accurately.

63.6.3 Rule-of-Mixtures to Estimate the Effective Properties of Circuit Boards

The rule-of-mixtures is a rough approximation that is of use to get quick estimates of board in-plane CTEs and moduli based on the thickness (h_i), CTE (α_i) and modulus (E_i) of each layer (index "I") in the board stack-up:

$$E_B = \frac{\sum_i E_i h_i}{h_B} \qquad (63.11a)$$

$$CTE_B = \frac{\sum_i E_i \alpha_i h_i}{E_B h_B} \qquad (63.11b)$$

In this author's experience, the rule-of-mixtures applies well to rigid, multilayer, epoxy-fiberglass boards that have a symmetrical stack-up without "compliant" layers that could give in shear. Advanced laminate and blending models are also available for more refined predictions of board properties (Sottos et al., 1999).

63.6.4 Single- versus Double-Sided Mirrored Assemblies

When identical components are mounted back-to-back in a mirrored, double-sided assembly, solder joint life under thermal cycling conditions can be reduced by a large factor, as much as two or three times (Juso et al., 1998; Primavera, 2003; Shih et al., 2004). The amount of life reduction is also component dependent because of board-to-component interaction that is controlled by their relative stiffness.

The driving force behind the reduction in solder joint life is suppression of the stress-relief mechanism associated with board bending. The board is no longer able to flex by bimetallic strip effect in the component mounting area. Solder joints are thus subject to higher shear forces than in a single-sided assembly. This effect is purely mechanical. In a mirrored assembly, the bending term, K_3, of the assembly stiffness K in Eq. (63.7a), becomes infinite and the board axial stiffness, K_2 in Eq. (63.7c), is reduced by a factor of two times because each component of the mirrored assembly acts on one half of the board thickness. The assembly

stiffness of a mirrored assembly is thus obtained from the formula (Clech, 1996):

$$\frac{1}{K_{\text{MIRRORED}}} = \frac{1}{K_1} + \frac{2}{K_2} \qquad (63.12)$$

where K_1 and K_2 are calculated as per Eq. (63.7b, c). This effect is purely mechanical. Since solder joint cyclic life goes as the inverse of the assembly stiffness [Eqs. (63.6), (63.8), and (63.9)], everything else being equal (e.g., no change in the board CTE), the ratio of solder joint lives for single versus mirrored assemblies goes as $K/K_{MIRRORED}$ (Clech, 2015), where the assembly stiffness K for single-sided assemblies is calculated by means of Eq. (63.7a).

63.6.5 SMD versus Non-SMD Pads

Board pad and solder mask design can affect solder joint life. The question is often asked which is better, solder mask design (SMD) pads or non-solder mask defined (NSMD) pads (Fig. 63.11)? Until recently, that is, for SnPb board assemblies, the industry consensus has been in favor of NSMD pads on the board side. SMD pads have been suggested as a way to mitigate pad cratering failures (Gray et al., 2010) that occur with stiff, lead-free solder joints. Some lead-free alloys being stiffer and having less ductility than standard SnPb, especially under high-strain rate conditions as under drop or shock conditions, solder joints can pull corner pads and the underlying epoxy out of the board. In SMD designs, solder mask holds the pads down and provide additional strength between board pads and epoxy-fiberglass boards.

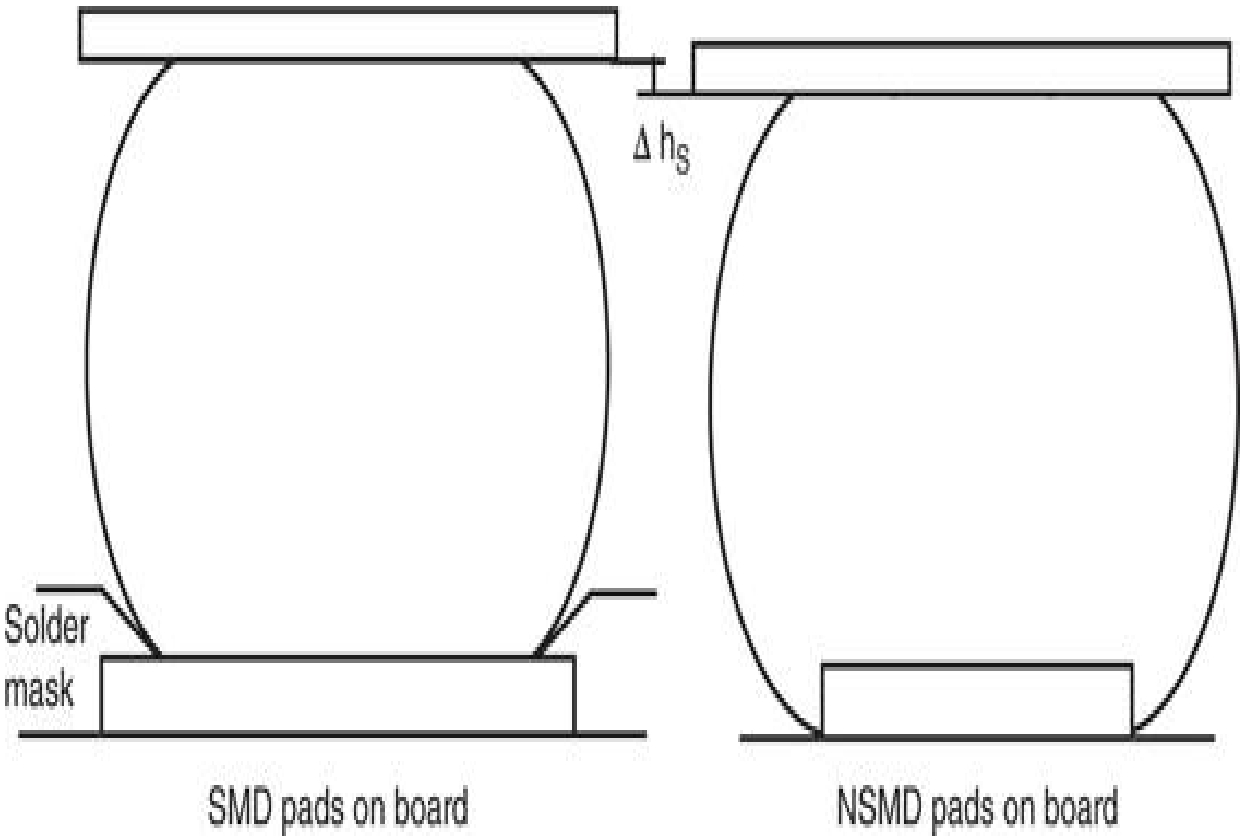

FIGURE 63.11 With solder mask defined (SMD) pads on the board side, the lower solder fillets are shaped by solder mask covering the periphery of the pads. With nonsolder mask defined (NSMD) pads on the board, solder wets the edges of the board pad, resulting in a small reduction in solder joint height, Δh_S.

SMD design pads may be preferable for boards under drop/shock/vibration loads. There is also evidence that SMD designs may enhance thermal cycling lives. Darveaux et al. (1995) reported that SnPb BGA assemblies with SMD pads had a 15 percent longer life than similar assemblies with NSMD pads on the board side. The slight decrease in fatigue life for NSMD assemblies was mostly due to their lower stand-off height, 20.8 mils versus 22.2 mils (Dh_S = 1.4 mils in Fig. 63.11). The industry consensus in favor of NSMD pads, contrary to the life improvement observed in the Darveaux (1995) experiment, is quality driven. Solder mask being susceptible to manufacturing offsets in the *x* and *y* directions of the board may encroach over board pads in an uncontrolled manner. The risk of uncontrolled solder mask

encroachment leads to reduced assembly yields and solder joints of uncontrolled shape with a reduced solder wetting area on the board pads, which, in turn, may result in infant mortality solder joint failures.

63.6.6 Board Pad versus Component Pad Size

Another common question related to board pad design is: given a component with a fixed pad size (diameter of solder-wettable area for BGAs and CSPs), what should be the pad size (diameter of solder-wettable area) on the board side? As a general rule, board pad diameters should not be larger than component pad diameters. Equal pad sizes are acceptable. Board pads that are slightly smaller (e.g., by 10 percent in diameter) than component pads provide for improved reliability under thermal cycling conditions (Ejim et al., 1995, 1996).

For a given solder ball diameter, equal or slightly smaller board pads provide for a slight increase in stand-off height, h_S, which increases solder joint life. A second argument is that, shear forces being equal at the solder joint to package and board interfaces, a slight reduction of the board pad wettable area is beneficial since it raises shear stresses (shear force divided by area) on the board side of the joint while reducing solder joint shear stresses on the component side, which is where most solder joint failures occur. However, much smaller board pad diameters should be avoided since this configuration leads to significantly higher shear stresses on the board side, a shift in failure location from the component to the board side, and failures that occur much earlier than they would on the component side.

When selecting board pad diameters, it is useful to estimate the expected solder joint height since the latter has

a significant impact on solder joint life. For many area array components that are light enough (e.g., plastic BGAs and CSPs), solder joints are barrel-shaped and actually take on the shape of a truncated sphere (Fig. 63.12). The solder joint height can then be estimated by back-solving the truncated sphere volume equation for h_S:

$$V = \frac{\pi h_S}{6}\left[h_S^2 + \frac{3}{4}(b^2 + c^2)\right] \tag{63.13}$$

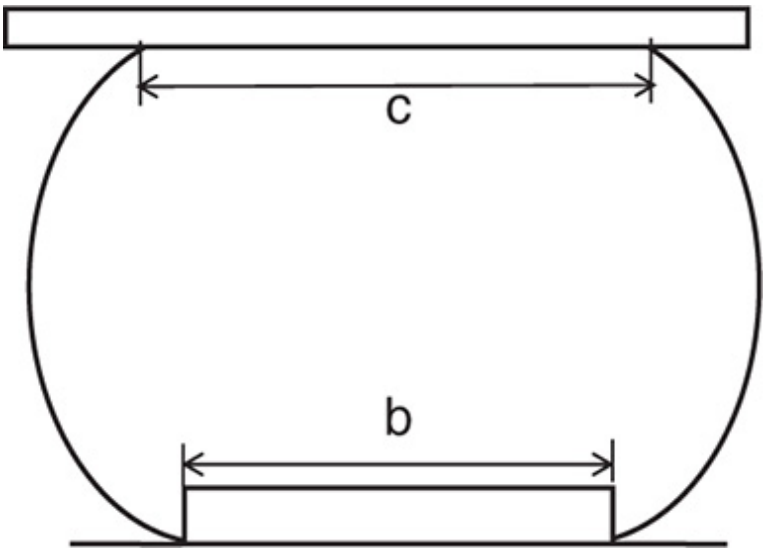

FIGURE 63.12 Component versus board pad size: on the component side, the solder-wettable pad area, with diameter "*c*," is determined by the package solder mask opening. On the board side, a slightly smaller, solder-wettable pad area, with diameter "*b*," provides for improved solder joint reliability under thermal cycling conditions.

where b and c are the board and component pad diameters and V is the total solder volume of the barrel-shaped solder joint (V = solder ball volume + solder volume in solder paste). Equation (63.13) has a closed-form solution for h_S. It can also be solved using a "Goal Seek…" menu in conventional spreadsheets.

63.6.7 Board Finish Effect

A correlation of lead-free thermal cycling data is shown in Fig. 63.13 as characteristic life scaled for the solder joint crack area versus the maximum cyclic shear strain computed as per Eq. (63.1). The data is for a variety of boards and components with SnAgCu solder balls and/or paste in the narrow composition range SAC387 to SAC396 (note: SAC387 has 3.8 percent wt. Ag and 0.7 wt. Cu, the rest being tin). The data points in Fig. 63.13 are highlighted by board finish: immersion Ag, organic solder preservative (OSP) or NiAu (after Fig. 2b in Clech, 2004).

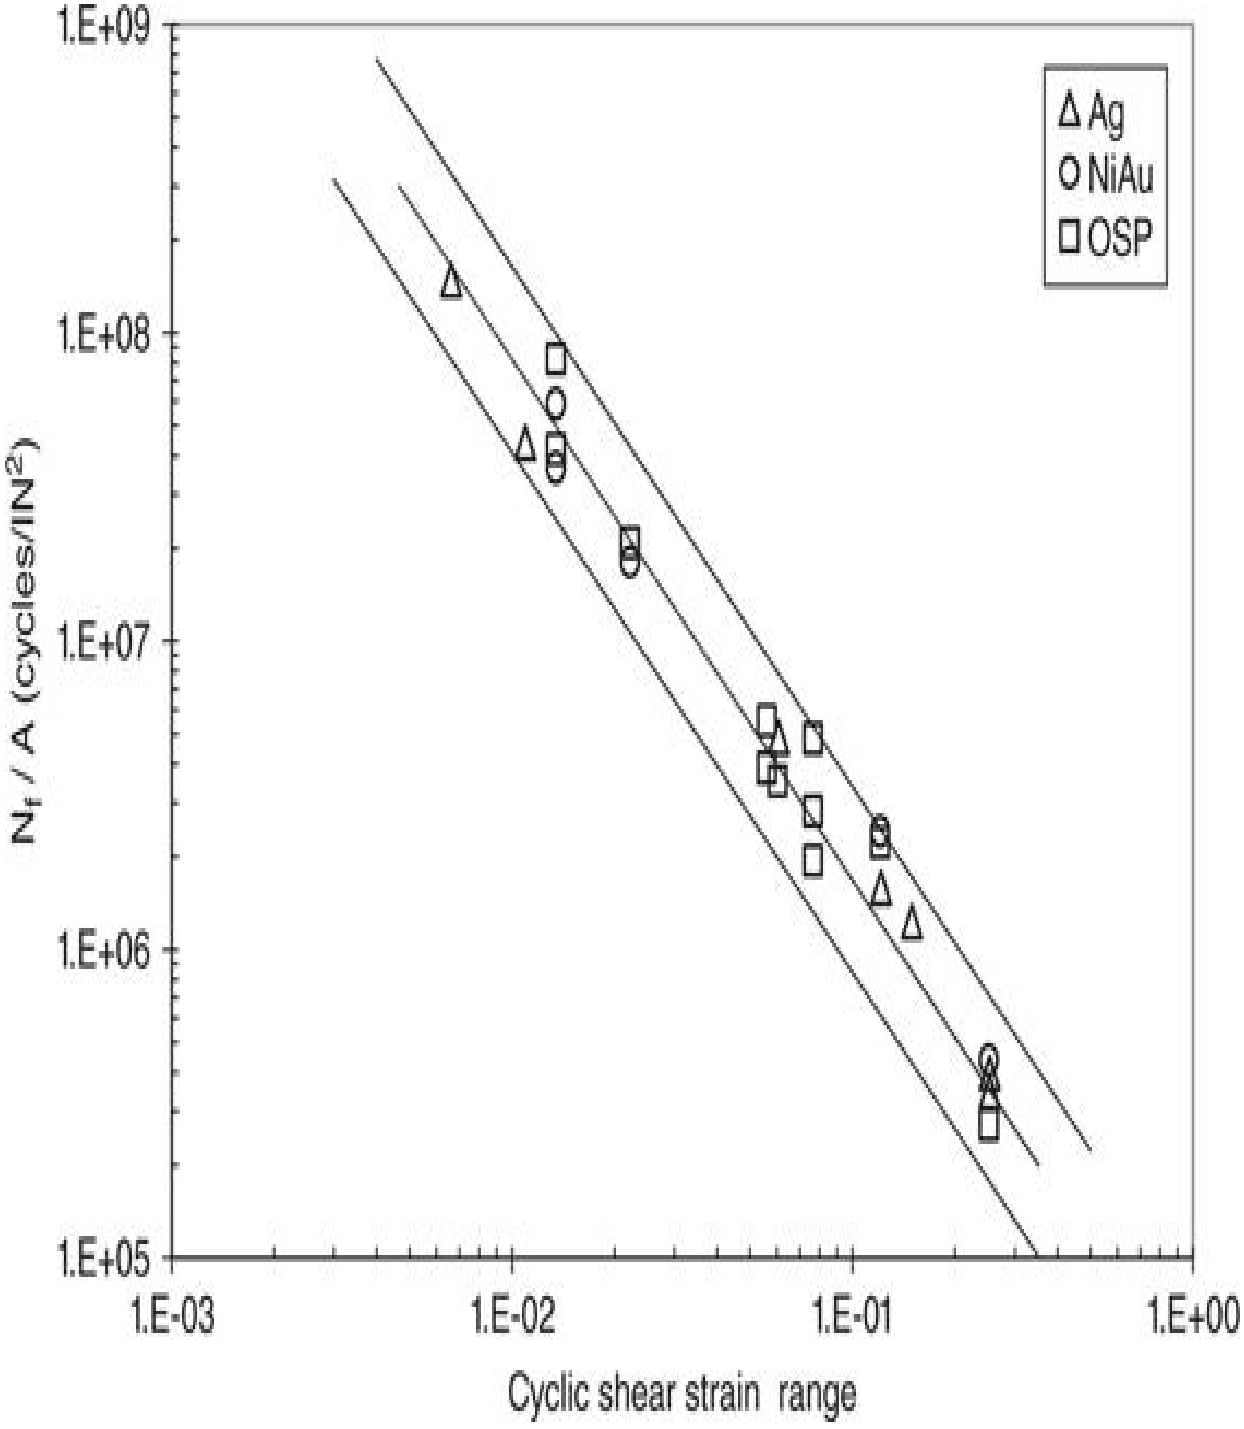

FIGURE 63.13 Correlation of lead-free solder joint life (N_f) scaled for the solder joint crack area (A) versus cyclic strain range during thermal cycling (after Clech, IPC Apex 2004). While the data is for a variety of components, the data points are shown in terms of board finish (Ag, NiAu, or OSP).

A centerline through all the data is shown as a dashed line which has a correlation coefficient of 96 percent, which indicates that the overall correlation is reasonably good. The spread of the data in Fig. 63.13 is typical of solder joint fatigue. The data points for a given board finish are above or below the centerline and no clear trend is visible per board finish type. Over a range of cyclic shear strains of more than one order of magnitude along the horizontal axis, none of the three board finishes appears to stand out and provide overwhelmingly better results than the others. The conclusion is not that board finishes do not matter. They do in terms of solder wetting, intermetallic formation and initial solder joint quality. However, the effect of available board finishes on solder joint fatigue life appears to be within the typical spread of fatigue data.

63.7 LEAD-FREE RELIABILITY TRENDS

63.7.1 Overview

A multitude of lead-free solder alloys have been developed over the years. Besides SnAg, SnBi, AuSn, and a few other eutectic compositions that have been in use for decades in niche applications, grand families of lead-free alloys have emerged such as SnAgBi (SAB), SnAgCu (SAC), SnCu, SnCuNi, SnZn, etc. … possibly with additions of a variety of elements. While Sn is the main constituent, alloy composition varies as well, for example, SAC0307, SAC105, SAC305, SAC387, SAC405 within the SAC family alone. Lead-free balls of one composition are also reflowed with lead-free paste of another composition. This leads to an infinite number of possible average compositions in actual solder joints, depending on ball and paste alloys, pad sizes and ball

and paste solder volume. Because of the proliferation of lead-free solder alloys, much work remains to be done for the field of lead-free reliability to be established as thoroughly as for standard SnPb reliability.

Solder alloy properties that are of use for lead-free reliability assessment include ductility, strength, toughness, ductile-to-brittle transition temperature, creep rates and creep rupture times, elasticity modulus, Poisson's ratio, their temperature dependence and their sensitivity to ageing conditions. For example, creep laws are essential to the simulation of stress/strain loops as shown in Fig. 63.8*b*, and to the development of acceleration factors (Clech, 2013; Darveaux, 2012). The above properties are not readily available for all new alloys, which may hinder the acceptance of some lead-free compositions.

Many lead-free alloys have a higher peak reflow temperature than standard SnPb. This has led to frequent changes in board and package materials that need to be tracked closely by all participants of the supply chain. Changes in circuit board epoxy, package substrate materials (including solder mask in BGAs and CSPs) and molding compounds can all affect assembly yields—for example, due to warpage (Ahsan et al., 2008)—and attachment reliability (Vandevelde et al., 2011).

63.7.2 Effect of Ag Content on Reliability

Among SAC solders, alloys with low Ag contents, for example, SAC105 with 1.0 percent wt. Ag, 0.5 percent wt. Cu, appear to have a better performance under drop test conditions than SAC alloys with higher Ag contents, for example, SAC305. Data from two sources (Syed et al., 2007; Yongping et al., 2013) are plotted in Fig. 63.14 as the number of drop to failures, normalized to SAC305, versus the %Ag

contents. The improvement for SAC105 versus SAC305 is a factor of 1.2 to 1.7 times.

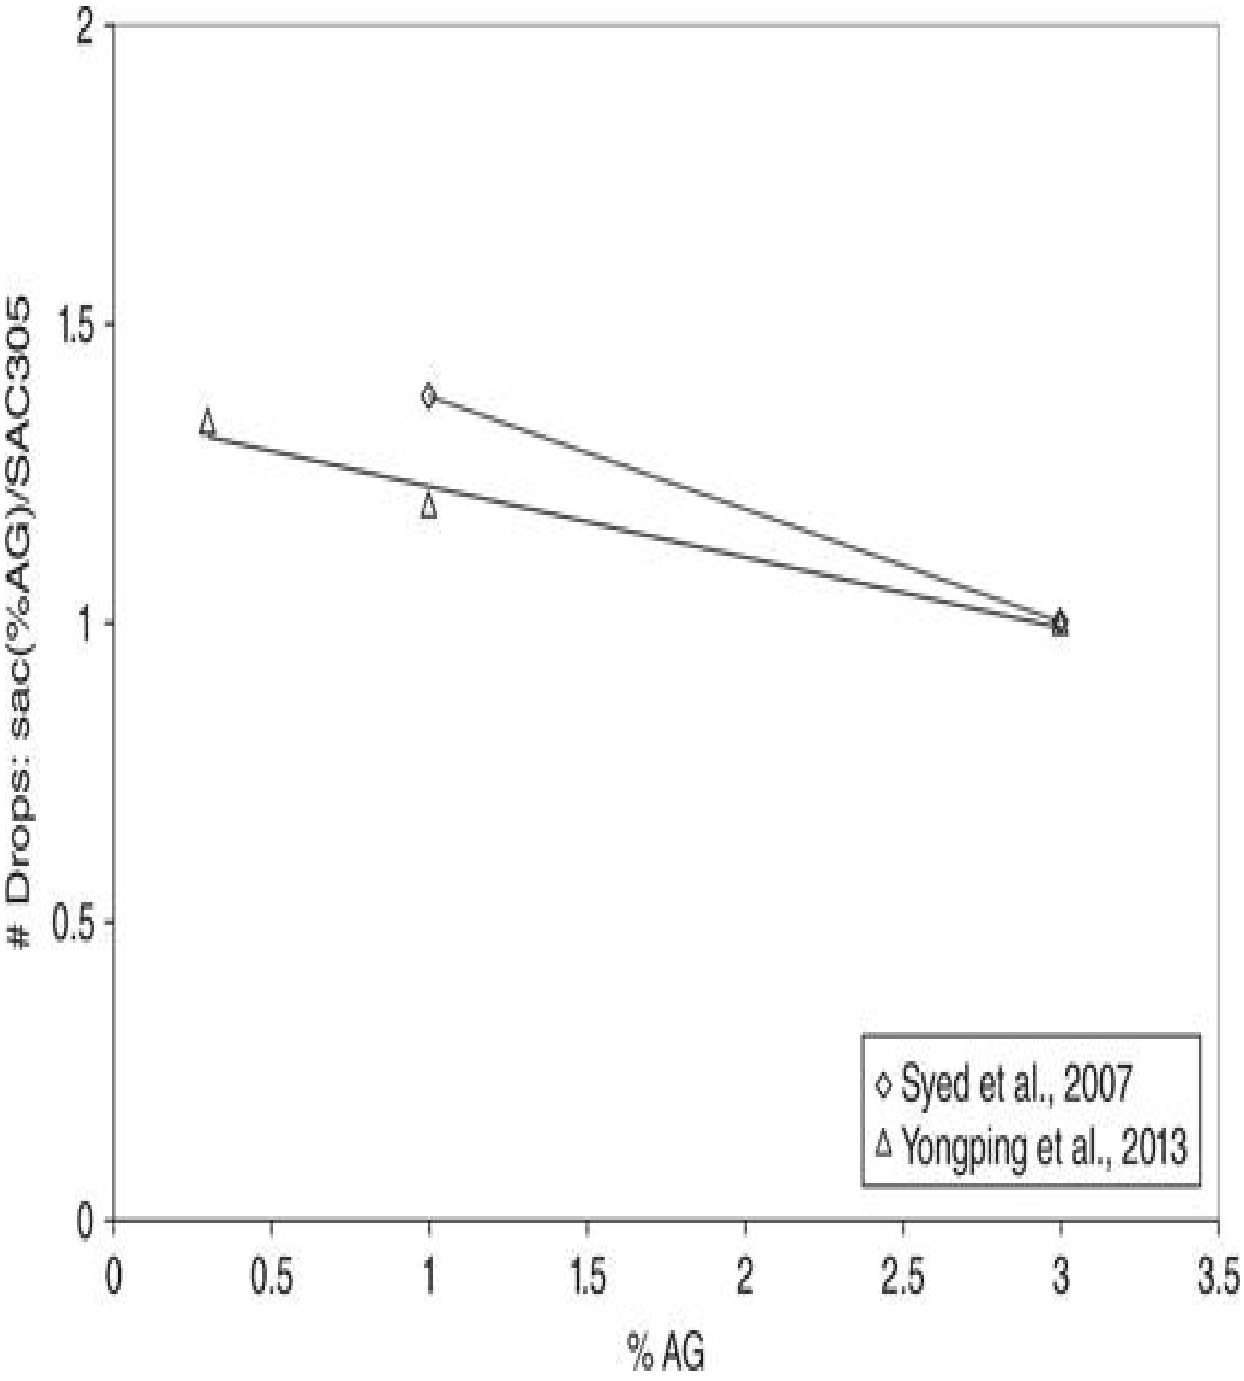

FIGURE 63.14 Effect of %Ag in SAC solder joints on the number of drops to failure. For each dataset, the data has been normalized to the number of drops to failure for SAC305 assemblies.

The trend is reversed under thermal cycling conditions. Figure 63.15*a*, *b* (after Fig. 20a, b in Clech, 2013) shows cycles to failure versus Ag content in SAC assemblies for a variety of components. The source of test data is indicated in the legend (Fig. 63.15*a*) or in the figure caption (Fig. 63.15*b*). The trends through each dataset are linear, at least in the plotted range of 1 to 4 percent Ag contents. The slopes of the linear trendlines vary by one order of magnitude depending on the component type and test conditions. The slopes decrease with an increase in thermal expansion mismatch between board and components, as seen in Fig. 63.15a when going from the PBGAs to the resistors to the bare chips datasets. The slopes also decrease under harsher test conditions, as seen Fig. 63.15b.

63.7.3 Impact on Accelerated Testing Conditions

For the most part, accelerated testing conditions to prove in the reliability of lead-free assemblies are similar to test conditions for SnPb assemblies. One noticeable difference is that IPC 9701 provides a longer dwell time option of 30+ min, instead of about 15 min for SnPb, for accelerated thermal cycling. The reasoning behind this is that, since lead-free solders creep at much slower rates than SnPb, more time is needed to provide sufficient stress relaxation at the temperature extremes.

Several studies on SAC assemblies have shown that the failure modes remain the same and failure times for short and long dwell conditions are correlated accurately by strain energy predictive models (Bath et al., 2005; Clech, 2005, 2013). The main impact of long dwell times is to lengthen the test duration to acquire a full failure distribution, as required by IPC 9701, possibly by a factor of 1.5 to 2.5 times or more.

The Industry Working Group (Bath et al., 2005) tested SAC396 assemblies between 0 and 100°C with cold dwells of 10 min and hot dwells of either 10 or 60 min. Stress/strain loop simulation for the critical solder joints of interest showed that the 10-min hot dwell cycle provided for 50 percent stress relaxation at 100°C and that the 60-min hot dwell cycle was not as effective in terms of damage per unit of time (Clech, 2005). This is because, at the start of a dwell period, creep rates in solder joints are at their highest level,

and as time goes on, the creep rates slow down rather quickly, leading to less creep damage per unit of time. The Industry Working Group concluded that accelerated thermal cycling with long dwell times was not necessary.

More recent studies lead to similar conclusions for SAC105 and SAC305 assemblies (Coyle et al., 2010; Clech, 2013). As an example, Fig. 63.16*a* shows cycles to failure, in terms of characteristic life, versus dwell times during thermal cycling of SAC105 and SAC305 Plastic BGA (PBGA) assemblies between 0 and 100°C. The data points (symbols) are from Coyle et al., 2010. The simulations (solid lines) are based on a strain energy model using different creep laws for SAC105 and SAC305 solders (Clech, 2013). The failure modes were similar for the three different dwell times in test (10, 30, and 60 min) and the predictive strain energy model correlates rather well with the test results. The thin lines through the SAC105 and SAC305 data points represent empirical power laws that are fitted to the test data. Their exponents are −0.18 and −0.22 for SAC105 and SAC305, respectively. Figure 63.16*b* shows the same results as Fig. 63.16*a* in terms of test duration (time to 63.2 percent failure in months) versus dwell time. The simulations and the data show a linear trend except for very short dwell times. Going from 10 to 30 or 60 min for the dwell times, the test duration increases by a factor of approximately 1.5 to 2.5 times. Given that a typical thermal cycling test runs from 3 to 6 months or more, the duration and cost of accelerated thermal cycling need be taken into consideration when deciding to extend the dwell times at the temperature extremes.

63.8 CONCLUSIONS

Solder joint reliability is critical to the performance of electronic systems. Numerous factors impact attachment reliability, including package and board geometry and material properties. The impact of board parameters was discussed in details in this chapter. Rules-of-thumb, design guidelines and simple equations are provided that should be of use for physical designers to make rational choices during the early stages of product development. These simple tools and guidelines are intended to minimize solder joint stresses and strains. They apply regardless of solder composition, SnPb or lead free.

Given the strong impact of board and package material properties, the solder attachment reliability assurance process rests heavily on suppliers' buy-in and participation. Reliability is in the details and requires input from the entire supply chain. At the very least, end users should be notified promptly of changes in materials. Reliable material properties, and updates, should also be readily available to physical designers.

Important trends in lead-free solder joint reliability were also discussed, such as the effect of Ag content on the performance of SAC assemblies. Opposite trends are established for SAC alloys with decreasing Ag content under drop conditions and accelerated thermal cycling. The projection of thermal cycling data from test to use conditions becomes critical in the selection of lead-free solder alloys. Some of the test and modeling techniques that may be of

use in the alloy selection process are discussed in Chaps. 62 and 64.

CHAPTER 64

COMPONENT-TO-PWB RELIABILITY: ESTIMATING SOLDER JOINT RELIABILITY AND THE IMPACT OF LEAD-FREE SOLDERS

Mudasir Ahmad
Cisco Systems, San Jose, California

Mark Brillhart
Palo Alto, California

64.1 INTRODUCTION

In Chap. 63, the critical design variables that could impact the reliability and manufacturability of printed circuit assemblies (PCAs) have been outlined. The use of various assessment tools to quantify the expected life of PCAs is an important aspect of design for reliability. Data collected from standard tests can be used with acceleration transforms and

finite element analysis to assess the expected service life of any interconnect. Experimental data play a crucial role in reliability assessments. Poor data or data obtained under incorrect experimental conditions can lead to grossly inaccurate reliability assessments. “Garbage in equals garbage out” is nowhere more true than in interconnect reliability assessments. The history and experience gained over years of use of tin-lead solders are no longer applicable to lead-free assemblies because lead-free solders behave differently under the same end-use conditions and relatively little data are available on the characteristics of lead-free solders. The formulas for predicting the field life of solder joint interconnects would have to be revisited and validated with extensive experimental data. Moreover, the introduction of lead-free materials is accompanied by new failure mechanisms that are yet to be fully understood and mapped into field-life prediction models.

64.1.1 Experimental Tests

The different levels of solder joint interconnects in a typical PCA are illustrated in Fig. 64.1.

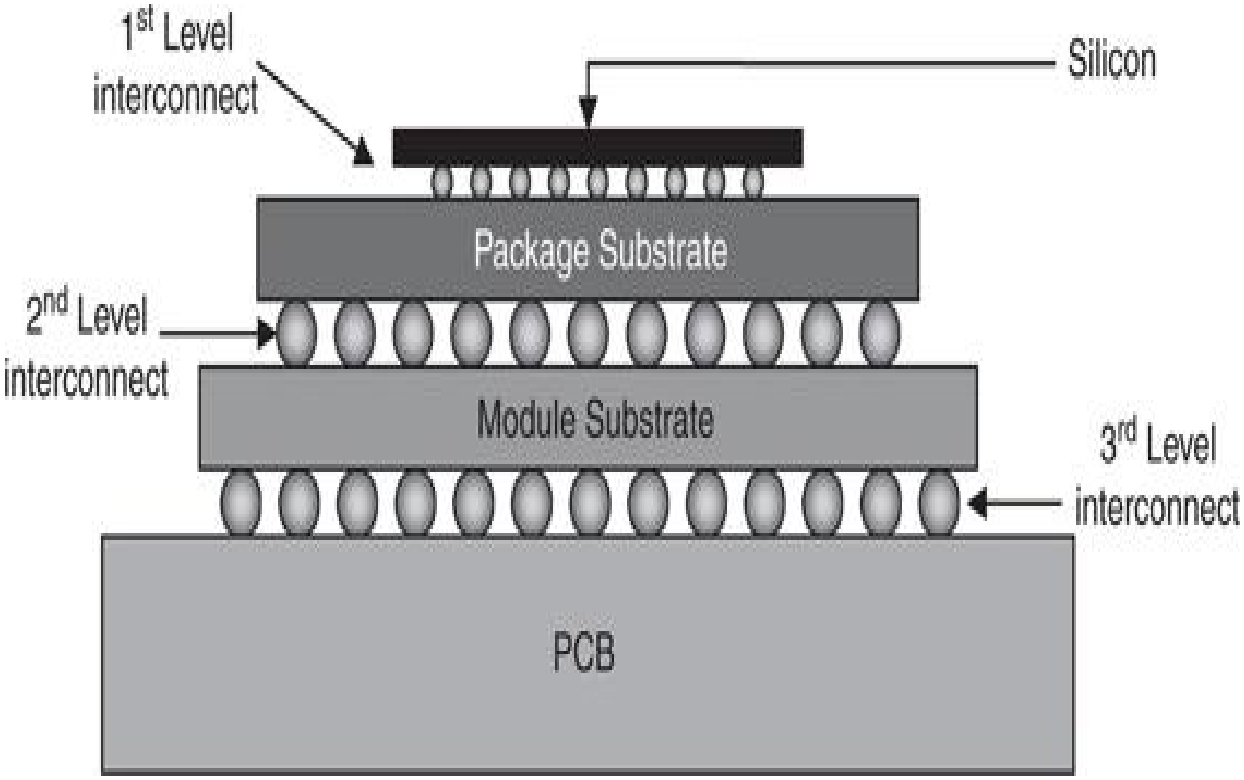

FIGURE 64.1 First-, second-, and third-level interconnects defined, employing a flip-chip assembly as an example. The first-level interconnect is the primary connection between the silicon die and the package substrate. In this example, the connection is created by the solder bumps between the die and the package. The second-level interconnect in this example is the next level of connection between the package substrate and the module substrate. The third-level interconnect in this example is created when the solder balls on the bottom side of the module substrate are attached via surface-mount technology (SMT) to the printed wiring board (PWB).

A myriad of experimental tools have been developed to assess solder joint reliability rapidly. These include

- Thermal cycling
- Thermal shock
- Air-to-air cycling
- Liquid-to-liquid cycling
- Mechanical bending
- Mechanical deflection
- Hyper-Peltier cooled thermal cycling

It is crucial for the PWB designer to understand the techniques employed, the applicability of the results, and the quality of the data when assessing the reliability of any package that will be placed on his or her PWB. Although rapid assessments are desirable, their benefit diminishes if the failure modes are fictitious and not indicative of expected field failures.

64.1.2 Impact of Lead-Free Materials on Reliability

The conversion to lead-free materials requires a reassessment of these experimental tools and field-life assessment techniques. New materials and failure modes need to be adequately captured in numerical and experimental test methods to model correctly the sort of thermal and mechanical conditions that an interconnect would be exposed to in field operating conditions.

The following key aspects of quantitative reliability assessment are discussed at length in this chapter:

- Thermomechanical reliability:
  - Temperature cycling tests used to determine the thermomechanical reliability of tin-lead and lead-free assemblies
  - The role of Weibull plots in estimating the failure distribution and characteristic life of solder joints from temperature cycling data
  - The acceleration transforms that can be used to estimate the field life of tin-lead and lead-free solder joints based on the results of temperature cycling tests
  - The role of power and minicycles in predicting the field life of solder joints

- Examples illustrating the use of acceleration transforms to compare the fatigue life of packages tested in different thermal cycling and end-use conditions
- Mechanical reliability:
  - Bend test methodologies and test methods that could be used to perform a relative comparison between different package types and surface finishes
  - Sample experimental data showing the comparative difference between different surface finishes and solder metallurgies
  - Shock test methodologies that could be used to perform a relative comparison between different packages and end-use conditions
  - Ball adhesion test methodologies: high-speed shear, pull testing, and impact testing

In addition, this chapter outlines the role of numerical analysis techniques in analyzing and improving the reliability of solder joint interconnects. Detailed procedures illustrating the use of finite element analysis (FEA)[1] in estimating the thermomechanical fatigue life of solder joint interconnects and monotonic bend testing are also discussed.

64.2 THERMOMECHANICAL RELIABILITY

In field operating conditions, ball grid array (BGA) solder joints are continuously subjected to strains due to the coefficient of thermal expansion (CTE) mismatch between the package and the PWB. These strains, which are caused by small but frequent fluctuations in temperature, accumulate as the device is powered up or down. As a result, cracks initiate in the solder joint interconnects and can

eventually propagate, leading to solder joint opens. The ability of the solder joint interconnects to withstand these differential strains during field operating conditions for a desired lifetime is generally referred to as *thermomechanical reliability*. The most common method for accelerating this failure in the lab is by thermally cycling the assembled device through extreme temperatures while recording any electrical opens that may occur during the test.

64.2.1 Temperature Cycling

Thermal cycle experiments have been the current industry standard for assessing second-level interconnect reliability. These types of tests tend to produce solder joint and solder joint-pad interfacial fractures that are typically seen in field failures. The fact that thermal cycle tests produce the same physical failures allows for detailed acceleration transformations and finite element-based life assessments to be made employing thermal cycle data as input.

The industry test method that is widely used for this testing is IPC-9701.[2] IPC-9701 provides detailed guidelines for the recommended temperature cycling test methods for evaluating the reliability of surface-mount solder joints. In addition, IPC-9701 also provides guidelines for estimating the performance of solder joints in different field-use conditions from the recommended accelerated thermal cycling tests.

An important benefit of performing industry standardized testing as recommended by IPC-9701 is that device suppliers can perform this test routinely for their devices, irrespective of where the device would be used. The results of the tests can then be used to determine whether the device will survive in a variety of end-use conditions. This saves significant testing cost and design time while providing a baseline for comparison of devices from different suppliers.

Where there are minor differences between the conditions in which the device is to be used, finite element analysis can be performed to bridge the differences between the tested device and the actual environment in which a very similar device would be used. The entire process by which the reliability of a device can be assessed is illustrated in Fig. 64.2.

FIGURE 64.2 Flowchart of the solder joint thermomechanical reliability qualification process. Experimental data generated in the lab environment is compared with the expected product end-use conditions. If the package tested is identical to that used in the product, the acceleration transforms are used to map the fatigue life in the lab to the fatigue life in the product end-use conditions. If the package tested is similar but not identical to that used in the product, FEA is performed to account numerically for the differences between the tested and actual package before using the acceleration transforms.

Thermal cycle experiments are typically performed in single-chamber ovens. Dual-chamber systems are sometimes employed, but single-chamber equipment tends to dominate the test space. The main drawback of a dual-chamber oven is the lack of control over the thermal loading profile when transferring from one chamber (or thermal zone) to the other. Regardless of whether a single or dual chamber is used, temperature is cycled from a maximum (T_{max}) to a minimum (T_{min}) value. Temperature is ramped from one temperature extreme to another at a controlled rate, referred to as the *ramp rate*. Temperature is also held at the maximum and minimum values for a predetermined time known as the *dwell time*. Table 64.1 lists typical experimental parameters for second-level reliability qualification. Figure 64.3 contains a plot of temperature versus time along with explanations of the key experimental parameters.

TABLE 64.1 Typical Thermal Cycle Test Parameters for Second-Level Reliability Qualification

Parameter	Value
Maximum temperature (T_{max})	100°C
Minimum temperature (T_{min})	0°C
Ramp rates from T_{min} to T_{max} and T_{max} to T_{min}	10°C/min
Dwell time at T_{max} and T_{min}	10 min

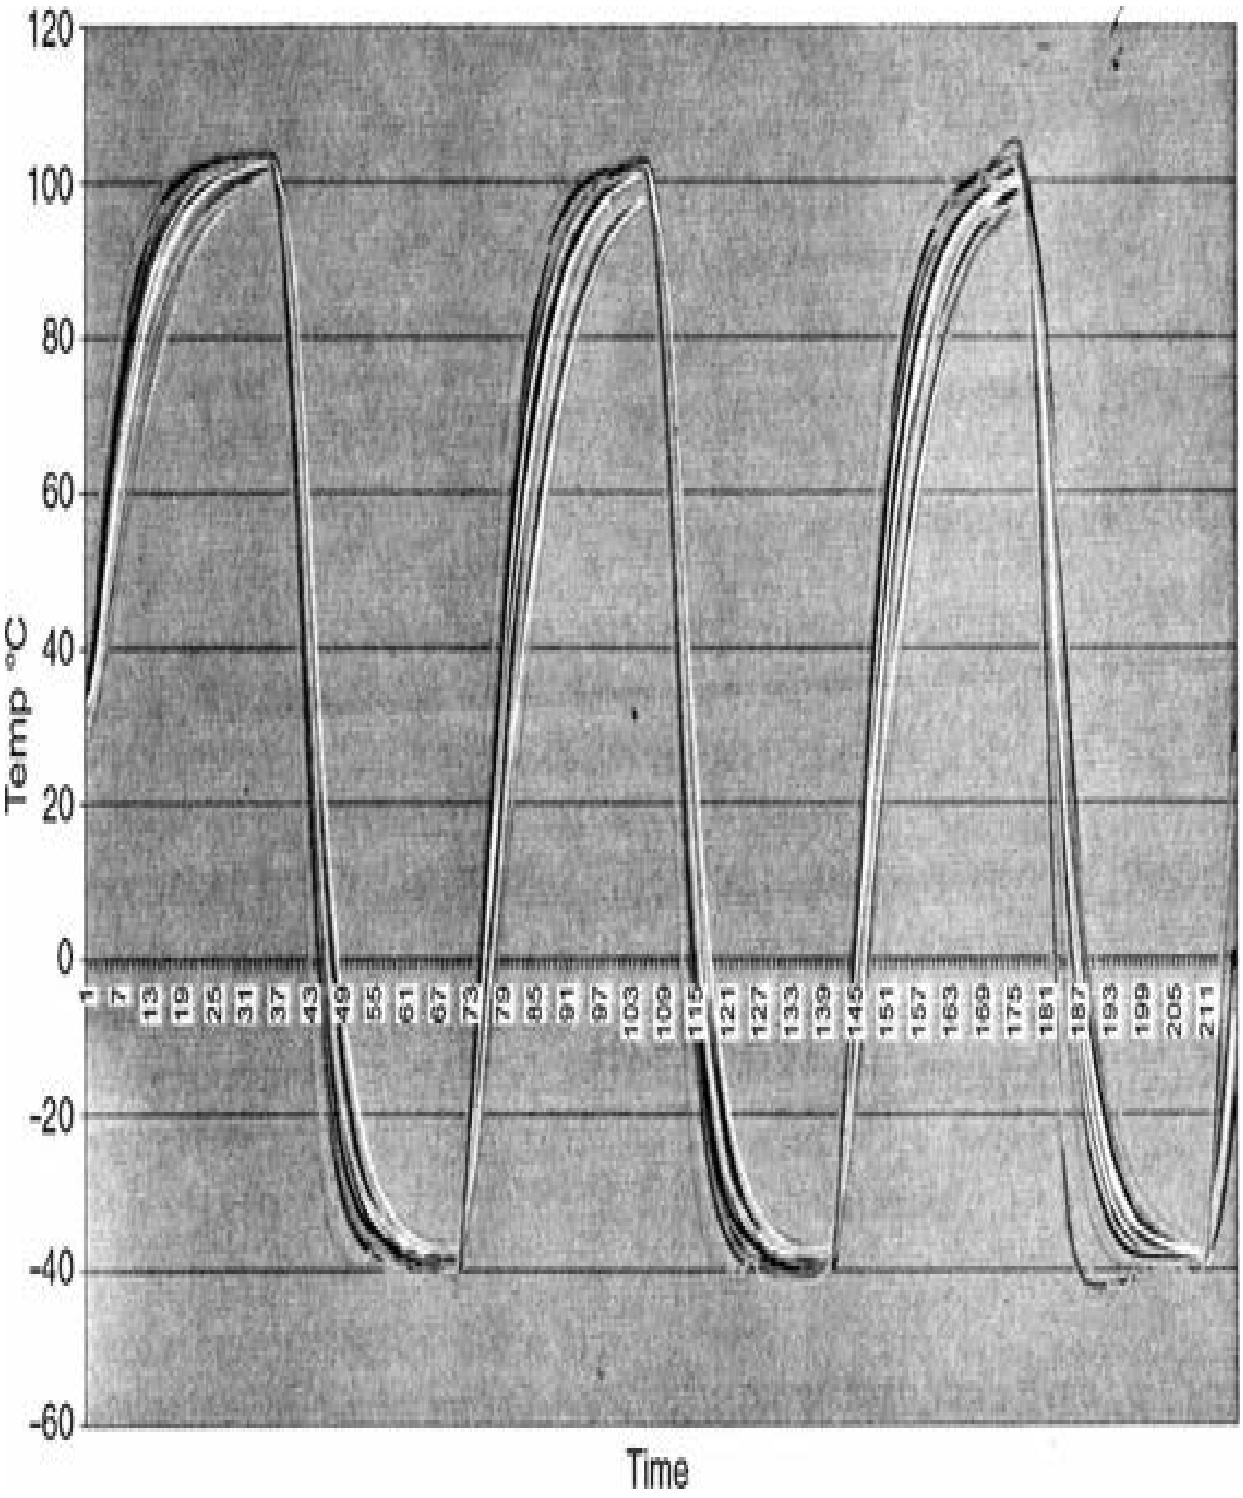

FIGURE 64.3 Typical thermal cycle profile. In this plot, T_{max} = 100°C, T_{min} = –40°C, and the cyclic frequency is 60 min.

Data acquisition systems and/or event detectors (commonly referred to as *glitch detectors*) are employed to

monitor resistance and/or scan for intermittent opens in real time. One of the early techniques for assessing solder joint integrity during thermal cycling was to remove parts periodically from the test chamber and measure resistance manually at room temperature.

The major risk associated with this technique is that opens are observed only at temperature extremes when the deformations due to CTE mismatch are largest. As the package cools to room temperature, most of the CTE-based deformations that pull cracked surfaces of solder joints are gone and there is a potential for cracked surfaces to be in enough physical contact to provide acceptable continuity. In some cases, the cycle number at which opens are observed at temperature extremes is much shorter than the cycle at which the same opens are observable at room temperature.

A schematic of a typical thermal cycling chamber, with the boards installed and connected to a data acquisition system, is shown in Fig. 64.4.

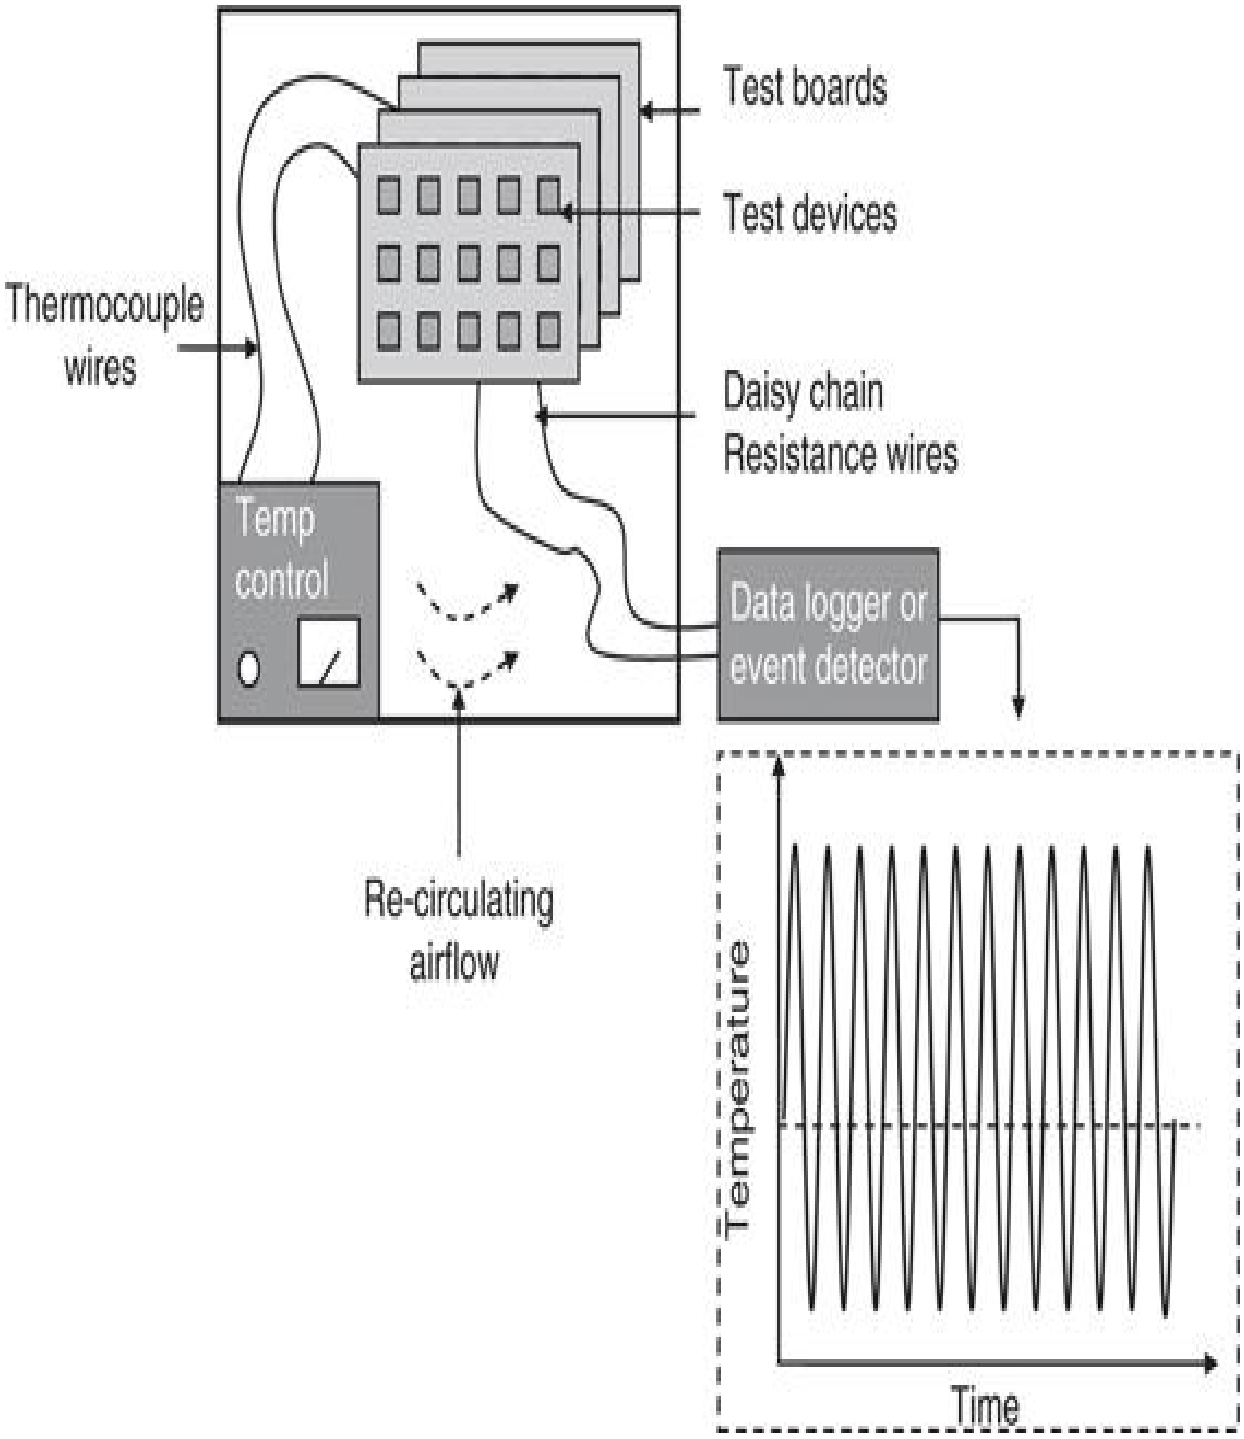

FIGURE 64.4 Schematic of a typical thermal cycling chamber and data acquisition system.

64.2.1.1 Effect of Lead-Free Conversion. The thermal cycling profile listed in Table 64.1 is also applicable to lead-free solders. Most of the damage accumulation occurs during

the high-temperature dwell phase. If the high-temperature dwell cycle is shortened, the damage accumulated per cycle would be reduced. It is desirable to maintain a high-temperature dwell long enough to allow creep saturation. However, practical limitations prevent this; as a result, the recommendations in IPC-9701-A[3] (Appendix B) are that a 10-min dwell time be used, and where possible a 30-min (or higher) dwell time could be used. Finite element analysis could be used to calibrate the experimental data and determine the effect of dwell time on long-term reliability.

64.2.1.2 Thermal Shock. Thermal shock experiments continuously cycle parts from a high to a low temperature very rapidly. These types of experiments are typically used as screening tools or to run parallel experiments on a known good part and a proposed new component to assess the relative performance of each part. Thermal shock experiments are quite rapid, with thermal shock test durations on the order of days rather than the months associated with thermal cycle test times.

The main drawback of thermal shock experiments lies in the fact that these types of tests tend to induce failure modes not observed in the field. Additionally, even if solder joint fatigue can be induced, it is very difficult to map the high ramp rates associated with thermal shock loading conditions to the more gradual thermal loading conditions that occur in the field. Consequently, this test technique is limited to relative comparisons between packages in which the failure modes have been shown to be comparable under the same thermal shock test conditions.

64.2.2 Weibull Distributions

The results of the temperature cycling tests described in Sec. 64.2.1 can be used to estimate the field operating life of the

solder joint interconnects by using the acceleration transforms outlined in detail in Sec. 64.2.3.

However, to determine the field operating life, one needs to know the life of the parts in lab testing. The raw data obtained from the lab test could be fitted with a failure distribution to determine the mean life of the parts. Typical failure distributions include Weibull, Normal, Lognormal, and Exponential. For wear-out type of failures, the Weibull and Lognormal distributions are usually used, with Weibull being the most common. Weibull distributions are lowest value distributions derived from the weakest-link theory.[4,5] Solder joint interconnects can be considered as connected in series. Usually, the failure of one joint at a critical location could cause the entire device to fail. The joints that fail early are usually located at the highest stress locations in the package. Devices with more resilient joints would not fail early. A Weibull distribution captures the minimum solder joint life, and the shape parameter captures the quality of the joints as a function of their construction and the applied stress.[4] There are different types of Weibull distributions: one-parameter, two-parameter, and three-parameter. The three-parameter Weibull Probability Distribution Function (PDF)[6] is as shown in Eq. (64.1).

$$f(t)=\frac{\beta}{\eta}\left(\frac{t-\gamma}{\eta}\right)^{\beta-1} e^{-\left(\frac{t-\gamma}{\eta}\right)^{\beta}} \qquad (64.1)$$

where $f(t)$ = Probability Distribution Function

β = shape parameter (which defines the shape of the distribution)

η = scale parameter (which defines the characteristic life of the distribution; this is the time in which 63.2 percent of the tested samples would fail)

γ = location parameter (which defines the location of the distribution in time)

t = time

Two-parameter and three-parameter distributions are commonly used to fit the temperature cycling data. The two-parameter distribution fits a straight line though the data, whereas the three-parameter distribution fits a non-linear curve through the data. In general, the two-parameter distribution is more conservative than the three-parameter distribution. Best practice is to perform regression analysis to determine which distribution best fits the data.

Another important factor in the statistical assessment of test data is the *confidence interval*. Confidence intervals (or *confidence bounds*) take into account the quality of the data based on the number of samples tested.[7] When two separate experimental data sets are being compared, double-sided confidence bounds are useful in normalizing the data based on the number of samples tested in each data set. An example of upper and lower confidence bounds set at 90 percent is illustrated in Fig. 64.5.

FIGURE 64.5 A typical two-parameter Weibull distribution. The plot shows two data sets with different shape parameter (β) values but comparable characteristic life (η). Extrapolating to 1 percent failure free life shows that the 90 percent lower-bound confidential interval for data set 1 is lower than that for data set 2, even though the characteristic lives are comparable.

64.2.3 Material Properties

A tremendous number of researchers have explored the reliability of Pb/Sn solder alloys.[8] A wealth of data, material properties, and proposed constitutive relationships have been captured in the literature.[8,9,10] However, there is relatively little information in the literature on the material properties of lead-free solders. Moreover, the material property information available is on slightly different compositions of lead-free solders, with tests performed in different ways.

One of the challenges with both Pb/Sn and lead-free solders is that they undergo viscoplastic deformation (creep) as a function of time, temperature, strain rate, and applied stress. A variety of creep deformation models have been used to model the viscoplastic behavior of lead-free solders. The Anand model has been successfully used to model the viscoplastic behavior of Pb/Sn solders. The model allows for the simultaneous incorporation of time-independent plastic deformation as well as time-dependent creep deformation.

The functional form of the Anand model is given as shown in Eqs. (64.2) through (64.5).[11,12]

$$\dot{\varepsilon}_p = A\left[\sin h\left(\xi\frac{\sigma}{s}\right)\right]^{\frac{1}{m}} \exp\left(\frac{-Q}{kT}\right) \tag{64.2}$$

where $\dot{\varepsilon}_p$ = inelastic strain rate
A = experimentally determined empirical constant
Q = activation energy
R = gas constant
ξ = stress multiplier
σ = equivalent stress
s = internal state variable
m = strain rate sensitivity parameter

$$\dot{s} = \left\{ h_o \left(|B| \right)^a \frac{B}{|B|} \right\} \frac{d\varepsilon_p}{dt} \tag{64.3}$$

$$B = 1 - \frac{s}{s^*} \tag{64.4}$$

$$s^* = \hat{s} \left\{ \frac{\dfrac{d\varepsilon_p}{dt}}{A} \exp\left(\frac{Q}{kT} \right) \right\}^n \tag{64.5}$$

where h_o = hardening/softening constant
a = hardening/softening strain rate sensitivity coefficient
s^* = saturation value of s for a given set of temperature and strain rate data
$\hat{s}$ = saturation coefficient
n = strain rate sensitivity coefficient for the saturation value of deformation resistance

The relevant material property information on the solder composition close to that recommended by iNEMI[13]

(Sn3.9Ag0.6Cu) is listed in Table 64.2.

One disadvantage of the Anand model is that it mainly captures steady-state creep of solder, but it does not capture primary creep (see Fig. 64.6). Since a significant portion of solder joints' field life is spent in the primary creep phase, it is difficult to predict fatigue life driven by end-use conditions. In other words, although the Anand model can be successfully used in predicting the fatigue life of solder joints tested in laboratory conditions, it may not be very accurate in predicting the fatigue life of solder joints in field use conditions. What may be needed is a time-hardening creep

model that can better capture primary, secondary (steady-state), and tertiary creep.

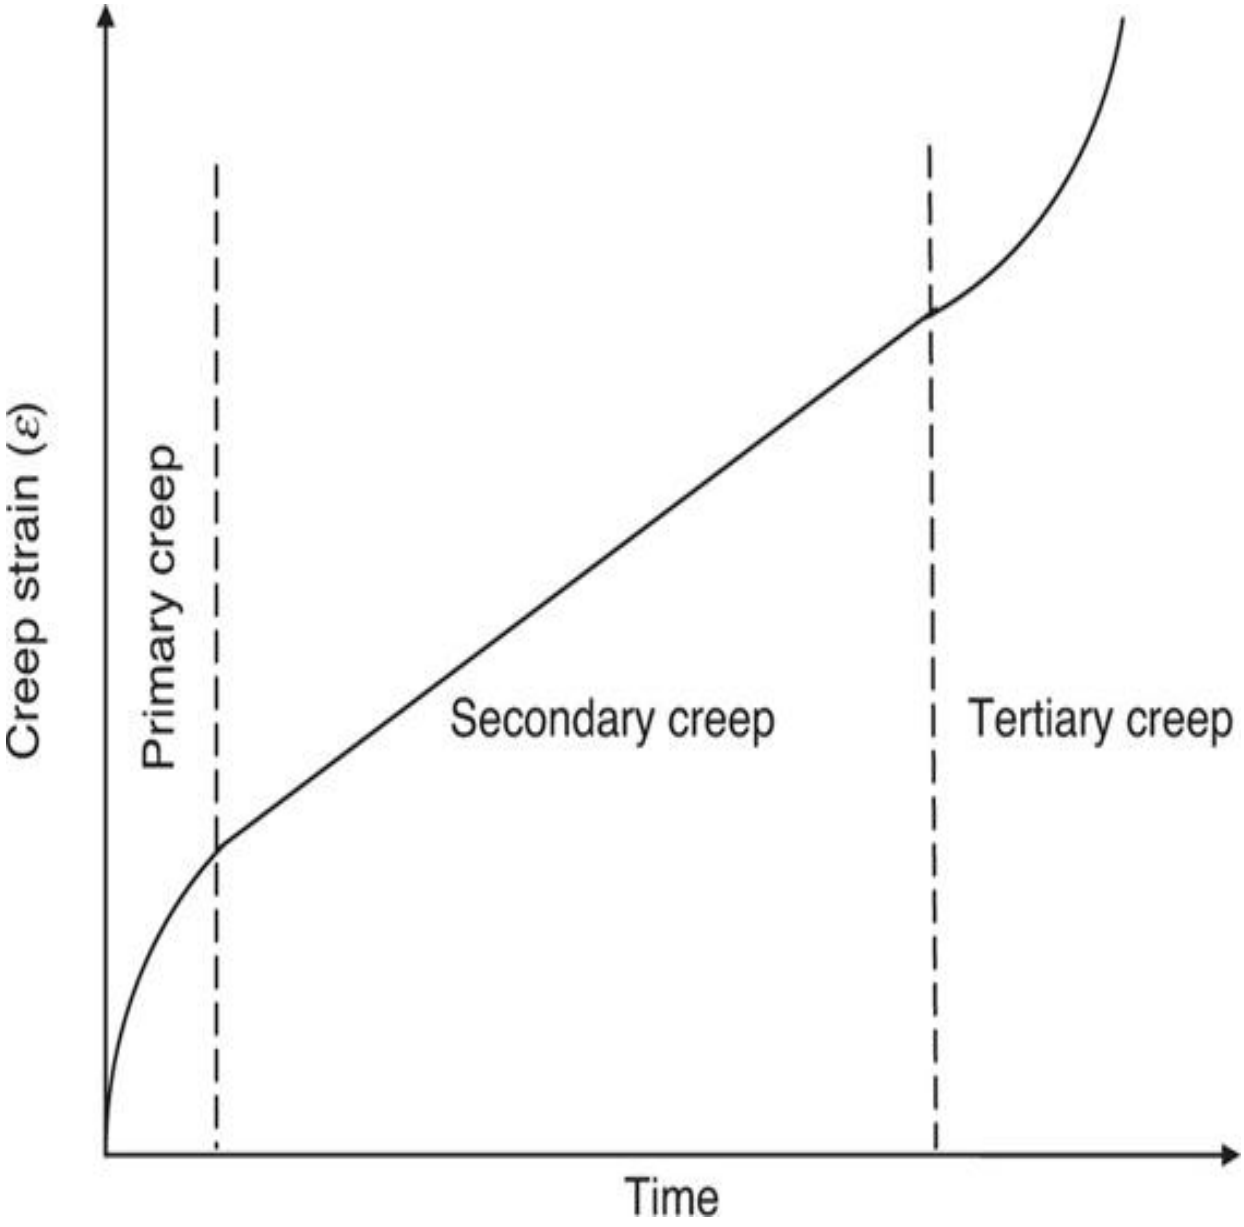

FIGURE 64.6 A typical creep strain versus time curve for viscoplastic materials. The curve shows that creep strain starts out as a non-linear curve, becomes steady for a significant period, and then increases significantly into tertiary creep. Most of the life of a solder joint is spent in the primary and secondary creep strain range of the curve.

Another model that proposes the incorporation of primary and tertiary creep strain rates is the A-Ω model.[17] This model

proposes that the primary creep strain rate be represented as an exponential decay function of increasing creep strain, and the tertiary creep strain rate be represented as an exponential growth function of increasing creep strain. However, this model is relatively new and has not been validated with independent experimental reliability data across the industry.

Other models available in the literature for different lead-free solder metallurgies are listed in Table 64.3.

TABLE 64.3 Material Properties for Lead-Free Solder[18]

A more comprehensive list of mechanical material properties of lead-free solders and other materials used in electronic packages can be found in Reference 22.

64.2.4 Norris-Landzberg Acceleration Transformation

PWB designers typically receive a failure distribution plot (see Fig. 64.5) as part of a second-level package qualification report. This failure distribution plot is typically obtained in a thermal cycle oven under controlled temperature profiles that include the maximum and minimum temperatures (T_{max} and T_{min}, respectively) of the thermal cycle along with the frequency (f) of the experimental thermal cycle. The designer must then relate these experimental data obtained under ideal conditions to a different thermal cycle condition (or conditions) encountered in the product end-use environment. Although relative comparisons of two packages thermally cycled under identical conditions can be made in a ranking sense, this type of analysis yields no information regarding the actual lifetime of the solder joints under field loading conditions. This section focuses on the mapping of a laboratory thermal cycle to different end-use thermal profiles using strain as a damage metric.

64.2.4.1 Fatigue Behavior. The fatigue behavior of many metals (including Pb/Sn and lead-free solder alloys) can be described by the Coffin-Manson relationship [Eq. (64.6)],[9] which relates the fatigue life of a metal to the plastic strain the material experiences during loading. Elastic strain is the reversible or recoverable deformation that occurs during a loading cycle. Plastic strain is the amount of irreversible (or permanent) deformation that occurs during a loading cycle.

$$\varepsilon = \varepsilon_e + \varepsilon_p = AN_f^{-c} + BN_f^{-m} \tag{64.6}$$

where ε = total strain per cycle
ε_p = plastic portion of the cyclic strain
ε_e = elastic portion of the cyclic strain
N_f = number of cycles to failure
A,B,c,m = experimentally determined empirical constants

Most solder joints fail in the low cycle fatigue region (less than 10,000 cycles to failure),[9] where strain is primarily plastic. Thus, neglecting the elastic component of strain, Eq. (64.6) can be simplified and rearranged to yield a relationship between the number of cycles to failure and the plastic strain [see Eq. (64.7)].[9]

$$N_f = (A/\varepsilon_p)^{1/m} \tag{64.7}$$

where ε_p = plastic portion of the cyclic strain
N_f = number of cycles to failure
A,m = experimentally determined constants

This can be further simplified to the most common form of the Coffin-Manson relationship shown in Eq. (64.8).[9]

$$N_f \propto \varepsilon_p^c \tag{64.8}$$

where ε_p = plastic portion of the cyclic strain
N_f = number of cycles to failure
c = an experimentally determined empirical constant

When any metal is cycled at a temperature above 50 percent of its melting temperature (homologous temperature), the strain rates, dwell times, and maximum

temperature influence its fatigue life.[9] This is due to the occurrence of creep, along with plastic and elastic deformation, within these temperature regimes.[9] Norris and Landzberg proposed a modified version of the Coffin-Manson relationship that considers the effects of frequency (f) and maximum temperature (T_{max}) on solder joint fatigue life [Eq. (64.9)].[9,10] This relationship is based on detailed physical and empirical analysis of the relationships between temperature and frequency on the thermal fatigue behavior of Pb/Sn solder alloys employed in interconnects.[10]

$$N_f = (A/\varepsilon_p)^{1.9} f^{1/3} \exp\left(\frac{0.123}{kT_{max}}\right) \tag{64.9}$$

where ε_p = plastic portion of the cyclic strain
N_f = number of cycles to failure
k = Boltzmann's constant (eV)
f = cyclic frequency
T_{max} = maximum temperature of the thermal cycle (K)
A = an experimentally determined empirical constant

64.2.4.2 Acceleration Factors. One of the challenges that must be addressed when attempting to employ Eq. 64.9 directly to assess fatigue life is the determination of the plastic strain and the value of the constant A. It is crucial to remember that the goal of this analysis is to develop an acceleration transform (or acceleration factor) that can be employed to use known fatigue-life data obtained under controlled laboratory conditions to estimate the number of cycles to failure under field conditions. The acceleration factor AF is defined as the ratio of the number of cycles to

fail in the field N_{fF} to the number of cycles to fail in the lab N_{fL} [see Eq. (64.10)].

$$AF = \frac{N_{fF}}{N_{fL}} \tag{64.10}$$

where AF = acceleration factor
N_{fF} = number of cycles to failure in the field
N_{fL} = number of cycles to failure in the lab

Substituting Eq. (64.9) for lab and field conditions into Eq. (64.10), one obtains Eq. (64.11).

$$AF = \frac{N_{fF}}{N_{fL}} = \frac{(A/\varepsilon_{pF})^{1.9} f_F^{1/3} \exp\left(\frac{0.123}{kT_{maxF}}\right)}{(A/\varepsilon_{pL})^{1.9} f_L^{1/3} \exp\left(\frac{0.123}{kT_{maxL}}\right)} \tag{64.11}$$

where AF = acceleration factor
N_{fF} = number of cycles to failure in the field
N_{fL} = number of cycles to failure in the lab
ε_{pF} = plastic portion of the cyclic strain in the field
ε_{pL} = plastic portion of the cyclic strain in the lab
f_F = cyclic frequency
f_L = cyclic frequency
T_{maxF} = maximum temperature of the thermal cycle in the field (K)
T_{maxL} = maximum temperature of the thermal cycle in the lab (K)
k = Boltzmann's constant (eV)
$_L$ = lab conditions
$_F$ = field conditions

Equation (64.11) can be algebraically rearranged to yield Eq. (64.12). Note that the "max" subscripts on the maximum temperatures have been dropped to simplify the notation.

$$AF = \frac{N_{fF}}{N_{fL}} = \left[\frac{\varepsilon_{pL}}{\varepsilon_{pF}}\right]^{1.9} \left[\frac{f_F}{f_L}\right]^{1/3} \exp\left[1414\left(\frac{1}{T_F} - \frac{1}{T_L}\right)\right] \tag{64.12}$$

where AF = acceleration factor
ε_{pF} = plastic portion of the cyclic strain in the field
ε_{pL} = plastic portion of the cyclic strain in the lab
f_F = cyclic frequency in the field
f_L = cyclic frequency in the lab
T_F = maximum temperature of the thermal cycle in the field (K)
T_L = maximum temperature of the thermal cycle in the lab (K)

When considering package interconnects of the same geometry and material set, one can reduce the strain term ε_p in Eq. (64.9) to the change in temperature.[10] This is a key feature that enables the development of an acceleration transform. The goal of this analysis is to develop a transform that allows one to map laboratory thermal cycle loading conditions to field loading conditions for the same package. Thus it is valid to assume that the strain term can be reduced to the change in temperature, as shown in Eq. (64.13).

$$\varepsilon_p \propto \Delta T \tag{64.13}$$

where ε_p = plastic portion of the cyclic strain

ΔT = difference between maximum and minimum temperature of the thermal cycle

Substitution of Eq. (64.12) (including $_L$ and $_F$ subscripts for lab and field, respectively) yields the final form of the acceleration factor relationship, which can be seen in Eq. (64.14).[10]

$$AF = \frac{N_{fF}}{N_{fL}} = \left[\frac{\Delta T_L}{\Delta T_F}\right]^{1.9}\left[\frac{f_F}{f_L}\right]^{1/3} \exp\left[1414\left(\frac{1}{T_F} - \frac{1}{T_L}\right)\right] \tag{64.14}$$

where AF = acceleration factor

f_F = cyclic frequency in the field

f_L = cyclic frequency in the lab

T_F = maximum temperature of the thermal cycle in the field (K)

T_L = maximum temperature of the thermal cycle in the lab (K)

ΔT_F = difference between maximum and minimum temperature of the thermal cycle in the field

ΔT_L = difference between maximum and minimum temperature of the thermal cycle in the lab

Figure 64.7 contains experimental failure data for a ceramic ball grid array (CBGA) cycled under the same two conditions. The predicted acceleration factor was calculated to be 3.2 employing Eq. (64.14). This predicted value correlates quite well with the CBGA data (acceleration factor ranges from 2.9 to 3.6). Note that this approach tends to be overly conservative when mapping large lab ΔT into small field ΔT (in the case of minicycles, to be discussed in a subsequent section).

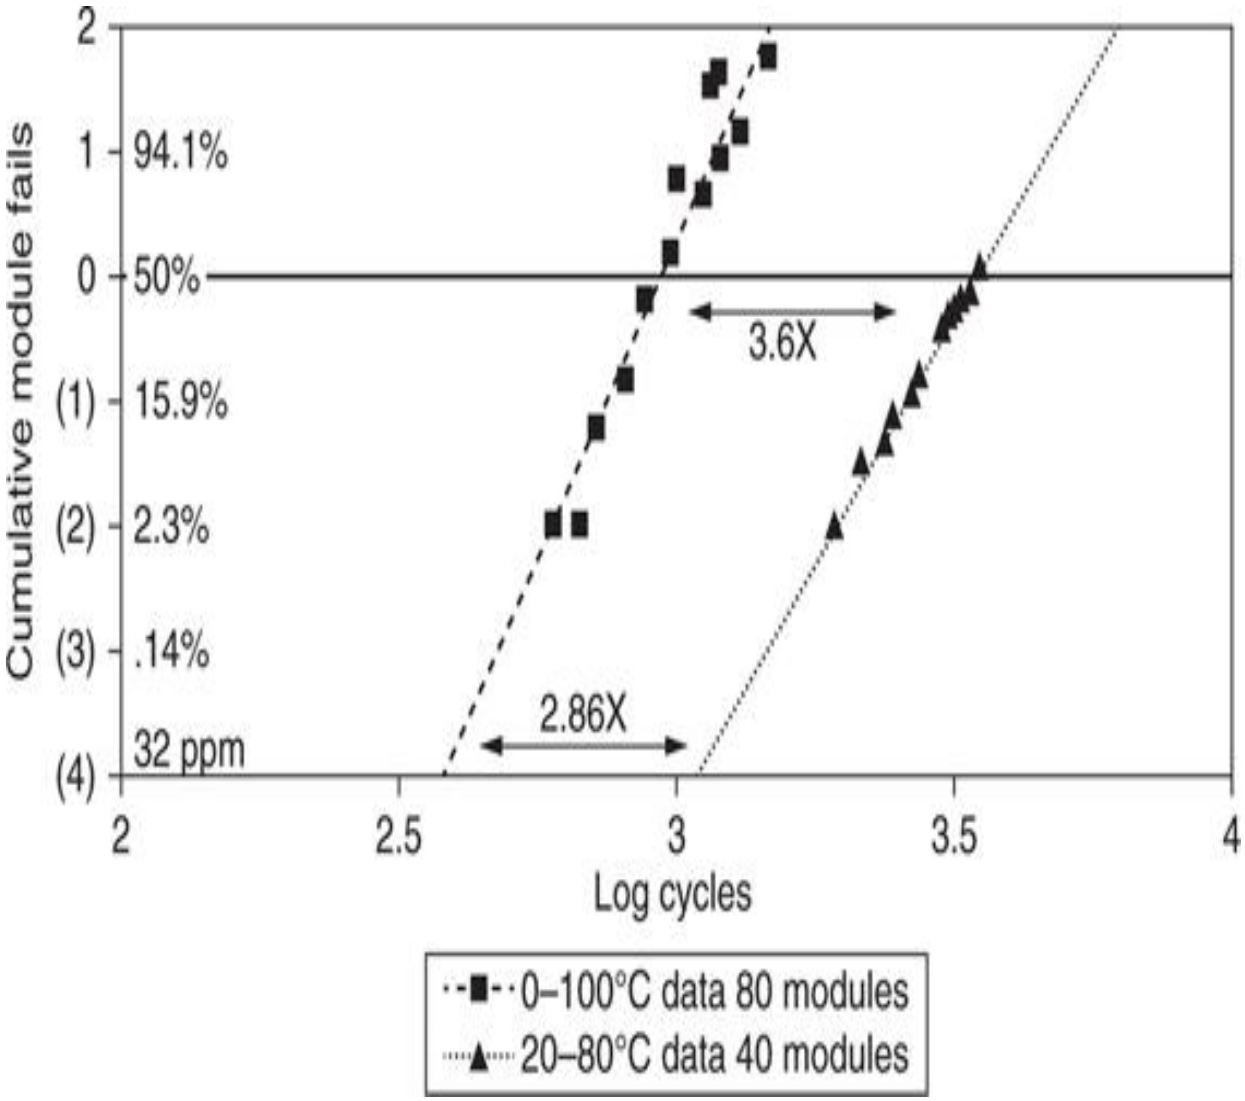

FIGURE 64.7 Weibull plots for a CBGA package cycled under two different loading conditions. Solid triangles and the dotted line are employed to indicate failures and associated failure distribution of a CBGA package cycled from 20 to 80°C (the least severe case presented in this figure). Solid squares and the dashed line indicate the failures and associated distribution for the identical package cycled from 0 to 100°C. Notice that an increase in the severity of the thermal cycle loading conditions (from 20 to 80°C to 0 to 100°C) creates an associated decrease in fatigue life. (*Reprinted with permission from J. Lau*, Ball Grid Array Technology, *McGraw-Hill, 1995, p. 162*.)

64.2.4.3 Effect of Lead-Free Conversion.

The acceleration factor equation [Eq. (64.14)] is specifically derived from experimental data for Pb/Sn solder joints. What remains to be conclusively demonstrated is an equivalent acceleration transform for lead-free solder joints. Several

studies have been performed, but there are no acceleration transforms accepted industrywide for lead-free solders. One of the acceleration transforms proposed is discussed in this section. A more comprehensive list of other field life prediction studies can be found in the appendix of IPC-9701-A.[3]

64.2.4.4 Modified Norris-Landzberg Acceleration Transform for Lead-Free Solder. Based on experimental data generated on a select variety of packages, Pan et al. proposed an updated form of the Norris-Landzberg acceleration transform [see Eq. (64.15)].[23]

$$AF = \frac{N_{fF}}{N_{fL}} = \left[\frac{\Delta T_L}{\Delta T_F}\right]^{2.65} \left[\frac{t_F}{t_L}\right]^{0.136} \exp\left[2185\left(\frac{1}{T_F} - \frac{1}{T_L}\right)\right] \tag{64.15}$$

where AF = acceleration factor
t_F = dwell time at high temperature in the field
t_L = dwell time at high temperature in the lab
T_F = maximum temperature of the thermal cycle in the field (K)
T_L = maximum temperature of the thermal cycle in the lab (K)
ΔT_F = difference between maximum and minimum temperature of the thermal cycle in the field
ΔT_L = difference between maximum and minimum temperature of the thermal cycle in the lab

The primary differences between Eqs. (64.14) and (64.15) are that the frequency term is replaced by the dwell time at high temperature, and the constants have been revised. This equation has been shown by Pan et al. to predict well within the temperature range of 0 to 100°C. However, predictions are less accurate for temperatures outside of this range.[23]

Although the aforementioned proposed acceleration transform is a first-order estimate, much more data would be needed to validate or improve this estimate. Several additional variables must be evaluated to study their impact on the acceleration transform. Some of the variables that impact the acceleration transform include the following:

- *Effect of different package types* The differential strain imparted on solder joints in a ceramic flip-chip ball grid array (FCBGA) is quite different from that imparted on a thin small outline package (TSOP) package, for example. As a result, the acceleration factors from one may not necessarily apply to the other. The construction and effective CTE mismatch of the packages to be qualified must be as close as possible to the packages tested.[23]
- *PWB thickness effect* A thick board is likely to constrain a package more rigidly than a thin board. Similarly, the number of layers in the board could significantly alter its overall stiffness. Tests are frequently done on thinner boards because they are less costly and easier to fabricate. However, if the end-use condition entails the use of a thicker board, IPC-9701 recommends performing the test on at least two different board thicknesses so that the data can be extrapolated to a range of board thicknesses. The effect of board stiffness on lead-free packages appears to be similar to that on Pb/Sn packages, as shown in Sec. 63.3.3 of Chap. 63.
- *Cycling frequency* As evidenced in the study performed by Pan et al. [23] and by Clech,[24] the temperature cycling frequency could have a significant effect on the reliability of the packages being tested. Both the ramp rate and the dwell time affect the results. Most of the damage accumulation during temperature cycling occurs in the hot dwell part of the cycle. A reduction in dwell time reduces the amount of damage accumulated per cycle, which in turn means longer solder fatigue life. A long hot dwell

would result in almost complete creep stress relaxation in the solder joints. Consequently, some studies have indicated that a longer dwell time could result in eventual creep saturation.[25,26,27] Increasing the dwell time has shown some reduction in fatigue life in some studies, but the reduction was not very significant in some of those.[28] In addition to hot dwell time, ramp rate of heating and cooling also impacts the effective fatigue life of lead-free solder joints. The amount of reduction in lead-free solder fatigue life due to ramp rate is a function of the package type. Packages with higher effective CTE mismatched substrates (e.g., CBGAs) are more sensitive to the ramp rate than packages with a less differential strain (e.g., plastic ball grid arrays [PBGAs]).

- *Temp cycling range* Clearly, the higher the temperature cycling range, the lower the fatigue life of the solder joints. Some studies have also indicated that an increased average temperature could also result in a reduction in the fatigue life of lead-free solder joints. In other words, both factors—high maximum temperature and high average temperature—could contribute to a reduction in solder fatigue life.[24]
- *The distance from neutral point (DNP) effect* This is the effective distance along the diagonal of the package, from the center to its outermost corner. Some studies have indicated that the DNP plays a significant role in altering the acceleration transforms of a lead-free package.[24]
- *Size and orientation of tin (Sn) grains*[29] Depending on the cooling rate, Pb free solders containing a high percentage of Sn tend to have very large Sn grains with varied orientation. Sn has very anisotropic material properties, and consequently, the bulk properties of the Pb-free solder joints could change significantly depending on the size and orientation of the Sn grains in any given solder joint. Consequently, the strength of the solder joints within a

single BGA could vary significantly. In other words, the joints at the high stress regions may not be the first to fail. This random orientation of Sn grains within a solder joint poses a significant challenge in determining the fatigue life and acceleration factors of Pb-free solder joints.[29]

It has also been observed that while the ductility of Pb/Sn increases with aging, the ductility of lead-free solders tends to decrease with aging.[30] In other words, the strain/strain rate characteristics of lead-free solders could change with aging. Further studies are also needed to quantify fully the aging effect and incorporate it into long-term field life prediction models.

64.2.4.5 Backward Compatibility. On small PWBs with relatively few components, it is possible to convert all the components to lead-free assemblies at once. However, in the transition to lead-free assemblies, there will be instances where not all the components on a complex PWB can be converted to lead-free solder. This would inevitably create situations where both tin-lead and lead-free parts are attached on the same board.

Consequently, the use of Pb/Sn paste to assemble lead-free components (backward compatibility) would have to be studied. Component suppliers do not recommend the use of mixed solder metallurgies for a variety of reasons:

- The peak reflow temperature of lead-free solders is higher than that of tin-lead solders. Assembling lead-free components with Pb/Sn paste would involve limiting the peak reflow temperature to that of Pb/Sn components (~220°C). Consequently, the lead-free solders may not fully melt during reflow, resulting in unpredictable long-term solder joint reliability.
- The thermal gradients across components and the PWB could vary significantly, and as a result, it is difficult to

ensure that the microstructure formed across the solder joints is consistent.

- There are no known and validated acceleration transforms to predict the field reliability of lead-free components assembled with Pb/Sn paste. Thus, even if the assembled parts pass temperature cycling relative to their Pb/Sn and lead-free counterparts, it is difficult to extrapolate to field conditions and predict how they will perform when subjected to actual end-use conditions.
- There is very little data on the bend/shock resistance of mixed-metallurgy solder joints. The intermetallics formed at the package-joint and PWB-joint interfaces can be quite complex and different. The resistance of these intermetallics to mechanical loading has not been characterized.

There is very little information in the literature on the process consistency of backward-compatible assemblies and their consequent long-term reliability. Some information can be found in References 28, 31, 32, and 34. Some reliability data have been shown to indicate that the reliability of backward-compatible assemblies can be significantly improved if the SnAgCu ball melts fully and good dissolution with the Pb/Sn paste is achieved.[31] However, the factors that influence the degree of dissolution, such as the peak temperature and time above liquidus (TAL), are generally difficult to control consistently. Moreover, the amount of dissolution obtained is a function of the solder ball volume relative to the volume of paste used. Consequently, packages with smaller solder ball pitch could also be more sensitive to assembly process variations in backward-compatible assemblies.

In view of all the unknowns and process dependencies outlined, the assembly of lead-free components with Pb/Sn paste is generally not recommended. If it has to be performed, detailed studies should be conducted to

benchmark the consistency of the assembly process as well as the consequent effect on the long-term reliability (both thermomechanical and mechanical) of the assemblies.

64.2.5 Power and Minicycles

Consider a processor in a server. The server may only be powered down and back up one time per month (a conservative estimate). Power-downs and power-ups are referred to as *power cycles*. A reliability estimate could be made assuming that one thermal cycle occurred per month from the operating temperature within the region of the package to ambient. This would yield a tremendously high lifetime estimate that would unfortunately be misleading. It is important to consider what happens to the packaged device during typical usage of the server. The device temperature will probably increase during usage and decrease when not in use. These smaller temperature rises can occur multiple times throughout a day. These types of thermal conditions are referred to as *minicycles* and can have a dramatic impact on the long-term reliability of an interconnect. Section 64.2.6.3 presents a technique for incorporating minicycles and power cycles in a lifetime assessment.

64.2.5.1 Miner's Rule. Miner's rule[33] is employed when attempting to assess fatigue life under multiple fatigue loading conditions. It is commonly used when addressing the combined power and minicycle thermal loading conditions described in the previous section. Miner's rule is based on the premise that fatigue damage accumulates over each cycle. When a critical quantity of damage has been imparted on a system, the system will fail.

Miner's rule states that the sum of the ratios of the actual number of cycles to fail of a given fatigue loading condition

to the number of cycles to fail if only that fatigue loading condition occurs is equal to 1. Equation (64.16) contains a general expression of Miner's rule.[9]

$$\Sigma \frac{N_{ai}}{N_{oi}} = 1.0 \qquad (64.16)$$

where N_{ai} = actual number of fatigue cycles that occur
N_{oi} = number of cycles to fail if only that specific fatigue cycle occurred

Miner's rule can be expanded and rearranged for power cycle and minicycle considerations. Equation (64.17) contains that expression.

$$N_{poweractual}/N_{poweronly} + N_{miniactual}/N_{minionly} = 1.0 \qquad (64.17)$$

where $N_{poweractual}$ = actual number of power cycles that occur before failure
$N_{poweronly}$ = number of power cycles to fail if only power cycles occur
$N_{miniactual}$ = actual number of power cycles that occur before failure
$N_{minionly}$ = number of minicycles to fail if only minicycles occur

The Norris-Landzberg acceleration transformation can be combined with Miner's rule to estimate the fatigue life of a package. Note that the Norris-Landzberg method tends to be conservative when assessing minicycles whose changes in temperature are much smaller than the experimental temperature change applied when qualifying the part.

64.2.6 Practical Examples

64.2.6.1 Comparing the Reliability of Two Packages Qualified under Different Thermal Loading

Conditions

Given: Thermal cycle qualification data and test conditions for packages A and B (Table 64.4)

TABLE 64.4 Package A and Package B Qualification Data

	Package A	Package B
T_{max}	110°C	100°C
T_{min}	−10°C	0°C
Frequency	1 cycle/h	1 cycle/h
N_{50} (number of cycles to 50% failure)	2291	3575

Solution: It is necessary to decide which thermal profile will be kept as a constant and which one will be mapped. This problem can be solved both ways—each temperature cycling condition could be mapped into the other. Either method requires utilizing Eqs. (64.10) and (64.14) to transform the number of cycles to failure. For clarity, let condition A refer to the thermal conditions that package A was qualified under, and let condition B refer to the qualification test conditions to which package B was exposed.

64.2.6.2 Map Package A Lifetime into Package B Thermal Loading Conditions. Using Eq. (64.10), one would derive Eq. (64.18).

$$AF = \frac{N_{fAA}}{N_{fAB}} \tag{64.18}$$

where AF = acceleration factor

N_{fAA} = number of cycles to failure in package A cycled from –10 to 125°C (condition A)

N_{fAB} = number of cycles to failure in package A cycled from 0 to 100°C (condition B)

Equation (64.14) can be rearranged to yield Eq. (64.19).

$$AF = \left[\frac{\Delta T_B}{\Delta T_A}\right]^{1.9} \left[\frac{f_A}{f_B}\right]^{1/3} \exp\left[1414\left(\frac{1}{T_A} - \frac{1}{T_B}\right)\right] \tag{64.19}$$

where AF = acceleration factor

f_A = cyclic frequency for condition A (1 cycle/h)

f_B = cyclic frequency for condition B (1 cycle/h)

T_A = maximum temperature for condition A (110°C, 383 K)

T_B = maximum temperature for condition B (100°C, 373 K)

ΔT_A = difference between maximum and minimum temperature of condition A (120)

ΔT_B = difference between maximum and minimum temperature of condition B (100)

Substitution of the values in Table 64.4 into Eq. (64.19) yields an acceleration factor of 0.641. Package A would be expected to survive 3574 cycles ($N_{fAB} = N_{fAA}/AF$ = 2,291/0.641) if subjected to condition B thermal loading conditions. The packages appear to be comparable.

64.2.6.3 Assessing Expected Field Life of a New Package Based on Thermal Cycle Data

Given: Thermal cycle qualification data for a new ball grid array package (use package B in Table 64.4) and estimates of field loading conditions (see Table 64.5)

TABLE 64.5 Field Conditions for Example

	Power Cycle	Minicycle
T_{max} (°C)	65	80
T_{min} (°C)	25	65
ΔT (°C)	40	15
Frequency	1 cycle per 30 days, 30 min duration	4 cycles per day, 60 min duration

Solution: The process for solving this problem is as follows. The experimentally obtained qualification data (presented in Table 64.4) must be mapped into number of power cycles to failure and number of minicycles to failure. These estimates assume that only power cycles occur and that only minicycles occur (that is the underlying assumption when mapping the experimental data to the end-use power cycle and minicycle conditions). After mapping the experimental data into field conditions, Miner's rule is employed to assess the number of cycles to fail based on the simultaneous occurrence of both power cycles and minicycles throughout the package lifetime.

When employing Eq. (64.14) to map power cycles and minicycles, it is important to consider the implications of how the *frequency* term is interpreted. The Norris-Landzberg approach assumes that the frequency corresponds to the duration of the cycle, not how often that cycle occurs.

Equation (64.14) can be employed to determine the acceleration factors. Equations (64.20) and (64.21) contain the expressions for power cycles and minicycles, respectively.

$$AF = \left[\frac{\Delta T_L}{\Delta T_P}\right]^{1.9} \left[\frac{f_P}{f_f}\right]^{1/3} \exp\left[1414\left(\frac{1}{T_P} - \frac{1}{T_L}\right)\right] \tag{64.20}$$

where AF = acceleration factor
f_P = cyclic frequency for a power cycle (2 cycles/h)
f_L = cyclic frequency in the lab (1 cycle/h)
T_P = maximum temperature of a power cycle (65°C, 338 K)
T_L = maximum temperature of the thermal cycle in the lab (100°C, 373 K)
ΔT_P = difference between maximum and minimum temperature of a power cycle (40)
ΔT_L = difference between maximum and minimum temperature of the thermal cycle in the lab (100)

$$AF = \left[\frac{\Delta T_L}{\Delta T_M}\right]^{1.9} \left[\frac{f_M}{f_L}\right]^{1/3} \exp\left[1414\left(\frac{1}{T_M} - \frac{1}{T_L}\right)\right] \tag{64.21}$$

where AF = acceleration factor
f_M = cyclic frequency for a minicycle (1 cycle/h)
f_L = cyclic frequency in the lab (1 cycle/h)
T_M = maximum temperature of a minicycle (80°C, 353 K)
T_L = maximum temperature of the thermal cycle in the lab (100°C, 373 K)
ΔT_M = difference between maximum and minimum temperature of a minicycle (15)
ΔT_L = difference between maximum and minimum temperature of the thermal cycle in the lab (100)

Substitution of the data in Tables 64.4 and 64.5 yields a power cycle acceleration factor of 10.6 and a minicycle acceleration factor of 45.6. Equation (64.10) can be rearranged to yield Eq. (64.22).

$$N_{fi} = AF_i \times N_{fL} \tag{64.22}$$

where N_{fi} = number of cycles to fail under minicycle (i) or power cycle (i)
N_{fL} = number of cycles to fail in the lab
AF_i = acceleration factor for minicycle (i) or power cycle (i)

Substitution of the lab number of cycles to fail from Table 64.4 into Eq. (64.22) for minicycle and power cycles yields 37,895 power cycles to fail (assuming only power cycles occur) and 163,020 minicycles to fail (assuming only minicycles occur).

Miner's rule [Eq. (64.17)] can now be applied to determine the actual number of cycles to fail. It is important to note that at this stage the number of minicycles to fail if only minicycles occur and the actual number of power cycles to fail if only power cycles occur is known. The actual number of minicycles and power cycles to fail remains unknown; thus Eq. (64.17) is only one equation, whereas two unknowns still exist: $N_{poweractual}$ and $N_{miniactual}$.

Therefore, it is important to consider the number of minicycles that occur per power cycle. In this case, there is one power cycle per 30 days and 4 minicycles per day. This equates to 120 minicycles per power cycle. Equation (64.17) can now be written as shown in Eq. (64.23).

$$N_{poweractual}/N_{poweronly} + K^* N_{poweractual}/N_{minionly} = 1.0 \tag{64.23}$$

where $N_{poweractual}$ = actual number of power cycles that occur before failure
$N_{poweronly}$ = number of power cycles to fail if only power cycles occur
$N_{miniactual}$ = actual number of minicycles that occur before failure
$N_{minionly}$ = number of minicycles to fail if only minicycles occur
K = number of minicycles that occur per power cycle

Equation (64.23) can be solved for the number of power cycles to fail, which yields a value of 1311 power cycles or 107.8 years. It is important to employ a confidence factor (safety factor). Taking 2 as a standard safety factor, the final fatigue life is estimated at 53.9 years.

64.3 MECHANICAL RELIABILITY

As discussed in Sec. 63.3.11 of Chap. 63 the surface finishes used on packages have been shown to have a significant impact on the mechanical robustness of BGA packages. With increased I/O density, finer pitch, and new substrate technologies (e.g., flex substrates), BGA packages tend to be more fragile and susceptible to mechanically induced failures. These failures are mostly catastrophic in nature, but the loading conditions could vary from bending during production assembly to shock due to shipping or accidental drops. Both monotonic and cyclic conditions could result in catastrophic failure either in manufacturing or field operating conditions. This section focuses on the test methodologies used in quantifying and benchmarking different mechanically induced loading conditions on printed circuit assemblies (PCAs). In general, the mechanical loading conditions that an assembly undergoes could be classified by the strain and strain rate level, as illustrated in Fig. 64.8. As Fig. 64.8 shows, bend and shock tests each cater to different ranges of the strain/strain rate spectrum.

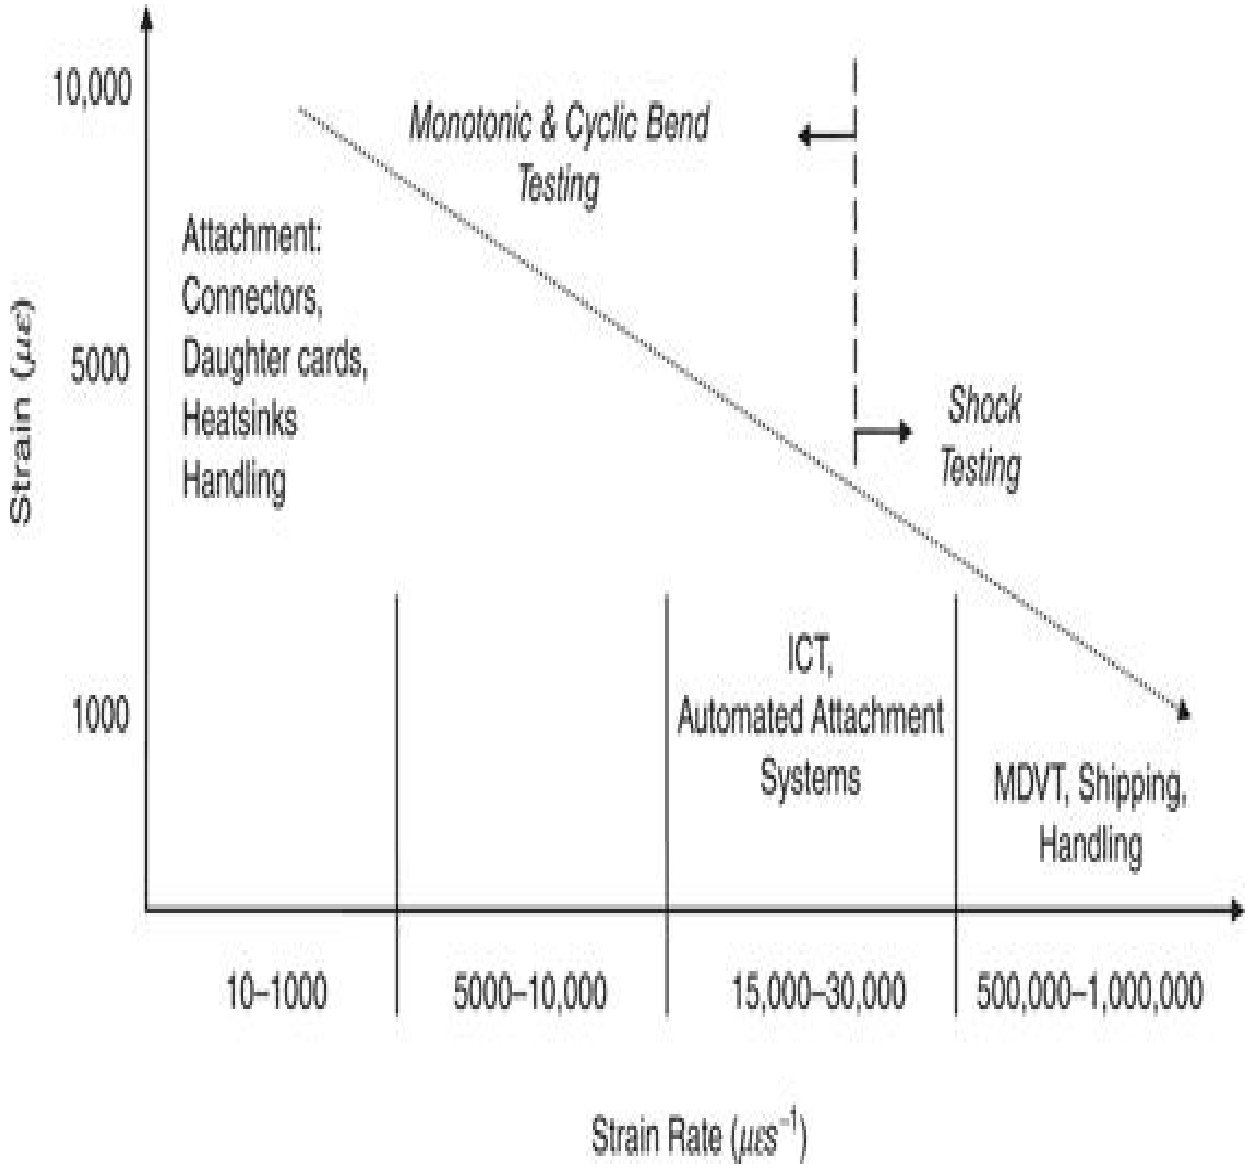

FIGURE 64.8 Spectrum of strain/strain rate in which mechanical testing fits with the assembly process. The monotonic and cyclic bend testing focuses on high-strain, low-strain rates, whereas the shock testing focuses on low-strain, high-strain rates.

64.3.1 Monotonic Bend Testing

Monotonic (bend-to-failure) testing is designed to simulate the assembly conditions to which a PCA is subjected in manufacturing. A variety of assembly steps impart loading conditions that are similar to a monotonic bend test, such as

heatsink attachment, connector attachment, in-circuit test (ICT), handling, and card-cage installation. These assembly steps could mechanically induce several different failure modes. Monotonic bend testing in a controlled condition serves two critical purposes:

- A comparative assessment can be performed between different package types and material sets.
- The failure modes induced at different strain levels can be catalogued. Production operations can then be characterized with strain gauges and compared with the monotonic bend test data to determine whether excessive strain was applied on the PCA during any given assembly step.

To ensure consistency in results and to allow for ease of comparison, an industry standard test method has been developed and published jointly by IPC and JEDEC (IPC/JEDEC-9702).[35] This test method outlines in detail the requirements of the monotonic bend test method. The test setup is illustrated in Fig. 64.9. The typical failure modes observed at the solder joint interconnects are shown in Fig. 64.10.

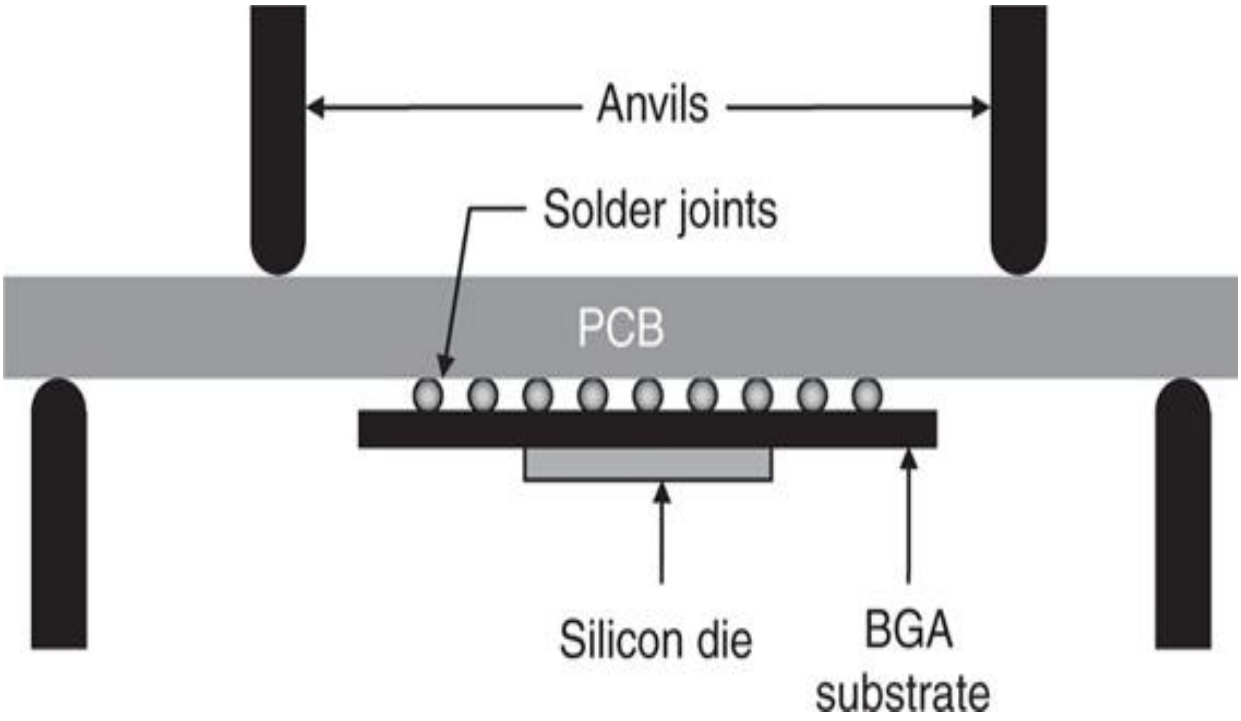

FIGURE 64.9 Schematic of four-point bend test setup. A four-point bend test setup is used to determine the strains-to-failure rate of the BGA solder joints.

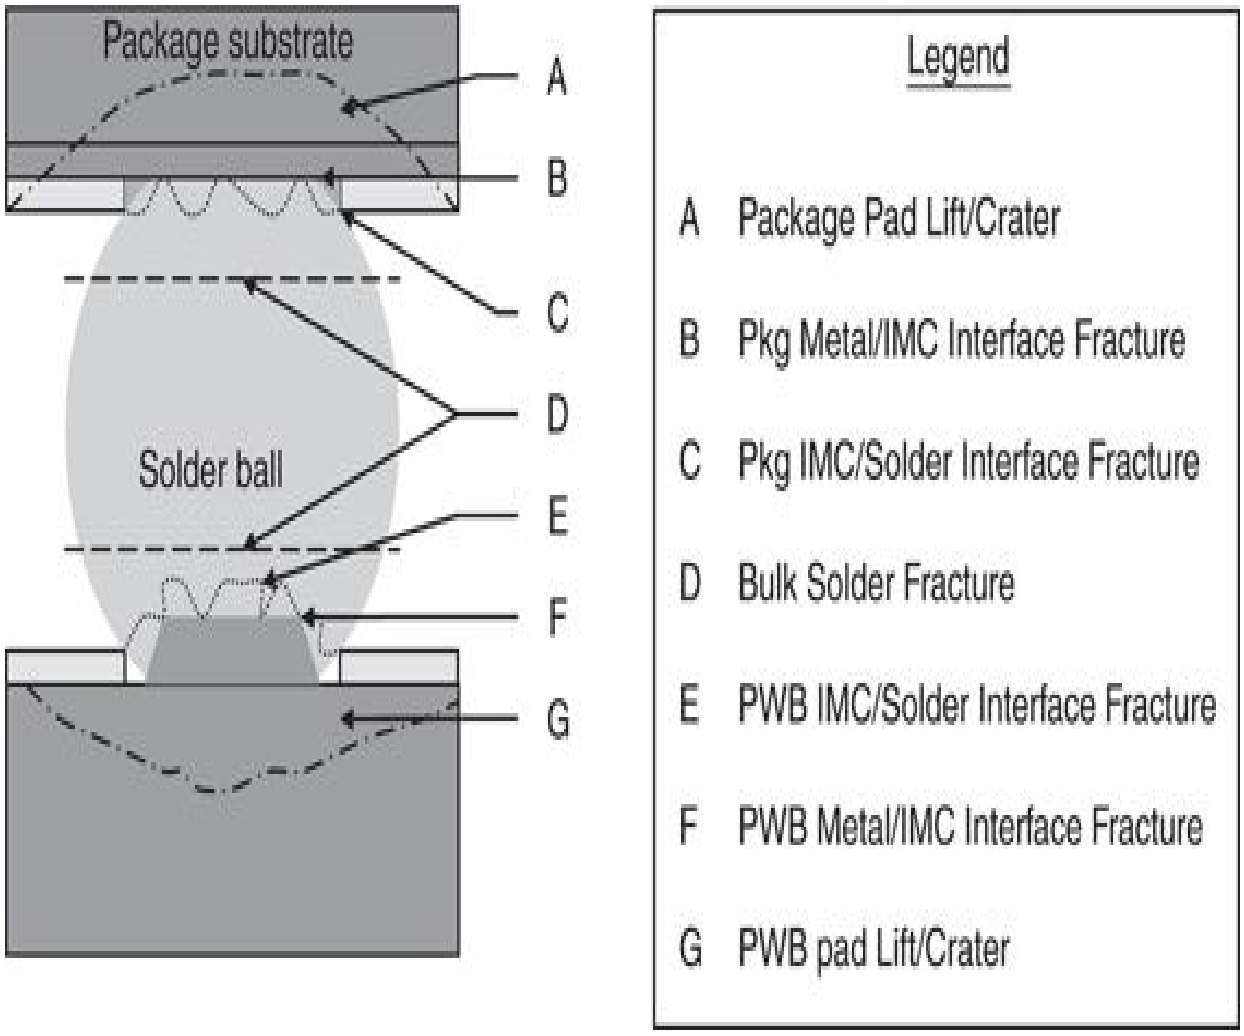

FIGURE 64.10 Different interconnect failure modes.

64.3.1.1 Strain Measurement in Production. A common procedure for performing strain measurements on live PCAs during production is outlined in IPC/JEDEC 9704.[36] This provides a comprehensive guideline on ways to perform strain measurements and reporting the recorded data. It also includes sample guidelines on the amount of strain/strain rate considered acceptable as a function of board thickness. One assembly process that is particularly susceptible to high strain/strain rates is ICT. Once the ICT fixture is engaged, there is a sudden spike in strain (high strain rate), which is again repeated when the fixture is disengaged, as shown in Fig. 64.11.

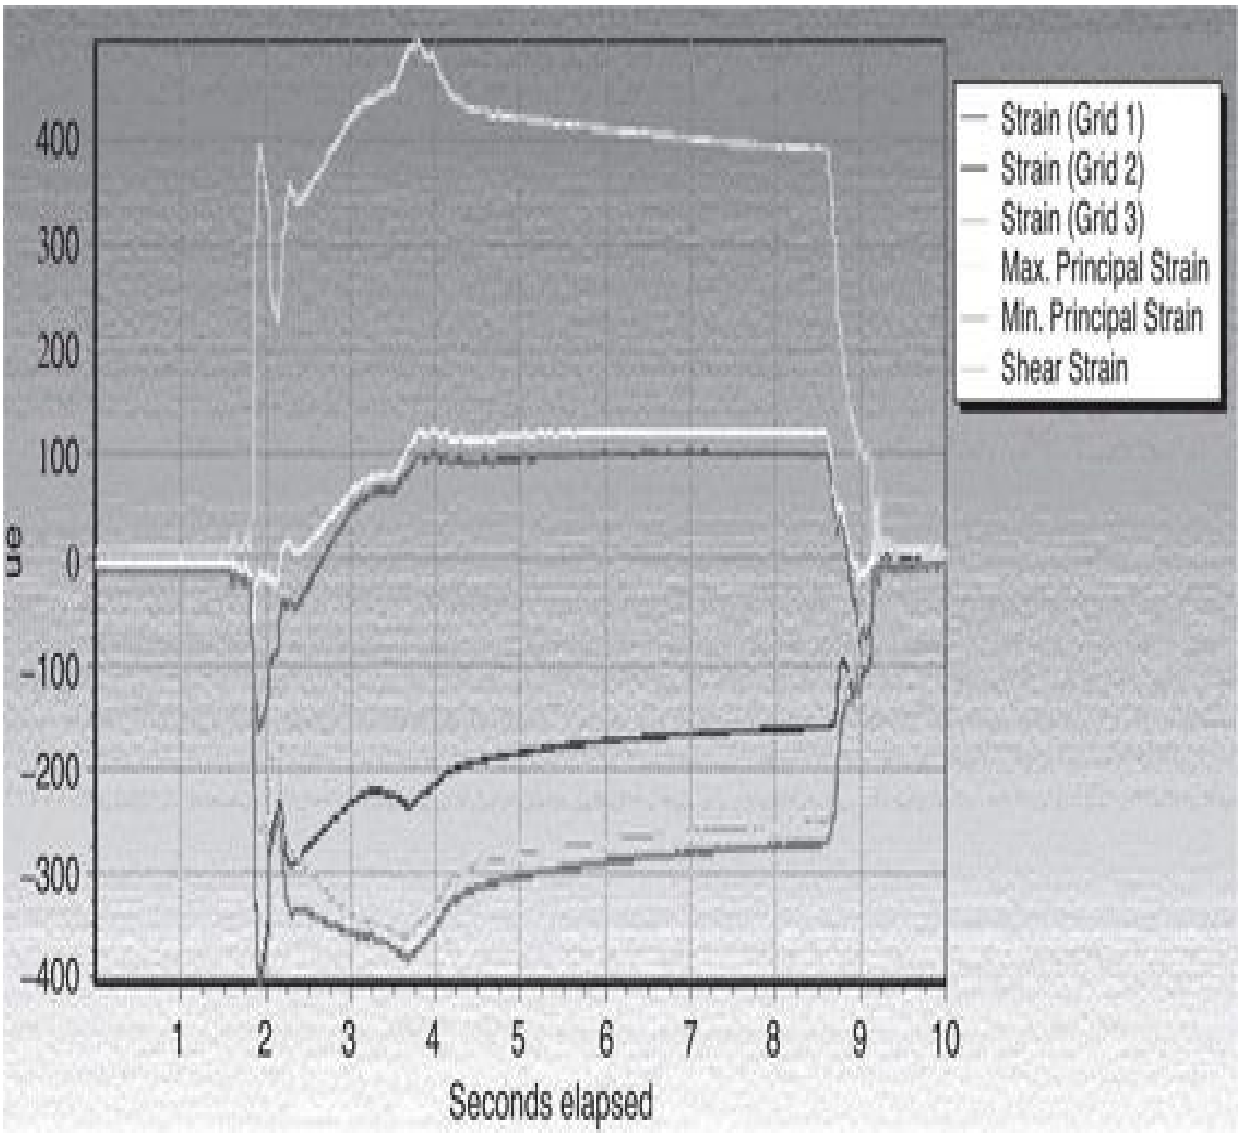

FIGURE 64.11 Strain versus time plot of an actual ICT fixture as it is engaged, the test is performed, and the fixture is subsequently disengaged. The sharp increase in strain during engagement and disengagement is the source of the high strain rate. The fixture is engaged at high speed to improve electrical contact between the probe pins and the PWB test pads.

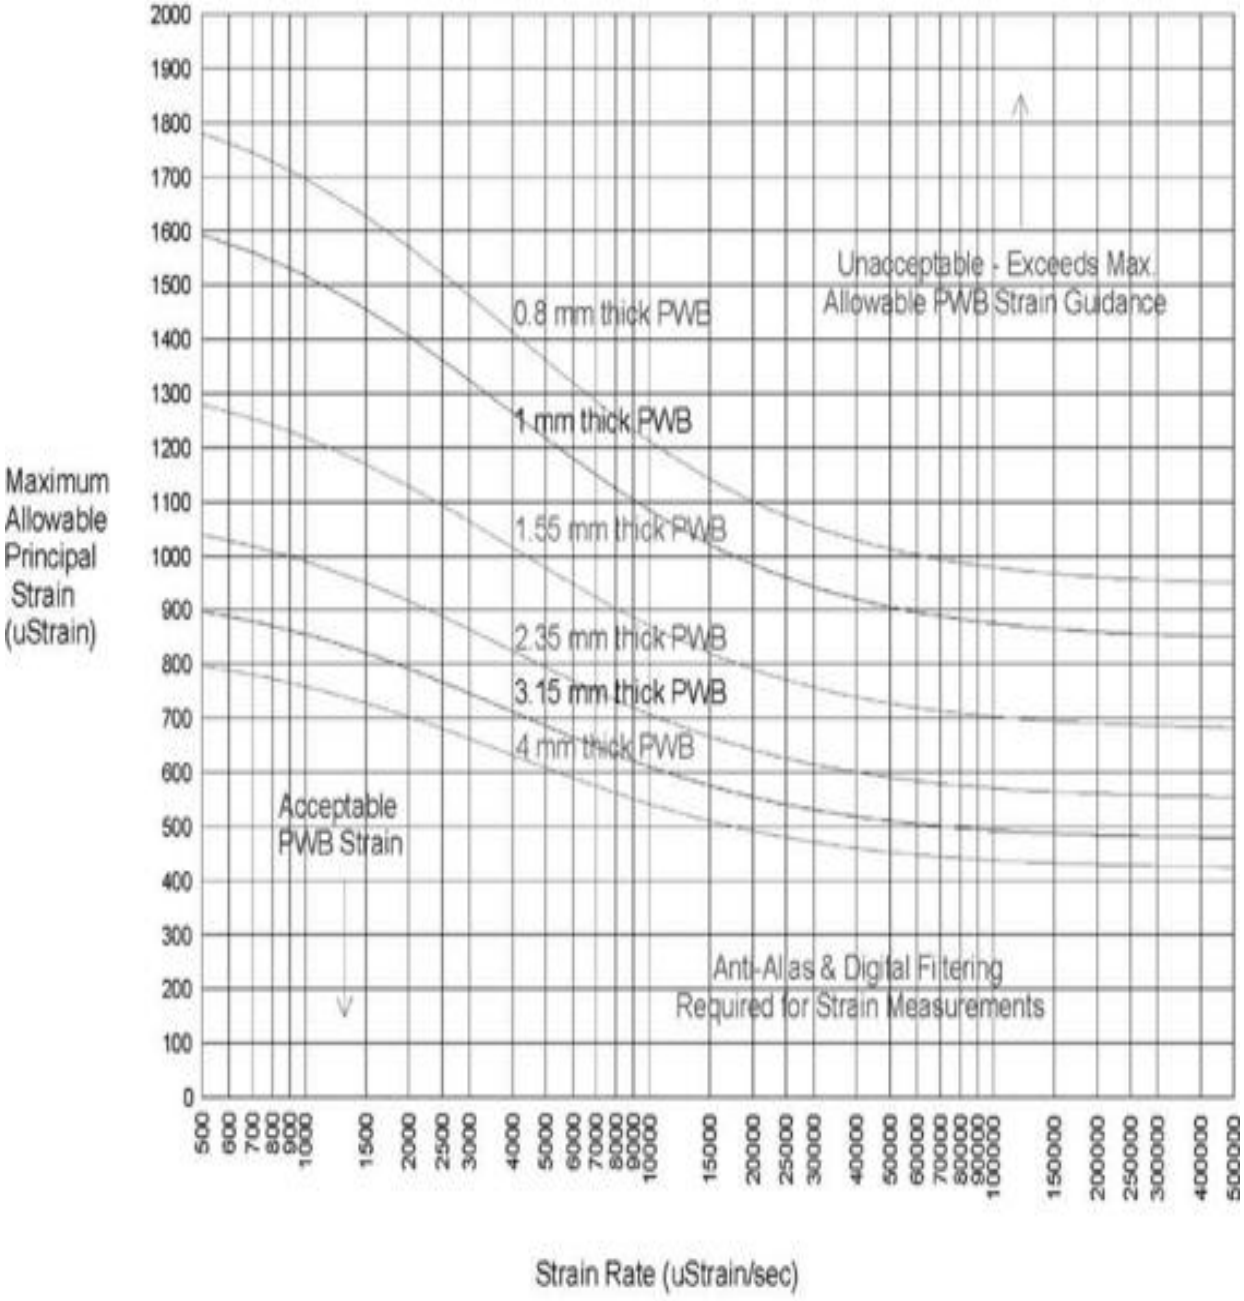
Based on experimentally generated data on the production floor and in controlled four-point bend tests described earlier, guidelines can be developed on the maximum range of strain for a given strain rate that would be acceptable for a package in different production operations. A typical example of such a guideline is given in Fig. 64.12. It is important to note that this is just a sample guideline.



PWB strain = max. principal strain (absolute value) measured immediately adjacent to cornermost solder joint

Strain rate = change in strain (absolute value) between consecutive readings

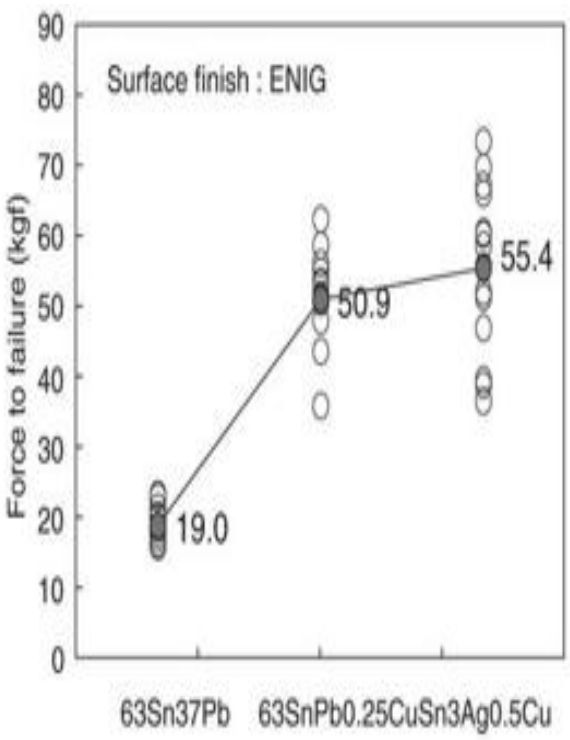
Max. allowable strain = sqrt[2.35/(PWB thickness)]*[550 + 2.2e6/(strain rate + 4000)]

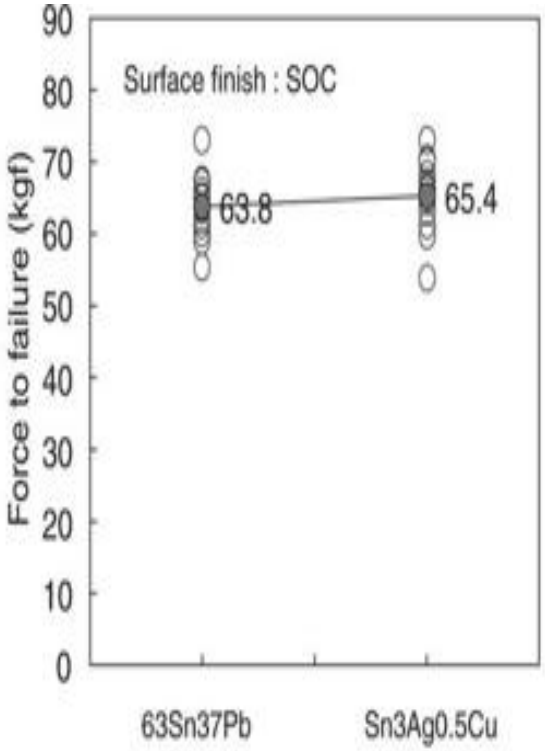
Units:

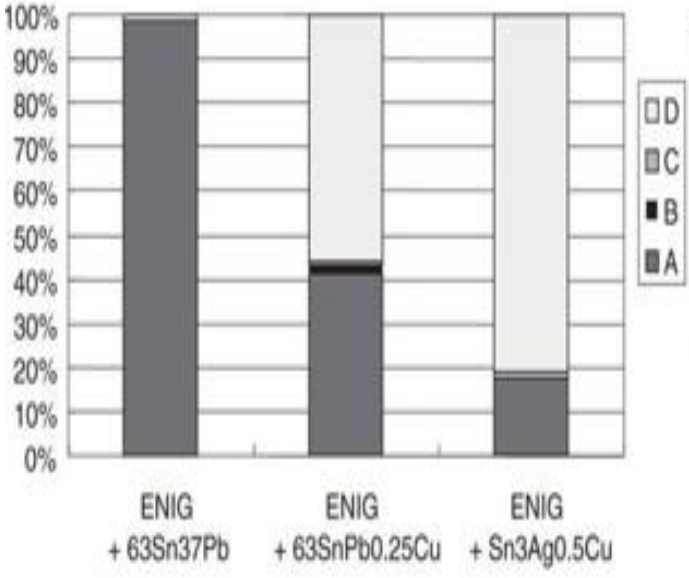
- Strain [uStrain]
- Strain rate [uStrain/sec]
- PWB thickness [mm]

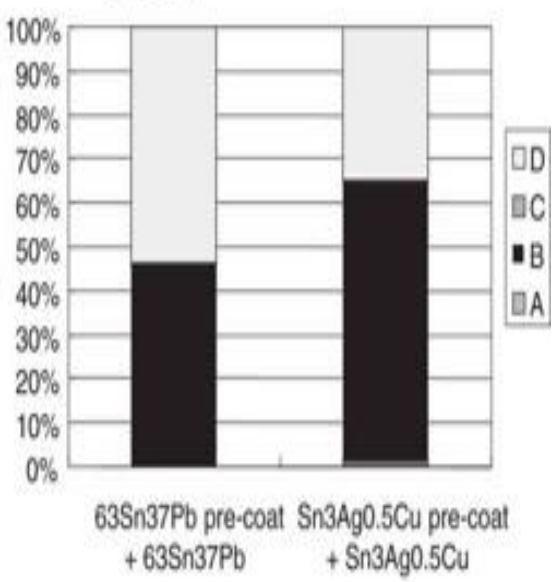
FIGURE 64.12 Typical example of strain/strain rate limits as a function of PWB thickness for BGA solder joint interconnect failure. Note that the acceptable strain limit decreases with increasing strain rate. Note also that for a given strain rate, the maximum acceptable strain limit decreases as the PWB thickness decreases. (*Reprinted with permission from Sun Microsystems, Inc*.)

64.3.1.2 Effect of Lead-Free Conversion. Because of the conversion to lead-free solder, the intermetallics formed at the package-joint and PWB-joint interface would be different from those in Pb/Sn assemblies. Consequently, the response to bending of a lead-free assembly would be significantly different from that of a Pb/Sn assembly. There are relatively little experimental data in the industry comparing the mechanical reliability of lead-free soldered assemblies with Pb/Sn assemblies. One data set showing a relative comparison between Pb/Sn and SnAgCu for two different surface finishes is shown in Fig. 64.13.[37]









Failure Mode Legend:

Mode A: within the solder joint on the substrate side

Mode B: pad lift on the substrate side

Mode C: within the solder joint on the board side

Mode D: pad lift on the board side

FIGURE 64.13 Data set comparing the force-to-failure rate of Pb/Sn, Pb/Sn/Cu and Sn/Ag/Cu assemblies for two different surface finishes (ENIG and SOC). The histograms show a comparison of the different failure modes obtained in the bend tests.[37] All samples were tested within one day of board assembly. (*Reprinted with permission from Kyocera SLC Technologies. /© [2005] IEEE*.)

The results in Fig. 64.13 show the following:

- For ENIG surface finish packages, the average force-to-failure value for the SnAgCu assemblies is almost three times that of the Pb/Sn assemblies. This is because the SnAgCu joints are stiffer than the Pb/Sn joints.
- Failure mode A is significantly more pervasive in the Pb/Sn assemblies but not as much in the SnAgCu assemblies. Thus, the propensity for brittle solder joint fracture is higher in the Pb/Sn assemblies with ENIG.
- The introduction of a small amount of copper in the Pb/Sn assemblies tends to increase the bending strength of the Pb/Sn assemblies by more than two times.
- The average force to failure with a solder-on-copper (SOC or SOP) surface finish is higher than that with ENIG, especially for the Pb/Sn solder joints. For the SnAgCu joints, there is a marginal increase in relative strength.

Thus, mechanical bend strength is a function of the solder metallurgy and the surface finish used. These results indicate that SnAgCu solder joints are stiffer and have a higher average force-to-failure value compared to Pb/Sn joints with the same surface finish. Another important factor in the bend strength of solder joints is the time after reflow, as shown in Fig. 64.14.[37]

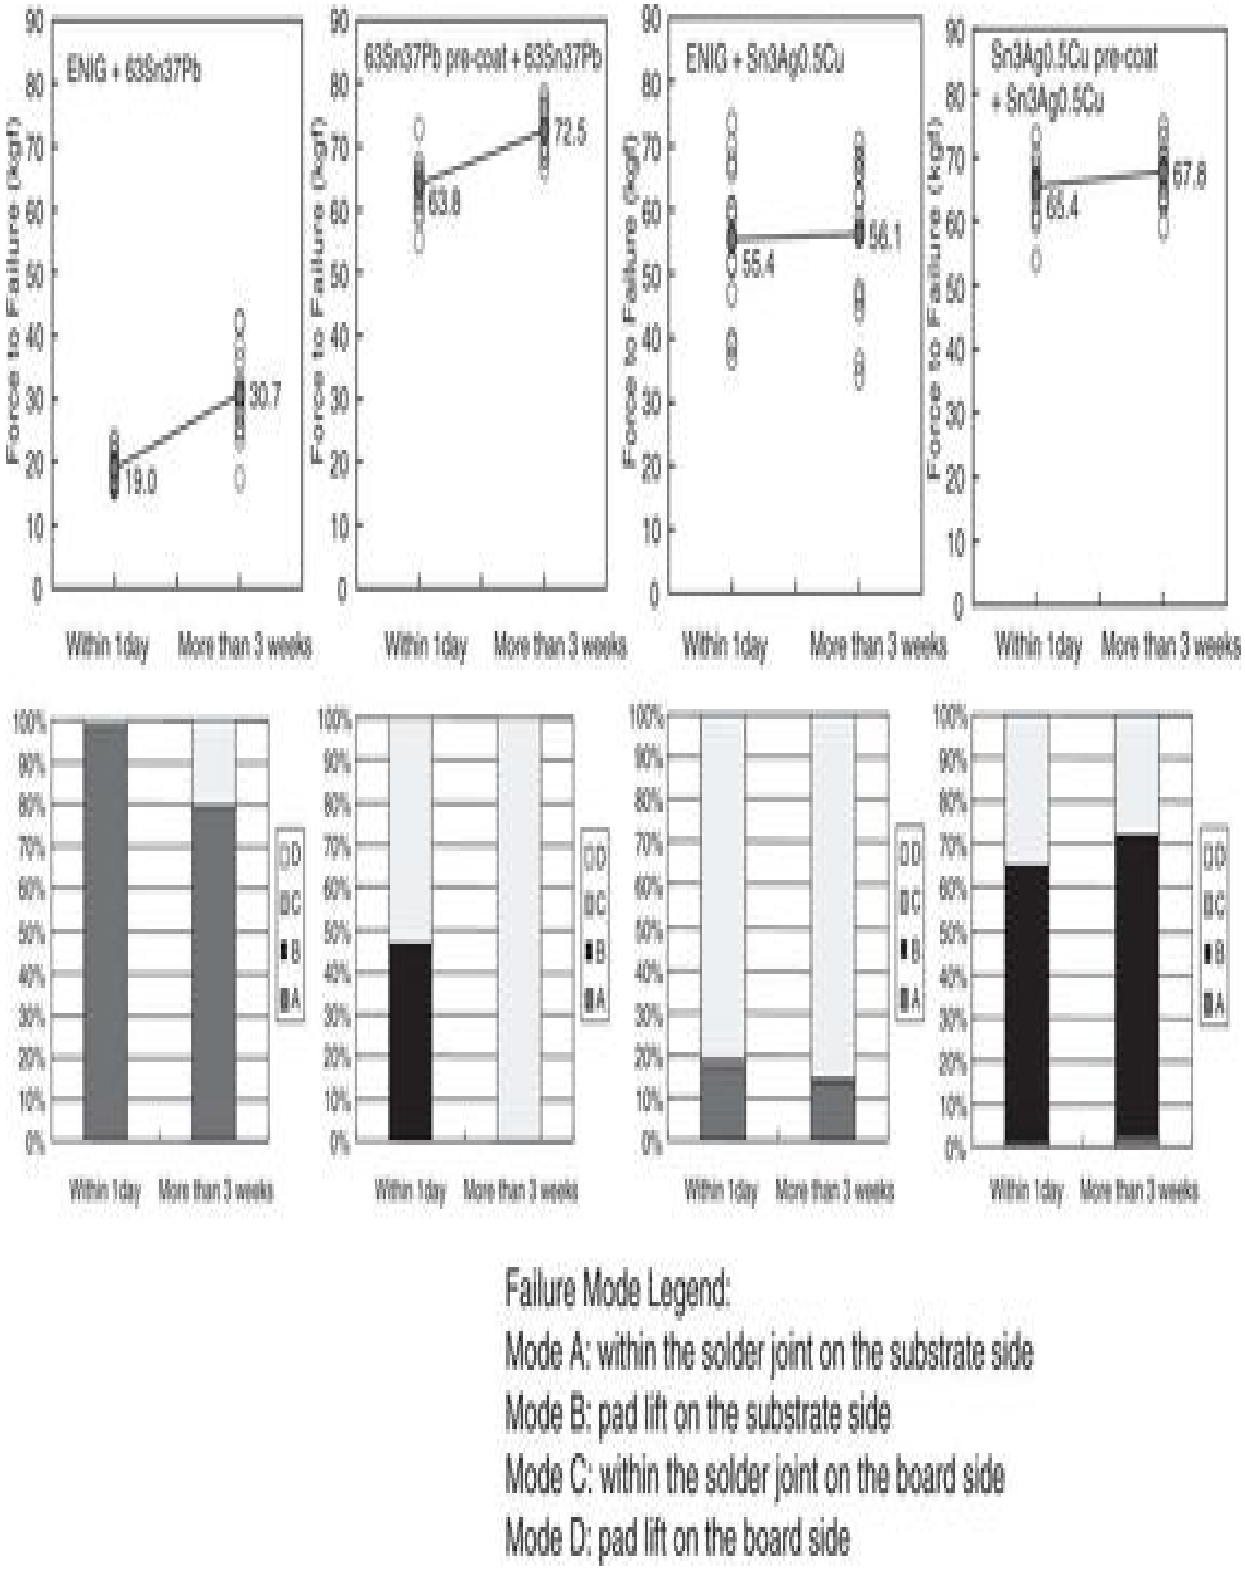


FIGURE 64.14 Data set comparing the force-to-failure value of Pb/Sn and Sn/Ag/Cu assemblies for two different surface finishes (ENIG and SOP) as a function of time after reflow. The histograms show a comparison of the different

failure modes obtained in the bend tests. (*Reprinted with permission from Kyocera SLC Technologies. /© [2005] IEEE*.)

The results in Fig. 64.14 show the following:

- For ENIG surface finish packages, Pb/Sn joints are more sensitive to time after reflow than SnAgCu joints. The average force-to-failure value of Pb/Sn joints with ENIG increased by more than 50 percent, whereas the average force-to-failure value of SnAgCu with ENIG did not change noticeably over time.
- For solder pre-coat (SOP) packages, the strength of Pb/Sn joints increased by slightly more than 10 percent over three weeks, whereas the strength of SnAgCu joints with SOP does not change noticeably over time.

Thus, mechanical bend strength is a function of the time after reflow along with solder metallurgy and surface finish. The underlying failure mechanisms have not been understood clearly enough to explain the dependence on time after reflow.

64.3.2 Cyclic Bend Testing

In addition to monotonic loading conditions, certain repetitive operations could also lead to mechanical failures. A typical example is a PWB used in cell-phone applications. The PWB could be subjected to multiple small deflections each time the cell-phone keypad is pressed. This can cause an incremental deterioration in the mechanical response of the PWB and lead to solder joint interconnect failures in BGAs mounted on the PWB. This sort of failure mechanism is more prevalent in relatively thin PWBs used in cell-phone applications. However, similar failures could also occur if, for example, multiple runs of ICT are performed on PCAs in high-end server/network applications. An industry standard test

method has been developed by JEDEC to characterize the response of a PCA to cyclic loading conditions (JESD22-B113).[38] The layout of the test board as specified in the test method is similar to that for the monotonic four-point bend test. Some data on the cyclic bend response of SnAgCu solder joints can be found in Reference 39.

64.3.3 Shock Testing

As with bend testing, a shock test methodology is needed to simulate the shock conditions that a PCA may undergo during assembly, shipping, and handling conditions. Shock test conditions usually induce strain rates on the order of 100,000 $\mu\varepsilon$/s. (microstrain per second), whereas typical monotonic bend test strains are on the order of 10,000 $\mu\varepsilon$/s. Thus, the strains to failure under typical shock test conditions are lower than the strains to failure under typical bend test conditions. However, the failure modes could be different. Hence the need to characterize both bend and shock conditions. There are different classifications of typical shock conditions. For example, those experienced by handheld products [cell-phones, personal digital assistants (PDAs), etc.] are different from those experienced by typical network/server products. The former requires resistance to more stringent shock levels (~1500 G),[40] whereas the latter requires resistance to shock levels on the order of ~500 G. An example of the typical shock test conditions applicable to these product categories is summarized in Table 64.6.

TABLE 64.6 Examples of Typical Shock Conditions Used for Different End-Use Environments (the Specific Conditions Tested Depend on the End Users)

Test Parameters	Typical Field Conditions	
	Handheld Products	Network/Server Products
Acceleration peak (G)	1500–2900	100–400
Pulse duration (ms)	0.3–0.5	1.2–2

In addition to shock testing, several component suppliers also perform drop testing. For handheld products in particular, some suppliers prefer to perform board-level drop testing instead. Details of the drop test method are outlined in JESD22-B111.[41] Several component suppliers perform vibration testing in addition to shock testing to simulate shipping conditions.

The design of the carrier tray or chassis in which the PWB is installed could significantly impact the reliability of printed circuit board assemblies (PCBAs). If the resonant frequency of the PCBA matches that of the chassis, and the mode shapes corresponding to the resonant frequency are such that they induce a strain above the critical solder joint failure strain, brittle fracture can occur. Accelerometers and strain gages should be used to characterize both mode shapes and strains in the PWB assemblies mounted on carrier trays or in chassis. The chassis design should be optimized to ensure that the strains that might impact the PCBAs are minimized, especially at the critical locations. Ways to do this include adding stiffeners, frames, and struts in the chassis at critical, high-strain locations.

Finally, an additional way to mitigate shipping failures is to use shock indicators in the shipped product. A typical shock indicator changes color if the applied G values exceed a preset threshold. The use of a shock indicator in products can help in root cause analysis of failed parts.

64.3.4 Ball Shear/Pull Testing

Ball shear testers are employed to quantify the strength of the interface between a solder ball and its package prior to second-level attach. Ball shear experiments can also be employed to assess the solder ball-package pad interface qualitatively. This is accomplished by assessing the failure mode observed during a ball shear experiment.

However, certain failure modes are a function of the speed of the test. The failure modes observed at relatively low speeds (0.0001 to 0.0006 m/s) are different from those observed at high speeds (0.01 to 1.0 m/s). In general, solder shear strength tends to increase with shear speed. It is therefore important that failure mode characterization as a function of shear speed be performed before this technique can be used effectively as an inline monitoring tool to control the quality of substrate lots. To address this, JEDEC has published a revised version of the standard ball shear test to include high speed shear testing procedures (JESD22-B117A[42]).

In addition to speed, a number of other factors could impact the fracture strength of solder joints, including surface finish, pad size, ball diameter, ball metallurgy, and pad construction. All these need to be taken into account when comparing ball shear data across different packages. Another important factor that could impact the force-to-failure and the failure modes induced is the time after reflow. It is preferable to perform the test as early as possible after reflow.[43]

In addition to the high-speed shear/pull test, other methodologies are also being explored to characterize the interface strength of solder joints. One is a Charpy impact type of test.[44] This involves impacting the ball with a pendulum. The amount of energy imparted into the ball is estimated and the failure modes as a function of impact

toughness are catalogued. This test is a sort of mini-shock test designed to produce an effect comparable to the high-speed shear test. Another methodology is the use of a hot pin pull test in which a heated pin is inserted into the solder ball, cooled, and then pulled at high speed. Efforts are being made to measure the force to cause failure, so that pull/shear force or impact energy could be used as a metric to assess the strength or weakness of a joint.

64.3.4.1 Effect of Lead-Free Conversion. Depending on the surface finish, the intermetallics formed in SnAgCu solders are different from those formed in Pb/Sn joints. Refer to Sec. 60.3.11 in Chap. 60 for more details. Preliminary results on high-speed pull/shear testing of SnAgCu joints indicate a higher interfacial fracture rate than Pb/Sn joint. However, the SnAgCu joints exhibited moderately higher fracture strength.[43]

64.4 FINITE ELEMENT ANALYSIS

Finite element analysis (FEA) is a numerical technique used to solve complex boundary value problems. It involves discretizing a complex geometry into smaller simpler geometries that can be represented by a set of differential equations. These equations can then be solved numerically to determine the deformation of the overall structure subjected to structural, thermal, or other loading conditions. FEA is a powerful numerical tool that has been used to assess the reliability of solder joints. FEA can be employed to

- Estimate the fatigue life of a new package
- Compare reliabilities of different packaging options
- Assess impact on reliability due to material and design changes to the package

- Assess impact on reliability due to PWB material and design changes
- Determine changes in warpage due to package density and location

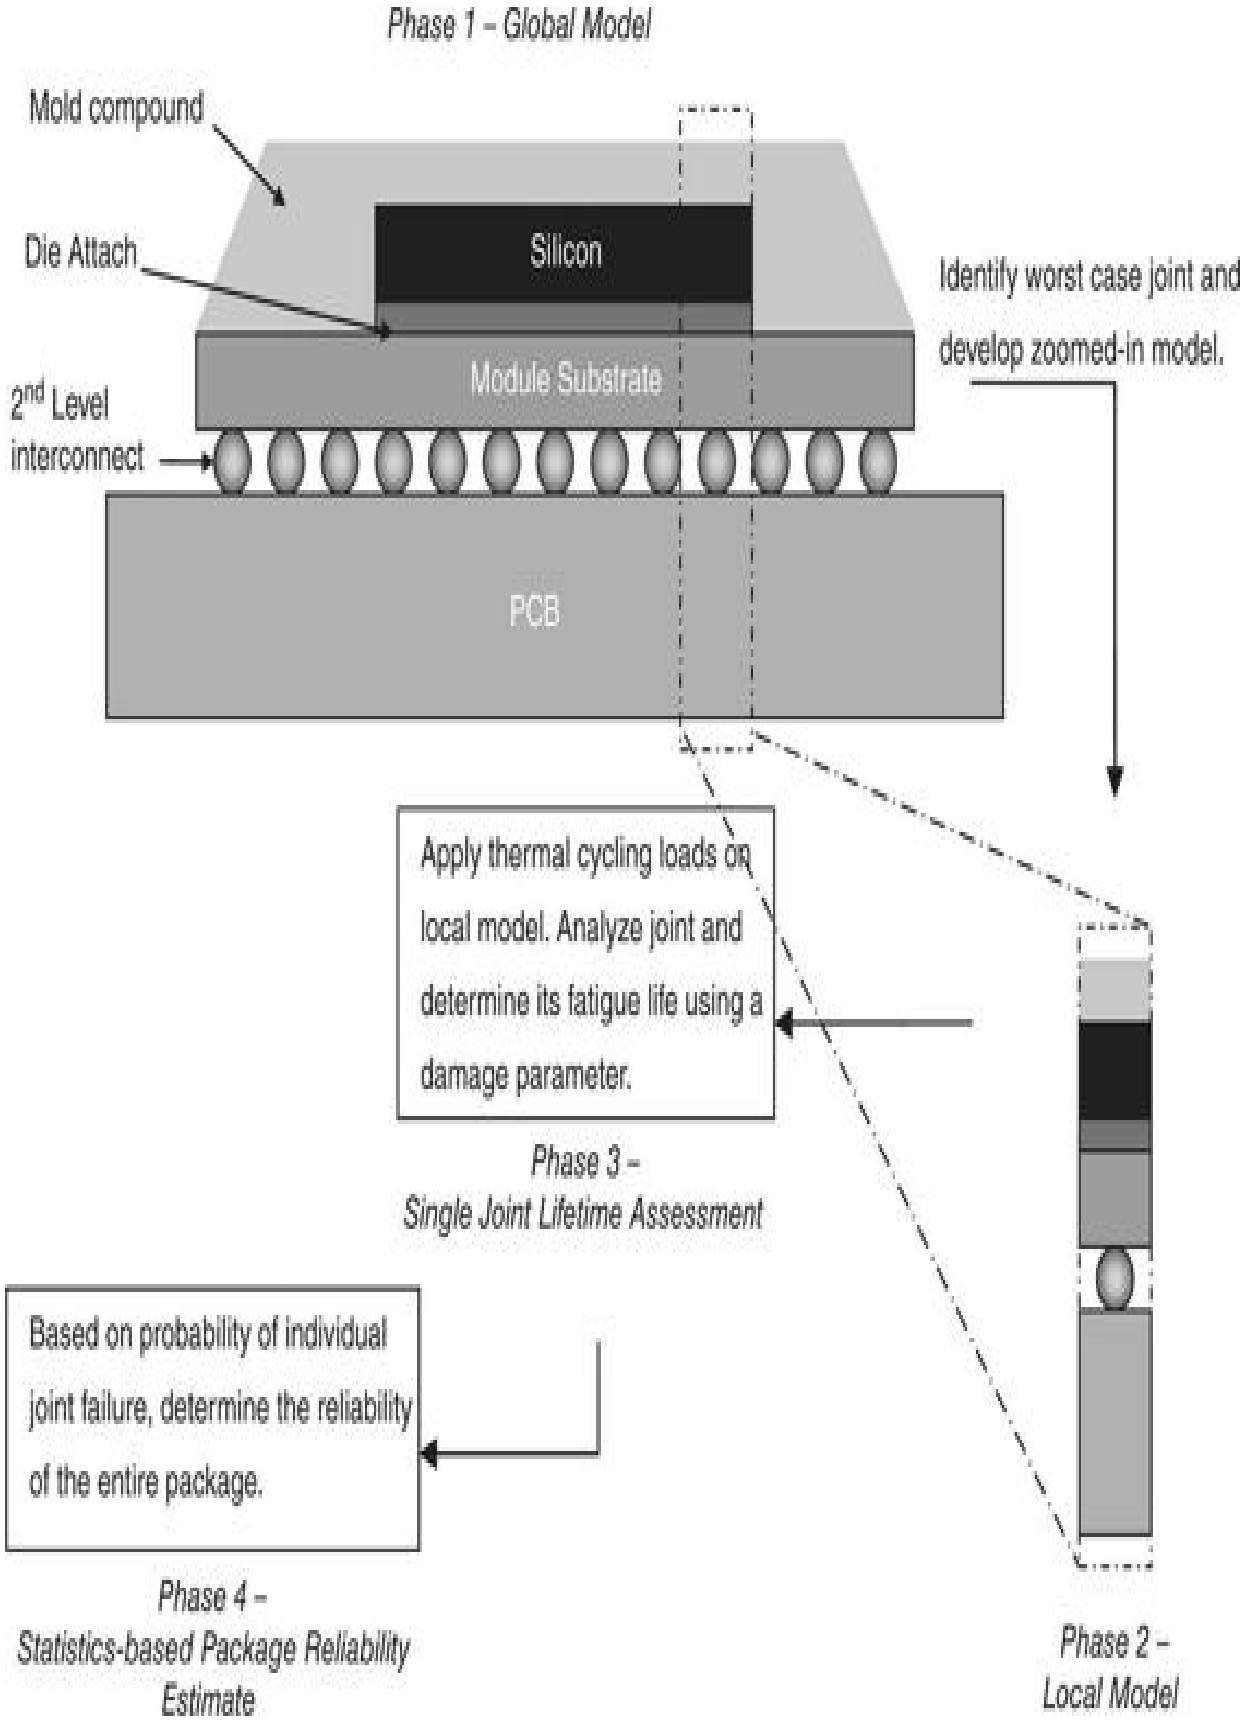
FEA has been used effectively in simulating thermomechanical, bending, and shock conditions. This section focuses on the use of FEA to determine the lifetime of packages subjected to thermomechanical strains, and the use of bend test simulations to determine the factors that influence the bend strength of a package.

64.4.1 FEA for Thermomechanical Lifetime Assessment

FEA lifetime assessments are typically broken down into four phases:

- Phase 1: global model
- Phase 2: local model
- Phase 3: single-joint lifetime assessment
- Phase 4: statistics-based package reliability estimate

Figure 64.15 shows the interrelationships between these four phases.



Phase 1 – Global Model
Mold compound
Die Attach

Identify worst case joint and develop zoomed-in model.
Apply thermal cycling loads on local model. Analyze joint and determine its fatigue life using a damage parameter.
Phase 3 – Single Joint Lifetime Assessment
Based on probability of individual joint failure, determine the reliability of the entire package.
Phase 4 – Statistics-based Package Reliability Estimate
Phase 2 – Local Model

FIGURE 64.15 FEA flowchart. Phase 1 involves creating the global model to determine global strains and displacements across the entire package. The global model also helps identify the locations of maximum stress. Phase 2 entails zooming into the location with the maximum strain. The boundary conditions applied around the local model are extracted from the global model. Phase 3 involves applying thermal cycling loads on the local model and determining the fatigue life of the worst-case solder joint in the local model. Phase 4 entails the use of statistical assessment tools to determine the reliability of the other solder joints relative to the worst case and thus estimating the solder joint reliability of the entire package.

64.4.1.1 Phase 1: Global Model.

Phase 1 involves building a global geometric model of the package. Models in FEA can be two-dimensional, 2.5-dimensional (strip), or three-dimensional. Two-dimensional models (plane strain or plane stress) are computationally very efficient as only a two-dimensional cross section of the assembled package is modeled. However, they are based on the assumption that the out-of-plane deformation and stresses in the assembly are negligible, which is not the case with discrete solder joints. Thus, although they are useful for providing qualitative deformation and stress comparisons, they are not useful for quantitative fatigue-life estimates. A 2.5-dimensional or strip model has a thickness, but it is very small—just enough to capture the round shape of the solder joints. While it is an improvement over a two-dimensional model, it does not capture the increased stress concentration at package corners. A three-dimensional model is a much closer representation of an assembled package. Although it is computationally challenging, it is the best way to estimate the deformation and stresses induced in an assembled package. A global model of one-eighth of a BGA package can be found in Fig. 64.16.

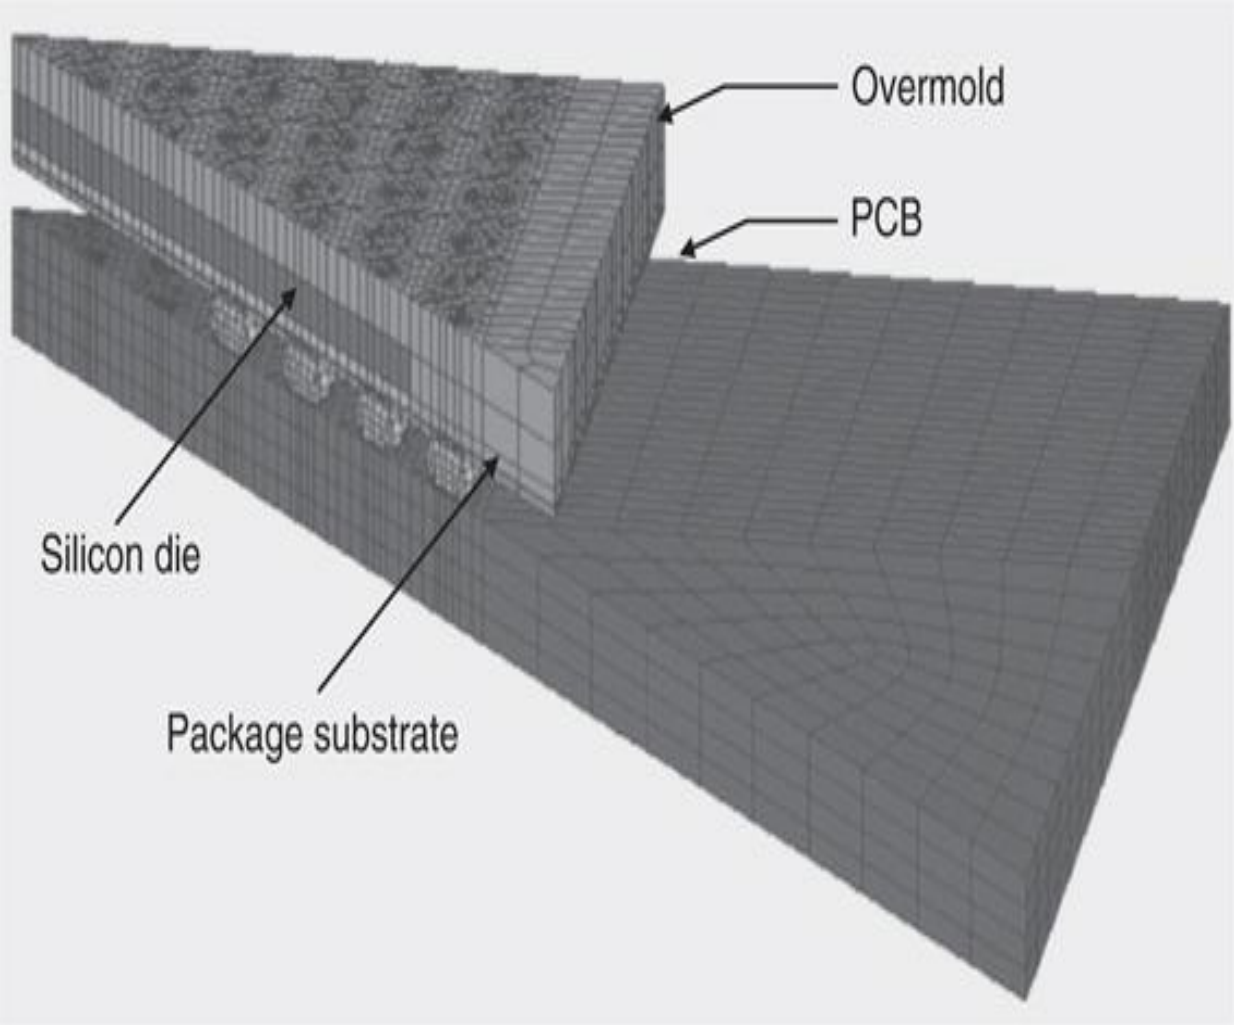

FIGURE 64.16 Global FEA model of one-eighth of a BGA. Note the PWB, package substrate, die, and overmold are all created by a series of elements.

Note that only one-eighth of the package is modeled (Fig. 64.16). This is due to the fact that the package is octant symmetric, and thus symmetry boundary conditions can be employed to reduce the model size, which in turn increases the speed at which a solution can be obtained.[46] Wherever possible, the deformation results of the global FEA model should be verified with experimental warpage measurement (using tools like Shadow Moiré[45]).

A unit temperature rise is applied to the global model, the worst-case joint is determined, and the displacements of the worst-case joints are calculated. Worst-case joint

determination is typically based on a maximum stress or strain in the solder joints. It is essential to obtain the displacements of the worst-case joint because those displacements can now be incorporated in a local model that will simulate multiple thermal cycles on a worst-case joint.

Only a unit temperature rise is applied to the global model to reduce the computational run time. An additional assumption employed in global models to reduce run time is that all materials are linear-elastic and temperature-independent. Because the goal of the global model is to determine the worst-case joint and the corresponding displacement, this approach is typically valid. Reference 46 contains a series of experimental cases and corresponding FEA predictions that validate the global/local approach and the linear elastic, temperature-independent unit temperature rise technique for the packages studied.

64.4.1.2 Phase 2: Local Model. A local model of the worst-case joint is created and subjected to simultaneous temperature cycle and temperature-scaled displacement-loading conditions obtained from the global model. The displacement field of the worst-case joint obtained in the global model when subjected to a unit temperature rise is scaled to match the expected displacement when the local model is subjected to actual thermal cycles. The advantage of this approach is that the local model can incorporate time and temperature material dependence because a reduced number of elements are employed when compared to the global model.

A local model of a solder joint can be found in Fig. 64.17. The local model is subjected to multiple thermal cycles and a final damage parameter is extracted. A typical thermal cycling loading profile to which the model is subjected is similar to that shown in Fig. 64.3. About two to four cycles are run to achieve stability of the hysteresis loop.

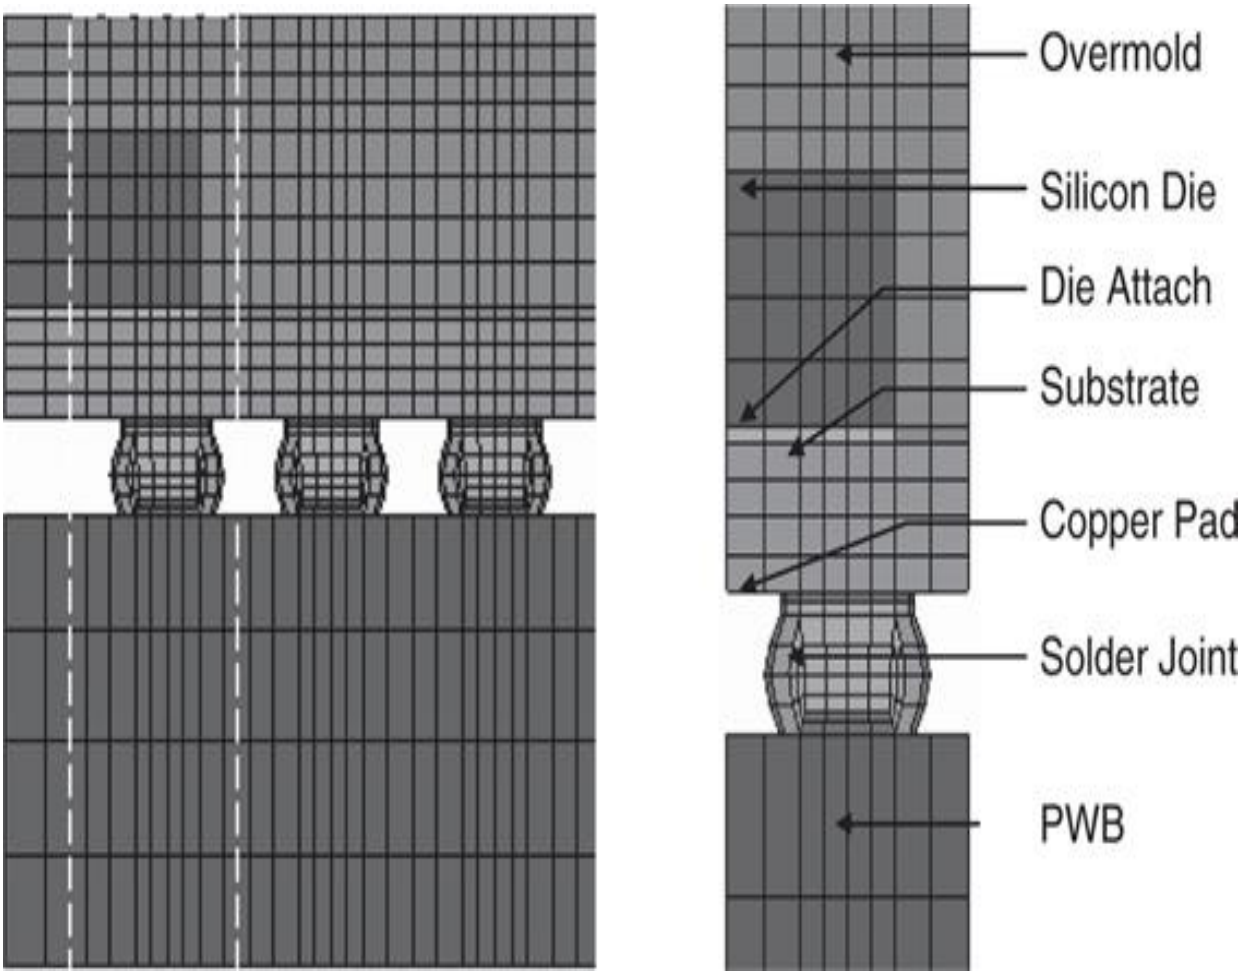

FIGURE 64.17 Close-up of three solder joints. The local model is created from one of the solder joints and its associated PWB, package substrate, die, and overmold. In this figure, the leftmost ball and associated material for the local model are indicated by the area inside the dashed rectangle.

Plastic work and plastic strain are two of the most common local damage parameters employed in solder joint lifetime estimations. The type of damage parameter selected is usually dictated by the experimental data available for a specific joint type (BGA, CCGA) that correlate damage with fatigue life. A methodology that employs plastic work and a correlation between plastic work and crack initiation and propagation can be found in References 10 and 46.

64.4.1.3 Phase 3: Solder Joint Fatigue-Life Assessment. The local model damage parameter is then

employed to determine the fatigue life of a given joint. Techniques for assessing lifetime based on a damage parameter range from employing plastic strain [Coffin-Manson relationship, Eq. (64.8)] to complex considerations of crack initiation and crack growth rates correlated with plastic work.[10,46] Regardless of the technique, the output of this phase is an estimate of the reliability of one joint: the worst-case solder joint.

Some of the fatigue-life prediction models that have been employed for lead-free solder joints are outlined in Table 64.7. In addition, other models for predicting fatigue life from the finite element models and performing relative comparative analysis can be found in References 16 and 47.

TABLE 64.7 Different Fatigue-Life Models for Predicting Fatigue Life from the Finite Element Model Results[18]

Fatigue-Life Model	Constants	Test Conditions	Reference
$N_f = C_1(\varepsilon_{cr})^{C_2}$ N_f = Number of cycles to fail ε_{cr} = Average equivalent creep strain	$C_1 = 4.5$ $C_2 = -1.295$	Flip-chip bumps with and without underfill. Wirebonded PBGA packages mounted on PWB	Schubert[48]
$N_f = C_1(\Delta W_{cr})^{C_2}$ W_{cr} = Average viscoplastic strain energy density/cycle	$C_1 = 345$ $C_2 = -1.02$	Flip-chip bumps with and without underfill. Wirebonded PBGA packages mounted on PWB.	Schubert[48]
$N_f = C_1(\varepsilon_{cr})^{C_2}$	$C_1 = 0.0468$ $C_2 = -1$	Several different BGA packages: CABGA, CBGA, FlexBGA, PBGA, TSCSP, etc. Double power law creep constitutive relations.[20]	Syed[49]
$N_f = C_1(\Delta W_{cr})^{C_2}$	$C_1 = 0.0015$ $C_2 = -1$	Several different BGA packages: CABGA, CBGA, FlexBGA, PBGA, TSCSP, etc. Double power law creep constitutive relations.[20]	Syed[49]
$1/N_f = 1/N_p + 1/N_c$ $N_p = (W_p/W_{p0})^{1/c}$ $N_c = (W_c/W_{c0})^{1/d}$ N_p = Number of cycles to failure due to plastic damage N_c = Number of cycles to failure due to creep damage W_p = Plastic work density calculated per load cycle W_c = Creep work density calculated per load cycle	$W_{p0} = 106.45$ $W_{c0} = 30.025$ $c = -0.51$ $d = -0.44$	Solder joint samples attached to copper coupons, subjected to cyclic loading. One-dimensional analytical model to derive constants.	Zhang[50]

A comparison of the results obtained by Schubert's[48] model with those obtained by Syed's[49] model can be found in Reference 51. It is important to note that these models are a function of the way that the material properties of the solder joints are modeled. In other words, the solder material properties used to derive these models play a significant role in the accuracy of the models. If a particular fatigue-life model is selected, the corresponding solder constitutive model used to derive the model constants should be used in the analysis.

In addition, several other factors could significantly alter the accuracy of a model, such as time step size, mesh density, material properties, reference temperature, element size, element type, and even software. All these need to be taken into account when using a model to predict fatigue life. Best practice recommendation is to run not just one, but a set of fatigue-life models and calibrate with existing experimental data before using the models to make fatigue-life predictions on packages on which no experimental data are available. Finally, it is important to note that these models only provide guidance on trends and relative comparisons. They should not be used as a substitute for experimental thermal cycle data for a given package under consideration.

64.4.1.4 Phase 4: Statistics-Based Package Reliability Assessment.

This final phase considers the reliability of all of the solder joints when determining the reliability of the package. Techniques employed here range from simply assuming that all joints are of equal reliability to performing a series reliability calculation to solve simultaneously an assumed distribution of failures (such as a Weibull distribution; see Sec. 64.2.2) considering each joint. It is also common to weigh the reliability of joints other than the worst-case joint by considering the displacement of all joints with respect to the displacement of the worst-case

joint.[46] This allows for the impact of DNP to be incorporated in the potential distribution of failures among joints at different locations.

64.4.1.5 Temperature-Dependent Material Properties. As mentioned earlier, the aforementioned procedure is based on the assumption that the mechanical properties of the package material set do not change significantly with temperature. There are certain packages, however, for which this technique is not applicable. A typical example is an FCBGA package in which the underfill material has a glass transition temperature (T_g) around 70 to 100°C and undergoes several orders of magnitude change in modulus above the T_g. Clearly, the properties of such a material are strongly dependent on temperature. In such a case, the following procedure can be followed:

1. The global model is cooled from its stress-free temperature (which is usually the adhesive cure temperature) to the lowest temperature to which the package has been thermal cycled (0°C if a 0 to 100°C thermal profile is used).
2. Cut boundary interpolation is performed at small temperature steps (such as 5 or 10°C), recording the deformation of the nodes at each temperature step. This information is stored in a set of data files.
3. A submodel is created of the worst-case solder joint (the one that shows the most stress or deformation in the global model). The files stored in step 2 are applied as load boundary conditions on the nodes forming the submodel boundary at each temperature step. Temperature-dependent material properties should be used in both models.
4. On completing the analysis, one can use the plastic work or strain accumulated to determine the expected fatigue

life of the package based on the worst-case solder joint, as outlined in Phase 3 of the previous section.

If computer resources are available, a complete global model could be used to determine the plastic work or strain per solder joint. However, this could be very time-consuming depending on the complexity of the package under consideration.

64.4.1.6 Impact on First-Level Interconnect. In FCBGA-type packages using temperature-dependent material properties, failure resulting from solder joint fatigue may occur not only at the board-level interconnect but also at the first-level interconnect (between the silicon die and substrate). The flip-chip bumps are encapsulated by the underfill to improve their thermomechanical reliability by evenly distributing the CTE-mismatch-induced strains between the die and substrate. If the underfill material properties are such that the underfill softens drastically above its T_g, then there is a possibility that the flip-chip bumps may fail early during thermal cycling.[52] To simulate this, the global-submodel approach outlined earlier can be used. In this case, the flip-chip bumps would also be incorporated in the submodel as shown in Fig. 64.18.

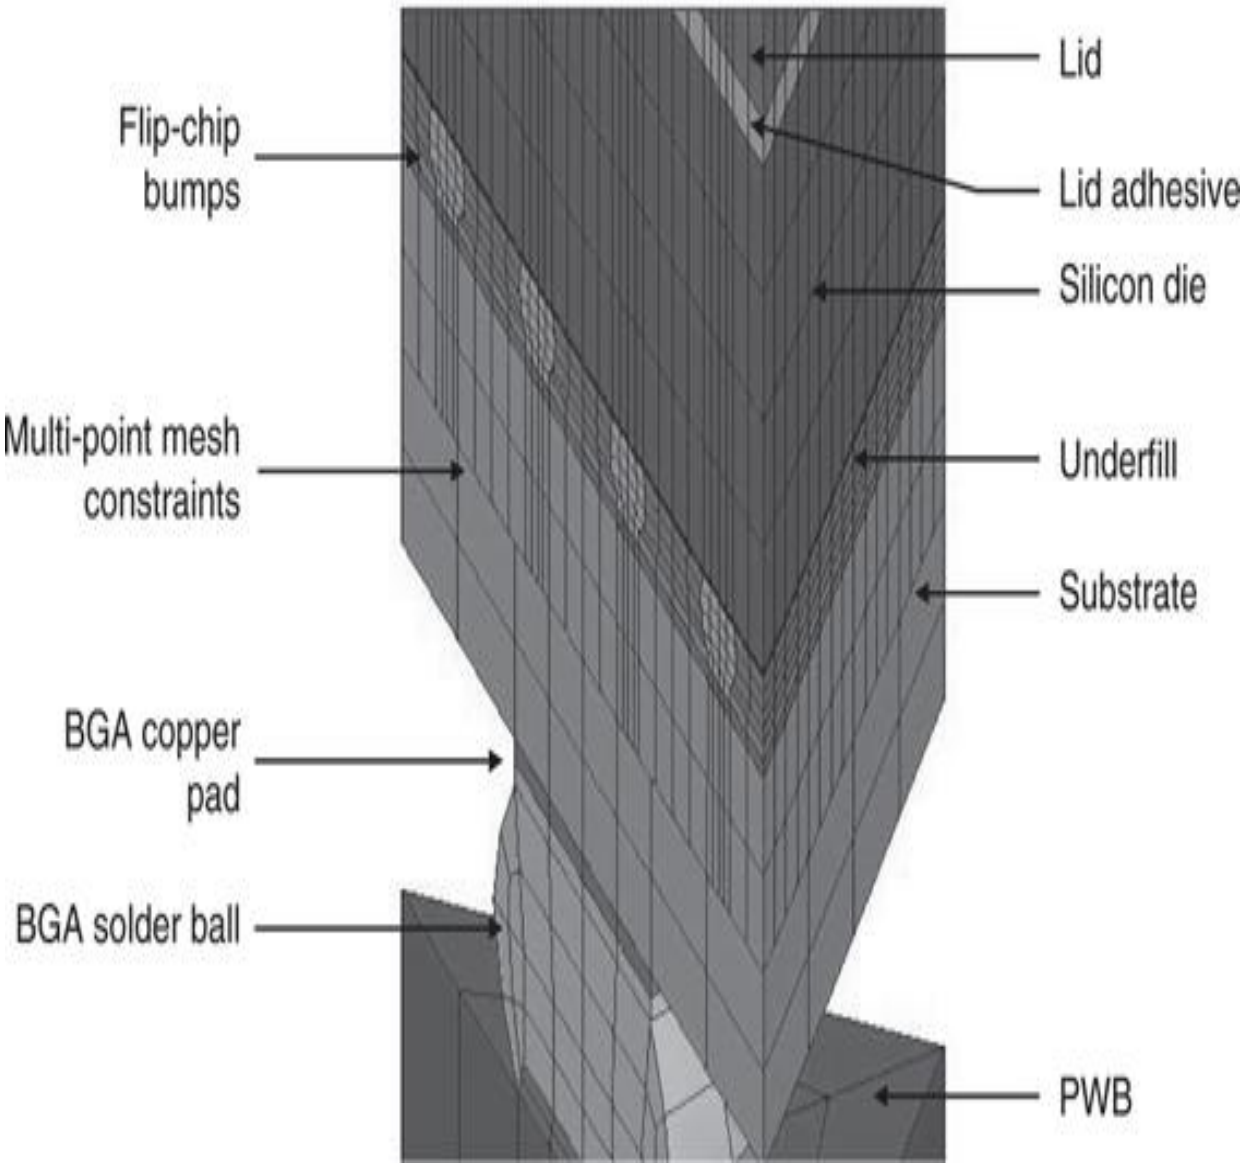

FIGURE 64.18 Three-dimensional submodel detail showing the flip-chip bumps and underfill included in the model. The submodel can be used to determine the fatigue life of the flip-chip bumps and the BGA solder joint underneath at the same time.

64.4.2 FEA for Monotonic Bend Testing

FEA simulations of monotonic bend testing involve a quarter-symmetry model of the assembly placed between anvils and deformed while monitoring the strains induced in the

package, solder joint interconnects, and the PWB. The details of the quarter-symmetry model are shown in Fig. 64.19.

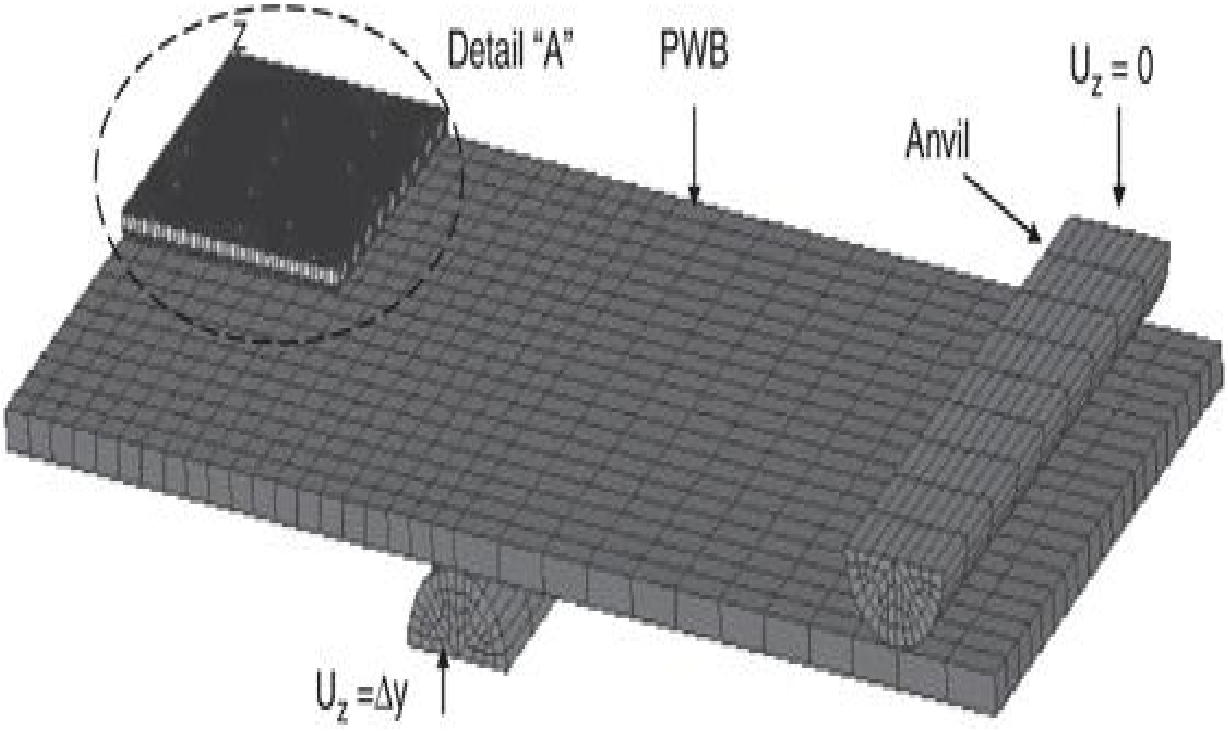

FIGURE 64.19 Three-dimensional quarter-symmetry model showing an FCBGA package mounted on a PWB between support anvils. Contact elements between the anvils and the PWB simulate the flexure of the PWB as one anvil set is moved vertically relative to the other. Detail A of the model is shown in Fig. 64.20.

Bend test FEA simulations achieve two primary objectives:

- To determine the relationship between PWB strain and critical joint strain. This in turn helps bridge differences between the controlled conditions in which the bend testing is performed and the conditions in which bending occurs during assembly.
- To perform a comparative assessment of different packages. FEA can be used to derive solder joint strains from experimental PWB strain data for different test conditions.

The FEA model is shown in Figs. 64.19 and 64.20. Solid structural elements are used to model the PWB, solder joints, and package details. Based on the premise that at high strain rates, the solder material becomes brittle and behaves almost like a linear elastic material, the solder joint elements are modeled as linear elastic. Contact elements are used at the interface between the PWB and anvils to simulate contact between the PWB and the anvils as the assembly is deformed. The solder joint geometry is modeled as closely as possible to the solder joints' actual shape after reflow.

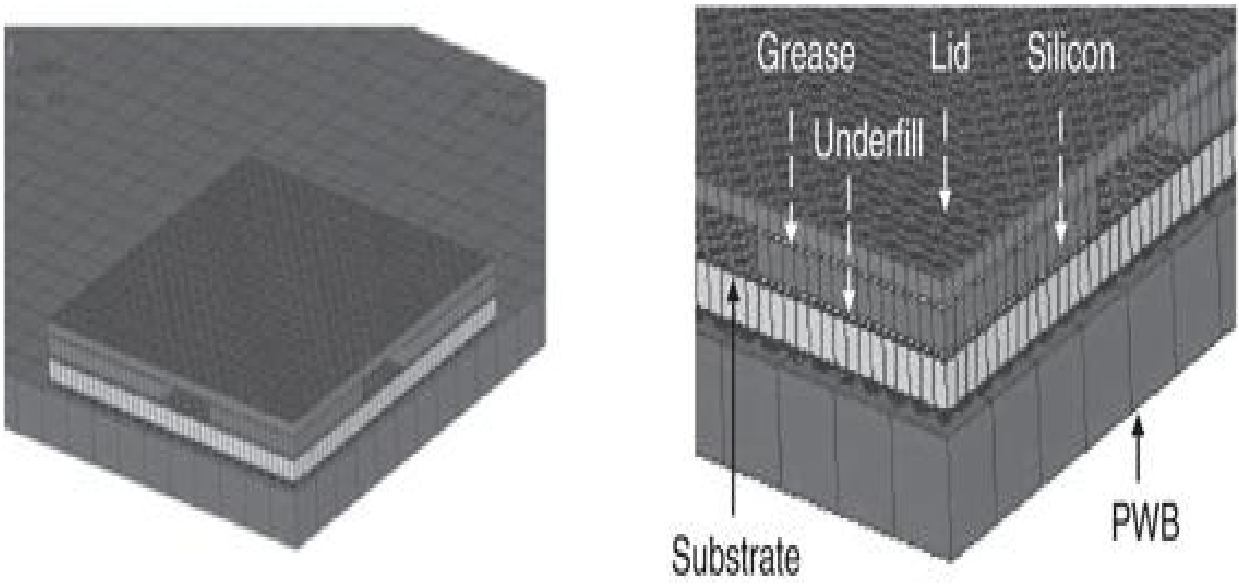

FIGURE 64.20 Detail A of the image model shown in Fig. 64.19. The image on the left shows the package (quarter-symmetry). The zoomed-in image on the right shows all the details of the FCBGA package construction.

A variety of different parametric analyses can be performed to determine the effect of different geometric variables on the critical joint strain. A few examples of such analyses are described in this section.

64.4.2.1 Strain Distribution Around the Package. Per IPC/JEDEC-9702, it is recommended that three strain gauges be placed around a package during four-point bend testing (see Fig. 64.21). These gauges are to be used to characterize

the strain response of the given package mounted on a board of a certain thickness. FEA was used to determine the joint-to-board strain ratio for each case, which in turn can be used to determine which strain gauge location is most or least sensitive to board flexure. The results of the simulation are shown in Fig. 64.22.

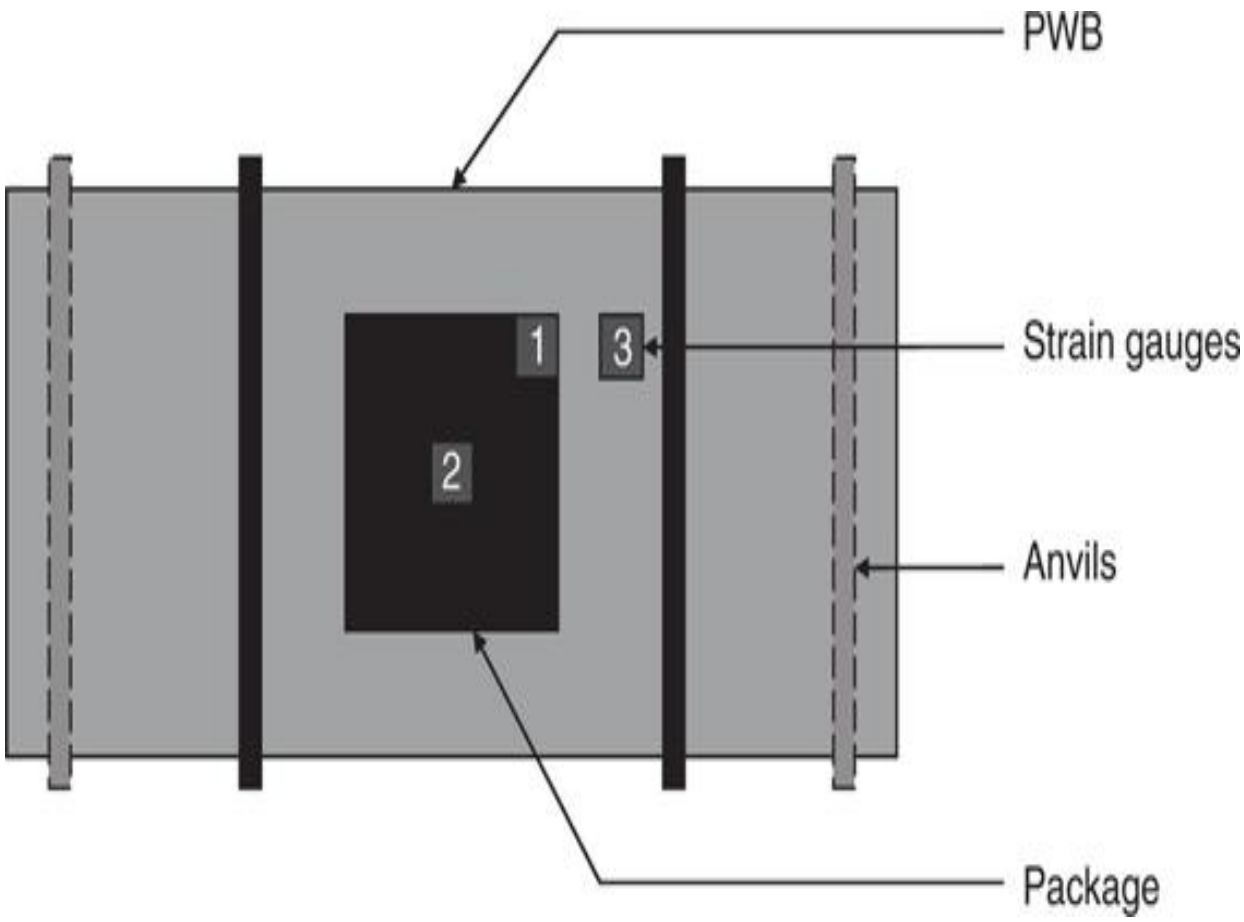

FIGURE 64.21 Nomenclature for the four-point bend test set up as outlined in IPC/JEDEC-9702. Three strain gauges are placed on the board to measure the strain distribution around the package. Gauge 1 is placed under the package, directly below the corner most solder joint. Gauge 2 sits directly below the package center. Gauge 3 is placed next to the package on the PCB topside, midway between the package edge and the anvil.

FIGURE 64.22 Solder joint-to-PWB strain relationship for three gauge locations. The results indicate that the gradient at locations 1 and 3 are relatively close. The gradient at location 2 is quite low. This indicates that the PWB strain at location 2 is least sensitive to variations in critical solder joint strain. The nomenclature for the strain gauge locations is given in Fig. 64.21.

The results indicate that the highest sensitivity to solder joint strain is obtained at locations 1 and 3 (see Fig. 64.21). Location 2 reflects the global bending of the entire assembly. These results are in line with measured experimental data. The absolute strain value and the change in strain at location 2 is least sensitive to the critical solder joint failure strain.

64.4.2.2 Effect of Package Pad Size on Joint-to-Board Strain. FEA can also been used to estimate the effect of changes in solder joint pad size on the joint-to-board strain ratio. Two different package pad sizes were used: 0.53 mm, solder mask defined, (pad design 1) and 0.4 mm, solder mask defined, (pad design 2) while the PCB pad design was kept constant (0.5 mm, non-solder mask defined). The results in terms of the joint-to-board strain at location 3 are shown in Fig. 64.23.

Joint strain

FIGURE 64.23 Two different solder joint pad sizes analyzed. The results indicate that for the same PWB strain, the solder joint strain is ~18 percent higher for pad design 2 as compared to pad design 1.

The results in Fig. 64.23 indicate that pad size change could have a significant impact on the strain in critical solder joints. As a result, care should be taken in using data generated with one pad size to qualify or accept the bending strength with another pad size, unless the absolute strain-to-failure value is much higher than the required strength.

PART 12

FLEXIBLE CIRCUITS

CHAPTER 65

FLEXIBLE CIRCUIT APPLICATIONS AND MATERIALS

Happy T. Holden

Co-Editor-in-Chief, Printed Circuits Handbook, *and PCB Technologist, Zeeland, Michigan*

65.1 INTRODUCTION TO FLEXIBLE CIRCUITS

Flexible circuits are a form of printed wiring interconnect structure built on thin, flexible substrates. They are also bendable to complete three-dimensional (3D) wiring that rigid circuit boards cannot achieve. Because of this flexibility, flexible circuits have many advantages over other wiring methods and have many applications in electronic equipment that require high-density wiring in a small space. As the samples in Fig. 65.1 show, most flexible circuits have cabling functions rather than the mounting functions of electronic components.

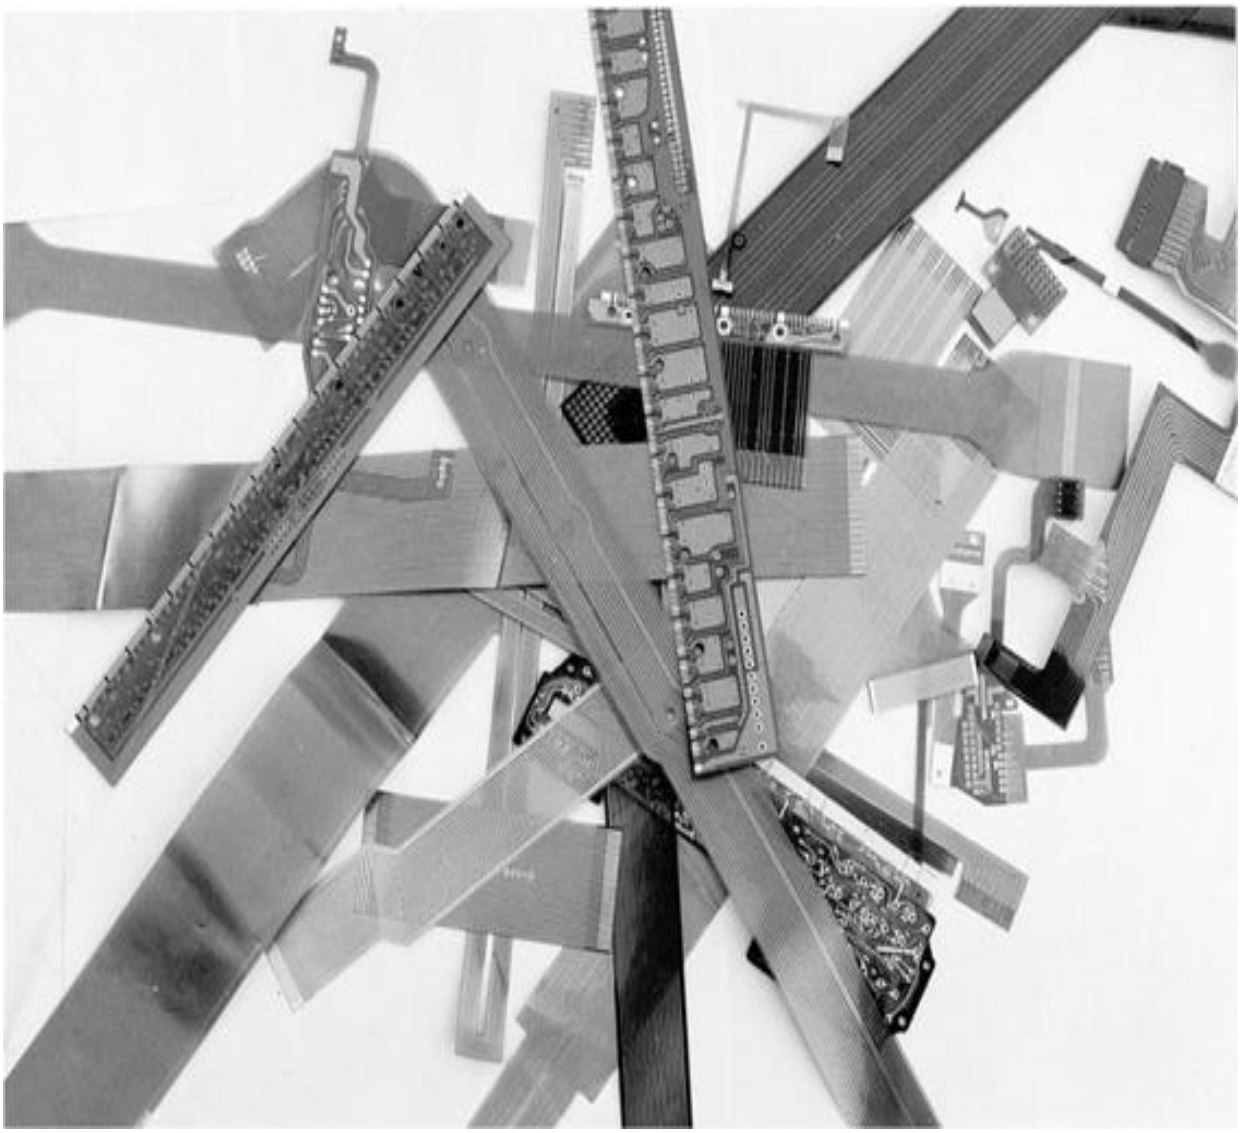

FIGURE 65.1 Various examples of flexible circuits.

Tape-automated bonding (TAB) has not been considered as a type of flexible circuit because of the slightly different manufacturing processes. However, the basic construction and materials of the final products are the same; therefore, TAB is categorized as a type of flexible circuit in this book (see Fig. 65.2).

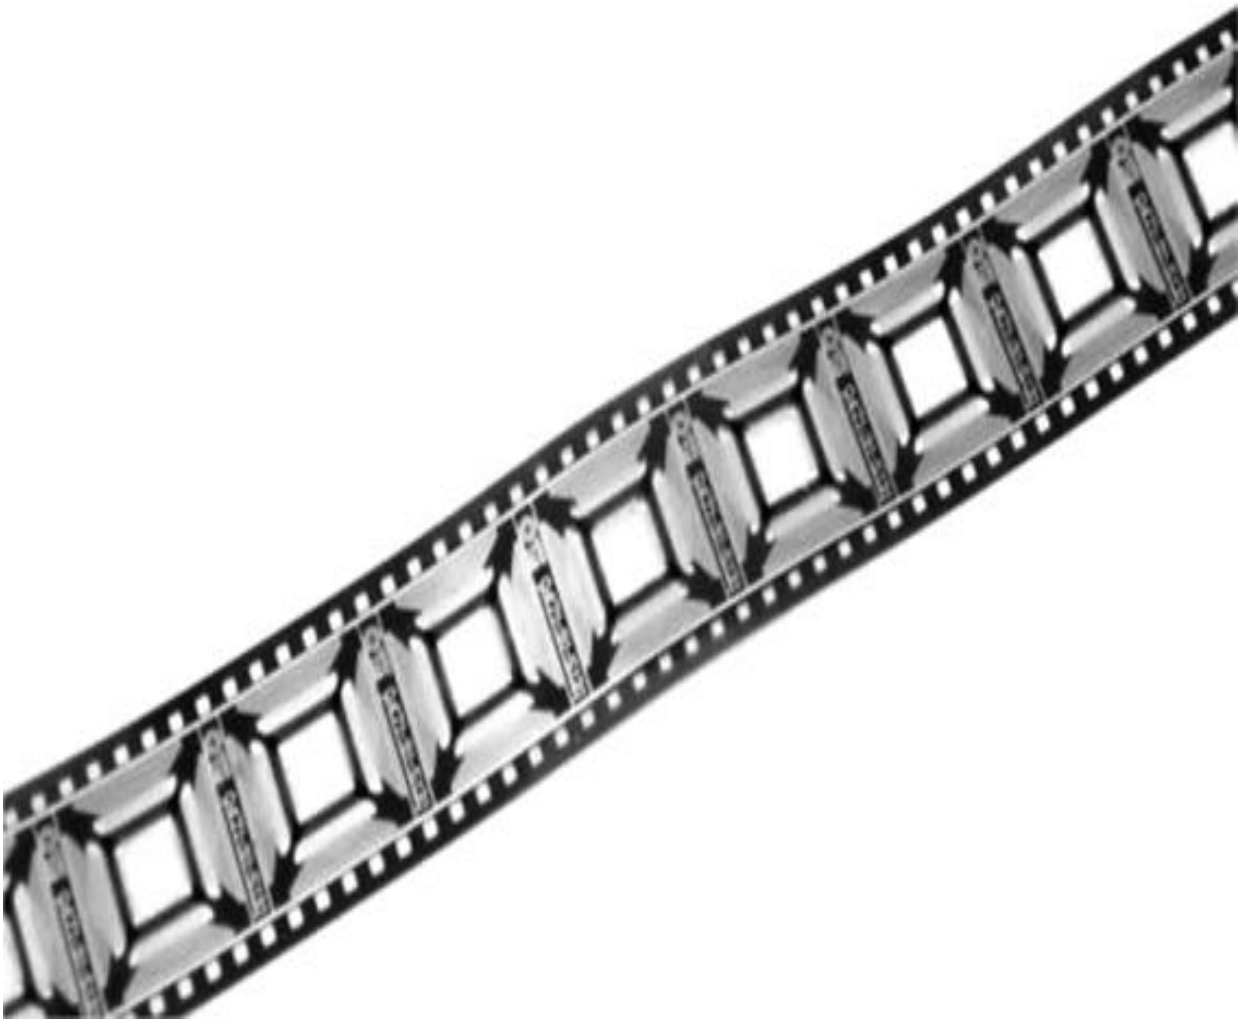

FIGURE 65.2 Example of fine TAB circuits.

65.1.1 Advantages and Disadvantages of Flexible Circuits

The basic advantages of the flexible circuits are its thinness and ability to bend. However, a thin flexible circuit generates many supplemental advantages not available with other wiring methods (see Table 65.1). A 3D wiring with component assembling in a small space and a long-term dynamic flexing with small radius are typical examples of what other wiring materials cannot replace. On the other hand, flexible circuits also have many disadvantages due to unstable thin

constructions. It is necessary to consider how to avoid the disadvantages when using a flexible circuit in a packaging system. Otherwise, overall process yield and productivity will be low and the final cost will be relatively very high.

TABLE 65.1 Advantages and Disadvantages of Flexible Circuits

Advantages	Disadvantages
Thin	Fragile
Light	Unstable dimensionally
Bendable	Low reliability—fatigue
Flexible	Difficult to design
Long flexing endurance	Complicated manufacturing process
3D wiring	Difficult to handle
High-density wiring in a small space	Need special tools for assembling
Avoid connectors and soldering	Low yield in assembling
Avoid missed wiring	Difficult to rework
Low total cost, including all elements	High cost of circuit fabrication

65.1.2 Economics of Flexible Circuits

The largest disadvantage of flexible circuits is that they cost more than rigid circuit boards or flat cables of the same size. Usually, flexible circuits are larger than rigid circuit boards to allow 3D wiring capability; however, the total circuit cost increases, using flexible circuits is still often cheaper than using multiple rigid boards and associated connectors.

That is, the cost of using flexible circuits must be compared to the total cost of rigid circuit boards in terms of the following:

- Connectors
- Wires
- Additional assembly costs

Because the total cost of a flexible circuit is greater than that of an equivalent rigid circuit board alone, designers should not choose flexible circuits over other wiring methods unless three-dimensional advantages are needed, especially for consumer applications that require low-cost wiring. A flexible circuit should be used only when it provides the solution for the application's wiring requirements (e.g., when the application requires bendable wiring in a small space, lightweight, long-flex endurance, and so on). The critical question is whether the value of a flexible circuit's performance is greater than its cost.

Miniaturization of electronic products requires extremely lightweight wiring in a small space, and therefore there have been many opportunities for flexible circuits. Figure 65.3 shows examples of flexible circuits applied to a digital camera in which their advantages make them the best technical solution, and also the least expensive. In this example, the entire circuit was divided into one multilayer rigid board and more than 10 flexible circuits to optimize the advantages and minimize the total wiring costs.

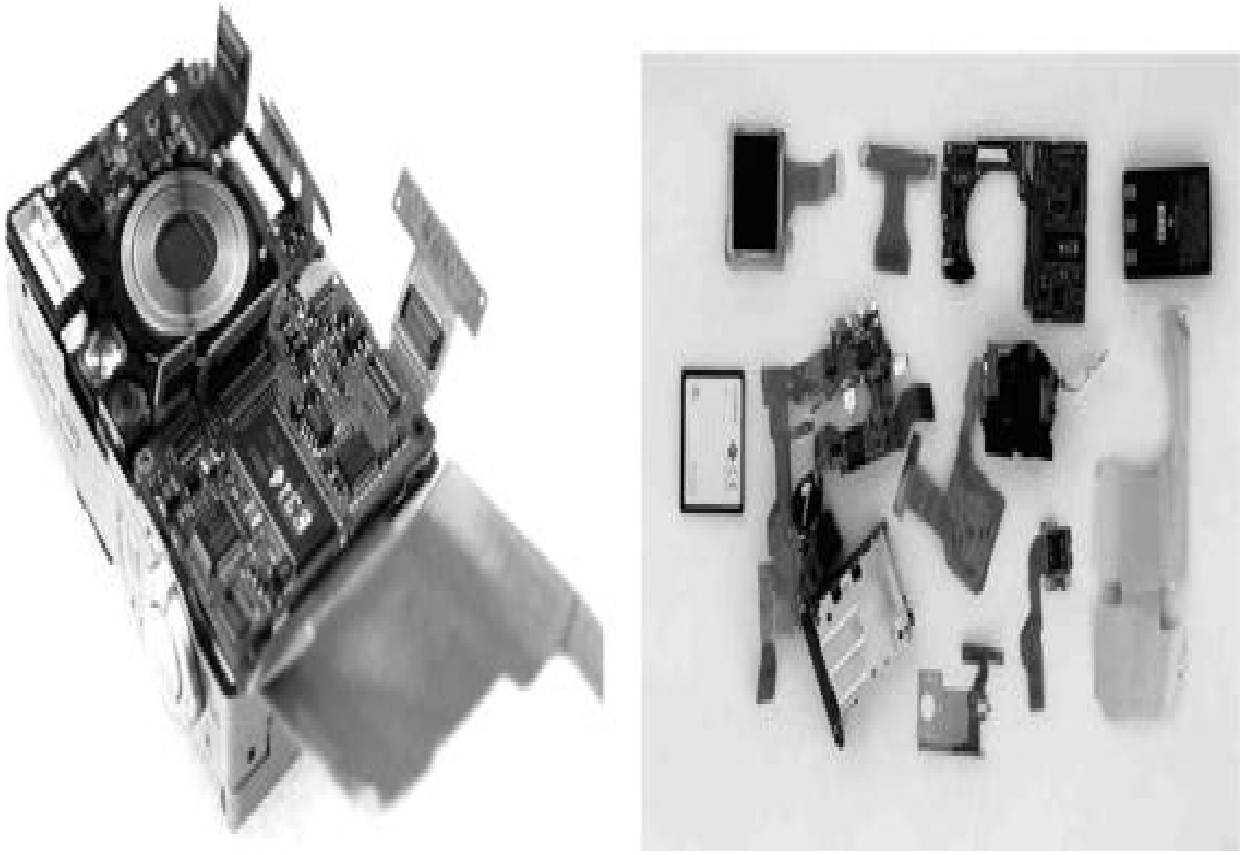

FIGURE 65.3 Flexible circuits applied for digital camera. (*Courtesy of Canon*.)

65.2 APPLICATIONS OF FLEXIBLE CIRCUITS

As described, a flexible circuit should be adopted only when other wiring or packaging methods cannot satisfy the application's requirements. Table 65.2 shows how features of flexible circuits relate to appropriate applications. The table shows typical examples of flexible circuit applications in electronic products. Portable electronic products such as cellular phones, digital cameras, automobile instrument panels, and handheld calculators require reliable 3D wiring in a small space. In some cameras, more than 10 flexible circuits are squeezed into a small space. Flexible circuits are used for the hinge wiring in many electronic products that

have mechanical moving parts, such as notebook computers, palmtop computers, and personal digital assistants (PDAs). Many new electronic products, such as hard disk drives, small printers, and clamshell type cellular phones, require a long-life dynamic flexible endurance. Multilayer rigid/flexible circuits have been effective in reducing wiring space and increasing wiring reliability in aerospace electronic equipment and small portable electronic products such as cellular phones. Only flexible circuits could satisfy all these wiring requirements. Efforts to minimize the cost of flexible circuit wiring for consumer applications are ongoing. Often, the miniaturization of a consumer electronic product assumes a wiring system with multiple flexible circuits, especially if the equipment has mechanical moving portions.

TABLE 65.2 Features and Applications of Flexible Circuits

Features	Applications
High-density wiring in a small space	Digital camera, cellular phone, flat panel display, video camera, facsimile, ultrasound probe
Lightweight	Calculator
3D wiring	Automobile instrument panel, cellular phone, camera, notebook computer
Reliable wiring	Aerospace applications, industrial applications
Long flexing endurance	Printer, hard disk drive, floppy disk drive, CD drive, VCR

65.3 HIGH-DENSITY FLEXIBLE CIRCUITS

Serious progress in the density of flexible circuits was made during the second half of the 1990s, owing to the extreme

miniaturization of electronic products. These products incorporate a new technical concept in the design of the circuits. They have a much higher density than traditional flexible circuits, with dimensions for traces, spaces, and via holes equivalent to those of rigid high-density interconnect (HDI) boards. (Details are described in the chapter on Special Construction of Flexible Circuits, Chap. 70.) They also have supplemental constructions on the circuit to allow higher termination capabilities. This type of construction is called an *HDI flexible circuit* (i.e., a flexible circuit for high-density interconnects).

65.3.1 Specifications

Table 65.3 shows typical requirements for interconnection in the end product, and the preferred specification of circuit parameters for the use of high-density flexible circuits.

TABLE 65.3 Common New Requirements for High-Density Flexible Circuits

Requirements for End Use	Preferred Specification for Flexible Circuits
High-density wiring	Pitches smaller than 150 µm, via holes smaller than 150 µm in diameter thin and light Base 25 µm or thinner, conductor thinner than 12 µm
High-density SMT	Small opening on coverlay, tin or lead-free plating High-density connection High dimensional accuracy (<0.3 mm diameter) bonding High-density flying lead, pitch <100 µm
Chip-on-flex, flip-chip	High-density microbump array, pitch <100 µm High reliability for vibration High bond strength of conductors
For mechanical shock	High bond strength between layers wide-range heat cycle High heat resistance
For salty moistures	High insulation resistance

Portable electronic products are exposed to more severe conditions than ever before. As a result, they need higher reliability for the circuits as listed in Table 65.3. In the case of portable telephones, they are often carried in the owner's pocket, where they may be exposed to a variety of conditions, including continuous vibration, mechanical shock, temperature, humidity, pocket lint, and even perspiration. Other portable electronic products, such as digital cameras, PDAs, and notebook computers, could be exposed to similar conditions.

65.3.2 Applications

Due to usage and assembly technologies, many applications require increased performance for high-density flexible circuits. The manufacturing processes for these circuits must adapt to new requirements imposed by additional process conditions. Table 65.4 lists major applications and the associated advantages of using high-density flexible circuits for a given purpose.

TABLE 65.4 Major Applications of High-Density Flexible Circuits

Applications	Reasons to Use High-Density Flexible Circuits
Wireless suspension of disk drives	High-density wiring in a small space Flexible, thin, light, 3D wiring Direct connection to magnetic heads
Interconnections of disk drive actuators	High-density wiring in a small space Flexible, thin, light, 3D wiring Repeated reparability
Interposer of CSP	High-density wiring in a small space Thin, light, 3D wiring
Flat-panel displays	High-density wiring in a small space Flexible, thin, light, 3D wiring Chip-on-flex capability High-density connection
Ultrasound probes	High-density wiring in a small space Flexible, thin, light, 3D wiring Direct connection to ultrasound device
Cellular phones	High-density wiring in a small space Flexible, thin, light, 3D wiring surface-mount technology (SMT) and COF capability
Inkjet printers	High-density wiring in a small space Flexible, thin, 3D wiring Direct connection to printer head device

Without high-density flexible circuits, these applications could not achieve miniaturization or support valuable new functions. For example, specially developed high-density flexible circuits can provide highly reliable connections at a low cost for new tiny magnetic heads of hard disk drives with

a vertical recording system. Chip-scale package (CSP) technologies can be developed with high-density flexible circuits. Driver integrated circuits (ICs) for flat panel displays in personal computers and large flat panel TVs are assembled with a set of chip-on-flex (COF) substrates. Due to the limited space within the camera bodies, small liquid crystal display (LCD) monitors for video cameras and digital cameras are assembled using long-tailed high-density flexible circuits. The wiring of the “next generation” of portable electronics cannot be completed without high-density flexible circuits.

65.4 MATERIALS FOR FLEXIBLE CIRCUITS

The basic difference between flexible circuits and rigid circuit boards is the thin and flexible materials used in the substrates of flexible circuits. Furthermore, because the flexible circuits have complicated constructions, supplemental materials other than copper-clad materials have been required to build a whole circuit.

65.4.1 Traditional Flexible Circuit Materials

Table 65.5 shows traditional major materials and typical examples of flexible circuits. A broad variety of the materials are employed to build traditional flexible circuits. Film materials, such as polyimide (PI) films and polyester (PET) films are the specially adapted for use in flexible circuits. For greater flexibility, rolled annealed (RA) copper foil is used as the major conductor material.

TABLE 65.5 Traditional Major Materials Used to Build Flexible Circuits

Application	Typical Materials
Base substrates	Polyimide film (PI), polyester film (PET), polyester terephthalate Thin glass-epoxy, fluorinated ethylene propylene (FEP), resin-coated paper
Conductors	Electrodeposited (ED) copper foil, RA copper foil, stainless steel foil, aluminum foil, etc.
Copper-clad laminates	Epoxy-based, acrylic-based, phenol-based (adhesive-based)
Coverlay	PI film, PET film, flexible solder mask
Adhesive layer	Acrylic resin, epoxy resin, phenol resin, pressure-sensitive adhesives (PSAs)
Stiffener	PI film, PET film, glass-epoxy, metal boards, etc.

Coverlays and stiffeners are typical examples of the special components needed to build flexible circuits. Many types of materials have been introduced to accommodate the designs of the end applications.

65.4.2 HDI-Oriented Flexible Circuit Materials

Since 1990, many new materials for flexible circuits have been developed in conjunction with design and manufacturing processes to satisfy new requirements in HDI applications. These include

- High-performance films
- Adhesiveless laminates
- Direct cast processes of liquid polyimide resins
- Photoimageable coverlay

See Table 65.6 for a list of new materials for HDI flexible circuits. There is a significant difference between traditional flexible circuits and HDI flexible circuits. For example, more than 80 percent of traditional flexible circuits were covered by adhesive-based copper-clad laminates that use the traditional polyimide films, Kapton H™ or Apical AV™. Conversely, the majority of high-density flexible circuits used in large-volume applications utilize all new materials.

TABLE 65.6 Materials for High-Density Flexible Circuits

Application Areas	New Materials for High-Density Flexible Circuits
Base dielectrics	Polyimide films (Kapton K, E, EN, KJ; Apical NP, FP; Upilex-S) Liquid polyimide resin, PEN film, LCP films
Conductor materials	Ultrathin copper foils, sputtered copper, copper alloys, stainless steel foil
Copper-clad laminates	Adhesiveless laminates (cast type, sputtered/plated type, laminated type)
Coverlay	Photoimageable coverlay (PIC) (dry film type, liquid ink type)
Adhesive sheets	Hot-melt polyimide film

HDI applications require finer traces and microvia holes in severe manufacturing and application conditions. For manufacturing convenience, flexible circuit producers prefer thinner conductors and substrates. However, physical performances of thinner materials may not be optimal. Thinner materials impact both the performance and manufacturing yield of the final flexible circuit.

Dimensional stability of the materials in high-density flexible circuits during manufacturing is a key to good process yields. To produce reliable high-density flexible circuits, conflicts between materials, constructions, and manufacturing processes must be resolved. Measures to accomplish this objective have been undertaken. For

example, new construction designs and manufacturing technologies now require use of the materials shown in Table 65.7.

TABLE 65.7 Comparison of Selected Properties of Flexible Base Materials

Substrate Material	Dielectric Constant	Dissipation Factor	Dielectric Strength, V/mil	Moisture Absorption, %	Tensile Strength, kpsi	Elongation, %
Polyester	3.2	0.005	7000	< 0.08	25	~120
Polymide	3.5	0.003	7000	1.3–3.0	25	~60
PEN	2.9	0.004	7500	1.0	30–35	~75
LCP	2.9	0.003	6000	0.02–0.1	15–25	~15
FEP	2.0	0.0002	5000	< 0.01	2–3	~300
PTFE	2.5	0.0002	5000	< 0.01	15–25	N/A
PVC	4.7	0.093	500	< 0.5	5	120–500
Aramid paper	2.0	0.007	380	3.0	11	~10

65.5 SUBSTRATE MATERIAL PROPERTIES

Many kinds of materials have been developed as the major dielectric layers of flexible circuits; however, polyimide films and polyester films have been the major core material for both substrate films and coverlay films with adhesive for traditional flexible circuits. The polyimide films have been the major substrate material for the soldering process and other high-temperature terminations processes, such as

wirebonding and flip-chip, because of their high-temperature resistance and good balance of physical properties. Polyester films are not available for standard soldering, but they are a low-cost solution for large circuits such as those used in automobile instrument panels and long cable circuits of printers.

65.5.1 Comparison of Substrate Materials

There have been examples of other materials, such as thin glass-epoxy, that have not been widely used. To satisfy the new concept of HDI flexible circuits, innovative uses of raw materials such as polyethylene naphthalate (PEN) film, liquid crystal polymer (LCP) film, and polyether ether ketone (PEEK) film have been introduced. Comparisons are shown in Table 65.8.

TABLE 65.8 Comparison of Substrate Materials

	Polyimide	Polyester	Thin Glass Epoxy	LCP	PEEK
Maximum operating temperature	>200°C	<70°C	~105°C	~90°C	>200°C
Standard thickness	12.5, 25, 50, 75, 125 µm	25, 50, 75, 100, 125, 188 µm	100, 150, 200 µm	(50 µm)	(50 µm)
Soldering	Applicable	Difficult	Applicable	Possible	Possible
Wire bonding	Possible	No	Difficult	Difficult	Possible
Color	Brown	Transparent	Transparent	Transparent	Milky
Moisture absorption	High	Low	Low	Low	Low
Dimensional stability	Acceptable	High	High	Good	High
Flexibility	High	High	Low	High	High
Cost	High	Low	Medium	Low	High

65.5.2 Polyimide Film

Polyimide film continues to be the major substrate material for flexible circuits because only it can support high-temperature processes such as soldering and wirebonding. Both Kaptons H, HN, VN, and FN films by Du Pont and Apical AV by Kaneka have been used in the flexible circuit industry for a long time. Both of these materials have a good property balance, and they are still the major substrates in traditional flexible circuits.

65.5.2.1 Properties of Polyimide Films. Table 65.9 shows major properties of typical polyimide films, Kaptons H(HN), VN, FN, and Apical AV. These have good mechanical properties and provide excellent performance as base substrate films and coverlay films in dynamic flexing

applications. They have flame-retardant characteristics, and it is not difficult to achieve Underwriters Laboratories (UL) flame class 94-V-0 or 94-VTM-0. The largest disadvantage of polyimide film is its higher cost compared to other common plastic films such as PET.

TABLE 65.9 Properties of Traditional Polyimide Films and New Polyimide Films

		Kapton H(HN)™	Apical AV™	Kapton FN™	Apical NP™	Apical HP™	Upilex S™
		DuPont	Kaneka	DuPont	Kaneka	Kaneka	Ube
Manufacturer thickness (μm)		12.5, 25, 50, 75, 125	12.5, 25, 50, 75, 125	12.5, 25, 50, 75	12.5, 25, 50, 75	12.5, 25, 50, 75	12.5, 25, 50, 75, 125
Tensile strength (kg/mm^2)	MD	25.2	25.0	28.3	30.0	28.6	39.4
	TD	22.3	27.0	25.4	32.0	29.0	40.2

	TD	0.20	0.03	0.02	0.02	0.02	0.10
Water absorption (23°C, 24 h)		2.8	2.9	2.2	2.5	1.1	1.9
Alkaline resistance		17.4	25.9	5.5	22.9	4.2	~0
Chemical etching		Possible	Possible	Possible	Possible	Possible	Difficult

There are several barriers to using traditional polyimide films as the major substrate materials in HDI flexible circuits. Dimensional stability is the largest issue. Both Kapton H film and Apical AV by Kaneka have coefficients of thermal efficiency (CTEs) higher than 30 ppm, which is not acceptable for the large-volume production processing of HDI flexible circuits. Relatively high moisture absorption is another major barrier to using these films as the base material of the flexible circuits. High moisture levels in the films cause a lot of supplemental problems, mostly in increased temperature processes. Higher-performance polyimide films are required as the substrate material of HDI flexible circuits.

The primary materials used in industry to optimize cost and performance have been 50-µm-thick polyimide film, used for industrial and avionics applications, and 25-µm-thick films, used for consumer applications. However, since late 1990s, films as thin as 12.5 µm have been specified to reduce thickness and increase flexibility.

65.5.2.2 High-Performance Polyimide Film. Various manufacturers have made several aggressive measures to commercialize high-performance polyimide films. Upilex-S by Ube Industry has excellent chemical stability, and it is a barrier for chemical processes such as adhesion with the other materials or chemical etching. Strong chemicals, such as hydrazine, are required to do the chemical etching. Upilex-S could be the major material as the substrate of TAB, which requires very high dimensional stability at high heat resistance. Newly developed polyimide films such as Kapton VN, E, EN, and Kaneka's Apical NP and FP have higher dimensional stability and lower moisture absorption rates. It is possible to etch these films using mild alkaline chemistry. Basic properties of the materials are summarized in Table 65.8.

Hot-melt-type (thermoplastic) polyimide films have been developed as high-heat-resistant adhesive materials. Mitsui Chemical's TPI, DuPont's Kapton KJ, Ube's Upicel, and Kaneka's Pixeo are typical examples. These are coated on dimensionally stable polyimide films to ensure good physical performance.

65.5.2.3 Liquid Polyimide Resin (Photoimageable). Many new HDI applications require special capabilities and properties on the substrates that are not provided by commercial polyimide films. In these cases, circuit manufacturers initiate production by manufacturing polyimide substrates. Sometimes manufacturers have to start from the synthesis of polyimide resins.

Several liquid polyimide resins have been developed as the base materials of high-density flexible circuits. Some of these liquid polyimide resins can be photoimaged, and have been used in high volume as the dielectric layer and coverlay in the wireless suspension of hard disk drives.

These liquid polyimide resins could be the major dielectric materials of special high-density flexible circuits that demand extremely high density, down to 5-µm pitches with 10-µm via holes. The cost of these materials is higher than that of polyimide film. However, they have broader capability for meeting nonstandard requirements such as ultrathin substrates with microvia holes. The properties are very dependent on the manufacturer.

65.5.2.4 Type H (HN) Kapton Polyimide Film Details. The polyimides are a class of chemical compounds. The word "imide" refers to the cyclic structure characterized by a double-bond linkage between one nitrogen atom (N) and two carbonyl groups. In a polymer the latter are usually attached to a benzene ring. A polyimide which is presently commercially available is obtained by a polycondensation reaction between an aromatic

tetracarboxylic acid anhydride and an aromatic diamine which yields a polyarnic acid intermediate. The acid is then dehydrated to yield a high-molecular-weight polyimide. Many variations and properties are possible by using a variety of amino compounds. In the case of Kapton, * 4,4’-diaminediphenyl ether, R is used as the aromatic amine. The resultant compound, in film form, is transparent, amber-colored, flexible, flame-resistant, and infusible (chars at 1500°F). It possesses excellent chemical resistance (except for strong inorganic acids and bases), and it has a useful operating range from −430 to 780°F. Its dielectric properties, such as dielectric strength and dissipation factor, are excellent and remain constant over a wide range of temperature and frequency.

The development of polyimide film materials has provided the necessary impetus to the design and manufacture of FPW devices. Shortly after and coincidentally with the introduction of this excellent engineering thermoplastic, FPW took a big jump in applications varying from complicated aerospace computers to camera interconnections. The properties of Kapton polyimide film are as indicated below.

- *Physical and thermal properties:* This polyimide film retains their physical properties over a wide temperature range. They have been used in field applications in which the environmental temperatures have been as low as −269°C and as high as 400°C, but most of the data fall in the −195 to 200°C range. Summaries of the physical and thermal properties of Kapton polyimide film are given in Table 65.10.

TABLE 65.10 Typical Thermal Properties of Kapton Polyimide Film

Property	Typical Values	Test Conditions	Test Methods
Melting point	None		
Zero strength temperature	815°C	20-psi load for 5 s.	Hot bar (DuPont test)
Coefficient of linear expansion	2.0×10^{-5} in/(in°C)	(–) 14°C to 38°C	ASTM: D-696-44
Coefficient of thermal conductivity	3.72×10^{-4} cal.cm/(cm^2)(s)(°C)	25°C	Model TC-1000
	$3\,89 \times 10^{-4}$ cal.cm/(cm^2)(s)(°C)	75°C	Twin Heatmaster
	4.26×10^{-4} cal.cm/(cm^2)(s)(°C)	200°C	Comparative Tester
	4.51×10^{-4} cal.cm/(cm^2)(s)(°C)	300°C	
Specific heat	0.261	cal/(g)(°C)	Differential calorimetty
Flammability	Self-extinguishing		
Heat-sealable	No		

[a]Kapton is a registered trademark of E. I du Pont de Nemours & Company.

- *Tensile stress-strain:* A series of tensile stress-strain curves for 0.001 in polyimide film as a function of temperature is shown in Fig. 65.4.

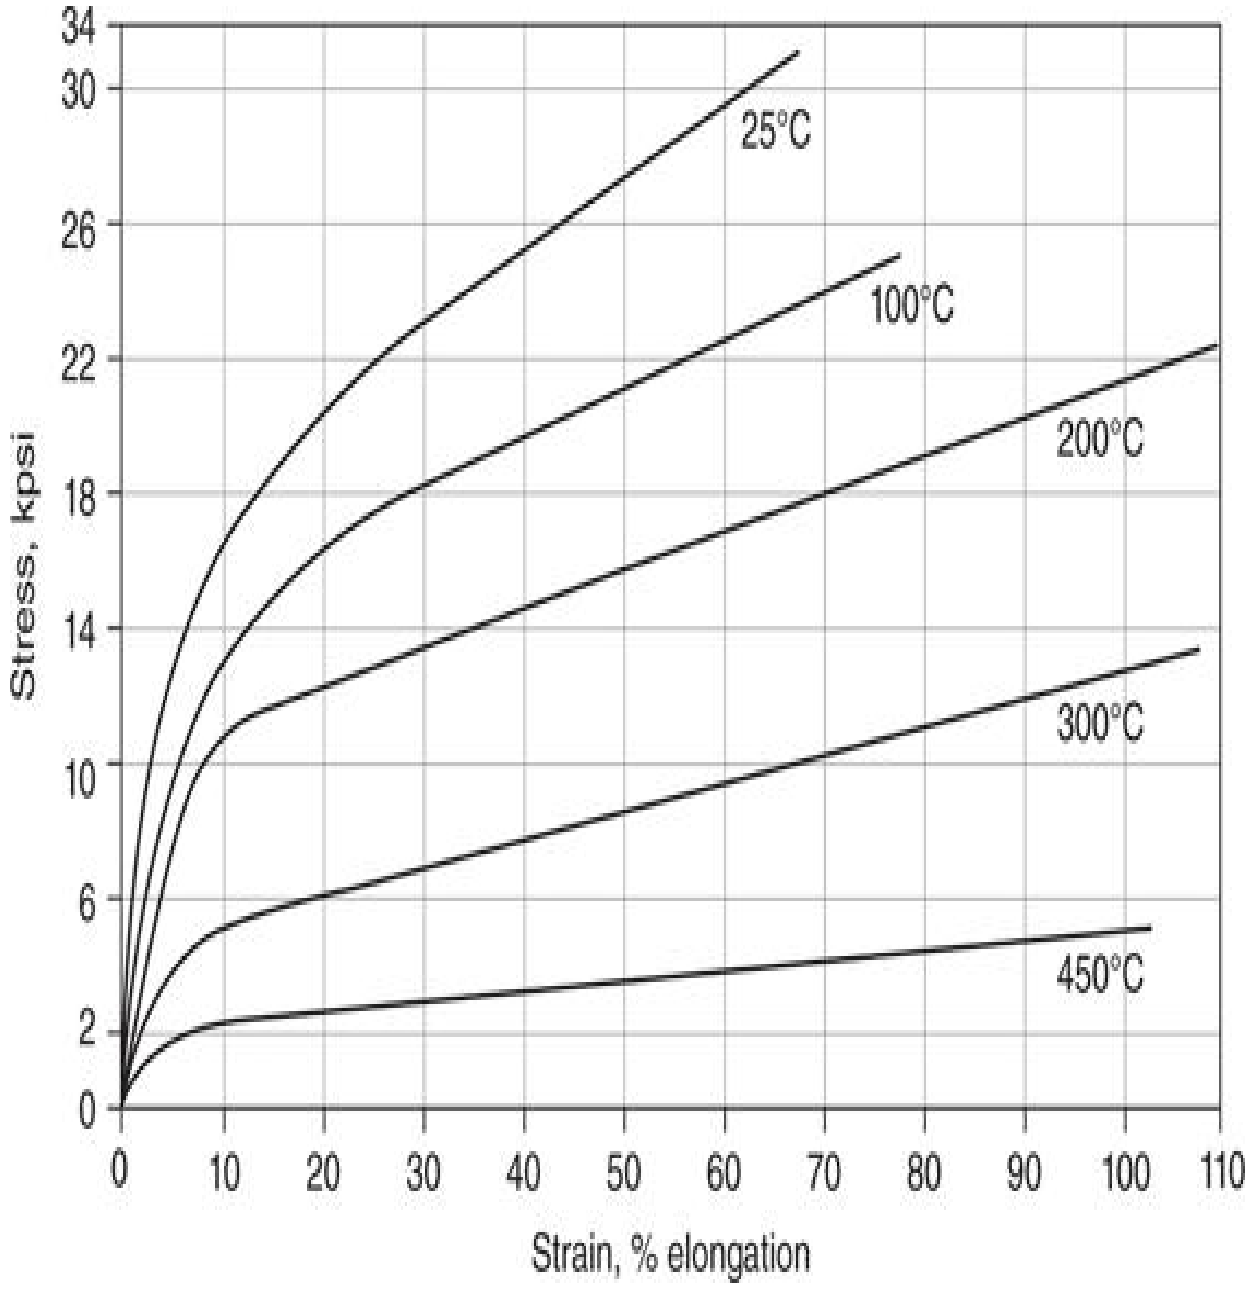

FIGURE 65.4 Tensile stress-strain curves of Kapton polyimide film.

The unusual values of tensile strength, tensile modulus, and ultimate elongation at various temperatures can be obtained from the typical stress-strain curves shown. Such properties as tensile strength and modulus have an inverse relation with temperature, and elongation peaks to a maximum value at 200 to 250°C. Other factors such as humidity, film thickness and Instron elongation rate were

found to have only a negligible effect on the shape of the 25°C curve.

- *Hydrolytic stability:* Kapton polyimide film is made by a condensation reaction therefore, its properties are affected by water. Although long-term exposure to boiling water, as shown in Figs. 65.5 and 65.6, will reduce the level of film properties, sufficient tensile and elongation remain to ensure good mechanical performance. A decrease in the temperature and water concentration will reduce the rate of Kapton property reduction, and higher temperatures and pressures will increase.

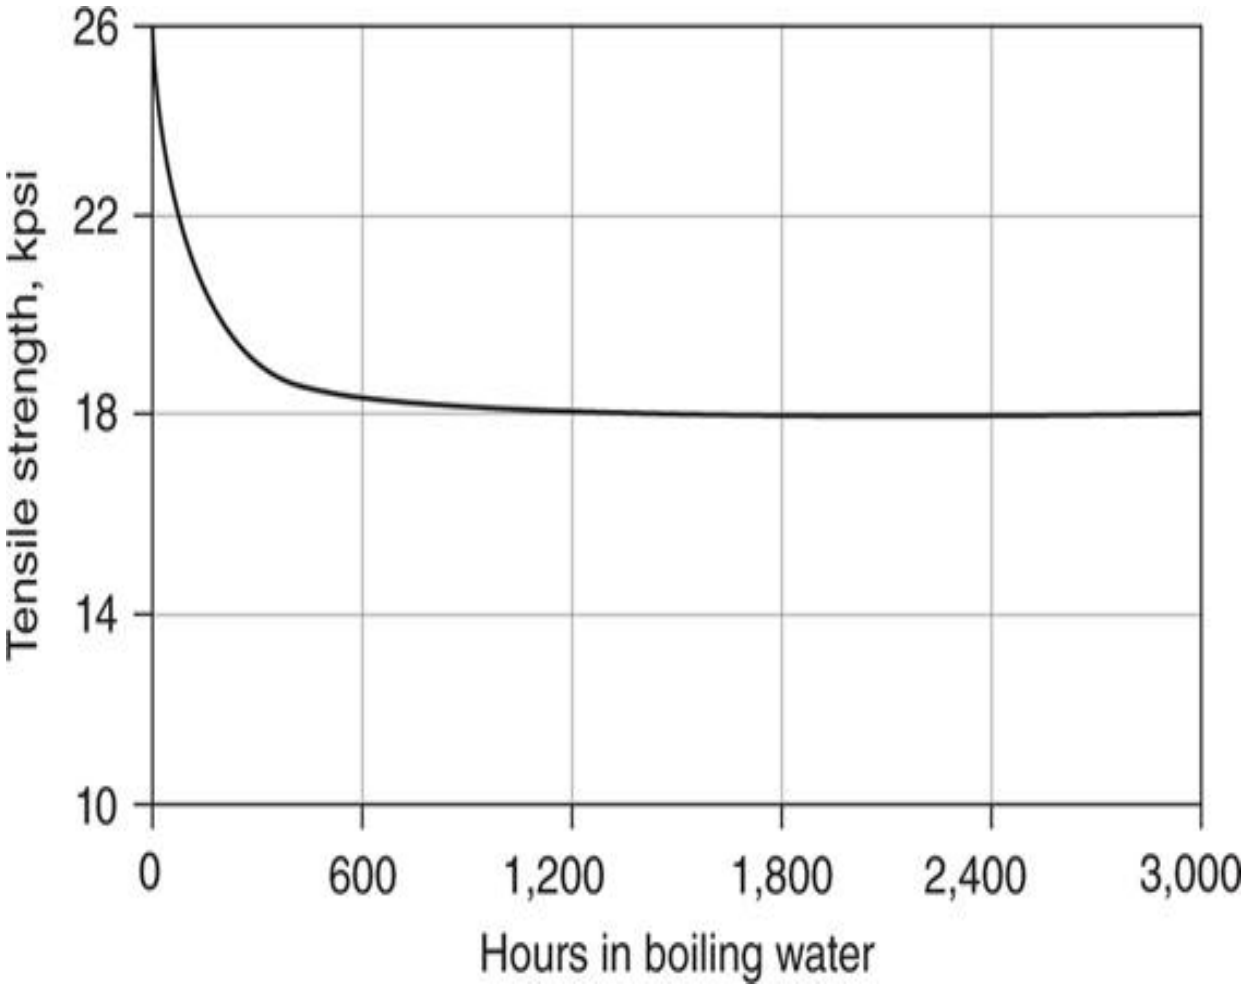

FIGURE 65.5 Tensile strength of Kapton polyimide film after exposure to water at 100°C.

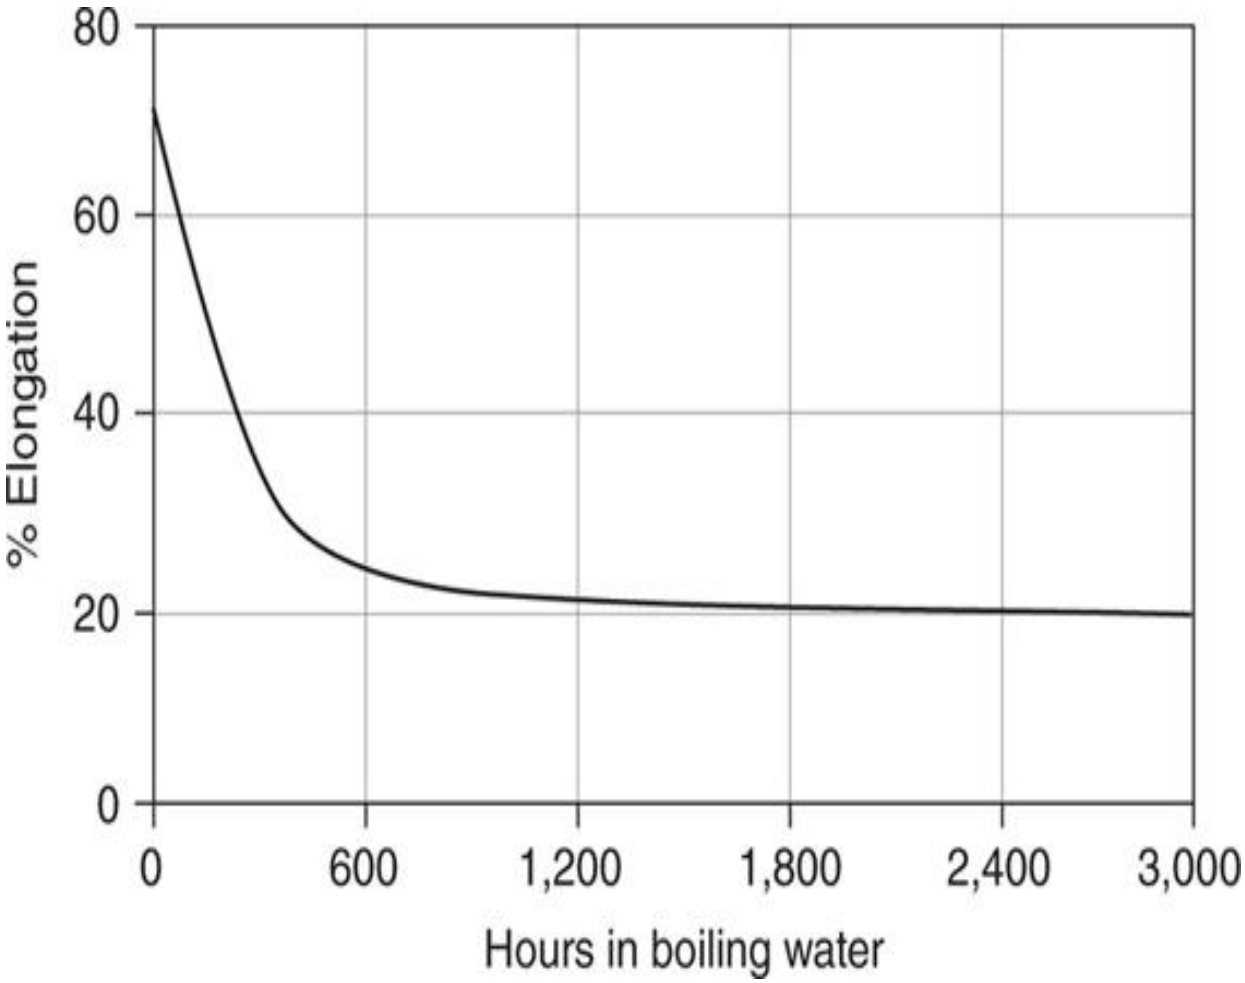

FIGURE 65.6 Ultimate elongation of Kapton polyimide film after exposure to water at 100°C.

- *Dimensional stability:* The dimensional stability of Kapton polyimide film depends on two factors: the normal coefficient of thermal expansion, and the residual stresses placed in the film during manufacture. The latter cause Kapton to shrink on its first exposure to elevated temperatures as indicated in the bar graphs in Fig. 65.7. Once the film has been exposed, the normal values for thermal expansion listed in Table 65.11 can be expected.

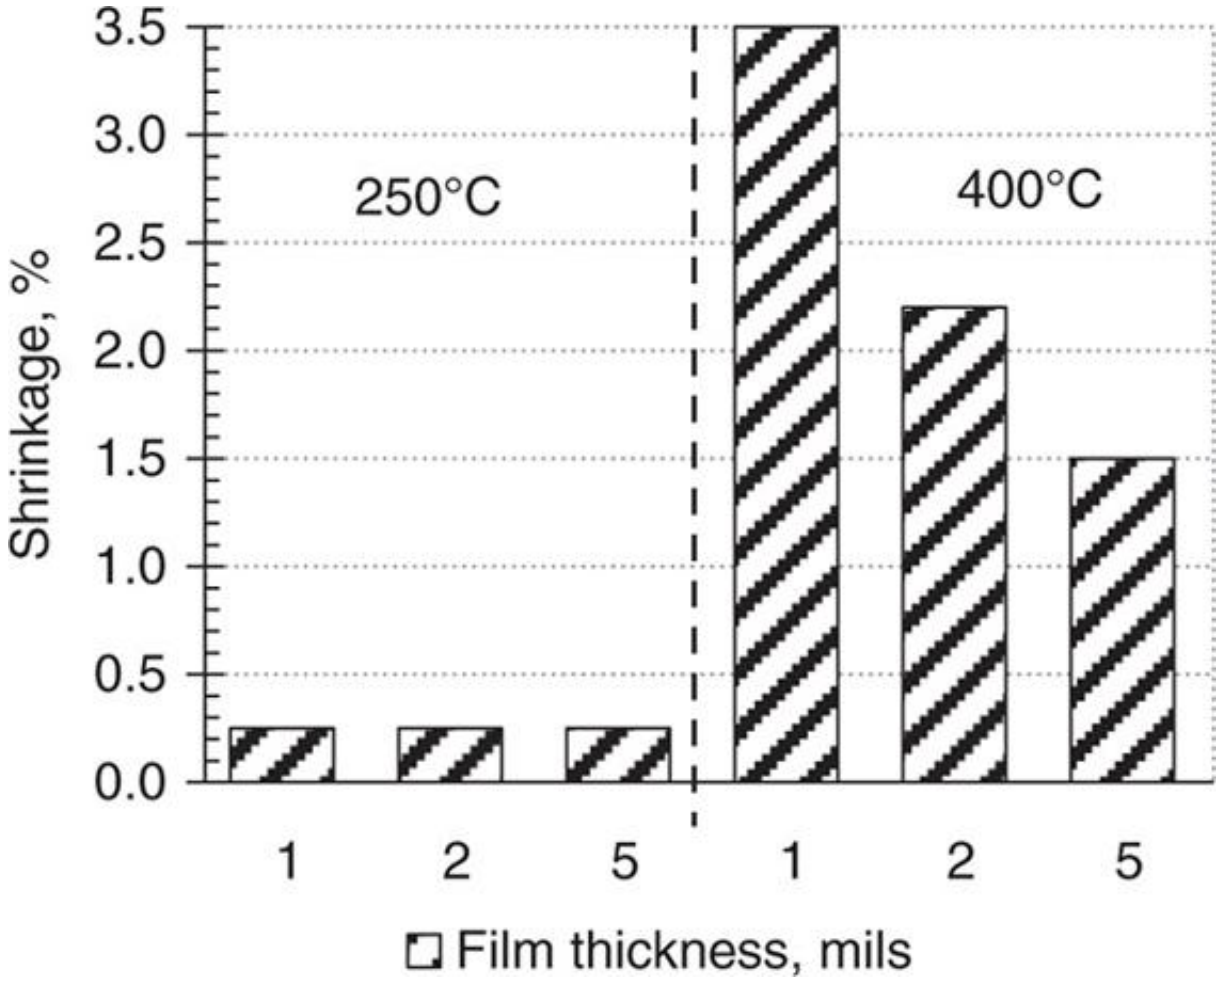

FIGURE 65.7 Residual shrinkage versus exposure temperature and gauge for 0.001 in, type H Kapton polyimide film.

TABLE 65.11 Thermal Coefficient of Expansion of Kapton Polyimide Film Thermally Exposed

Temperature Range, °C	K, in/(in)(°C) $\times 10^5$
23–100	1.80
100–200	3.10

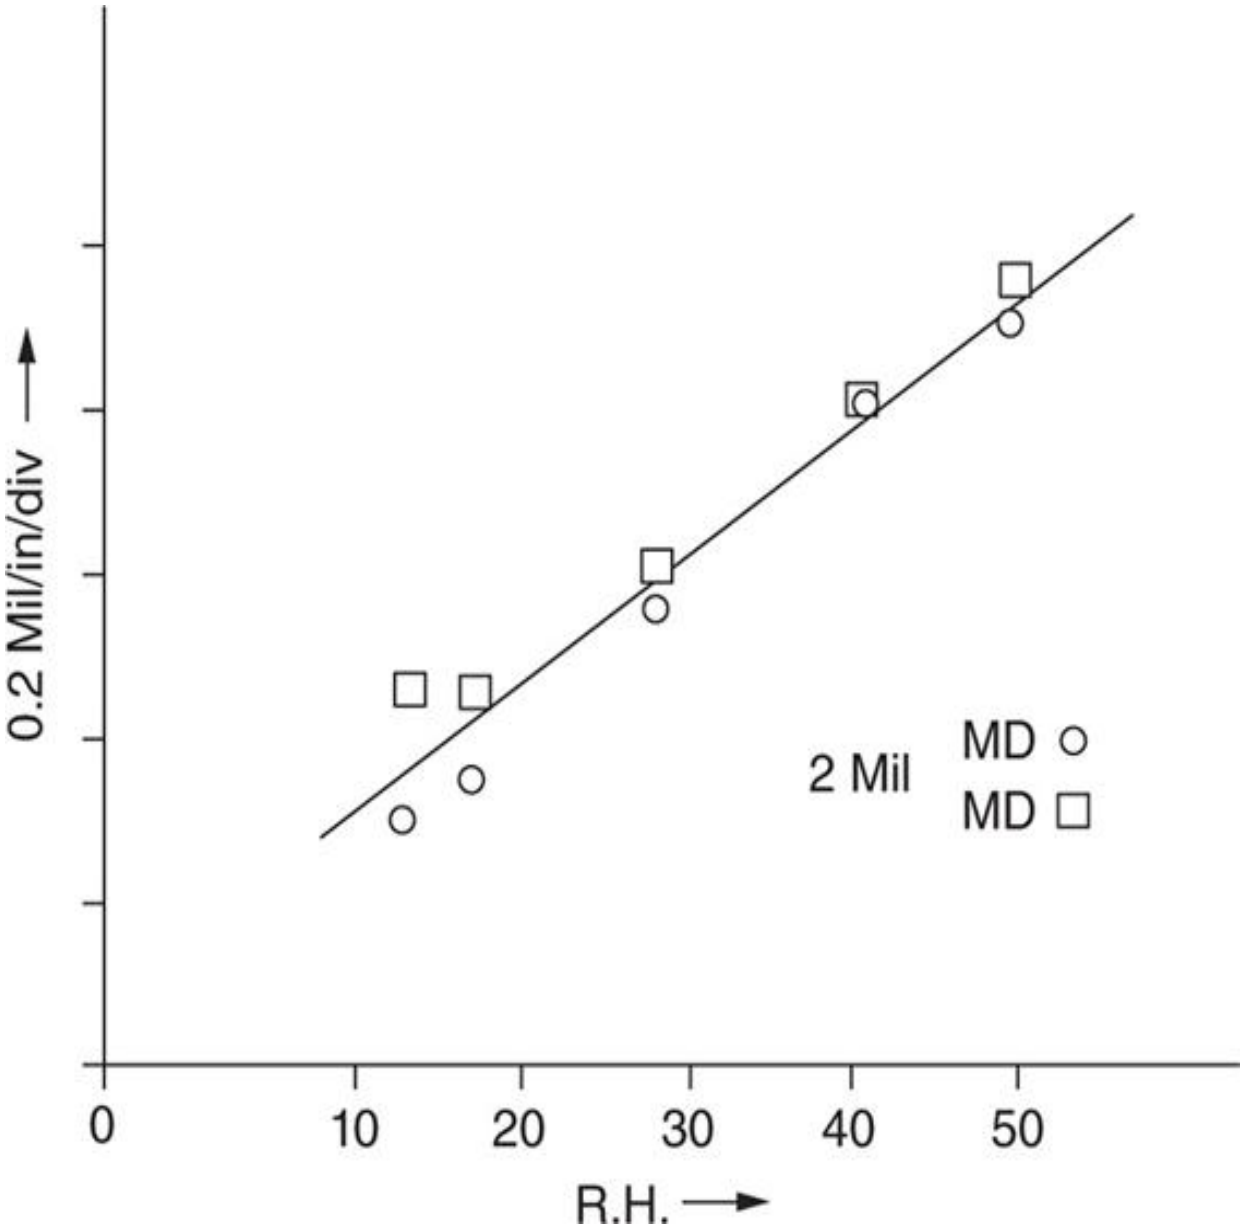

FIGURE 65.10 Dimensional change of Kapton film versus relative humidity.

- *Cut-through and cold-flow film:* Most organic films exhibit a tendency to flow or thin out under high compressive stresses, especially at elevated temperatures. Kapton film possesses an extremely high resistance to such stresses. Test procedures described: ASTM D-876-61 have been adapted to flat films to provide data in Figs. 65.11 and 65.12. Stresses range from an infinitely high point load to 12,000 psi at cut-through for 0.001 in film.

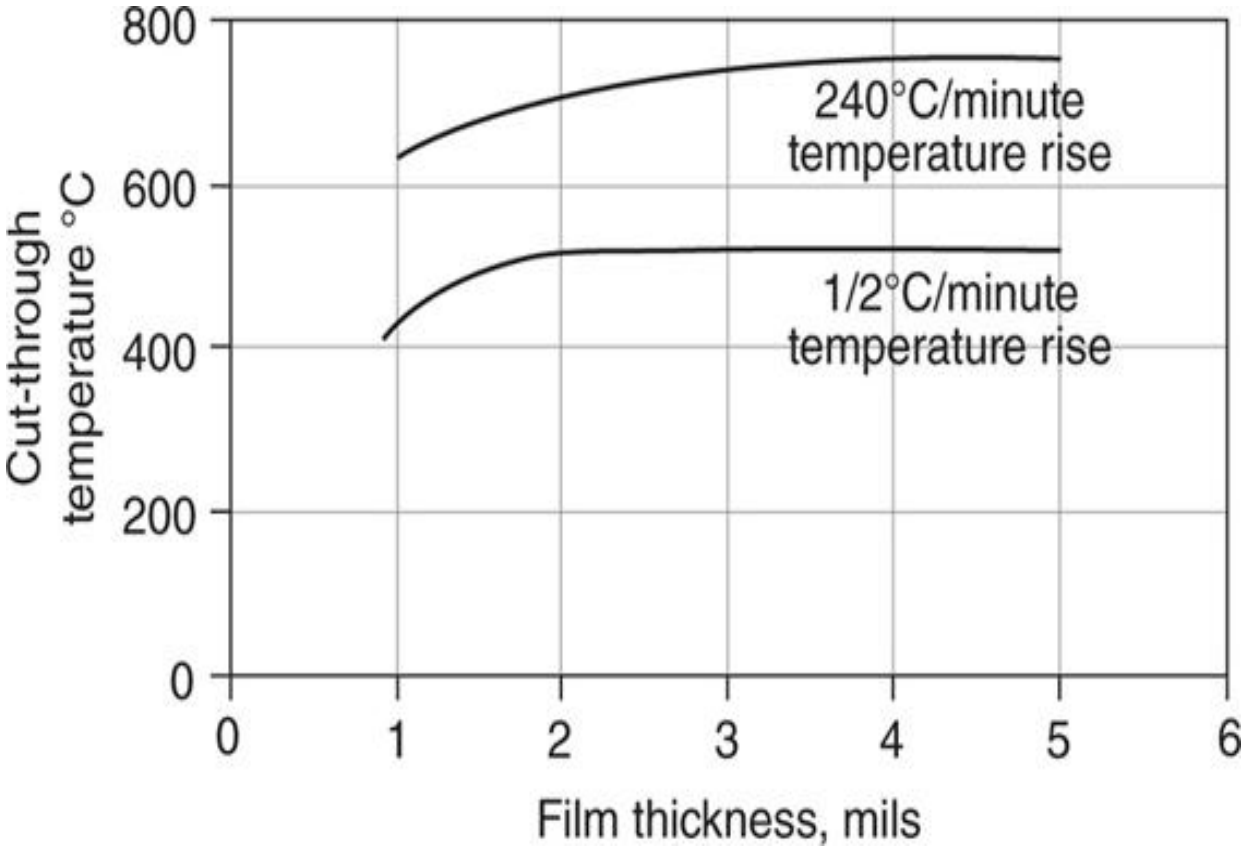

FIGURE 65.11 Cut-through temperature of Kapton film versus rate of temperature rise and gauge.

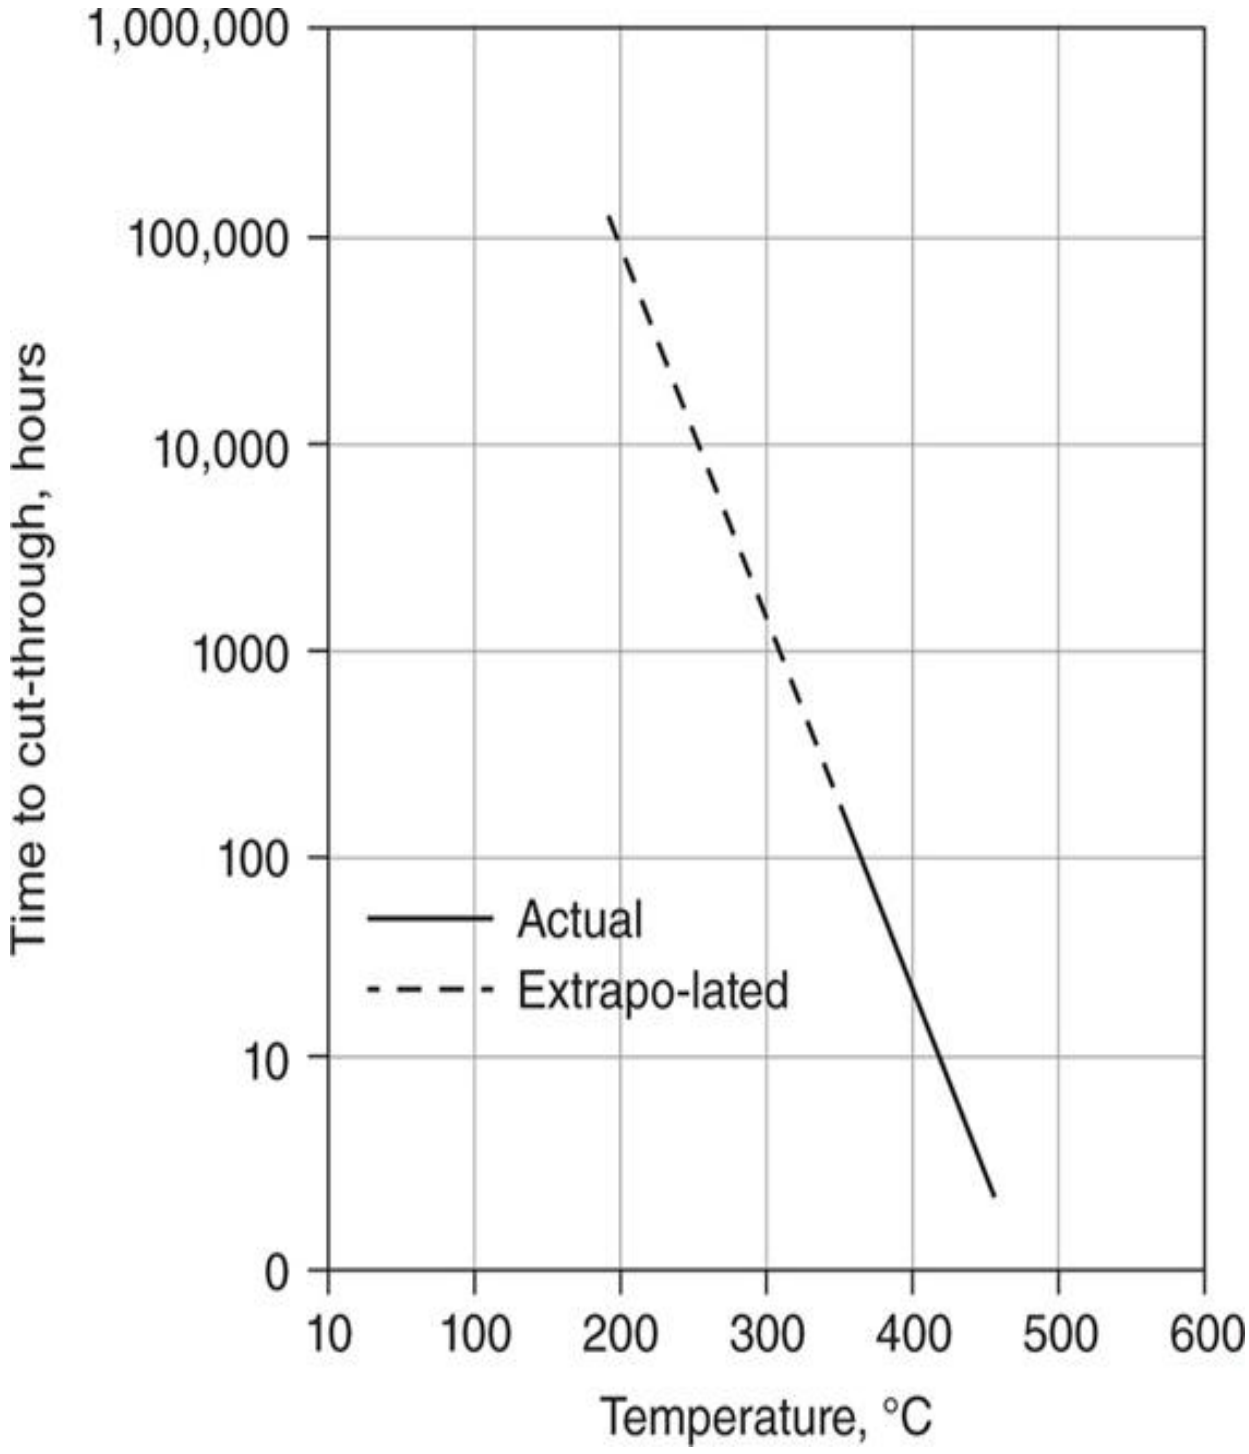

FIGURE 65.12 Resistance to cut-through temperature of Kapton film versus temperature.

Kapton film is subject to oxidative degradation. Therefore, its useful life is a function of both temperature and oxygen concentration in the test environment. The

effect of those factors is shown in Figs. 65.13 to 65.16 and Table 65.14.

- *Electrical properties of Kapton polyimide film* The most common electrical properties of Kapton film in various gauges are given in Table 65.15. They are measured at 25°C and 50 percent relative humidity. The effects of such factors as humidity, temperature, and frequency on these basic values are shown in forthcoming tables.

TABLE 65.15 Typical Electrical Properties of Kapton Polyimide Film

- *Effect of humidity* Because the water content of Kapton film can affect the film's electrical properties, electrical measurements are presented for 0.001-in film after exposure to environments of various humidities at 25°C. The amount of moisture absorbed in Kapton film depends upon the relative humidity, as shown in Fig. 65.17. Table 65.16 shows the effect of humidity on the electrical properties of Kapton film. The effect of temperature on the value of the dielectric constant and dissipation factor of Kapton film at various isotherms are shown in Figs. 65.18 to 65.21.

TABLE 65.16 Relative Humidity versus Electrical Properties of Kapton Polyimide Film

Relative Humidity, %*	AC Dielectric Strength, V/in × 10^{-3}	Dielectric Constant	Dissipation Factor
0	7800	3.0	0.0018
30	7300	3.3	0.0021
50	7000	3.5	0.0025
80	6500	3.7	0.0037
100	6200	3.9	0.0047

*For calculations involving absolute content, 50% RH in our study is equal to 1.3% water in the film and 100% RH is equal to 2.9% water, the maximum absorption possible regardless of the driving force.

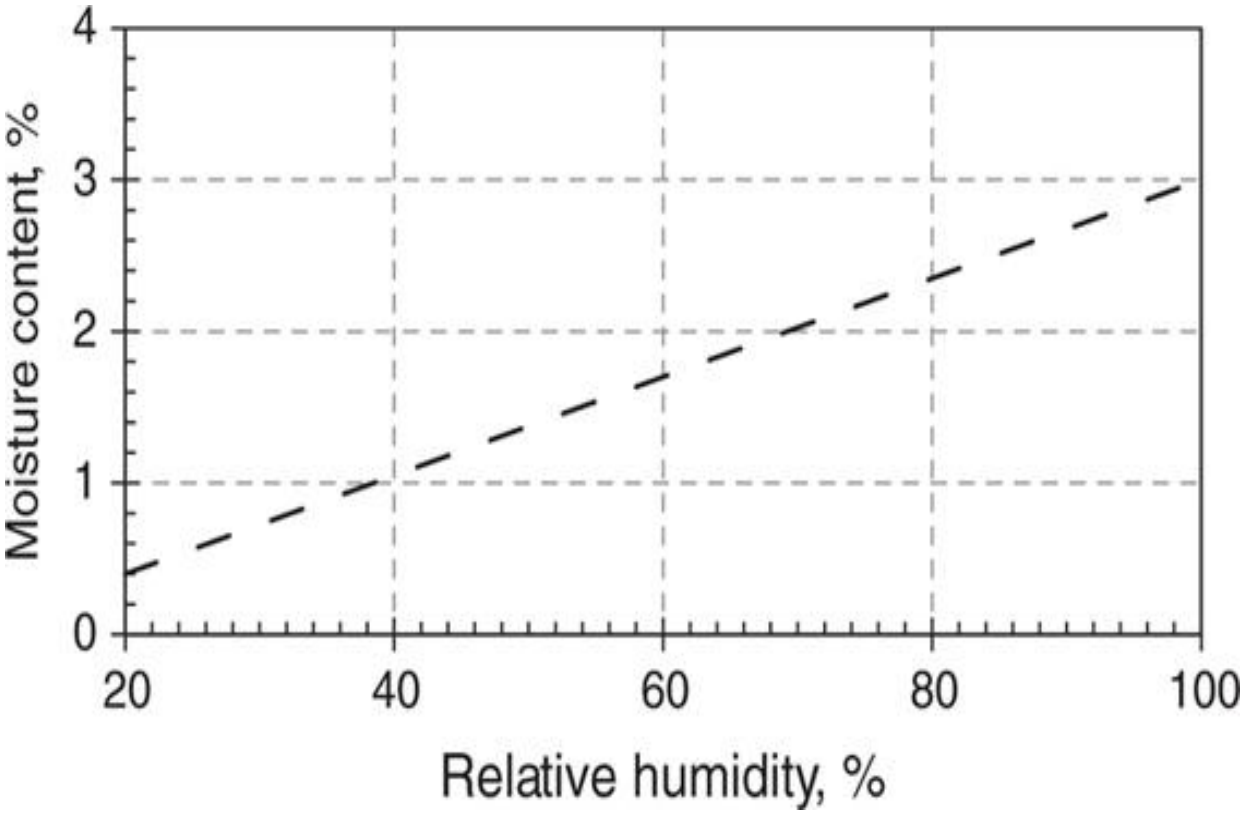

FIGURE 65.17 Moisture content of Kapton polyimide film versus typical relative humidity values at 23°C.

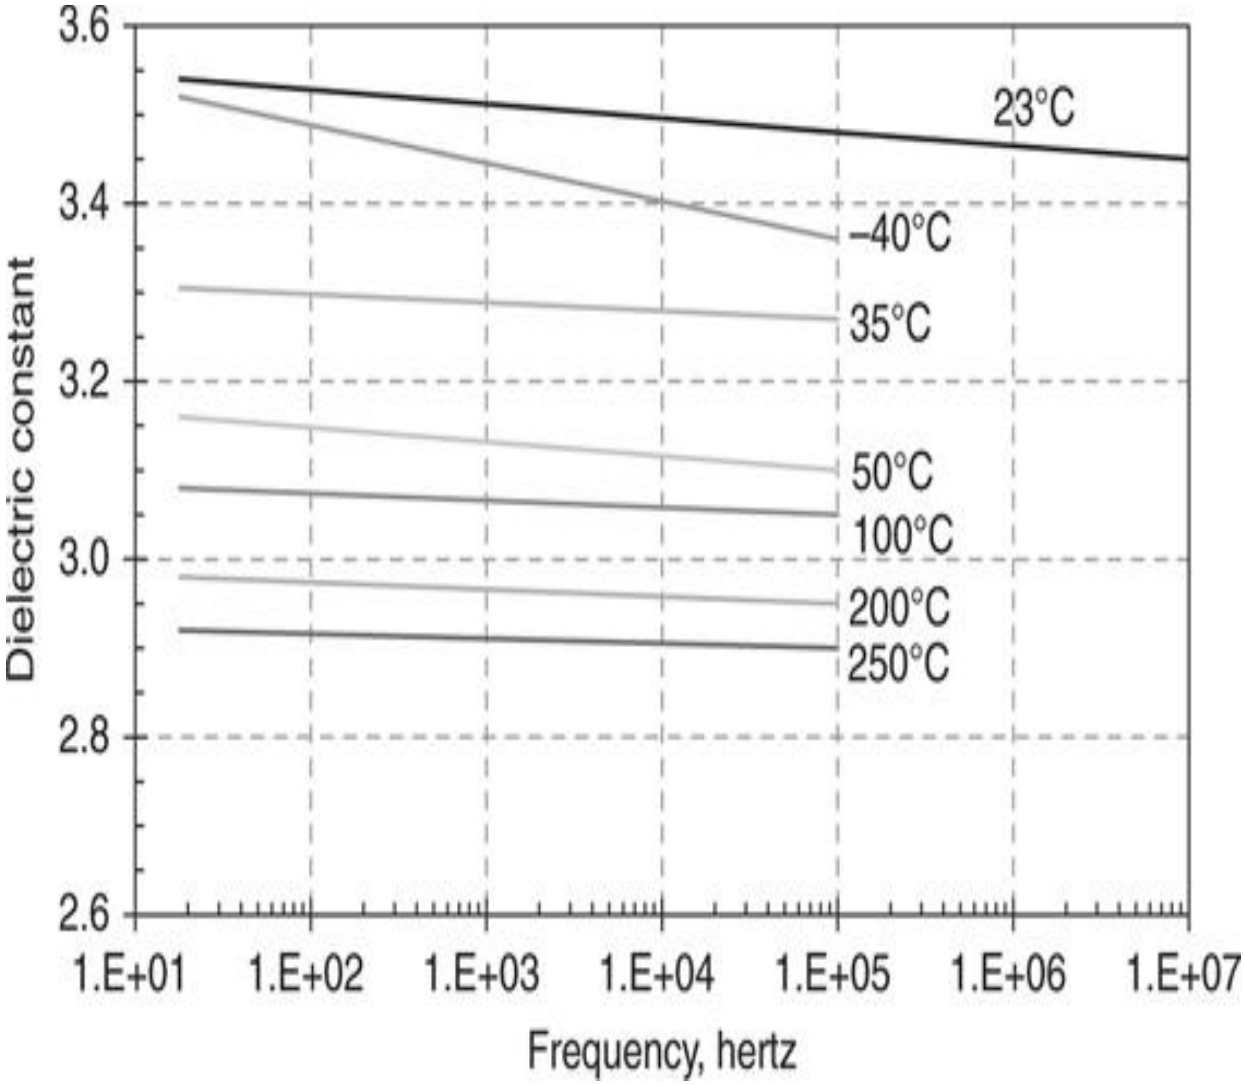

FIGURE 65.22 Volume resistivity of 0.001-in Kapton film versus temperature.

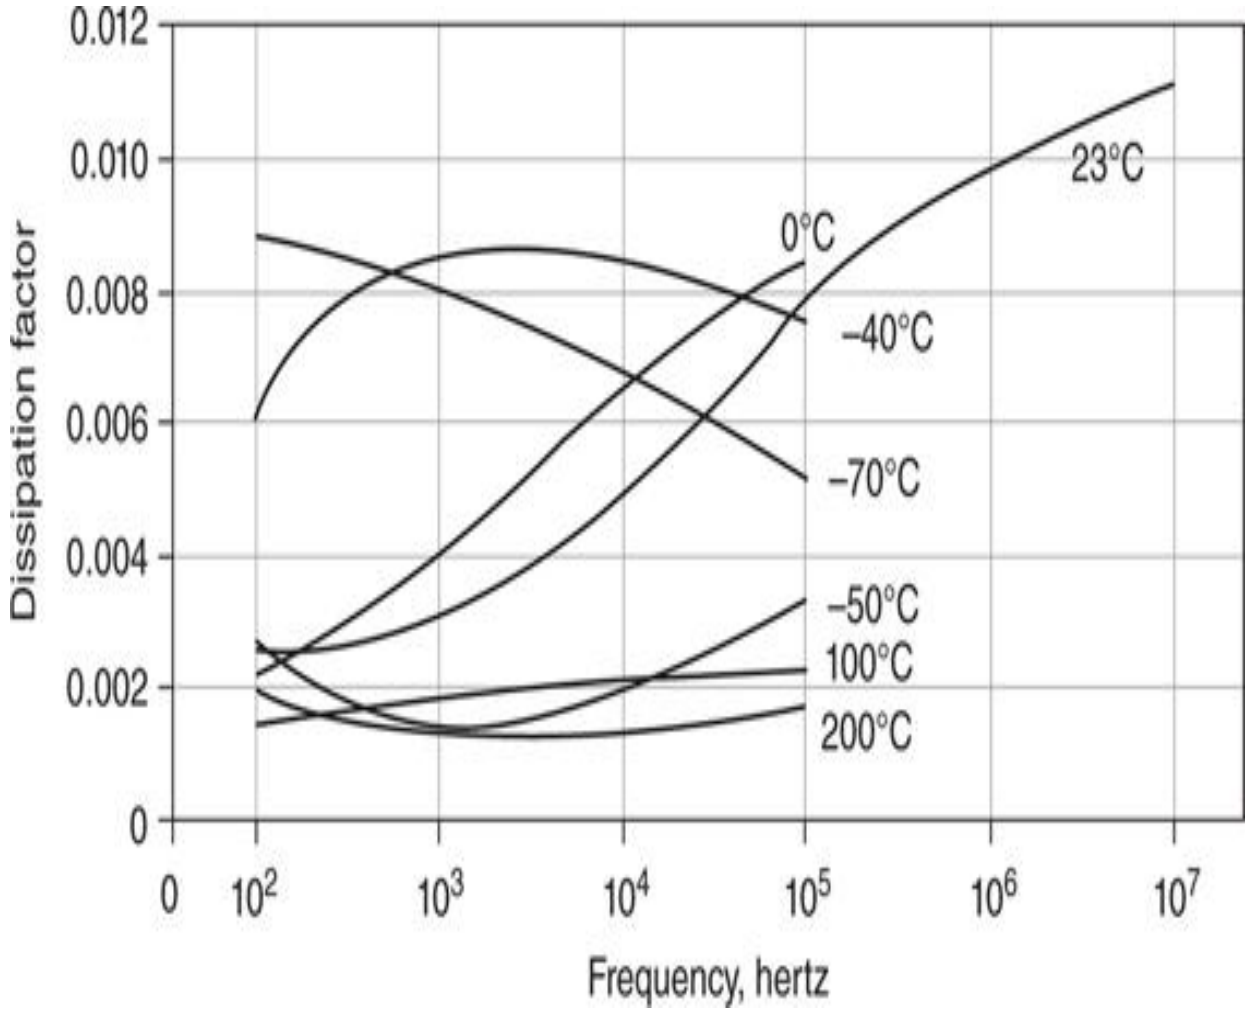

FIGURE 65.23 Volume resistivity of 0.001-in Kapton film versus temperature.

- *Conditioning prior to lamination Kapton polyimide film* In making and processing copper laminates and flexible printed wiring, it must be remembered that, under normal plant conditions, Kapton contains small amounts of moisture absorbed from the atmosphere. The moisture does not have a major effect on film properties, but it must be eliminated during high-temperature manufacturing and processing steps to avoid blisters and delamination in laminates and circuits.

During lamination to copper and any subsequent high-temperature processing steps, moisture must be dried from Kapton to avoid blistering and delamination of the film from

copper. Under severe high-temperature lamination conditions, embrittlement of the Kapton can occur. The rate at which moisture is absorbed or dried from Kapton depends on the temperature, relative humidity, film thickness and adhesive coating. Sheets of uncoated Kapton type H conditioned at 23°C, 100 percent RH and then placed in a 23°C, 0 percent RH dry box lost moisture at the rate shown in Table 65.17.

TABLE 65.17 Rate of drying of Kapton Polyimide Film at 23°C

Film Thickness, in	Time for Half of Moisture to Leave Film, min
0.001	3
0.002	10
0.003	21
0.005	54

65.5.3 Polyester Film

The most significant polyester used in the manufacture of flexible printed wiring is that referred to as Mylar, which chemically is polyethylene terephthalate. It is formed by the condensation reaction of ethylene glycol and terephthalic acid, and it is available only in film form. Its unusual balance of properties makes it especially useful in electrical and electronics fields as a replacement for heavier, conventional insulating materials. Mylar polyester film has a dielectric strength of 700 V/in $\times 10^{-3}$ for 0.001-in film, a tensile strength of 23,000 psi, and excellent resistance to most chemicals and moisture; it can withstand temperature extremes from −60 to 150°C. It remains flexible and does

not become brittle with age. Mylar can be laminated, embossed, metalized, punched, dyed, or coated. Adhesives are available for laminating it to itself and practically any other material. The film can also be coated with heat-sealable, friction, or abrasive materials.

There are eight types of Mylar polyester film. Each is manufactured in roll or sheet form in a range of thicknesses from 0.00025 to 0.0140 in and in widths from ½ to 60 to 72 in depending on gauge and type. It is important to know the correct type in order to specify properly. The individual types are as follows:

1. Type A. General-purpose; has exceptional high-temperature durability properties. It is available up to 0.014 in thick. This type is normally used in motors, wire and cable, lamination, and flexible printed wiring.
2. Type C. Has a higher level of insulation resistance than type A films; it also has more clarity and sparkle than type A film. It is especially designed for capacitors, and it is also normally used for metallization and metallic yarn.
3. Type D. Has high transparency in the heavier gauges. It is used in cartography and drafting and for graphic arts applications where appearance and dimensional stability are important.
4. Type HS. Used for jackets of capacitors. It shrinks 30 percent in both directions when heated to 100°C. The film remains strong and tough after shrinking.
5. Type M. Has a heat-sealable polymer coating and is highly moisture proof. Like all types of Mylar polyester film, it does not get brittle with age and has a long shelf life.
6. Type S. For stationery supplies, book jackets, and sheet protectors. The film is very transparent and has a brilliant surface.

7. Type T. Has an unusually high tensile strength in the longitudinal direction. It has more longitudinal stiffness than equivalent gauges of the other films. It is used for magnetic and pressure-sensitive tapes.
8. Type W. Resistant to the sun's ultraviolet radiation. It was specifically developed for exterior glazing applications. Greenhouses made with it last 4 to 7 years in sun or snow.

The important physical, thermal, and electrical properties of Mylar are given in Table 65.18. The properties of Mylar (polyester) and Kapton (polyimide) are similar except for the higher temperature capability of the polyimides films.

TABLE 65.18 Basic Properties of PET Films (Nonflammable Grade)

Test Items	Properties	
	MD	TD
Tensile strength (kgf/mm^2)	16	16

Dielectric constant	3.0 for 1 MHz	
Dielectric loss	0.03 for 1 MHz	
Breakdown voltage	13.6 kV	
Light transmission	46%	
Chemical resistance	Stable in weak acid and alkaline solution Stable in organic solvent	
Flammability	UL-94-VTM-0	

Data courtesy of Mitsubishi Plastic.

PET film (polyester film or polyethylene terephthalate) has been produced as a common film for general use, for the following reasons:

- It can provide a low-cost solution.
- It has excellent mechanical performance at room temperature.
- It has low moisture absorption and its dimensional stability is excellent.

Unfortunately, PET film cannot keep its high performance at higher temperatures than 70°C, and it is available for only nonsoldering applications. (Several soldering technologies have been developed for PET-based flexible circuits, but they are very specialized.) Also, PET films are flammable and it is difficult to achieve UL flame class certification. Not many available PET films can satisfy the flammability requirements of UL-94. Typical properties are shown in Table 65.18.

65.5.4 Other Materials Used for Flexible Circuits

Thin glass epoxy sheets less than 200 μm thick can be flexible and can be used as a base substrate of low-cost flexible circuits. Their physical properties are basically the same as those of rigid circuit boards, and standard manufacturing processes and assembling processes for rigid circuit boards are available for these materials. Standard soldering processes are applicable. But glass epoxy sheets do not have high flexibility, and they are not available for repeated flexing use. The basic properties of these materials are listed in Table 65.19.

TABLE 65.19 Properties of Thin Glass/Epoxy Substrate

Items	Risho Industrial		Matsushita Electric
	MD	TD	(R-5766 Series)

Bond strength (kg/cm)	—		1.39
Soldering resistance	—		260°C × 120 s
Flammability	—		UL-94-V-0

These materials are supplied as copper-clad laminates.

Fluorized carbon polymer films have been applied as a low-loss substrate material for flexible circuits. However, they do not have good dimensional stability or adhesion characteristics. High cost of the materials is the major reason that they cannot be standard in flexible circuits. In the last 20 years, several heat-resistant films, such as polypalabalic acid film and polysulfon film, have been

developed as alternative substrate materials in flexible circuits instead of polyimide films. Unfortunately, there was no successful material from a business standpoint. LCP films and PEEK have been considered as the new materials of high-speed flexible circuits based on the low dielectric constant and loss tangents.

65.6 CONDUCTOR MATERIALS

As flexible circuits have various mechanical stresses, their conductors also have requirements for more flexibility and toughness than traditional ED copper foils of standard rigid circuit boards. An RA copper foil is the solution for high flexing endurance. It is necessary for dynamic flexing use. RA copper foils are more expensive than ED copper, especially at thicknesses of less than 18 μm. Therefore, high-ductility electrodeposited (HD-ED) copper foils have been developed that have greater flexibility than ED copper foils and a lower cost than RA copper foils. The differences between the copper foils are shown in Table 65.20.

TABLE 65.20 Basic Properties of Copper Conductors

	ED Foil	HD-ED Foil	RA Foil
Manufacturer	Furukawa Electric	Furukawa Electric	Japan Energy
Grade	STD foil	HD foil	RA
Thickness (μm)	9, 12, 18, 35, 70	18, 35	12, 18, 35, 70
Tensile strength (kg/mm^2)	TD 34	TD 32	MD 21.5
			TD 18.9

			TD 9.5
Surface roughness (μm)	8	10	<3.5
Cost	Low	Middle	High

Data measured for 35-μm thick foils.

Due to the stringent requirements of fine-line etching, thinner copper foils have been developed with small surface profiles. RA copper foil 12 μm thick is a standard product. Low-profile 12-μm-thick ED copper foils have also been commercialized for fine-line etching. A special treatment has been developed to ensure reliable bond strength with each adhesive material. In the next 5 years, these materials will be standard and utilized in large volume. RA copper foils thinner than 10 μm are available; however, processing and high material costs need to be addressed before large-volume production can commence.

Copper foils thinner than 5 μm will be demanded for the semi-additive process to generate 10-μm wide traces or finer since the beginning of 2000s. Two types of technologies have been developed to have ultrathin copper foils. The first one is the “etch-down” process used to reduce the copper

thickness from standard thick RA copper foils. Through this process, foils 3 to 5 μm thick can be obtained from 12-μm RA copper foils. The second is the use of ultrathin foils. ED copper foils 1 to 5 μm thick have been commercialized with the carrier copper foils. Ultrathin copper layers have been built on the smooth surface of other copper foils with standard thickness. The carrier copper foils are removed mechanically after the lamination with the base layers. Ultrathin copper foils have been applied to adhesiveless laminates through casting or lamination processes.

In addition, sputtering and plating technologies have achieved conductors thinner than 5 μm with semi-additive processes. Among others, these processes can generate copper, nickel, and gold conductors. Also, they can produce fine traces at less than 10 μm pitch on flexible substrates. Plating baths and chemicals have been developed for these technologies.

Special metal and alloy foils other than copper ones have been developed for specific applications.

Aluminum conductors have been developed as the low-cost solution. They have been applied for volume production of the keyboards of calculators, antennas of wireless devices, and so on. But they could not be universal conductor materials of standard flexible circuits because of difficulty in soldering and the special chemistries needed for etching. The wireless suspension of disk drives has consumed a large volume of special stainless steel and copper alloy foils because of the special mechanical performance of the circuits. A high-resolution printer head has also utilized thin tungsten foils as the conductor of thermal printer head circuits. Nickel-chromium alloy foils have been developed as the conductor materials of flexible heater circuits.

65.7 COPPER-CLAD LAMINATES

The majority of flexible circuit manufacturers start the process with copper-clad materials. The properties of these materials depend on the capabilities of laminate manufacturers, even though the same base films and copper foils are used. To choose the right materials, manufacturers must carefully consider the basic properties of each laminate material.

65.7.1 Adhesive-Based Laminates

Historically, copper-clad laminates with acrylic or epoxy adhesives have been the major materials for flexible circuits. Each manufacturer has developed a special resin grade or special additives to ensure reliable flexibility and bond strength. Other adhesive materials such as phenol resin or silicon resin have been developed; however, they have not become standard adhesive materials in flexible circuits.

The adhesive-based copper-clad laminates still represent more than 50 percent of the traditional flexible circuit market. The major properties of the materials are shown in Table 65.21. The manufacturing process is illustrated in Fig. 65.24. Mostly, these films are processed and supplied in roll form. The surfaces of polyester films and polyimide films undergo special processes such as sandblasting and plasma treatment to achieve a reliable bond strength. A specially blended adhesive resin is coated on the film and dried. Then a copper foil is laminated continuously under appropriate temperature and pressure. The surfaces of the copper foils receive a specific treatment according to the requirements of each laminate's manufacturer.

TABLE 65.21 Basic Properties of Adhesive-Based Copper-Clad Laminates (Polyimide-Based)

Items	Properties		
Manufacturer	DuPont	Nikkan	Shin-Etsu
Grade	Pyralux LF	Nikaflex	RAR Series
Adhesive layer	Acrylic	Epoxy	Epoxy

Flammability	No	UL-94-VTM-0	UL-94-VTM-0

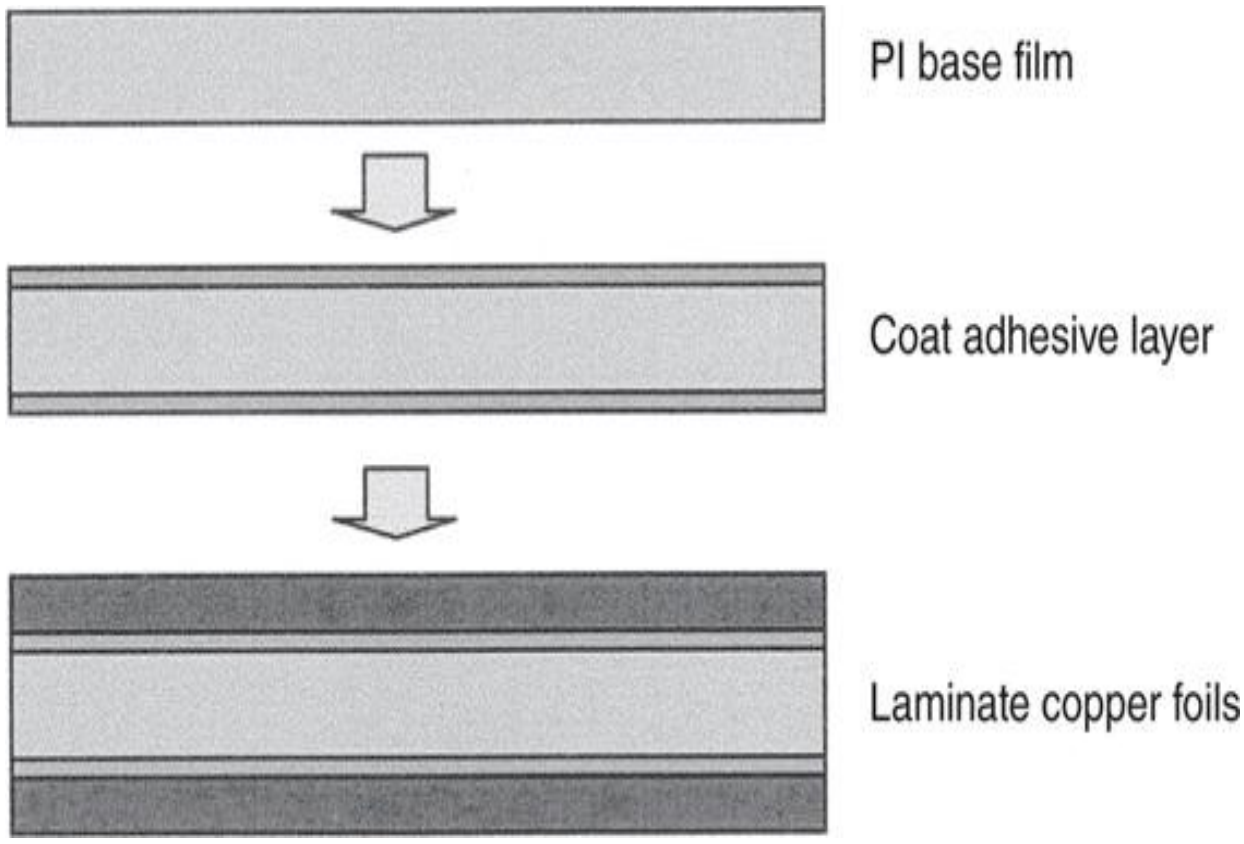

FIGURE 65.24 Manufacturing process for adhesive type laminate, showing a polyimide-based film combined with an adhesive layer coat and laminated to copper foils.

The same process is repeated for double-sided copper-clad laminates. (Some laminate manufacturers, however, have developed simplified manufacturing processes that can make the double-sided laminate in one single process to reduce manufacturing cost.) A well-conditioned aging process is important to achieving reliable bond strength and flexible characteristics of the laminates as the raw material of flexible circuits.

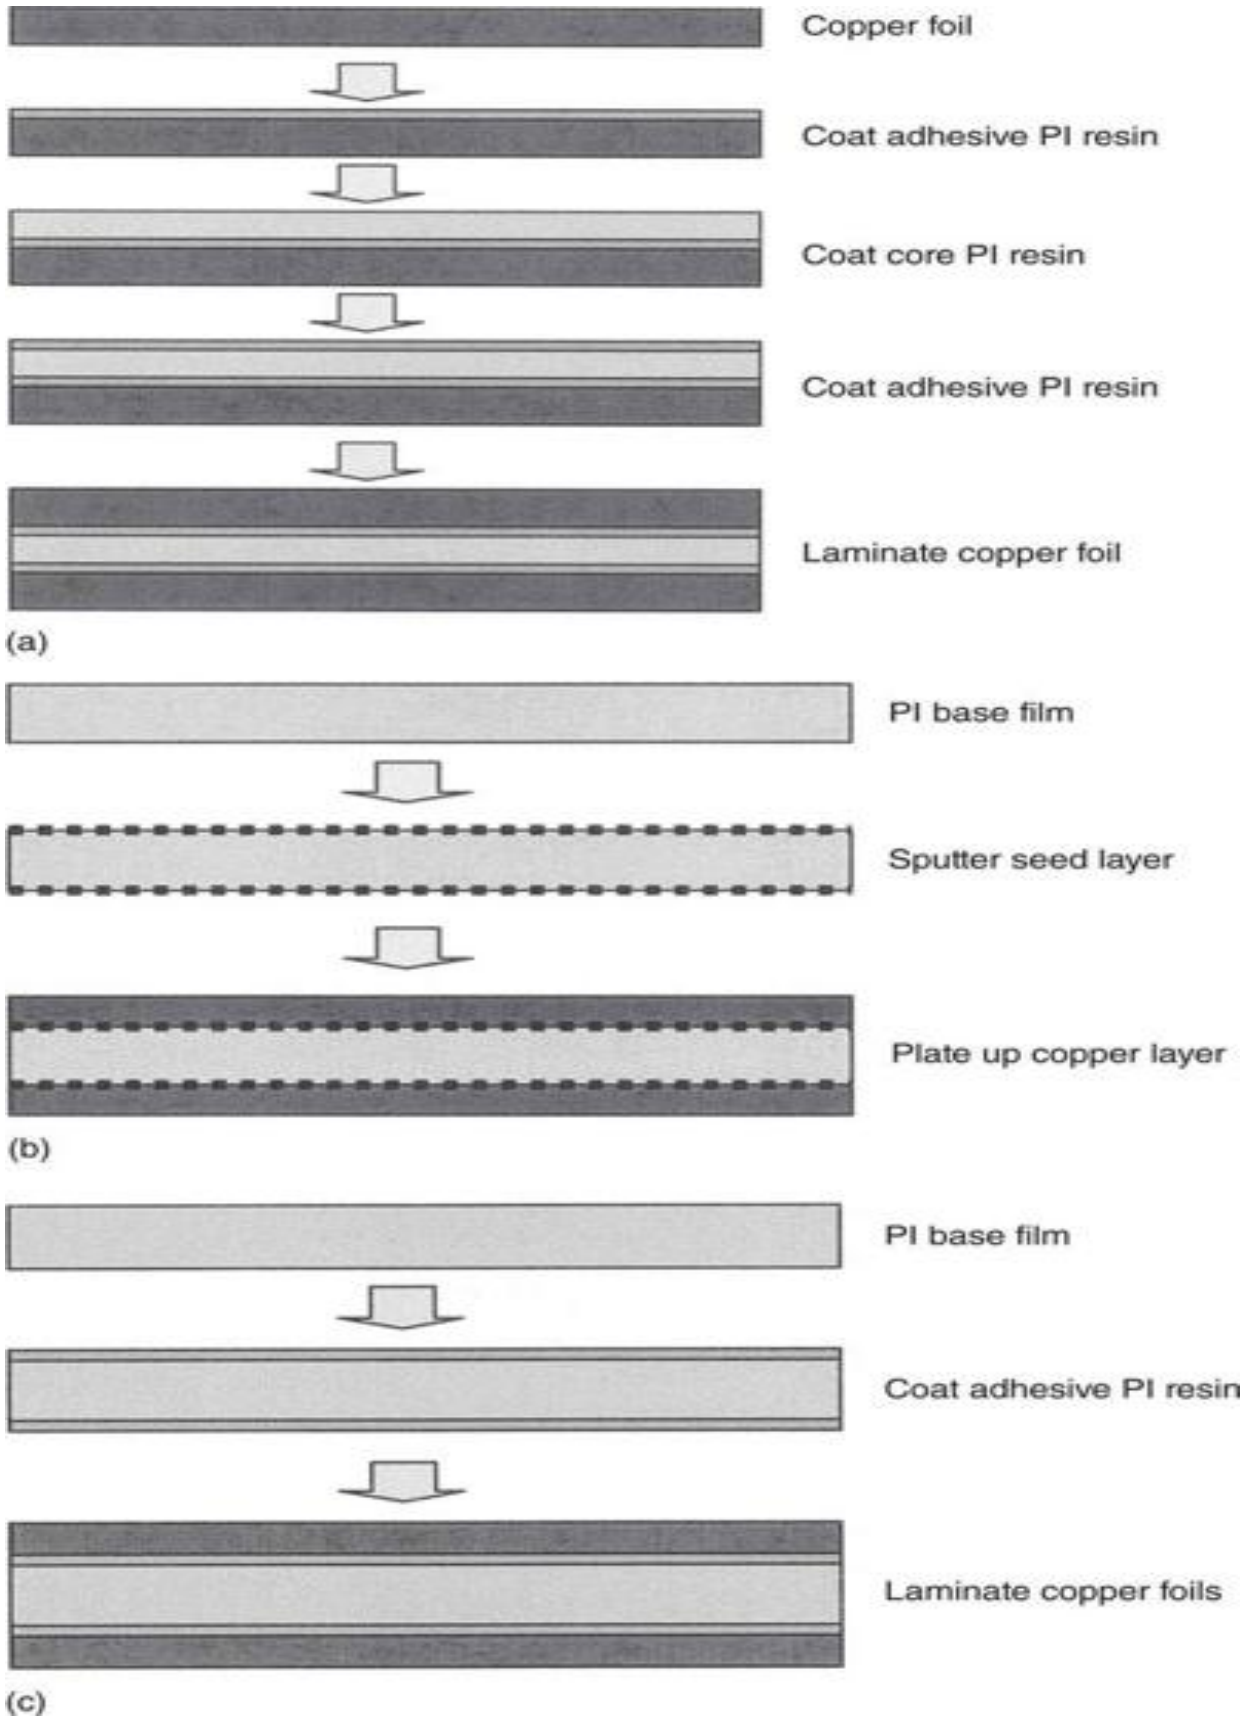
Most of the adhesive resins have lower heat resistances than polyimide films and are the bottleneck for high-temperature processing of flexible circuits (e.g., lead-free soldering and wirebonding).

The flame-retardant properties of the laminates depend on the composition of the adhesive materials used by each

manufacturer. Usually, a normal flame-retardant component in an adhesive resin has a negative effect on bonding. Several adhesive resins contain organic bromine molecules as the flame-retardant components, and will be eliminated for the ecological concerns. (For a discussion of this issue, see Chap. 6.) As soldering temperatures increase, heat-resistant adhesives or adhesiveless laminates systems are required.

65.7.2 Adhesiveless-Based Laminates

Several laminates without adhesive layers have been developed as the advanced materials for the next generation of flexible circuits. Lamination technology using epoxy resin or acrylic resin has been almost eliminated from HDI flexible circuits even though it uses new high-performance polyimide films as the substrates. Three types of adhesiveless copper-clad laminates have been developed (see Fig. 65.25):



Copper foil
Coat adhesive PI resin
Coat core PI resin
Coat adhesive PI resin
Laminate copper foil

FIGURE 65.25 (*a*) Manufacturing process of adhesiveless laminate using the cast process, (*b*) manufacturing process of adhesiveless laminate using plating process, (*c*) manufacturing process of adhesiveless laminate using lamination process.

- Cast
- Sputtering/plating
- Lamination

Each has different manufacturing processes and advantages as the major materials of HDI flexible circuits. Table 65.22 shows basic performances of typical adhesiveless laminate materials. Currently, there is no perfect solution that satisfies all requirements including cost. Suitable adhesiveless laminate materials should be chosen according to the specifications of the final flexible circuits and the convenience of manufacturing processes.

TABLE 65.22 Comparison of Adhesiveless Copper-Clad Laminates

Items	Sputtering/Plating Process	Cast Process	Lamination Process
Manufacturer	Gould Electronics	Nippon Steel Chemical	DuPont
Grade	GouldFlex	Espanex	Pyralux AP
Choice of dielectric	Wide	Small	Small
Base etchability	Fair	Difficult	Difficult
Dielectric thickness (μm)	12.5–125	12.5–50	12.5–150
Choice of conductors	Small	Wide	Wide
Conductor thickness (μm)	~35	12–70	12–70
Bond strength	1.2	1.5	1.4
Double-sided	Available	Available	Available
Flexing endurance	N/A	180 (MIT 0.8R)	N/A
Dimensional change after etching	MD: −0.05%	MD: −0.02%	MD: −0.05%

Roll clad	Standard	Standard	Not available

65.7.2.1 Cast-Type Adhesiveless Laminates. The cast-type adhesiveless laminates have a good cost/performance balance. They have a high bond strength between substrate layers and conductor foils. They can also use special conductors such as copper alloy, nickel, stainless steel, etc. In addition, they have good flexibility to generate

very thin substrate layers down to 12 µm thick. They can have a wide range of copper thicknesses because of the process. There is no difficulty in making 70- or 105-µm copper laminates. Because it has been around longer, the cast-type laminate has a relatively broader availability than other adhesiveless laminates. The process can produce both single-sided and double-sided laminates.

The liquid polyimide resins are coated on a metal foil, directly controlling mechanical stress on the materials. Air-floating conveyors have been employed to reduce the stress. A thermal treatment process is the key to ensuring good physical performance of the laminates. Generally, two or more polyimide layers are coated on the metal foil to ensure both good dimensional stability and high bond strength. Usually, it is difficult to apply the chemical etching process to adhesive polyimide resins using standard alkaline solutions.

Producing double-side laminates through casting requires a special process because the chemical imidation reaction generates a lot of moisture and results in delamination during the lamination process. One special process is to coat hot-melt-type polyimide on the top of the substrate layer, and another is to laminate another copper foil at high temperature and pressure. Physical performance varies depending on the combination of the polyimide resins and lamination conditions. Usually, higher temperatures than 300°C are required.

65.7.2.2 Sputtering/Plating-Type Adhesiveless Laminates. A two-step process is required to produce sputtering/plating-type adhesiveless laminates. The first step is a kind of sputtering process to produce seed layers on substrate films. The seed layers have two functions: to generate conductive layers on the nonconductive plastic films, and to increase the bonding strength between base films and conductor layers. Generally, the sputtered layers are thinner than 100 nm. Therefore, the second step builds

the thick conductor layers by electrical plating. To produce double-sided laminates, the process is usually repeated twice.

Sputtering/plating-type adhesiveless laminates can generate the thin conductors required for high-density circuits. Theoretically, these laminates provide stable conductor layers thinner than 10 μm at low cost. Technically, it is very possible to have 0.1- to 1.0-μm-thick conductors. Although plating-type laminates provide more substrate material choices, their basic physical properties depend heavily on substrates. The majority of manufacturers introduced the sputtering process to generate a seed layer for good bond strength between the substrate and the conductor. Two or three steps of sputtering processes with nickel, chromium, and their alloys are employed to strike a good balance of chemical, physical, and electrical performance. Sometimes seed layers cannot be etched.

Few choices are available for conductor materials. Thick conductors are not optimal because they require a longer plating process. Micron-size pinholes in the conductor layer are the biggest issue with this material. Several manufacturers have introduced additional chemical processes to eliminate these pinholes. Generally, the bond strength of the laminate is lower than that of other types.

65.7.2.3 Lamination-Type Adhesiveless Laminates.

Thermoplastic-type polyimide resins with high-temperature melting points have been developed to serve as the hot-melt adhesives between copper foils and dimensionally stable polyimide films. The adhesiveless flexible laminates are produced by a heat lamination of the copper foils and base polyimide films that have thin hot-melt polyimide layers coated on the surface of the core polyimide films. The polyimide films, with hot-melt polyimide layers, are supplied by the major polyimide film suppliers. Temperatures higher than 330°C are required to produce

reliable laminates. Materials processed at temperatures lower than 200°C are available for several hot-melt polyimide resins; however, their physical properties are inferior to those of standard laminates.

Producing double-sided laminates is not tremendously difficult. A conventional vacuum heat press with a higher processing temperature than 350°C is available to produce the laminate for small-volume production. A high-temperature roll laminator or belt laminator is used for high volume production.

Lamination-type adhesiveless laminates have advantages in small-volume production. Special polyimide films that have hot-melt polyimide resin on the surface of dimensionally stable polyimide film are available commercially. If a manufacturer has high-temperature heat press equipment, it is not difficult to produce the laminates. A compact roll-type heat laminator was developed to produce the rolled laminates.

Many choices of conductor materials are available for lamination-type adhesiveless laminates. Due to the special combination of conductor materials with stainless steel and copper alloy foils, this material has a variety of uses in multilayer rigid/flexible aerospace applications and in wireless suspension of disk drives. Generally, the adhesive polyimide is difficult to etch using standard alkaline etching solutions, so strong chemistry or a physical process such as plasma etching is required for the process.

Figure 65.26 shows the thickness ranges available for the substrates and conductors for each type material. All of the laminates have expanded their capabilities, and several thicknesses are overlapped. Therefore, circuit manufacturers have more choices for specific thicknesses and can consider other performance variables, including cost.

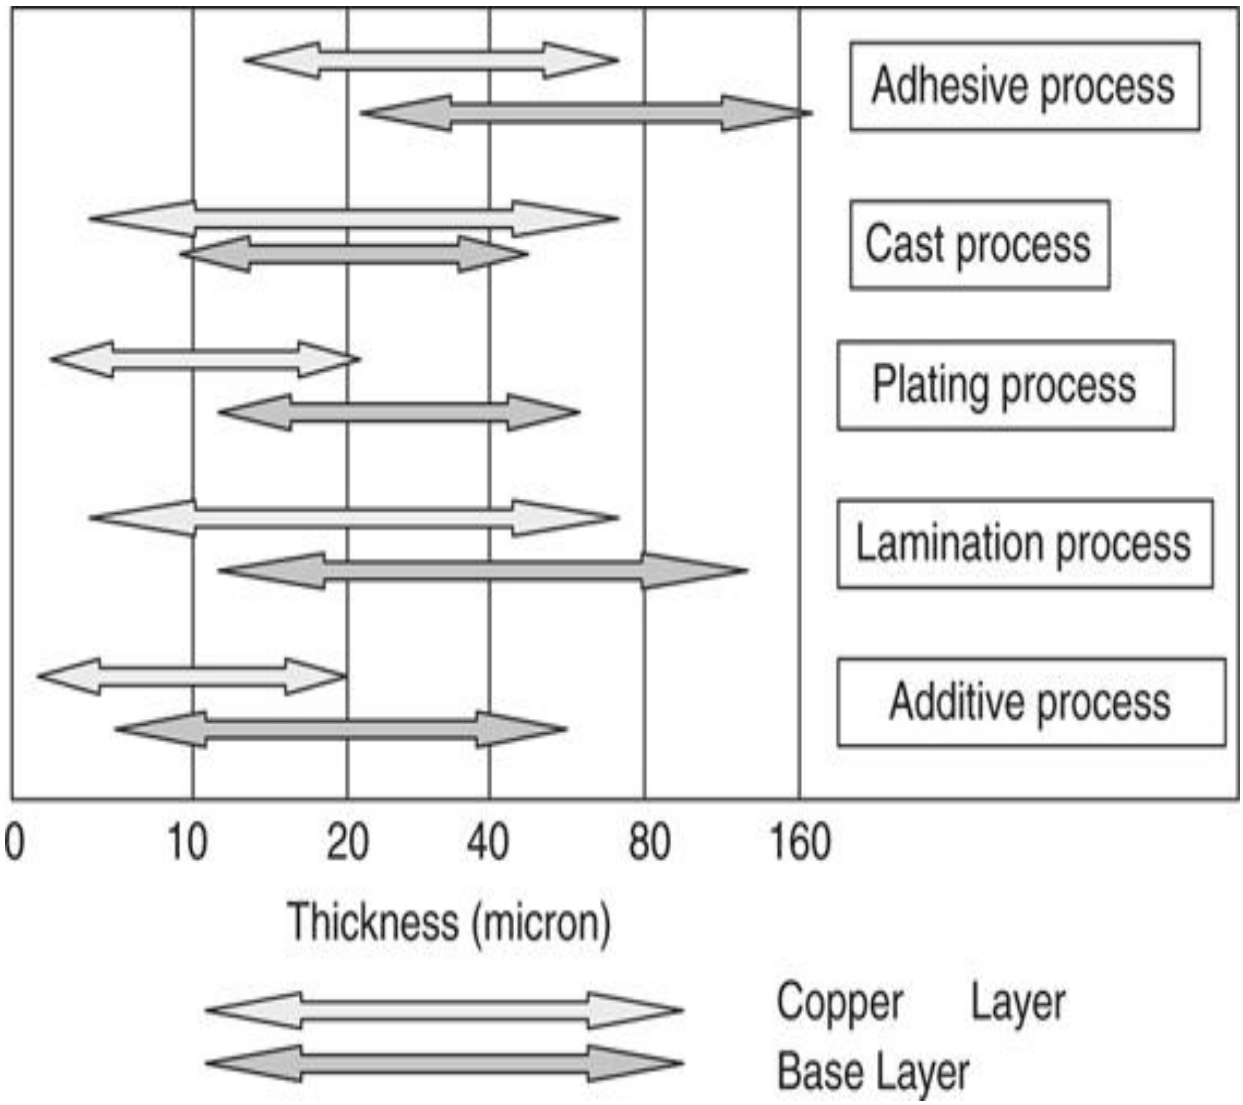

FIGURE 65.26 Thickness range of the copper-clad laminates.

65.8 COVERLAY MATERIALS

One of the major differences between flexible circuits and rigid circuit boards is coverlay. In addition to the solder mask used for assembly, coverlay is the mechanical protector for the fragile conductors on flexible circuits. Film-based coverlay and flexible solder mask have been standard materials for traditional flexible circuits. Several types of photoimageable coverlay materials have been developed to

satisfy the fine-resolution requirements of HDI flexible circuits:

- Film coverlay
- Screen-printable coverlay (flexible soldermask)
- Photoimageable coverlay (dry-film type and liquid type)

Several types of the materials are available for each coverlay type.

65.8.1 Film Coverlay

Usually the same films are chosen for the coverlay films as are used for the substrate layers. The films are coated with semicured acrylic or epoxy resin, which is used as an adhesive layer. The surfaces of the adhesive layers are covered with release films when the materials are delivered to circuit manufacturers. Semicured adhesive resins are unstable at room temperature, so film coverlay must be kept in refrigerators. The adhesive resins of the coverlay usually have only weeks of pot life even when they are kept in low-temperature environments, and exact conditioning is required for processing.

The process of manufacturing with film coverlay is very complicated, which makes process automation difficult and increases the cost. The manual registration process and the use of unstable film material are major issues when considering film coverlay for HDI flexible circuits due to small hole capability and lower dimensional accuracy. Basic properties of the typical materials are shown in Table 65.23.

TABLE 65.23 Basic Properties of Film Coverlay (Polyimide Film Base)

Manufacturer	DuPont	Nikkan Industry
Grade	Pyralux LF	CISV
Adhesive	Acrylic	Epoxy
Lamination temperature	180°C	160°C
Storage condition	Room temperature	Refrigerator
Bond strength (kg/cm)	1.3	1.0
Surface resistivity (Ω)	1.0 × exp 13	3.0 × exp 14
Volume resistivity (Ω-cm)	1.0 × exp 14	1.2 × exp 16
Soldering resistance	288°C × 5 min	280°C × 10 s
Flammability	No	UL-94-V-0

65.8.2 Screen-Printable Coverlay Ink (Flexible Solder Mask)

A screen-printing process similar to that used for rigid circuit boards is available for flexible circuits as the low-cost coverlay process. However, specially conditioned liquid solder mask materials are required to produce appropriate flexibility for the circuits. Standard solder mask materials designed for the rigid boards have small cracks and delaminations when bending. Basic properties of the typical materials are shown in Table 65.24.

TABLE 65.24 Basic Properties of Screen-Printable Coverlay

Manufacturer	Taiyo Ink	Nippon Polytech
Grade	S-222	NPR-5
Base resin	Epoxy	Epoxy
Color	Green	Green
Hardness	5H	H
Peel strength	100/100 (crosshatch)	100/100 (crosshatch)
Flexibility	N/A	0.5 mm diameter
Soldering resistance	260°C × 20 s	260°C × 20 s
Insulation resistance (Ω)	>1 × exp 13	>1 × exp 12
Flammability	UL-94-V-0	UL-94-V-0

Generally, because of poor resolution, a screen-printing process does not satisfy the requirements of high-density SMT assembling on flexible circuits. Also, such as process does not provide good mechanical performance for dynamic flexing. Typical property examples are shown in Table 65.25.

65.8.3 Dry-Film–Type Photoimageable Coverlay

The basic idea of the photoimageable coverlay is to satisfy both of fine resolutions of the opening and physical flexibility by one single material. Also, its simple manufacturing process should reduce costs.

From a processing standpoint, there are two types of PIC materials: dry film and liquid. The dry-film type is easily processed when manufactured with vacuum laminators, which provide good encapsulation with the fine conductors. A vacuum press is also available for a small-volume production. However, the cost per unit area is higher for the dry-film type than for liquid materials.

Dry-film–type and liquid ink–type photoimageable coverlay materials have been developed with different resin matrixes to satisfy different technical requirements of HDI flexible circuits. A comparison of the materials is given in Table 65.26. Properties of the materials are shown in Tables 65.27 and 65.28.

TABLE 65.26 Comparison of Photoimageable Coverlay Materials

	Dry Film Type		Liquid Ink Type	
	Acrylic-Base/Epoxy-Base	Polyimide-Base	Epoxy-Base	Polyimide-Base

The materials were developed assuming different applications; therefore, measured data are not exactly equivalent.

65.8.3.1 Acrylic or Epoxy/Dry-Film Type. Acrylic or epoxy/dry-film types were the first materials developed to act as the flexible photoimageable coverlay for HDI flexible circuits. They have the same product concept as the photoimageable solder mask of rigid circuit boards. The same vacuum laminators and imaging equipment are available for these materials.

Managing the conditioning of the process is not difficult. Acrylic or epoxy/dry-film types are good for small-volume production because of the flexible manufacturing process. They may need some more improvements in electrical performance and chemical resistance if they are to be used in the general application of high-density flexible circuits. The present version of the materials, however, yields a good balance of performances for both high-density soldering and flexing endurance.

65.8.3.2 Polyimide/Dry-Film Type. The physical performance of the polyimide/dry-film type is excellent. When applied to polyimide-based adhesiveless laminates, it provides very high heat resistance and good dimensional stability. Also, it has high electrical properties. It has been applied in high-density wiring of interconnection in the head suspension of disk drives. The major issues with this material are the complicated pattern-generation process and high material cost. It requires multiple chemical processes using special chemical solutions. A high-temperature baking of over 250°C is another difficulty. This is required to complete the standard manufacturing process of flexible circuits.

65.8.4 Liquid-Based Photoimageable Coverlay

Eventually, photoimageable coverlay could be the practical solution for HDI flexible circuits in large-volume production. It

is similar to the solder mask of rigid circuit boards; however, the materials for flexible circuits must have high flexibility. None of the materials developed as solder masks for rigid boards are available for flexible circuits, even though dynamic flexing is not required. The liquid PIC requires special coating equipment such as a screen printer or sprayer. It can, however, provide a low-cost coverlay for large-volume production.

65.8.4.1 Epoxy/Liquid Ink. This material combination has been providing the best cost/performance combination for large-volume applications. Many manufacturers have tried to develop a good photoimageable coverlay with this combination, and Table 65.29 shows several successful examples. They provide good performance balances in mechanical, electrical, and chemical properties. A specialty is that these materials yield higher flexibility, without serious curling during the thermal processing, than other materials offer.

TABLE 65.29 Comparison of Stiffener Materials

	Paper/Phenol	Glass Epoxy	Polyimide	Polyester	Metal
Thickness range (μm)	500–2500	100–2000	25–125	25–250	Very wide
Soldering	Possible	Possible	Possible	No	Possible
Adhesion by thermoset resin	No	Possible	Possible	No	Possible
Cost	Low	High	Medium	Low	Medium

These materials are available by screen printing, spray coating, and other coating methods. UL-certified grades are available for commercial use. The flexibility of the materials allows several cycles of bending; however, the materials are

not available for the long-term flexing that applications such as hard disk drives and printers require.

65.8.4.2 Polyimide/Liquid Ink. This material concept was generated as the reliable thin dielectric layer of flexible circuits for both substrates and coverlay. Polyimide/liquid ink is highly reliable for a wide range of thicknesses. A 10-μm-thick layer could have sufficient performance to be a coverlay of a high-density flexible circuit. An appropriate combination with an adhesiveless copper laminate allows long-term dynamic flexing. The major issues are short pot life and high cost. Some of the ink materials must be stored at a temperature lower than 0°C. The materials require severe process conditions, especially for the final curing, where they require a temperature higher than 300°C. The cost of polyimide-based photoimageable materials is 5 to 10 times higher than for epoxy-based materials.

65.9 STIFFENER MATERIALS

All kinds of sheet or board material could be used as stiffener materials for the flexible circuits; however, several materials are commonly used. Typical stiffener materials for the traditional flexible circuits are listed in Table 65.29. Paper phenol boards and glass epoxy boards are employed for relatively thick requirements. Polyimide films and polyester films are employed for relatively thin requirements. Aluminum plates and stainless steel plates are commonly used as the stiffener materials of flexible circuits. A specialty of the metal stiffeners is their forming capabilities after they are bonded on flexible circuits. Paper phenol and polyester are not available for thermo-setting adhesives because of the low heat resistance.

65.10 ADHESIVE MATERIALS

Several different types of adhesive materials can be used in flexible circuits depending on the application, except for the adhesive layer of copper laminates and film coverlays. The major applications are the bonding of stiffeners and multilayer constructions.

Table 65.30 compares the materials. Pressure-sensitive adhesives (PSAs) provide a low-cost solution due to their simple application process. A problem of PSA is creep characteristics under mechanical stress, as PSA cannot maintain the exact positions of the stiffener boards under the stress. Thermosetting adhesives provide a reliable bonding between the layers, but they require a long processing time in a heat press with suitable press pad materials and impose a higher processing cost.

TABLE 65.30 Comparison of Adhesive Materials for Flexible Circuits

	Thermosetting Epoxy and Acrylic Resin	Hot-Melt-Type Polyimide Resin	Pressure-Sensitive Adhesives (PSAs)
Reliability	High	High	Acceptable
Bond strength	High	High	Acceptable
Creep	Small	Small	Large
Soldering	OK	OK	OK
Application process	Complicated	Complicated	Simple
Process temperature	160–180°C	>330°C	Room temperature
Material cost	Low	High	Low
Total cost	High	Very high	Low

Usually, the adhesive materials are supplied on or between separation sheets by rolled form. They should be kept in the refrigerators. The mechanical pretreatments are conducted with the separation sheets.

65.11 RESTRICTION OF HAZARDOUS SUBSTANCE ISSUES

Two issues have arisen regarding restriction of hazardous substance issue (RoHS) requirements for the flexible circuit materials: flame-retardant molecules with bromine in adhesive resins, and heat resistance for high-temperature processing with lead-free soldering. Although the issue of bromine is not actually a part of the RoHS requirement, it has been linked to the general environmental issues of printed circuit materials and processes.

Adhesiveless copper laminates can be the solution for the both of these problems because they do not use adhesive layers and have much higher heat resistance than adhesive-based laminates. However, because some of the applications need adhesive-based copper laminates, manufacturers of flexible laminates have been developing alternative materials without bromine-based flame-retardant reagents.

There have been technical barriers to developing new materials with a good balance of performances for coverlay eliminating bromine compounds. Film coverlay have to have an adhesive layer with some flame-retardant reagent. Few new epoxy resins have good balance for all of the physical performances without bromine compounds.

New materials of photoimageable coverlay have been developed without bromine molecules. Not many choices offer a balanced performance, especially high flexibilities for dynamic flexing. Polyimide-based photoimageable coverlays are the solution to satisfy the all of the physical

requirements, but these polyimide materials are remarkably more expensive.

65.12 ACKNOWLEDGMENTS

The author extends his appreciation to the industry and the many who contributed to the progress of flexible circuit activities, specifically J. R. Cannizzaro, who authored this chapter in prior *Printed Circuits Handbooks*. Sincere thanks also goes to Dominique K. Numakura, at DKN Research, for his authorship of this chapter in the previous (6th) edition of *Printed Circuits Handbook*.

CHAPTER 66
DESIGN OF FLEXIBLE CIRCUITS

Happy T. Holden
Co-Editor-in-Chief, Printed Circuits Handbook, *and PCB Technologist, Zeeland, Michigan*

66.1 INTRODUCTION

Because of the broad wiring capabilities now available, it is possible to cover all 3D wiring of an electronic product by one flex circuit, or by a set of multilayer rigid/flex circuits, without the need for connectors, extra cables, and soldering. However, to achieve this, the shape of the flex circuit may be very complicated and the size may be large. As a result, the final cost could be extremely high. If so, the use of flexible circuits is not an acceptable solution, especially for large-volume consumer applications. It may be better to divide the wiring into two or more parts to make each circuit simpler. A combination of simple circuits can be less expensive than one flex circuit, even though it mandates several connections between different circuits. A circuit designer should also consider the manufacturing convenience of flex circuits. There are serious differences among rigid circuit

boards. A small design modification can sometimes reduce the total cost significantly.

66.1.1 Design Procedure

To achieve the best cost-performance combination for a wiring design with flex circuits, an appropriate design procedure is recommended, as illustrated in Fig. 66.1. The steps in the process are as follows:

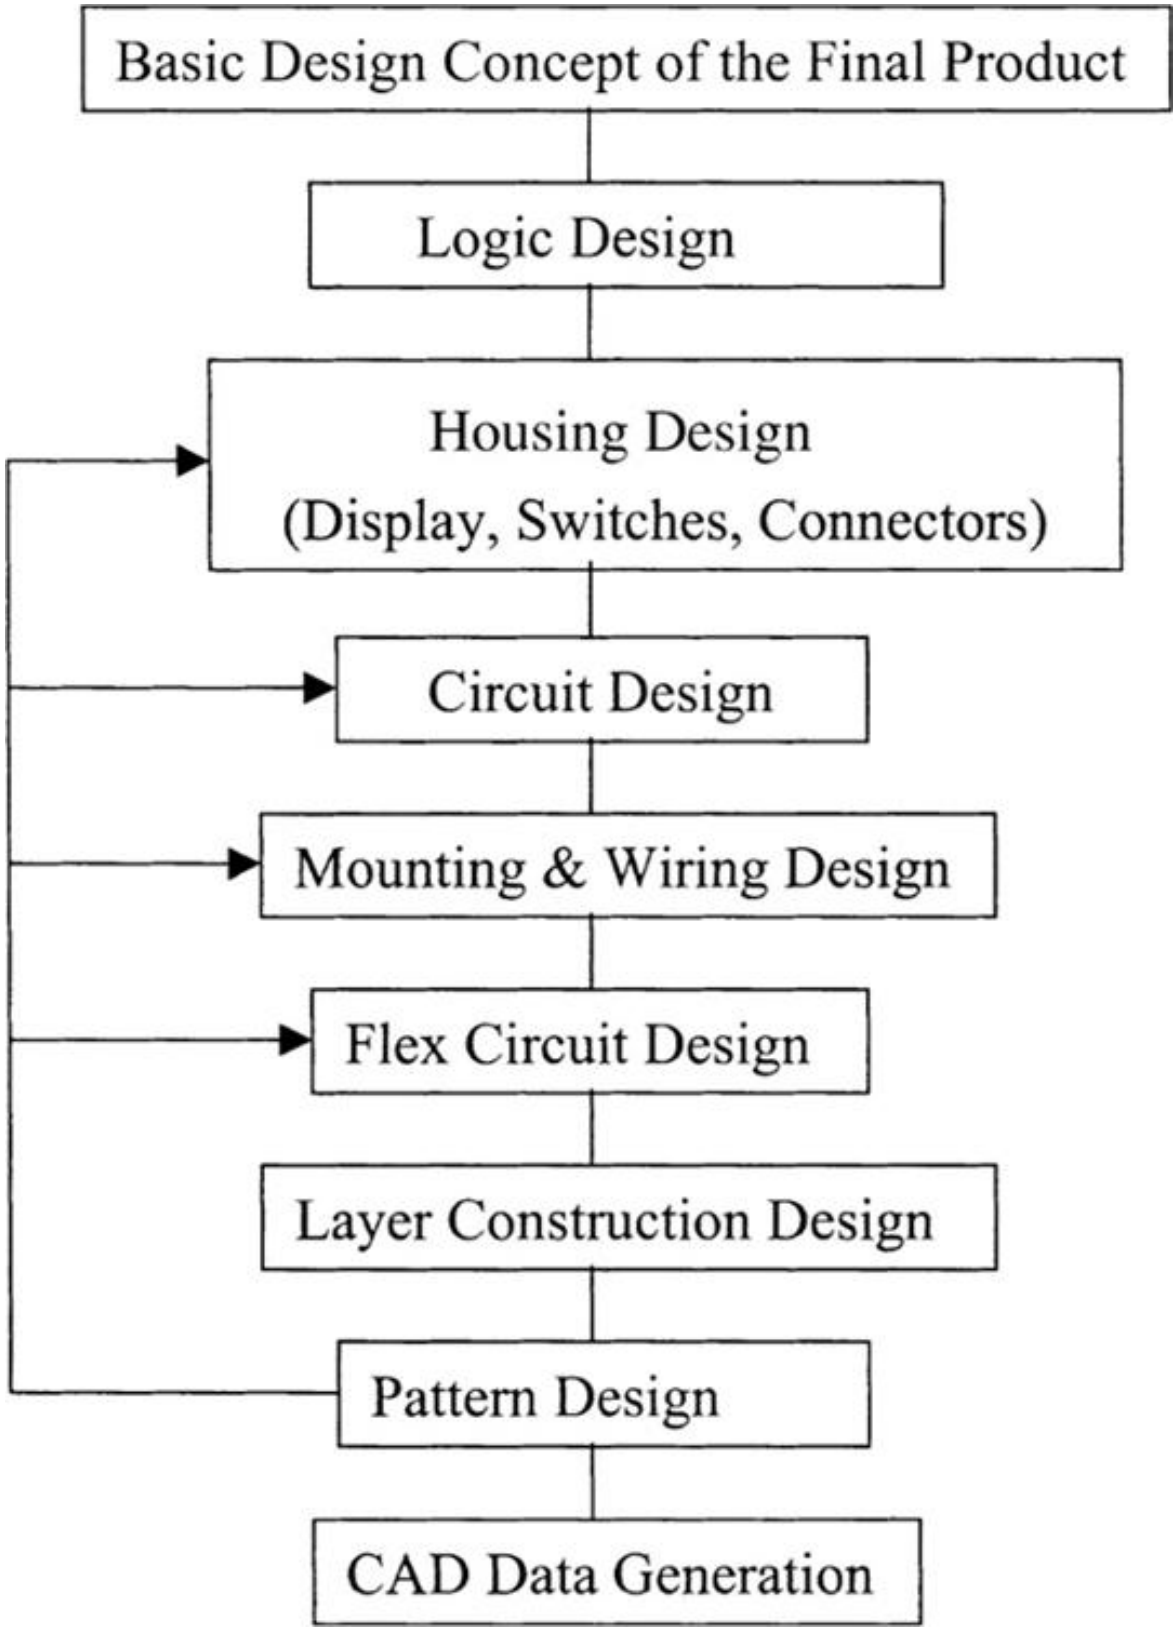

FIGURE 66.1 Design procedure for flexible circuits.

- A design concept for an electronic product is determined according to the basic specifications for the final product.
- A logical circuit design and electronic circuit design are formulated.
- A design for the equipment housing is made according to the final product concept. (This should sometimes be done independently in the case of consumer applications, especially for portable electronic products.)
- The circuit design is formulated. Appropriate circuit selection is conducted depending on total conditions such as allowed space, sizes of components, operating temperature, possible assembling process, required reliability, and so on.

A flex circuit or a combination with a flex circuit is considered to be the solution for a small wiring space.

- If the first circuit design does not satisfy the original specifications, the previous design steps are repeated to solve the conflicts.
- A suitable value analysis is done to minimize the total wiring cost.
- Conductor trace patterns and coverlay opening patterns are designed to minimize the mechanical stress.
- Numerical data for photo plotter, NC drilling, punching dies, and other tooling is generated.

66.2 TYPES OF FLEXIBLE CIRCUITS

Flexible circuits allow for more variety in their basic structures and supplemental structures than do rigid circuit boards, as shown in Table 66.1. Flexible circuits have single- or double-side constructions with through holes similar to rigid boards. However, multilayer construction has significant

differences from rigid boards; this is because the flexibility of the composite board will be very low when the circuit has more than two conductor layers. Therefore, the flexing parts of the circuit have to have special layer constructions to keep flexibility. The construction is called rigid/flex when the rigid part includes rigid board materials such as glass/epoxy. A simple single- or double-side flexible circuit is mechanically fragile, so coverlay and stiffener boards are generally added as the supplemental structures of the flexible circuits. Further special constructions, such as flying leads and dimples, are used for specific applications.

TABLE 66.1 Construction Types of Flex Circuits

Classification	Structure Types
Basic structure includes	• Single-sided flexible circuits
	• Double-sided flexible circuits with or without through holes
	• Multilayer flexible circuits with through holes
	• Multilayer rigid/flexible circuits with through holes
	• Blind via holes, inner via holes
	• Flying-lead structure
Supplemental structure includes	• Coverlay structure
	• Stiffener structure
	• Dimple structure
	• Microbump structure

An appropriate combination of a basic structure and supplemental structures should be chosen according to the requirements of the application. Also, appropriate termination technologies and suitable circuit constructions must be considered together.

66.2.1 HDI Flexible Circuits

There are significant differences in design, materials, and manufacturing technologies between traditional flexible circuits and new high-density flexible circuits developed for high-density interconnect (HDI). Figure 66.2 shows one way of defining the areas of high-density flexible circuits by using the technical hurdles of manufacturing for both trace densities and via hole sizes. Advanced etching technology is needed to give the high-density flexible circuits fine traces. Also needed are new micro via hole generation technologies other than traditional mechanical drilling, such as laser, plasma, and chemical etching.

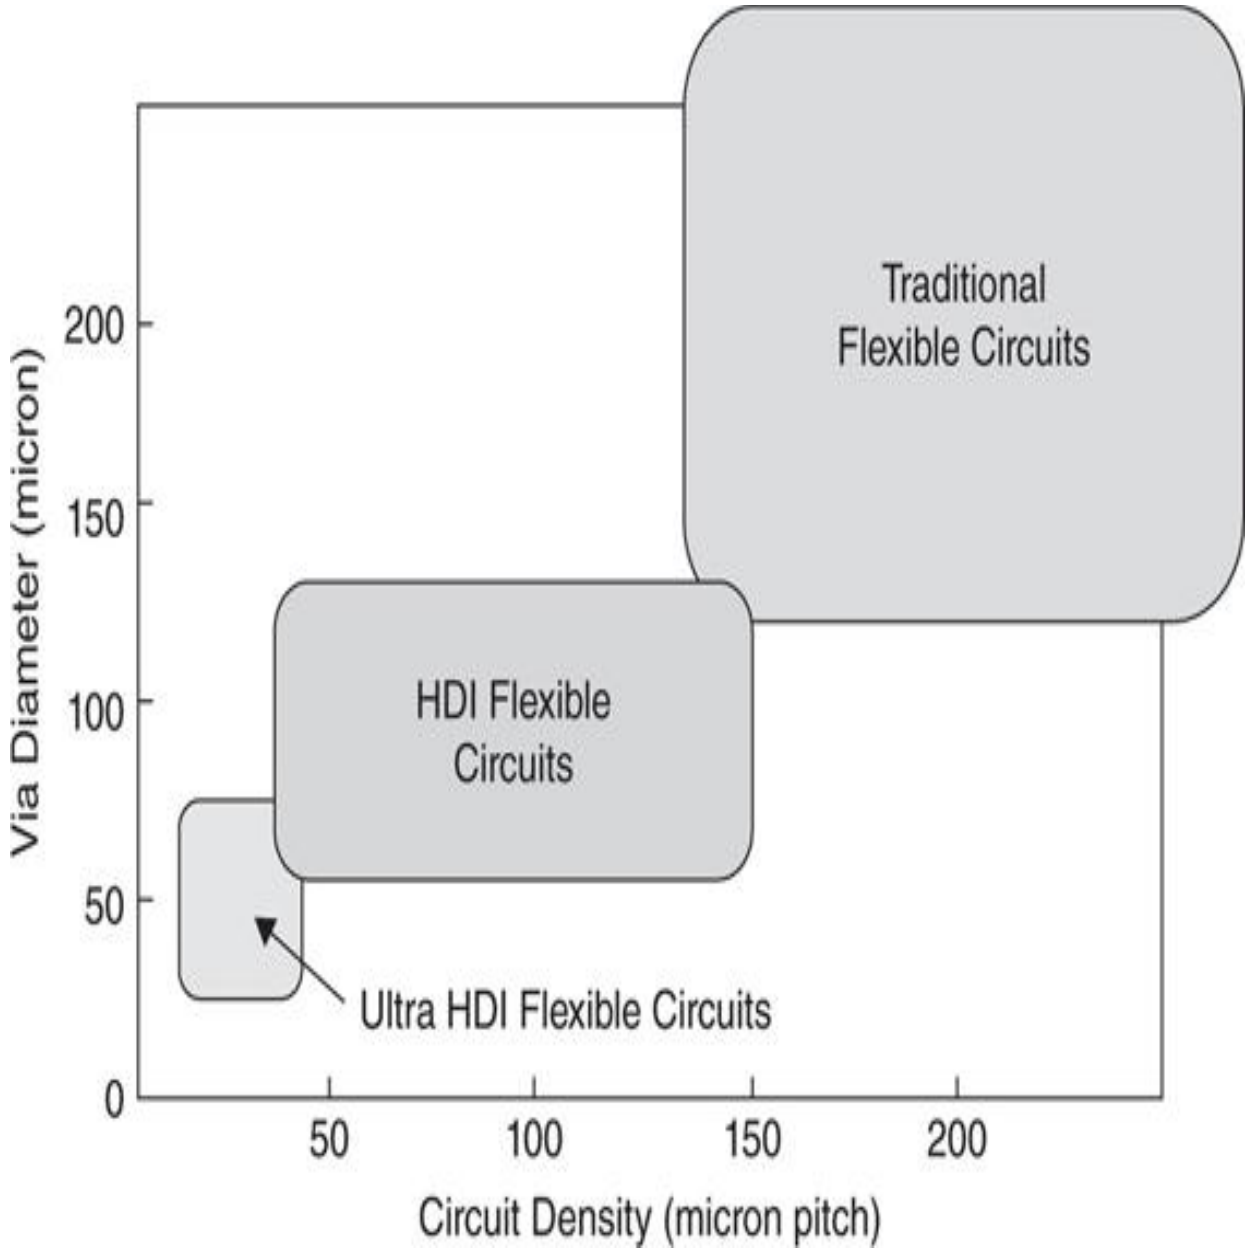

FIGURE 66.2 Definition of HDI flexible circuits.

Ultrahigh-density flexible circuits have been developed for special applications. They have extremely fine circuits that are smaller than 20 μm in pitch, as well as micro via hole connections smaller than 25 μm in diameter. Product concepts for ultrahigh-density flexible circuits are very different from those for traditional flexible circuits in construction and manufacturing technologies. They need

completely new concepts for the manufacturing processes, such as an additive process with new materials and new equipment. (See Chaps. 25 and 26 for detailed discussions of HDI design and fabrication.)

New high-density flexible circuits have supplemental structures such as flying leads and microbump arrays to complete high-density terminations. As volume production is limited, the designers should consider the manufacturers' process capabilities seriously.

66.2.2 Single-Sided Circuits

A bare single-sided flex circuit has a construction very similar to those of the single-sided rigid circuit boards, except for the thickness of the substrate layers. On the other hand, the protection of the conductors of the flexible circuits is very different from the rigid boards. A film coverlay system is introduced for the flexible circuits instead of solder masks (see Fig. 66.3). As introduced in Chap. 61, there are several choices of substrate (see Table 66.2). A 25-μm-thick polyimide film substrate is the most common material for consumer applications, with large volume due to its low cost. For higher reliability thicker film should be chosen, while for lower reliability, a thinner film can be used.

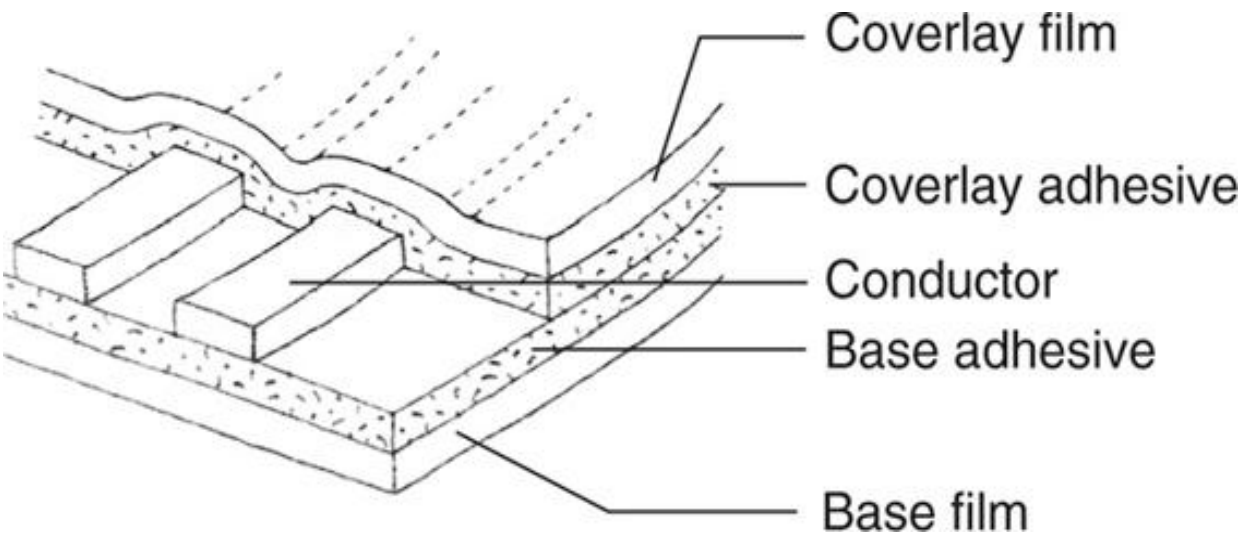

FIGURE 66.3 Basic structure of single-sided flexible circuit.

TABLE 66.2 Thickness of Base Substrates

	Base Film, µm	Adhesive, µm
Polyester base/adhesive type	25, 38, 50, 75, 100, 125, 188	25–50
Polyimide base/adhesive type	12.5, 25, 38, 50, 75, 125	25–50
Polyimide base/adhesiveless type	12.5, 25, 30, 35, 40, 50	No
Glass-epoxy	100, 200	~0

Adhesive layer thickness is doubled for double-sided laminates.

The thickness of the adhesive layers must be counted when total thickness is considered.

Possible fine-line capability is illustrated for each copper thickness in Fig. 66.4. Currently 18- and 35-µm copper foils are standard. Copper foils 12 µm and 9 µm thick are becoming the new standard to enable finer pattern etching. Thinner copper foils are available in sputtered/plated adhesiveless laminate materials. The fine-trace etching

capability depends very much on the manufacturer, especially the exposure process and etching process.

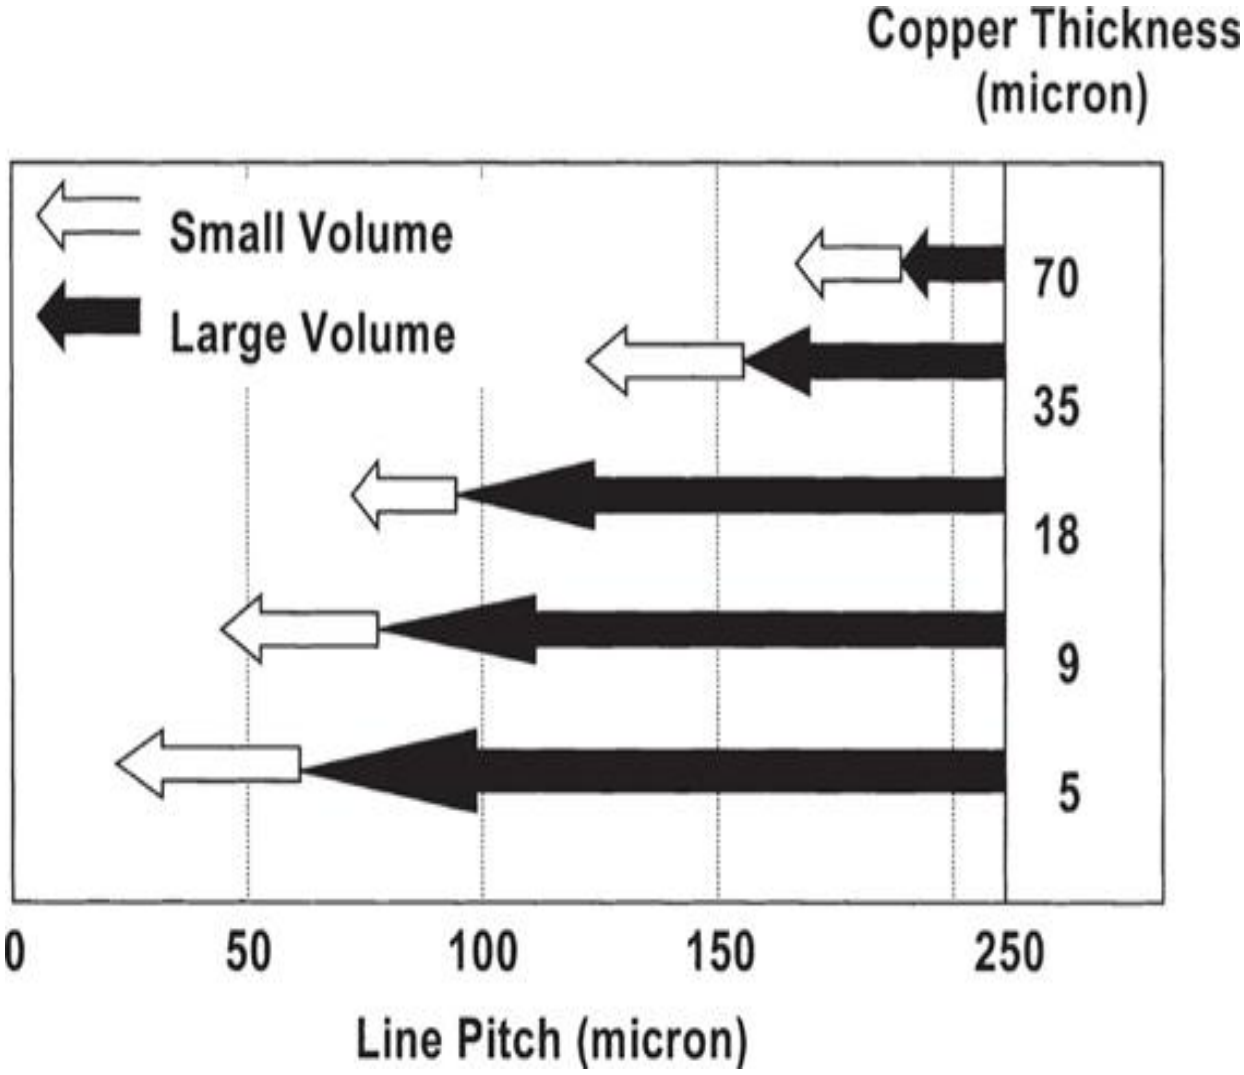

FIGURE 66.4 Fine line capabilities. Potential line pitch is noted for copper thickness alternatives along with whether a given thickness leads itself to high-volume production or requires too a high level of technical interaction.

66.2.3 Coverlay System of Flexible Circuits

The coverlay system of flexible circuits is one of the big differences from rigid printed circuit boards, as shown in Fig.

66.3. A coverlay has to have more functions than the solder mask of rigid boards. It should not only have solder dam capability, but also mechanical protection capability for the fragile conductors of flexible circuits. Also it is required to have high toughness to survive long flex endurance and to optimize the major advantage of flexible circuits.

Appropriate coverlay material and thickness including adhesive layers have to be chosen to have the best balance between the layers. Generally, the same film material laminated with appropriate adhesive as base substrate is selected as the coverlay materials. Polyimide film coverlay should be selected for the high temperature assembling processes such as soldering.

The manufacturing process for the film coverlay is very complicated compared to the solder masks of the rigid boards, so the final cost of the circuits cannot be low. Flexible, screen-printable inks are a low-cost solution; however, most of the ink materials made of epoxy resins do not have good mechanical properties and cannot be applied for dynamic flexing usage. A combination of polyimide-based screen-printable coverlay on adhesiveless copper-clad laminate provides the smallest total thickness with very long flexing endurance life. A comparison of cross sections is shown in Fig. 66.5.

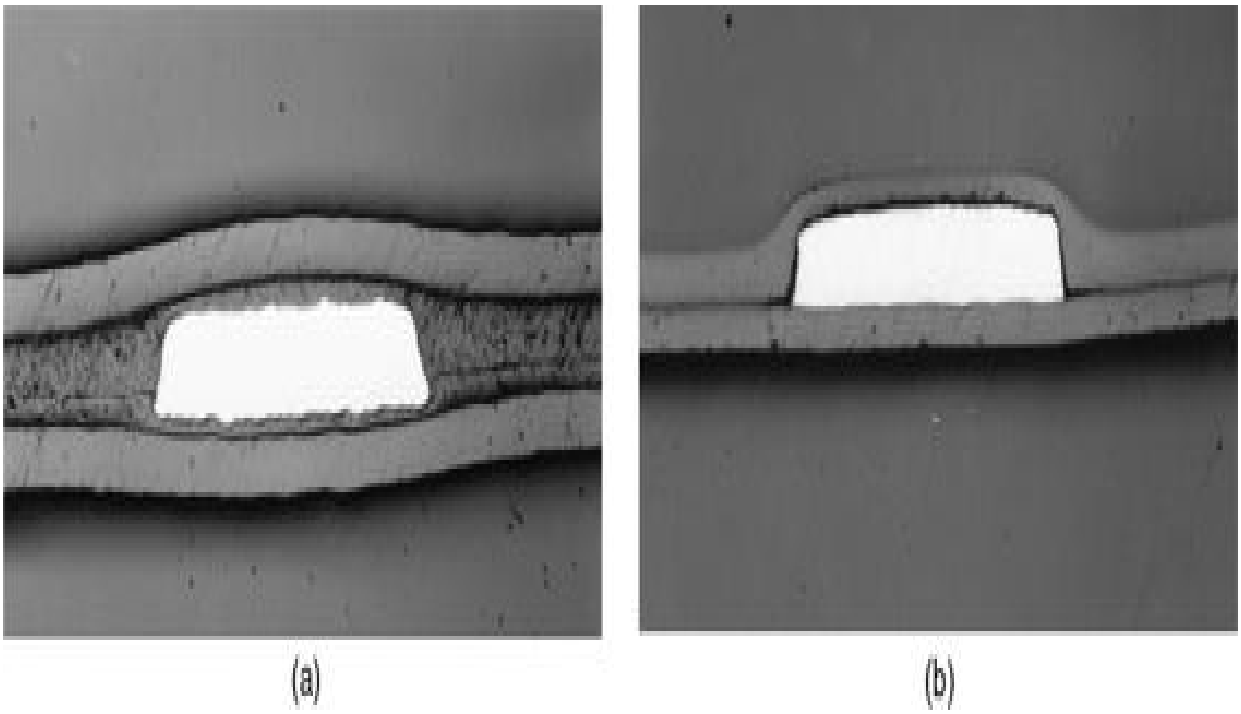

FIGURE 66.5 Cross-section of a single-sided flexible circuit showing (*a*) adhesives-based laminate and film overlay, (*b*) adhesiveless laminate with liquid coverlay.

High-density flexible circuits that have been developed since 1990 need a small pitch opening with high accuracy on the coverlay. Because traditional coverlay technologies have no capabilities to meet these requirements, new technologies were required. Many new technologies and new materials have been developed to satisfy the new requirements of high-density flexible circuits. The capabilities of the major technologies are shown in Table 66.3.

TABLE 66.3 Varieties of Coverlay

	Material Selection	Thickness, µm	Dimensional Accuracy (Minimum Opening)	Reliability (Flexing Endurance)
Traditional film coverlay	PI, PET	30–100	±0.3 mm (800 µm)	High (long)
Film coverlay + laser drilling	PI, PET	30–100	±50 µm (50 µm)	High (long)
Screen print liquid ink	Epoxy, PI	10–20	±0.3 mm (600 µm)	Acceptable (short)
Photoimageable (dry film type)	Epoxy, PI, acrylic	25–50	±50 µm (80 µm)	Acceptable (short)
Photoimageable (liquid ink type)	Epoxy, PI	10–20	±50 µm (80 µm)	Acceptable (short)

For example, laser drilling is capable of generating openings smaller than 100 µm on the traditional film coverlay; therefore, it satisfies the requirements of physical performance and high density surface-mount technology (SMT) assembling. However, the processing costs of the laser abrasion are much higher than other coverlay processes, and it is difficult to apply for the high-volume production of consumer applications. A screen-printing process provides a slightly higher resolution than traditional prepunching process of the film coverlay, but the process can not satisfy the recent requirement for high density SMT assembly. A practical solution is the combination of film coverlay for the flexing areas and solder mask for the SMT areas. It needs supplemental processing to complete the construction, accordingly the total process yield will be lower and the final cost of the circuits could be higher.

The idea of the photoimageable coverlay could be the final solution to solve the all requirements, including the processing cost. The photoimageable solder mask materials developed for rigid boards are too brittle, however, and a lot of cracks can be created easily by small radius bending—requiring flexible materials. Several types of flexible

photoimageable coverlay materials have been developed with different base resin systems. Most of the photoimageable coverlay materials provide finer resolutions than 200-μm pitches, but the physical performances very depend on the base resin systems. Suitable material should be chosen for the applications.

Appropriate surface treatments for the bare conductors after the coverlay construction should be chosen according to termination technologies. Several examples are listed in Table 66.4. Details are explained in Chap. 64.

TABLE 66.4 Surface Treatments and Termination Technologies

Surface Treatment	Termination Technologies
Solder and lead-free solder	Lead-free soldering, FFC connector
Lead-free Hot-air leveling	Lead-free soldering
OSP (preflux)	Lead-free soldering
Hard Ni/Au plating	Connector, pressure contact
Soft Ni/Au plating	Wire bonding, direct bonding
Tin	Lead-free soldering

66.2.4 Surface Treatment Alternatives Stiffener Boards

Thinness and bendability are the major advantages of flexible circuits. However, flexible circuits can lose mechanical strength when it is necessary as part of a composite assembly. The addition of stiffeners on flexible circuits is a practical solution to solve the conflicts, but

appropriate stiffener board materials and adhesive materials have to be chosen based on the applications purposes.

Figure 66.6 illustrates typical examples of the stiffener systems. The first one shows a stiffener construction for an insertion part into a connector. A stiffener adjusts the total thickness of the insertion part. Heat resistant materials, such as polyimide films, are not required for the construction. PET films with pressure-sensitive adhesive (PSA) could provide the low cost combination. A second example shows a case of the assembling of the traditional lead components. A relatively thick stiffener board, such as glass/epoxy, is bonded on the component side to support heavy parts. The soldering for the leads is conducted at the other side. Heat resistant materials including adhesives have to be chosen to survive the high temperature soldering process. Thermo-setting type adhesives should be chosen instead of PSA for the high reliability requirements. The third example indicates the case of SMT assembling. A thin heat resistant stiffener material such as polyimide film is bonded on the other side of SMT assembling.

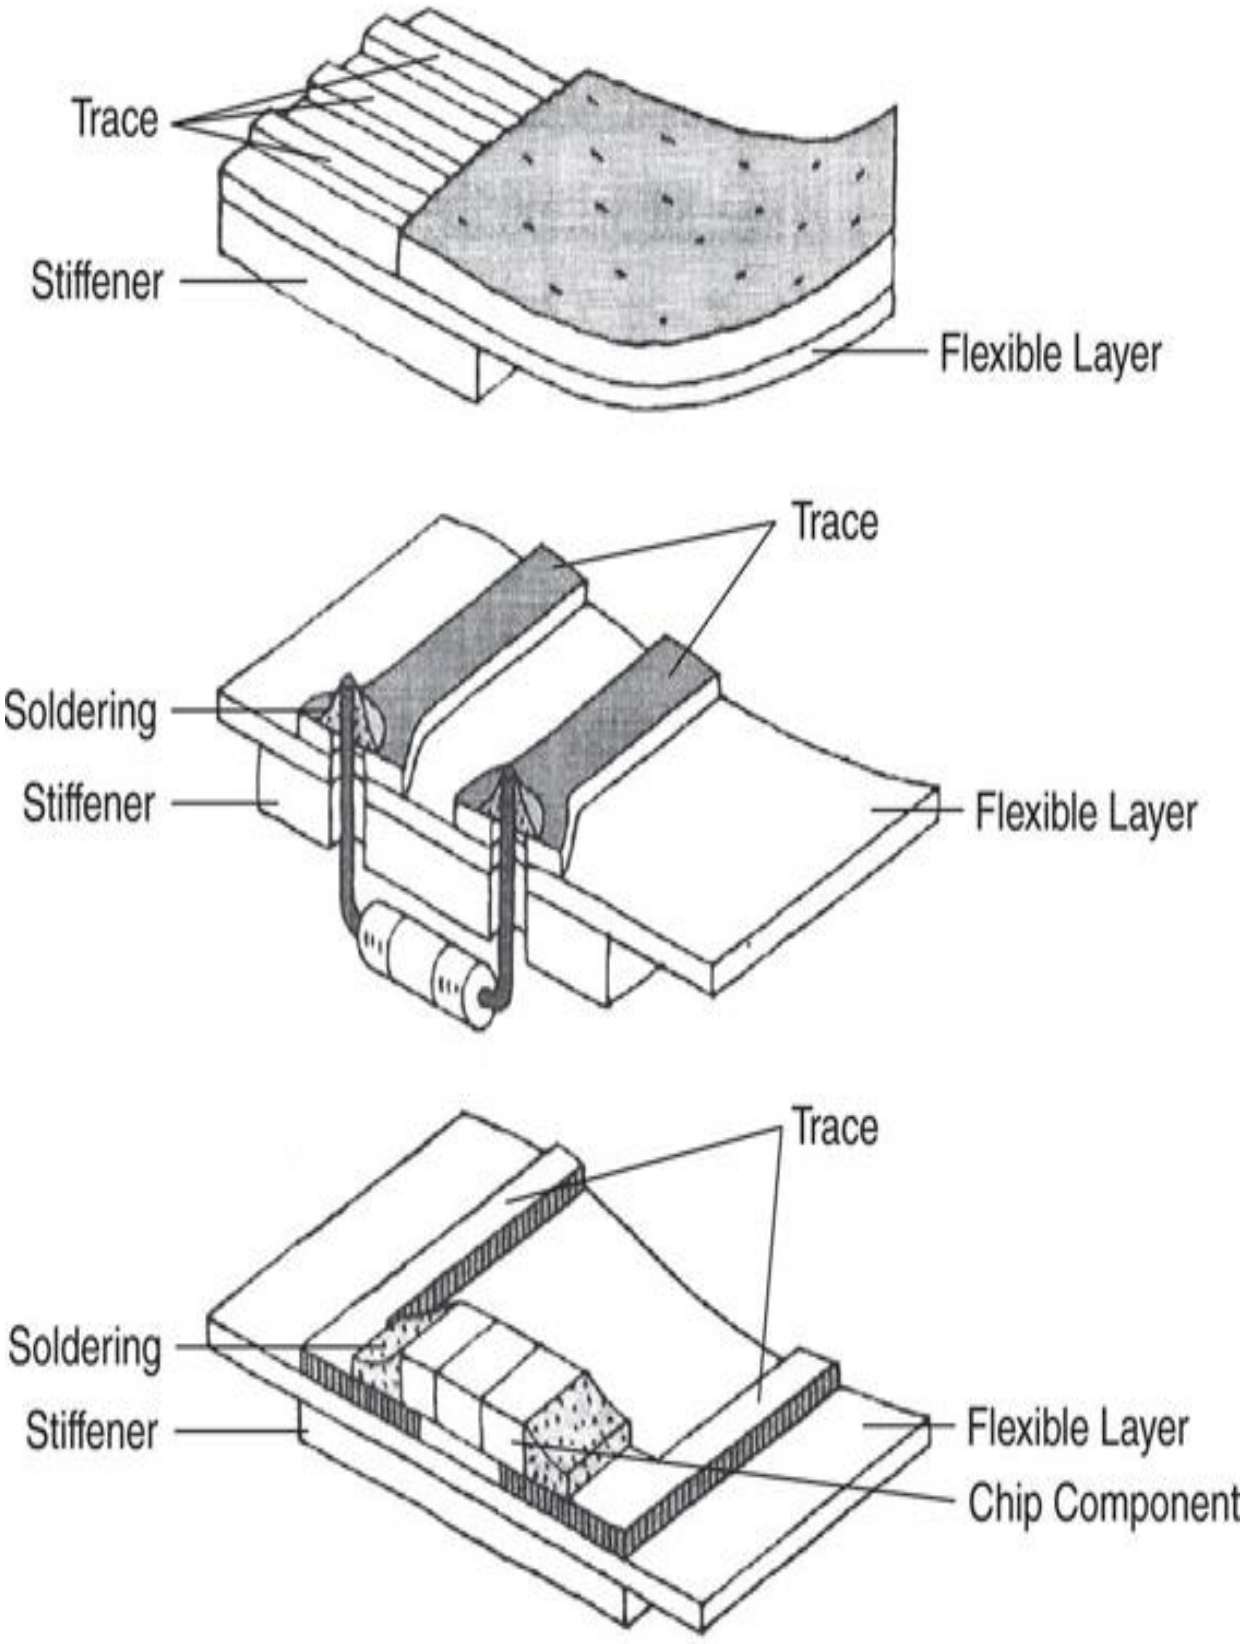

FIGURE 66.6 Stiffener systems for flexible circuits.

66.2.5 Double-Sided Circuits with Via Holes

A double-sided flexible circuit can have the same through-hole structures for the traditional designs as rigid circuit boards. However, there are several critical differences in micro via holes on flexible circuits. Most of the differences come from a thin-film base substrate such as polyimide film. Electrically plated copper conductors are much more brittle than rolled-annealed copper foils; therefore, thin copper plating is preferred to maintain the flexibility of the circuits. Generally, sufficient through-hole reliability is established with 15-μm-thick copper plating. Copper plating should be eliminated from the dynamic flexing area by using a suitable masking method.

Adhesiveless, copper-clad laminates that have simple and uniform substrate layers and smooth copper surfaces have become popular in high-density flex circuits. Because of thin film materials, there are several choices in small hole generation and copper plating processes. Flex circuits can contain both through holes and blind via holes for double-sided circuits as shown in Fig. 66.7. Micro-size blind via holes on double-sided flex circuits confer the ability to make SMT assembly density much higher.

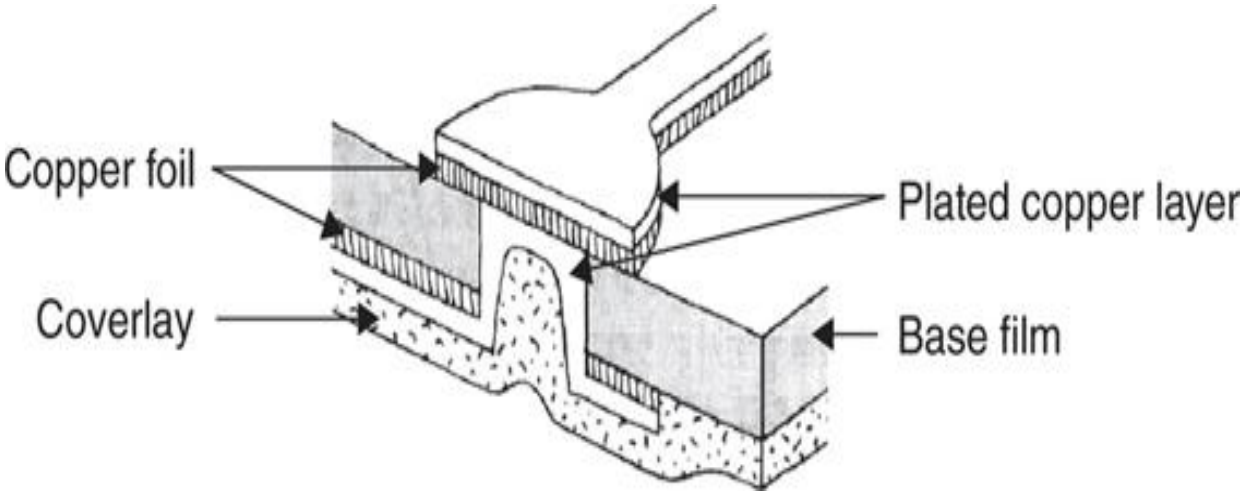

FIGURE 66.7 Blind via structure of double sided flexible circuits.

The micro via hole capability depends on the process used by the manufacturer; however, general ideas are introduced in Chap. 61. Certainly the smaller via holes are available for the thinner substrates. Using the latest technology, such as excimer laser drilling, micro via holes smaller than 40 μm are available for 25-μm-thick adhesiveless polyimide base substrates.

Microvia hole capabilities for polyimide substrates are shown in Fig. 66.8.

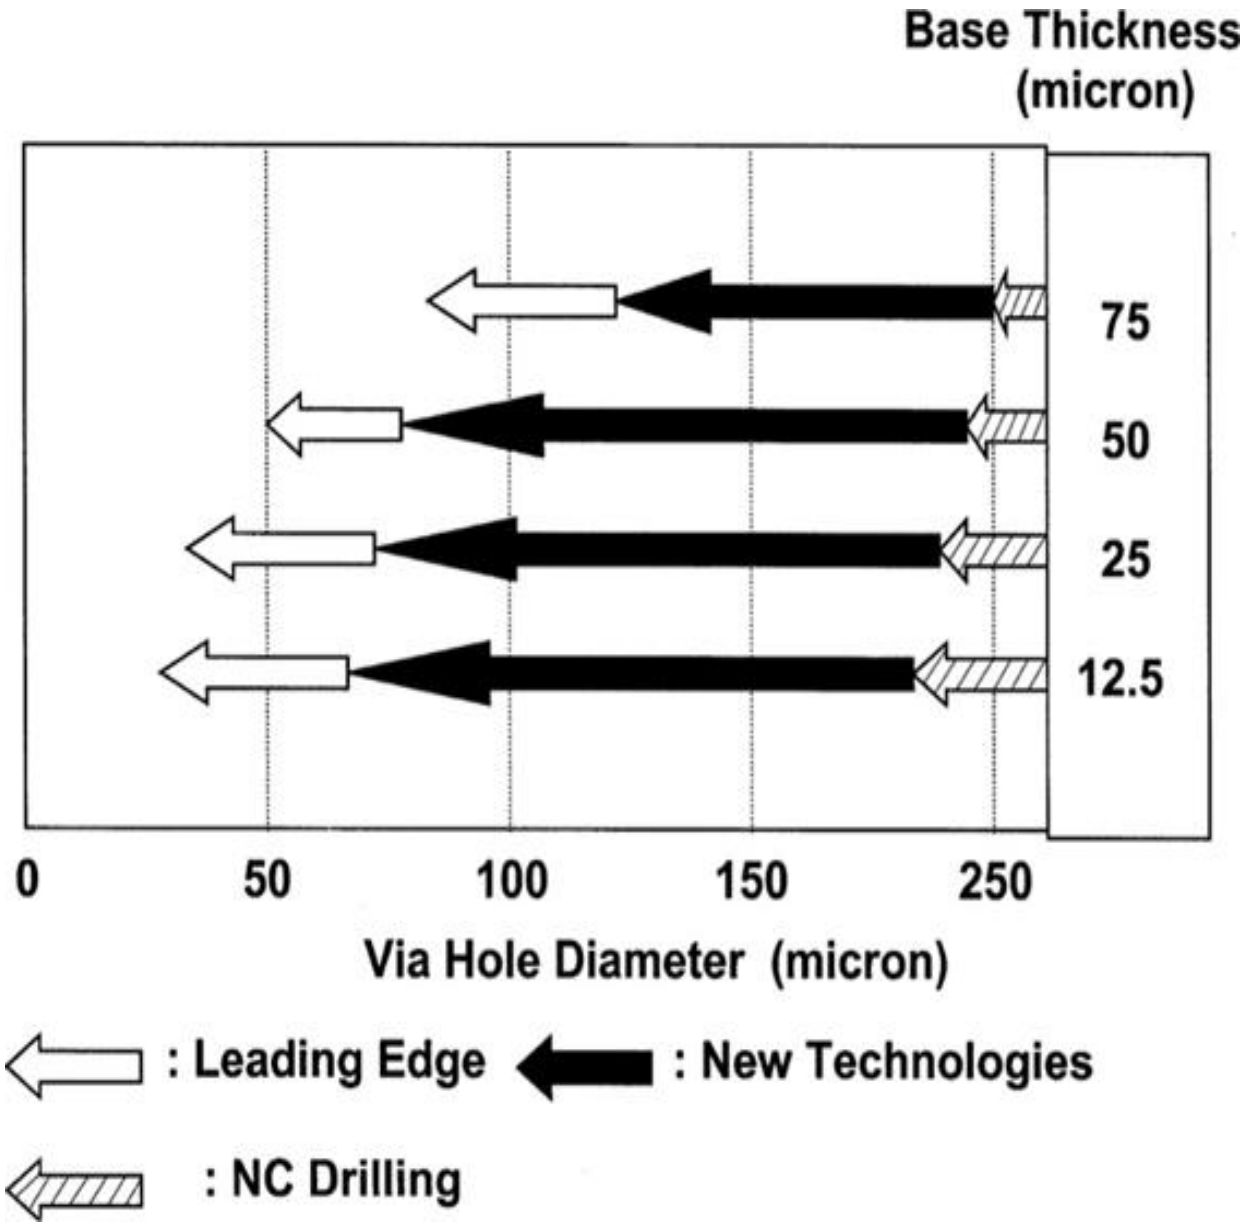

FIGURE 66.8 Microvia capabilities shown by base thickness and hole diameter. Also shown is the range of technologies from HDI to mechanical drilling required to create the vias.

Basically, the same construction systems of coverlay, stiffeners, and surface treatments as single-side flexible circuits could be available for double-side flexible circuits.

66.3 MULTILAYER RIGID FLEX (MULTILAYER FLEX)

A simple, multilayer, flexible circuit does not make sense other than for its small thickness, because these circuits will not have any more flexibility. Therefore, rigid/flexible constructions that contain both rigid parts and flexible parts have been developed. A typical layer construction is illustrated in Fig. 66.9. It is not a simple combination of flexible circuits and rigid circuits. Generally, there are common flexible layers that are separated in the flexible parts. A flexible layer of the flexible parts can have only one or two conductor layers to keep high flexibility. At the rigid parts, the flexible inner layers are sandwiched by cap layers that consist of rigid circuit materials such as glass epoxy or glass polyimide. The constructions of rigid parts are very similar to those of rigid multilayer circuits except for the thin polyimide dielectric layer inside. Thin polyimide films were used as the cap layer at the rigid part to reduce the total thickness required in portable electronics such as cellular phones. The multilayer construction in these cases, the circuits are called multilayer flex.

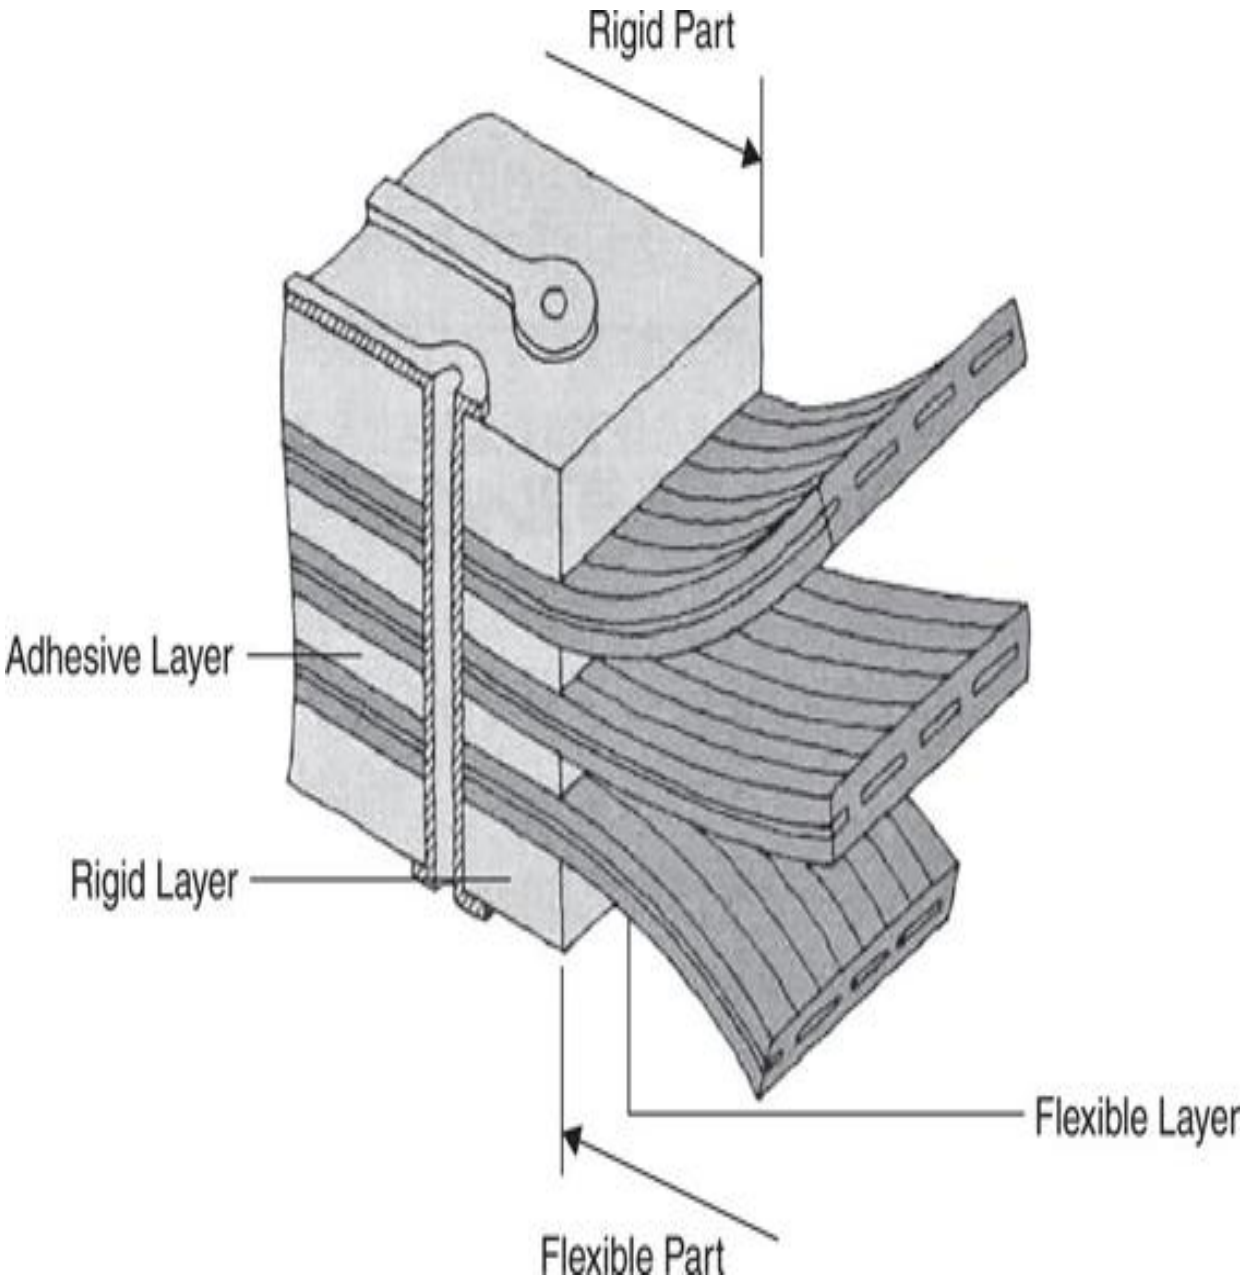

FIGURE 66.9 Multilayer rigid flex construction.

Through-hole and blind via hole constructions similar to those of multilayer rigid circuit boards are available using coated copper foil or photo-via processes for multilayer flexible and rigid/flexible circuits. However, there are more varieties from which to choose in both materials and manufacturing processes. Basically, the same assembly technologies are available on the rigid parts. The latest

portable electronic equipment, such as palmtop computers, requires high-density SMT assembling on the rigid parts.

There are no limits to the number of flex layers. More than 30 layers are built into one rigid/flex circuit for aerospace applications. However, the circuits require very complicated manufacturing processes—more so than the standard rigid multilayer circuits—and therefore their costs are much higher than costs for rigid boards of the same size. Design should be considered seriously prior to manufacturing to reduce the total cost based on the capability of the manufacturer. A higher circuit density can reduce the layer counts and the total manufacturing cost.

66.3.1 Flying-Lead Construction (Double Access Construction)

A specialty construction for flexible circuits is the double-electrical access capability on even single conductor layer circuits, achieved by removing the base insulation layer under the conductors as shown in Fig. 66.10. It can be an alternative construction instead of double-side circuits with through holes for the low cost 3D wiring. When the insulation layers are removed from both sides of the conductors, they can then be partially free from the organic materials. Unsupported conductors, also known as flying leads or flying fingers, are not a new idea in the construction of flexible printed circuitry (Fig. 66.10). The biggest advantage of flying-lead technology is its extremely high heat resistance and thermal conductivity when compared to standard conductors insulated by dielectric substrate materials. Based on the lack of insulation, flying leads can be treated as a bare conductor material similar to bare wire. There are many high-density flexible circuit applications that require flying-lead terminations. Details are discussed in Chap. 64.

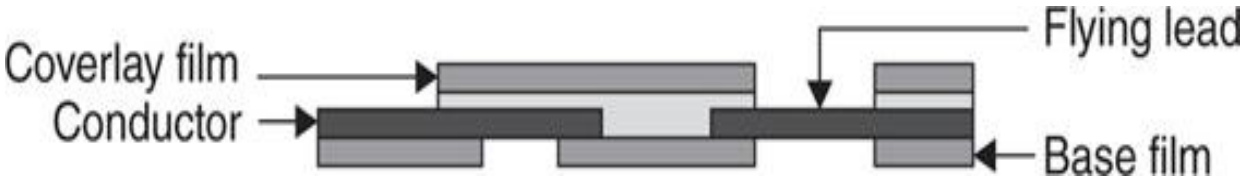

FIGURE 66.10 Flying lead construction (double-sided construction).

Consideration must be given to specific surface treatments required on the flying leads to make each of the various application terminations. Previously, tin/lead plating was the most common treatment for various soldering processes; however, it is expected to be replaced by lead-free technologies, which need higher temperatures for the soldering. Soft gold plating with a nickel underplating is the standard surface treatment for the wire bonding and direct bonding to the other devices. The purity and the thickness of the plated gold, along with the bond strength of the plated layer, are important factors in bond performance.

Copper thickness is a key consideration when developing a new circuit design involving flying leads. Although it is easier to manufacture high-density circuits utilizing thinner copper, the resultant flying lead may be extremely fragile and will not have the mechanical strength of the thicker copper circuits (see Fig. 66.11). Manufacturing yield plays an important role in the overall circuit costs, and thinner copper foils typically result in more damage during processing. It is important to understand this correlation as poor circuit design can affect manufacturing yields.

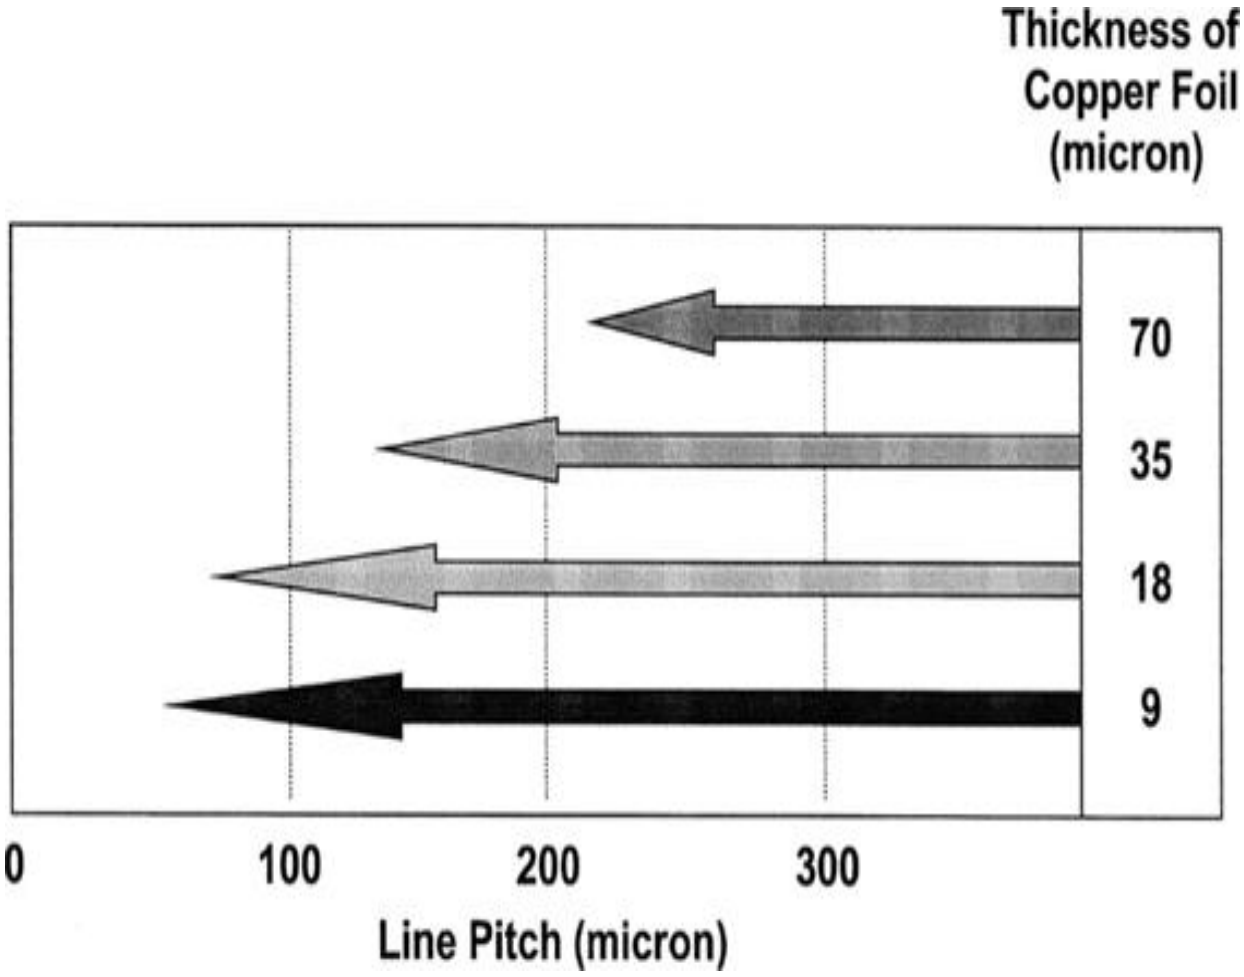

FIGURE 66.11 Flying lead capability of copper foil, showing potential line width versus thickness of the copper foil.

Because the flying leads are basically bare conductors, suitable surface treatments should be conducted according to termination technologies.

66.3.2 Microbumps and Dimples

Many kinds of microbump arrays and dimple arrays have been developed for high-density terminations of flexible circuits other than solder ball grid arrays. Recent technologies allow for a wide variety of shapes, materials, sizes, and pitches; down to 50 μm. The solder ball arrays are built by similar processes of the rigid ball grid array (BGA)

substrates. The combinations of the electrical and electroless-plating process provide a lot of choice for the shapes and sizes of the microbump arrays on flexible circuits. The double-access capabilities of flexible circuits provide more choices for the locations of the microbumps, as shown in Fig. 66.12, other than through coverlay. The microbumps can be built on the bottom side of the conductors through base layers. They can be also built on both sides of the flying leads. An appropriate design should be chosen according to the requirements of the terminations. Whether it's a permanent connection or nonpermanent connection is one of the key points needed for designing the basic constructions of the microbumps. Bump density and reliability are other factors needed to design the microbump structures. Details of the manufacturing processes are described in Chaps. 64 and 67.

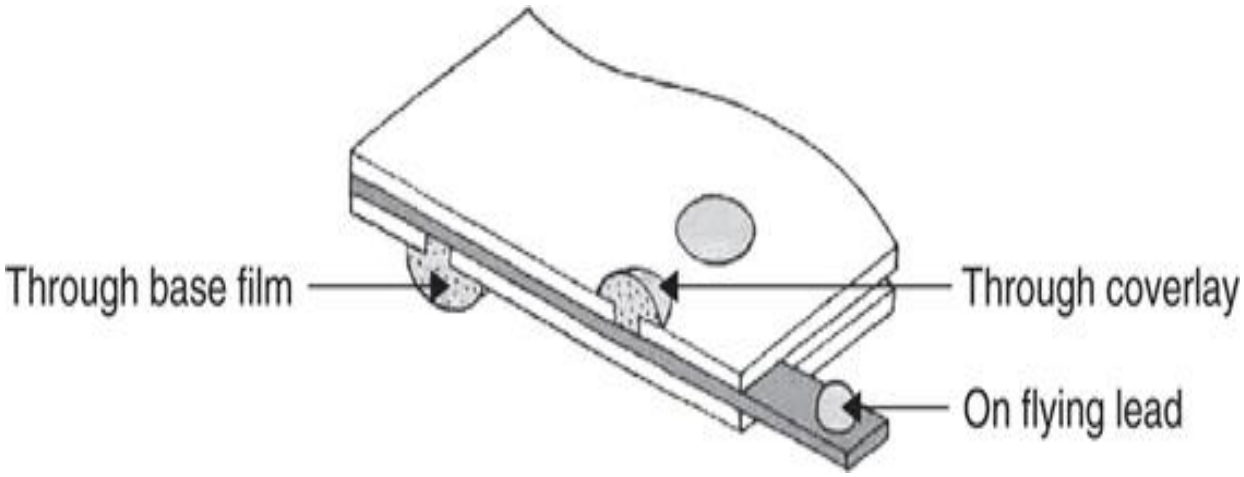

FIGURE 66.12 Locations of microbumps.

Dimple structure of flexible circuits is a low cost solution for the nonpermanent termination. Multiple dimple arrays can be formed on the polyimide base or PET base flexible circuits by simple pressing processes. (Details are shown in Fig. 66.13.) A typical example of the dimple termination is the connection of the disposable cartridges of ink jet printers. Over 60 dimples with hard gold plating are formed

at the end of flexible circuit for the connection with the ink cartridge. The dimple arrays can make reliable connections over one thousand times.

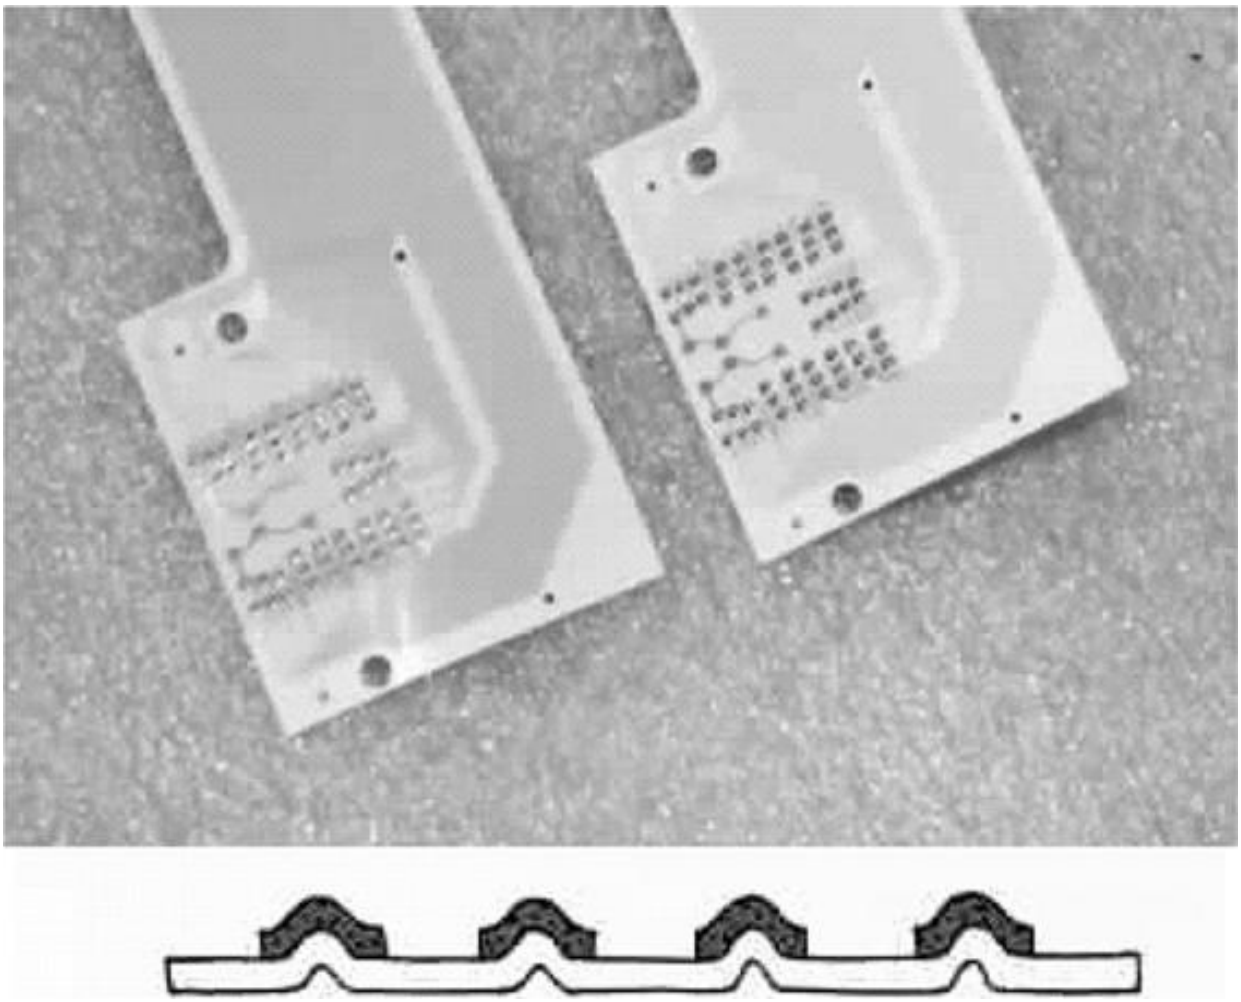

FIGURE 66.13 Dimple structures (ink jet printer).

66.4 CIRCUIT DESIGNS FOR FLEXIBILITY

One of the major features of flexible circuits is their long flexing endurance. A suitable layer construction and

materials survives over billion times of flexing with a small radius (Fig. 66.14).

Hinge Type	Shell	Revolve	Universal	Slide
Diagram				
Copper Thickness	RA copper ½ oz	RA copper ½ oz	RA copper ½ oz	HTE copper ⅓ oz
PI	1 or ½ mil	1 or ½ mil	1 or ½ mil	0.7, 0.8, or ½ mil
Structure suggestion	1. Single side flex 2. Double sided flex with one side trace 3. Multi-layer with air gap	1. Single side flex 2. Double sided flex with one side trace	1. Single side flex 2. Double sided flex with one side trace	1. Single side flex is preferred 2. Double sided flex with one side trace 3. Due to very tight space, air gap is not preferred
Application				

FIGURE 66.14 Four types of flexible hinges with copper, bend, structures, and applications.

A basic idea of the mechanical stress during the bending is illustrated in Fig. 66.15*a*. To have the longest flexing life, the conductor layer should be the center of the layer construction. It should have symmetrical layer constructions for both sides of the conductor layer. The flexing life will be remarkably shorter when the conductor layer is outside of the bending center as shown in Fig. 66.15*b*. A rolled annealed copper foil should be used instead of ED copper foil for a longer flexing life. But there is no exact relation between roll direction and flexing endurance; the exact performance should be evaluated for each material. Generally, 35-µm-thick RA copper is more expensive than the same thick ED copper foil. The cost difference between RA copper foil and ED copper foil will be larger at thinner thickness. A high ductility ED copper foil could be alternative choice for middle class dynamic flexing. Its flexing life is shorter than RA copper foil, but it is less expensive and it can survive one million flexing instances with an appropriate layer construction and flexing radius.

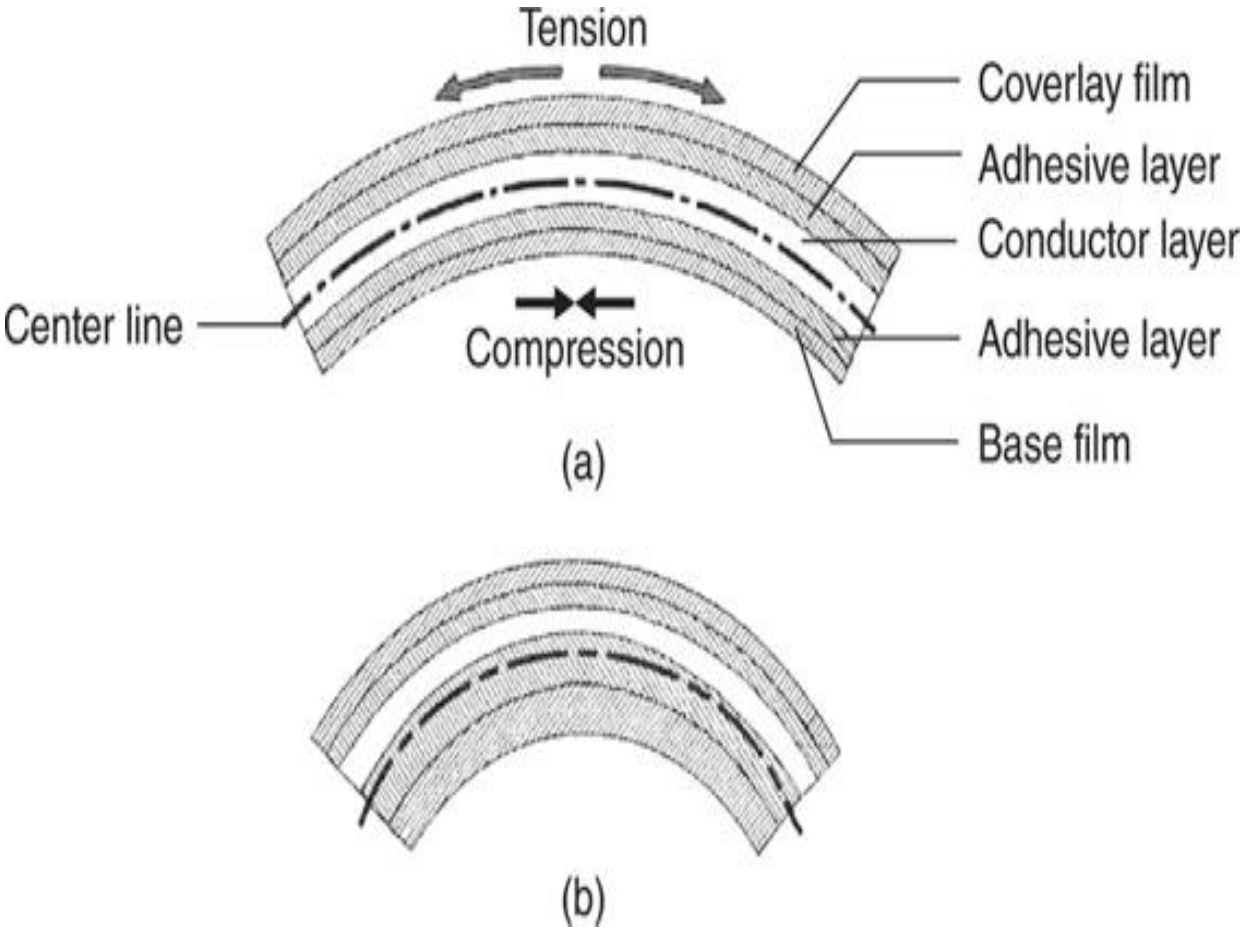

FIGURE 66.15 Mechanical stress at bending: (*a*) symmetrical, (*b*) nonsymmetrical.

Another principle is that for dynamic flexing, the thinner the layer, the better. An 18-µm-thick copper foil has a longer flexing life than a 35-µm-thick copper foil. A 12.5-µm-thick polyimide film provides a longer flexing life than a 25-µm-thick polyimide film (Fig. 66.16). Adhesive layers should be as thin as possible for dynamic flexing. But thin adhesive layers do not have good bond strength and good encapsulation for traces, and therefore a suitable thickness should be determined based on experimental data. Generally, polyimide films have a longer life than polyester films. The combination of a thin, adhesiveless, polyimide base laminate and a thin coverlay of liquid polyimide resin could be the best solution to have the longest flexing life.

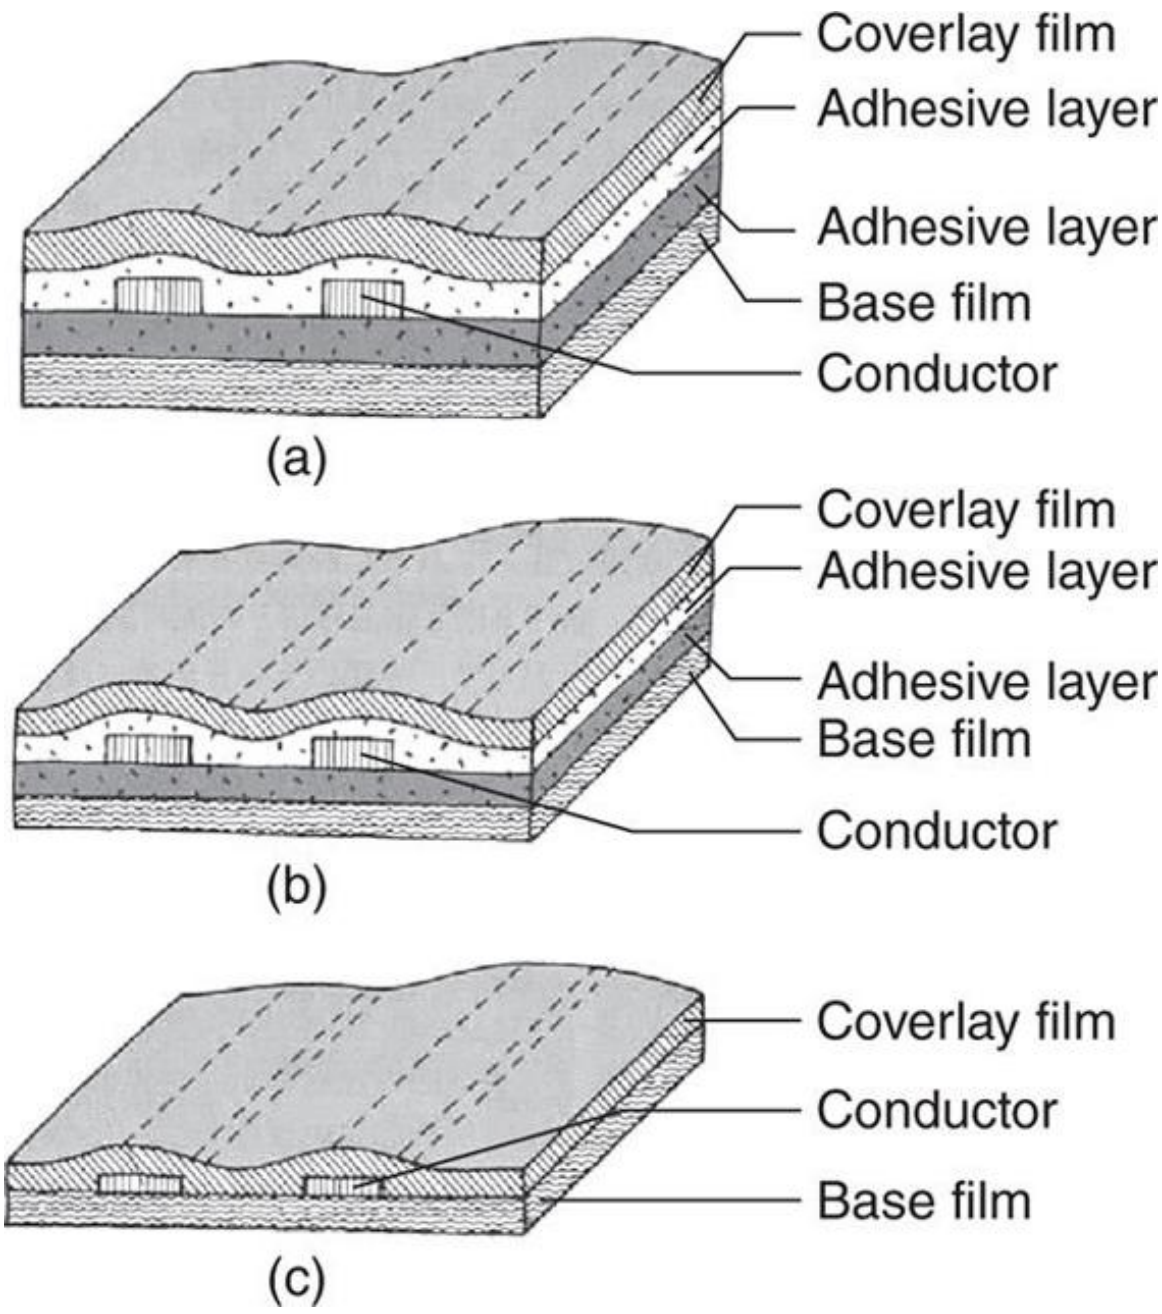

FIGURE 66.16 Layer construction for dynamic flexing: (*a*) standard layer construction, (*b*) dynamic flexing construction with thin adhesive layers, and (*c*) dynamic flexing construction without adhesive layer.

Many kinds of bending modes on flexible circuits could be practical, but in IPC-TM-650 it is recommended to evaluate the flexing life using the movement shown in Fig. 66.17.

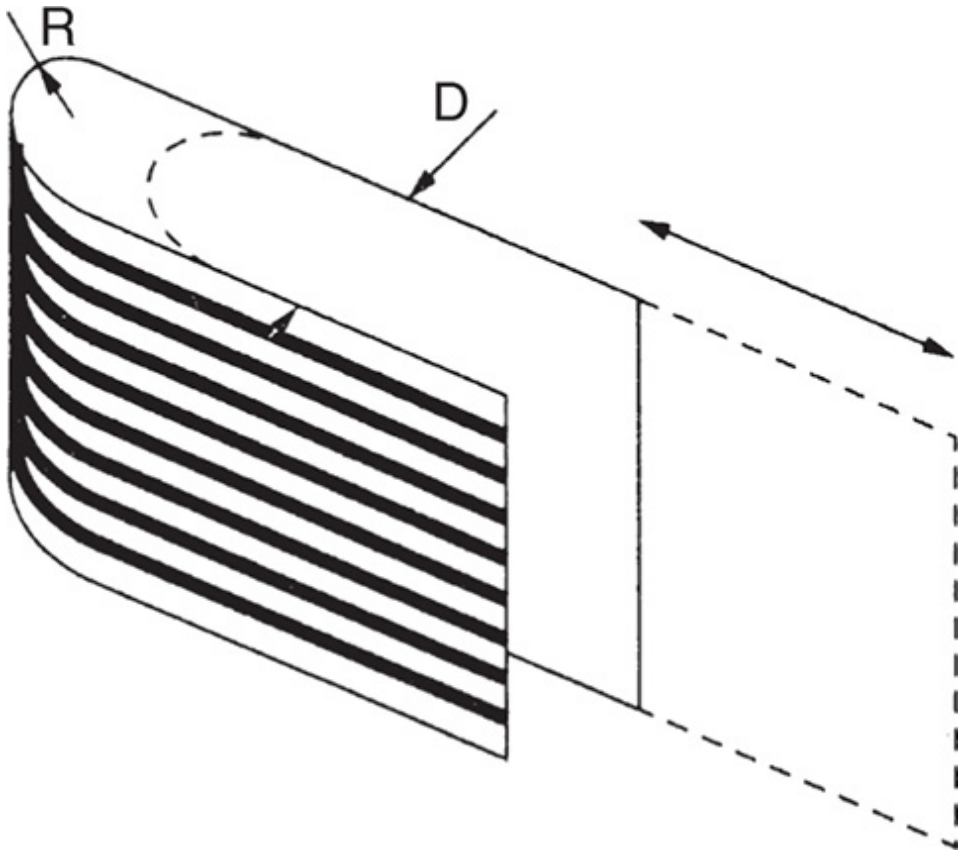

FIGURE 66.17 Typical dynamic flexing mode of flexible circuit specified by IPC-TM-650.

The larger flexing radius provides a longer flexing life, as shown in Fig. 66.18.

FIGURE 66.18 Flexing radius and life as specified by IPC-TM-650 test method. Bending diameter (mm): (*a*) RA copper foil, (*b*) ED copper foil.

There are several ideas for reducing the risks of flexing failures in actual cases for electronic products; Fig. 66.19 shows some examples.

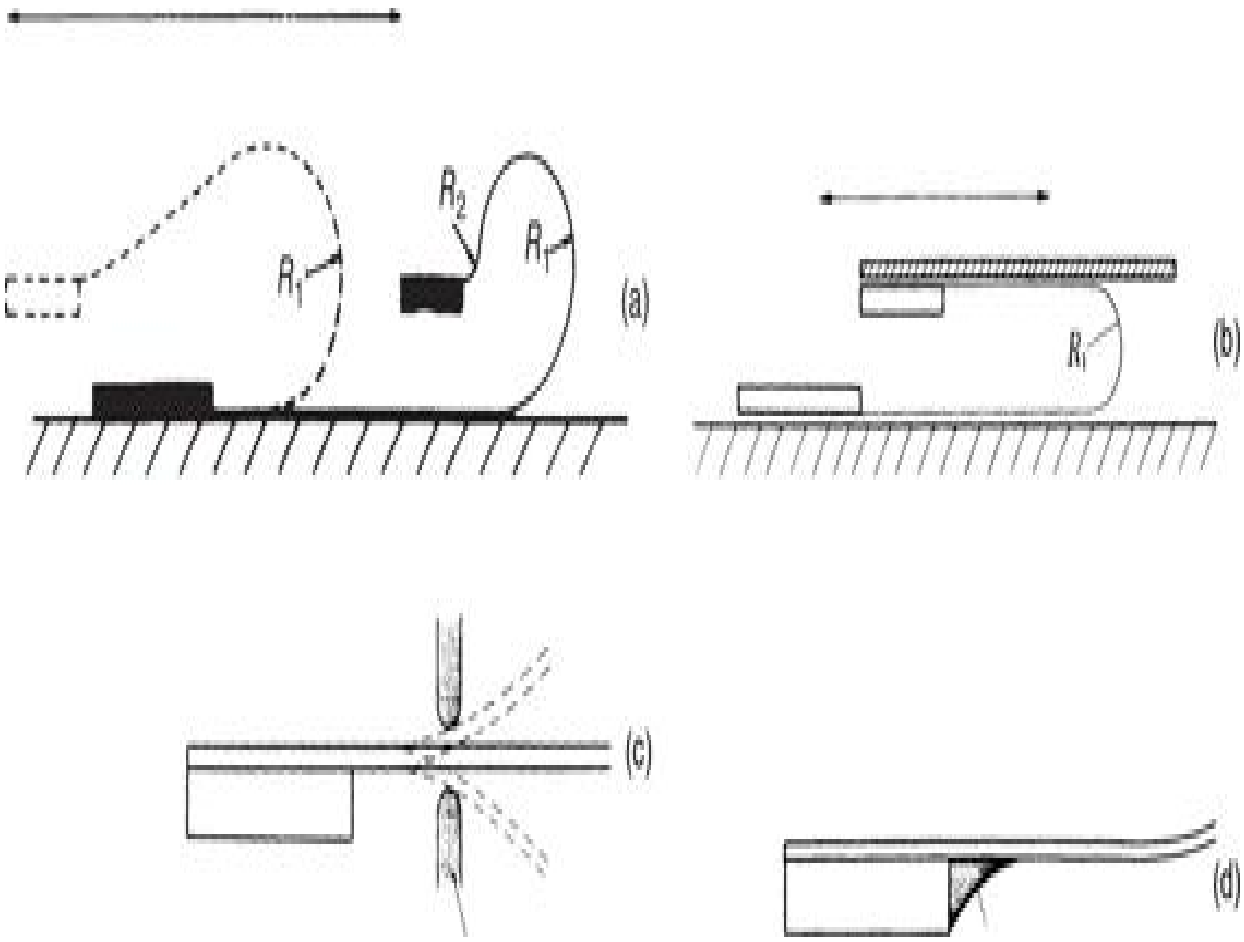

FIGURE 66.19 Design of dynamic flexing part of flexible circuits: (*a*) unacceptable technique, (*b*) guide board, (*c*) loose guide, (*d*) silicone rubber.

Basically, double-sided flexible circuits with through holes are not available for dynamic flexing. The flexibility depends on the configuration of conductors in both sides of the base substrate, as shown in Fig. 66.20 shows examples. Bending the circuit with thin copper circuits on the outside of the flexible circuits may cause them to break, because the mechanical stresses are concentrated on the small traces.

A dynamic flexing area of a double-sided flexible circuit should have only one conductor layer. Coverlay on the other side of conductor should also be eliminated to enable symmetrical layer constructions. Copper plating for the through holes of double-sided flexible circuits should be eliminated from dynamic flexing areas using a plating mask.

66.5 ELECTRICAL DESIGN OF THE CIRCUITS

There is no significant difference between the electrical performance of flexible circuits and that of rigid circuit boards. But there are small differences in conductivity and insulation resistance depending on the materials. Also, there are small differences in dielectric constant and tangent delta. Therefore, similar calculations can be applied to determine electrical performances for a flexible circuit. However, flexible circuits have a relatively long parallel circuit for cabling capability, and impedance should be managed carefully, especially for high-speed circuits with high frequencies.

66.5.1 Insulation Resistance

Insulation resistance (IR) is one of the most critical parameters from both a design and materials standpoint. IR tests are utilized in determining the raw materials properties, as well as controlling quality of the end product, since they are indicators of moisture and other contamination

commonly found in the manufacture and handling of flexible printed wiring. The test is conducted by performing IR measurements between conductors on a layer and/or between the layers in a double-sided or multilayer board after a specified time in a humidity and temperature cycle. A voltage of 100 V AC is applied during the test, and measurements are made immediately thereafter.

Cover-coated flexible wiring retain their high-IR values even under severe humidity conditions. Wiring that is not cover coated usually retains high-IR values provided the surfaces are clean and free from flux, fingerprints, etc. The insulation resistance of a 30-ll, polyimide, FPW device of microstrip design and cover coated with a 0.001-in polyimide film-phenolic modified polyvinyl butyral adhesive is shown in Table 66.5.

TABLE 66.5 Insulation Resistance of 30 Ω Microstrip Flexible Printed Circuit (Average Readings)

FPW Device No.	Initial, $\Omega \times 10^{11}$	After Humidity, $\Omega \times 10^{9}$
Line to line		
1	5	7.1
2	5	3.9
3	5	3.6
4	5	4.8
Line to shield		
1	5	11.6
2	5	3.2
3	5	9.0
4	5	8.2

1. All after-humidity readings were taken within 0 to 2 h after removal from humidity.
2. Above readings are average for 45 measurements per FPW.

66.5.2 Dielectric Withstanding Voltage

This property of the wiring is dependent upon the *air* density and conductor spacing. The important factor for the designer to consider is the potential at which flashover occurs in the air above the conductors. The results in Fig. 66.21 will serve as a design guide. The de breakdown voltage variation, as a function of conductor spacing for cover-coated flexible

printed wiring, is shown in Fig. 66.22. *As* indicated, increasing altitude lowers the insulating properties of air, owing to ionization, and thus greater conductor spacing is required.

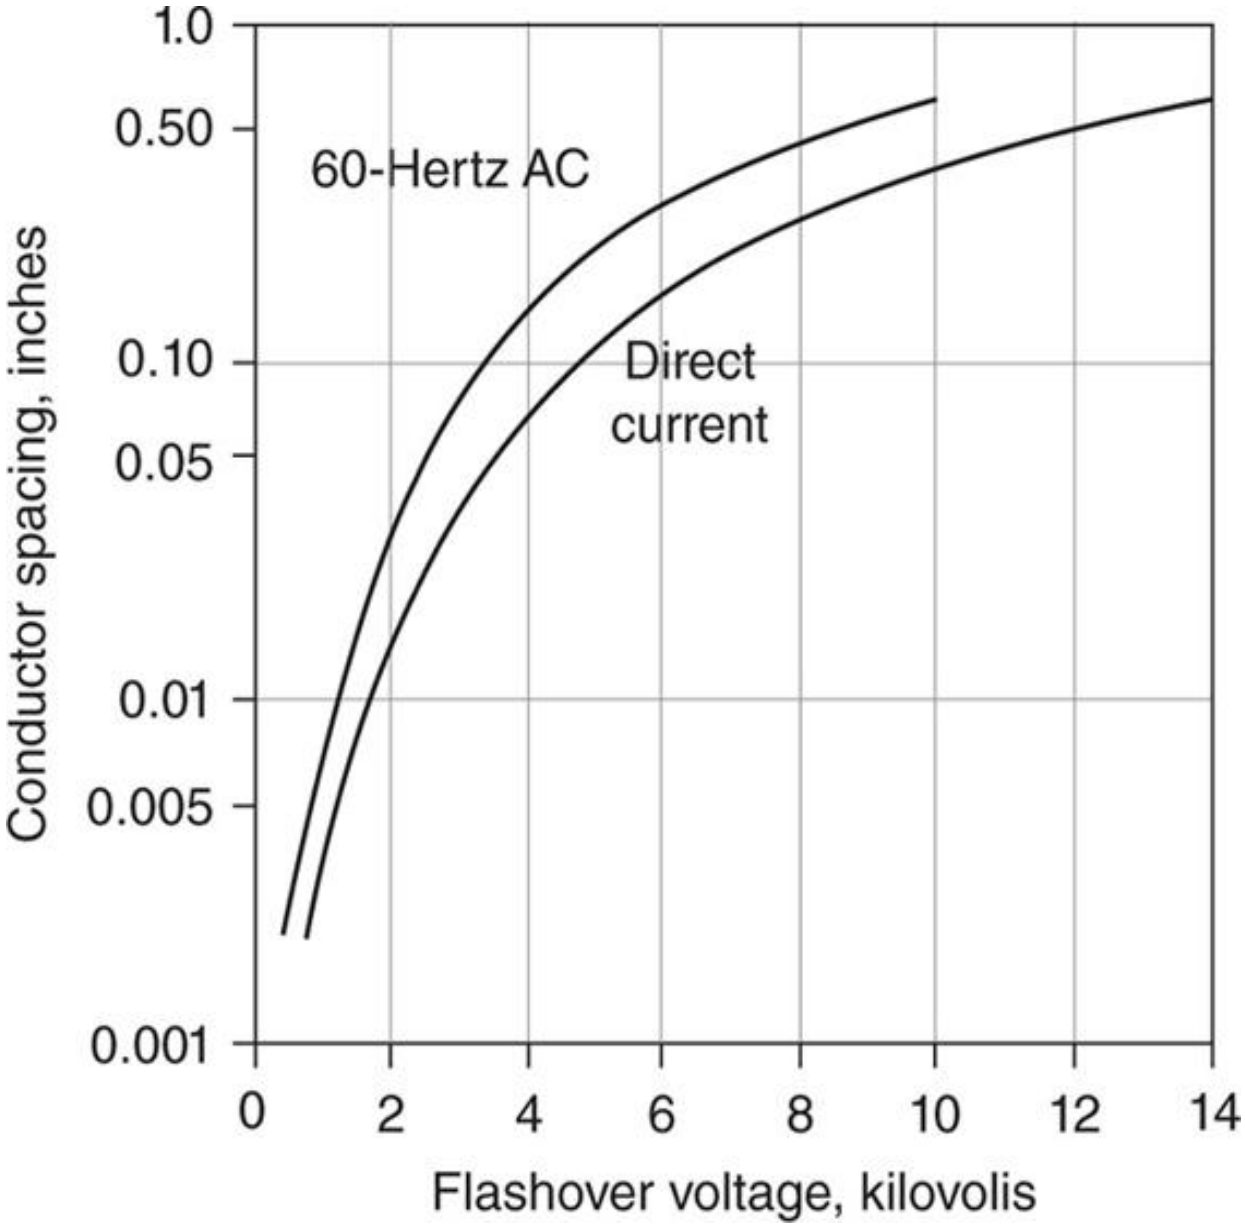

FIGURE 66.21 Flashover voltage in air. (*Sanders Associates*.)

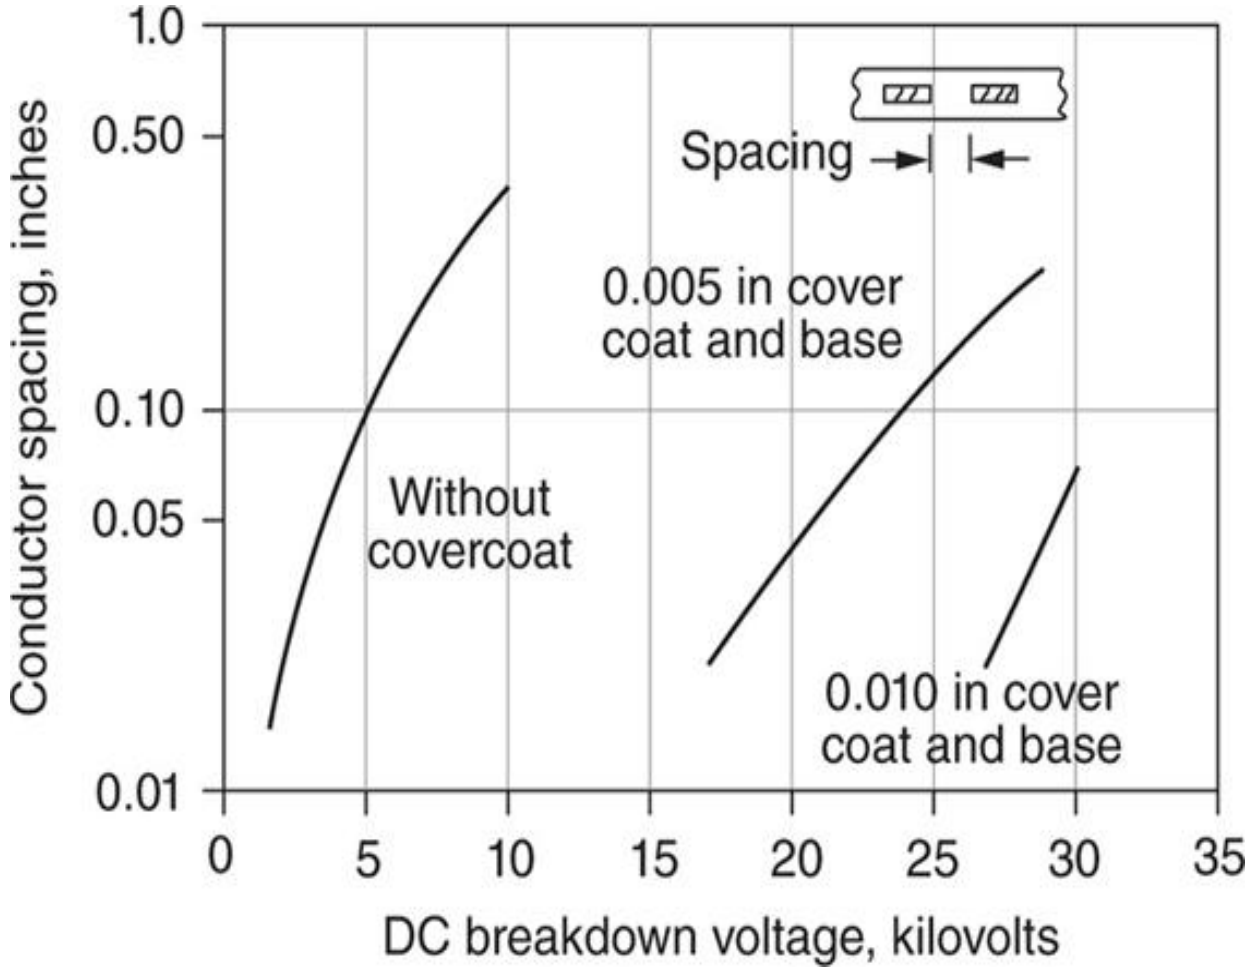

FIGURE 66.22 Breakdown voltage between insulated conductors. (*Sanders Associates*.)

66.5.3 Determination of Conductor Size

The size of a conductor for a given printed wiring application is based upon the following parameters:

- Current-carrying capacity
- Conductor resistance
- Maximum allowable temperature rise in conductor
- Derating effect of multiple conductors in same wiring
- Effects of mounting on current-carrying capacity

- Fusing current
- Capacitance

66.5.4 Capacitance

Capacitance between adjacent conductors consists of both parallelplate capacitance C_P and fringing capacitance C_r, as shown in Fig. 66.23. Parallel-plate capacitance is generally negligible, since the conductors are very thin and thus have small areas opposing each other. Fringing capacitance is therefore the principal form of distributed capacitance between adjacent conductors in flexible printed wiring. Since some portion of the fringing field (usually about half) extends into the air outside the thin insulation, calculation of exact capacitance depends on thickness and dielectric constant of the insulation, dielectric constant of the surrounding medium, widths and thicknesses of the conductors, spacing of the conductors, presence of nearby grounds, and frequency (dielectric constants change with frequency).

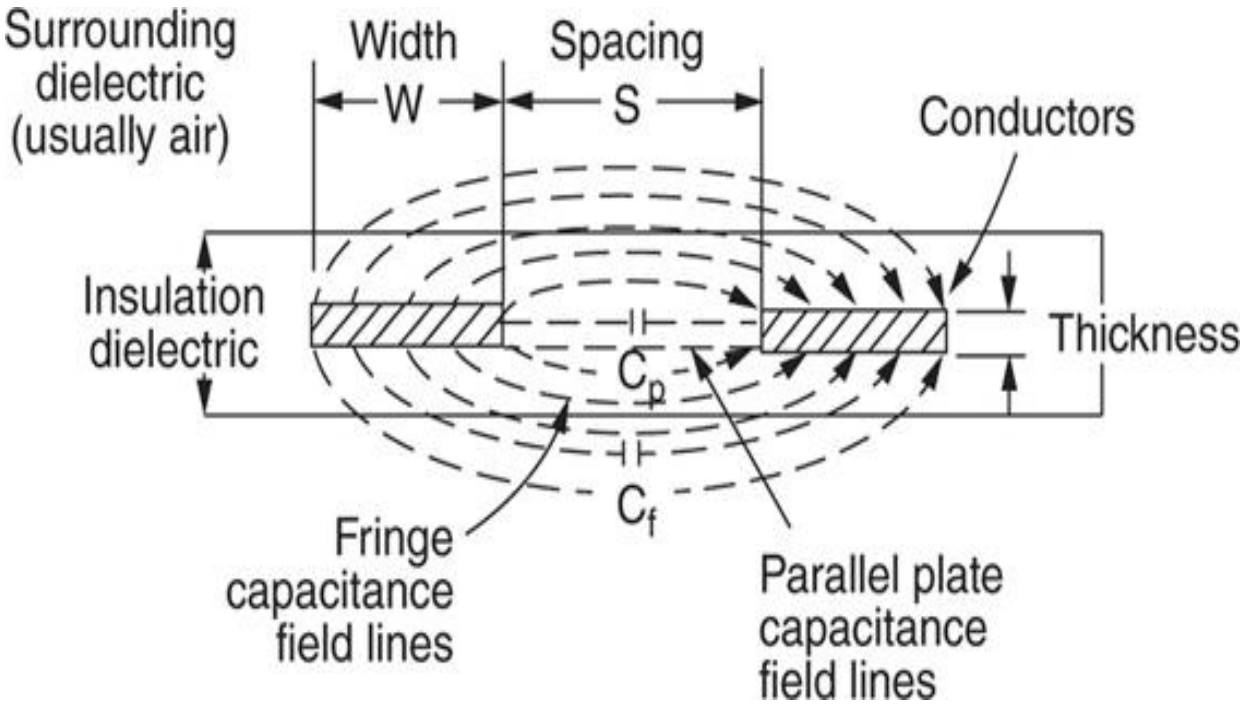

FIGURE 66.23 Distributed capacitance between conductors is and that of air. The capacitance fringing C_f capacitance.

Actual measurements are required to obtain accurate capacitance values. However, distributed capacitance can be roughly examined by establishing a dielectric constant of "median value," which falls between that of the insulating material values calculated by using that approximation serve as guidelines to the distributed capacitance which will actually exist in a given circuit configuration. The results of such a calculation are shown in Fig. 66.24. The capacitance per foot at l kHz between two conductors in flexible printed wiring insulated with 0.005 in of polyester is shown. To determine capacitance values for similar flexible wiring with other insulation materials, multiply the values found from Fig. 66.24 by the proper dielectric constant ratio found from Table 66.6. The values shown in Fig. 66.24 assume a conductor pair free from the influence of other surrounding conductors or ground planes.

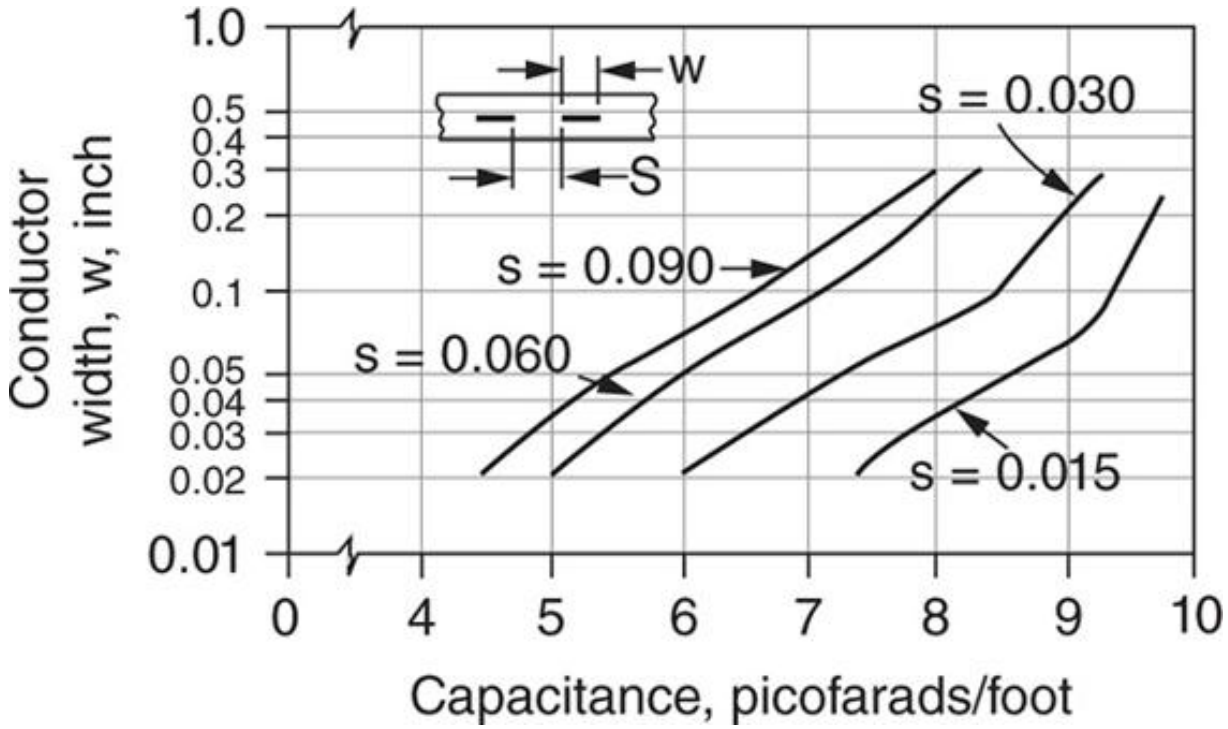

FIGURE 66.24 Calculated capacitance between two adjacent parallel conductors insulated with 0.005 in of Kel-F or polyester (heat sealable); calculated for 2-oz conductor at 1 kHz.

TABLE 66.6 Ratio of Dielectric Constants

Polyester	1.0
FEP Teflon	0.90
Polyethylene	0.93
Vinyl (PVC)	1.4
Polymide (Kapton)	1.21

In practice, the isolation shown in Fig. 66.25*a* is seldom encountered, and measurements made between two conductors "guarded" by two other grounded conductors, in *b*, show capacitance values reduced by approximately 20 percent from those found by using

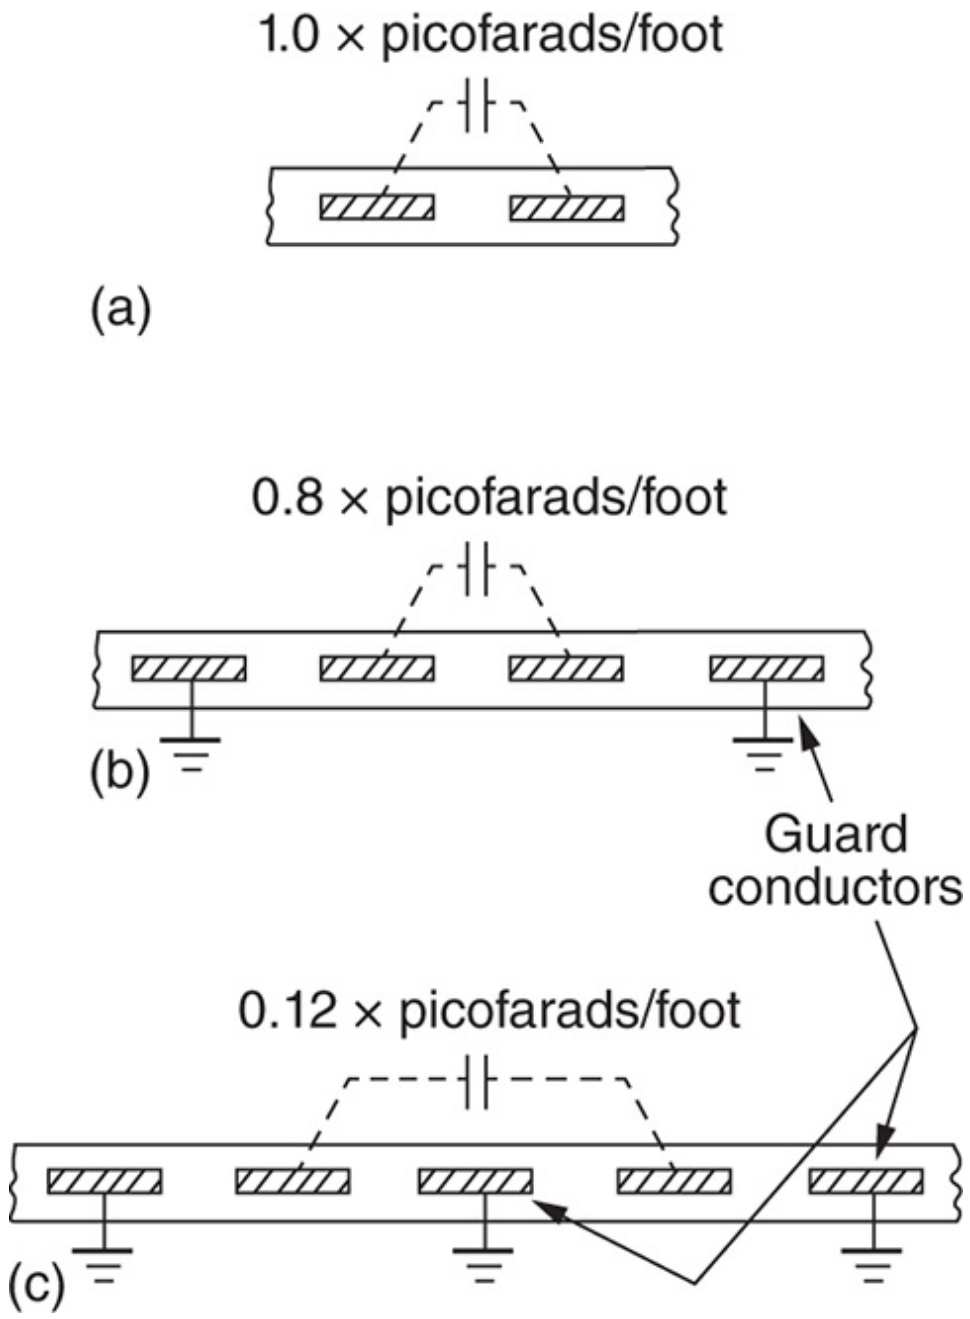

FIGURE 66.25 Typical conductor shielding effect resulting from “guarding” by adjacent grounded conductors: (*a*) no guard conductors, (*b*) peripheral guard conductors, (*c*) interspersed and peripheral guard conductors.

The reduction occurs because some of the fringing flux lines normally joining the measured conductors now terminate on the surrounding grounded conductors and therefore do not contribute to the measured value. Capacitance between two conductors was even more

drastically reduced (about 85 percent) when a grounded conductor was placed between the conductors and grounded conductors also were placed on either side (Fig. 66.25*c*). If the guard conductors of *b* and *c* are floating rather than grounded, capacitance between the measured pair will increase slightly. That situation is seldom encountered in practice, since conductors other than spares usually are not floating.

For some applications it is desirable to find the capacitance between two flat conductors which are completely enclosed by the insulation and have and have their wide surfaces facing each other. Figure 66.26 illustrates the geometry of the problem. Capacitance in that case can be found using one of the two following relations:

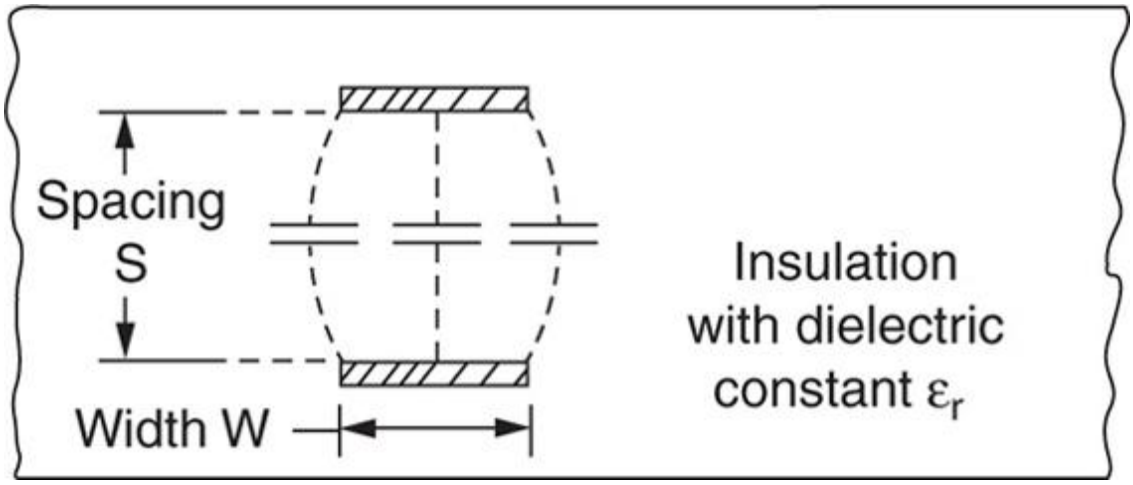

FIGURE 66.26 Capacitance between two conductors with large surface opposing is largely parallel-plate capacitance.

For $\frac{w}{s} < 1$

$$C_{\text{total}} = \frac{3.68\varepsilon_r}{10_{10}\left[\frac{45}{w}\right]} \quad \text{pF/ft}$$

where w = width, ft
s = dielectric separation between conductors, ft
C = capacitance, pF/ft
ε_r = effective dielectric constant

In this case, the result will be approximately 2 percent higher for w/s <1/2 and approximately 10 percent high for w/s = 1

For w/s > 1

$$C_{\text{total}} = 2.7\frac{w}{s}\varepsilon_r x\left[1+\frac{s}{\pi\omega}\left(1+2.303\log_{10}\frac{2\pi\omega}{s}\right)\right] \text{pF/ft}$$

In this case, the result will be approximately 4 percent low for w/s = 2 and approximately 10 percent low for w/s = 1.

For w/s > 1

$$C_{\text{total}} = 2.7\frac{w}{s}\varepsilon_r x\left[1+\frac{s}{\pi\omega}\left(1+2.303\log_{10}\frac{2\pi\omega}{s}\right)\right] \text{pF/ft}$$

In this case, the result will be approximately 4 percent low for w/s = 2 and approximately 10 percent low for w/s = 1.

Figure 66.27 is an approximate guideline to the capacitance between two flat conductors which are exposed to air on either side of a dielectric layer. Capacitance of flat conductors to surrounding metallic shields and/or ground

planes is shown in Fig. 66.28 for standard flexible printed wiring using FEP Teflon insulation.

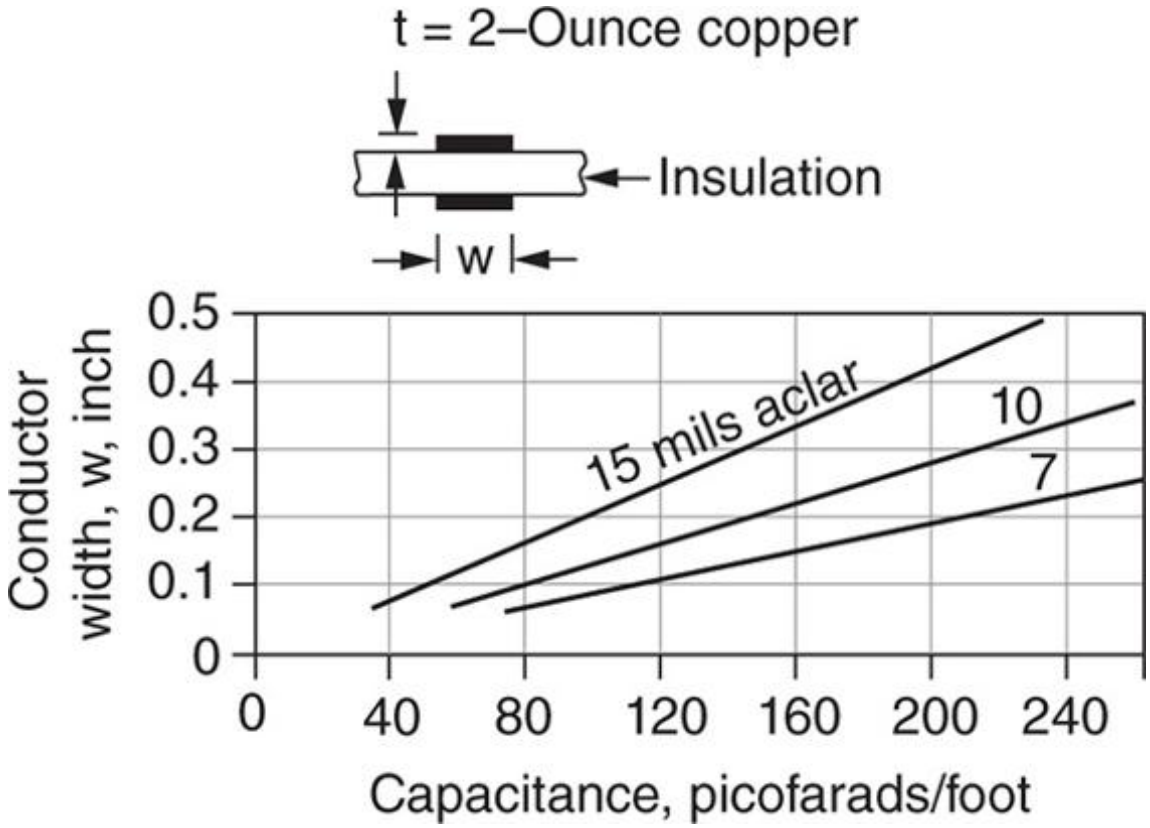

FIGURE 66.27 Typical capacitance at 1 MHz between two flat conductors exposed to air on either side of a dielectric layer.

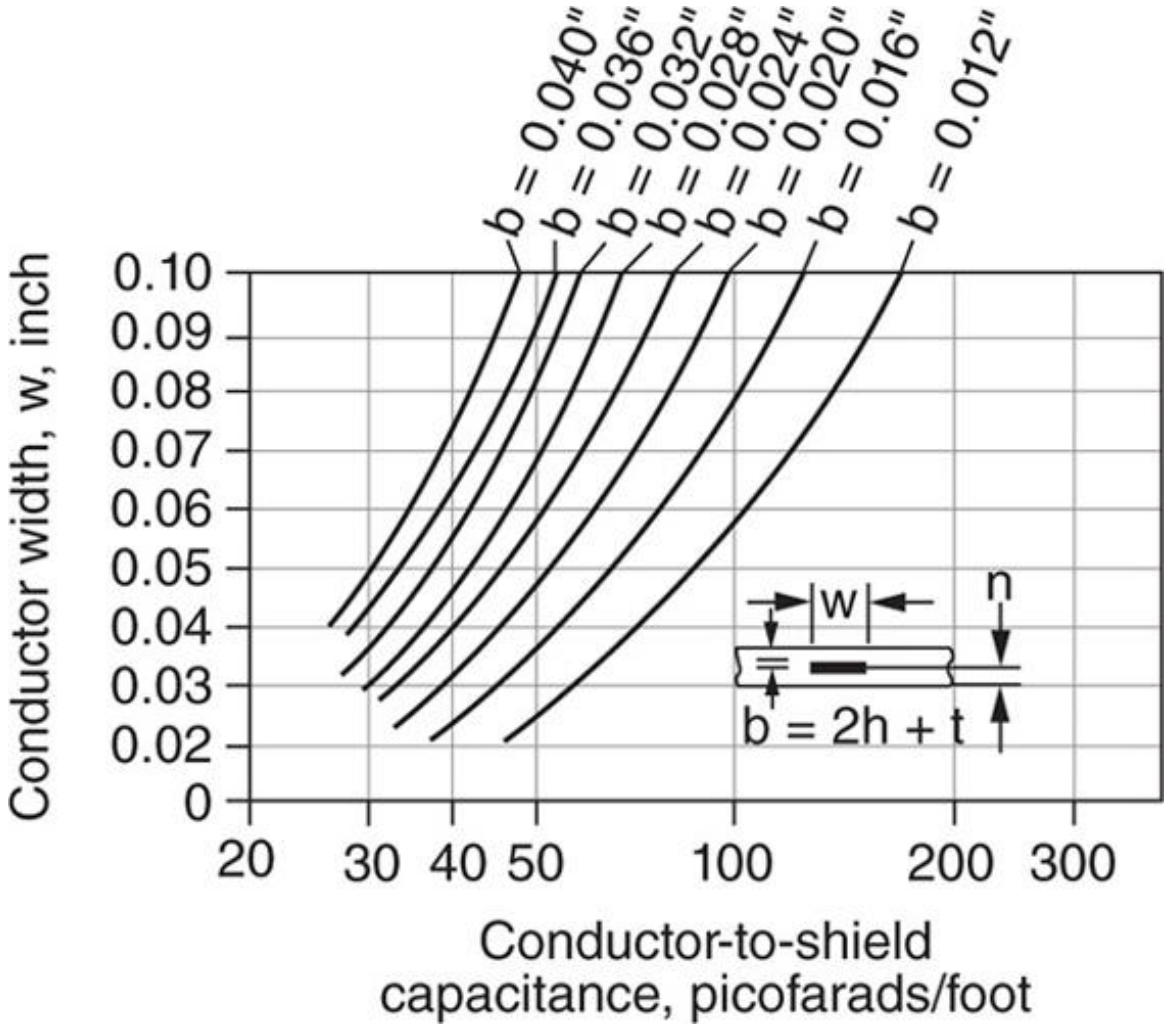

FIGURE 66.28 Typical conductor-to-shield capacitance for 2-oz copper conductor insulated with FEP Teflon.

66.6 DESIGN OF FLEXIBLE PRINTED WIRING WITH TRANSMISSION LINE PROPERTIES

Flexible printed wiring has found widespread use in transmission line applications either as a replacement for coaxial wires or in initial designs of high-speed circuits. With the advent of LSI devices the use of printed wiring with transmission line properties has increased manyfold. This

section will provide the designer with sufficient data to effectively design flexible printed wiring with transmission line properties.

The Institute of Printed Circuits defines and explains the term “transmission line” as follows: “‘Transmission line’ is one signal-carrying circuit composed of conductors and dielectric material with controlled electrical characteristics used for the transmission of high-frequency or narrowpulse type signals.”

Transmission lines are a group of electrical interconnections on an organic base which are used in highfrequency applications, usually above 50 MHz. In such circuitry the interconnecting metallic conductor is acquiring additional electrical characteristics and acts as the transmission line waveguide.

Two types of such transmission line configurations are utilized: “microstrip,” in which the conductor is located above a single ground plane (Fig. 66.29*a*) and “strip-line” in which the conductor is located centrally between two ground planes (Fig. 66.29*b*). Important parameters of such conductors are line width, dielectric separation to ground plane, and dielectric constant of the insulating materials, all of which determine the impedance, signal propagation, and cross-talk characteristics of the lines. The following parameters govern the design of flexible printed wiring transmission line devices.

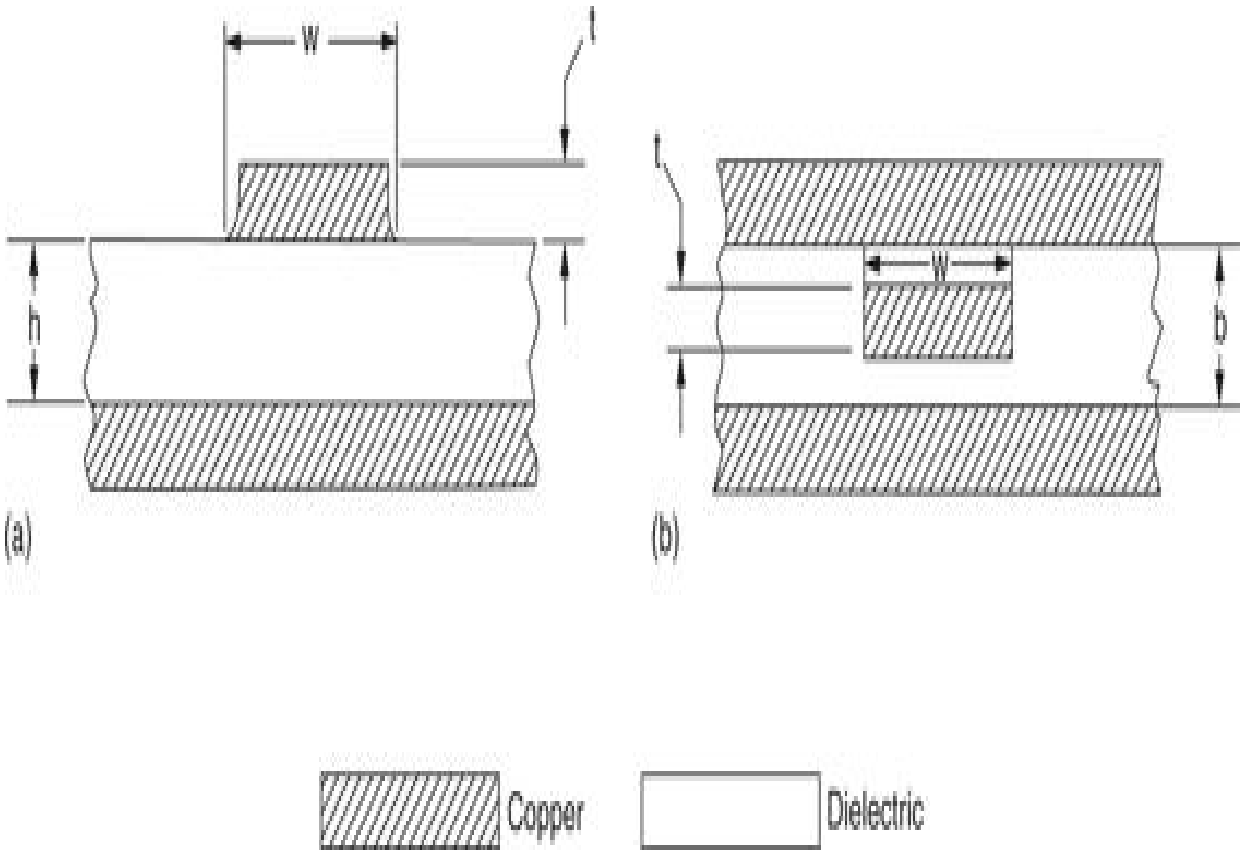

FIGURE 66.29 Printed wiring transmission line configurations.

Characteristic impedance The single and most important electrical parameter in determining the performance of high-speed circuits is the characteristic impedance of the conductors. If Z_0 is controlled, signal reflections which result from the passage of fast pulses through an impedance discontinuity or mismatch at the load end of the line will be avoided. The characteristic impedance is dependent upon the conductor line width *w*, dielectric thickness *h* or *b*, conductor thickness, dielectric constant of the insulating medium, and the configuration (microstrip or strip-line) of the device. The general equation for characteristic impedance of any high frequency transmission line is as follows:

$$Z_0 = \sqrt{\frac{R + j\omega L}{G + j\omega C}}$$

where Z_0 = impedance, Ω
R = resistance per unit length of line
L = inductance per unit length of line
G = conductance per unit length of line

$$\omega = 2\pi f$$

C = capacitance per unit length of line

If the line is lossless, the equation is simplified:

$$Z_0 = \sqrt{\frac{L}{C}}$$

66.6.1 Microstrip Configuration

A specific formula for microstrip is the following:

$$Z_0 = \frac{h}{w}\frac{377}{\varepsilon_r}$$

where *h* and *w* are given in the diagram and *is* the effective dielectric constant of the material (considering the effect of air). This analytical method disregards fringing effects and leakage flux and gives validity to the notion that more reliable values may be obtained by measurement. To account for the fringing effects of microstrip transmission

line, and if the analytical method must be used, the following formula is recommended:

$$Z_0 = \frac{h}{w} \frac{377}{\sqrt{\varepsilon_r}\ [1+(2h/\pi\omega)(1+\ln \pi\omega/h)]}$$

If the microstrip line is embedded or covercoated as shown in Fig. 66.30, the Z_0 values will be reduced by approximately 22 percent. Typical values of Z_0 for microstrip fabricated of an epoxy glass base material having a dielectric constant varying from 6 at 1 kHz to 5 at 25 MHz when conductors are exposed to air, are given in Fig. 66.31.

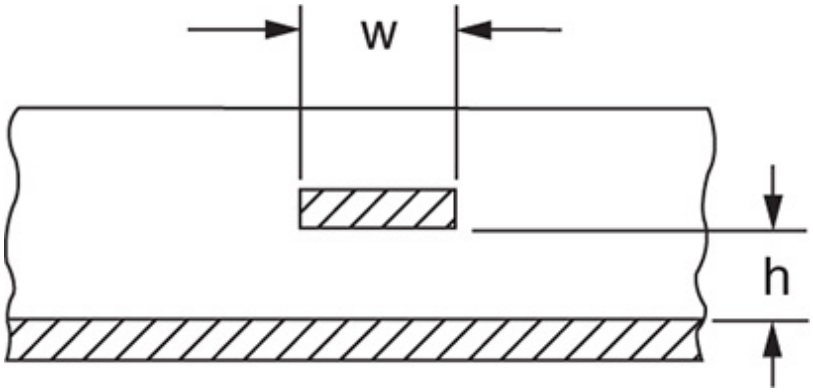

FIGURE 66.30 Schematic representation of embedded or cover-coated microstrip FPW.

board material dielectric constant relatively stable with frequency varying from about 6 at 1 kHz to about 5 at 25 MHz.

66.6.2 Strip-Lines

The characteristic impedance Z_0 of strip transmission line when $w/b >> 0.35$ can be determined by the following relation:

$$Z_0 = (60/\sqrt{\varepsilon_r})[\ln(4b/d_0)]$$

where d_0, the effective *wire* diameter for square configuration, is $0.567w + 0.67t$.

Representative values of Z_0 for microstrip and strip-line transmission line wiring are presented in Fig. 66.32. The use of curves to determine strip-line parameters is preferred over the more cumbersome methods of calculation. A family of curves that has proved to be very useful for that purpose is shown in Fig. 66.33. It is applicable to a wide range of copper thicknesses.

FIGURE 66.33 Graph of Z_0 versus w/b for various values of t/b.

If one were to fix the parameter t at 0.0028 in (2-oz copper), the family of curves could be redrawn to show the relations of w and b for various values of normalized characteristic impedance $\varepsilon_r Z_0$. That family of curves is shown in Fig. 66.34, and it is usable for any insulating material whose dielectric constant is known or measurable.

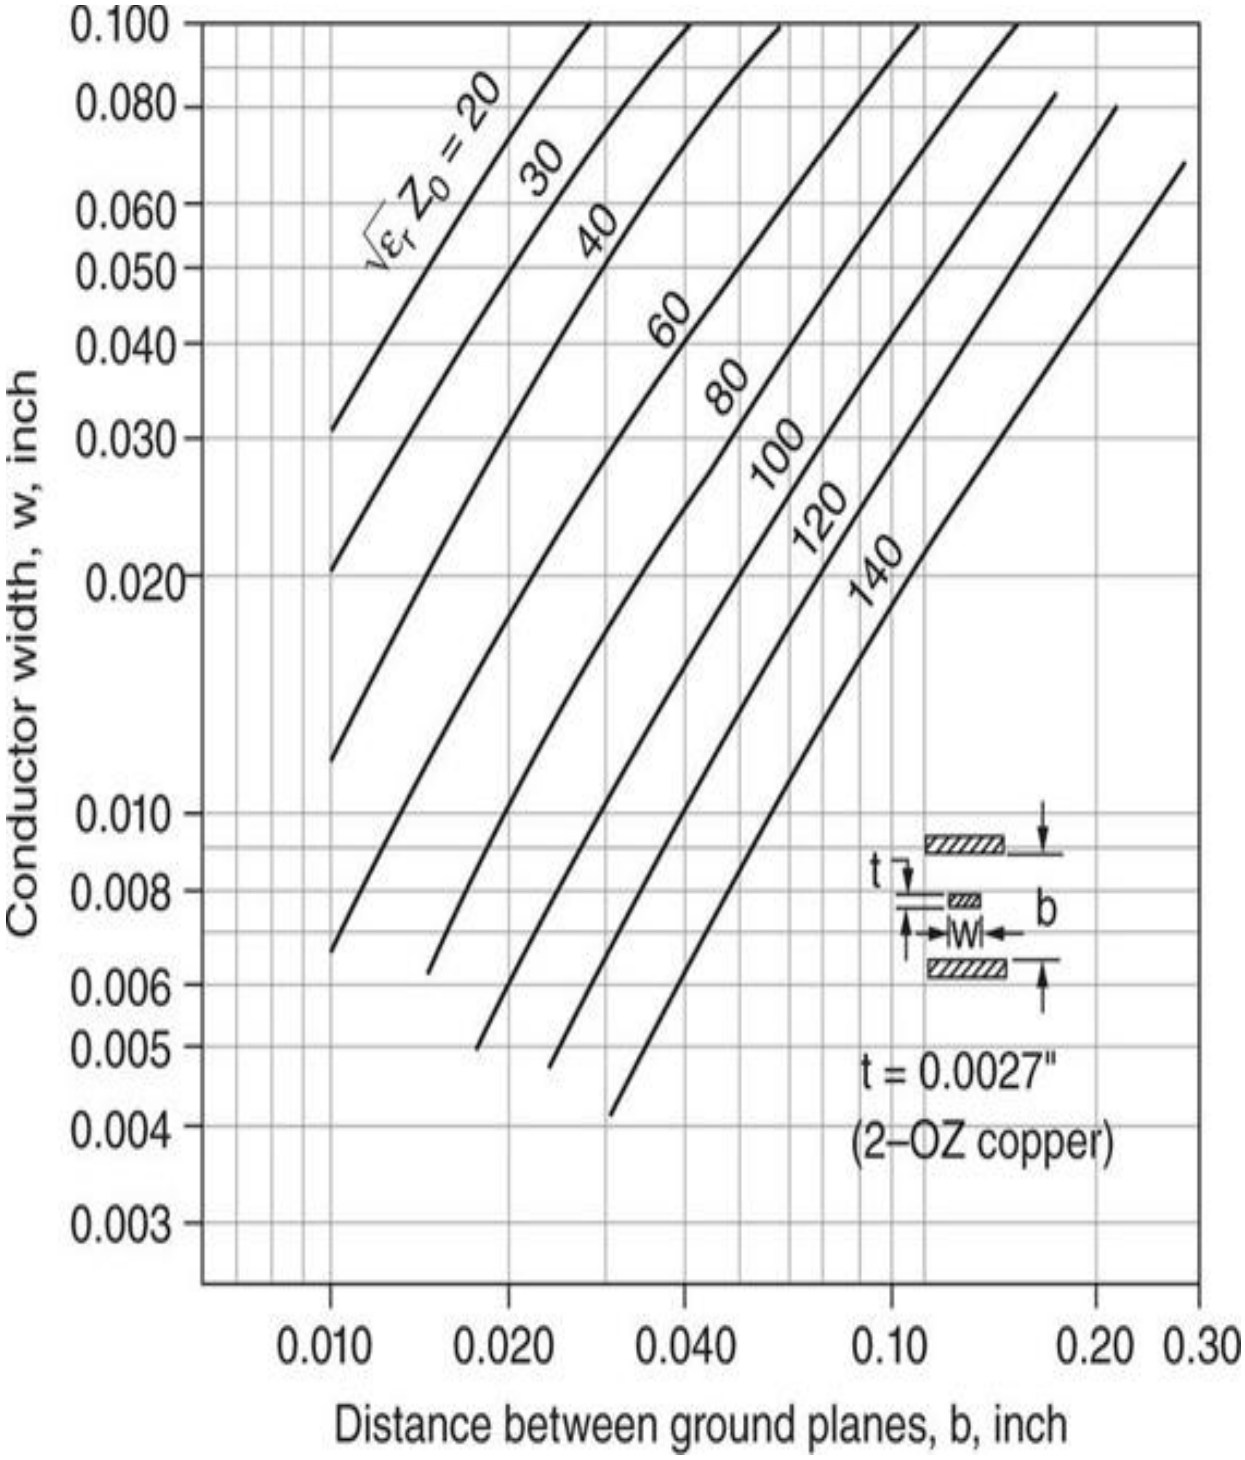

FIGURE 66.34 Normalized impedance $\varepsilon_r Z_0$ as a function of conductor width *w* and dielectric separation *b* in strip-line configuration.

Specific Example: The following exercise is presented to familiarize the designer with the use of the curves in the

solution of a typical design problem given these conditions:

Flexible printed wiring, cover coated
$Z_0 = 75\ \Omega$
Overall thickness = 0.062 in
Material = Teflon, $\varepsilon_r = 2.1$

Determine the proper curve in the family. Since the material has been designated as Teflon with an ε_r of 2.1, the suggested curve would be $\varepsilon_r Z_0 = 110$.

Determine dielectric separation b. Knowing that the overall thickness should not exceed 0.062 in, the value of b should be set at 0.050 in. The number is based upon the difference between the overall thickness and the expected thickness of the two ground shields and two cover-coated layers.

Determine conductor width w. The value of w as read from the graph is 0.017 in.

The construction of the strip-line in this hypothetical case is shown in Fig. 66.35. The spacing between conductors is determined by FPW width, electrical parameters, and processing limitations.

66.6.3 Special Transmission Lines for Flexing

Three high-speed differential transmission line configurations are available:

1. Edge-coupled differential microstrip with mesh GND
2. Coplanar differential microstrip w/o opposing GND
3. Broadside coupled differential microstrip w/offset GND

1. Edge-coupled differential microstrip with mesh GND is very common. Figure 66.36 shows a closer view of the mesh GRN and the E-fields.

66.6.4 Electrical Parameters

Capacitance *C* for double-sided wiring is determined by the formula:

$$C = \frac{0.2249}{d}\varepsilon_r A$$

where C = capacitance, pF/in
ε_r = dielectric constant relative to air = 1
A = area of smallest electrode, in^2
d = thickness of dielectric, in

Under normal conditions, lines that are parallel and are separated by 0.062 in on 0.062-inthick epoxy glass ($\varepsilon_r = 5$) will have a capacitance of 0.5 pF/in. Corresponding wiring fabricated from Teflon will have a *C* of 0.3 pF/in.

In multilayer boards, capacitance is calculated by a different formula, although the conductors are still capacitively coupled when they physically approach each other in the horizontal or vertical direction. An approximate value for the amount of capacitive coupling may be calculated by the equation:

$$C = \frac{w\varepsilon_r}{h4.45}$$

where ε_r = effective dielectric constant
h = height, in $\times 10^{-3}$
w = width, in $\times 10^{-3}$

for the configuration shown in Fig. 66.39.

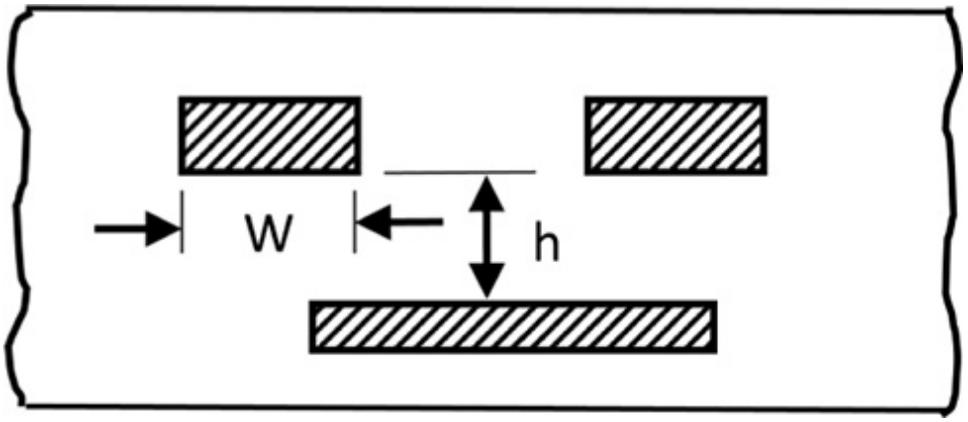

FIGURE 66.39 Schematic of multilayer printed circuit.

Microstrip may be used as a single wiring layer or the outside layer of a multilayer board. Strip transmission line may be used either as one or a multitude of wiring layers. Capacitance of strip transmission line can be approximated by the equation:

$$C = 0.9 \frac{w/b}{1-(t/b)} \varepsilon_r$$

66.6.4.1 Time Delay. The delay in the signal propagation velocity in microstrip line can be calculated using the formula:

$$T_d = 1.015\sqrt{\varepsilon_r} \text{ ns/ft}$$

where T_d is time delay per unit length of conductor and ε_r is effective dielectric constant of the transmission line or the dielectric constant of the board's dielectric if the conductor is embedded.

The equation is valid only when the conductor's capacitance is greater than the load capacitance that results when switching circuits are added to the line. Embedding microstrip lines, as in multilayer printed wiring, makes the circuit appear "electrically larger." That is, a signal takes longer to travel a given distance in the embedded line than in the unembedded or pure microstrip line. Therefore, embedding the lines means that critical wiring lengths must be reduced 22 percent to maintain the same time delay (length embedded = 0.78 × length unembedded). It is apparent that line delays may approach circuit delays. Figure 66.40 shows graphically the relation between circuit and line delays. The solid lines represent circuit delays and the broken lines represent percents of logic delays: 10, 20, 30, 40, and 50 percent. For a required maximum total delay and a given logic delay, the maximum line length can be determined.

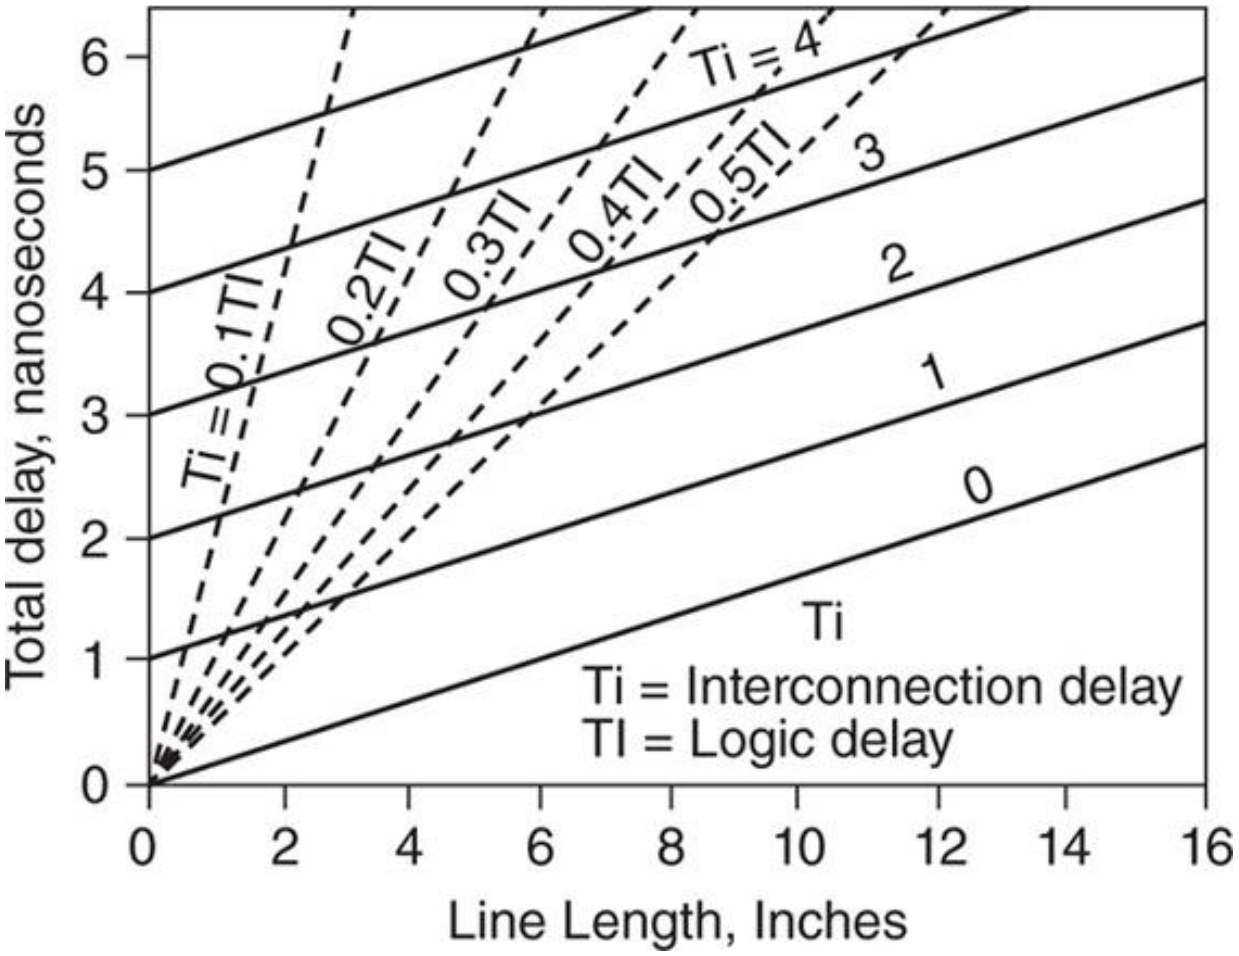

FIGURE 66.40 Interconnection delay and logic delay versus length for a dielectric of 4.5.

66.6.4.2 Cross Talk. Cross talk is the undesirable coupling of energy between signal paths. The unwanted transfer of energy between lines results from the capacitive and inductive coupling of the lines and is a function of length of the lines, space between the lines, and the dielectric constant. The phenomenon is often a limiting factor in high-speed digital systems in which coupling between lengths of parallel lines may be the only alternative to the high wiring density which is required. Cross talk between an active line, that is, the line carrying the voltage pulse, and a passive line in the vicinity places a spurious pulse on the passive line. If the latter pulse is of sufficient amplitude, it could falsely switch circuits on the passive line. Traditionally, before cross

talk could be calculated it was necessary to calculate or measure mutual inductance, mutual capacitance, propagation velocity, and impedance of the lines. Analytical methods are unwieldy because of the effect of air on the dielectric constant and the uncertainty of fringe field effect. A method that is now available depends only on the geometric cross section of the lines and is independent of time, length, and voltage.

For the case of microstrip, then, induced voltage values due to cross talk may be calculated by use of the formulas:

$$V_B(t) = K_S\left[V_i(t) - V_i(t - 2l\sqrt{LC})\right]$$

$$V_F(t) = K_F l \frac{dV_i}{dt}(t - l\sqrt{LC})$$

where l = length of coupled region

V_B = induced backward voltage as seen at the ends of the coupled region

V_F = induced forward voltage as seen at the ends of the coupled region

V_i = input voltage

K_S = backward cross-talk constant

K_F = forward cross-talk constant

t = time, ns

K_B is always positive with respect to the driving signal; K_F is negative for microstrip and will be zero for homogeneous dielectric media. To determine cross-talk constants for any system, use line lengths in which $2T_d$ is significantly greater than the rise time and use the following formulas:

$$K_B = \frac{V_B}{V_t} \quad \text{and} \quad K_F = \frac{V_{F\max}}{dV_t/dt_{\max}} \frac{1}{l}$$

where l = length of coupled region
V_B = induced backward voltage
V_F = induced forward voltage
V_t = input voltage

Pulse cross talk is represented by

$$V_B(t) = K_B\left[V_i(t) - V_i(t-1)\sqrt{LC}\right]$$

$$K_B = V_i \qquad K_i = V_i \qquad V_t \rightarrow V_i$$

Empirical values for K_B and K_F are given in Figs. 66.41 and 66.42.

66.6.4.3 Attenuation. Power may be lost in transmission lines by radiation, heating of the conductors, and heating of the dielectric. Heat losses in both the conductor and the dielectric increase with frequency. Conductor losses are greater the lower the characteristic impedance of the cable. The converse is true of dielectric losses. Because of its low impedance, the specified printed wiring has an attenuation higher than that of the most common coaxial cables. Typical data for a frequency range of 1 to 3000 MHz are shown in Fig. 66.43.

66.7 CIRCUIT DESIGNS FOR HIGHER RELIABILITY

Because of the thin and fragile materials used, flexible circuits have lower mechanical reliability than rigid circuit boards. They have a low conductor bond strength and low base substrate tear strength. Nevertheless, most of the flexible circuits are subject to more mechanical stresses due to movement. This means that special care is required in the circuit design to gain higher circuit reliability.

There are several ways to make the reliability higher. Figures 66.44 and 66.45 show several common ideas for increasing the reliability of flexible circuits by modifying conductor patterns.

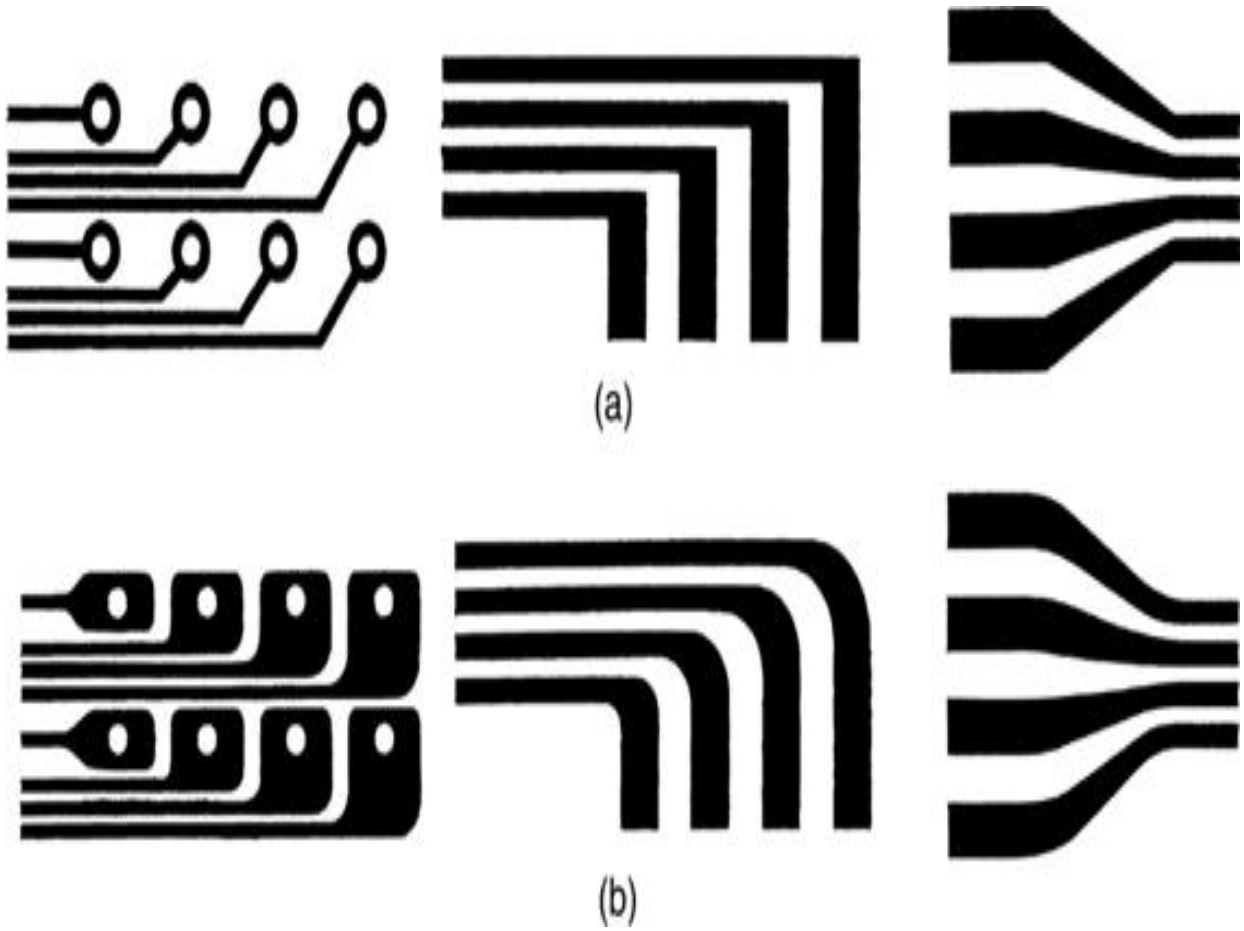

FIGURE 66.44 Reliability design for flexible circuits: (*a*) unacceptable, (*b*) preferred.

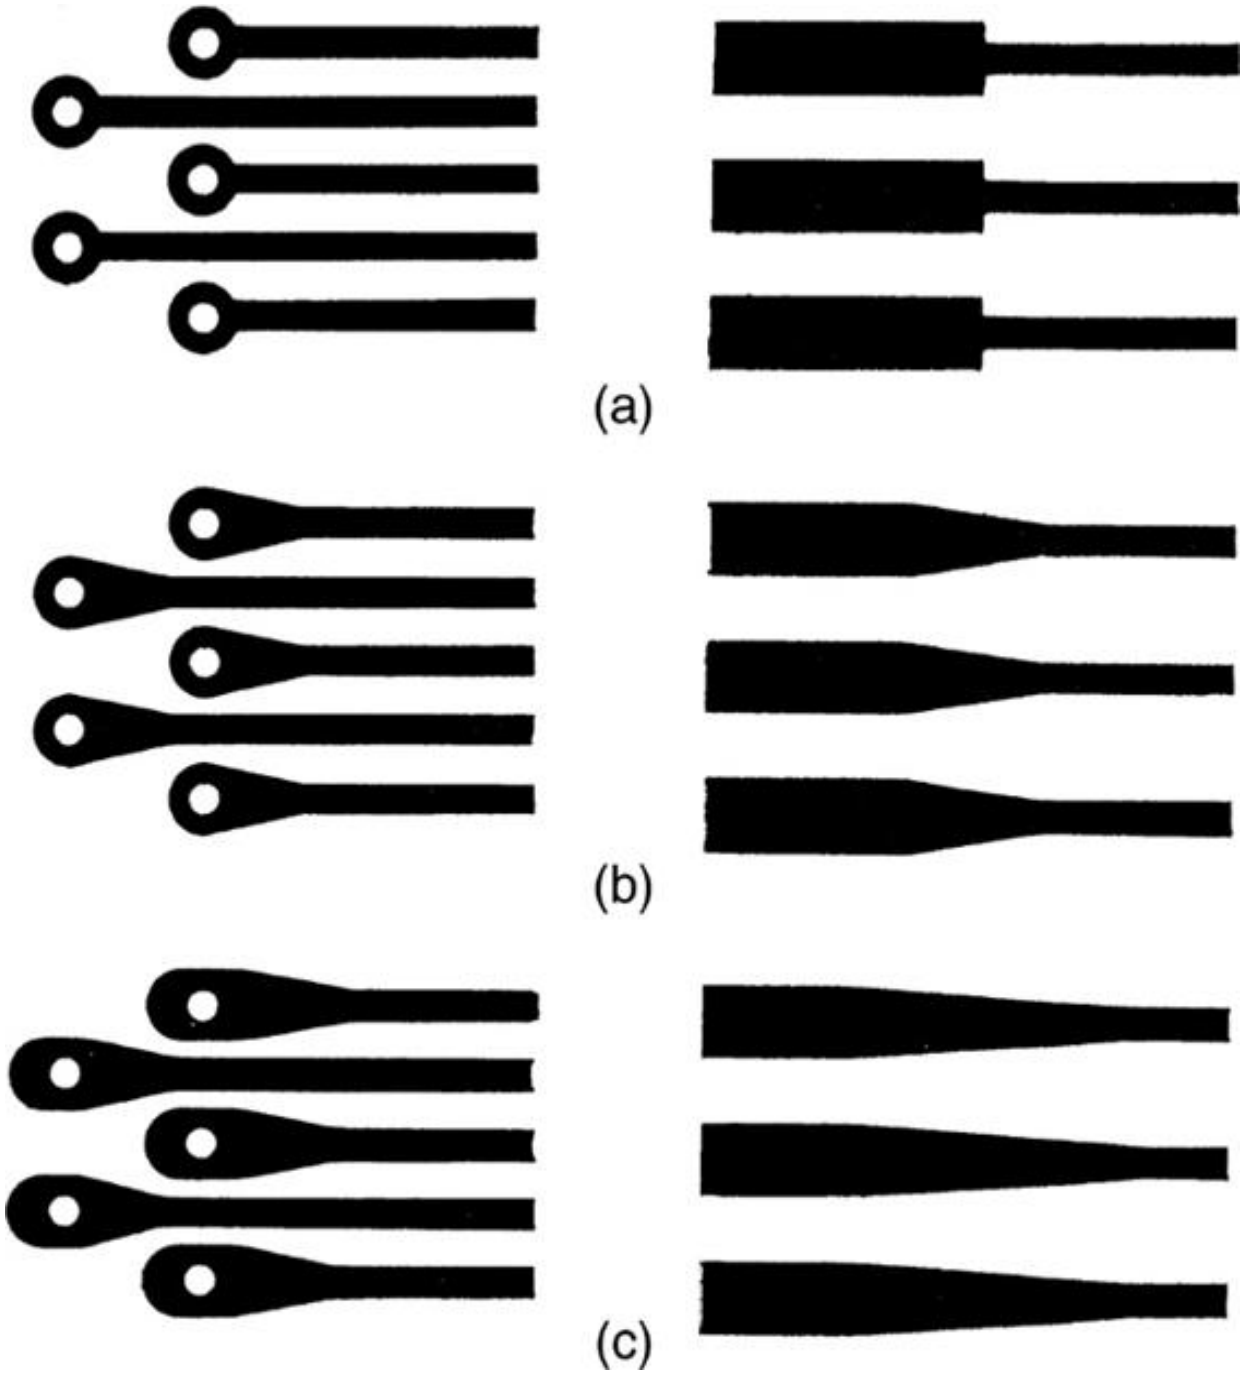

FIGURE 66.45 Reliable pattern design for flexible circuits: (*a*) unacceptable, (*b*) acceptable, (*c*) preferred.

The trace patterns should be smooth slopes between different widths. The pad size should be as large as possible. Figure 66.46 shows an example applied for automobile instrument panels. The conductors are designed to be as

wide as possible, and the spaces between conductors are kept in the safety range. A suitable coverlay opening could increase the reliability, as shown in Fig. 66.47. The amount of squeeze-out of coverlay adhesives should be minimized, however. The edge areas of stiffener boards are dangerous places in which mechanical stresses are concentrated. Figure 66.48 shows ways of reducing these risks.

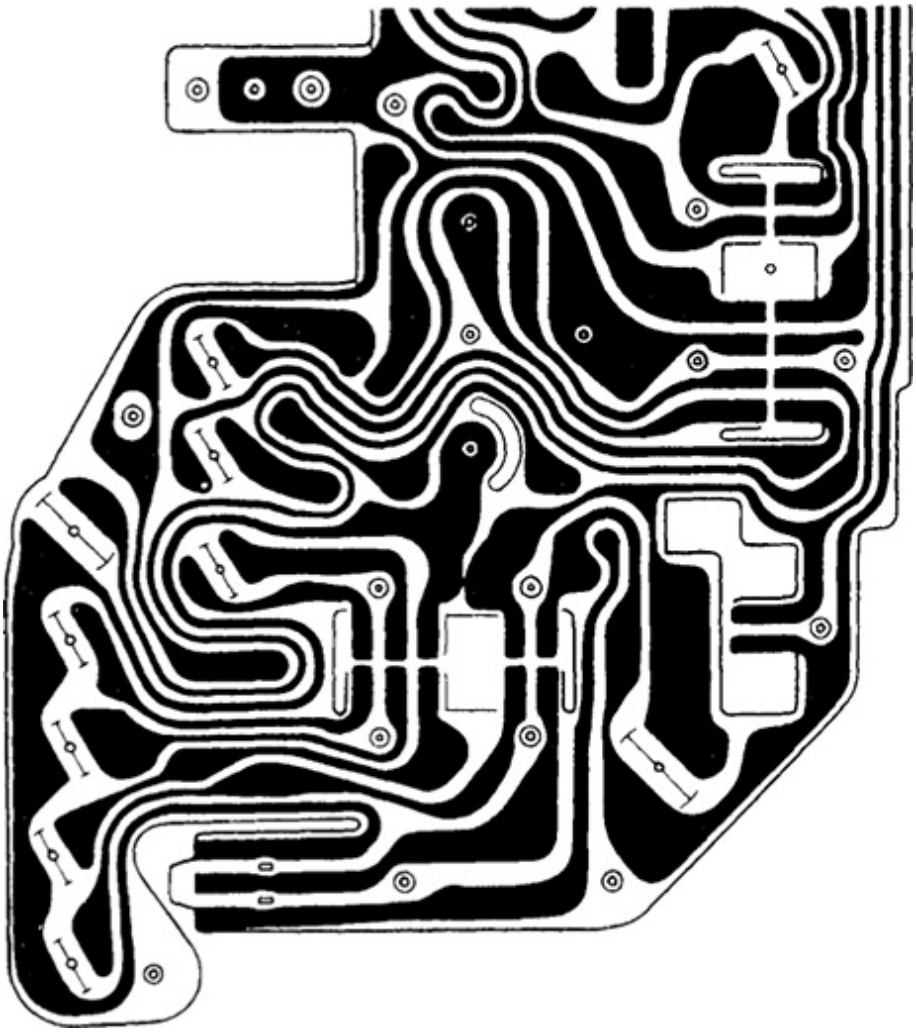

FIGURE 66.46 Conductor pattern designed for the instrument panel of an automobile.

66.8 ACKNOWLEDGMENTs

The author extends his appreciation to the industry and the many who contributed to the progress of flexible circuit

activities, specifically J. R. Cannizzaro, who authored this chapter in prior *Printed Circuits Handbooks*. Sincere thanks also goes to Dominique K. Numakura, at DKN Research, for his authorship of this chapter in the previous (6th) edition of *Printed Circuits Handbook*.

CHAPTER 67

MANUFACTURING FLEXIBLE CIRCUITS

Joseph Fjelstad
Verdant Electronics, Seattle, Washington

67.1 INTRODUCTION

The manufacturing of flexible circuits is fundamentally the same as the manufacturing of rigid PCBs. Any facility capable of manufacturing rigid single, double-sided or multilayer circuits has all the basic tools required to make single-, double-sided, multilayer and rigid/flexible circuits; however, there are some significant differences in terms of the ancillary tooling and materials required to be successful. Compared with rigid boards achieving high productivity at high yield is much more challenging when manufacturing flexible circuits. The thin materials used for flexible circuits are much more delicate and prone to damage thus learning how to handle and process flexible materials are critical elements of their successful production. Manufacturing facilities for achieving high-volume production of flexible circuits must be engineered from the ground up and

specialized equipment is often called for, one of the most obvious of which is equipment designed for roll to roll processing. This chapter discusses some of the various methods and approaches to manufacturing flexible circuits and include discussions on some of the limitations of the processes used beginning with Table 67.1 which highlights some of the unique and significant differences between processing flexible circuits and rigid ones

TABLE 67.1 Unique Flexible Circuits Processing Features and Steps

Area of Concern	Issues for Processing Flexible Materials
Materials	Thin, low stiffness materials Low dimensional stability
Fragility, mechanical distortion	Less amenable to panel processing automation
Automation	Roll to roll processing
Flex specific features	Coverlayers and stiffeners

Most of the issues related to flexible circuit manufacture are a function of the delicate nature of the base which can be easily damaged. Coverlayers or cover-coating materials and the use of stiffeners in constructions are typically specific to flexible circuits and they require supplemental manufacturing processes. Because every additional process can impact manufacturing they can also impact process yield. The limitless variety of circuit outlines and shapes used in flexible circuit designs can often impact material yield and productivity which can increase cost. In addition being thin and delicate flexible base materials can easily incur serious, often fatal damage if they are handled improperly.

Flex materials can also undergo significant dimensional change in the manufacturing process resulting in a pattern

shift relative to mechanical features such as drill holes and the circuit pattern which can negatively impact yield. While some inroads are being made toward automation much flex circuit manufacturing requires skilled “touch labor” and labor intensity, of course, impacts product cost. Successful manufacturing of flexible circuits requires a partnership between design and manufacturing. Decisions made in design can have a significant impact on manufacturing yield, thus it is highly recommended the design and manufacturing have a continuing dialogue on an ongoing basis to ensure mutual success.

As a final note of introduction roll-to-roll (RTR) manufacturing systems are available where there is need for high-volume and high productivity manufacture of flexible circuits. However, it should be noted that RTR manufacturing is not flexible and not well suited to nonstandard flexible circuit constructions. For the most part they are dedicated manufacturing lines best suited to the production of single sided circuits and, to a slightly lesser extent, double-sided ones due to intrinsic limitations of the process.

67.2 FUNDAMENTAL FLEX CIRCUIT PROCESSING STEPS

Figure 67.1 provides a flow diagram of the fundamental steps required and manufacturing of the double-sided flexible circuit having both plated-through holes and stiffeners attached. The fundamental steps for producing a single-sided flexible circuit are incorporated within this process flow as well. The first half of the manufacturing process of flex through and including imaging and etching steps is relatively fundamental and is amenable to automation using roll to roll processing. However, processing subsequent to the steps through the etching process is

typically more labor-intensive and is thus a source and cause of increase cost in manufacturing. The designer who understands and appreciates the manufacturing process well can help control the total cost of his design and production. It is highly recommended that designers familiarize themselves with the manufacturing process to the greatest extent possible as the decisions they make in design will inevitably have an impact on both productivity and yield. The design coupled with a good process can reduce the total cost significantly, especially for complicated constructions.

67.2.1 Preparation of Flex Materials

It is common for materials used in flexible circuit manufacturing to be supplied in roll form; however, materials are often supplied in sheet form. Copper clad flexible laminates are, for example, often made available in boxes as flat sheets. In contrast coverlay films are most often supplied in rolled form. In manufacturing the first step in processing is to slit and cut the rolled materials into workable panel sizes. It is possible to cut with a manual shearing tool; however, it is advisable to use an automated feeding and cutting tool to get a consistent size and minimize handling damage. The surface preparation for copper foils on clad laminates, especially for single-sided laminates, is arguably best done before cutting and while still in roll form provided such RTR processing equipment is available. Chemistry used should be capable of removing any machine processing oils remnant from the processes used in its manufacturing. It may be accompanied by a light etch and/or a soft brushing step to ready the material for imaging and etching. Any such equipment when used should not produce any scratches nor induce any mechanical stresses in the copper clad laminate. Any scratching or deformation of the material in the process is capable of reducing manufacturing yield significantly so care is advised.

67.2.2 Direct Casting of Polymer to Copper Foil Processing

For special substrate constructions, especially ultrathin substrates or ultrahigh-density flexible circuits, a unique process involving the direct casting of polyimide resin onto

copper foils has been developed as an alternative to copper foil laminated to polyimide films. In some cases, photosensitive polyimide varnish is coated on to a carrier stainless foil. Electroless and electrolytic coppers are thereon plated to provide a thin conductor layer which can be circuitized. The photosensitive polyamide varnish materials used in the casting process can also be used to produce a reliable coverlay alternative for HDI flexible circuits. The technology of the direct casting is also useful in the building of multilayer constructions using semi-additive processing techniques. Special proprietary surface treatments of the polyimide film is required to assure suitable bond strength. The thin copper layers built in sequence can be imaged and etched to generate fine traces. When completed, the finished circuit can be removed from its stable stainless steel foil base to provide the desired flexibility. In some cases, the carrier foil is patterned and etched for use as an integral stiffener.

67.2.3 Mechanical Generation of Through-Holes

There are several different methods available for producing through-holes in flexible circuits. Method is predicated on a number of criteria including the materials being processed, the circuit construction and features size. Additional considerations include matters related to manufacturing volume, circuit density, and desired reliability.

Figure 67.2 in cross sectional view the major process steps in series used in the manufacture of a double-sided flexible circuit. Drilling can be performed using numerically controlled drill machines of the type used in the manufacture of typical rigid boards. One advantage in the manufacture of flex circuits is that, owing to the thinness of the material, more circuits can be drilled in a stack at one time when

compared to the rigid counterparts. However, appropriate backing boards and drilling conditions should be determined to ensure hole quality. A suitable combination of the NC drilling machine conditions and proper drill bit selection will allow the producers to generate smaller holes than 100 mm in diameter.

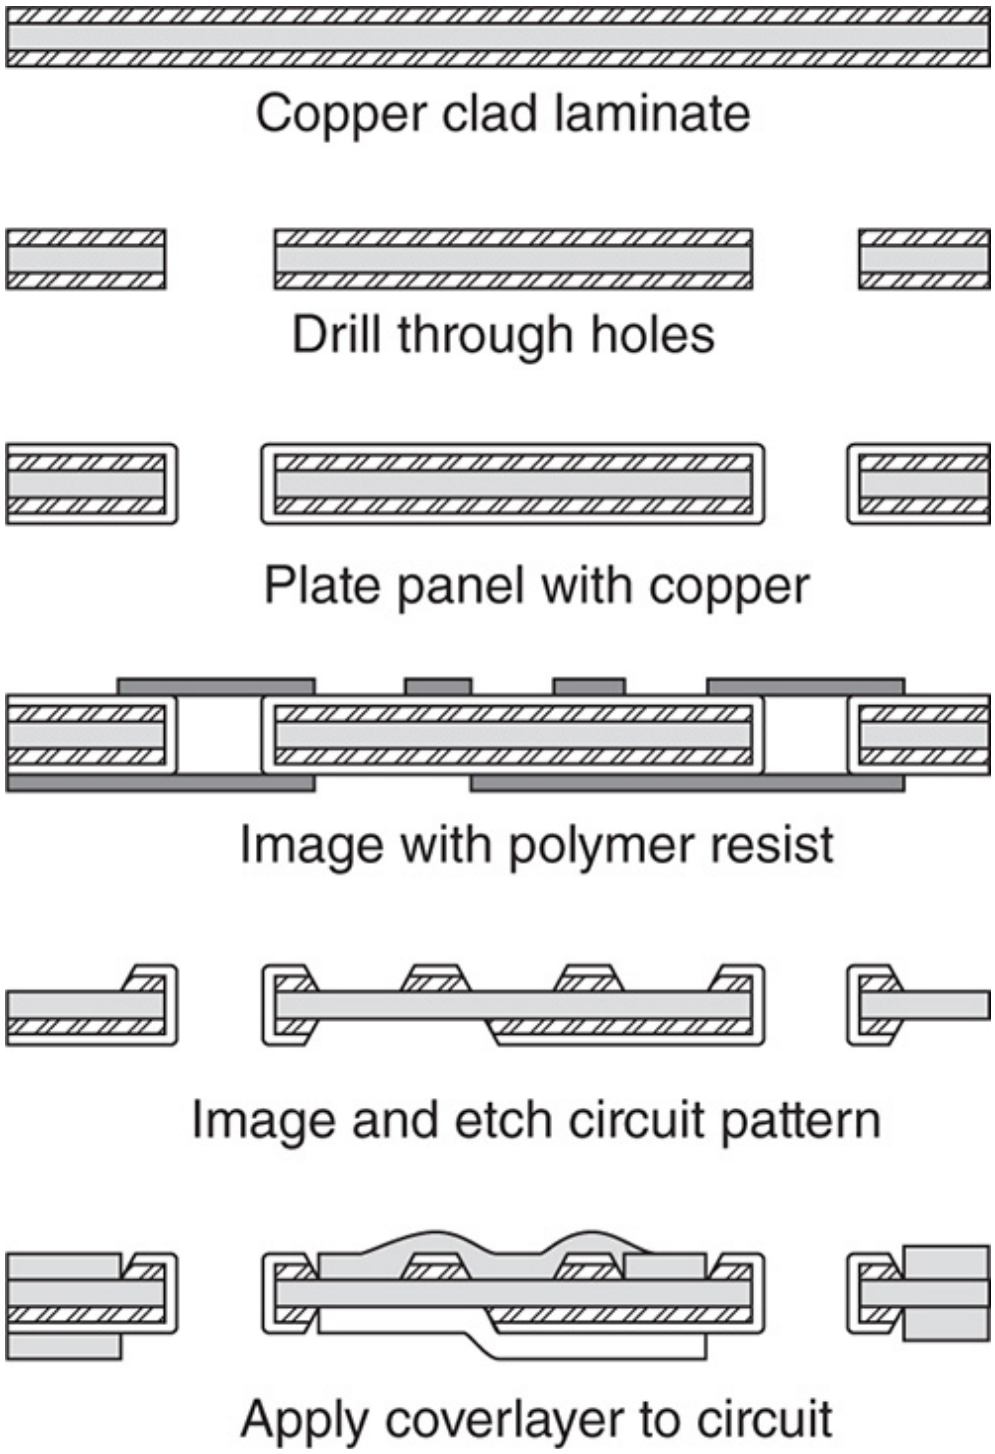

FIGURE 67.2 Typical manufacturing process steps for a double-sided flexible circuit.

Numerically controlled punching tools employing a suitable die set and punch conditions can also produce very small holes and thin copper clad laminates. Punching can be a low-

cost solution; however, it often requires a high volume production to offset the high-cost punch and die tooling. Such tools can generate holes smaller than 100 µm in diameter at very high rates, especially where repeating patterns with many holes in grid form are required. An example would be an IC packaging, such as a BGA. Another advantage of the punching process is that it easily adaptable to RTR processing. One drawback of punching is that it is not capable of producing blind via constructions.

67.2.4 Through-Hole Metallization Processes

Through-hole plating processes, similar to those used in rigid board fabrication, are available for, flexible circuits. More detail on the actual processes can be found in other chapters of this book.

To begin a mild cleaning process is applied prior to the chemical plating process because of thin base layers and relatively small smear amounts. Standard electroless (chemical plating) and electroplating processes are used. In addition direct copper-plating processes which employ a conductive carbon coating have been used successfully for the seed layer in the holes. Once a seed layer is established a suitable thickness copper is electrolytic deposited over the entire surface of the panel in addition to the through-holes. In general, thinner copper (i.e., nominally 20 µm) is recommended to ensure greatest flexibility of the circuits. Thicker copper plating in the through-holes (i.e., greater than 25 µm) is generally recommended higher reliability applications.

Selective copper plating of the through holes (sometimes referred to as button plating) requires an additional imaging step. Such structures are often required for dynamic flexing circuits. Precise thickness control of the through-hole copper

is highly desirable, unfortunately electroplated copper does not naturally deposit uniformly on the surface of the base copper foil. This had spillover effects in that nonuniform plated copper will cause a lower etching yield and reduce through hole reliability, especially for small pitch traces.

To mitigate the problem electromagnetic flux fields within the plating solution must be managed to improve distribution. Specialized plating fixtures and good contact at multiple points on the plated panel within the plating fixture is a requirement to obtain the desired results. In addition, proper design of plating fixtures and electrode configuration in the plating process is critical for achieving uniform copper thickness. Finally, well-designed fixturing is required because thin, flexible sheets made wave and flop about due to agitation in the plating bath. In short, while it is not easy to achieve very uniform copper thickness over panels, and especially large panels, with care it can be managed.

Figure 67.3 shows a comparison of a hole plated with an adhesive-based laminate and a hole plated with adhesiveless laminate. The adhesiveless laminate provides a sharp through-hole shape compared to the traditional laminate with adhesives.

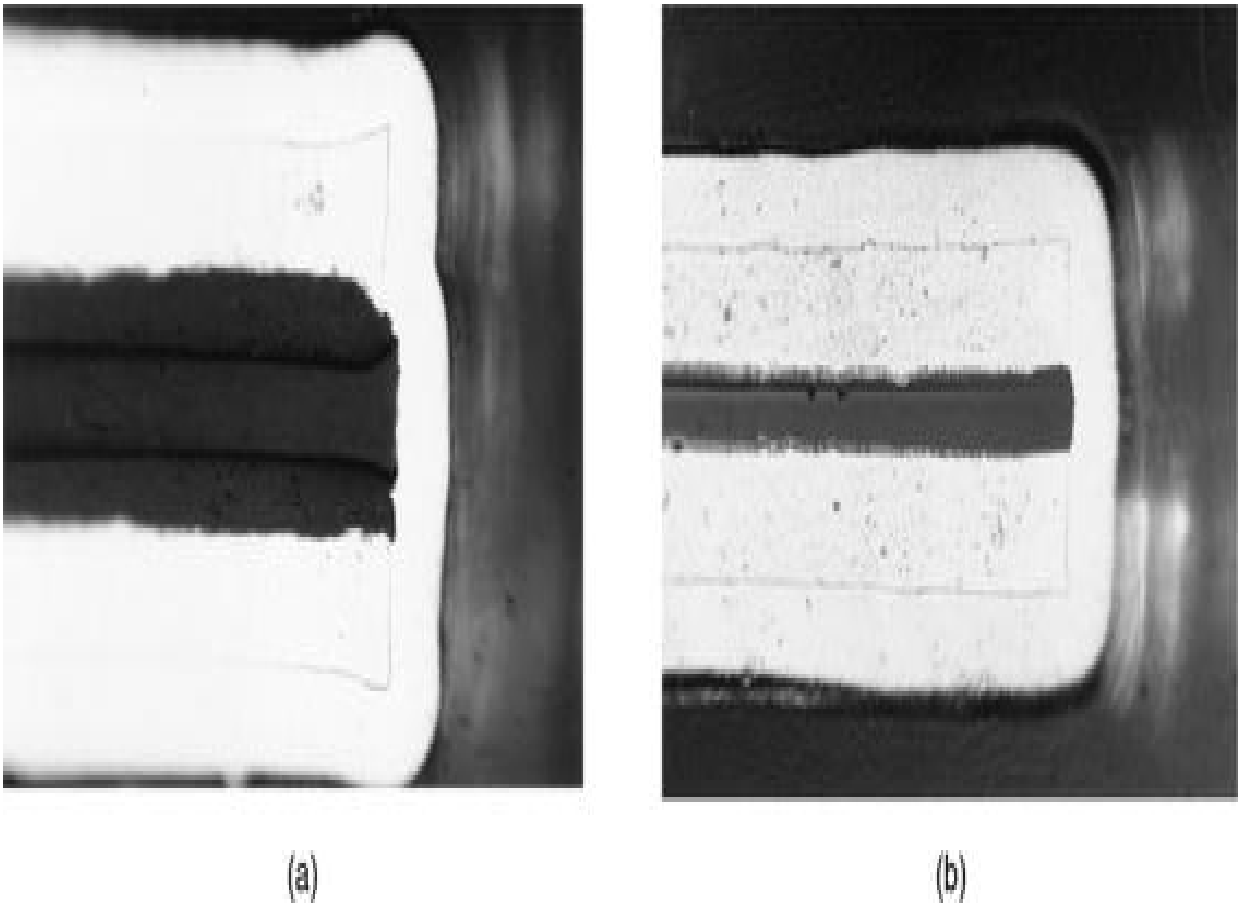

FIGURE 67.3 Adhesiveless copper-clad laminates (those without an epoxy or acrylic resin used to bond copper foil to the base film) provides excellent through-hole definition without desmearing processes a as illustrated above. Cross-section (*a*) is of through-hole of a double-sided circuit with adhesive-based laminate. Cross-section (*b*) is of through-hole of a double-sided circuit with adhesiveless base laminate.

67.3 EQUIPMENT FOR WET PROCESSING OF FLEXIBLE MATERIALS

As with rigid printed circuit boards, many of the processes used in the manufacture of flexible circuits involved the use of liquids. However, the conveyer systems for wet processes designed originally for rigid circuit boards do not work properly for thin flexible materials. They are generally incapable of providing a high process yield because they are

capable of generating wrinkles or scratches in the delicate flex material. This is true even when the flexible sheet is fixed on a leader board or carrier frame. Thus any conveyer system should be engineered to handle thin flexible circuits.

Conveyor systems designed to handle thin flexible materials in the wet manufacturing processes and which have proven successful in production have some distinct modifications over those used for rigid boards. One example is the use of larger diameter conveyer rings with smooth surfaces. Such systems have successfully reduced the scratches on the soft thin copper foil surface. Another attribute is the incorporation of reduced pitch on the transport rings, both line direction and transverse direction. The resulting redundantly overlapped conveyer system, mitigates the problem of the flex material diving down between the rings and/or winding of the thin materials on rolls. While the use of polymer strings and/or thin bars between the conveyer rings can mitigate the diving problem some manufacturers avoid such a solution suggesting that such devices are capable of creating small scratches on the soft copper surface of the flexible material. An example of a system suitable for flexible circuits is illustrated in Fig. 67.4.

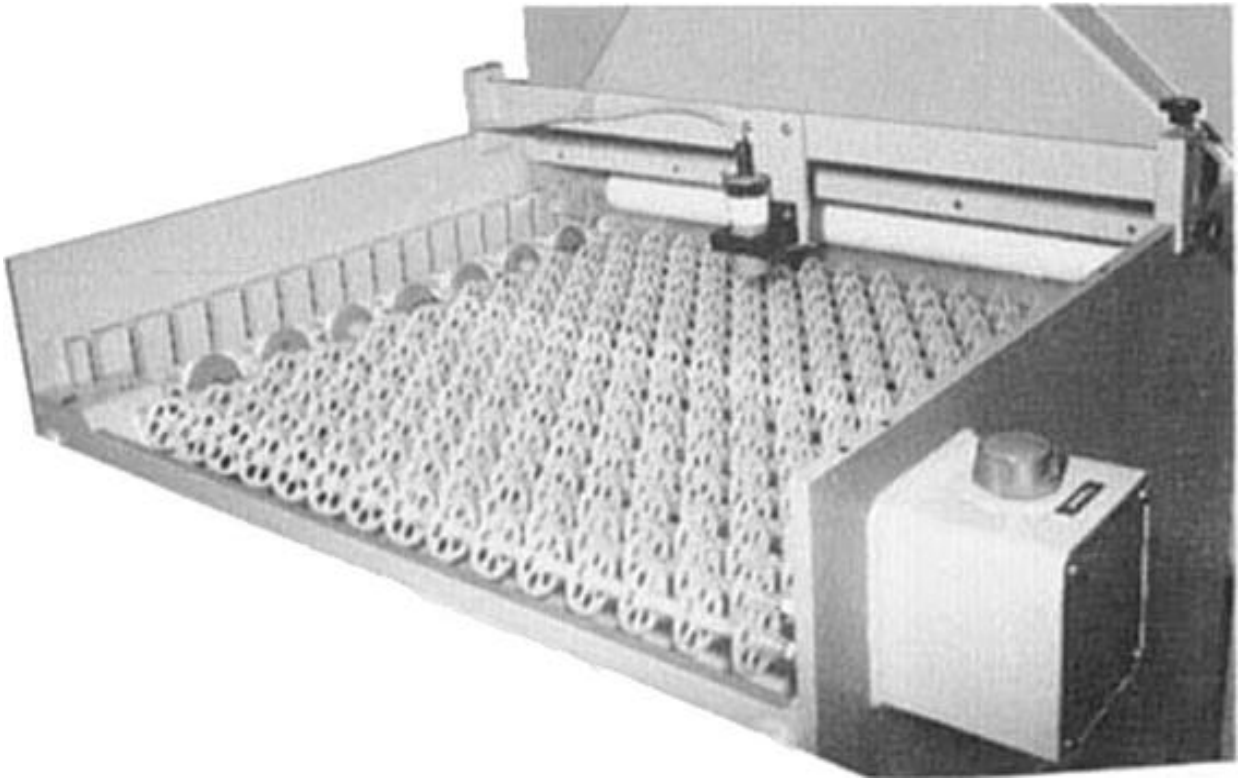

FIGURE 67.4 Special wheel conveyor system for thin, flexible materials showing high-density and smooth wheels. (*Source: Camellia*.)

In combination with a good transport system is a need for an effective sprayer system for delivering process chemistry to the panels passing under and above the conveyer. To ensure good coverage many sprayers oscillate, though fixed spray systems are not uncommon. Spray pressure is of importance. If the spray pressure is too high and or/unequal some fluttering of the panel is likely. This can introduce unwanted distortion for the thin materials especially after etching. Soft rubber rollers are often employed between process and rinse chambers to both minimize dilution of process chemistry and drag out which can result in excessive contamination of rinse waters.

67.3.1 Surface Cleaning of Flexible Materials

A precleaning process is required to remove the stains and oxidation from the surface of the copper foils prior to the coating of screen printed circuit pattern or photo resist material used to define the circuit pattern photolithographically. In addition, adhesiveless laminates typically have an extremely smooth and shiny copper surface; therefore, the chemical cleaning has an important function in making for better adhesion to the etching resist used. This is especially important for fine trace patterning.

A mild chemical cleaning process is preferred. There are a number of proprietary solutions available which employ a diluted organic acid. The treatment should be applied without inducing mechanical damage to the circuit which could negatively impact imaging process yield. Soft scrubbing or soft brushing may be used if a mechanical process is necessary to remove tough stains or oxidation on the copper surface. However, an overly aggressive mechanical brushing can produce mechanical stresses on the thin materials causing loss of dimensional uniformity. As an alternative to conveyer honest chemical processing, a soft brushing processing equipment incorporating a belt conveyor has been developed is available and 10 clean surfaces with minimal mechanical damage to flexible materials; however, process works only for one side of the laminates. Thus, for double-sided laminates the process must be repeated on the second side.

67.3.2 Etch/Plating Resist Coating of Flexible Materials

The photoimageable and screen printed etching resist inks commonly used for rigid circuit boards are suitable for flexible circuit imaging as well. In the case of screen printing, the process inks are generally suitable for relatively coarse pattern etching, especially with large volume production. Dry

film photo resists and resist laminators of the type used for rigid production can be adapted to flexible circuit production.

In the case of RTR processing, the resist material can be paired with unload and take up rollers for step imaging in a suitable imaging system. Because many photoresists can become brittle following exposure it is necessary to make sure that the film is suitably flexible to ensure it does not inadvertently break up during processing. In addition, because tenting of plated-through holes is often performed with double-sided flex circuit panels, it is necessary to make certain that the thickness chosen will withstand the etching process without breaking down and allowing at solution to enter and etch away copper within the plated-through hole.

A thinner dry film can be used for the single-side circuits. Then are photoimageable films are generally capable of resolving much finer features than thicker films. Dry films which are 15 to 20 µm thick are capable of producing 30- to 40-µm lines and spaces at high yield when using 12-µm-thick copper foils. As an alternative a liquid photo resist can be used as thin films can be coated and provide very fine feature definition for high-density circuit traces having pitches of less than 40 µm.

67.3.3 Circuit Pattern Generation on Photoresists

The same type of exposure systems used for rigid printed circuit production can be used for flexible circuits as well. Such systems should have a highly collimated light source as it is generally required for defining high-density circuit traces having pitches smaller than 50 mm at high yield.

The tooling system chosen and employed should be capable of providing good alignment between the circuit pattern and the hole pattern on the copper clad laminate. Moreover, it should be able to achieve good pattern

alignment with high productivity. Auto alignment systems employing CCD cameras have been introduced to help minimize the pattern shift from the via holes generated and plated through in the panel.

Because some dimensional change may occur in the earlier mechanical and wet process manufacturing steps, some dimensional correction to the photomask compensate may be required.

In general a glass photomask tool is recommended for tracers finer than 50 µm pitches over more commonly used polyester base film masks. The setup should ensure that the heavy glass masks are accurately positioned in the machines. Precise alignment between top mask and bottom mask is required for the production of high-density double-side flexible circuits. On occasion, partial dimensional corrections may be required to adjust for random distortions of the thin flexible materials due to processing. Alignment accuracy of better than ±10 µm is required for lines and space pitches' finer than 50 µm.

It is possible to make a corrected photo mask for the imaging process in order to minimize the misalignment. Unfortunately, the distortion of the flexible laminate is generally random and thus not predictable, as a result it may be necessary to generate an image corrected mask for each job lot. In such cases, it is necessary to segregate the materials being processed and hold them until the corrected mask is available for use.

As a practical matter, one of the easiest ways of managing tight dimensions is to reduce panel size; however, the reduction of panel size will also reduce productivity. That said high productivity at low yield is not a desirable situation. Moreover, while it is arguably possible to employ a "step and repeat" approach to imaging similar to that used in the semiconductor industry it is not common. The method involves multiple exposures of the same circuit over a panel.

A recently introduced technology trade named Rainbow, is a self-contained clean environment imaging system, where double-sided copper panels are automatically processed on both sides simultaneously through the stages of etch resist coating, imaging, developing, and rinsing, resulting very high levels of throughout with very fine detail achievement (line and space). Key to the process is a proprietary solvent-free liquid etch resist which is coated at 5 mm thickness and cured instantly using a bank of integrated UV LED lights. In the processing, immediately after coating, phototools are brought into direct contact with the wet resist on the panels before the UV LEDs are used to cure the exposed areas. The phototools are mounted offline into a cart-mounted registration system, which can be swapped out at the process line very quickly resulting in minimal downtime during part changeover. Except for phototooling setup, handling is fully automated thus no human interaction is required during the processing, minimizing risk of contamination and offering the potential of high yields. Designed for innerlayer processing, it is uncertain how the process will work for flex but it appears promising.

Perhaps the most promising solution is the use of laser direct imaging equipment (LDI). Laser direct imaging is capable of making image corrections for any distortions induced in flexible materials in real time. While LDI has been a process of choice since its introduction for prototype and low to middle volume production, recent improvements in the technology and imaging rate as well as the ability to expose both sides of the panel simultaneously make it very attractive for future high-volume production as well. It has been suggested that LDI is not as well suited to the production of circuit traces finer than 25-µm lines and spaces but this seems a minor limitation compared to the benefits and the fact that many circuits do not require features smaller than 25 µm.

67.3.4 Chemical Etching of Copper Clad Flexible Materials

A number of different chemistries are available for use in the etching of copper circuits. Ferric chloride is perhaps the most utilitarian of available etching solutions being capable of etching a wide range of metals and metal alloys including copper. One of its drawbacks is that anything the solution touches is often left with an unsightly brown stain characteristic of ferric chloride processing. In more common choice is a cupric chloride solution which is capable of etching copper effectively and rinses cleanly. Cupric chloride etching solutions are often used in the production of interlayer is for rigid multilayer circuits. A third choice for etching copper is an ammonical alkaline solution. Alkaline etchants offer higher processing speeds; however, this can be a disadvantage when trying to etch very fine line circuits in addition alkaline solutions may chemically attack some types of polyamide films which could undercut very fine circuits that should be used with caution in such applications.

Process engineers should characterize the etching process with the chosen chemistry for the feature sizes being sought at a given copper thickness. The objective is to provide a correction factor to the traces that will be employed in the imaging process. In short, etching is an isotropic process meaning that as the copper is etched down into it is also etched laterally reducing trace width. One relatively simple way to characterize the process is to image patterns of lines and spaces of the target size and shape and etch them followed by accurate measurement of the results. This data can then be fed back to the photo tool maker to adjust line and space to appropriate values. There can be a significant difference in etching factors between middle conductors and edge conductors. The use of nonfunctional conductor

patterns adjacent to circuit features can help ameliorate the effect.

Finally, provided circuit performance is not dependent nor adversely affected by trace width modification, the tapering of traces can be employed to maximize dimensional stability by assuring maximum copper area in the circuit design.

67.4 COVERLAYER/COVER-COATING METHODS

Coverlayers or cover coats are direct analogues of solder mask on rigid circuit boards; however, in the case of flexible circuits the coverlayer or cover coat must remain flexible and not crack in use. The distinction between a coverlayer and a cover coat is that a coverlayer is generally an engineered material which must be preprocessed (i.e., drilled) and then laminated to the flexible circuit with holes aligned to circuit features where some type of interconnection or component lead must be terminated. In contrast a cover coat is often screen printed onto the flexible circuit began leaving open the features of interest. There is a third type of coating for flexible circuits, which is fundamentally a photoimageable polymer film bonded to the flexible circuit exposed and developed. Table 67.2 summarizes the comparison of traditional coverlay technologies and new technologies.

TABLE 67.2 Coverlay Process Options

	Accuracy (Minimum Opening)	Reliability (Flexing Endurance)	Material Selection	Equipment/ Tooling	Technical Hurdles	Cost
Traditional film coverlay	Low (800 µm)	High (long)	PI, PET	NC drill, heat press	Need long experience	High
Film coverlay + laser drilling	High (50 µm)	High (long)	PI, PET	Heat press, laser	Low	High
Screen print liquid ink	Low (600 µm)	Acceptable (short)	Epoxy, PI	Screen printer	Medium	Low
Photoimageable, dry film type	High (80 µm)	Acceptable (short)	Epoxy, PI, acrylic	Laminator, exposure, developer	Medium	Medium
Photoimageable, liquid type	High (80 µm)	Acceptable (short)	Epoxy, PI	Coater, exposure, developer	Relatively high	Low

Among these types, traditional film coverlay generally has the best balance of physical properties and provides the highest reliability especially in dynamic flexible circuit applications where high flexible endurance is required. Unfortunately, traditional coverlayer films are the most difficult to process and not easily automated and thus tend to be more touch labor intensive than the other two methods. While it tooling system can be used to provide gross alignment and operator is normally employed to visually check, adjust fine alignment and tack in place using a hot iron. Moreover, the method is not very amenable to the production of circuits requiring small openings due to squeeze out of the adhesive used in lamination onto the circuit features which need to be free and clear of any foreign material.

Given the increasing demand for ever finer features (i.e., openings in terminations smaller than 200 µm in diameter requiring better than ±100 µm positioning) such as is required for fine pitch BGA, CSP, and other chip type passive components more exacting methods are required. While screen printing of flexible ink cover coats can provide a low-cost solution for volume production, it cannot provide such small openings as are required with high dimensional accuracy. Thus photoimageable coverlayer technologies are often being selected in applications having very small openings with tight dimensional accuracy. The technology has been generally available for many years and improvements in the materials and processes have been ongoing.

67.4.1 Coverlayer Preparation and Lamination

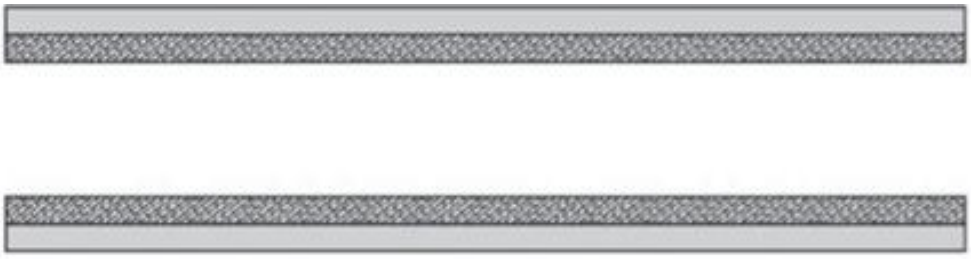
As mentioned earlier adhesive backed polymer films are referred to as coverlayers. The adhesive is generally a partially cured, flexibilized epoxy or acrylic. These are preprocessed with holes or apertures in desired locations and then laminated to the flexible circuit using heat and pressure for specified dwell-time to cure the adhesive, which can vary from a few minutes to up to an hour. In general coverlayer is made up of the same materials set that is used for the creation of a copper clad laminate.

Epoxy-based coverlay films have a relatively short shelf life and room temperature and thus must be kept refrigerated when not actively being processed. Openings for access windows to circuit features of interest are most often made by NC drilling or punching. The surfaces of the flex circuits must be must be thoroughly cleaned before coverlay lamination takes place. Specialty roller tools have been developed for this purpose. In addition the processing area

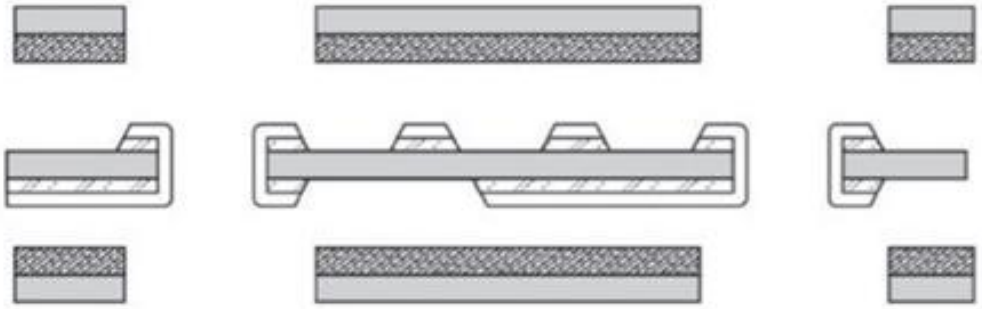
should be kept clean and environmentally controlled to minimize static charge buildup which can attract dust and debris to the circuit surfaces. While keeping relative humidity and the work area can mitigate static charge buildup, moisture is also deleterious as excess moisture in the laminate can cause blistering of the coverlayer.

Automation of the coverlayer lamination process is challenging because the coverlayer material is generally less stable after holes and window openings are formed. For the most part, manual alignment of coverlayer to laminate is used. A talented and attentive technician can achieve very good results aligning and tacking the coverlayer to the circuit for subsequent lamination. For this process unless the circuit needs an accurate registration in the range of 50 to 75 mm. After the coverlay film is temporarily fixed on the circuit, the adhesive layer is cured in a heat press or autoclave similar as multilayer rigid boards. A suitable curing condition should be chosen carefully based on the circuit design and material conditions. Epoxy resins change flow properties significantly by thermal aging, even though they are kept at a low temperature; therefore, a detailed conditioning should be performed based on the flow properties of the adhesives. A high flow of the adhesive resin makes good encapsulation of the conductors, but it also causes a squeeze out of the resin in the openings and resulting potentially deleterious deposits and staining on the copper traces. On the other hand, a low resin flow causes a poor encapsulation and results low bond strength and exposed air voids beside the traces. The selection of the press pad materials and separation films is another key factor to have good encapsulation and minimum squeeze out of the glue from the edges. A vacuum press or a vacuum autoclave helps to make good encapsulation of the conductors, eliminating voids or air traps beside the traces, especially for a thick copper foil.

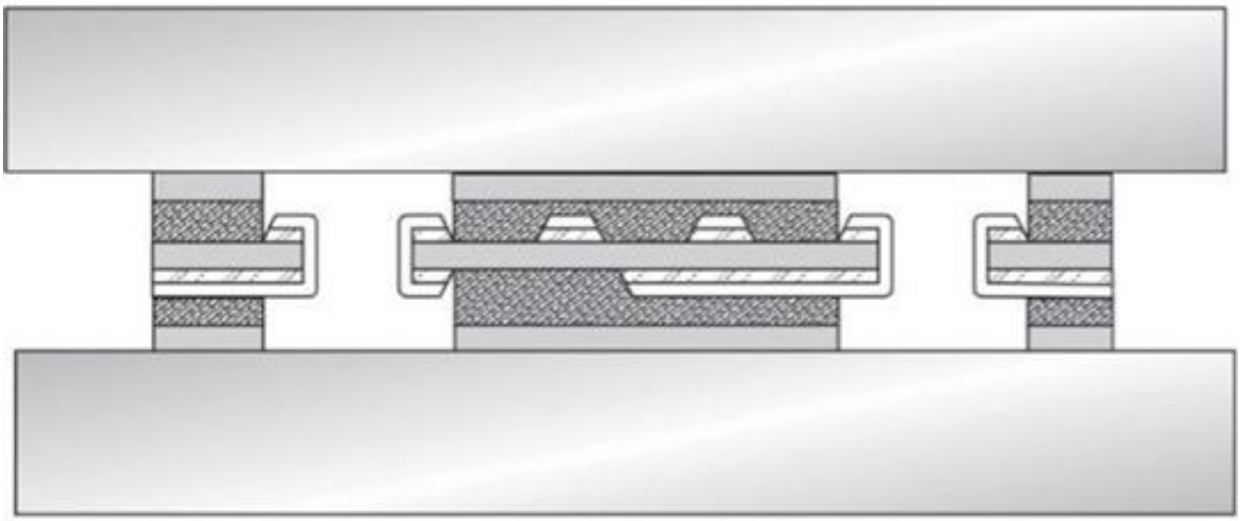
It takes more than one and a half hours for a nominal heated heat press lamination cycle to complete the chemical curing reaction of the adhesive resins, therefore the batch size and the lamination equipment have been becoming larger to make the productivity higher. But it makes the process flexibility lower. A quick press system has been developed to have a better flexibility. One set of coverlay films and an etched flexible circuit panel is hold in a small vacuum press for less than 2 min as the preliminary lamination. After that, several numbers of panels are baked in a thermal oven to complete the chemical curing of the adhesive resin. This process needs a special epoxy resin for the adhesives, but it provides a high flexibility for the small volume and prototype productions. A typical coverlay manufacturing process is shown in Fig. 67.5.



Prepare upper and lower coverlayer film



Align coverlayer to top and bottom of circuit



Laminate using heat and pressure

FIGURE 67.5 Basic coverlayer processing steps are shown above. Coverlayer material is selected and apertures provided to access features of interest and oriented and laminated to surface of the flex using heat and pressure. Special materials are used to ensure good conformance to and sealing of circuits on the surface.

67.4.2 Screen-Printing Coverlay

The screen printing process has been a part of printed circuit manufacturing since the earliest days of the industry. Originally for printing the actual circuits, then as an etch and plating resist and most recently for application of solder mask and legend to the surfaces of the printed circuit board. The same processing methods are suitable for the application of flexible screen printable polymer inks to the surfaces of finished flexible circuits. The major differences in processing are related to fixturing for alignment and the use of the vacuum system in concert with a perforated base to hold the flexible circuit flat and in place during the screen printing process. Care should be exercised relative to the vacuum intensity as it is possible to create a dimpling effect on the surface of the flex circuit which can be seen in the screen printed polymer ink. Postimage curing should be performed a suitable carrier, that is one which will hold the coded flex circuit flat without inducing potential defects. The selection of the ink, carrier and curing conditions should be such that any potential shrinkage of the materials is uniform resulting in a uniformly flat circuit. The basic process is illustrated in Fig. 67.6.

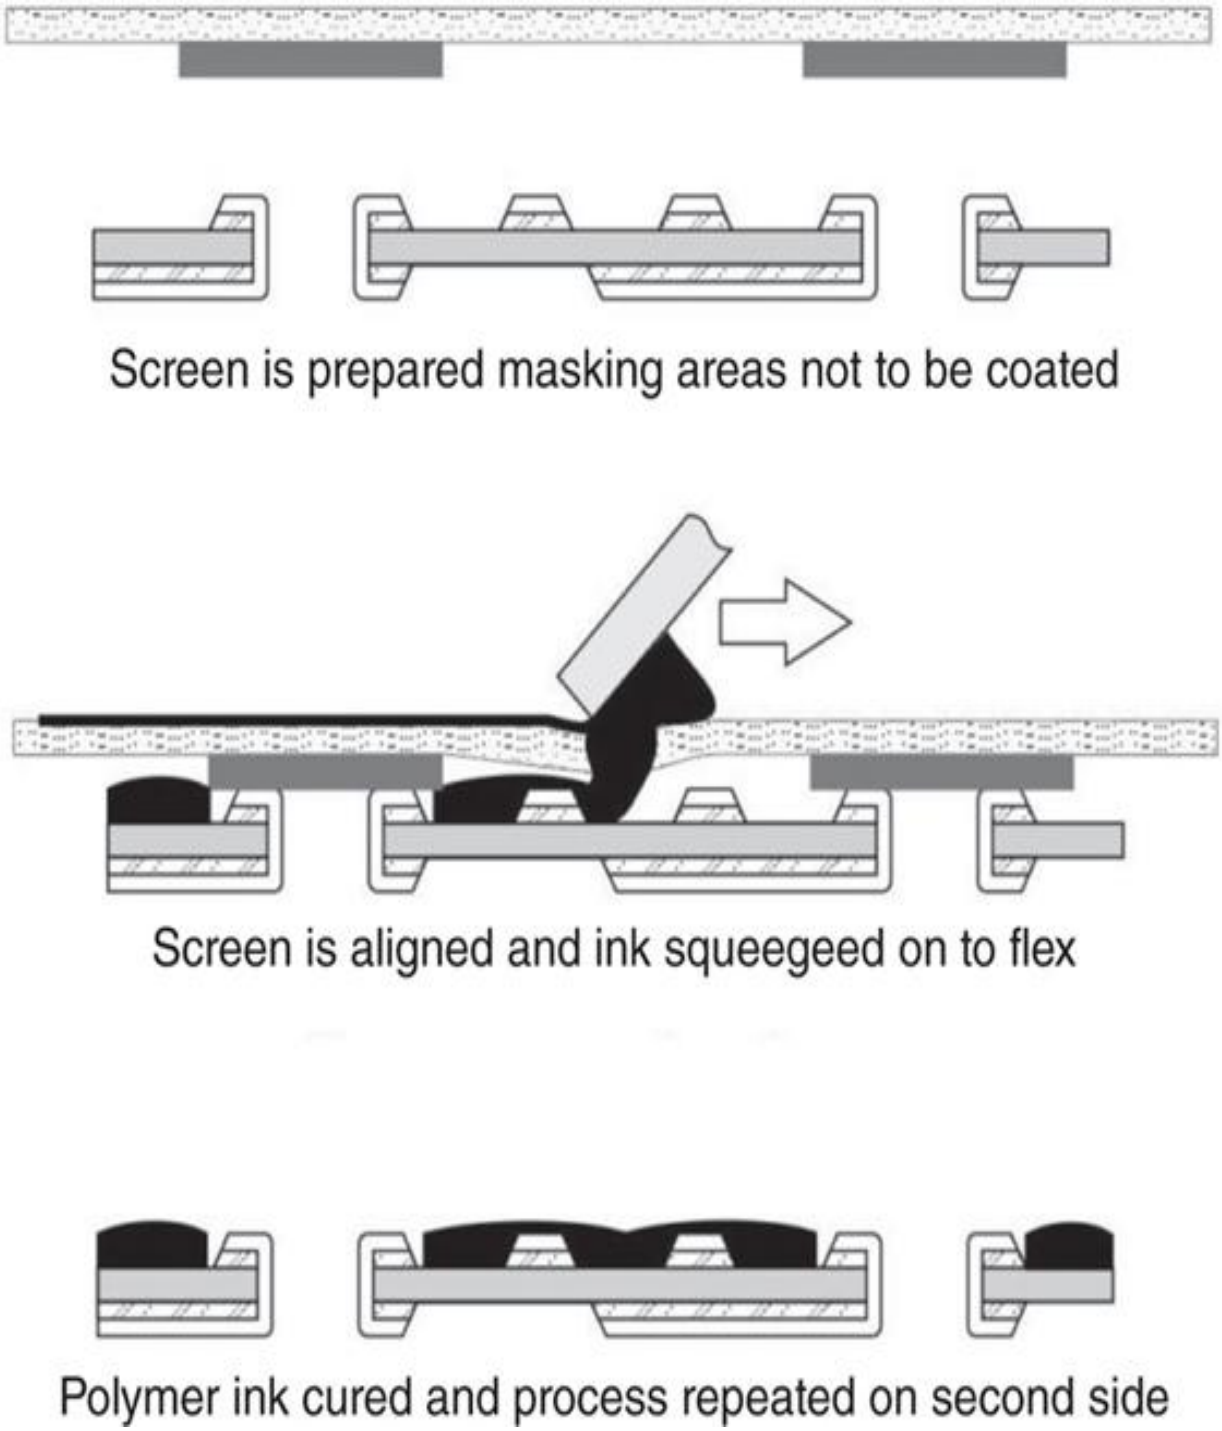


FIGURE 67.6 Screen print process for polymer ink coverlayer deposition.

67.4.3 Photoimageable Coverlay

As photoimageable solder mask systems for rigid circuit boards were developed in the 1980s, similar ideas were tried for flexible circuits. Fine openings and high-dimensional accuracy were expected. Unfortunately, the materials for rigid circuit boards were too brittle for flexible circuits, and therefore new materials were required. As a result, chemical specialty companies developed photoimageable polymer materials in both liquid and dry film forms specifically for use as coverlayers for flexible circuits. The materials found volume opportunities in a number of different markets including automotive, computer, and consumer products. While there were some problems with earlier versions present day materials are much improved. There are differences in terms of the performance of liquid and dry film coverlayers and thus the designer should familiarize themselves with the limitations of each.

The processing steps for the two different types of photoimageable material are quite similar in terms of fundamental steps except for the method of application of the material to the flexible circuit and the need for a baking step in the case of photoresist applied in liquid form as illustrated in Fig. 67.7.

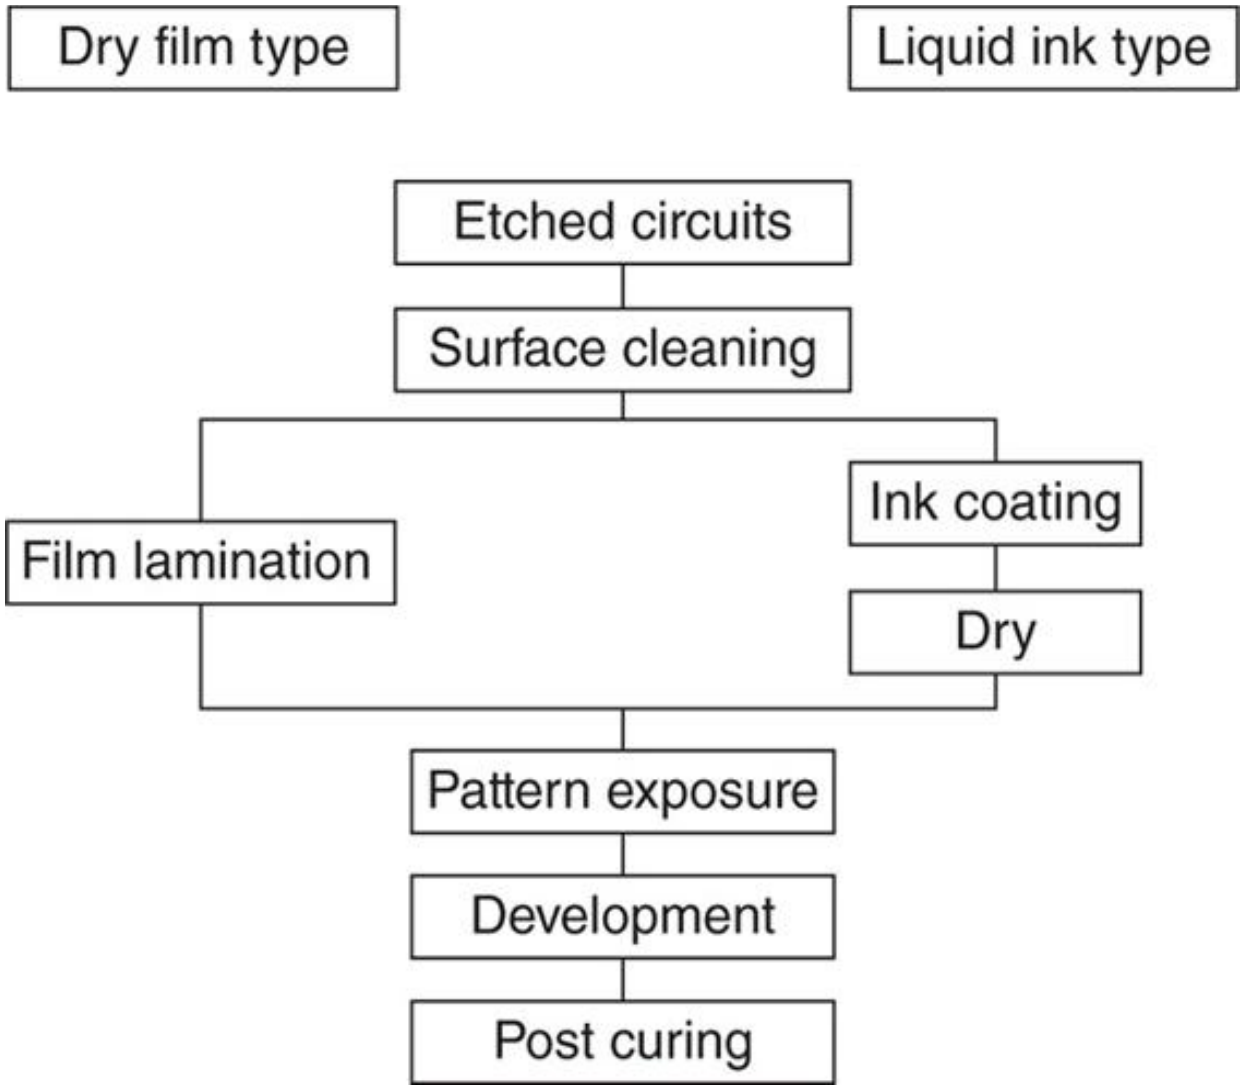

FIGURE 67.7 Comparison of process flow for dry film and liquid polymer photoimageable coverlayers.

In the case of dry film photoimageable coverlayers, they are commonly applied using a heated roll coating process to coat one or both sides of the flexible circuit with the dry polymer film. This is often done in combination with a vacuum lamination system to assure the removal of air and complete encapsulation of the circuits. However, roll coating laminators used for rigid boards can be quite suitable for roll coating of dry film coverlayer material. That said when thick copper circuit traces are tightly spaced elimination of air entrapped between the traces can be very difficult without

vacuum. It is normally recommended that there be a hold time of between 15 and 30 min to allow the photoimageable polymer to stabilize before exposure.

With respect to the application of polymer ink photoimageable coverlay material there are a few options. The simplest of these is to use a screen printing process to fully coat the surface of the flexible circuit. Another option is to use a spray process and the third is to employ a curtain coating process where the circuits are passed underneath a continuously flowing curtain of liquid photoresist to apply a uniform coating over the entire surface of the circuit as it passes under and through the flow of material. The latter to processes require special capital equipment the cost of which is much greater than a simple screening chase; however, the productivity can be quite high offsetting the cost. For all of the aforementioned processes the steps must be repeated for two-sided circuits and thus a drying step is required between coatings. There exist automatic coating machines capable of processing double-sided circuits; however, they are best suited to very high-volume production application.

Following drying the same ultraviolet exposure equipment used for manufacturing traditional printed circuits can be used to expose coverlayers of both dry film and liquid form. Likewise development process can be carried out using the same equipment and chemistry as is commonly used for the development of rigid printed circuit board solder masks (i.e., 1 percent aqueous solution of sodium carbonate). Following development a baking step is normally employed to ensure the coating material’s long-term performance. This is carried out at a nominal temperature of 150°C usually for about one half hour for full cure. Conventional air convection ovens can be used. In addition conveyorized infrared ovens have been used for post baking by some manufacturers successfully. Good process controls in such applications are of great importance.

Figure 67.8 provides a graphic representation of the basic processing steps for application of a photoimageable coverlayer and Fig. 67.9 shows a photo micro-graphic example of an opening formed in a photo imaged and developed coverlayer material.

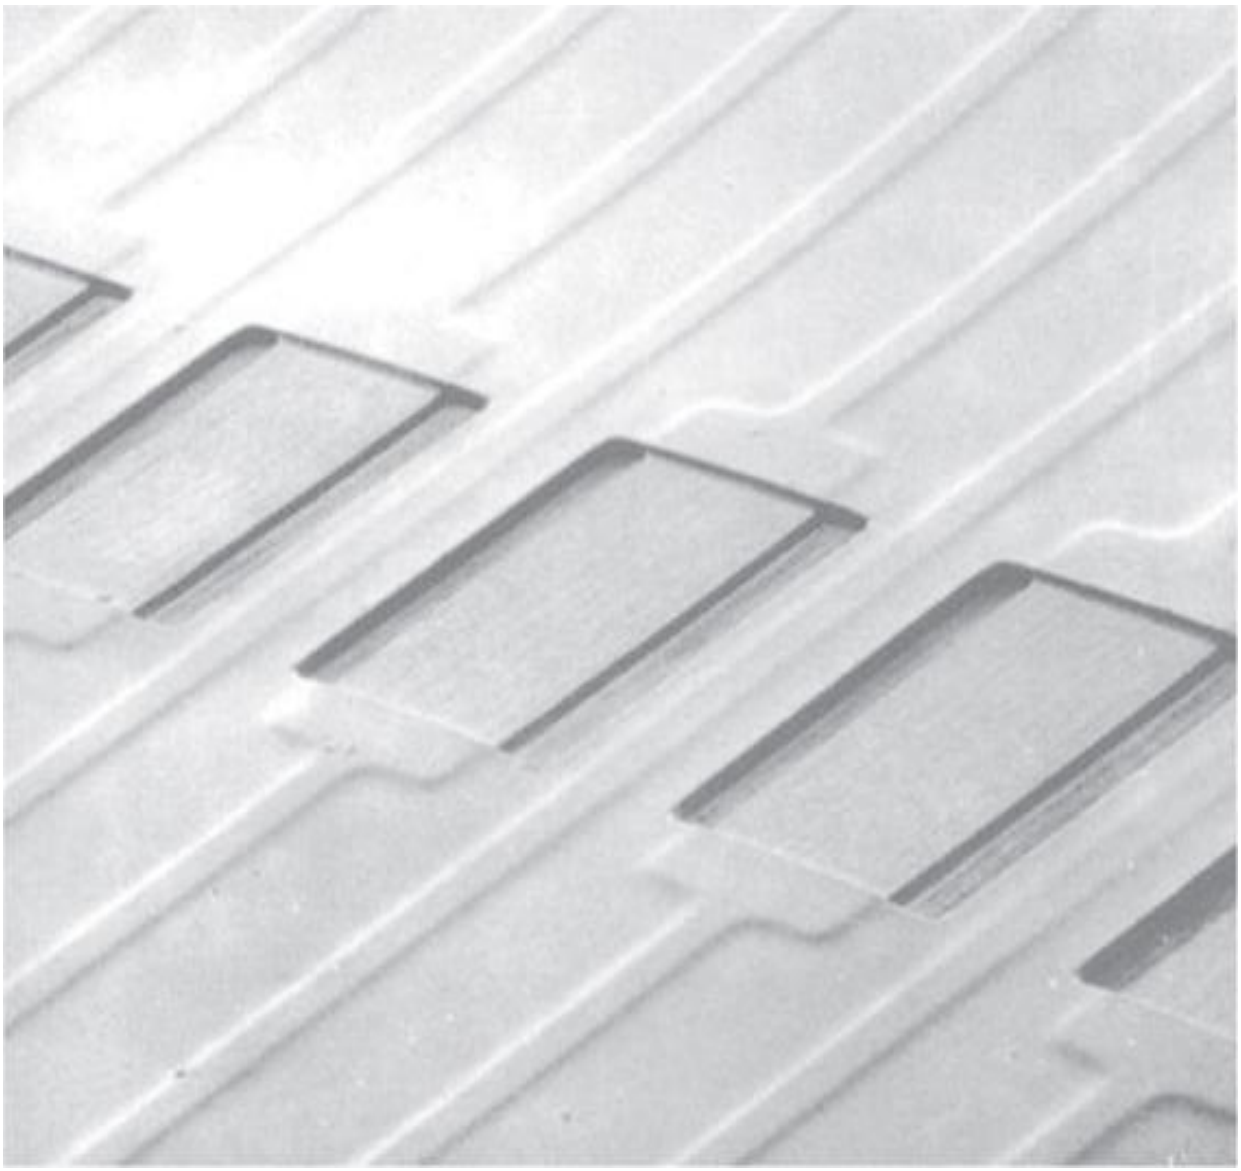

FIGURE 67.9 Photoimaged coverlayer defining terminations on flex. Lead pitch is 500 µm.

67.4.4 Laser Drilling on Film Coverlay

Lasers have seen a significantly increased in use in the processing of rigid printed circuits. The primary use of lasers has been to make small holes in circuit material. Depending on the thickness of the material small through holes can be

made with significant success; however, the major interest for the use of lasers in printed circuit manufacture is to make blind vias. Thus it should come without surprise that lasers have been adapted to the manufacture of flexible circuits especially in the ablation of polymer materials and most especially in the ablation of polymer materials over features of interest such as is common in the use of coverlayers.

One of the advantages of using lasers to ablate polymer is that it obviates the need for a number of process steps required by the photoimaging process. In this regard they are well suited to the manufacture of prototype circuits or small volume production runs.

Another advantage of lasers is that they have the ability to ablate very fine features as might be required by some designs that the traditional photoimageable polymer approach cannot accomplish. For example, excimer lasers can provide extreme detail openings with feature sizes down to 50 μm and less leaving a clean surface behind. Other lasers including CO_2 and YAG lasers are equally capable of ablating polymer materials and/or an order of magnitude more effective in terms of rate of material removal but often require additional steps to remove char and other residue from the underlying copper surface.

Again while excimer lasers provides excellent results in many applications the ablation rate, depending on the thickness of the material, can be appreciably slower than alternative lasers and are thus best suited to unique applications. The basic process as illustrated in Fig. 67.10 and a photomicrographs of an excimer laser ablated hole and a CO_2 laser ablated hole can be seen in Fig. 67.11. Finally it is worth remembering that lasers can perform other tasks and can, for example, also be used to cut the circuit from the flexible panel.

67.5 INTERCONNECTION SURFACE TREATMENTS

Regardless of the method used for creating holes in the coverlayer the exposed copper surfaces normally require some additional treatment either to preserve the solderability of the feature as in the case of land pattern is for electronic components, or to assure a reliable contact surface on terminations designed for interconnection by electromechanical connectors or to provide a surface for wire

bonding integrated circuit chips directly to circuit terminations. Both electroless and electrolytic processes are used to plate metals for these differing purposes.

Metals commonly used to protect solderability include tin, solder, and nickel-gold. Molten solder can also be applied to the surface by a roll tinning process. Hot air leveling processes can also be used. In such a process the circuit is first fluxed and then dipped into a molten solder bath using special fixturing. The finished circuit will emerge with all copper terminations coated with a solder alloy. The process is challenging because it is difficult to get a uniform finish over all of the exposed contacts.

OSP (organic solderability protectant) coatings are also common for flexible circuits because they are easily applied and provide good results. There are limitations in terms of the shelf life of such finishes, however. Moreover, given that many electronic assemblies have components attached on two surfaces, there is need for them to withstand more than one reflow cycle while maintaining their solderability.

Nickel and gold as mentioned above can serve multiple purposes. The gold plating used should match the purpose. In the case of a wire bonding application, the goal should be a soft gold and in the case of a contact surface for connector the hard gold is preferred. An electroless nickel-gold plating process is often used for plating exposed contacts through coverlayer openings. There are a number of purveyors of proprietary chemistries for this purpose. One should be mindful of the fact that certain chemistries, especially strong alkaline chemistries having a high pH, can attack both the polymer film and the adhesive used to bonded to the flex circuit. The chemistry formulator should be capable of providing proven recommendations relative to the processing. That said it is important to remove any stains or residues before plating with an electroless chemistry elsewise it is likely that skips in the plating will occur. In some cases the mechanical brushing step may be required

but if such is performed it should be done with care so as not to distort the circuit.

A summary of surface treatments for flexible circuits can be found in Table 67.3.

TABLE 67.3 Treatments for Exposed Connecting Metal Surfaces on Flexible Circuits

	Materials	Process Conditions
Electroplating	Ni, Au, Sn, solder, etc.	Wet process
Electroless plating	Ni, Au, Sn, solder, etc.	Wet process
Hot-air leveling	Solder	>260°C
Solder roll coating	Solder	>260°C
OSP	Organic molecules	Wet process

67.6 DEPANELIZATION OF FLEXIBLE CIRCUITS

As a final step in the process the flexible circuits must be removed from the panel on which they were fabricated. The final step is commonly referred to within the circuit manufacturing industry as depanelization. Flexible circuits are often designed with fanciful contoured shapes with many curves, thus removal of the circuit from the panel can be challenging if the method chosen is not well-suited to the task. That said, owing to their thickness flexible circuits can be depanelized in a number of different ways. For example, the prototype circuit could be cut from the panel by simply using household scissors (with great care, of course). In addition they can be cut out using and numerically controlled

table cutter such as is used in the sign industry. As mentioned earlier, a laser can be employed to cut the flexible circuit from its panel. It is even possible, though not common, to depanelized flexible circuits using a chemical milling process such as is used in the fabrication of tape automated bonding (TAB) circuits. Flexible circuits can also be depanelized en masse using an NC router, a method used daily in the manufacture of rigid printed circuits. However, the method most frequently used in too depanelize flexible circuits is punching or blanking as it is also known. A punching press similar to those used in the processing of rigid boards can be used for the blanking of flex circuits; however, again owing to their thinness flexible circuits have the added advantage that they can be punched using steel rule die technology in addition to the much more robust Class A punch and die set tooling used for rigid printed circuits. In addition due to their thinness press tonnage can be significantly less.

Steel rule dies are especially well-suited to flexible circuits and the tooling can be turned around rapidly. The only drawback of steel rule die tooling is that there is mention of accuracy is not as good as Class A tooling. Moreover, steel rule die cutters have a shorter operational life than Class A tools and the blades must be replaced with greater frequency. The comparison between steel rule die and Class A tooling is offered in Table 67.4. Figure 67.12 shows an example of steel rule die in Fig. 67.13 illustrates the operation of a steel rule die.

TABLE 67.4 Comparison of Punching Technologies

Items	Steel Rule Dies	Hard Tool Dies
Accuracy	~0.2 mm whole tool	~0.01 mm whole tool
Minimum hole size	3 mm diameter	0.4 mm diameter
Minimum slit width	Zero	0.5 mm
Minimum corner radius	0.5 mm	0.1 mm
Delivery time	Days	Weeks
Weight	Light weight	Heavy, lift required
Tooling cost	Low	High
Processing cost	Moderate (low rate)	Low (high rate)

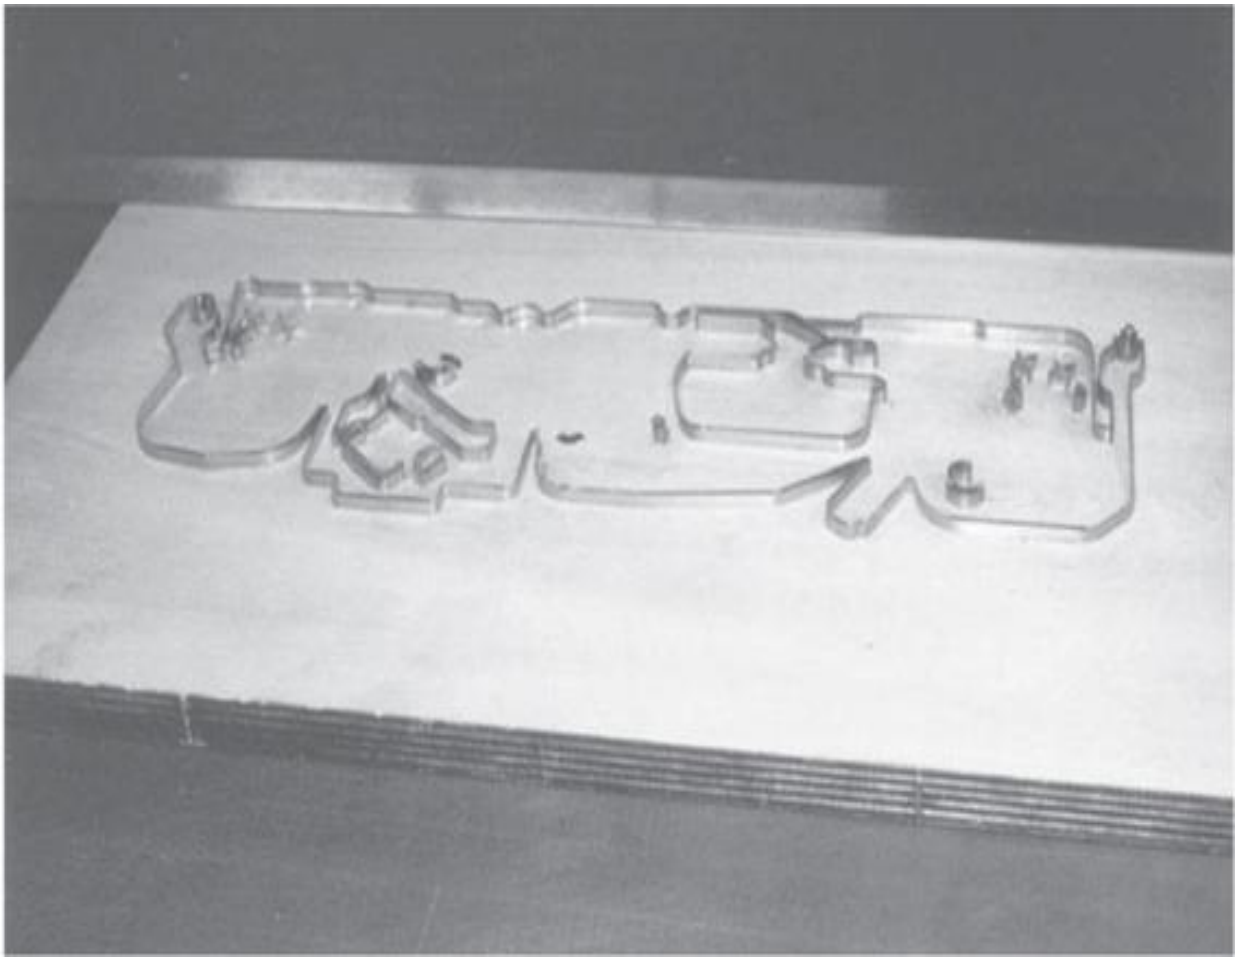

FIGURE 67.12 Steel rule die for blanking flexible circuits.

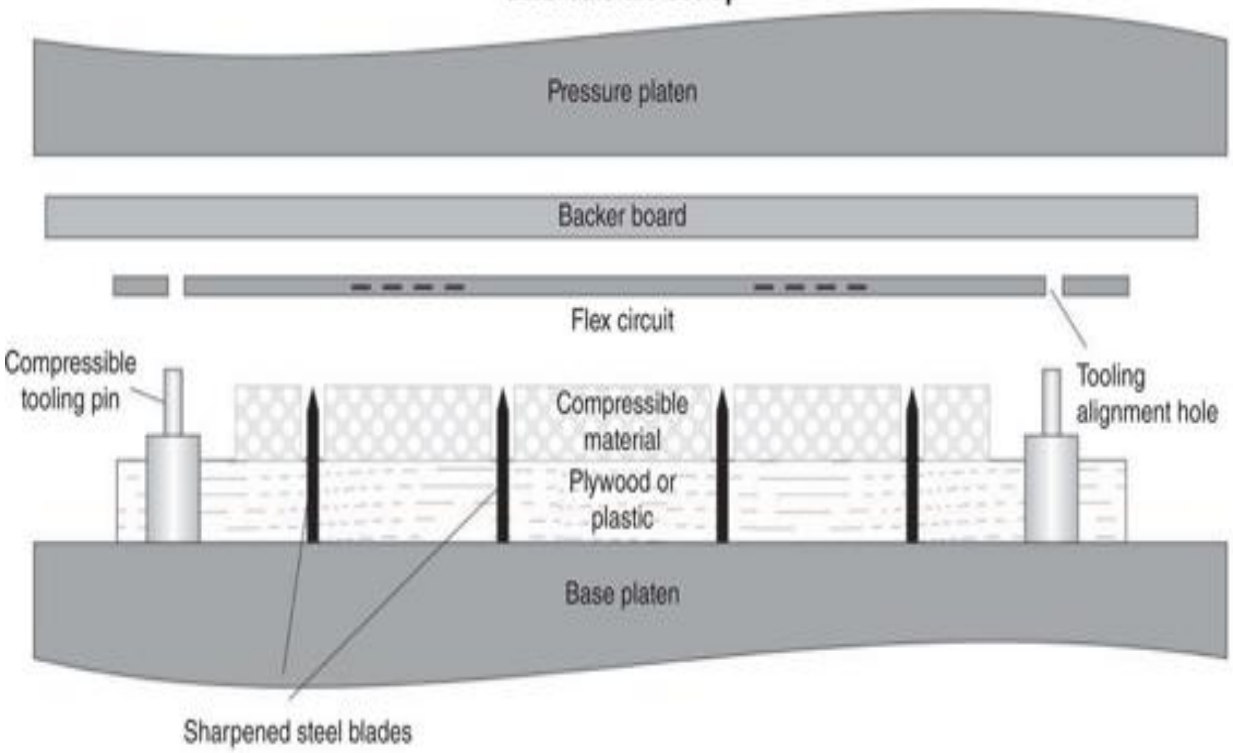
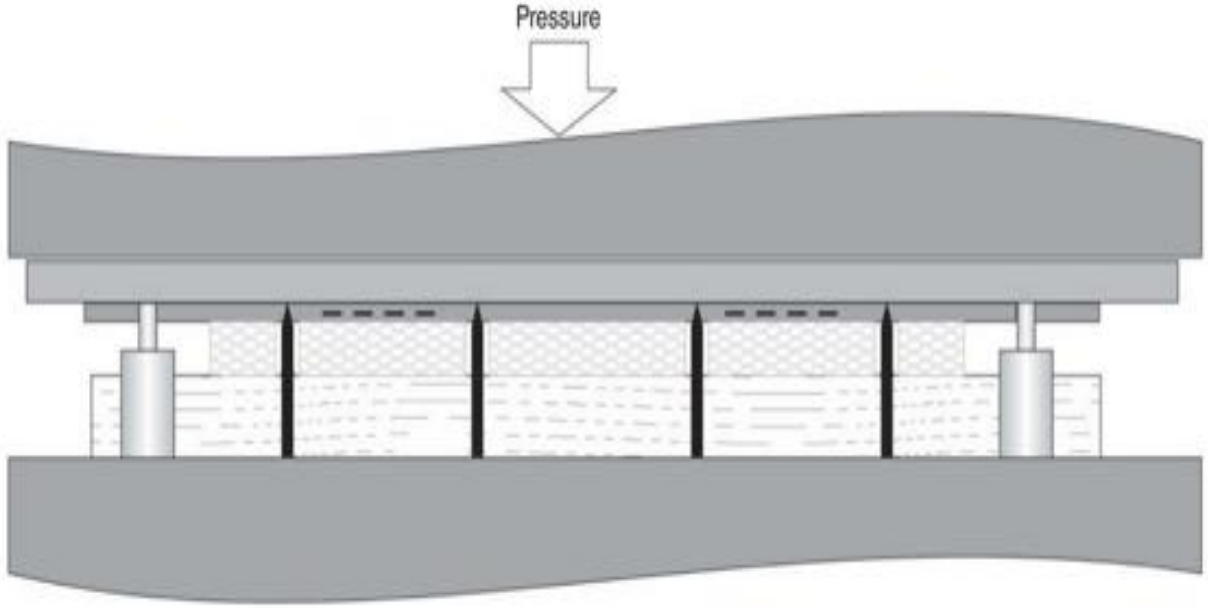
Steel rule die set-up



Steel rule die operation



De-panelized parts

FIGURE 67.13 Steel rule die set up and operation.

Tooling hole location accuracy is vital in ensuring that the circuit pattern and finished circuit outline are properly matched. Because, as has been pointed out many times earlier, flexible circuit materials are unstable dimensionally care is required both in design and in process. Some manufacturers have found it useful to provide several sets of tooling holes in the panel both outside and inside the circuit area. Such tooling holes are used only once in each process requiring their use. Some equipment suppliers also provide machines which have ability to identify and accurately punched through specially designed features on the panel through the use of CCD cameras. Such tooling methods facilitate punching of tooling holes with great accuracy (±50 μm) and as needed during processing and can as well even be punched after coverlayer lamination. Tooling holes punched after coverlayer lamination are well-suited to serving as alignment holes for depanelization of the circuits from the panel on which they were built. Figure 67.14 and Table 67.4 show the limitations of steel rule dies.

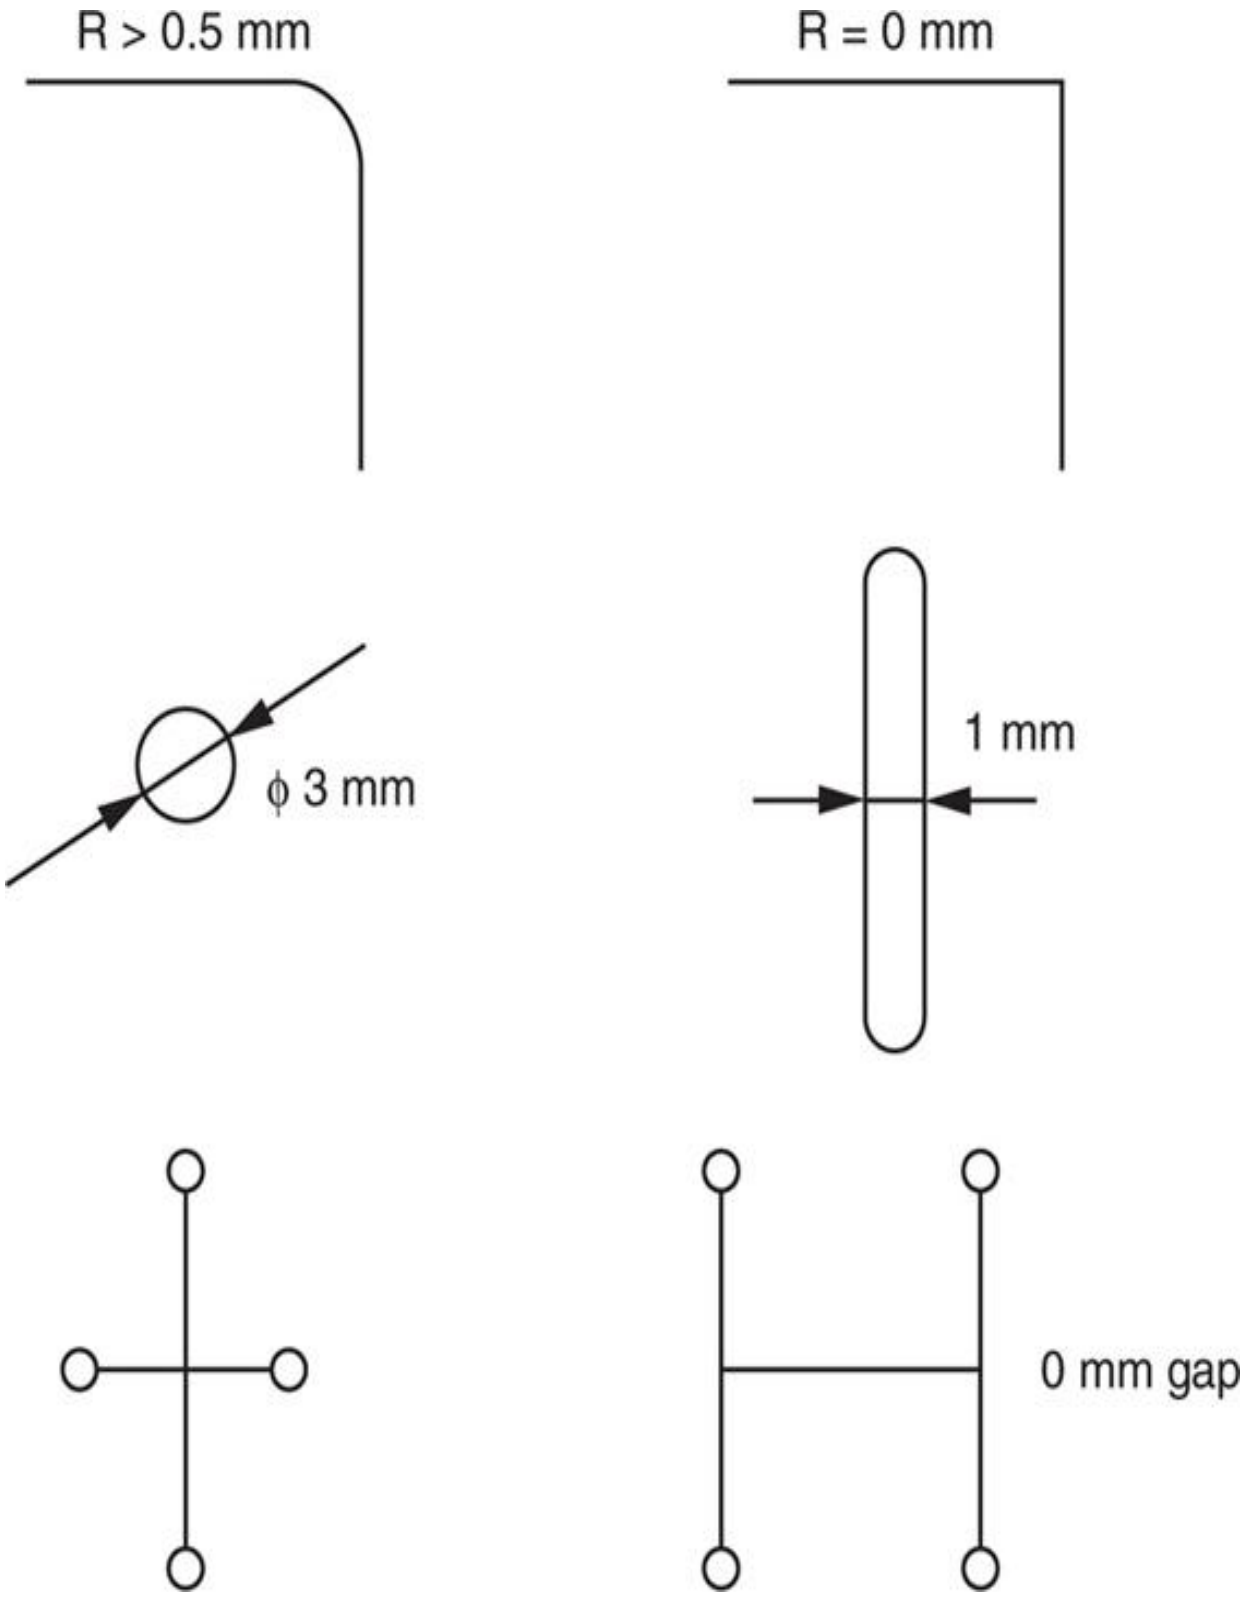


FIGURE 67.14 Limitations of steel rule die features.

67.7 STIFFENER PROCESSES

Stiffeners are a common feature on many flexible circuits. Their purpose is to support the weight of electrical components and connectors mounted on their surface or with component leads passing through the plated-through holes on the flexible circuit. Many different materials can be used as stiffeners including glass epoxy laminates, sheet metal, refractory materials, and even additional layers of the materials used in flexible circuit construction. Stiffeners are generally attached using an adhesive. Often the adhesive is pressure sensitive type, though thermally cured adhesives and flex circuit bonply materials may be used. Processing conditions and parameters should be in accordance with the manufacturer's recommendations.

Stiffener attachment typically involves touch labor and thus can add to cost. However, with judicious use of design it may be possible to offset cost by having the stiffener serve a dual function as a support carrier through subsequent assembly processes such as soldering. This is illustrated in Fig. 67.15.

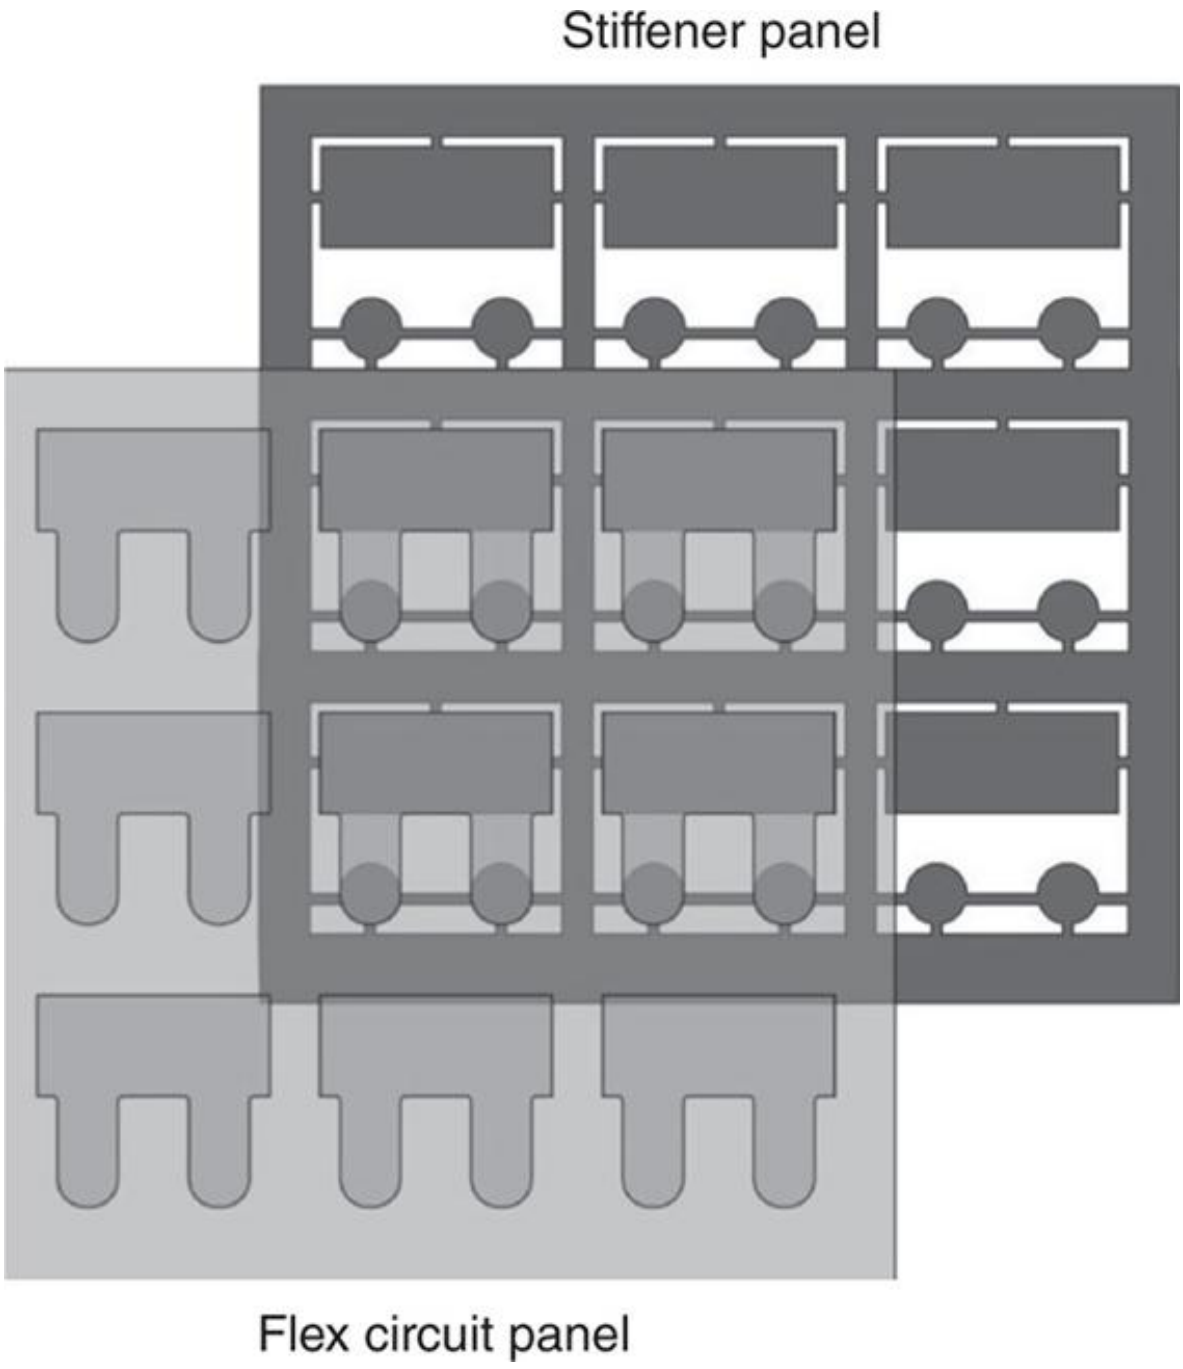

FIGURE 67.15 Flexible circuit panels and stiffener panels can be joined to facilitate mass assembly and separated afterward by cutting away tabs.

In high-reliability applications it is recommended that some matter of strain relief be employed at the transition from rigid to flex to avoid damage to the circuit. As illustrated in Fig. 67.16.

FIGURE 67.16 Methods for relieving strain from flex to rigid transition areas.

67.8 PACKAGING FOR FLEX

Over the years numerous approaches have been employed in the packaging of flexible circuits. There are a few important attributes which all suitable methods share. First they prevent the circuit from being deformed in transit or storage. This is not a function of simply making a flex circuit stay flat, in some cases the flex circuit is actually pretty formed into a shape by the flex circuit manufacture. Special fixtures are developed expressly for this purpose. Often he is employed at temperatures which are close to the glass transition temperature of the resin used and it is allowed to cool in place so that the shape is held. In such cases special packaging of a three-dimensional construct is required. More commonly, however, the flex circuits are shipped in a flat condition with or without stiffeners. Because many flexible circuit materials are hygroscopic and absorb moisture is important to make certain to the extent possible that they are well sealed with moisture impervious materials and perhaps as well with a desiccant to absorb any moisture within the packaging. This will serve well the needs of those in the assembly process as it will not only protect solderability but also help to prevent damage to the circuit during the soldering operation due to explosive outgassing of entrapped moisture. Where there is a good relationship between the manufacturer and the assembler it may be of

advantage to create or have made special containers for the flexible circuit which can be reused.

67.9 HIGH-DENSITY FLEXIBLE CIRCUIT MANUFACTURING

High-density flexible circuits are as the name implies a subset of traditional flexible circuits. High-density circuits are most often employed in high-end applications such as chip packaging, read-write disk drive heads and especially now for smartphones. The point of departure between the two is predicated on the circuit feature sizes. While there is no standardized threshold where circuit design crosses over from standard definition features to high-density features, most observers consider feature sizes under 100 µm to be within the domain of high density. This includes both circuits and through-holes. Because they are a subset there are some differences in materials and processing chemicals and equipment required to make these higher-density flexible circuits. Table 67.5 provides a listing of some of those process and equipment needs for making high-density flex circuits.

TABLE 67.5 New Manufacturing Technologies for High-Density Flexible Circuits

Processes	New Technologies
Raw materials	Stable polyimide film (~20 ppm CTE) Thin copper foil (9, 12 μm) Adhesiveless copper-clad laminates
Microvia hole drilling	Laser (excimer, UV:YAG, carbon dioxide) Microhole punching High-accuracy *x-y* table Plasma etching, chemical etching
Copper plating	Direct plating Seed layer sputtering
Surface cleaning	New cleaning reagent
Etching resist	Thin dry film (~15 μm) Liquid resist
Exposure	Collimated light source, auto aligner Laser direct imaging
Etching	High-resolution etchant
Coverlay	Laser drilling Photoimageable coverlay (dry film type and liquid type)
Surface finishing	Electroless plating for Ni, Au, solder High-speed plating
Flying leads	Laser/chemical etching Chemical etching
Guide holes	Automatic high-accuracy punching machine
Inspection	Universal AOI Noncontact electrical tests
Roll-to-roll system	Low-tension EPC system Automatic aligner with CCD camera

Leading-edge of high-density flexible circuit applications have features sizes with holes, lines, and spaces on the order of 20 µm and less. Some of the technologies that are used in the manufacture of high-density flexible circuits are relatively new while others are derivative of technologies which have been used for more than 30 years. In fact the general process flow for high-density circuits varies little from the process used for the manufacture of standard flexible circuits as is illustrated in Fig. 67.1. And most of the processes and process requirements described in the first portion of this chapter are not entirely different from those required for high-density flexible circuits. This includes material preparation cleaning handling system and the like. The major differences are in the basic materials used, the nature of the drilling process employed and some nuanced elements of process which allow for high-density circuits to be manufactured. This will become clear as a different processing methods are described and illustrated.

67.9.1 Imaging Processes for Making High-Density Flex

Making high-density flexible circuits requires both proper material selection and suitable processing methods. Thus one of the key elements required when it comes to making high-density flexible circuits is the base material, and more specifically the thickness of the copper which is bonded to the polymer. The etching process is an isotropic one thus during etching the copper is etched both down and laterally beneath the resist which defines the circuit features. Thus the thinner the copper, the easier it is to define a fine line feature this is illustrated in Fig. 67.17.

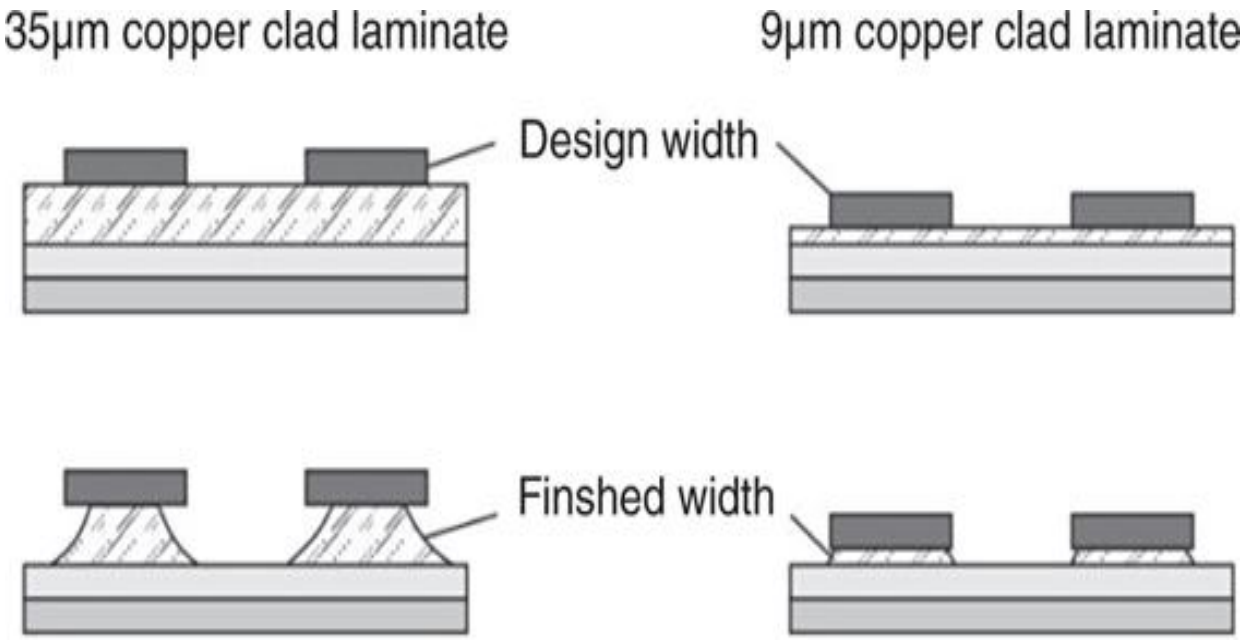

FIGURE 67.17 When the key requirements to making finer line circuits is to use their copper foil to begin with. The fact that etching is an isotropic process and that circuits are etched both laterally and down means in circuit features will take on a nominally trapezoidal shape with thicker copper. Within or copper the finished etched circuit is much more representative of the design.

However, no feature can be resolved at any yield without suitable processes and equipment. In that regard Table 67.6 is provided to alert the reader to the direct and ancillary processes and processing equipment that may be required to reliably produce the high-density circuits being pursued at high yield.

TABLE 67.6 New Technologies Needed to Generate Fine-Line Traces on Flexible Substrates

Processes	New Technologies
Surface treatment	New soft etching chemicals (organic)
	Sputtering of seed layer
Resist coating	High-resolution liquid etching resist and plating resist (spray coater, dipping coater, etc.)
	Thin dry film (~15 µm)
	High-sensitivity dry film with high resolution (10 mJ/cm^2)
	Wet laminator
Exposure	Collimated light source with glass mask (~15-µm line/space)
	Autoalignment system for double-sided circuits (with accurate dimension compensation system, ~5 µm)
	Roll-to-roll conveyor system with low tension
	Laser direct imaging system (30–40 µm line/space)
Etching	High-resolution etchant (cupric chloride, ferric chloride)

With the basic understanding of the fundamentals of making fine line circuits, as illustrated in Fig. 67.17, there are occasions when simple subtractive circuits will not work. Thus when current carrying capacity requirements are higher it is still possible to produce fine line circuit features. This is accomplished by patterning a thin client flexible laminate with a negative image of the circuit pattern and plating up copper within the channels. When plating is complete the resist is stripped from the panel and panel is etched. In the process some of the plated copper is removed at the same time as the background copper. While the features may be nominally diminished in size the process can characterized and modified to meet the needs of almost any circuit

requirement. The general process as illustrated in Fig. 67.18 and a circuit pattern representative of the potential features possible is shown in Fig. 67.19.

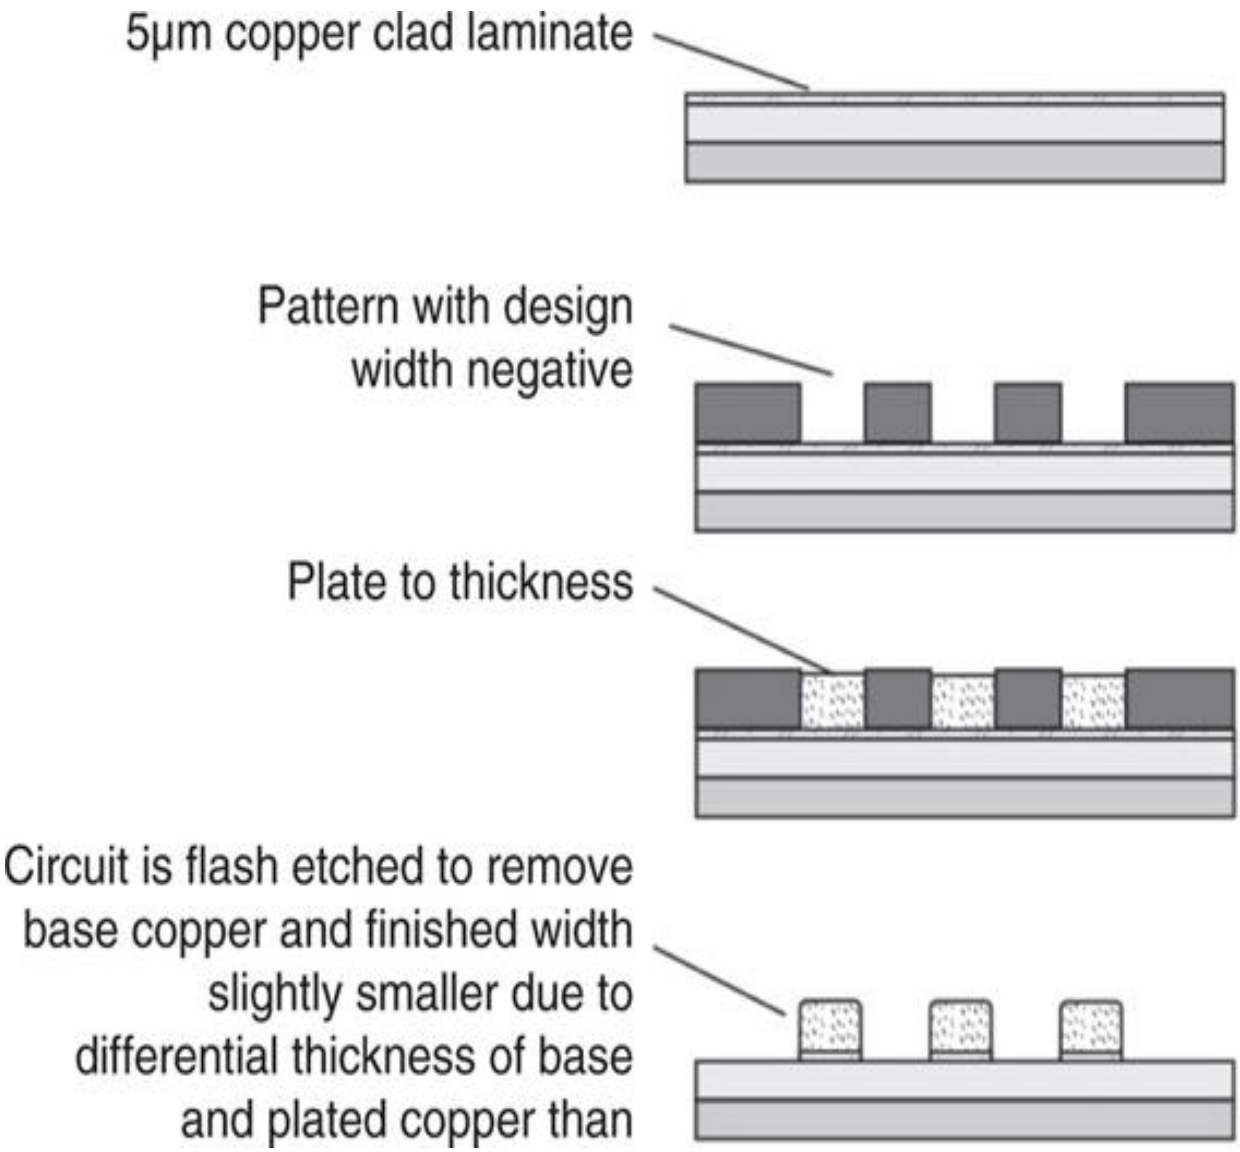

FIGURE 67.18 Illustrated above are the process steps for making a semi-additive or semi-subtractive circuit.

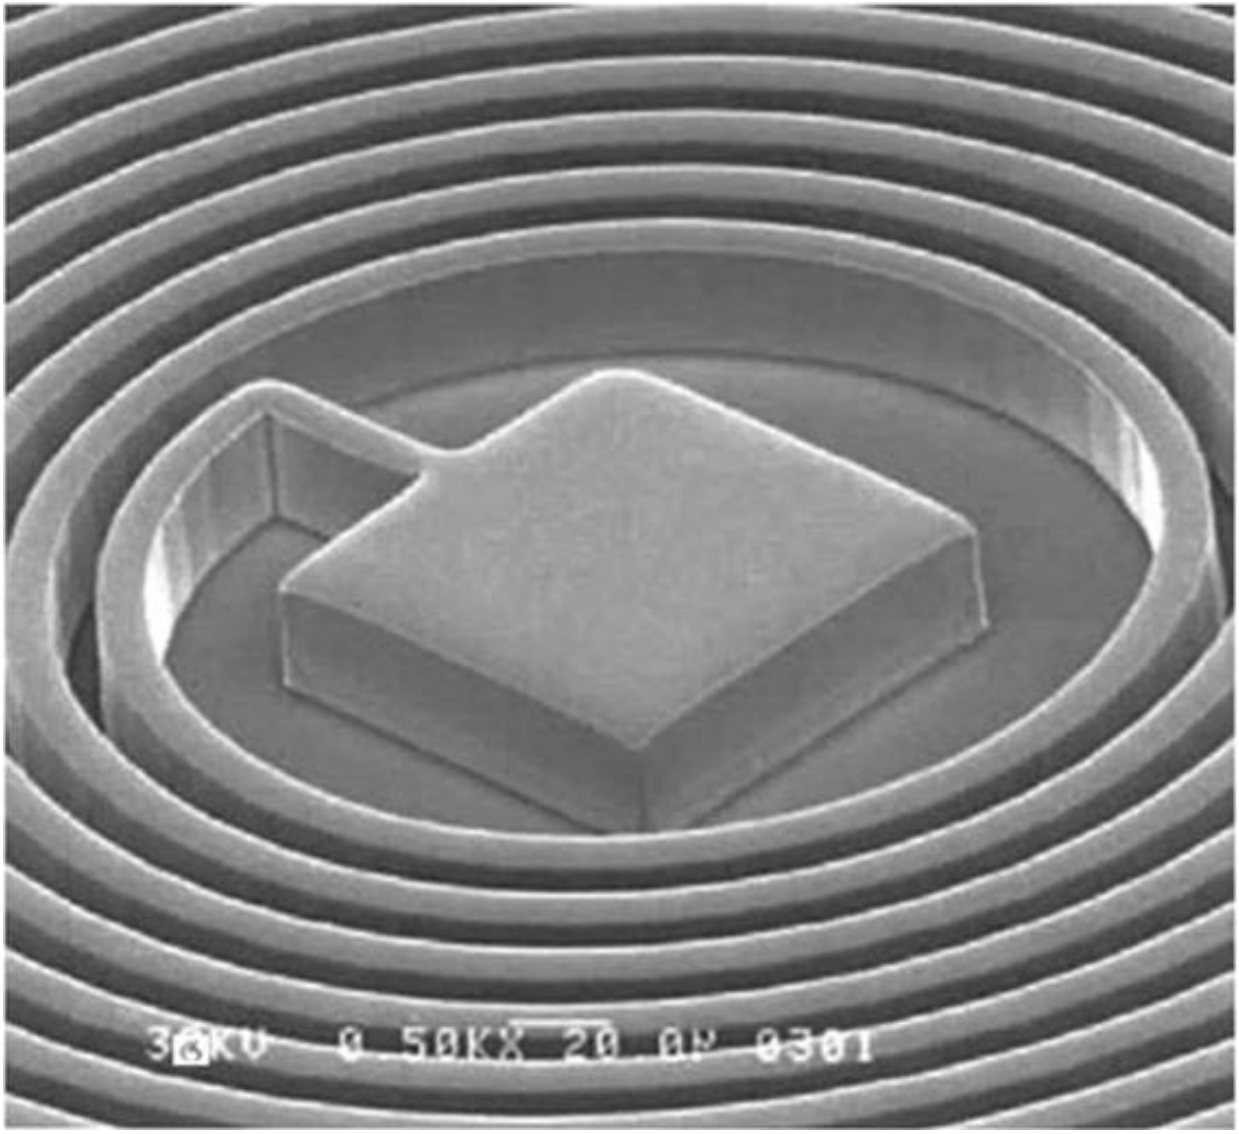

FIGURE 67.19 Shown above is a photomicrograph microscopic inductor. The nominal trace with of the conductor is 10 µm while the nominal thickness is 25 µm.

While there are more exotic ways of creating fine line features for flexible circuits these two methods, subtractive, and semi-additive, generally dominate. While rigid circuits have been produced using a full build electroless copper on a catalytic substrate the approach never found much favor in the flexible circuit world due to the fact that the mechanical properties of the electroless deposits were not well suited to flexible circuit applications. There is, however, an additive

method which has seen some commercialization in flexible circuits. Method is one which employs inkjet technology to deposit a catalytic material onto the surface of bare polymer. The patterned polymer is then immersed in an electroless copper solution wherein copper metal is reduced on the catalyzed surfaces only providing a copper circuit. The process as illustrated in Fig. 67.20.

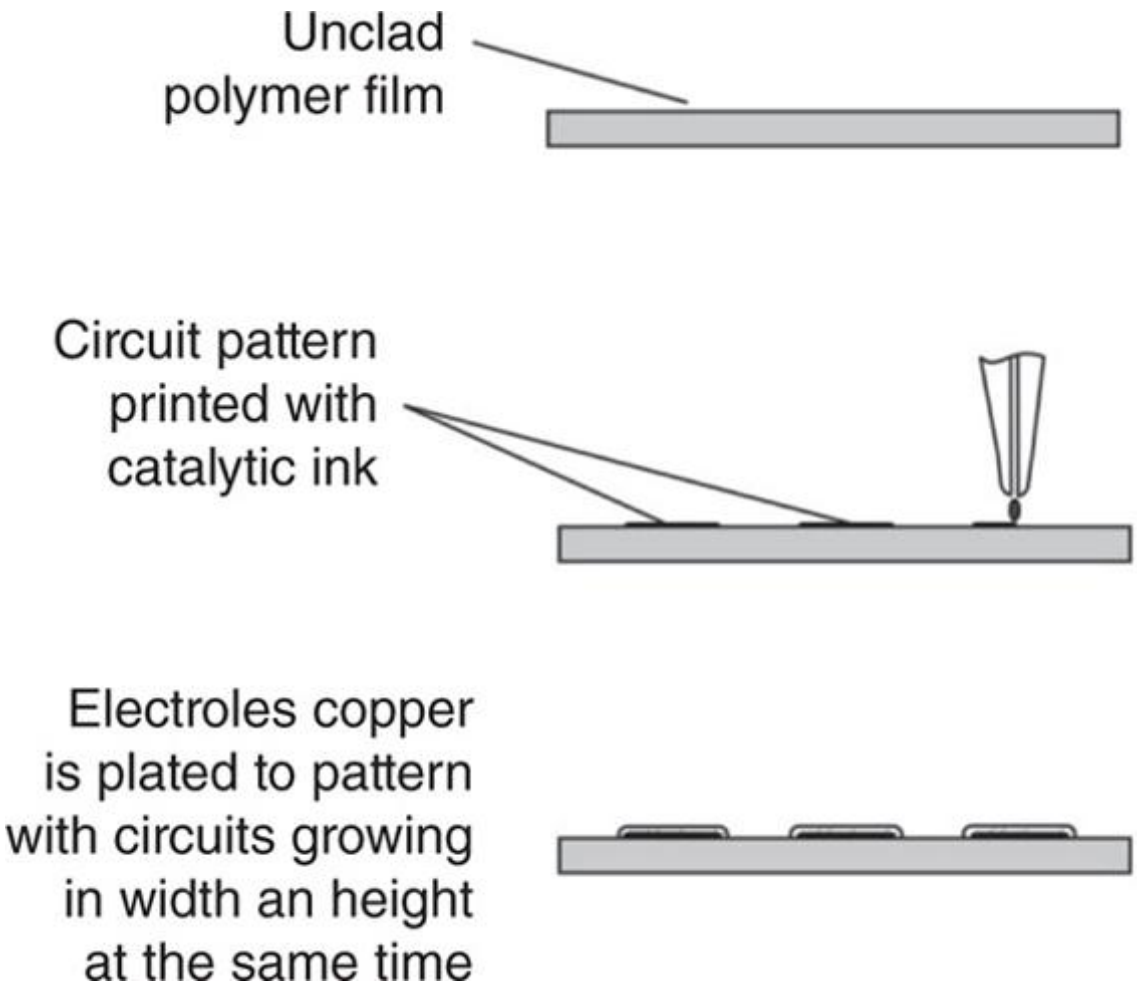

FIGURE 67.20 Above are illustrated the process steps for inkjet printing and electroless plating of catalytic ink circuit patterns.

The last method for making fine line features and circuits is one which has been employed by the semiconductor industry. It is referred to as a resist liftoff process. The method involves coating and patterning a substrate, in the

present case polyamide film, with a resist. The material is then sputtered with copper metal, which is normally preceded by deposition of an angstroms thick layer of nickel and chromium to improve adhesion of the copper to the polymer film. Because sputtering is a nominally “line of sight” process little copper is deposited on the sidewalls of the resist. Thus when the resist is removed the copper deposited on it surfaces is removed at the same time, leaving a thin copper circuit pattern on the polymer film. The processes generally referred to as a “liftoff process.” Again this is not a common method but if one has the equipment that represents an alternative approach. Moreover it is not well-suited to producing circuits with large unmetallized areas. In such cases it may be necessary to abrade the copper surface deposited on the resist to provide the stripping solution better access to the resist.

In concert with all the other methods just described there is one other worthy of inclusion that is particularly well-suited to flexible circuit applications this technique is often called “button plating” or “holes only plating” is a process wherein holes are drilled and plated through in advance and a second imaging step is used to etch the circuit pattern. This helps to keep the copper thin everywhere except in the through-holes and the vicinity of them. The process as illustrated in Fig. 67.21.

Copper clad laminate

Strip resist to expose thin base copper

FIGURE 67.21 Above is illustrated the processing steps for making a button plate circuit and method which allows the base copper to be at its nominal thickness while providing robust plated-through holes.

67.9.2 Microvia Hole Processing for High-Density Flex Circuits

The other critical features relative to the manufacture of high-density flexible circuits are the micro via holes that are required to interconnect circuit features on different layers. The general discussion on hole formation provided earlier in this chapter provides important background which will be useful in understanding what follows. For purposes of this discussion microvias are defined as through-hole or blind features which are less than 100 µm in diameter. The methods used to create such features fall into three different categories. Holes which are produced mechanically, holes which are produced using photonics, and holes which are produced chemically either by means of a gas or liquid. Thus included in this discussion are all of the methods discussed earlier: mechanical drilling, punching, and laser drilling, and as well this section also includes discussion of liquid and gaseous methods capable of removing exposed polymer, especially polyimide, which is a dominant material used in high-density flexible circuit manufacturing. Table 67.7 provides a general overview of the different methods which will be discussed in the balance of this section.

TABLE 67.7 Comparison of Technologies for Hole Generation on Dielectric Layer

	Drilling	Punching	Laser Drilling	Plasma Etching	Chemical Etching	Photo Polymer Process
Hole diameter	~50	~70	~10	~70	~70	~70
TH for D/S	Yes	Yes	Yes	Yes	Yes	Yes
TH for multilayer	Yes	No	Possible	No	No	No
Blind via hole	No	No	Yes	Yes	Yes	Yes
Material choice	Wide	Wide	Wide	Fair	Small	Small
Technical flexibility	Small	Small	High	Fair	Small	Small
Chemical waste	No	No	Small	Small	Serious	Fair
RTR availability	No	Possible	Possible	Difficult	Possible	Possible

67.9.3 Mechanical Microvia Hole Creation

Drilling and punching of the two dominant methods of hole formation covered under the term “mechanical.” Punching is limited to through hole formation while numerically controlled drilling can be employed for making both through holes and in certain cases blind vias. Present generation numerically controlled drilling machines are capable of producing micro via holes smaller than 100 µm using specially developed drill bits. Some of the latest generation drills have demonstrated ability to drill 50-µm holes in 50-µm-thick copper clad flexible laminate. However, there are limits in drill stack height and thus productivity drops off wherein such small drill bits are used. Numerically controlled micropunching systems are also capable of producing small holes on the order of 70- and 25-µm polymer films at very

high rates. Multipin punch tool sets for predetermined patterns can greatly boost productivity when they can be used. Such tools have found utility in the manufacture of high volume real to reel circuit patterns such as are required for IC circuit packaging.

67.9.4 Laser Microvia Hole Creation

There are three predominant laser technologies used in drilling flexible circuits. They are excimer lasers CO_2 lasers and UV:YAG lasers. All technologies are capable of producing very fine holes on the order of 50 µm and less, though each has its own technical sweet spot. UV:YAG lasers, for example, have the ability to drill through both copper and polymer while excimers are best suited to drilling exposed polymer. Excimer lasers can, however, produce very fine features at high rates. Carbon dioxide lasers have the highest productivity when via holes greater than 60 µm in diameter are required. One of the challenges for CO_2 lasers was their inability to drill copper effectively; however, it was learned through experimentation that if the surface of the copper is given an oxide treatment before drilling both the copper and the base polymer can be drilled at once. This is especially useful in the formation of blind vias. In advantage of laser technology in general is that it is readily adapted to roll to roll processing. Examples of laser drilled features are shown in Fig. 67.22.

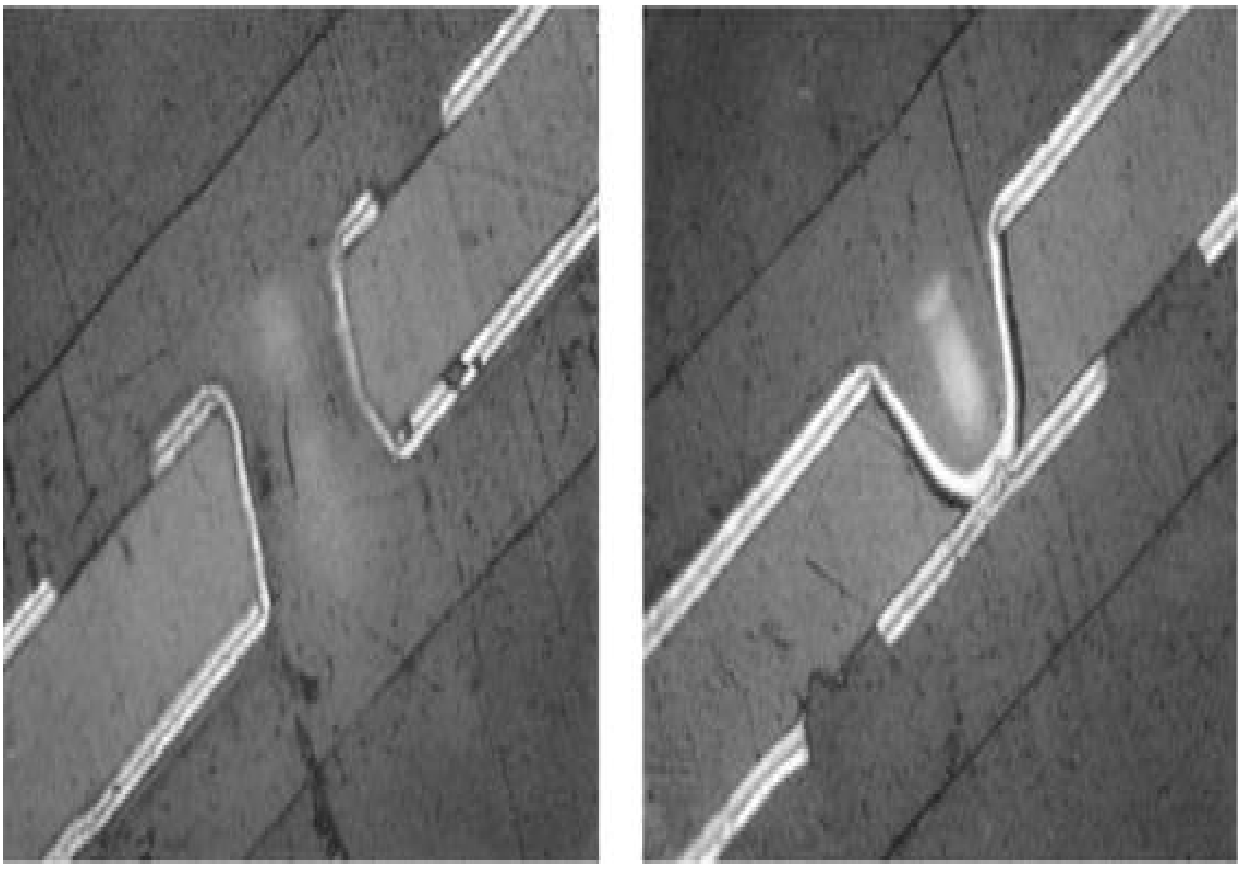

FIGURE 67.22 Examples of laser drilled through and blind vias in polymer film. Note that the features are over coated with a polymer to protect the circuit features.

67.9.5 Chemical Microvia Hole Creation

There are to primary chemical methods employed to produce microvias in flexible base materials. The two processes vary significantly in terms of their capital cost and processing methodology. The older of the two methods is chemical. Chemical etching of polymer is been used by the TAB industry for many years when it was learned that certain polyimide chemistries would etch readily in hot caustic solutions. Processing must be carefully monitored; however, as it is possible to leave residue in the holes which could obviate the making of an electrical interconnection to

exposed copper. In this regard, one of limitations of these types of processes is hole feature sizes in general either process is capable of producing features down to 100 µm in material 50 µm thick.

The other method for making microvias which is also arguably chemical in nature is plasma etching of microvias. The process is performed in a vacuum and a gas mixture comprise typically of CF4, oxygen, and nitrogen is excited by microwave generation to form a plasma which breaks down exposed polymers into fundamental hydrocarbons. While these two methods differ significantly in terms of their fundamental operation, both have distinct advantage over other methods in that a virtually unlimited number of holes can be made at one time. That is whether one etches just one hole or millions in copper clad flexible polyimide substrate, the processing cost is the same.

In this regard, both of the just described processes are best suited to the use of a conformal mask, which is fundamentally, where the copper cladding of the laminate is etched to expose the polymer where holes in the polymer are desired. The basic process steps are illustrated in Fig. 67.23.

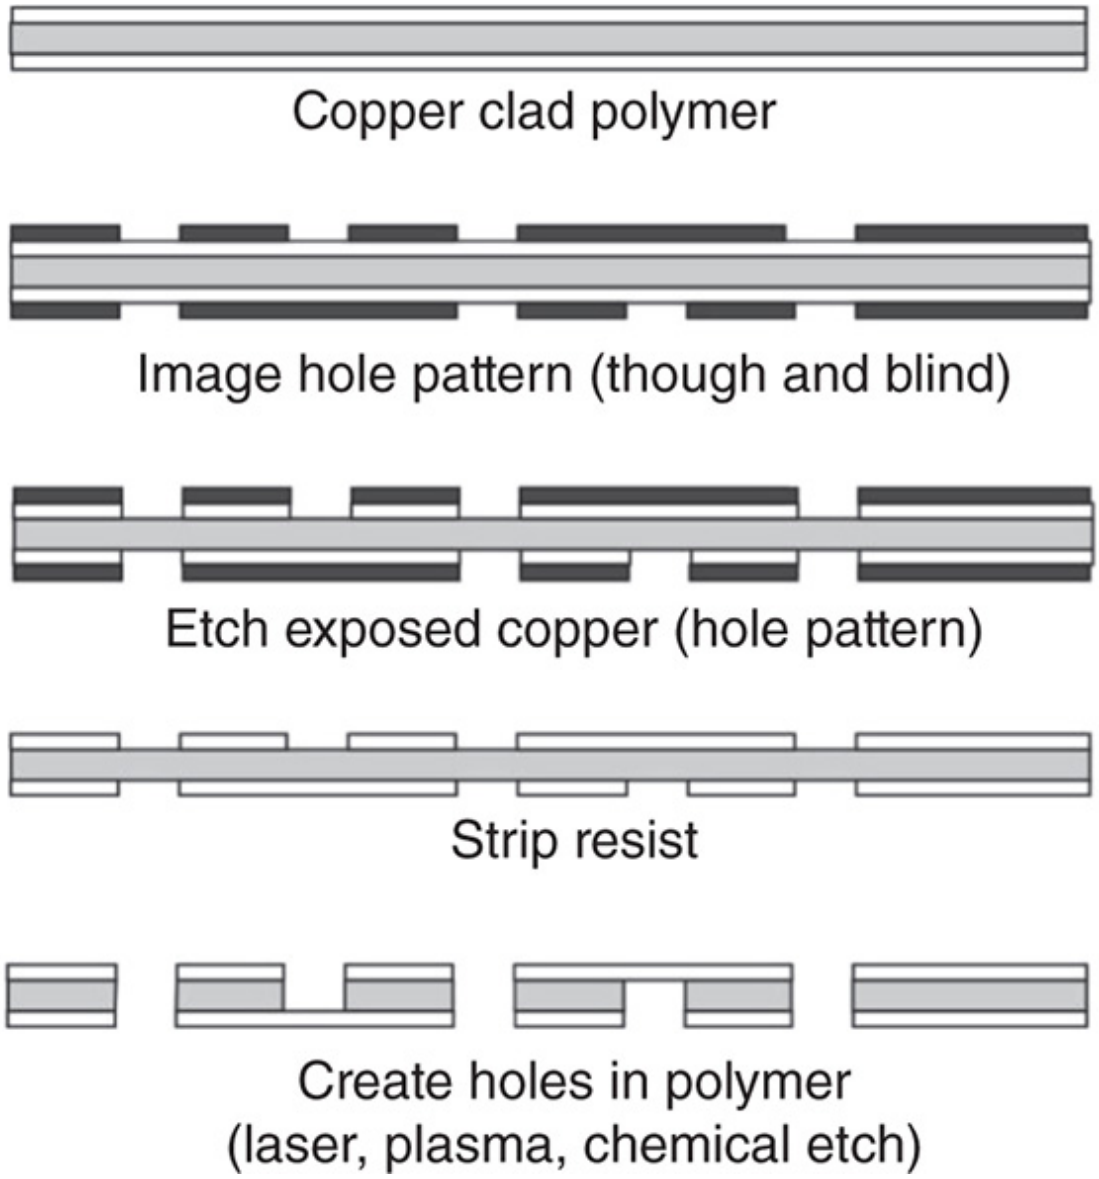

FIGURE 67.23 The conformal mask process is perhaps best suited to plasma and chemical etching of polyimide but can be used with lasers as well.

The difference between the two processes is that chemical processing must be tailored to the polymer and the most well suited to the process is polyimide. In contrast, plasma processing can breakdown almost any polymer so it has wider applicability where and when it may be required in certain special circuit structures. Finally one process attribute that is common with both is undercutting of the surface copper which can make subsequent processing more

challenging with regard to chemical solution exchange, where the metal lip is present. This effect can be seen in Fig. 67.24.

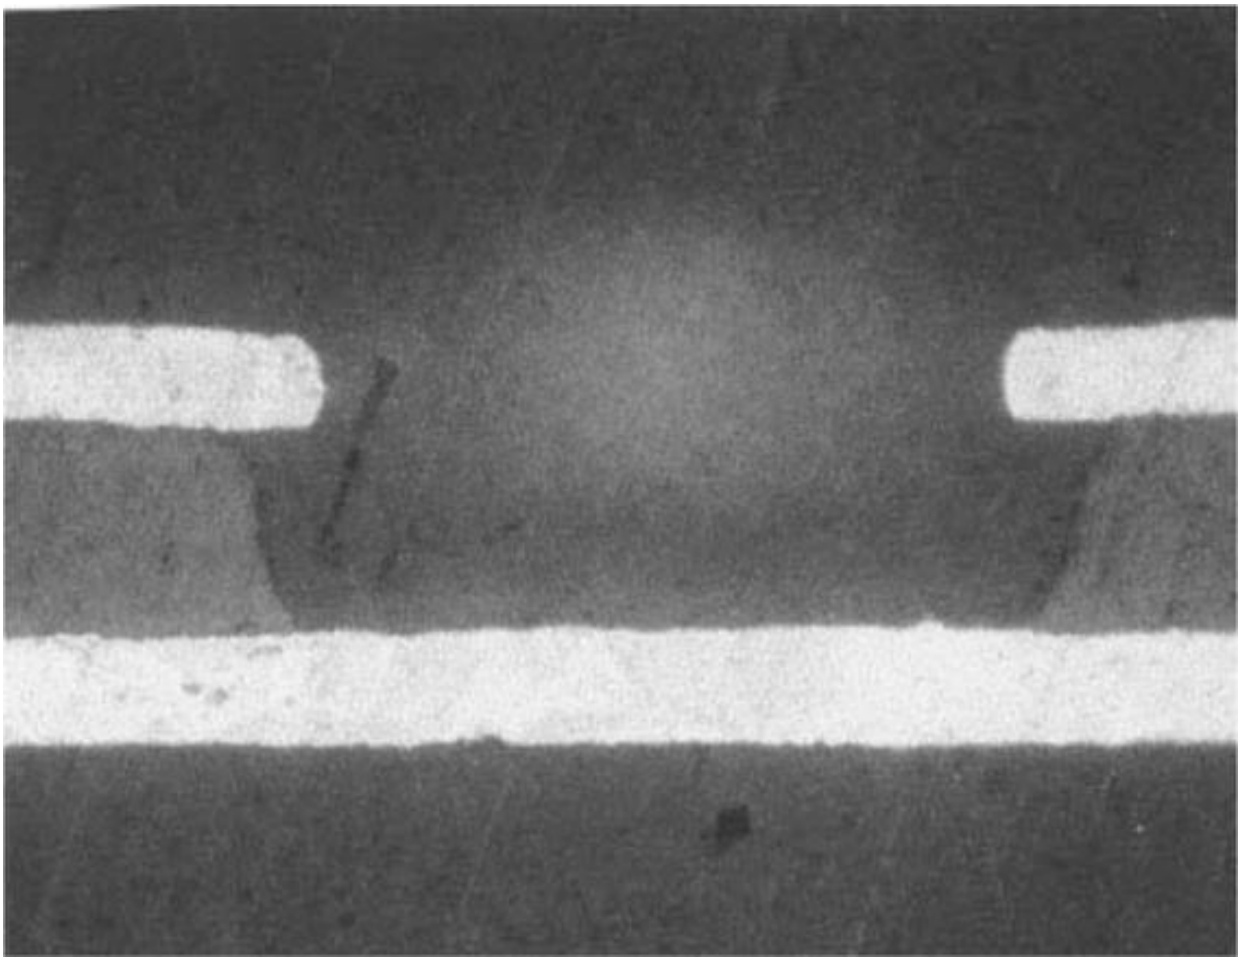

FIGURE 67.24 Microvia generated by plasma etching. The hole diameter is 200 µm. Note the undercutting of the upper copper foil.

With all three general approaches to hole formation in high-density flexible circuits, there are limitations in terms of their technical capabilities these are compared and contrasted in Table 67.8 and a graphic representation of the general capabilities in areas of overlap between the different processing methods is provided in Fig. 67.25. Finally a cost analysis of the various methods discussed for drilling holes using a common 50-µm base material is provided in Fig. 67.26.

Having provided a reasonable overview of the processes used for making microvias in materials used for high-density flex, the adage "use the tool best suited to the task" is found to be no less true in the manufacture of high-density flexible circuits than it is in any other manufacturing discipline. With that in mind Table 67.9 is provided to give the reader an appreciation of which technology is best suited to the type of material being processed

TABLE 67.9 Material Processing Suitability

In summary the manufacture of flexible circuits, both traditional revenue center of gravity and leading-edge high-density structures is vital to the creation of new and useful products of every sort. While there similarities in processing and some areas of crossover between the two technologies

there are also definitely significant differences between the two. As a result, flexible circuit manufacturing is today split along technological lines. Both types of circuits will be required now and in the future and understanding the nature of the processes required to build both is important to the success of both the manufacturer and the customer. The final figure in this chapter (Fig. 67.27) is provided so that the reader can assess where their products present and future fit in the overall picture of flexible circuit manufacturing in the present day.

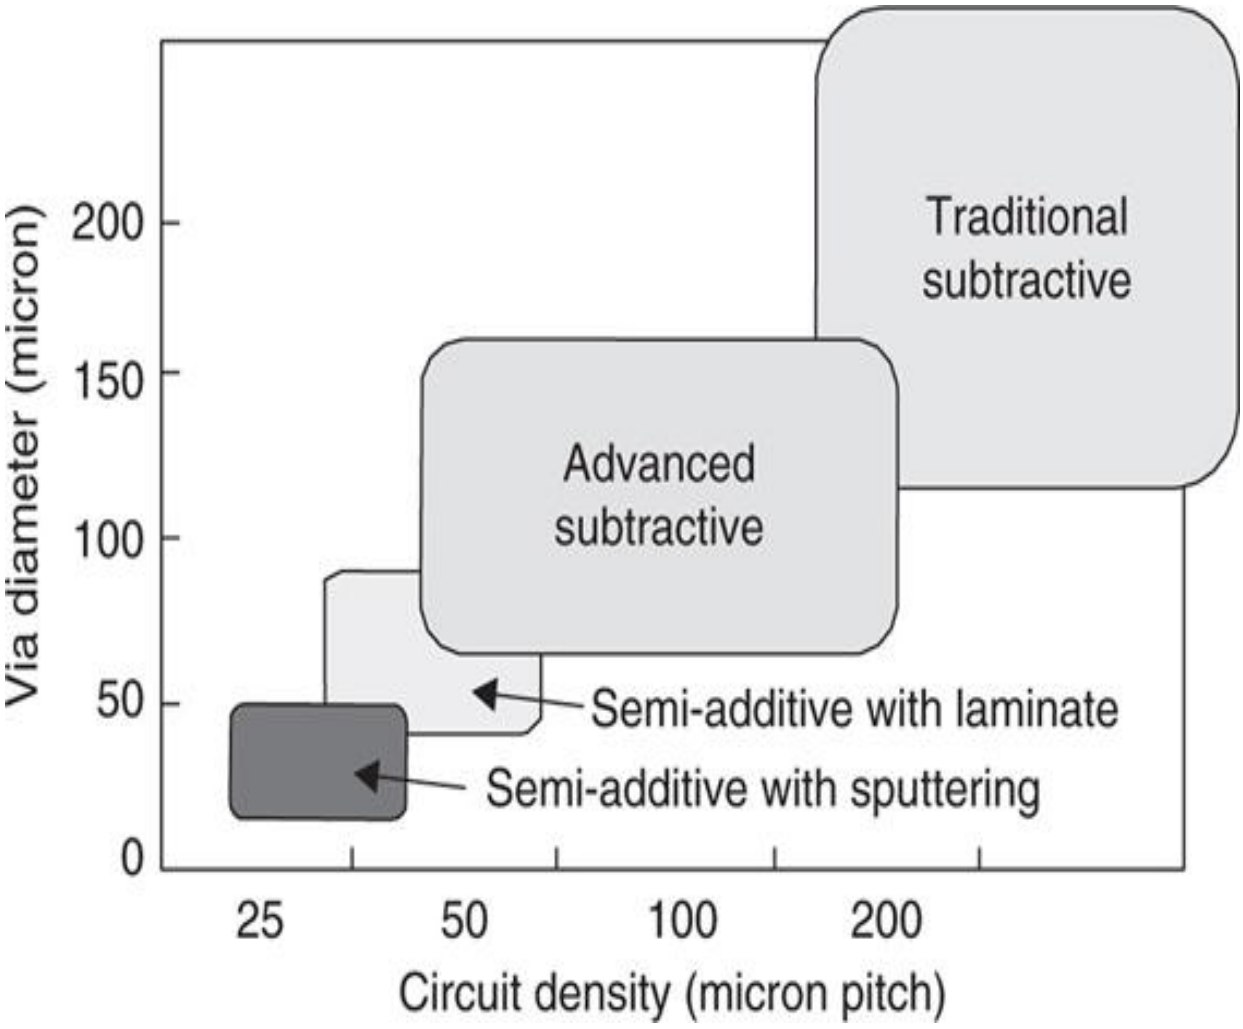

FIGURE 67.27 Total high-density capability.

67.10 ACKNOWLEDGMENTs

The author extends his appreciation to the industry and the many who contributed to the progress of flexible circuit activities. Sincere thanks also goes to Dominique K. Numakura, at DKN Research, for his authorship of this chapter in the previous (6th) edition of *Printed Circuits Handbook*.

CHAPTER 68

TERMINATION OPTIONS FOR FLEXIBLE CIRCUITS

Joseph Fjelstad
Verdant Electronics, Seattle, Washington

68.1 INTRODUCTION

Flexible circuits are highly useful substrates used for interconnecting both electrical and electronic assemblies. To make those vitally important interconnections, termination features are required. These features are typically apertures in one or more of the insulating layers, which cover the metal circuit patterns exposing up to those areas where interconnection is required. The types of materials and processes which can be employed used to make these interconnections can vary widely. For example, some features may be disposed to be interconnected by wire bonding technology, others by a pressure contact of some sort, are still others by solder or some type of conductive or even nonconductive adhesive. Typically the termination areas are provided with a corrosion resistant conductive finish. A common finish for separable contacts is nickle/gold,

though other metal combinations are possible as described in other chapters of this handbook. That said, expensive noble metals are not required for every application and even a carbon ink may be suitable in some cases.

The choice of termination method will influence certain flex circuit design features, such as termination length and width and the type of surface finish that is applied. In many cases the flex circuit may be outfitted with a support material such as a stiffener either to bear the weight of the component or provide a stiffener backer to the flex to allow it to be inserted into an edge card connector, for example. While it is not possible to name and discuss every one of the myriad types of connections that might be used in detail, the major approaches to terminating flexible circuits in a manner that allows them to be interconnected to one or more modules, additional circuit assemblies or connectors it is possible to explore in broad brush strokes the major categories of termination types that are used. By employing a classification process familiar in science we will begin at the highest levels and work our way down to the finest level of interconnect bearing in mind that the approach to interconnection can vary widely even within a particular group this will be illustrated by example. The determination of what solution to employ at each level must be drawn out to the consideration of matters specific to the individual design and its operational environment along with reliability expectations of the customer.

68.1.1 First-Level Consideration—Permanent, Separable, or Intermittent?

The first decision that one must make relative to the type of termination needed is predicated on the nature of the

interconnection. This can be broken down into two fundamental options with a common but less recognized third option, the intermittent contact which is an option generally limited to contact switches. The interconnection may be desirably permanent or the interconnection may be desirably separable, that is allowing the interconnection to be made and broken some specified number of times over the life of a product. In the case of electrical and electronic components (i.e., through hole or surface mount components and connectors), a permanent connection is the default choice and with such devices solder is the typical interconnection medium of choice; however, there are other options as will be shown. For separable interconnections with flexible circuits there are a wide range of commercially available connector solutions to meet the growing demand for diverse solutions. Table 68.1 provides an overview of the basics of permanent and separable connections.

TABLE 68.1 General Capabilities of Separable and Permanent Connection

Mating Objective	Mating Method	Connection Density
Permanent connection	Array soldering	0.35-mm contact pitch
Permanent connection	Linear soldering	150-µm contact pitch
Permanent connection	Anisotropic conductive adhesive	30-µm contact pitch
Permanent connection	Wirebonding	100-µm contact pitch
Permanent connection	Direct bonding (e.g., TAB bonding)	70-µm contact pitch
Separable connection	bumped contact interconnect	20 contacts per square centimeter
Separable connection	SMT mated pair	0.5-mm contact pitch
Separable connection	ZIF connectors	0.25-mm contact pitch
Separable connection	Film connector	100-µm contact pitch
Intermittent	Elastomer buttons, dome switches	0.25- to 10-mm contact pitch

68.1.2 Permanent Interconnection Options

As mentioned above solder is the dominant technology for making permanent connections between electrical and electronic components and circuit boards whether flexible or rigid. Solder makes electromechanical interconnection between circuits and components by forming intermetallic bonds between component leads and circuit termination surfaces. Lap soldering of flex circuits to a circuit substrate has proven a useful method. Hot bar soldering tools have been developed to facilitate such connections. When connected (as illustrated in Fig. 68.1), the flex should be strain relieved in some to protect the interconnection. The subject of soldering is covered in great detail elsewhere in

this book so the reader is referred to that material. That aside the discussion will turn to other options for making permanent connections with flexible circuits.

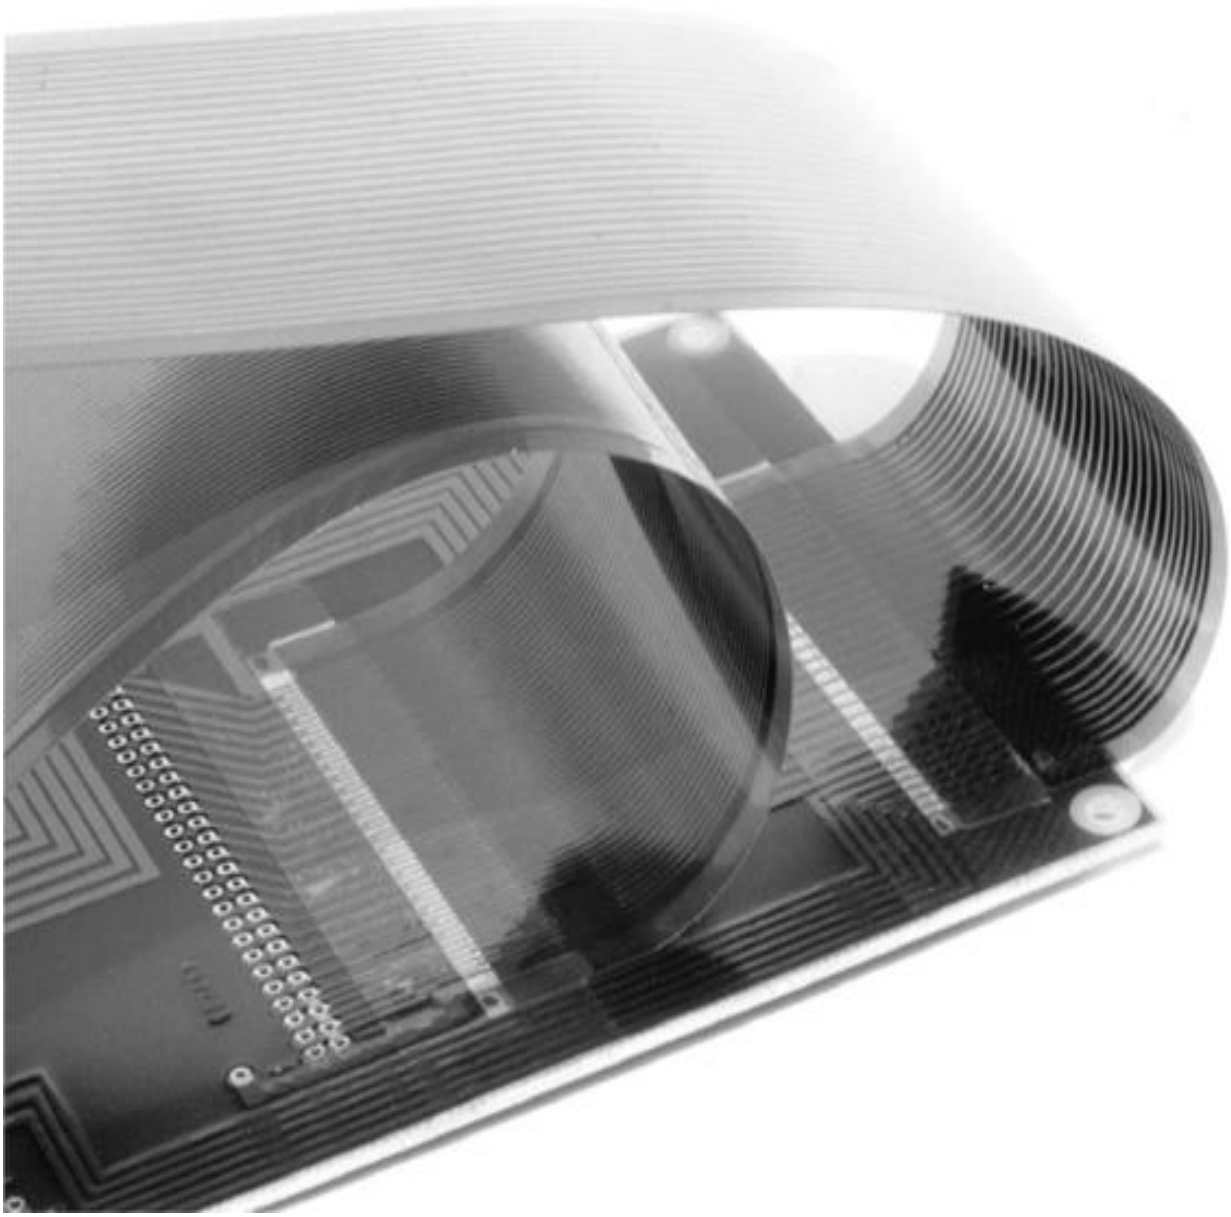

FIGURE 68.1 Flexible circuits connected to a rigid board by solder fusing.

68.2 WIREBONDING TECHNOLOGY

Wirebond technology is used primarily for making interconnection directly from an IC chip to a lead frame, a packaging substrate, or a rigid or flexible substrate. The latter has been historically referred to as chip on board or COB technology. There are three basic types of wirebond technology, thermocompression bonding, thermosonic bonding, and ultrasonic wedge bonding. Wedge bonding is arguably the most versatile because it is a room temperature process and employs relatively inexpensive aluminum wire for making interconnection. While most commonly used for making interconnection between chip and substrate, the technology can also be used for making jumpers in certain applications. Circuit terminations must necessarily have a nickel gold finish. Wedge bonding terminations require a very thin gold flash because Kirkendall voiding can occur with thicker gold deposits. On the other hand thermosonic gold wirebonding requires a thicker gold to make a reliable gold to gold connection (Fig. 68.2).

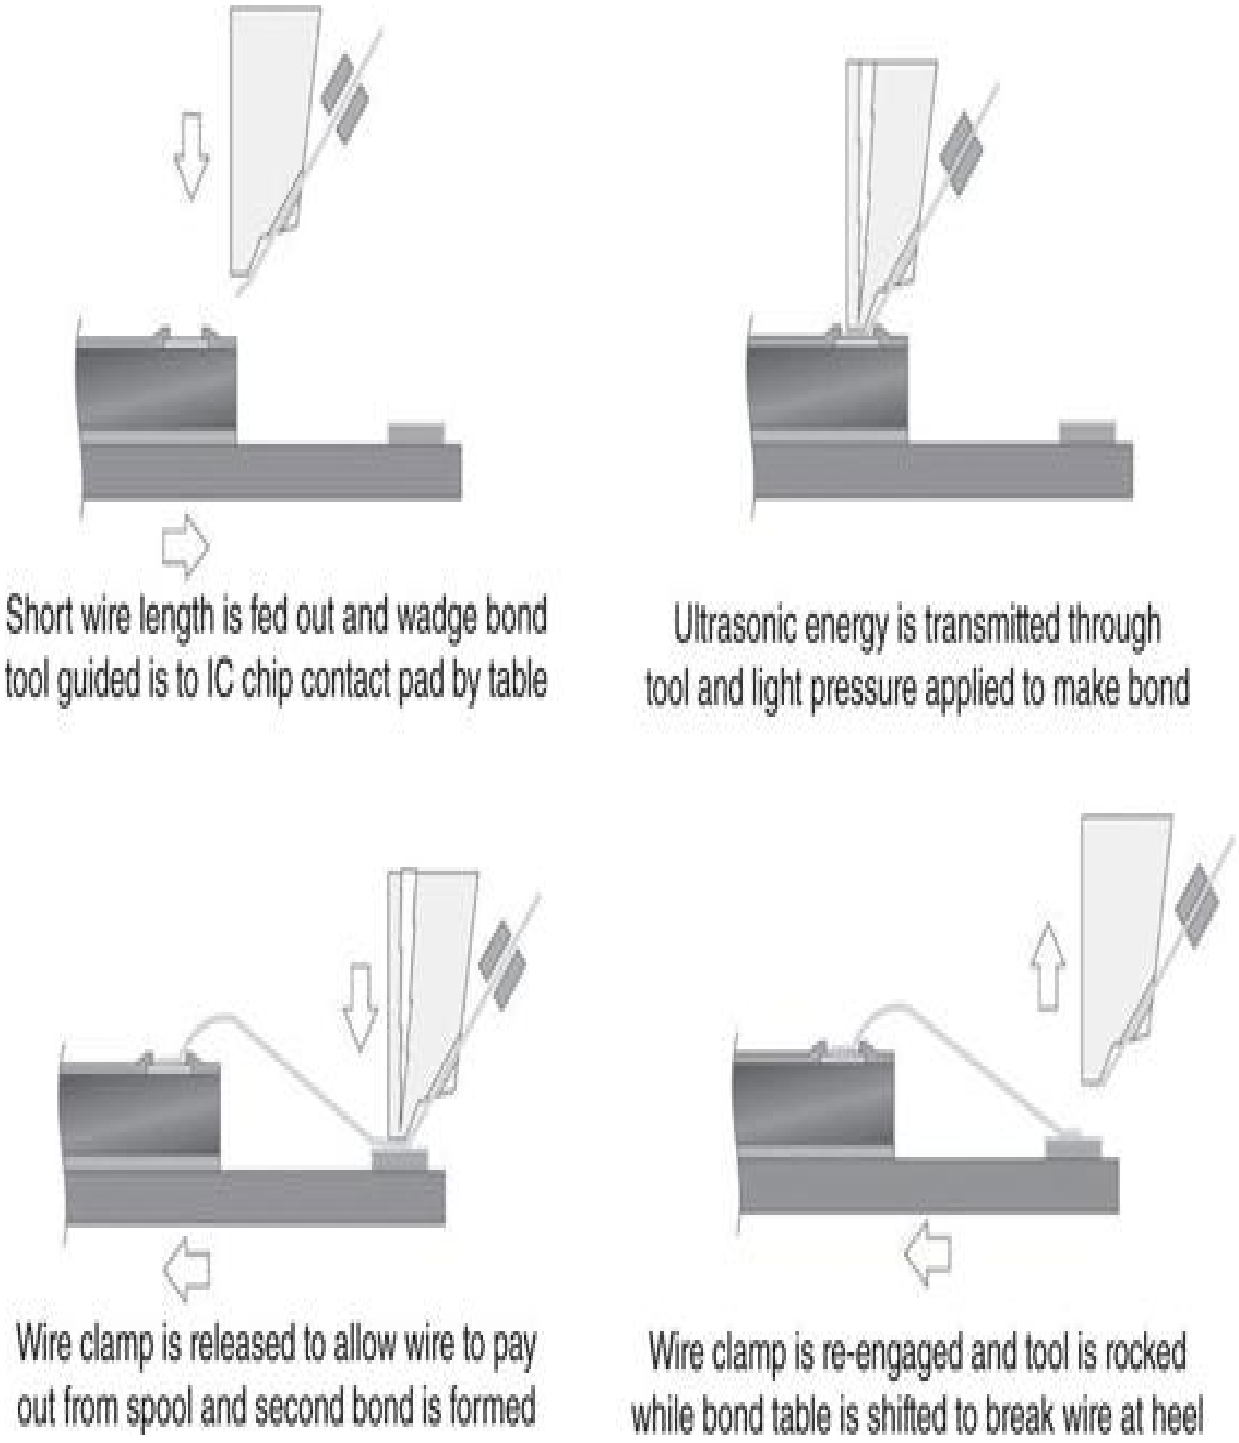

FIGURE 68.2 The basic wedge bonding process.

68.2.1 Conductive Adhesives

There are two general types of conductive adhesives used for electronic interconnections: isotropic conductive adhesives and anisotropic conductive adhesives. However, in some special applications nonconductive adhesives may be used such as where capacitive coupling is employed for the transference of signals, thus discussion here will be limited to the more common types of materials used. Descriptions of the two major types follow and Fig. 68.2 graphically illustrates the difference.

68.2.2 Isotropic Conductive Adhesives

Conductive adhesives are normally mixtures of powdered metal (typically powdered silver) and an adhesive such as epoxy. While the conductivity of conductive adhesives is not quite as good as solder they are quite suitable for many applications. They can deposited en masse onto a substrate in a manner similar to that used with solder paste such as by a stencil or as dots using a dispensing technology. During the cure of the resin adhesive there is typically some shrinkage which draw the conductive particles closer together to improve bulk conductivity.

68.2.3 Anisotropic Conductive Adhesives

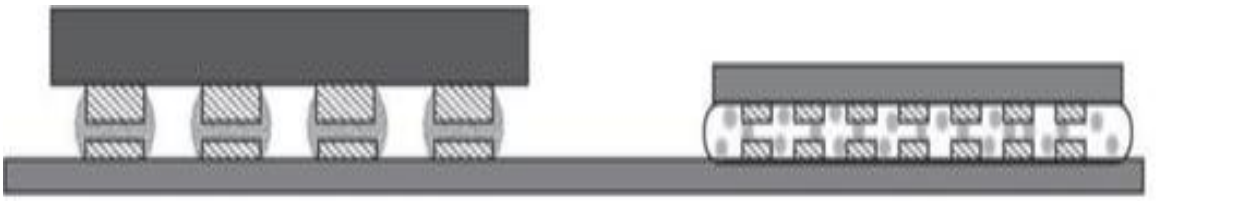
Anisotropic conductive adhesives differ from isotropic conductive adhesives in that they only conduct electricity in the *Z* or vertical axis this is because conductive particles are widely dispersed within the adhesive (Table 68.2). Anisotropic conductive adhesives can be provided in both liquid and film forms. An application and use multiple redundant contacts are made between mating surfaces. The

technology is capable of making very fine pitch interconnections and is widely used for interconnecting driver circuits to displays of every sort (Fig. 68.3).

TABLE 68.2 Capabilities of Certain Anisotropic Conductive Adhesives

Proprietary Formula	A	B	C
Applications	FOG, TCP	FOG, COF	FOB, TCP
Min. pitch	70 µm	50 µm	200 µm
Thickness	25 µm	20 µm	45 µm
Matrix	Epoxy	Epoxy	Epoxy
Particle size	5 µm	5 µm	6 µm
Surface treatment	Gold plating	Gold plating	Gold plating
Process temp.	170°C	190°C	170°C
Process time	15 s	10 s	20 s
Repair	Possible	Good	Possible

FOG: film on glass, FOB: film on board, TCP: tape career package, COF: chip on film.



Isotropic conductive adhesive
– Dense conductive particles
– Conducts in all directions

Anisotropic conductive adhesive
– Dispersed conductive particles
– Conducts in Z (vertical) axis only

FIGURE 68.3 A visual comparison of isotropic and anisotropic conductive adhesives is provided above. In applications isotropic conductive adhesives are

generally better suited to coarser pitch applications while anisotropic conductive adhesives well-suited to fine pitch applications.

68.2.4 Permanent Direct Metal to Metal Interconnection

Beyond the use of an intermediate material to make interconnection between different metallic contacts it is also possible to make direct metallic interconnection between contacts by other means. Three often seen approaches to making such connections include gas-tight interference fit connections, resistance-welded connections, and ultrasonically welded connections. A brief discussion of these follows.

68.2.4.1 Metal to Metal Interference Interconnection. Direct metal to metal interference interconnection is widely used in the backplane industry, where connectors are press fit into slightly undersized plated-through holes resulting in a gas-tight seal between the pins of the connector and the through holes into which they are inserted. The method is not commonly used in flexible circuits but an analog version is reasonably common. This version comes in the form of insulation piercing connectors, which as the name implies have pointed contacts designed to punch through the insulation of a flexible material having copper conductors. The punching process brings the contacts of the connector and the conductor traces of the flexible element in intimate contact to make direct electrical interconnection without an intermediate material. The contacts are often wrapped around the conductor and crimped into place to secure them in position. The same general technology is widely used in the electrical industry, where insulation-coated round wires are commonly used.

68.2.4.2 Resistance-Welded Interconnection.

Resistance welding is a technique used more often in circuit repair than in circuit production. A resistance welded is accomplished by pressing one metal tightly against the other to ensure a good electrical interconnection and then pulsing the joint with a short duration of high current energy causing the interface between the metal surfaces to instantaneously melt and weld together. Most of the equipment that has been developed is suited better to coarser pitch interconnections rather than the fine pitch more commonly found in use today

68.2.4.3 Ultrasonically Welded Interconnection.

The same general type of technology which is used for wirebonding can be used with flexible circuits by design when and where it suits the purpose of the design. Tape automated bonding (TAB) technology has employed this method for making interconnection directly to chips for decades. The delicate leads on the flexible circuit are desirably secured in place until the moment of bonding. One way to do this is to keep them attached on both sides of the aperture that exposes the leads. When the bonding process is ready the leads can be broken and attached and a single bonding step. To ensure that the leads break in the appropriate location a notch may be provided either by etching or embossing the lead at the point where the break is to occur. The technique was first used in volume for chip scale packaging in the mid-1990s. Figure 68.4 shows an example of such an interconnection.

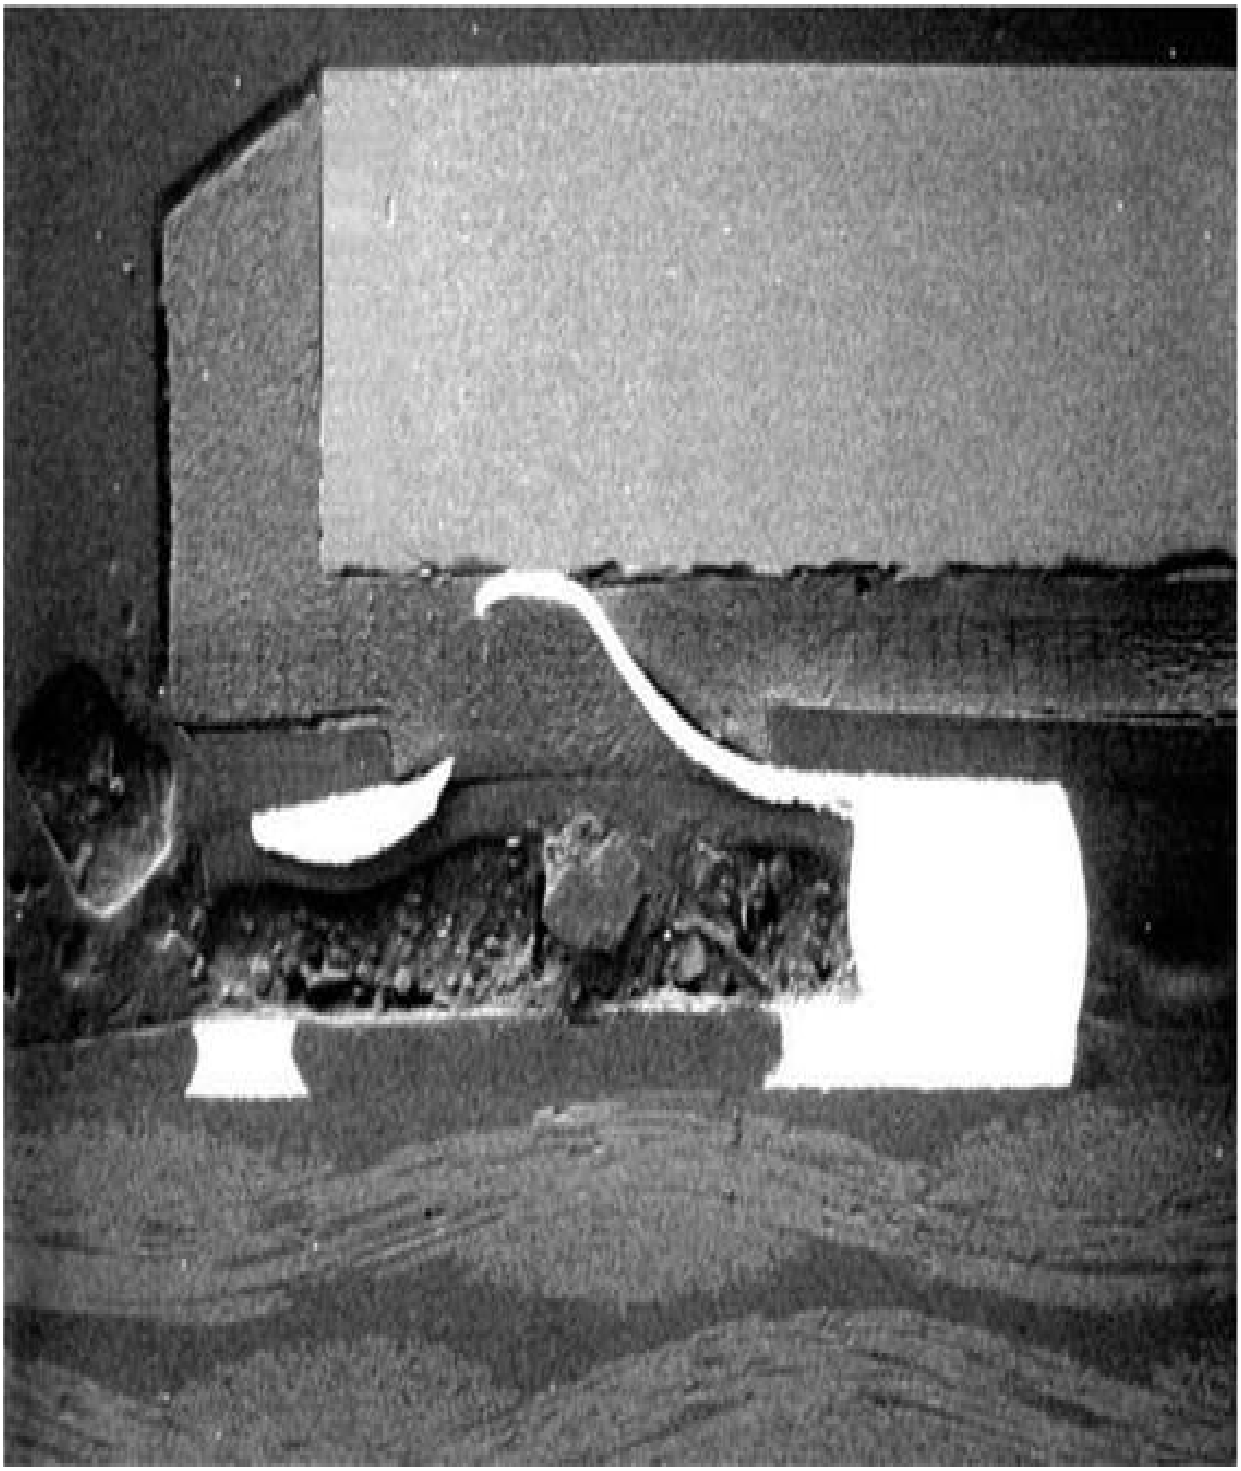


FIGURE 68.4 In cross-section is shown interconnection of the lead of a flexible circuit to an IC chip in a CSP.

68.2.5 Separable Interconnection Options

Separable interconnections are for the most part interconnections made from one specific set of conductors to another. This is typically accomplished through a connector. In the realm of flexible circuits separable interconnection surfaces can reside on the surface of the flex circuit itself or the flex circuit may be permanently joined to a connector of some sort, which is historically, and especially for the military and aerospace sectors which prefer mated pair connector systems and especially bulkhead type connectors wherein half of the connector is passed through the wall of the electronics box in which it resides. Because of the diversity of connector concepts available, the range of connectors which have been used to date is extremely wide. For the purposes of this discussion, the focus will be more limited to general approaches rather than specific solutions, though some specific solutions may be required to carry the message.

68.3 SOLUTIONS WHERE THE FLEX CIRCUIT IS HALF OF THE MATED PAIR

Rigid printed circuits have served as a half of a mated pair interconnection through an edge card contact system almost since the beginning of the electronics industry. One reason is that it reduces by half the number of the connectors required where system elements are joined. It should come without surprise then that the same objective would hold for flexible circuits as well. One of the challenges of making direct connection to a flex circuit, however, is that they are very thin, and the material somewhat more plastic and thus prone to deformation through material creep under pressure and

over time. This is not a major concern when there is sufficient resilience in the spring contact which makes to the flex to ensure continuous contact even as material creeps. Treatment of the flex circuit half of the contacts set ranges from simply providing a surface which is resistant to corrosion (e.g., nickel gold) to providing a topographical element on the contacts (e.g., providing bumps at the point of connection). Metallic bumps can be formed or plated. Formed bumps can be created by embossing the circuit from the backside often in concert with a mating die having cavities into which the copper can distend to form the bumps. This method was used with considerable success with the flex circuits used to interconnect inkjet printheads. Bumps are often provided in an area array configuration to help improve density in terms of contacts per unit area. When pressure forming bumps the lands need to be sufficiently large to allow the formation of the bump. If the lands or pitch are too small there is a potential for the fracture of the copper. That said variation potential is to remove the material from around the periphery of the contacts in the area where they are to be used and provide some sort of resilient material in a bump pattern beneath the areas where contact is to be made. Figure 68.5 shows examples of different contact structures possible on flexible circuits.

FIGURE 68.5 The termination areas of flexible circuits can be modified in a number of ways provide raised contacts.

68.3.1 Connectors for Mating to Flex Circuits

There are a wide variety of commercial connectors available from different suppliers for making connection to flexible circuits. Where the flexible circuit is provided with a stiffener the number of legacy connector possibilities expands appreciably because edge card connectors have been used for rigid boards for decades. Rigid boards typically have beveled edges to facilitate insertion into the connector with flexible circuits on stiffeners it is useful to provide for a similar type interface if possible. For a single-sided connection the flexible circuit can be wrapped around the rigid stiffener and bonded in place to achieve the effect if two flexible circuits are to be connected on the opposite sides of a single stiffener then those two should be bonded to each other to form a small nib at the end of the step and area. The two approaches are illustrated in Fig. 68.6.

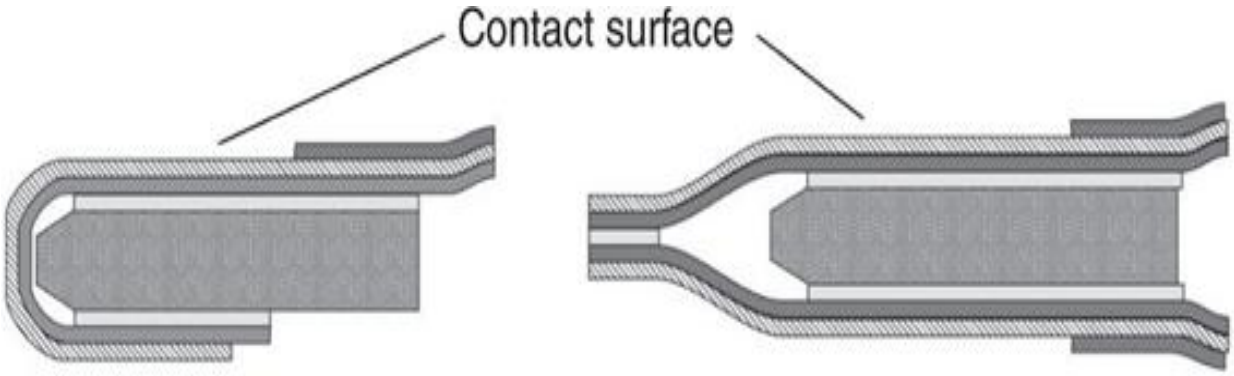

FIGURE 68.6 To allow for easier mating and insertion into standard edge card connectors, the flex circuit is bonded to a stiffener to meet with mating connector requirements for thickness. Beveling is used on standard rigid cards and flex circuits need a similar treatment as illustrated. Flex circuits may be bonded to one or both sides.

68.3.2 ZIF (Zero Insertion Force) Connectors for Flex

In many cases it is desirable to use the thin flexible circuit's edge connections to mate with other electronic elements. Zero insertion force connectors are well-designed to meet such needs because it is otherwise normally too difficult to try and insert with force flexible circuit into mating connectors. ZIF connectors typically have a latch which is listed to allow for easy insertion of the flexible circuit, once the circuit is in place the latches closed locking down the contacts and providing connection from connector to flex. Figure 68.7 shows an example of a ZIF connector.

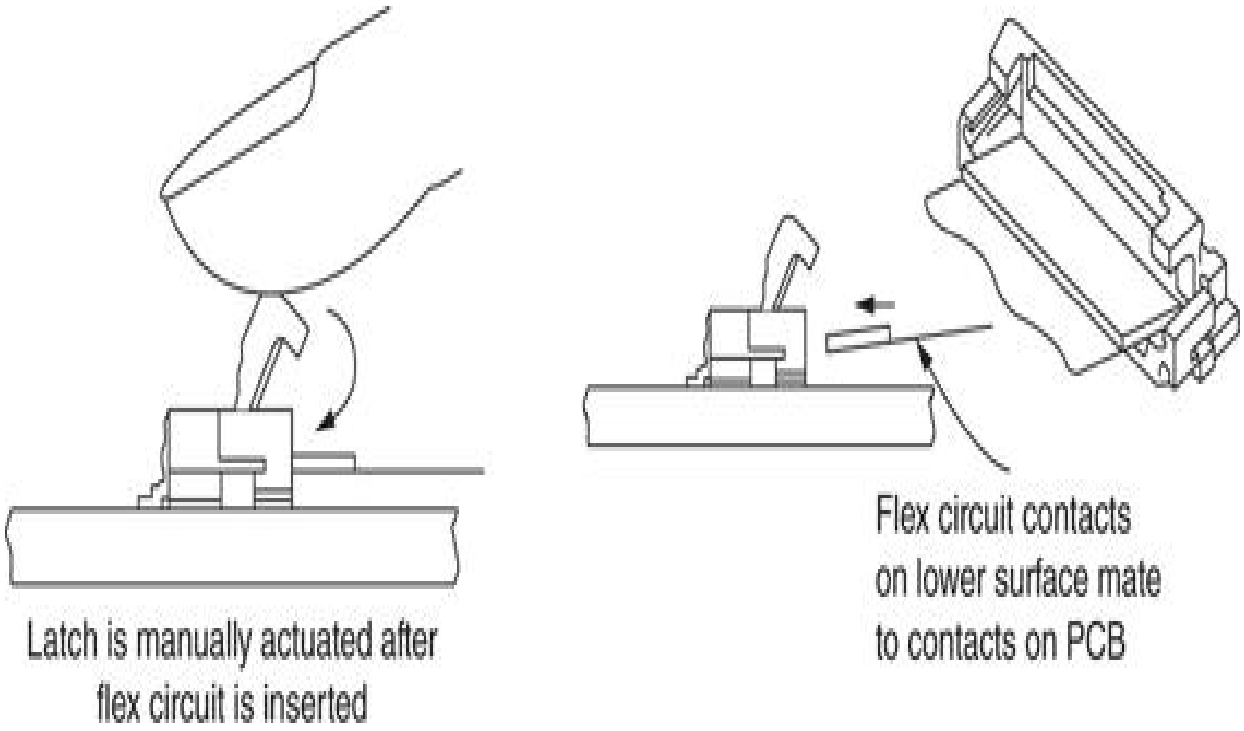

FIGURE 68.7 ZIF connectors are well suited to flexible circuit applications.

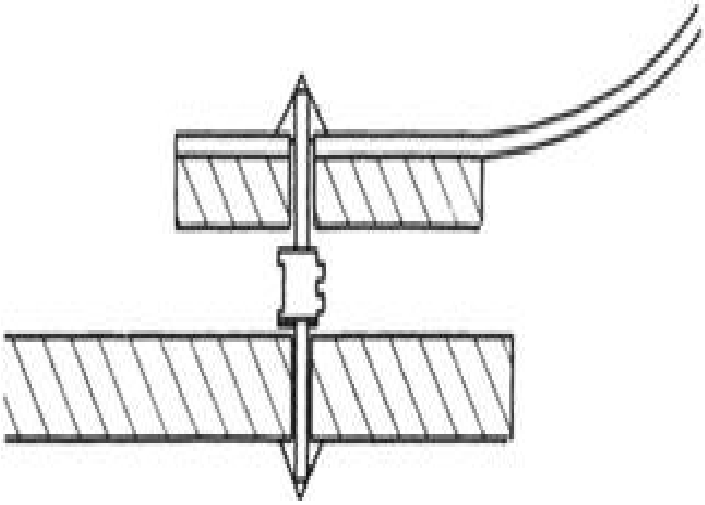
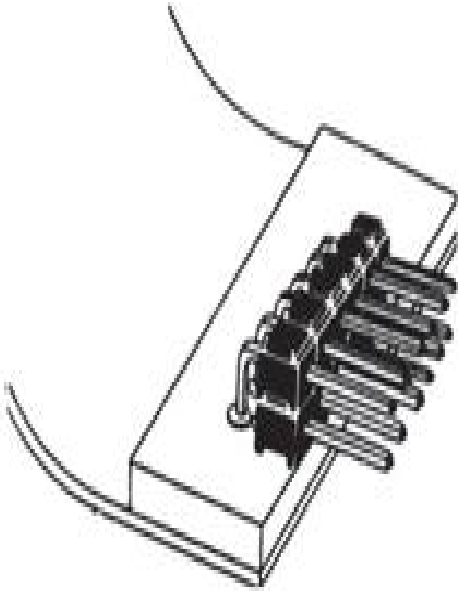
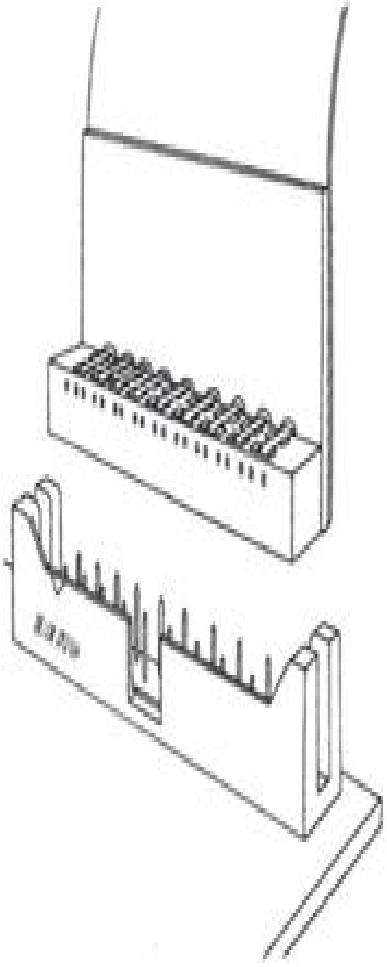
68.3.3 Header (Pin in Socket) Through-Hole Connectors for Flex

A popular format in printed circuit design is a so-called pin and socket approach. One half of the mating pair involves a header with pins projected through a plastic body, which holds them in accurate alignment and the other half is a socket that accepts the pins in the mating process. There are a number of different approaches to the design of such structures, a few of which are illustrated in Fig. 68.8.







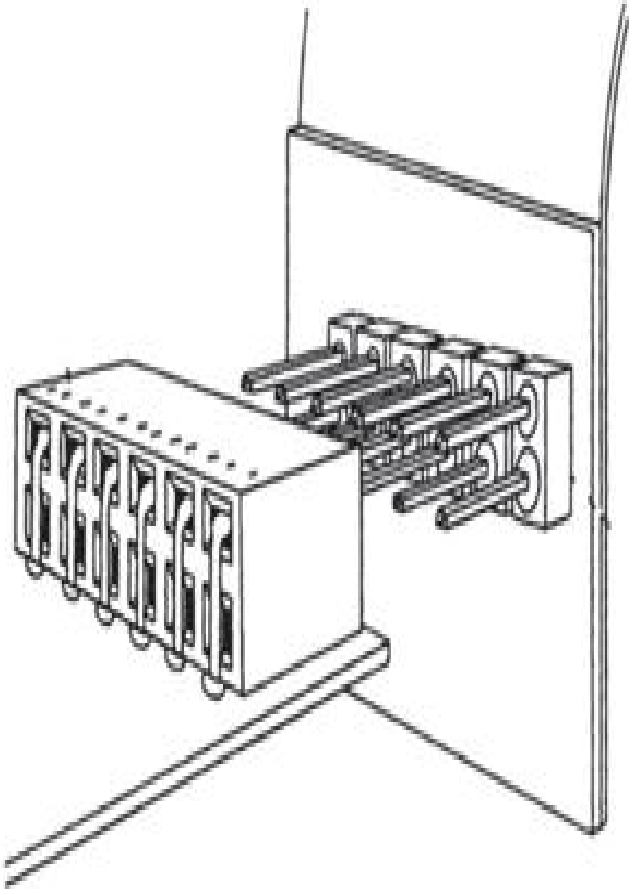


FIGURE 68.8 Examples mated pair through-hole connector concepts involving pin and socket interconnection between flex circuit and rigid board.

68.3.4 Mated Pair Surface Mount Connectors for Flex Circuits

Mated pair surface mount connector technology has been readily adapted to use with flexible circuit technology with great success. And it has served well the design objective of interconnecting many tens of circuits at low profile in a wide range of products including cell phones, digital cameras, and the like. Contact pitch can range down to 0.5 mm and less (down to 0.2 mm in some present advanced generation designs) which offers significant space savings in *x, y*, and *z* dimensions. Figure 68.9 provides an example.

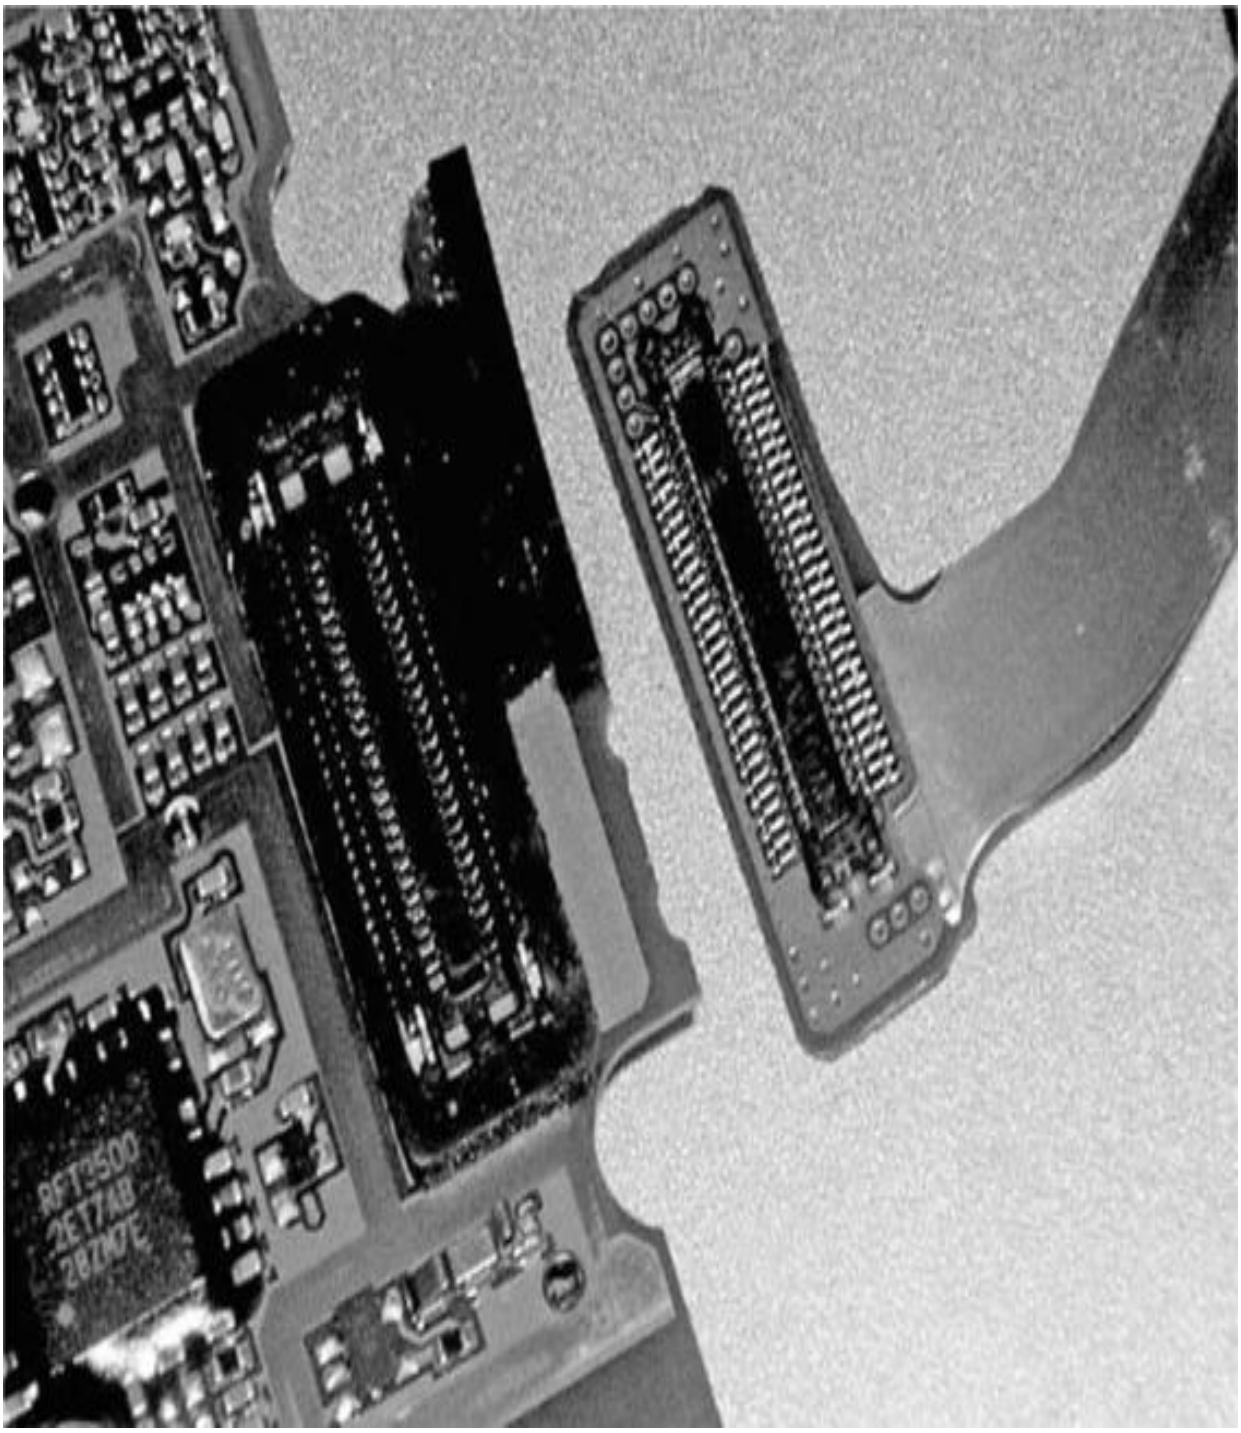

FIGURE 68.9 SMT mated pair connectors for flexible circuits. Example shown is for connection in cellular phone.

68.3.5 Zebra Strip Elastomeric Connectors for Flex

Zebra strip is a term applied to a unique elastomeric method of making connection between flex and rigid boards. The material is comprised of multiple layers of conductive and insulating elastomeric materials and allows for redundant connection between the mated pairs. The latest generations of the material have a 200-µm linear pitch resolution. The disadvantage of the material is that the contact resistance is relatively high making it not suitable for all applications, especially high current applications. Figure 68.10 shows an example of a zebra strip connector in an application.

68.3.6 Military Style and Bulkhead Connectors for Flex

Military style and bulkhead connectors are used for so-called black box electronics the connectors are designed to port electronic signals to the outside of a box through a weatherproof seal. The devices are typically round body and use pin in socket type interconnection with the mating cable being tightened and sealed by a screw ring cap that joins the mating halves of the connector (Fig. 68.11).

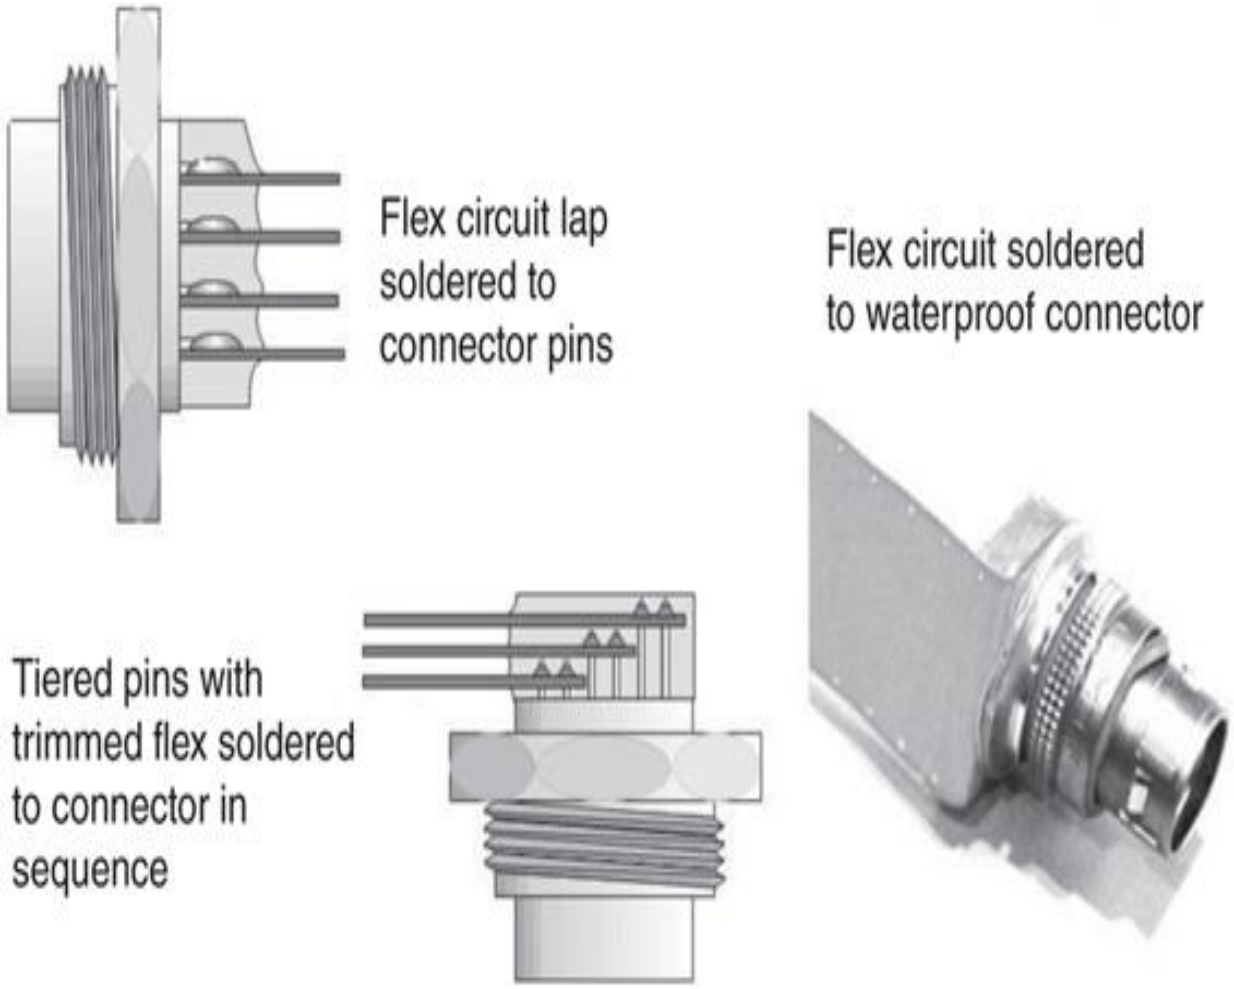

FIGURE 68.11 Examples of flexible circuits integrated into bulkhead and military type connectors.

68.3.7 Intermittent Connectors for Flex

The last type of connection in this overview of termination options for flexible circuits is the intermittent contact. With flexible circuits this means a low profile contact. It is often associated with membrane switch technology which is used in keyboards of every imaginable sort. Here the objective is to make contact and release. There are a number of different ways to execute this objective. Often because they circuits run at relatively high voltages and low current they can be produced using polymer thick film technology (i.e., silver ink). Figure 68.12 shows an example of structural elements of such a circuit and Fig. 68.13 show a perspective view of how contact is made.

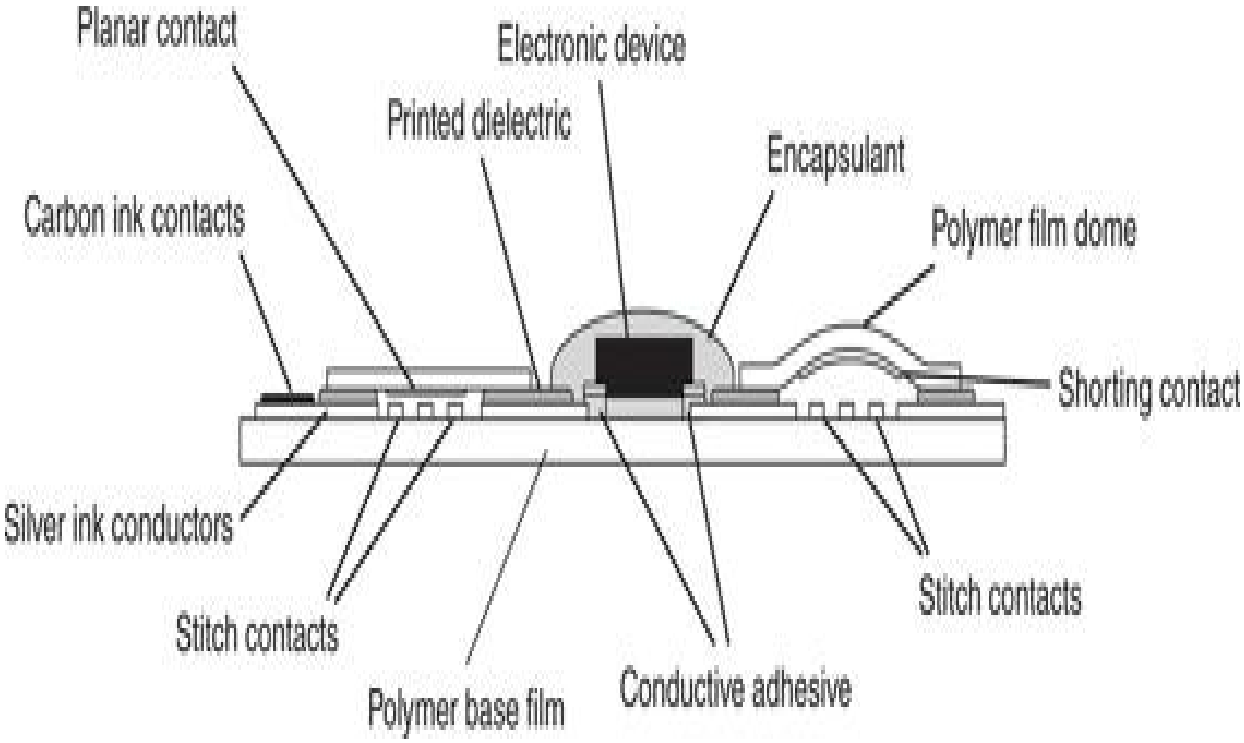

FIGURE 68.12 Representative elements of a membrane switch polymer thick film circuit are illustrated in the above graphic.

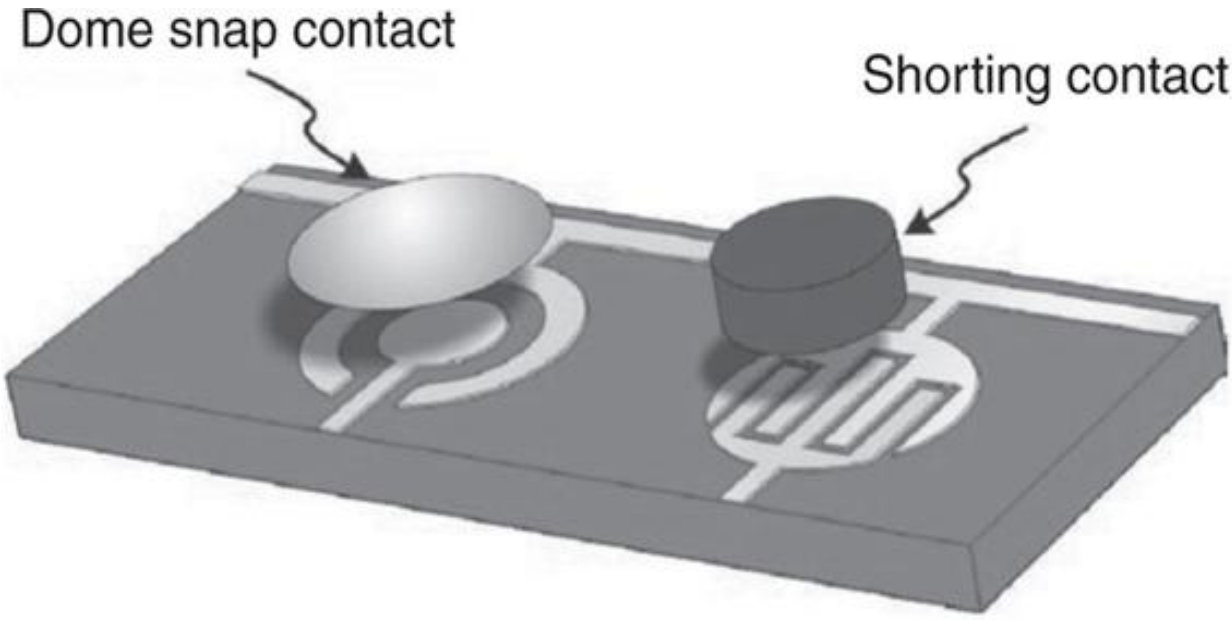

FIGURE 68.13 Shown above are different approaches to making intermittent contact to a flexible circuit the upper interconnecting and insulating elements are absent from the graphic.

68.4 SUMMARY

The methods for terminating flexible circuits permanently, separately, and even intermittently are varied. The correct solution among options available and the examples shown is the one that best suits the objectives of the design. This brief discussion is not meant to be exhaustive but to serve as a guide for the designer so they can have a better grasp of what options are available to them before they set out to create a new design. It is recommended that the designer reach out to connector suppliers for their input on which solutions might be best suited to the application in hand.

68.5 ACKNOWLEDGMENTS

The author extends his appreciation to the industry and the many who contributed to the progress of flexible circuit activities. Sincere thanks also goes to Dominique K. Numakura, at DKN Research, for his authorship of this chapter in the previous (6th) edition of *Printed Circuits Handbook*.

CHAPTER 69

MULTILAYER FLEX AND RIGID FLEX

Joseph Fjelstad
Verdant Electronics, Seattle, Washington

69.1 INTRODUCTION

Multilayer flexible circuits and multilayer rigid flex (a.k.a. flex rigid) circuits represent the technological peak of flexible circuit technology. Presently multilayer flexible and rigid flex circuits have become increasingly important in many high-end consumer products especially applications requiring high-density multilayer flex, where space product is at a premium, while, rigid flex circuits have tended to be employed in lower volumes and serving unique applications often found in military and aerospace product designs.

These interconnection types also tend to be much more engineering intensive requiring a great deal of care both in the aerospace design and the manufacturing process. Interestingly the original idea of stacking together thin layers of flexible material supporting conductors goes back more than 100 years to a patent credited to a German inventor

Albert Hansen. However, the first patent for what we would today call a rigid flex circuit was issued in the mid-1960s to Sanders Associates a pioneer in the technology (see Fig. 69.1). First applications for the technology wherein the aerospace industry where they were used to replace complex wire harnesses in an effort to both improve reliability and reduce weight, while minimizing total volume, all key objectives in virtually every aerospace application. Still rigid flex circuits have been employed in some volume applications in the past, perhaps the most memorable being found in a laptop computer. More recently they have been used in some cell phone designs and high density display driver applications so opportunities for future use and application appear to be on the rise.

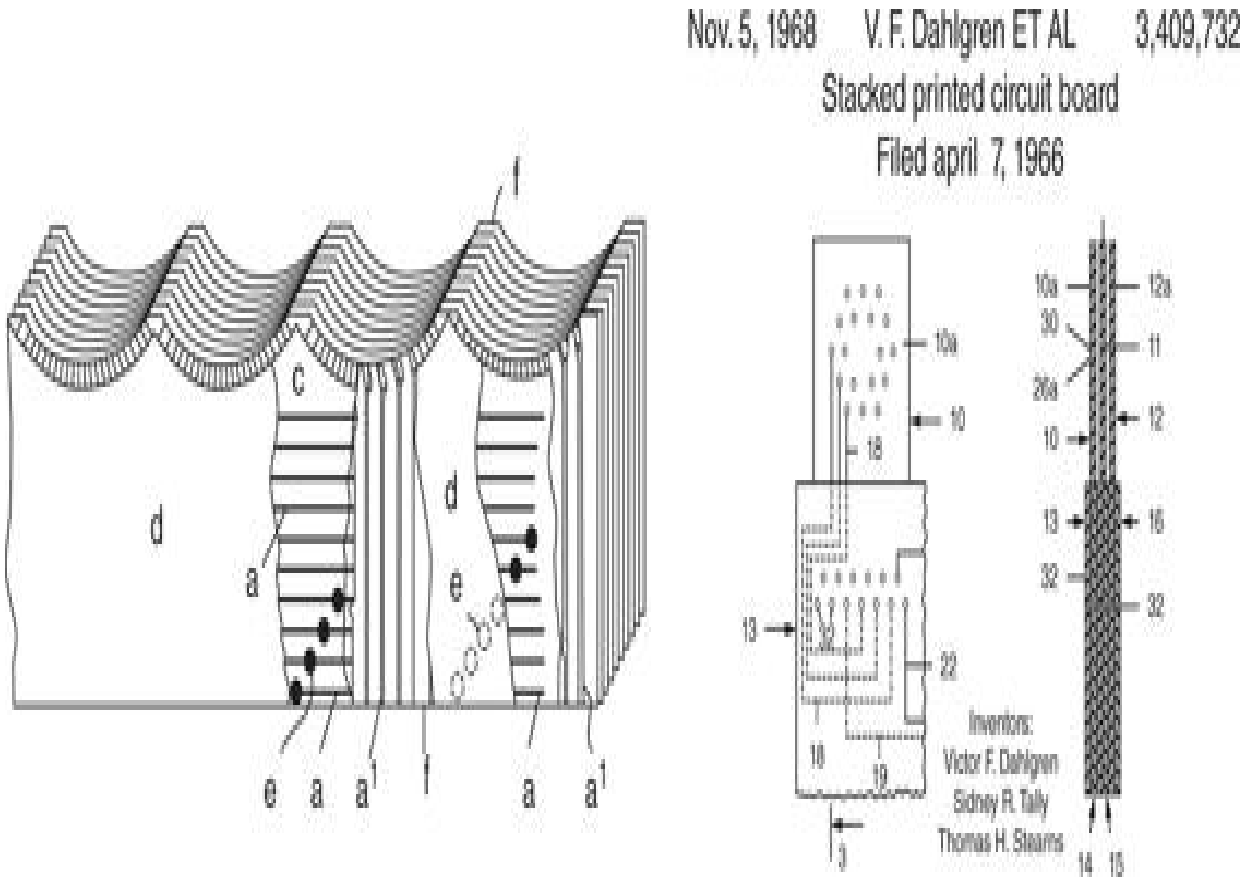

FIGURE 69.1 Drawings from two patents issued more than 60 years apart. On the left a drawing clearly showing multiple layers of interconnecting elements

issued to Albert Hansen and on the right a patent for a rigid flex circuit issued to Victor Dahlgren, Sidney Tally and Thomas Stearns.

Because rigid flex circuits subsume and entail most of the same concerns as are extent for multilayer flexible circuits, this chapter will focus on rigid flex constructions and will examine some of the varied structures and approaches to manufacturing rigid flex circuits, past, present, and prospective.

69.2 MULTILAYER FLEX VERSUS RIGID FLEX

A multilayer flex circuit is as the name implies a circuit structure comprised of multiple layers of flexible materials bonded together and interconnected by plated-through holes. In this overarching definition they are fundamentally the same as multilayer rigid printed circuits. However, they are distinct and the materials and processes associated with their manufacture do have points of departure from more traditional multilayer circuits. Like their rigid flex counterparts multilayer flex can have multiple areas where flexible circuit tentacles ingress from the main body of the circuit. Multilayer flexible circuits may also have stiffeners attached to them to support the weight of components or connectors within the main body or at the distal lands of flexible tentacles. This can make multilayer flexible circuits appear similar to a rigid flex circuit; however, they are different.

Multilayer rigid flex is at the core a combination of rigid multilayer and flexible circuit processes. The finished structures have islands of rigid printed circuit material interconnected by flexible circuits and having plated-through holes, which pass through both the outer rigid printed circuits and the flexible circuits which passed between the

rigid layers which contain them providing electrical interconnection. However, the successful accomplishment of this combination requires a high level of skill in both areas, and it is important to have a clear understanding of the abilities and limitations of the chosen fabricator before designing this type of circuit for a product.

69.2.1 Fundamental Rigid Flex Constructions

There are many different concepts in the construction design of multilayer rigid flexible circuits. Figure 69.2 shows examples of just a few of the arguably endless construction. Layer counts can vary from as few as two to as many as 30 layers or more. For the uninitiated or neophyte who encounters a flexible circuit with a stiffener attached they may be deluded into thinking they are looking at a rigid flex circuit. That said it is important to keep that option in mind when setting out on the design the manufacture of a single double-sided are multilayer flex to which a stiffeners attached post manufacturing is typically going to be a much more cost-effective solution. That said, early rigid flex circuits were originally used mostly with through-hole connectors, which were soldered into the rigid sections and employed in aerospace applications. Today the technology is used with most of the types of components and assembly methods used with rigid PCBs except perhaps for direct chip attach solutions such as wire bonding and flip chip and rigid flex technology serves a much broader array of markets.

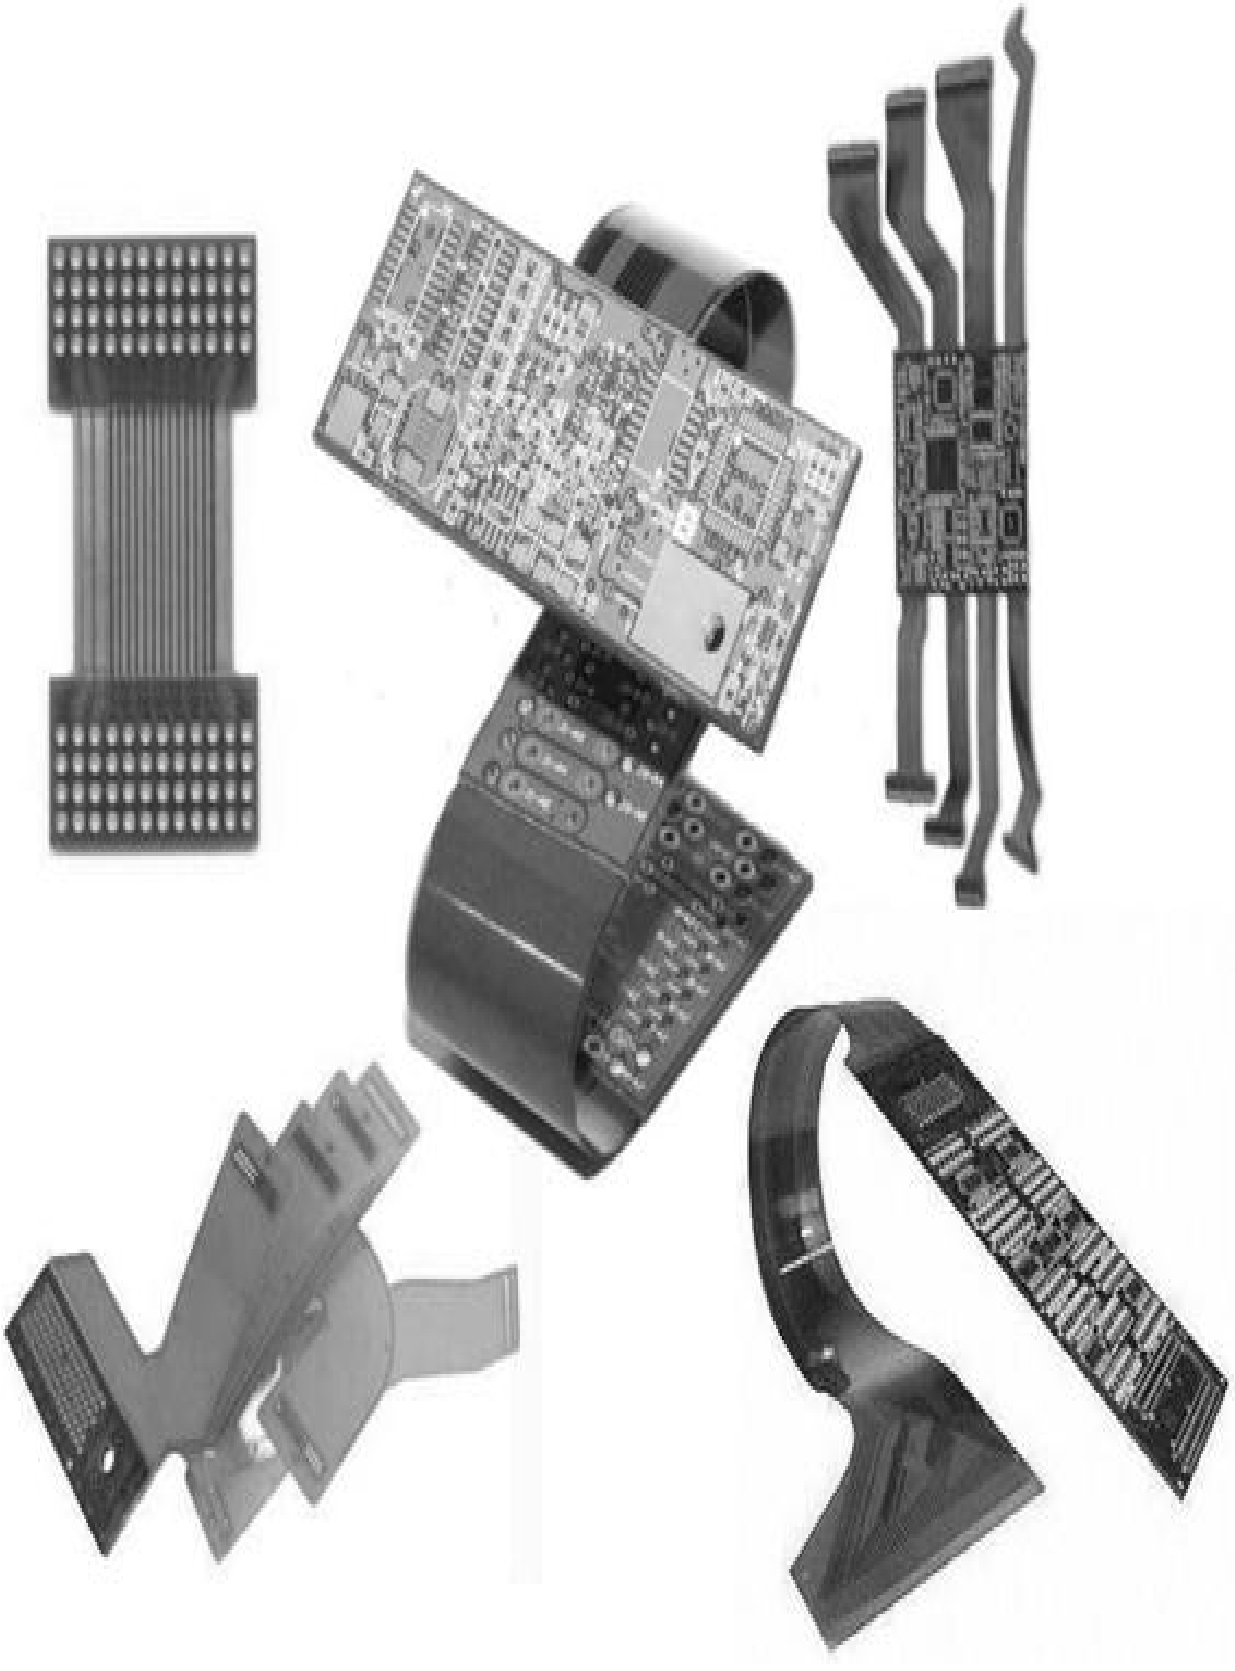

FIGURE 69.2 Rigid flex circuit technology enables a wide range of structures and solutions from simple jumpers (upper left) to highly complex (upper right). The structure in the lower left corner is perhaps the most complex because it has terminations both in rigid and in flexible area of its structure. Each inner circuit layer must be preprocessed before they are laminated to integrate them into the whole where they are interconnected by plated- through holes in the small rigid section on the left.

Over the years there have been a number of innovations incorporated into the rigid flex circuit design and manufacture process to improve both manufacturing and assembly yield as well as field life.

Figure 69.3 shows in cross-section examples of common early approaches to the structure of rigid flex circuits along with an improved design which is much more robust. The improvement came when it was observed that plated-through-hole reliability was suffering and thermal excursions due to the high expansion rate of the body of the circuit, which was caused by the use of unreinforced materials such as flexible circuit bond ply cause sufficient stress fracture plated-through holes either in the barrel or at the corners. In the improved approach flexible bond ply material was replaced with glass reinforced prepregs material such as is commonly used in the manufacture of rigid printed circuits.

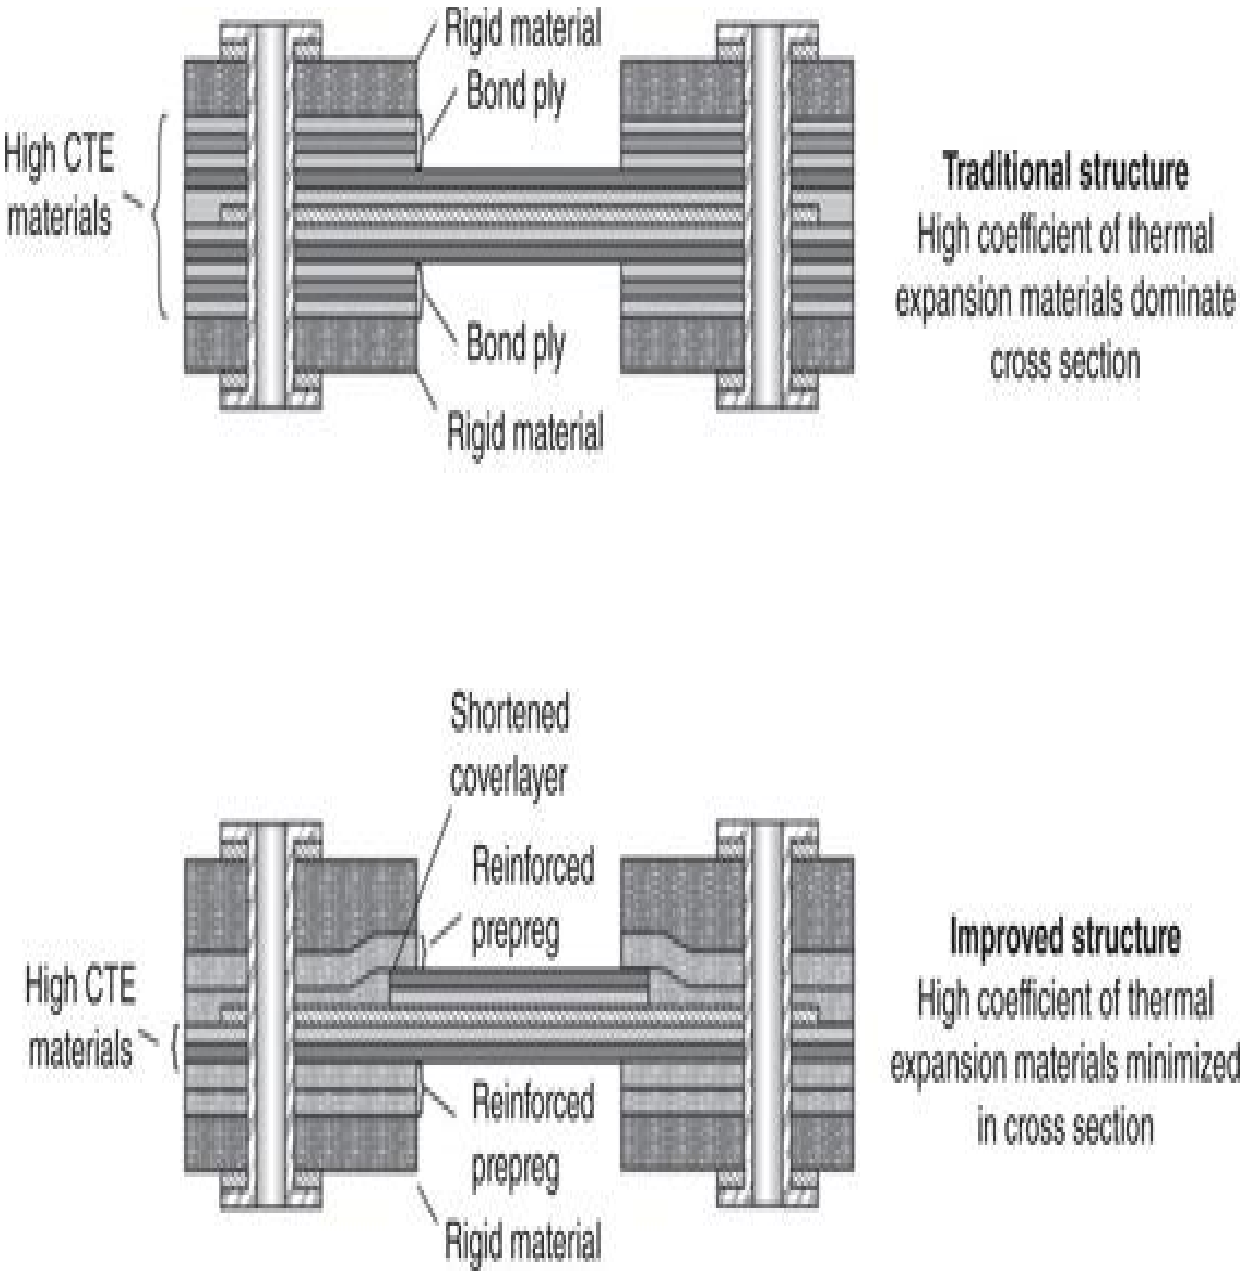

FIGURE 69.3 High coefficient of thermal expansion materials dominated cross-sections in early approaches to rigid flex design and manufacture improves structures refined design, processing and materials to minimize the amount of high CTE material.

Because a material's stiffness increases as a cube of its thickness, the incorporation of air gaps between flexible layers and flexing or bending zones is commonly designed and engineered into the rigid flex manufacturing process. Figure 69.4 illustrates one prospective approach to

manufacturing which achieves the objective of an air gap between layers.

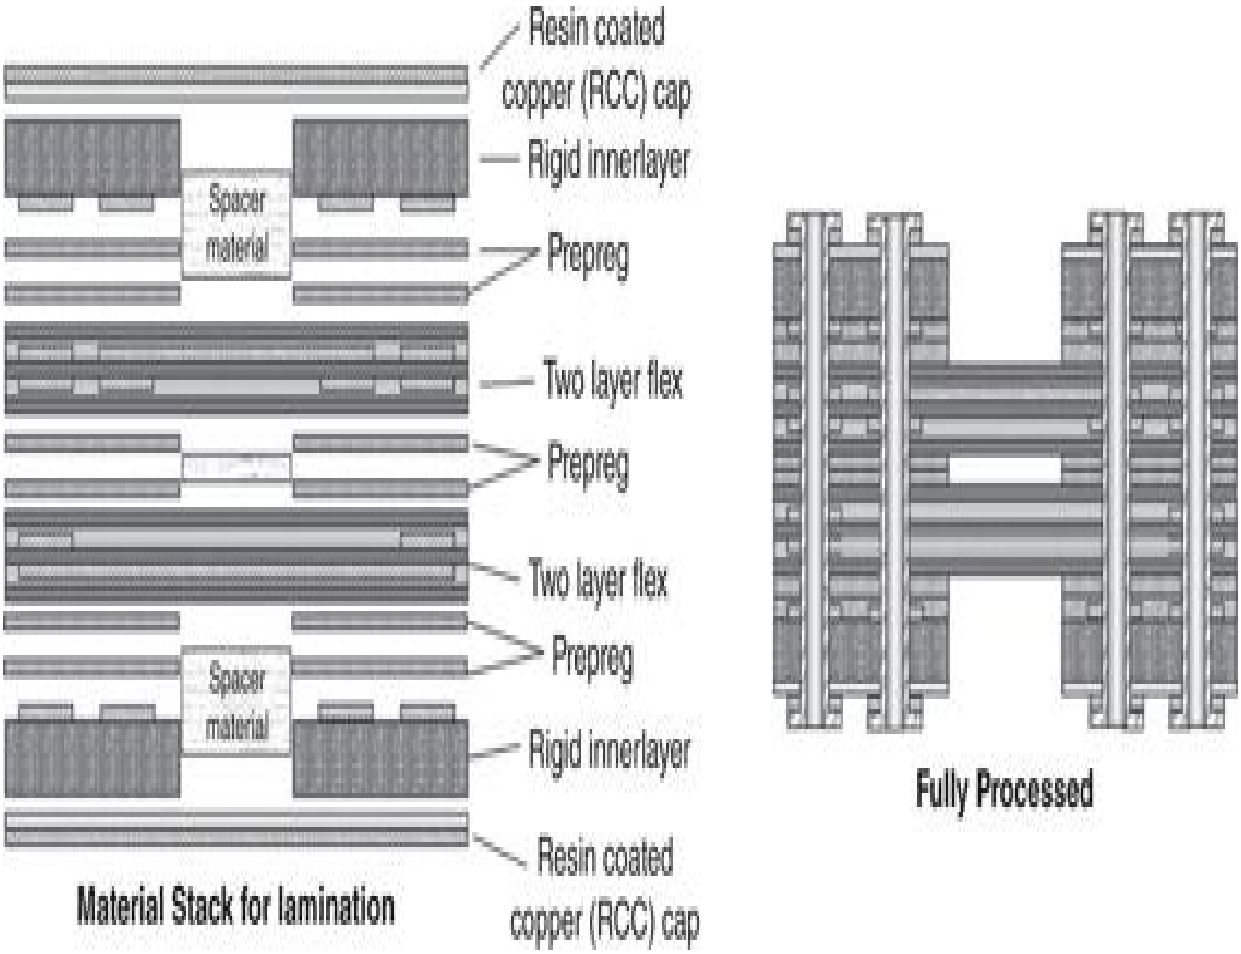

FIGURE 69.4 Shown in cross-section above is a prospective material stack for the manufacture of an eight-layer rigid flex circuit with two double-sided flex circuits incorporated into the center of the circuit.

In another example illustrated in Fig. 69.5, there is shown a multilayer flex circuit comprised of a multilayer distal head for a connector which terminates at two other distal ends through two other multilayer flex circuits each comprised of one single- and one double-sided flex circuit bonded drilled and plated through before the final lamination and plating through. It is a complex and highly engineering intensive structure both from design and manufacture’s perspectives.

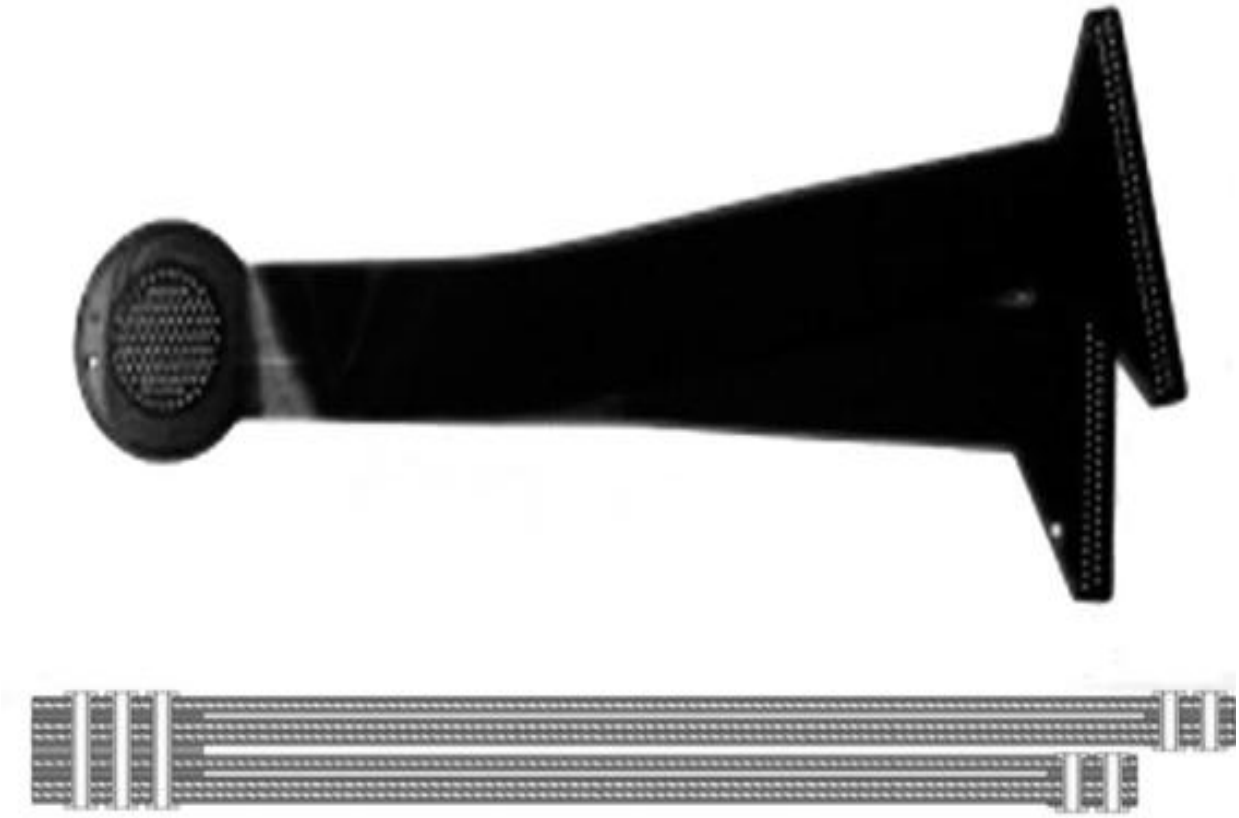

FIGURE 69.5 Multilayer flex circuit can be visually simple, but structurally quite complex as the construction below the circuit image illustrates.

These applications are still common and the designs and constructions are normally fairly straight, except that they often require the use of a technique described earlier called *bookbinder construction*, where each successive layer is lengthened in bend areas in anticipation of and to mitigate the strain-related damage to the outer conductor layers or buckling of circuits that will occur if the technique is not used. The term comes from recognition that such measures are required to keep pages flush on a closed book. Figure 69.6 illustrates the concept in exaggerated cross-section and Fig. 69.7 shows an example of such an implementation.

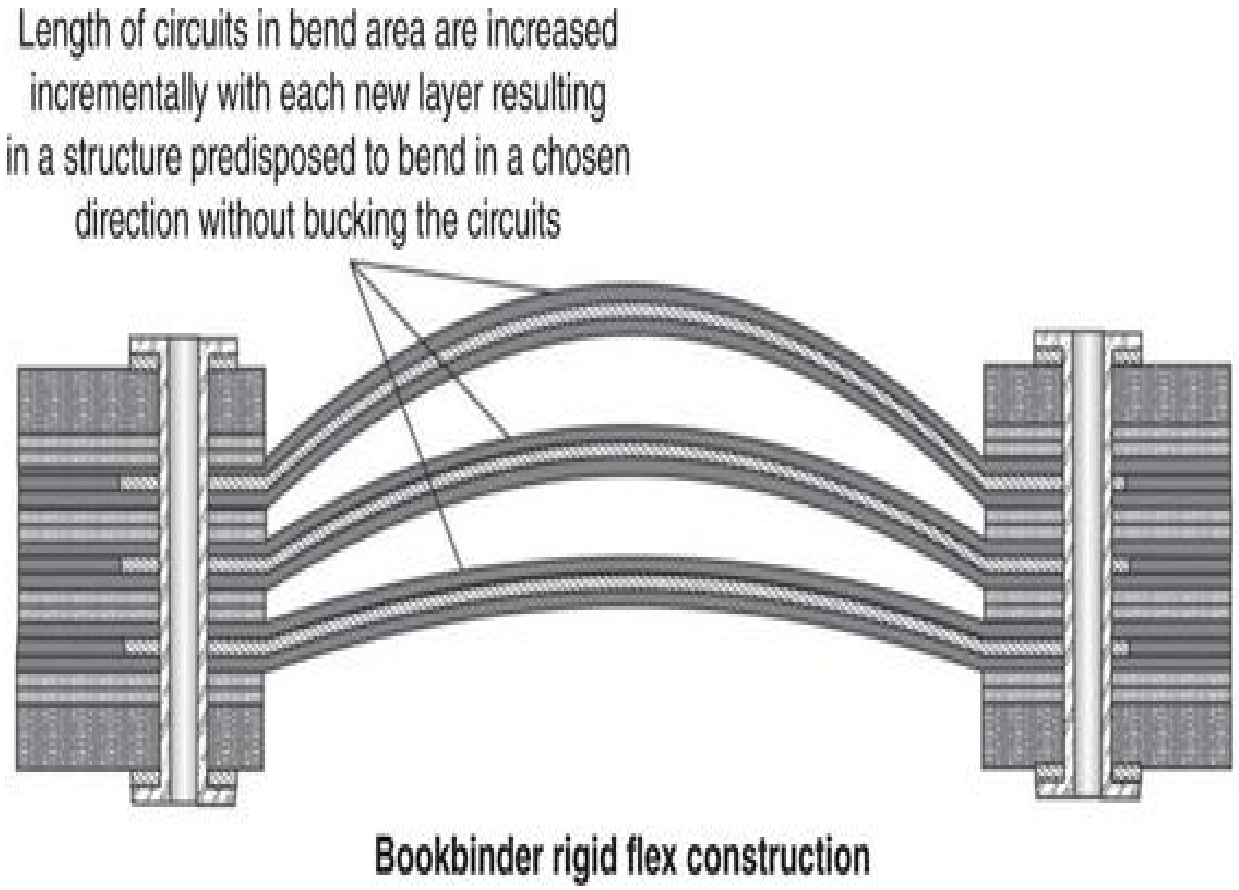

FIGURE 69.6 The bookbinder structure (exaggerated in graphic) is achieved by building circuits having slightly different lengths through the bend area (nominally 250 θm added to circuit length in bend area per layer) so that circuits do not bind or buckle when bent. Tooling is required around the area to hold the circuits in bowed shape during lamination and an aperture in the lamination plates is often required to prevent the area from being flattened.

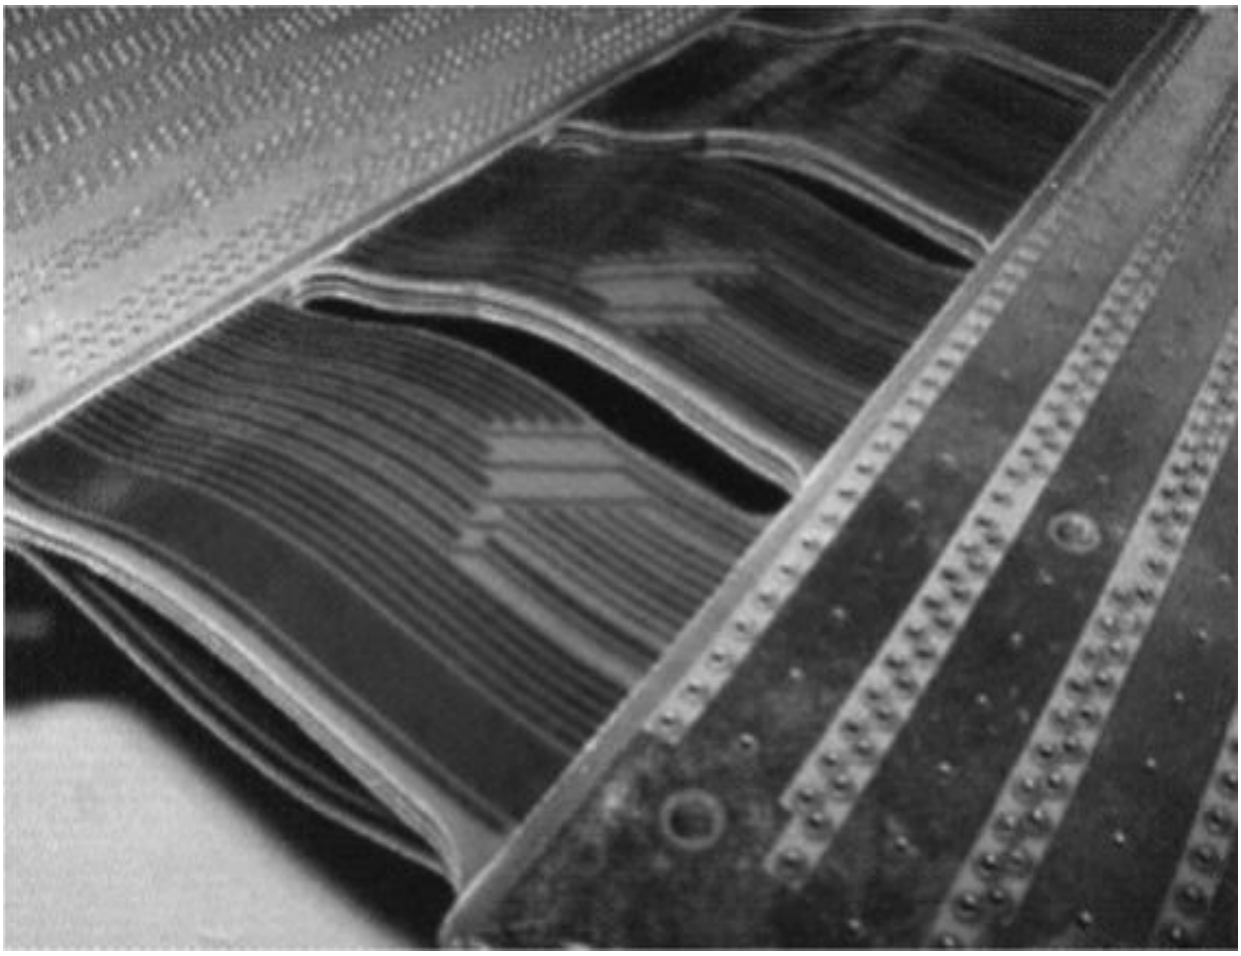

FIGURE 69.7 The bookbinder shown in an application.

69.2.2 Materials for Rigid Flex Manufacturing

As one might expect the material set required for the manufacture of rigid flex circuits is a composite of the materials used for the manufacture of both rigid printed circuits and flexible circuits. Thus flexible base materials, coverlayers, bond plies, and rigid laminates as well as glass reinforced prepregs are part of the material set. In addition, there are specialty materials used in processing including materials for providing conforming pressure to the laminate. In this regard while traditional. Heated hydraulic press

lamination is not uncommon, in the manufacture of rigid flex it is much more common to use vacuum assist lamination or lamination in an autoclave system.

Owing to their applications and the need to solder connectors and other components to them rigid flex materials must be able to withstand high temperatures. This is especially true as we endure the many problems associated with lead-free soldering.

All materials employed in any design should ideally be highly dimensionally stable to minimize movement of features in the lamination process which can make drilling and plating through-holes more challenging if the material is substandard in terms of its dimensional stability. Since rigid flex circuits are only rarely used in dynamic flex applications some leeway can be found in material selection. To improve reliability the use of adhesiveless base materials is a good option. This is because adhesives have a much higher coefficient of thermal expansion than do the base polymers of flexible films. There are a range of adhesives available for bonding coverlayers to flexible circuits again because the rigid flex circuits are rarely dynamically flexed there is some latitude in the choice of material properties for the adhesive. Acrylic adhesives have been a mainstay for coverlayers; however, flexibilized epoxies are suitable in many applications. The use of epoxy glass prepregs and polyamide prepregs help to control *z*-axis expansion in the rigid areas of the circuit assembly.

In general for inner layers on rigid flex 50 µm is suggested as a minimum thickness for the polyamide. The materials must have high heat resistance and high dimensional stability to survive during several high-temperature processes. Thicker polyimide films (greater than 50 µm) are generally recommended because the thicker dielectric materials provided better dimensional stability in the manufacturing processes. Acrylic adhesive systems are frequently used for flexible copper-clad laminates, as well as

and coverlay film and bonding sheets. However polyimide adhesives which have a higher heat resistance than either acrylic or epoxy systems, are also good choices and well suited to the manufacture of a highly reliable product.

Adhesiveless, copper-clad laminates are also well suited for use in the flexible elements of a rigid flex board. Adhesive is laminates made by casting polymer to foil or lamination of foil director polymer normally usually perform better in high-temperature conditions both in process and in use. Adhesive is laminates also provide value owing to the fact that they can reduce the total thickness of the finished board. Finally hot, melt-type, polyimide adhesive systems, including coverlay films and bonding sheets, have been developed to have very high reliability and smaller thicknesses. They can reduce smear level in drilled holes significantly. But they must be processed at temperatures higher than 300°C, and therefore require special facilities and conditioning. Table 69.1 provides a list of material options which may be employed in the manufacture of rigid flex circuits.

TABLE 69.1 Materials for Multilayer Rigid Flexible Circuits

Materials Used	Standard	High Performance
Flexible substrates	Traditional polyimide films (Kapton H, Apical AV)	Improved polyimide films (Kapton E, Apical HP, Upilex S)
Copper-clad laminates (double-sided)	Rolled copper bonded with acrylic or epoxy adhesive	Rolled copper with cast or laminate polyimide film
Coverlayer	Traditional polyimide films coated with acrylic or epoxy adhesives	Newer polyimide films coated with hot-melt polyimide adhesives (one side)
Bonding sheets	Polyimide coated with acrylic glue (two sides) Epoxy glass resin perpreg	Newer polyimide films coated with hot-melt polyimide resin (two sides) Polyimide glass prepregs
Rigid substrates	Copper clad glass/epoxy laminate	Copper clad glass–BT resin boards and glass-polyimide boards
Solder mask	Liquid or dry film, photoimageable	Liquid or dry film, photoimageable
Conductor finish	OSP, NiAu, solder	OSP, NiAu, solder

69.2.3 Manufacturing Process Flow for Rigid Flex

Because of the great diversity of designs and potential layouts and structures of rigid flex circuits, they are much less amenable to a fixed approach when it comes to describing a manufacturing flow. That said Fig. 69.8 is provided to give a general idea of a prospective flow for the manufacture of a rigid flex circuit. It is recommended that anyone looking to embark on a rigid flex design engage the

services of an experienced rigid flex manufacturing engineer who can guide them around potential pitfalls (Fig. 69.8).

FIGURE 69.8 Material construction for multilayer rigid flexible circuits.

The process illustrated presumes the use of flexible, double-sided copper-clad laminates; however, single-sided flex may be employed as well of course. The flexible laminates are imaged and etched and any plated vias between first and second metal layers must necessarily be incorporated before the coverlay films are bonded. No openings in the coverlay are generally required as interconnections to terminations in the flexible circuit areas will be accomplished after subsequent laminations with rigid materials. In some cases the flexible layers may be machined by numerically controlled routing; however, it is common practice to machine the bond material which will be used to join rigid and flex elements of the circuit. Machining process prevents the flexible circuits from being bonded to the rigid caps. There are several choices for bond material and the choice can have impact on subsequent processing. While acrylic coated polyamide bond plies are commonly used epoxy glass or polyamide glass bond plies are options. And all polyamide construction should be considered when possible as it minimizes the potential for drills smear.

A spacer material of the dimensions and thickness of the cavity formed are produced and placed in the openings before lamination to help maintain surface planarity. The spacers are removed when the rigid flex circuit is routed from the background. The rigid cap layers commonly have circuitry imaged and etched on the surface that will be joined to the flex in the lamination process.

All of the materials except for the spacers share a common tooling system to ensure that all the features align properly during lamination. The vacuum autoclave lamination system is best suited to the manufacture of rigid flex boards because it ensures highly uniform bonding across the entire surface of the material stacked. Because of the employment of the vacuum any air entrapped in the body of the laminate will

create internal pressure which could lead to delamination, therefore venting holes may be required. These venting holes will require sealing in some manner before wet processing. One common practice of tradition is to place a small dot of epoxy over the vent hole.

Following lamination the panel can generally be processed in the same manner as traditional rigid multilayer circuits; however, drilling and processing conditions can vary. A drill study is recommended when the material set is unusual or the layer count unusually high, this is performed to maximize hole quality while minimizing drill smear. Also because of the materials that and the frequent use of acrylic adhesive which is prone to smearing on hole walls and over internal conductor surfaces, the use of plasma etching is recommended. Keep in mind that because the plasma process takes place in a near vacuum that vent holes may again be needed to prevent delamination. Bear in mind that these vent holes will need to be sealed in some manner before any wet processing can proceed. While plasma is commonly recommended for rigid flex construction, wet processing is also employed to remove drill smear. The common chemistry is a heated solution of potassium permanganate. Care must be used in such processing as excessive dwells can cause swelling of some of the resins and hole wall. This can have deleterious effects on further processing and the ultimate reliability of the plated-through hole.

Because of the diverse material set found in a rigid flex through hole, the choice of processing chemistry is very important. The hole wall may consist of polyamide, epoxy glass and acrylic adhesive for example. The first step in through-hole processing is arguably the most important because it involves the wetting of the surfaces of the hole wall making the surfaces receptive to the catalyst, carbon or graphite material which will provide a conductive path through the hole for electrolytic copper.

Following electroless copper or sensitization of the through holes, the process is largely indistinguishable from that used for standard multilayer board. The major difference comes in the routing process at which time special handling and processing may be required especially at the areas where rigid and flex circuit elements join. Depending on how one has preengineered the transition a great deal of caution may be required. There is often a good deal of touch labor involved at this point. Since there is no one way this problem has been addressed over time it is highly advisable that the transition be discussed in advance with the manufacturing engineer who will be responsible for ensuring any rigid materials including spacers are removed from the flexible areas and the final product.

69.3 ALUMINUM RIGID FLEX CIRCUIT —PROSPECTIVE STRUCTURE FOR THE FUTURE

Aluminum is a ubiquitous metal and the third most abundant element on the planet representing 8.3 percent of the earth’s crust. Given its ubiquity and unique properties is deemed a potentially suitable candidate for the manufacture of rigid flex circuits. However, it is not a drop-in replacement as the use of aluminum requires both the designer and the manufacture to reconsider what they have learned over the years relative to the manufacturing of rigid flex circuits, or for that matter any type of circuit. What follows is a description of a prospective process for manufacturing a rigid flex circuit which is manufactured in accordance with the precepts consistent with what has come to be called the Occam process, where electrically tested and burned- in components are embedded in insulating materials which proximately matched to the coefficient of thermal expansion

of the components used in the assembly. In broader terms, the concepts that will be described in this rest of this chapter fall under the umbrella term of SAFE an acronym which stands for either “solderless assembly for electronics” or “solder alloy free electronics.” Regardless of term, the design and manufacturing processes associated with SAFE manufacturing are relatively simple compared to traditional circuits and the cost should prove significantly lower. These topics will be discussed more fully after a brief description of the process.

69.3.1 Aluminum Rigid Flex Process Steps

First, a sheet of aluminum (other metals are also possible if desired) is prepared with cavities that can be either machined (chemically, mechanically, or laser), embossed into the metal sheet or cast. One or both sides of the metal can be provided with components. The cavities that receive the components are ideally formed such that the depths will match the components’ height so that when components are placed into their assigned cavities with leads facing up, the lead terminations will be flush with the surface. While the use of bare die is possible, the IC components to be used are ideally packaged (CSPs are very well suited). Packaged devices are preferred because packaged IC devices are much more easily tested and burned-in and because they have standardized lead patterns and physical outlines making the design process simpler, especially if a single lead pitch is used for all components (e.g., 0.5 mm). Additionally, nearly all packaged components use copper as the base metal for interconnections which is advantageous for more than just that one reason alone, as will be shown.

While untreated aluminum can be used effectively for many applications, there are some advantages in other

applications to either treating or coating the surfaces. Anodizing of aluminum is a very common industrial process, which results in the surface of the aluminum being converted to alumina (Al_2O_3), an insulator. Another alternative is to coat the aluminum with an organic coating such as an epoxy, which can be done by powder coating or painting by electrophoretic or electrostatic methods resulting in a very uniform coating over the entire substrate. When either anodizing or coating is used, it is important remember that all such processes will reduce all the dimensions of the cavity, with X and Y dimensions potentially being more profoundly impacted, so characterization of any process chosen will likely prove important. Finally, the aluminum could also and alternatively be plated with a metal such as copper for electrical reasons that will again be discussed in more detail later.

After the components are placed and affixed permanently on one or both sides, layers of flexible insulation are applied to one or both surfaces of the metal sheet covering the components. A flexible clad laminate may also be used if desired. At this point, the assembly can be processed almost as if it were a standard rigid printed circuit with high density build-up layers on one or both sides, using lasers to drill holes down to access component terminations and commonly practiced plating and imaging processes to create the circuits. A key difference is that a fill step with an insulating material may be required if through-holes have expose metal. However, if coated with epoxy, this may not be necessary. One caveat for those circuit manufacturers considering exploring processing circuits of this type is that if the aluminum is untreated, the edges need to be sealed to prevent contamination of subsequent processing chemistries that will be used in manufacture.

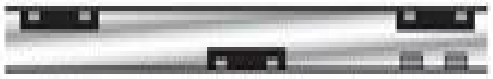
Once all of the circuit layers are complete, a final flexible film (i.e., cover film or coverlayer on one or both sides) is applied, leaving open any features required for

interconnection at the next level. The coverlayer and/or flexible base film will ultimately need to be absent from the areas that are going to require flexing, as well as those that will define the outline of the completed circuit. This can be accomplished by mechanical, chemical or laser methods either alone or in combination with one another. Once the metal is exposed, it can be etched using a suitable chemistry either completely or to some predetermined depth if the designer desires to leave a conductive path between rigid component bearing areas.

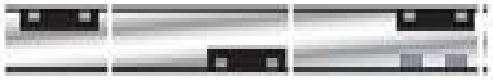
When all of the required interconnections and circuits are added, the assembly can be partially machined to thin the metal carrier enough to allow the residual metal to easily bend and, if the metal is thick enough, hold its shape after bending. Again, the residual metal can serve as a common ground layer for the assembly. If ground isolation is required between rigid areas or desired for purposes of creating a more flexible connecting bridge between rigid areas, the residual metal can be etched using chemistry appropriate for the metal used as component carrier. For the subject aluminum rigid flex constructions, alkaline chemistries such as solutions of sodium hydroxide and sodium gluconate are suitable for aluminum. However, other chemistries such as ferric chloride are also suitable. In fact, ferric chloride is nearly universal in terms of its range of applicability as a metal etchant. The process steps just described are illustrated in Fig. 69.9. Note that the process as illustrated shows complete removal of the metal between rigid areas which is an option where greatest flexibility is desired.

Machine metal base (e.g. Al) with cavities for electronic devices

Place and bond electronic devices into machine cavities



Coat assembly with flexible polymer, liquid or film

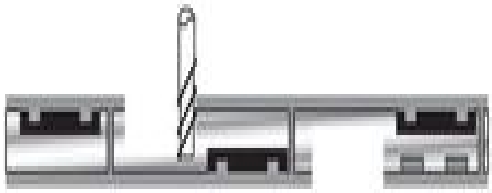


Drill holes where connections to second side is required

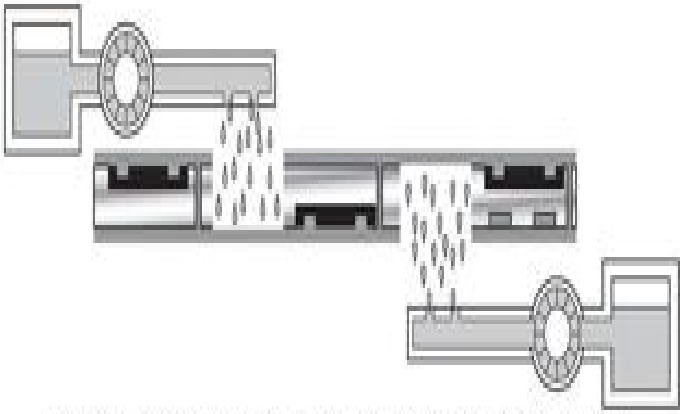
Fill holes with insulation polymer such as filled epoxy

Second drill holes filled with insulating fill polymer

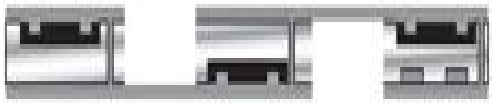
Use build up and thru hole processing for circuits & apply top flex layer



Control depth machine carrier metal part way through in flex areas



Etch remaining metal using chemistry appropriate for metal (optional)



Complete processing (e.g. route circuits for panel (not shown))

Form metal rigid flex circuit to desired shape

FIGURE 69.9 A novel approach to design and manufacture of a rigid flex circuit having metal areas with components placed in routed (as shown) etched, embossed or cast cavities with terminations facing away from the surfaces and a flexible polymer or polymer film bonded to them with interconnections between devices made by using commonly practiced build-up processing methods. Routing and/or etching processes can be used to complete the separation of the metal areas leaving them interconnected by flexible circuits. Other embodiments will be the subject of future articles (patents pending).

Finally, while not a topic of discussion here, the assemblies described can be stacked and interconnected creating 3D assemblies that offer substantial potential to solve a wide range of electronic interconnection problems.

69.3.2 Advantages of Aluminum Rigid Flex Assemblies

There are a striking number of advantages to the design and manufacture of electronic assemblies that do not use solder to make interconnections. The advantages of products manufactured using SAFE techniques also circumscribe the full range of benefits normally considered desirable for any electrical or electronic product, including: economic, electrical, thermal and mechanical performance, security, reliability, regulatory compliance, and environmental friendliness. Following are brief discussions of each of these areas of benefit:

69.3.2.1 Economic Benefits. In a highly cost competitive global economy, the cost of manufacturing is always a high order concern. Looking fist at material, note that the primary material is aluminum. Aluminum is a simple an abundant material sold by weight regardless of thickness and it is less expensive per unit volume than composite materials. Though aluminum is admittedly denser than FR-4 laminate, (2.8 g/cm^3 aluminum versus 1.8 g/cm^3 for FR-4) the amount of aluminum required can be less for reasons,

which will be discussed later making it the finished assemblies very cost competitive from a materials use and cost standpoint. Moreover, with the price of polymers tied to the volatility of the price of oil, there are advantages to being able to use a material such as aluminum the price of which is reasonably predictable because of its global abundance (Fig. 69.9).

Next, as is inferred in the process shown in Fig. 69.9, the number of manufacturing steps is reduced significantly, which obviously reduces manufacturing cost. What should be highly evident is that the entire soldering process with its many steps and requirements is omitted. No stenciling of solder, no reflow, no post-assembly cleaning, etc. There is also no need to be concerned with moisture sensitivity of components. Thus the energy and time wasting baking steps that are commonly called for in conventional processing are obviated. Depending on the complexity of the design, as it has been estimated independently by a number of manufacturing experts, the final cost of such assemblies could be 25 to 35 percent lower than traditional methods (exclusive of the cost of the actual components). Obviously the final number will depend heavily on the specifics of the design and actual savings may be less; however, any savings in today's highly competitive global markets is both welcome and highly prized especially if the final product is not subject to intense environmental scrutiny in search of metals and materials which are proscribed by EU regulations.

Another economic benefit is that the components used do not require special finishes to maintain solderability, nor do they need special treatment to keep out moisture because they will not experience the high temperatures required for lead-free solders. The lack of a need for a finish can and should reduce the cost of the components at some point in time, but it is still possible that electronic component suppliers may in the near term actually charge a premium to the user for *not* adding solder balls or nickel-gold finishes

processes that, paradoxically, in fact, *add* cost to the package.

Finally, reliability, which will be discussed in more detail, also has an impact on economics as warranty payouts for failed products can quickly cut into profits and perhaps even more importantly, undercut a company's reputation with its customers.

69.3.2.2 Electrical Benefits. Such constructions as have been described offer several electrical/electronic benefits. For example, where connections are made to terminations on component lands, the point of interconnection can be made without benefit of a large pad, which can reduce parasitic capacitance. This also frees routing space, allowing for a potential reduction in total layer count (further reducing cost). If proper planning is used in choosing components of a common grid pitch, the integrated power mesh system (IPMS) design layout approaches may be employed, reducing layer counts while improving signal integrity. The metal core is can serve as power or ground with a copper-over-plating as mentioned earlier, to allow for such. This makes it possible to provide both power and ground immediately adjacent to every component (this will be the subject of a future paper). Finally, the completed assembly can also be relatively easily provided with a metal plating after the assembly is complete (or in the latter stages of construction), making the entire assembly metal jacketed and thus EMI and ESD immune, as well as nearly hermetic, exclusive of those areas left open for external I/O connections.

69.3.2.3 Thermal Benefits. Aluminum is a common choice for heat spreaders for high-operating-temperature electronic devices, and in the present case, the heat spreader is an integral part of the assembly. This approach allows the designer to solve any potential thermal problems

on the front rather than the back end of the manufacturing process. The inverse relationship between long-term reliability and the number, temperature extremes and durations of the thermal excursions that must be endured by electronics components having a built-in thermal management solution is a value-added element and thus a potential economic benefit as well.

69.3.2.4 Mechanical Performance Improvements. Since the components are encapsulated in the assembly and thus part of an integrated whole, they are fundamentally immune to the effects of shock and vibration. The CTE (coefficient of thermal expansion) of aluminum and copper are relatively close (22 ppm/°C versus 18 ppm/°C), which reduces the potential stress on interconnections; moreover, the materials expand predictably in all directions, whereas reinforced laminates have CTEs that may vary in X, Y, and Z dimensions, sometimes quite appreciably (e.g., X ~20 ppm/°C, Y ~23 ppm/°C and Z ~80 ppm/°C) and in the case of flexible circuit materials much worse.

The microvias which are used to make connections to components and to any additional build-up layers have been proven superior to solder joints, which have continually proven a weak electromechanical link in traditional electronic assemblies (though there was recent report of microvias also being damaged by the lead-free soldering process). Moreover, there is possibility in some cases to use relatively thin aluminum base material, which could allow the developer to bypass the final etching process and permanently form the final assembly into the desired shape, opening up new possibilities to the clever product designer.

69.3.2.5 Design Security. The methods suggested for the manufacture of a rigid flex circuit as described offer a design security benefit that may not be immediately obvious to many product developers. The methods used obscure the

components used in fabrication, making tear-down and reverse engineering of a product much more daunting and difficult for those wishing to understand what might differentiate the product in hand with previous competitive products. This benefit extends to all kinds of products, from consumer to military. Furthermore, the assembly makes it much more difficult for unscrupulous individuals to extract and reuse components, injecting them into the supply chain as counterfeit devices.

69.3.2.6 Reliability Improvement. Improvement in reliability is largely a by-product of various elements of the electrical, thermal and mechanical performance benefits just discussed, combined with the benefits that can be obtained by simple bypassing of a high-temperature lead-free soldering process. To this point, it is worth repeating that the soldering process is typically the largest cause of defects in assembly and that solder joints are the most common sites for failure of electronic interconnection systems. Moreover, in a solderless assembly, concern over tin whiskers, a topic that has returned to prominence in recent years, is relieved. Finally, conductive anodic filaments (CAF), which is the growth of conductive fibers between adjacent vias in reinforced materials and tin whiskers are obviated by the ability to use homogeneous, unreinforced materials and elimination of solder, respectively.

69.3.2.7 Regulatory Compliance. The EU's RoHS legislative mandate to eliminate lead from electronics solder has proven very costly, however, this stricture is automatically accommodated if one eliminates solder completely. The finished structure described is basically an all-copper interconnection system. On the finished product, only the surface sites required for making electrical connection to the other system elements, such as switches, connectors and the like, need to have a contact finish. The

key point is that since neither copper nor aluminum is considered a problem, both the RoHS and REACH concerns should be obviated provided the other materials selected and used in the assembly (e.g., the flexible polymers) are compliant. Additionally, the material declaration process is greatly simplified. These same benefits hold true relative to the use of conflict materials which is of growing concern among increasing numbers of both governmental and nongovernmental organizations (NGOs) as the structures completed as described are completely devoid of any proscribed or sanctioned materials. In short, the assemblies described allow a product to much more easily pass regulatory scrutiny.

69.3.2.8 Environmental Friendliness. During the last few decades, concern over the environment has moved steadily into the consciousness of government officials, business leaders and the consuming public around the world. The term *social responsibility* is also often used to describe the concern; however, the fact that the industry makes products that impact the environment at the lowest possible level has become increasingly important. With that in mind, consider an electronic structure constructed principally of a material which is desirably and easily recycled, such as aluminum. Moreover, there is the significant amount of energy that is used in traditional manufacturing in component and assembly preparation and in the soldering process, which can be saved when solder is not used. Moreover as suggested earlier in this paper additional energy savings can be found by obviating need for all of the process steps leading up to and following the soldering process.

69.3.3 Discussion

As has been shown there are many reasons to embrace SAFE manufacturing methods for the fabrication of rigid flex circuits. Still, even with all of the cited benefits, there is one recurring concern that is often raised and/or registered relative to products which might be fabricated using SAFE methods: “How does one test and rework such assemblies?” The question is perhaps best addressed with a separate question: “If the process is executed properly and the components are not subjected to thermal extremes, why is there a need to test and rework?” The simple fact is that most electronic assembly problems are related to the inherent weakness of the soldering process and solder joint failure remain a common cause especially when there is shock or vibration. Moreover, below 0.5 mm lead pitch, which is where the component roadmap trends are headed, assembly yields drop off appreciably, even with multiple preassembly inspection steps implemented and/or applied. The EMS industry has come to accept the weakness of its assembly and cleaning processes even as it strives to constantly improve them, making marginal improvements through new materials and equipment and as a result has come to also expect that rework and repair are a natural part of the manufacturing process. This acceptance carries with it what can be best described as a self-defeating ingrained attitude and results in the manufacturing having to continually carry out a process that might otherwise be made unnecessary. In short, if the components are fully tested and burned-in and the processes used are properly controlled, the final product should be high yielding, provided the design is inherently valid and robust. The limits of reliability of future electronic products could well be better defined by IC reliability than the reliability of the circuits and plated vias that are used to interconnect them.

Such structures as have been described in the last section of this chapter are simple to design and eminently possible to manufacture. They can be easily produced using well-

established manufacturing infrastructure tools, equipment, and processing techniques which are simply reordered to make highly useful electronic products in a rigid flex format suitable for use in everything from consumer to high-reliability automotive, military and aerospace products. The limits are likely to be defined more by the imagination of the designer than the limits of the fundamental technology which has been described. Test vehicles are being prepared at this time and will soon be available for evaluation.

69.4 SUMMARY

Mulilayer flex and rigid flex circuits are seasoned and venerable technologies capable of solving many interconnection challenges as they have demonstrated over the last nearly 50 years. They are also typically highly complex structures requiring a great deal of engineering in order to realize a successful design. There was not sufficient space allotted to examine all of the variations possible when it comes to the design and manufacture of rigid flex circuits. With that in mind, it is again recommended that the reader seek the counsel of an experienced manufacturing engineer, one who understands the nuances of rigid flex manufacture before embarking on a rigid flex circuit design.

69.5 ACKNOWLEDGMENTS

The author extends his appreciation to the industry and the many who contributed to the progress of flexible circuit activities. Sincere thanks also goes to Dominique K. Numakura, at DKN Research, for his authorship of this chapter in the previous (6th) edition of *Printed Circuits Handbook*.

CHAPTER 70

SPECIAL CONSTRUCTIONS OF FLEXIBLE CIRCUITS

Dominique K. Numakura
DKN Research, Haverhill, Massachusetts

70.1 INTRODUCTION

Because of thin base layers, the flexible circuits can have many special constructions that are impossible to build by traditional manufacturing processes of the rigid circuit boards. These special constructions generate further functional values for the flexible circuits. This chapter introduces the major constructions in use, along with their manufacturing processes.

70.2 FLYING-LEAD CONSTRUCTION

Flying-lead construction is a special case of the double access flexible circuit. The base layer under the traces are removed and the conductors are completely free from the

organic materials. New HDI flexible circuit applications have arisen involving flying-lead constructions. Applications such as wireless suspension of hard disk drives, interposers for chip-scale packaging, and ultrasound probes depend on the reliability of this high-density interconnect. In competitive markets such as these, it is imperative that flying-lead applications offer low cost and high volume. The TAB (tape automated bonding) is one of the major application of the flying lead costructions.

Traditional manufacturing processes used to create flying leads, such as prepunching or predrilling, are not conducive to the quality levels and manufacturing yields required to achieve low cost, and alternative processes are needed, as described later.

70.2.1 Basic Design

A flying-lead structure is composed of a single layer of high-density-pitch copper conductors accessed from both sides of the substrate. Generally, the substrate side of a conductor on a circuit board is not electrically accessible because the conductive foil is typically laminated to the substrate board in sheet form. In the case of a flex circuit, however, the substrate can be removed by various methods. Dual access is created by removing the coverlayer in the same area on both sides.

Figure 70.1 indicates two basic structures of dual-access conductors, in both the single sided and double-sided types of flexible circuits. Figure 70.2 shows actual examples of the fine flying leads built on the single side circuits and double side circuits. Basically, a coverlayer is applied to the side of the conductive layer opposite the substrate. The coverlayer can be processed easily to create the top-side exposure. The flying lead is created when the base substrate is also removed in the same area.

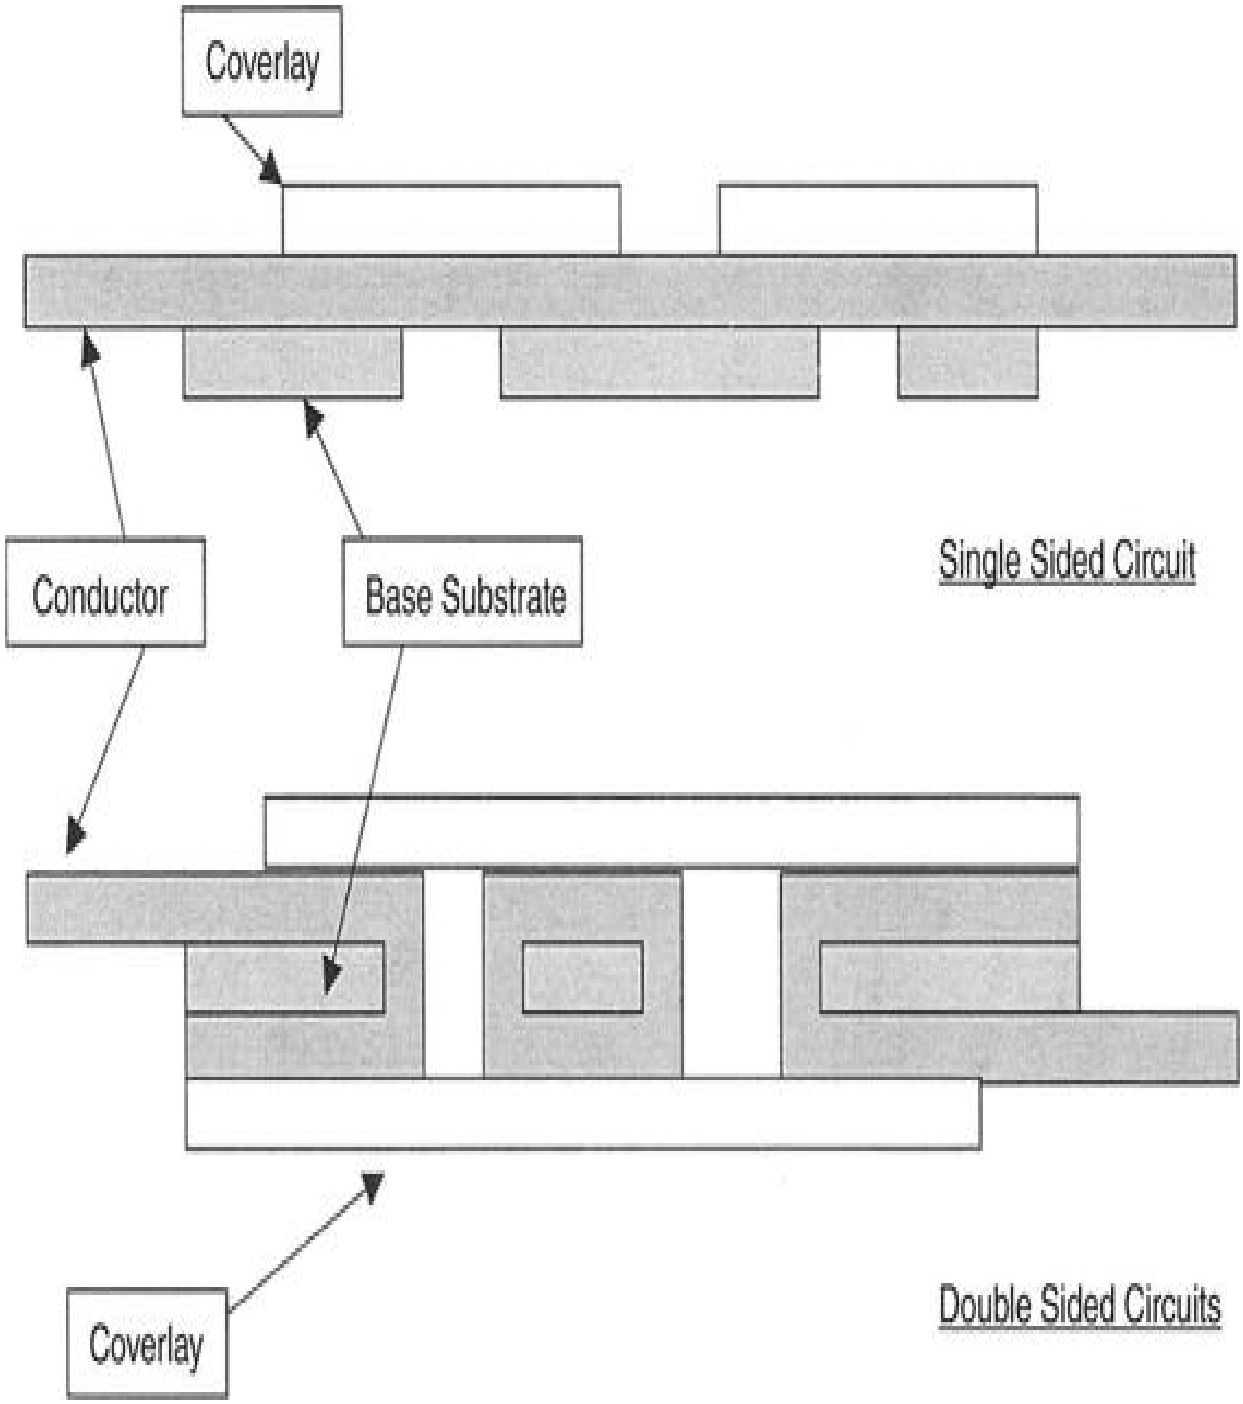


FIGURE 70.1 Basic constructions for flying-leads for flexible circuits.

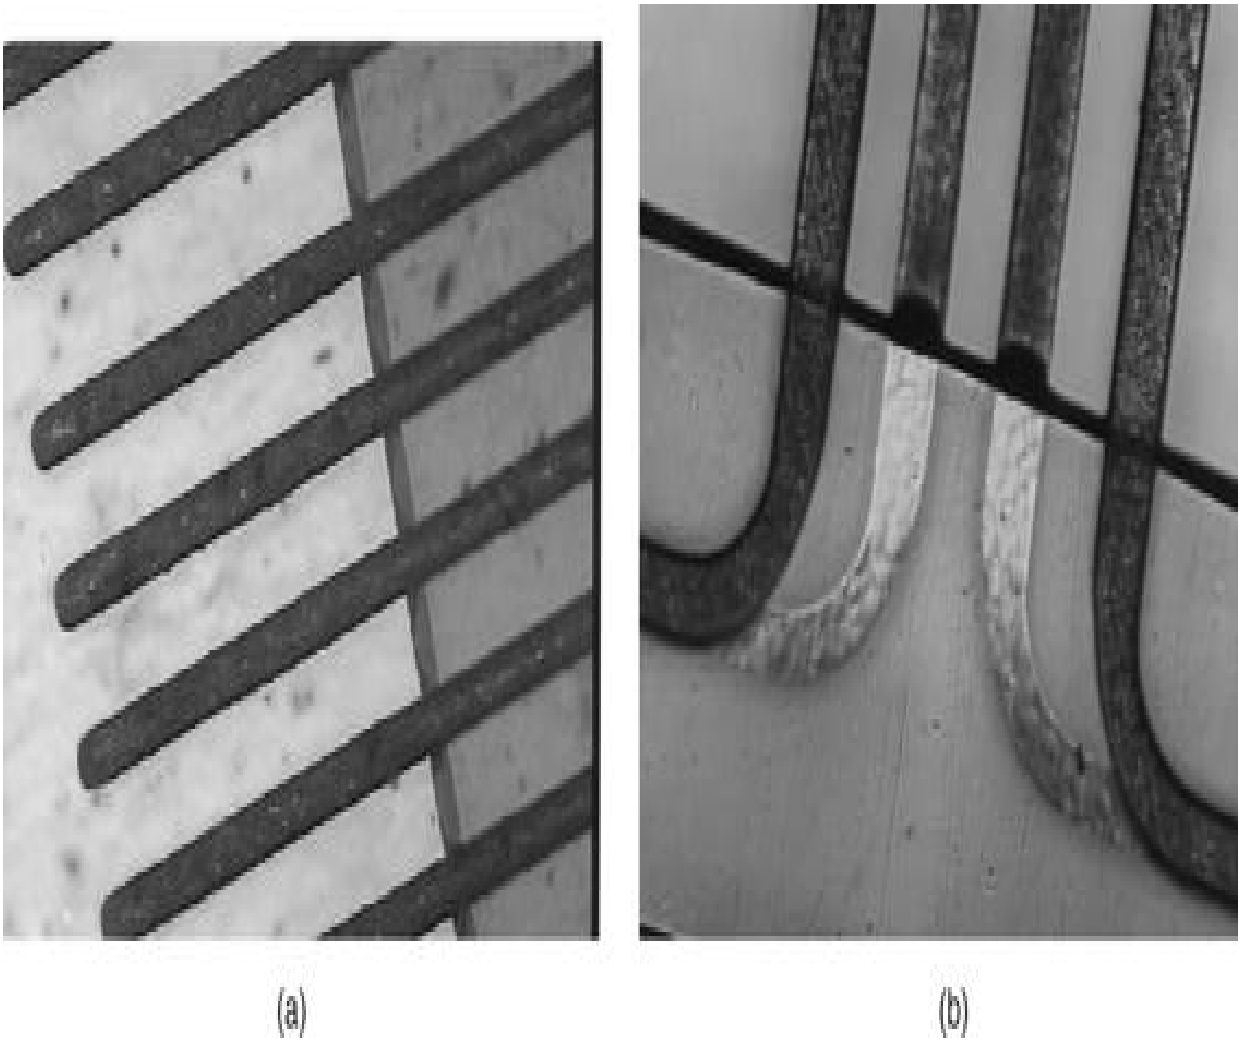

FIGURE 70.2 Typical fine flying leads construction (*a*) single side, (*b*) double side.

70.2.2 Manufacturing Processes for Flying Leads

The fragility of flying leads, caused by the lack of dielectric support, is probably the largest disadvantage in the manufacturing process. Proper circuit design and layout is the key to the manufacturing process yield and subsequent cost and physical performance of the circuit. The most conventional manufacturing process for generating a flying-lead construction involves a prepunching process similar to

the device hole process of tape automated bonding (TAB). Figure 70.3 shows this process schematically. There is no proprietary technology or special tooling required for manufacturing the prepunched window in the base substrate. This process, however, offers the manufacturer very little flexibility and is fairly labor intensive, which makes it difficult to maintain high productivity rates.

Punching or Drilling
Copper Foil Lamination
Copper Etching & Coverlay

FIGURE 70.3 Manufactuirng process for flying-lead flexiblse circuit construction using prepunching method.

The handling of unstable punched films, along with thin, fragile copper foils, makes it difficult to achieve the high manufacturing yields required to support the cost model associated with high-density flexible circuits. These unstable film substrates also make it difficult to maintain dimensional accuracy between the fingers and the window, a key element for HDI flexible circuits. Adhesive flow or squeeze-out from the edge of the punched film along the conductor can also be an issue when dealing with small window exposures. Openings of less than 1.0 mm are difficult to create with high dimensional accuracy and yield.

Alternative technologies have been developed to generate high-density flying-lead designs with higher accuracy. Laser ablation, plasma etching, and chemical etching are just a few of the possibilities and are illustrated schematically in Fig. 70.4. A comparison of small opening capabilities of each of the processes is illustrated in Fig. 70.5, while a comparison of the technical capabilities of the processes is shown in Table 70.1. With these manufacturing technologies, many kinds of flying-lead constructions became possible.

TABLE 70.1 Comparison of Flying-Lead Manufacturing Technologies

	Prepunching (NC routing)	Laser Abrasion	Plasma Etching	Chemical Etching
Minimum slit width (μm)	800	50	100	70
Material availability	Fair	Wide	Wide	Limited
Design flexibility	Limited	Wide	Limited	Limited
Capability for high-density flying leads	Limited	Wide	Fair	Fair
Technical hurdles	Low	Fair	High	High
Registration	Difficult	Fair	Fair	Fair
Damage on flying leads	Serious	Small	Fair	Fair
Process cost	High	High	Low	Low
Investment for large volume	Small	High	High	Medium

70.2.3 Laser Abrasion

The excimer laser process has the capability to generate small openings with clearly defined edges on high-density flexible circuits. The narrow slit openings can be made smaller than 50 mm wide. The excimer process is available for all types of flexible circuit materials with high accuracy and fine openings. A carbon residue, typically removed by a suitable wet cleaning process, is found around the edges of the openings. One of the biggest disadvantages of excimer laser system is its slow speed, which accounts for the high processing cost when dealing with larger openings.

The UV:YAG laser process offers a higher productivity rate than the excimer laser for very small openings. It has the ability to cut both copper foil and organic substrate materials with good quality, which makes it suitable for cutting small openings on a wide range of high-density flexible circuits. Unfortunately, the productivity rate becomes extremely slow

when cutting larger openings. Actually, it becomes impractical from a cost standpoint to utilize a UV:YAG laser system for openings larger than 10,000 mm^2.

Carbon dioxide TEA lasers, as well as diamond carbon dioxide lasers, have a much higher productivity rate when producing openings wider than 70 mm. The definition of the opening and quality of the edges, however, is somewhat less desirable than for other laser systems. In order to facilitate surface plating, a suitable cleaning process such as plasma is required to remove the thin residue remaining on the copper surface. A copper mask process helps to improve both quality and speed of the carbon dioxide laser process.

The excimer laser process, like the UV:YAG laser system, minimizes the potential for thermal damage on very thin flying leads. The carbon dioxide laser generates a remarkable amount of heat. The beam power density of the laser must be controlled carefully in order to process 18-mm copper with high-density flying leads narrower than 100 mm wide.

70.2.4 Plasma Etching and Chemical Etching

Plasma and chemical etching processes are other suitable choices for generating high-density flying-lead structures. Although their capabilities are somewhat less than those of laser processing, these processes can provide a lower-cost model of high-volume processing. A copper foil mask is required in order to define the exposure area, and specific process conditions are required to remove organic substrates effectively. These processes are quite effective for single-sided substrates. Double-sided substrates can be processed in this manner given very specific materials and construction.

A big advantage of these processes is the unlimited number of holes or openings that can be processed simultaneously. Performance value is high, while manufacturing costs remain fixed when larger sizes or higher numbers of holes are processed. The plasma process is capable of etching all kinds of organic materials; however, it must be performed in a vacuum chamber.

Capital investment is relatively large for high-volume production. Another issue involves uniform quality over a large working area/panel size in a vacuum chamber of limited size.

Depending on the process conditions, plasma etching creates a wall slope of 30° to 60° at the edge of the openings, and it is difficult to make holes smaller than 100 mm in diameter on a 50-mm-thick polyimide layer.

Chemical etching also offers a low-cost process for creating access openings in high volume on polyimide-based high-density flexible circuits. This process offers the capability of generating openings smaller than 100 mm in diameter or slit width on 25-mm substrates, while providing a very small slope on the wall definition of the opening. The issue in this process is finding the appropriate chemicals and creating the suitable conditions to etch the various flexible substrates.

Sodium hydroxide and potassium hydroxide are popular chemicals for etching Kapton type polyimide materials. Dangerous chemistries and tightly controlled process conditions are required to etch dimensionally stable polyimide substrates such as Upilex. Serious consideration must be given to choosing the appropriate circuit design, materials, and manufacturing processes. On the other hand, chemical processing such as this requires no specialized capital equipment, and it is extremely suitable for high-volume roll-to-roll manufacturing systems.

Typical high-density flying leads produced by new processes are shown in Fig. 70.6.

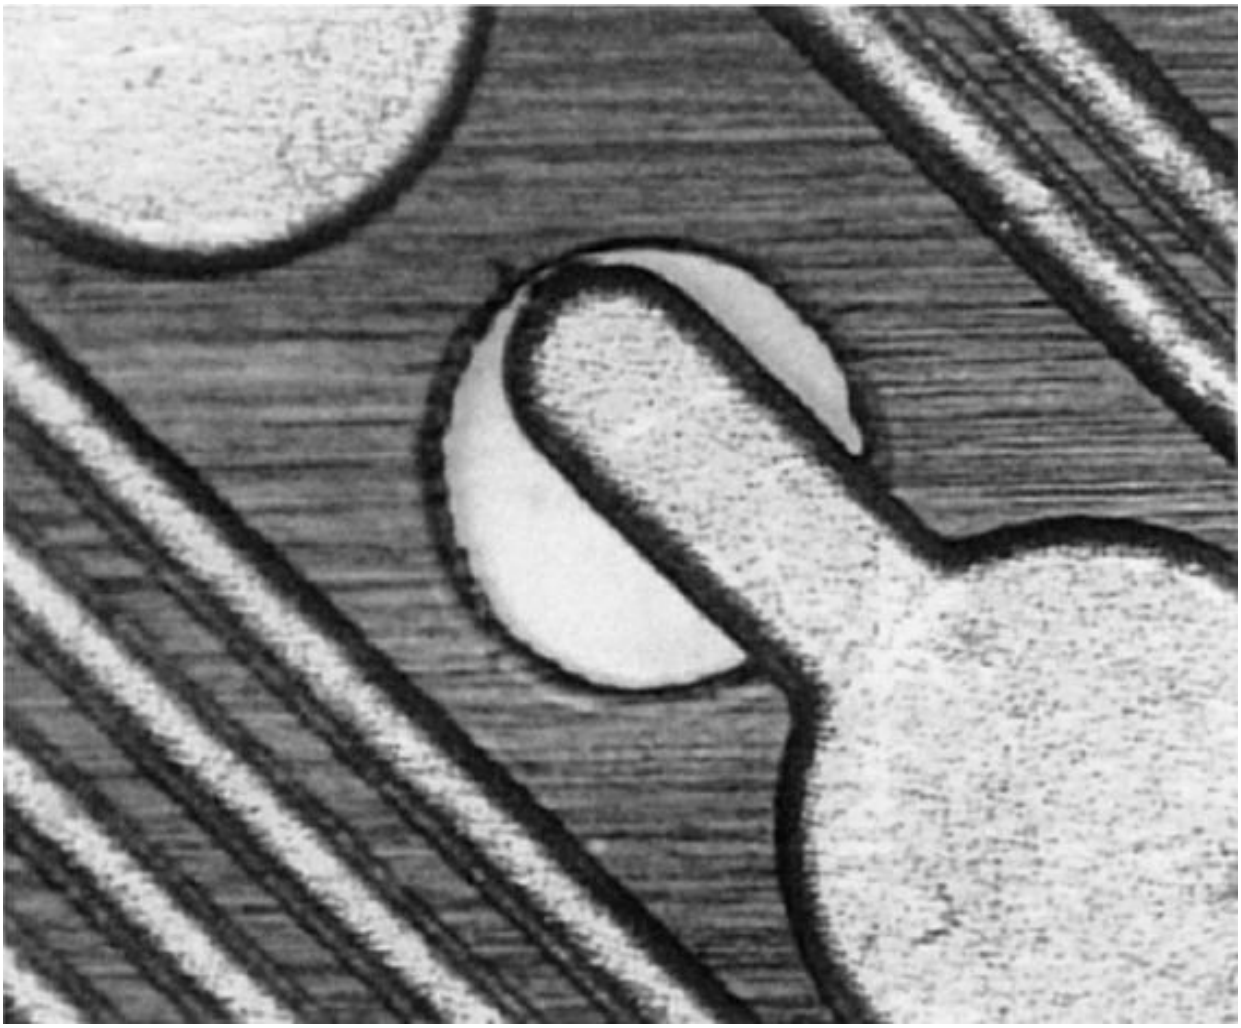

FIGURE 70.6 An example of a tab-shaped flying lead flexible circuit construction. (*Source: Asahi Fine Technology*.)

70.2.5 Economical Comparison

Each technology has its own cost structure, which is dependent on the conditions. Figure 70.7 shows a comparison from an economic study of the various technologies. This study was conducted on 25-mm-thick polyimide substrate with a 300-mm^2 working size. The opening size is assumed to be 0.1 × 3 mm, with flying leads at a 150-mm pitch processed on 18-mm-thick copper.

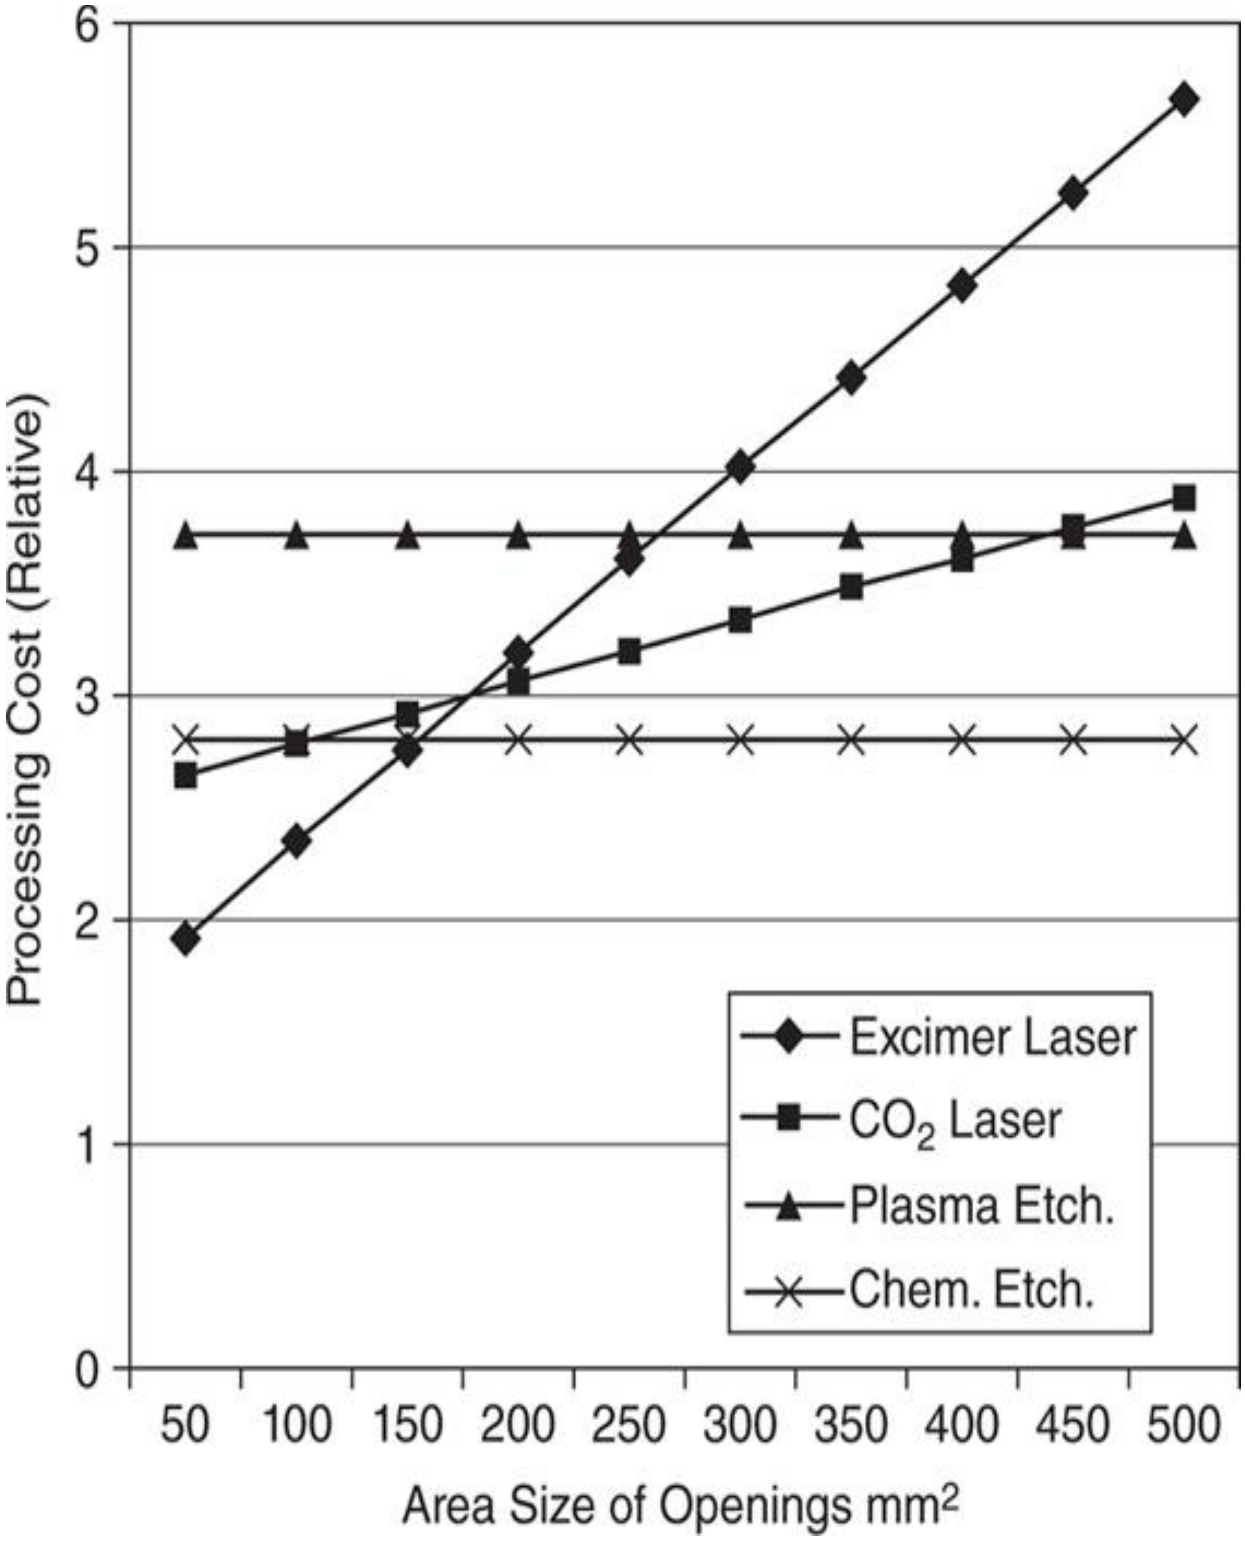

FIGURE 70.7 Cost comparison of flying-lead flexible circuit manufacturing processes.

Plasma and chemical etching processes have little dependency on the size or numbers of openings because they are based on batch processing of the materials in sheets. In contrast, the relative costs of the excimer and carbon dioxide laser process are proportional to the size of the area being processed as well as the opening sizes. This is primarily based on the small size of the laser beam as compared to the size of the opening, and on the need to overlap with each pass of the laser in order to remove the substrate in larger areas. The carbon dioxide laser, however, has higher manufacturing costs than the excimer laser process because of the additional chemical processes required to remove the organic residue left on the copper surface, but it has a lower associated manufacturing cost for larger opening sizes due to faster abrasion speeds.

70.3 TAPE AUTOMATED BONDING

TAB has been developed as the special wiring material for IC chips and liquid crystal displays (LCDs). Although it was developed separately from standard flexible circuits, they have similar constructions and they use similar materials, and can be categorized as one kind of flexible circuits.

70.3.1 Basic Concepts

Basic construction of TAB is the same as that of the flying-lead structure of flex circuits except for the web size used in manufacturing and the sprocket holes made for reel-to-reel conveyor systems which give TAB an appearance similar to that of cinema film. A 35-mm-wide web is the most common standard width for TAB. Webs 70 and 155 mm wide are available for larger circuits, nowadays. Because of the small working areas, TAB is good at producing fine traces with

flying leads. The reeled circuits are convenient for automation of circuit manufacturing and termination. A short strip circuit made by standard manufacturing processes for flex circuits is also called a TAB circuit because it has the same functions. (Examples of TAB are shown in Fig. 70.8.)

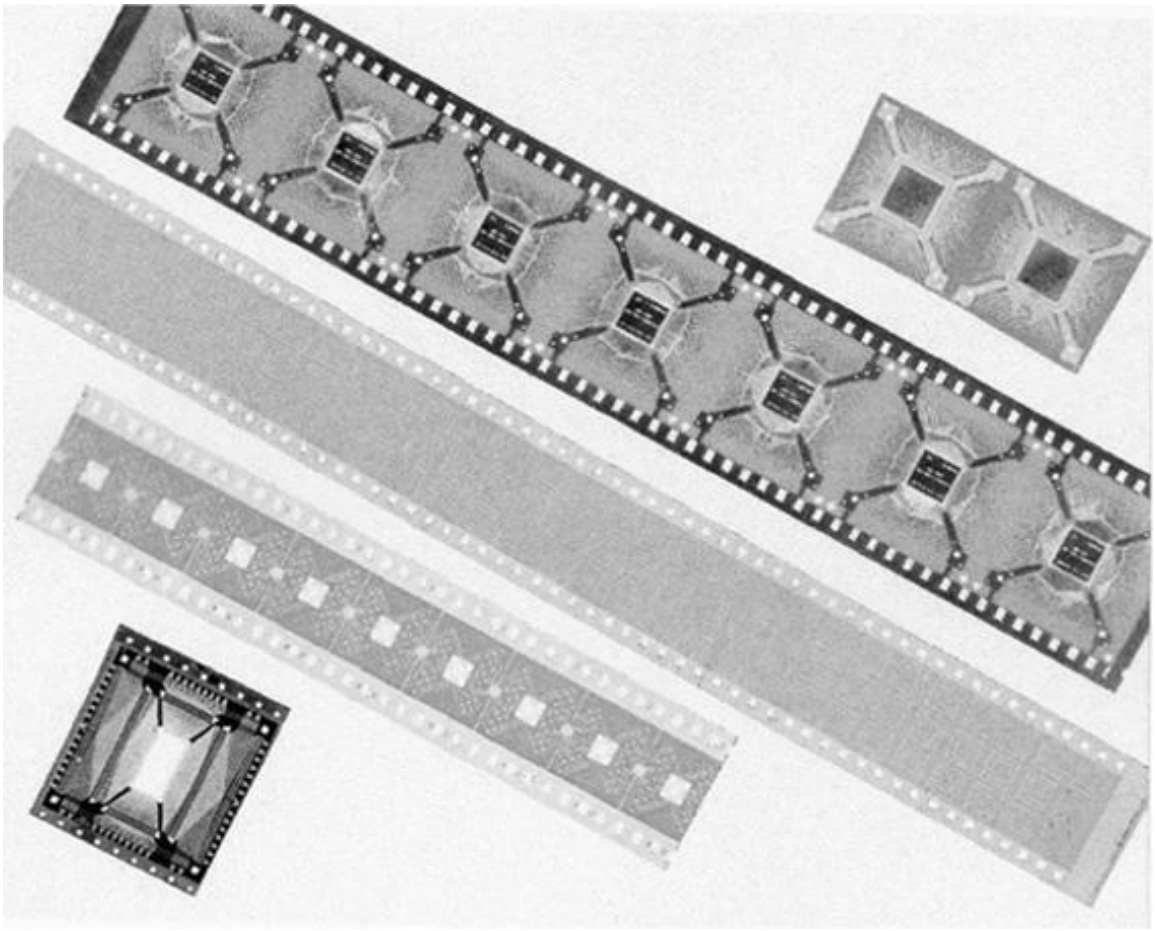

FIGURE 70.8 Examples of TAB high-density flexible circuits.

70.3.2 Manufacturing Processes

The basic manufacturing flow of single-sided TAB is the same as that of the traditional prepunch manufacturing process of flying-lead construction. Basically, all manufacturing processes of TAB are designed for automatic reel-to-reel equipment. Actual processing steps are slightly different as

shown in Fig. 70.9. The process starts from a plain film, mostly polyimide film. The first parts of the manufacturing are glue coating and punching of the hole generation. Secondary, a copper foil is laminated and the fine traces are generated by photolithography and chemical etching. Thirdly, final finishing such as cover coating and surface finishing is conducted. All of the processing equipment has to have loader and unloader by reels. The machines should be free from manual handling to eliminate the mechanical damages on the fragile fine flying leads. The whole process has to be kept in clean rooms to avoid the contamination for the fine lithography processes.

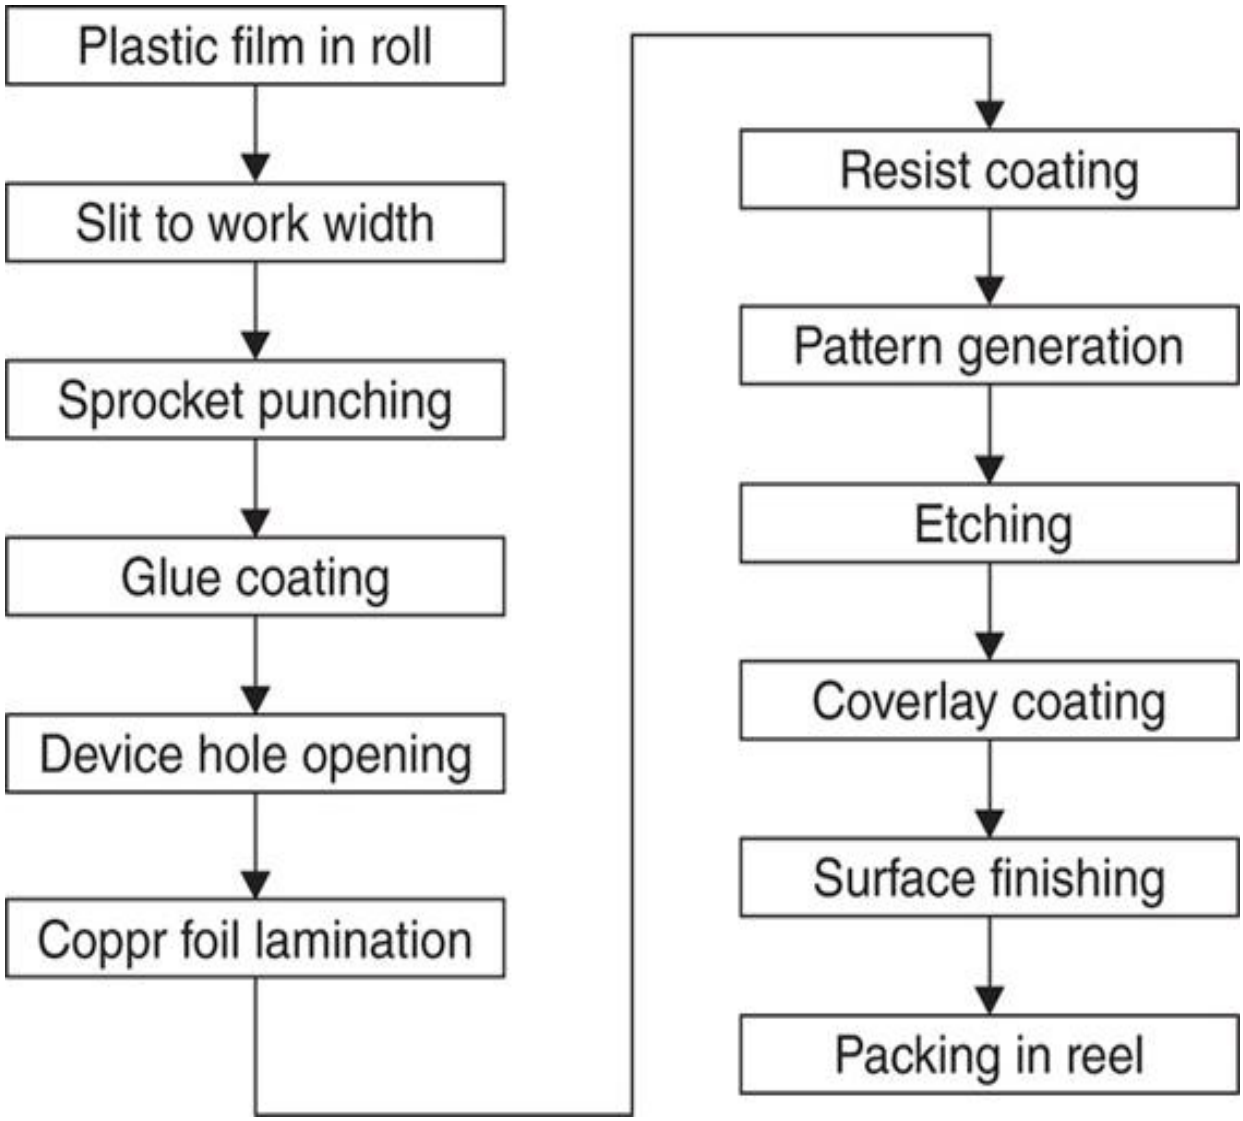

FIGURE 70.9 Manufacturing process flow of TAB.

Because of the narrower material width, TAB constructions have high capability for fine-line generation with good dimensional accuracy. The chemical etching process is also available to generate device holes. The technology can generate 40-mm-pitch traces as the flying leads.

The manufacturing process for the double side TAB with fine flying leads and micro via holes is much more complicated. Very few manufacturers are capable to produce the products with high yield.

70.3.3 Technology Movement of TAB

The TAB manufacturing technology has been experiencing a great progress since 1980s. However, it has been facing a turning point to change the basic process drastically for the finer circuitries.

TAB's manufacturing capabilities are very different from traditional flexible circuits and they cover different application area as shown in Fig. 70.10. TAB has been focusing single side fine traces with flying lead constructions. It has advantages for the volume productions of the small size circuitries because of special reel-to-reel manufacturing.

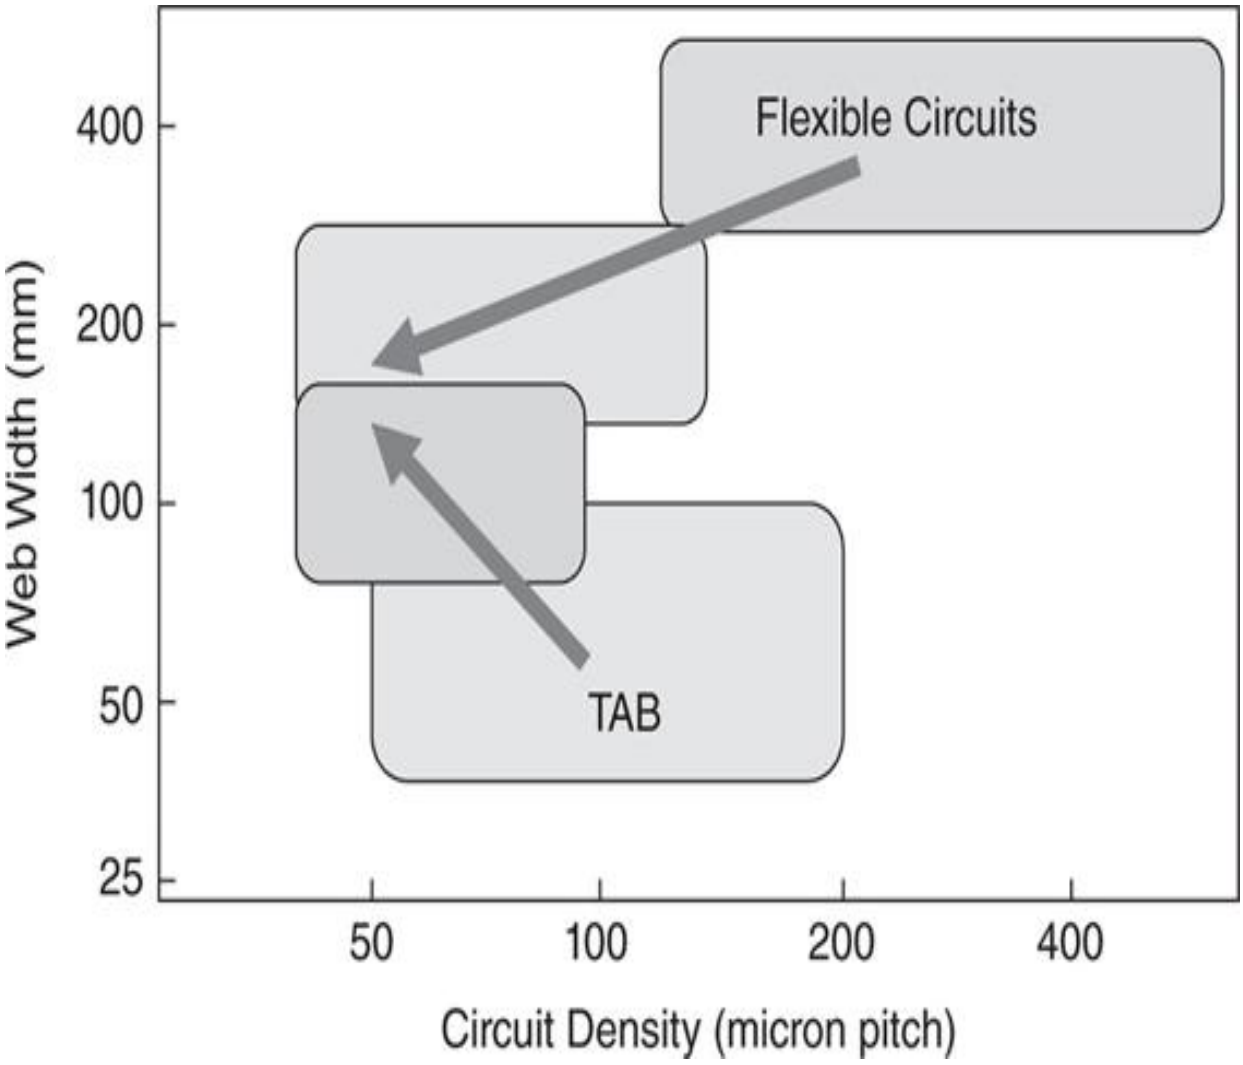

FIGURE 70.10 Recent movement of TAB and high density flexible circuits.

In early usage, only 35 mm wide web was available to have high dimensional stabilities. But the latest RTR manufacturing equipment can manage 155 mm wide materials to generate 40 µm pitch flying leads. Several new processes such as laser drilling and through hole plating have been introduced to produce double side TAB with fine flying leads.

Forty micro meters pitch of traces is almost the technical limit to manage the fragile fine flying leads for both of manufacturing and termination. Therefore, the technology is moving to COF (Chip on Film), that does not have device holes and flying leads, to have finer traces than 40 µm pitches. The manufacturing process and materials do not have significant differences from the roll-to-roll manufacturing process of the fine flexible circuits. On the other hand, the fine line capabilities of the flexible circuits have been getting better reducing their RTR web size.

TAB and flexible circuits had different capabilities in the past. But they have been moving to the same fine circuit area, and there have not bee remarkable differences in their manufacturing processes as shown in Fig. 70.10.

70.4 MICROBUMP ARRAYS

A variety of shapes and materials for micro bump arrays on flexible circuits have been developed to accommodate specific applications.

70.4.1 Varieties of the Bump Shapes and Applications

There are several choices of places to build micro bumps on flexible circuits, as described in Chap. 64 (see Sec. 64.3.8). The same processes used to build ball grid arrays on rigid circuit boards are appropriate for flexible circuits with flexible photo imageable solder mask. It is possible to build micro bumps on bare conductors using plating masks. Many micro bumps are built on fine flying leads without solder masks. A valuable construction of a flexible circuit is micro bumps built on the other side of the circuit through the dielectric layer. This can provide a reliable micro bump array because of the stable construction.

Many different shapes have been developed for micro bump arrays. The fusing solder process can make a spherical bump shape easily. Electrical plating of copper, nickel, gold, and combinations of these elements can provide many varieties of bump shapes. Changing the combination ratios and other factors can generate flat disks, flat domes, straight columns, etc. (Fig. 70.11). The best combination can provide 100- to 150-mm-pitch micro bump arrays on 50-mm-thick dielectric layers.

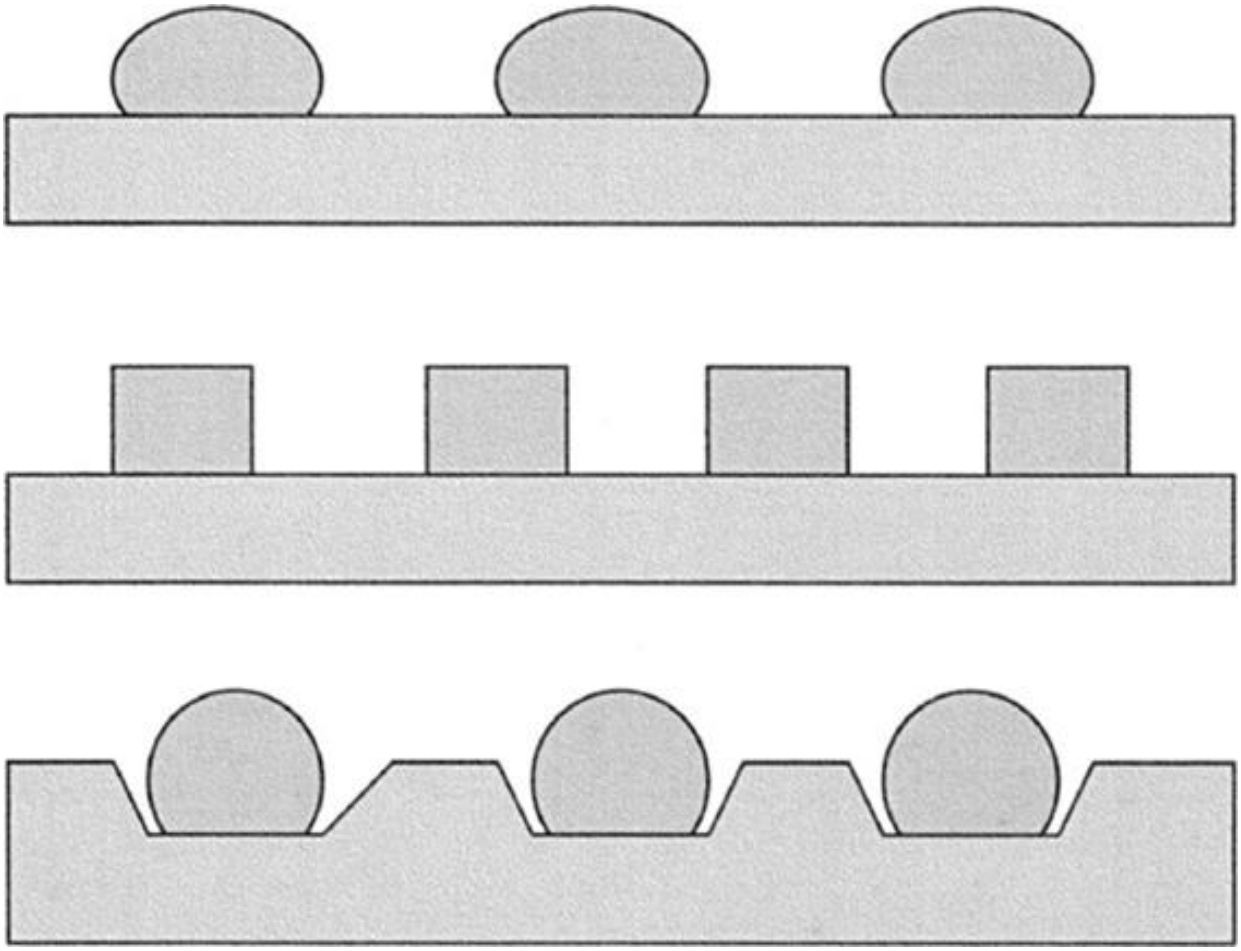

FIGURE 70.11 Microbump arrays on flexible circuits: examples of bump shapes.

Most of the micro bump array constructions of flexible circuits have been developed for high-density termination (e.g., flip-chip, CSP, test probes, etc.). A suitable design shape and materials should be chosen according to the requirements of the termination. Several examples are shown in Fig. 70.12.

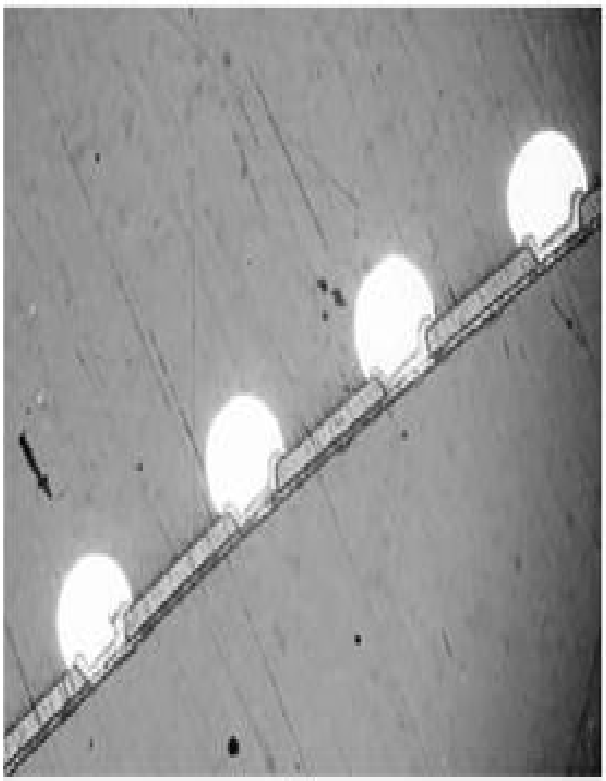
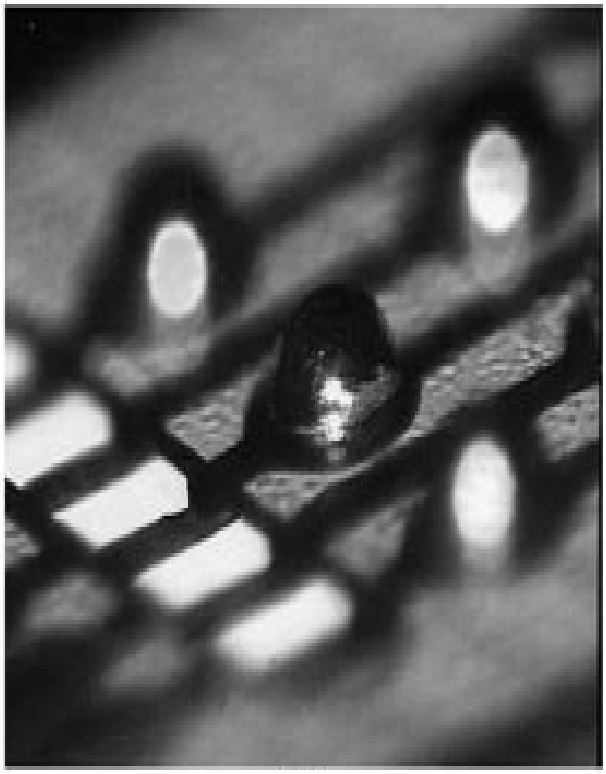
(b)



(c)



(d)

FIGURE 70.12 Various micro bump arrays on flexible circuits: (*a*) column shape copper bump array on the bare traces, (*b*) column shape Ni/Au bump array built through covelay, (*c*) solder ball array built though base substrate, (*d*) combination of flying leads and solder ball array.

70.4.2 Manufacturing

There are two kinds of manufacturing processes for the micro bump array on flex circuits:

1. The same technology as for ball grid arrays may be used. Solder paste is dispensed on the pads of the circuits with a liquid dispenser or screen printer. The solder paste will form spherical shapes for a refusing process. The process is available for relatively large solder balls.
2. Electroplating processes are used for small solder balls and nonspherical micro bumps.

Suitable combinations of different metal plating can provide wide varieties of micro bumps.

There are several factors that determine the shape and size of the bumps. The thickness of the dielectric layer and the size of the opening are the major factors in determining the bump shapes. The bump shapes will be more spherical when the aspect ratio of the opening is large.

The bump shapes will be like flat discs when the aspect ratio is small. An appropriate plating mask will help to build straight, high bumps.

When the micro bumps need to be built through the insulation layers, it requires a suitable hole generation process. Several laser drilling processes are recommended for small sizes but exact dimensions. Plasma etching and chemical etching are recommended for low cost processing with large numbers of the holes.

70.5 THICK-FILM CONDUCTOR FLEX CIRCUITS

A thick-film circuit is a type of additive manufacturing process. If an organic resin matrix is used, the conductor can be flexible, and this process has been applied in flexible circuits.

70.5.1 Materials

A silver paste conductor with an acrylic resin matrix is the most popular conductor material as the major thick-film conductor material for flexible circuits. It can provide very flexible conductor layers via a simple screen-printing process. Copper-based and carbon-based paste materials have been developed as the low-cost materials, but their conductivity is very low and unstable, and therefore their applicable areas are limited.

The screen printing process with conductive paste provide low cost solutions for the large size flexible circuit employing economical plastic films such as PET films.

70.5.2 Applications

A silver paste thick-film flexible circuit built on polyester film can provide the lowest-cost solution for large circuits. Unfortunately, the conductivity of the traces is much lower than for copper foil conductors, and this material is not available for power circuits or signal layers of high-speed circuits. Standard soldering is not available because of the acrylic-based matrix.

The largest application of thick-film-based flexible circuits is in membrane switches, which need large circuit spaces but

do not carry large currents. The majority of membrane switches are covered by silver paste thick-film flexible circuits. Major switching circuits of keyboard switches are also covered by the same constructions. Most of the key board circuits are covered by the silver paste base membrane switches. Most of the touch panel switches designed for micro waves, office appliances and medical equipment also use PET based membrane switches. Several examples are shown in Fig. 70.13.

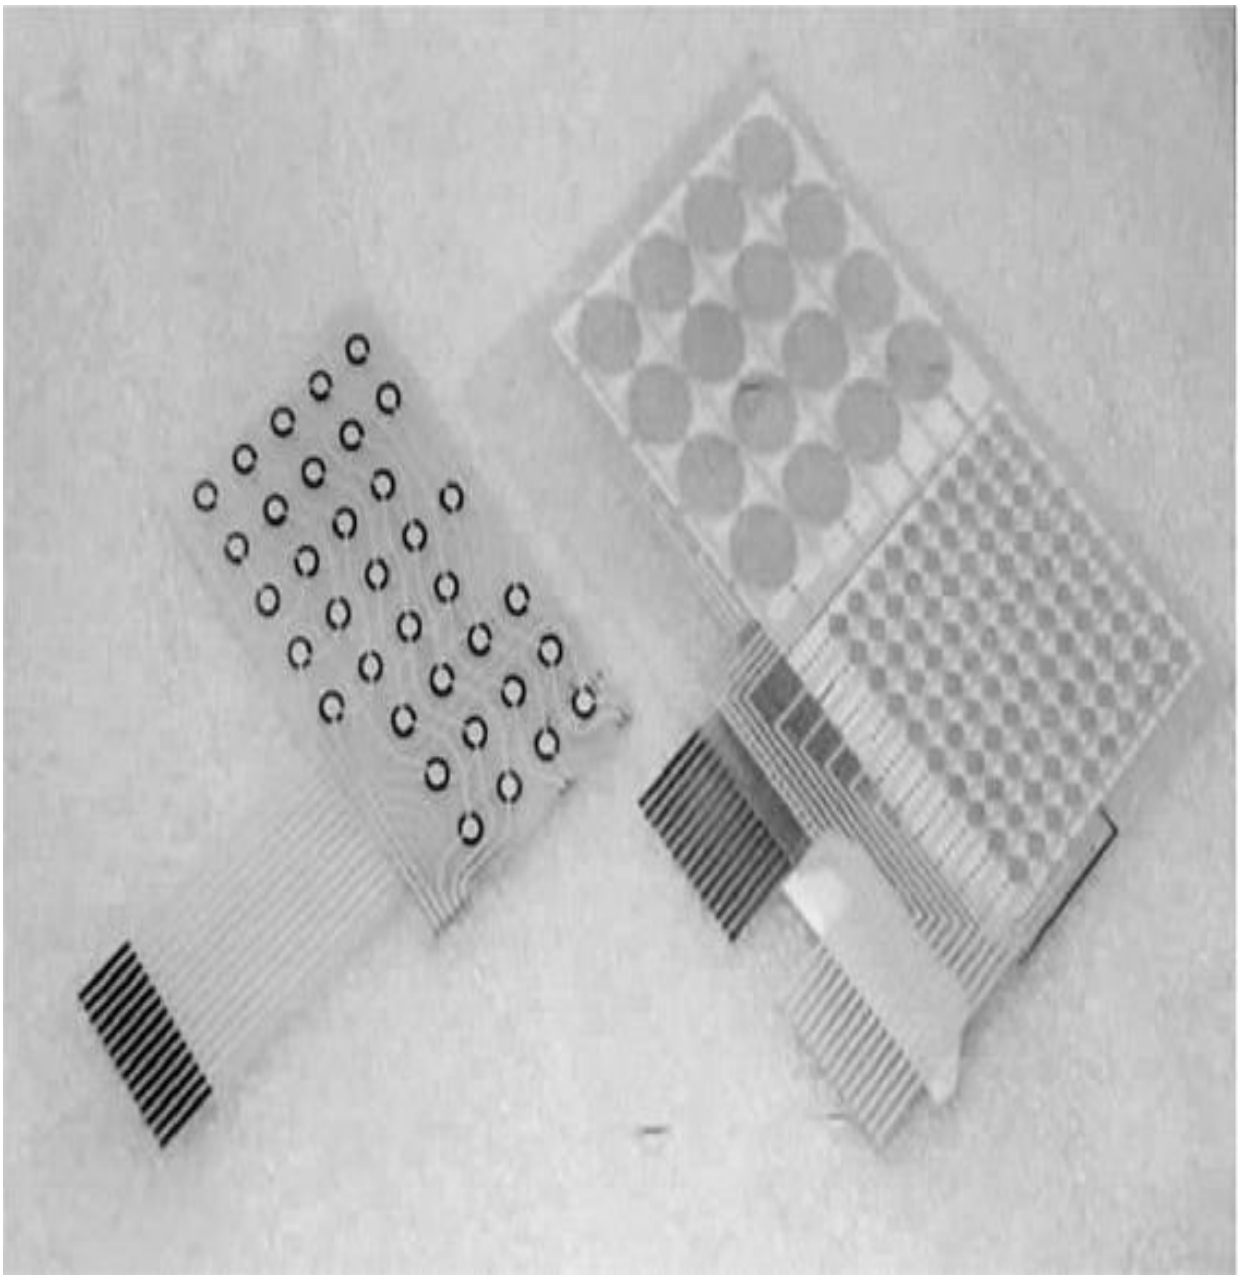


FIGURE 70.13 Membrane switch made by thick film process.

PET based thick film flexible circuits have been consumed for the touch panel switches of the electronic terminals such as PDA because of their transparency.

70.5.3 Manufacturing Process

It is a very simple process to build a thick-film flexible circuit. There are two steps:

1. Screen printing on a flexible film followed by baking
2. Blanking

This still requires that the process conditions be controlled carefully. The basic properties of these circuits change significantly depending on these conditions. A prebaking step is recommended for polyester film substrate to eliminate thermal shrinkage during baking for printed conductor paste. It is not difficult to apply the roll-to-roll manufacturing system for large volume because of the simplicity of the processes.

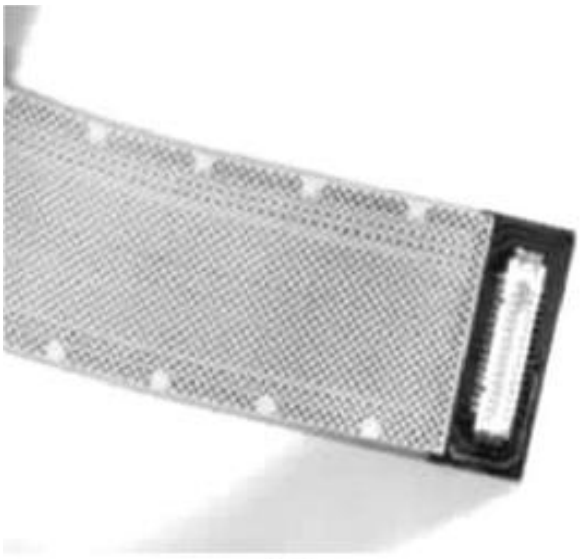
The latest technologies of the printers and screens are able to produce 10- to 15-mm line space with low cost. The electrical properties and trace densities are very depend on the conductor paste. A combination with screen printable nano conductive paste will provide fine conductive traces by a simple manufacturing process.

70.6 SHIELDING OF THE FLEXIBLE CABLES

When the flexible circuits are used as the cables for the high-speed telecommunications, appropriate shielding systems are required. Generally, the cable will be bent frequently, therefore the shielding layers should also have high flexibilities.

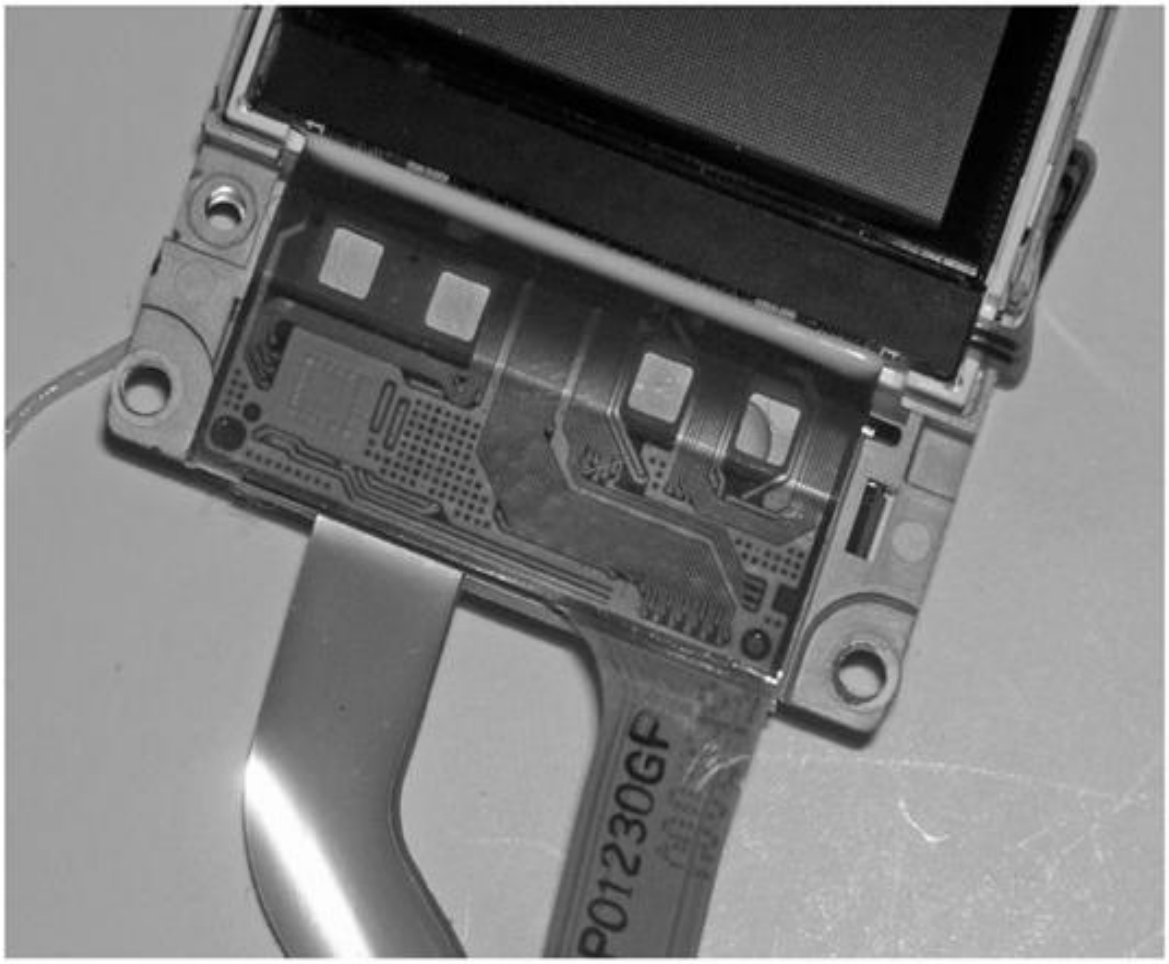
Several materials and constructions are available for the shielding of the flexible cables as shown in Fig. 70.14. Screen-printing of silver paste provides both high shielding effect and high flexibility. Screen-printing of carbon paste provides low cost solution. But its shielding effects are

limited. Thermal lamination of a thin aluminum foil with thin flexible adhesive provides a reliable solution for both shielding efficiencies and flexibilities.



(a)

(b)



(c)

FIGURE 70.14 Shielding of the flexible cables: (*a*) screen-printing of silver paste, (*b*) screen-printing of carbon paste, (*c*) lamination of thin aluminum foil.

70.7 FUNCTIONAL FLEXIBLE CIRCUITS

Various new processes have been developed to build functional elements and devices on the flexible substrates. They have been generating more functions than wiring or assembling board of the discrete components. They are the similar ideas as embedded passive technologies of multilayer boards, but they generate more values with flexible substrates. Table 70.2 shows several material examples and applications. Printed electronics (PE) is the 'next step' in this evolution of flexible interconnects.

TABLE 70.2 Functional Materials for Flexible Circuits

CHAPTER 71

FLEXIBLE CIRCUIT QUALITY ASSURANCE: PRINCIPLES AND PRACTICES

Joseph Fjelstad
Verdant Electronics, Seattle, Washington

71.1 INTRODUCTION

There is an old adage which goes: “Individuals tend to do what is inspected rather than what is expected” is a bit cynical but it is also not entirely without merit. It is not than individuals seek to create manufacturing errors but rather that without knowledge of what is being inspected for they have no way of knowing what is expected as a result of their efforts. As a result testing and inspection are among the most important elements of any manufacturing operation. This is because these important operations at once:

- Provide valuable feedback on the health of the manufacturing operation

- Can prevent the escape of defective parts into the assembly process
- Can prevent failure in assembly
- Can prevent failure in the end-use environment

Quality and reliability managers often have a conflicted relationship with manufacturing. As the source of in house “reality checks,” quality and reliability managers are tasked with finding and either repairing or scrapping discrepant circuits. Quality and reliability managers serve as customer advocates in that they seek to prevent discrepant material from shipping to the customer. To many manufacturing people, inspection and testing does not seem to add value to the product. But inspection and testing do add value by helping to ensure customer satisfaction and secure repeat business. On-time delivery helps to meet short-term goals and immediate customer needs, while quality and reliability help to achieve longer-term goals, such as preventing returns and assuring the return of loyal customers.

Today’s methods of just-in-time procurement and assembly make the issue of discrepant material being delivered to the customer particularly damaging. Circuits that do not meet contractual agreements or functional requirements add cost by requiring that circuits and assembled components be remade or replaced. Discrepant product increases cost, monetarily and in terms of capacity reduction that results in a ripple effect upstream that can reach the original equipment manufacturer (OEM). Liability of the fabricator is often extended to include replacement of discrepant circuits as well as assembled parts that cannot be salvaged by the assembler.

Moreover with the mandated implementation of lead-free assembly there has been a significant impact on quality and reliability requirements of flex circuits, raising the bar from former times. What was once an acceptable quality level in a tin-lead assembly may fail catastrophically in a lead-free

assembly and/or rework situation. Whereas tin-lead assembly could be performed at a process temperature of 230°C, lead-free assembly requires temperatures as high as 260°C. As a result new failure modes have been identified (e.g., microvia pullout) and attributed to the high temperatures associated with lead free assembly. Aerospace satellites that fail prematurely in orbit, equipment that fails in the pitch or battle and failure of life support systems are obvious examples of why inspection and test are so important to the electronics industry. Contrary to popular belief, quality and reliability requirements for consumer electronics are increasing and becoming tighter. The requirement for consistent, repeatable quality with appropriate reliability is being mandated, but of course the goal is to achieve this level of quality without incurring additional costs. Pricing was once the major consideration for procurement, but cost is becoming the more dominant factor. Quality and reliability are more important than ever to prevent significant costs to the fabricator, contract manufacturer, OEM, and customer. Quality and reliability, while often referred to interchangeably, actually have different purposes. Quality is mostly about adhering to specified requirements to meet contractual obligations or industry-established minimums. Quality is concerned with the correct part number, revision, amount, dimension requirements, physical and electrical attributes, and requirements including opens, shorts, copper weights and thicknesses, impedance and other variables. Reliability is a measurement of the sum total of the quality requirements and other unspecified attributes of the circuit. Quality confirms that a circuit meets requirements, while reliability demonstrates that the effects of those requirements produce a product that will survive assembly and be functional in the end-use environment.

71.2 BASIC CONCEPTS IN FLEXIBLE CIRCUIT QUALITY ASSURANCE

Because of the different design concepts and materials, there are several significant differences in managing quality assurance for flex circuits versus that for typical rigid circuit boards. In addition, special test methods are required to guarantee the finished quality of high-density flex circuits, and new inspection technologies have been developed for this purpose.

The basic concept of quality assurance for flexible circuits is the same as that for rigid boards, in the sense that any critical defect must be identified and prevented from shipping. The list of identified types of failures is long and varied as will be shown in this chapter. There are concerns not only with circuit continuity but with the viability of the terminations that will be made on the circuits during the assembly process. In concise terms it is a goal of quality assurance to confirm or refute that the circuit meets or exceeds quality requirements and reliability expectations contractually expressed by the customer. In general it is on the manufacturing floor where quality assurance plays its two most important roles, manufacturing floor health monitoring and final evaluation using its two most important tools, inspection, and test. In short, quality control performs test and inspection with the goal of assuring that the process is working properly and furthermore to make sure that the products built meet the requirements and reliability expectations of the customer. This is not an easy task but it is an important one.

The list of variables that must be monitored in process and adjusted as required to ensure consistent outcomes during circuit fabrication is daunting. Variables in the process are monitored and adjusted to ensure consistent outcomes during circuit fabrication. For example there is need to

monitor, test and track such process variables as temperature, pressure, chemical concentrations, pH, and the like. The results are commonly analyzed using statistical methods and tightly controlled to ensure that the process is continuing to produce an acceptable product. Moreover, the materials used in manufacture are necessarily tested with some frequency to ensure that they have not fallen out of conformance with requirements. Quality assurance provides a feedback loop of measurement and adjustment helps to achieve consistency of process and product. Sample circuits, or representative coupons, are submitted to a testing program. It is important that the sample has the same construction and conformation as the circuit being tested. Samples of circuits from a given fabrication lot, taken off the production panel, should be nearly identical and testing of the sample should reflect the attributes of all the associated circuits.

Testing should not be confused with inspection, although they do have complimentary roles. Inspection finds variation that results in the need to sort to separate acceptable from discrepant circuits. Weeding out and rejecting discrepant production circuits reduces production yield, but knowing the production yield is one of the most useful tools for obtaining objective feedback about the general health of the fabrication line and the product being built. Inspection must also be used to assess the quality of the product and ensure that it conforms to established requirements. With increasingly fine line circuits challenging human capabilities the use of automated optical inspection (AOI) is becoming increasingly important. Used properly it can both provide a feedback to manufacturing relative to potential discrepancies in phototools used in the imaging process and can as well provide early feedback to manufacturing whether there will be need to restart a production run to meet manufacturing deadlines.

100 percent testing of any product, including flexible circuits, though possible, is not normally practical therefore testing is commonly done on a sample basis to maintain some manufacturing economy. Moreover, some types of testing actually degrade the quality of the circuit in the process of testing. Still under some circumstances, 100 percent testing may be required.

As alluded to earlier there are fundamentally two levels of interest for inspection and test: the raw material level and the finished circuit level. Raw materials are inspected and tested to ensure that they will meet the requirements established by industry. Raw material testing provides a level of assurance that only acceptable material will be committed to manufacturing, reducing the potential for circuit discrepancies. The final product is also tested to make certain that it meets or exceeds the specified requirements, which are typically related to form, fit, function, and performance in the endues environment. The balance of this chapter will identify and briefly discuss the types of inspection and test that are required for both material and final product.

71.3 RAW MATERIAL TESTING

Raw materials (e.g., base materials, adhesives, foil-clad laminates) are tested to ensure that they are of a high enough quality to produce end-products that are compliant with requirements and will not limit the circuit’s performance as it moves through assembly and to the end-use environment. Material performance is evaluated in several categories (physical, chemical, electrical, and environmental) that reasonably represent the spectrum of potential areas of concern for a product. The following is a review of some of the tests that may be required for flexible raw materials.

71.3.1 Material Physical Performance Testing

The physical performance of the raw material is measured to ascertain that certain minimum physical properties are present in the material and to ensure that it is compliant with the specified requirements. The following common mechanical tests are performed to determine the values of two key physical properties of the flexible base material: the ultimate strength of the base film and the degree to which the material can be stretched before failure. These are important mechanical considerations and are useful in predicting the suitability of a material for a given application. They are also important data input values used in finite element modeling (FEM) and/or finite element analysis (FEA).

- *Initiation tear strength:* A test used to determine how much force is required to initiate tearing in a material. It is a measure of the toughness of the base material, an important factor for flex circuits given the somewhat delicate nature of thin materials.
- *Propagation tear strength:* Evaluated to determine the toughness of the material. This test is designed to measure the force required to propagate a tear in a material after a tear has been initiated. Propagation tear strength can be a vital determinant of the ultimate reliability of a product. The lower this value is, the more important it is that tear-stop features be added to the flex circuit design.
- *Low-temperature flexibility:* Performed to evaluate material resistance to embrittlement and possible fracture at low-temperature conditions, as might be encountered by flex circuit end-products in some applications.
- *Dimensional stability:* Measuring and characterizing a base material’s dimensional stability is important to both the designer and the manufacturer. Any variability in the

materials dimensional response to the manufacturing process is vital to product yield. One of the concerns is the propensity of a material to shrink during the etching process as the elimination of copper removes the truly dimensionally stable element of the laminate. In general, the more dimensionally stable the material, the easier it is to predict the locations of design features after manufacture.

- *Peel strength:* Measured to ensure minimum bond strength. It is normally applied to the measure of copper foil, but it can be applied to other combinations as well. Tests are run under the following conditions to ensure that adequate peel strength is retained after exposure to different conditions.
  - As received to check for minimum bond strength of copper to the flexible dielectric base
  - After floating the sample on 289°C solder for 10 s to check for degradation after simulated assembly and rework.
  - After exposure to five cycles of −50°C, +150°C with 30-min dwells at each extreme, with a 15-min intermediate dwell at room temperature between exposures at extremes to simulate accelerated aging effect on bond strength.
- *Volatile content:* A potential source of outgassing and delamination. The test is employed to determine that the weight percentage of volatile elements in flexible laminate is at a desirably low value.

71.4 ELECTRICAL PERFORMANCE TESTS

The electrical performance of a flex circuit is often critical to the performance of the final product and the electrical performance is often a function of the material itself and its electrical properties. This is increasingly the case as higher performance circuits find their way into ever increasing numbers of applications. The electrical properties are verified by checking material samples and determining values for all of the following attributes.

- *Dielectric constant:* A unitless value, the dielectric constant (D_k) of a material is an important factor and determinant in many predictive calculations of electronic performance. A low D_k is especially important in high-speed applications. It is fundamentally the ratio of the capacitance of the material to the capacitance of air.
- *Dissipation factor:* Fundamentally defined by the relationship between the material's permittivity (capacitance) and its conductivity, when measured at a given frequency. This is an important material property which assist the circuit designer in making calculations of the electronic performance of the end-product. Moisture uptake is a common contributor to increases in dissipation factor and signal loss and will become increasingly important as signal speeds and operating frequencies continue to rise.
- *Dielectric strength:* Is determined to establish the minimum breakdown voltage of the material. It is of particular interest and importance in the fabrication of high-voltage circuits as well as circuits that are to operate at high altitudes and are prone to electrical arcing.
- *Surface and volume resistivity:* Values are measured and established to ensure the material conforms to minimum values for volume and surface electrical resistance under damp heat conditions (such as those that might be encountered during exposure to highly humid

environments), if the resistivity is too low it can negatively alter electronic circuit performance. The test provides a measure of a material's propensity for current leakage under such conditions.

71.4.1 Environmental Performance Testing

Environmental performance testing is undertaken to evaluate certain physical and electrical attributes of the material that may change as a result of exposure to the environment over product life.

- *Moisture absorption:* A determination of how much moisture the base material will absorb under humid conditions. Moisture absorption is relevant to electrical considerations since moisture absorption will alter the dielectric constant of the material. However, it is also a potential concern in assembly since excessive moisture absorption can cause explosive outgassing of absorbed moisture and delamination of cover layers. This is an increasingly important concern with lead-free solder since there is a doubling of vapor pressure between traditional soldering temperatures and nominal temperatures required for lead-free soldering.
- *Moisture and insulation resistance:* Evaluated to determine the effects of extended exposure to moisture on the insulation resistance of the raw material. The purpose is to verify that electrical properties do not degrade beyond established limits for the material under test conditions.
- *Fungus resistance evaluation:* Performed to determine if the material is a nutrient for fungi or other biological material that might be capable of degrading the electrical properties of the flex circuit.

71.5 GENERAL TESTING REQUIREMENTS FOR FLEXIBLE CIRCUIT MATERIALS

There are a range of material tests that are desirably performed on flexible circuit base materials to ensure conformance to requirements. Following are the two primary areas of concern:

- *Chemical performance testing:* Such requirements for flexible circuits are very limited. Processing and application are two major areas of concern relative to chemical performance of raw materials used in flex circuit manufacture. Flexible circuits can be exposed to a variety of chemicals both in process and in use does it is important to determine resistance of the material to any such chemistries that may encounter to assure there are no deleterious or lingering negative effects
- *Flammability testing:* Performed to determine the minimum level of oxygen required to sustain combustion of the laminate. For printed circuitry, a commonly required rating is Underwriters Laboratories' UL 94 V-0, which indicates that the material is nonflammable. While, in the past, UL 94 V-0 ratings for flex laminates were uncommon, advances in flex circuit materials have resulted in a number of materials that meet the requirements of a 94 V-0 rating.

71.6 FLEXIBLE CIRCUIT VISUAL EVALUATION

The final test and inspection of flexible circuits is performed to ensure the products conformance to requirements. The reader will note that the testing of finished flex circuits duplicates many of the tests performed on the raw material. This is to ensure that the manufacturing process has not degraded the material beyond acceptable limits with respect to certain key properties. As with the raw materials, testing requirements have been established in several key areas to ascertain that the product is acceptable for its intended purpose.

Major categories for testing the finished flex circuit include: visual inspection, metal finish solderability, physical dimensions, physical properties, circuit construction integrity, plated-through-hole quality (both before and after thermal stress), electrical properties, environmental properties and cleanliness. Testing requirements for each of the above-mentioned categories are reviewed here in brief fashion. IPC documents describing the precise test methods are available and should be read if more detail is sought or if one wishes to perform the actual testing.

- *Visual inspection requirements:* Visual inspections are commonly performed as part of quality assurance process to ensure conformance to requirements not readily captured by other test techniques. The following are key attributes that are determined visually.
- *Delamination:* Fundamentally any separation of the material from itself (e.g., conductors from laminate, cover films from conductors) constitutes evidence of delamination. It is generally seen as an indicator of improper processing, lack of cleanliness or thermal stress excesses. In nearly all cases, delamination is considered a rejectable condition.
- *Circuit edge condition:* The edges of flex circuits are commonly seen as a site of potential failure thus edge condition is inspected to check for nicks or tears that could

be sites for tear propagation and failure of the circuit. This is of great importance in dynamic flex circuit applications where nicks along the edges of a flex circuit can become sites for tear initiation. Edge condition testing is important for static applications as well, since circuits could be inadvertently stressed and torn during assembly.

- *Stiffener attachment Quality:* Stiffeners normally perform vital mechanical component support functions. As a result, the attachment is checked to ensure integrity of the bond on the flex circuit to the chosen stiffener substrate. If filleting of stiffener edges or an edge break is specified, this inspection step will also verify its presence.
- *Solder wicking under coverlayer:* Evidence of solder wicking along the surfaces of traces away from openings in the coverlayer may be an indication of improper lamination of the coverlayer or excessive exposure to molten solder. The condition is desirable but is generally considered to be acceptable if it is within specified or agreed upon limits.
- *Marking of the circuit:* Marking is checked to verify compliance to the master drawing and to prevent mislocation or misorientation of components during assembly or later, when field repair of the circuit would be required. If serialization of the circuit is used, it can also be checked at this time.
- *Plated-through-hole quality:* As with all printed circuits the quality of plated-through holes is vitally important with flexible circuits as well. Voids of unacceptable size or quantity are inspected in order to avoid soldering or reliability problems with the copper-plated-through hole. Ring voids are a major concern and a definite cause for rejection. If not discovered in inspection during assembly, the problem of voiding in plated-through holes is frequently manifested as an outgassing condition or blow hole in the solder joint.

- *Workmanship:* A catch-all inspection category covers miscellaneous items such as the presence or absence of dirt, oils, fingerprints, wrinkles, bends or creases, and other nonspecific indicators of the workmanship of the circuit's manufacturer. Workmanship inspection may be subjective, but it can provide an indication of the quality of the circuit manufacturer's process.

71.7 FLEXIBLE CIRCUIT DIMENSIONAL REQUIREMENTS

Dimensional measurements of the finished flex circuit are taken to ensure the form and fit of the accuracy is often important to the actual function and ultimate reliability of the circuit. The following are some key points of inspection and measurement:

- *Minimum annular ring determination:* The lack of sufficient annular ring can affect both the solderability and the reliability of an interconnect. Requirements differ greatly for plated and nonplated-through holes. Nonplated-through holes in single-sided flex normally requiring a much greater solderable area to ensure a reliable joint. Thus, annular ring is checked to ensure that minimum requirements are met.
- *Hole pattern accuracy:* Checked to ensure that through holes are in their proper locations. This is an important issue for circuit assembly, especially when automated plated-through-hole assembly procedures are employed. It is also important when the holes are to be used as tooling holes for surface mount assembly.
- *Coverlayer registration:* Has a net effect similar to that of the annular ring because coverlayer misregistration can encroach on the solderable area, resulting in a less reliable

connection. The coverlayer should register on the pad to meet the minimum specified requirements. Registration requirements can vary with pad design features, with some approaches being more forgiving. With single-sided flex circuit designs, where the coverlayer serves to prevent pad lift, registration can be a very important concern. A minimum of 270 percent of land capture is normally recommended.

- *Adhesive squeezeout onto pads:* A fairly common by-product of manufacturing during coverlayer lamination due to adhesive flow under heat and pressure. There are standard allowances for squeeze-out onto lands, but the amount of squeeze-out may need to be negotiated. Good process technique and materials can minimize the effects by damming off the adhesive with conforming press-pad materials. With newer photoimageable coverlayers, this factor is generally not a concern.
- *Air entrapment along the edges of flex circuit traces:* Phenomenon commonly referred to as soda-strawing, it can occur in dense, closely packed circuit designs or when very thick copper is called out by design. While it is not harmful in all applications, acceptability is often based on application of the end product. Capillary wicking of moisture is possible if the effect runs to the edge of the circuit or land. Limits should be agreed upon between the user and manufacturer.
- *Foreign entrapments:* Foreign materials are sometimes present in the raw material and/or under the coverlayer of flex circuits. They are considered acceptable in various applications, provided that they do not bridge conductors or reduce spacing between conductors to less than acceptable limits. They may also be a concern if located in a critical bend area.
- *Hole sizes in flex circuit:* All such features are checked to verify conformance to print requirements and to preempt

assembly problems. If made too small, circuit holes may make insertion of component leads difficult. If the hole is too large, it may be difficult to form solder joints of preferred quality in the assembly process. For tooling holes, hole size inaccuracy is a concern because loss of positional accuracy is a possibility.

- *Circuit conductor pattern:* Obviously the finished conductor pattern on the flex circuit should accurately represent the master drawing. While allowances exist for localized reductions of up to 20 percent in conductor trace width due to nicks or mouse bites, an excessively large number of occurrences is likely to be indicative of problems in the manufacturing process.
- *Conductor width and spacing:* Evaluated because it is increasingly critical especially as line and space on circuits diminish in size. Proper sizing may be critical to ensure proper electrical and/or electronic performance. Evaluation requirements should be defined on and controlled by the master drawing.

71.8 PHYSICAL TESTING REQUIREMENTS FOR FLEXIBLE CIRCUITS

Physical testing is another key part of flex circuit testing. It helps to verify the physical appropriateness of the product for the application. The following tests are performed to ensure product quality and reliability. The flex testing sections are especially important in dynamic flex circuit applications.

- *Plating adhesion:* Tests performed to ensure a good metallurgical bond of plated metals to the base laminate copper foil. One method that has been employed for many

years is the use of home and office tape which has been bonded to the circuits and then rapidly foldaway. The test is commonly referred to in the industry as the tape test. Low bond strength could result in latent failure of the circuit due to conductor lift or shorting.

- *Unsupported hole bond strength:* Evaluated to ensure that the circuit can endure assembly and repair without excessive damage. The land must endure five cycles of soldering and desoldering in accordance with common specifications.
- *Conductor pattern bond strength:* This test which is similar to the plating adhesion test is performed to ensure that the circuit manufacturing process has not reduced foil bond strength to unacceptable levels. Test conditions are essentially identical to those described for raw materials.

71.8.1 Flexibility Testing Requirements for Flexible Circuits

Flexibility is a hallmark feature of flexible circuits and thus evaluating the flexibility of the circuit as a finished product is of significant importance. There are two general types of tests performed one is a folding flexibility test and the other is a flexibility and endurance test.

- *Folding flexibility tests:* Performed to ensure that the circuit can be successfully formed to meet the requirements of the master drawing without delaminating or breaking conductors. Information required for proper testing of folding flexibility includes: location of bend, radius of bend, angle of bend, direction of bend, and number of cycles.
- *Flexibility endurance testing:* Most important for dynamic flex applications it provides important information about

both the circuit and the process. Testing apparatus can vary with customer requirements. Standard test methods using equipment such as the fatigue ductility (a.k.a. Engelmaier) flex tester may require anywhere from a few minutes to several hours to perform. Many disk drive manufacturers opt to test circuits under simulated operating conditions. Flexibility endurance testing can take weeks or even months to complete, but can provide manufacturers with the comfort of hard statistical reliability data. Examples of some of the most commonly used flexibility endurance test concepts are provided in Fig. 71.1.

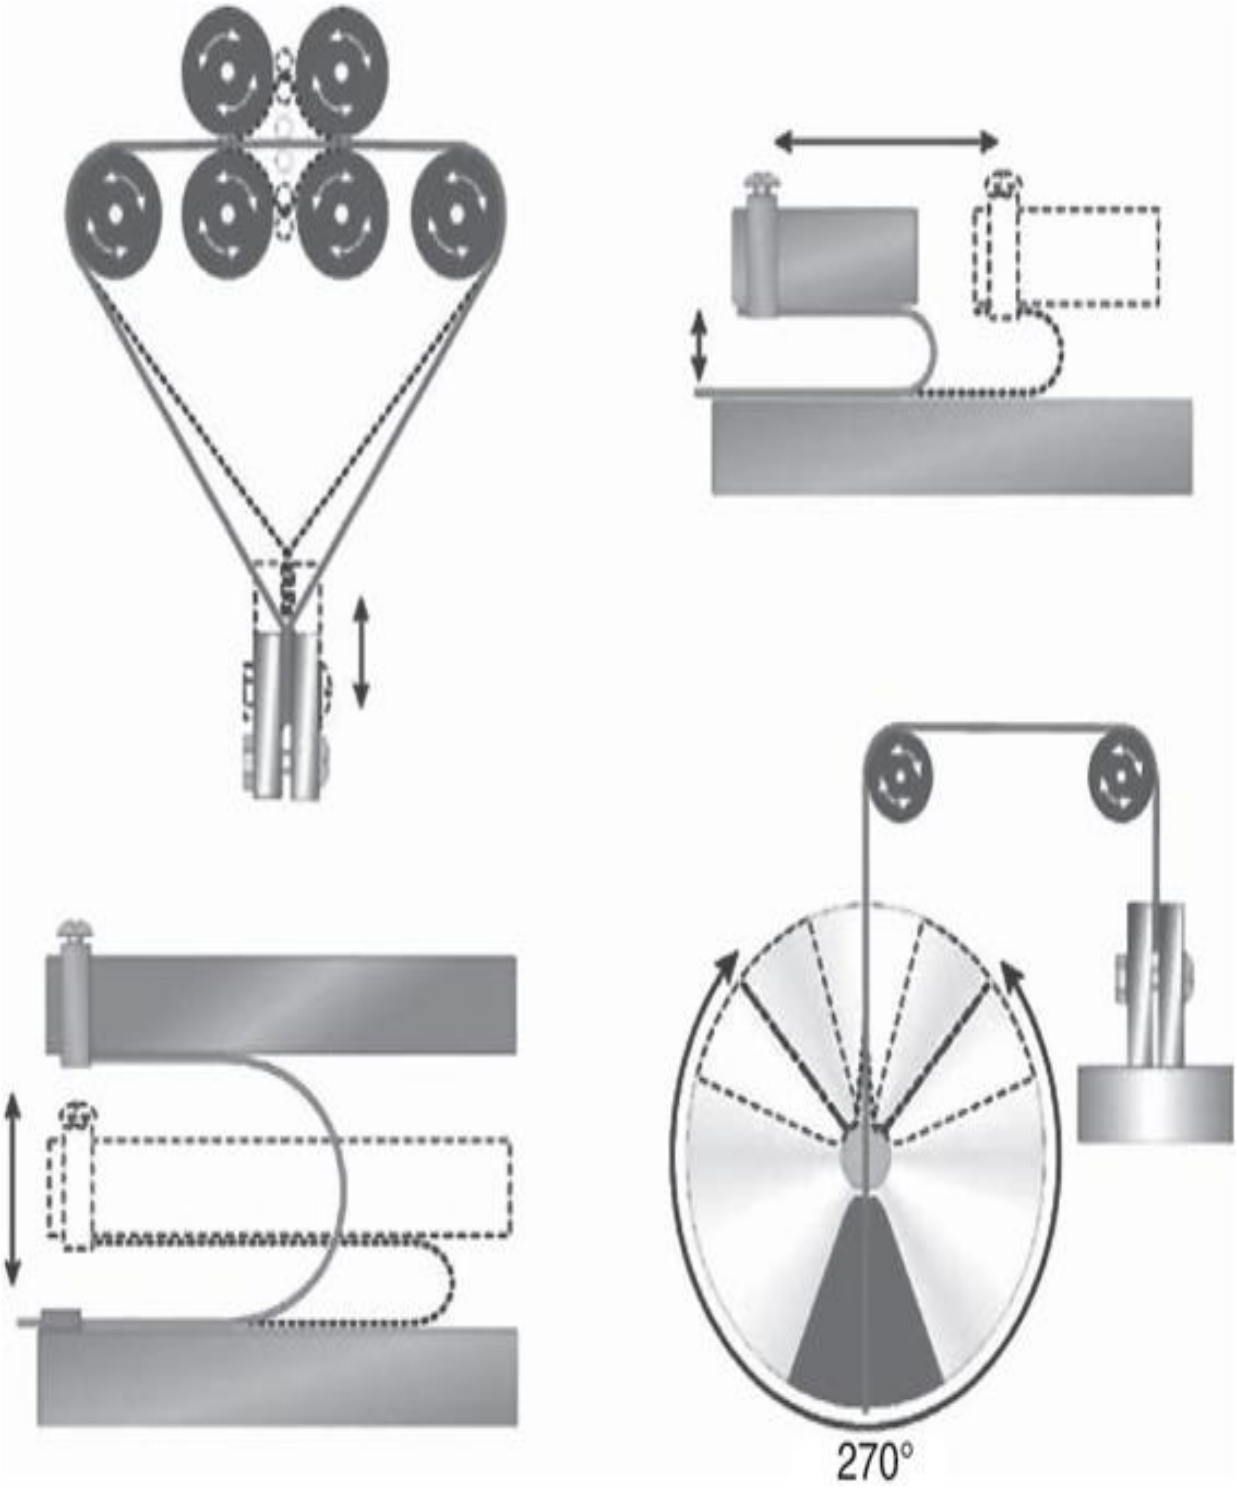

FIGURE 71.1 Examples of testing methods used to elvauate flexual endurance of flexible circuits. Clockwise from upper left: the Engelmaier fatigue ductility flex tester, rolling flex test (Rogers), MIT flex test, and collapsing radius (IBM/Xytratex).

71.8.2 Flexible Circuit Construction Integrity Requirements

The construction integrity of a flex circuit is best evaluated by performing a microscopic evaluation of a cross-section of the product before and after thermal stress testing. This type of inspection is used to reveal the presence of microscopic defects that may impact the reliability of the finished flex circuit. Inspections are performed both as received (prestressed) and after various thermal stress tests have been performed (postthermal stress). The tests are performed to ensure that product quality and reliability are not degraded by the thermal exposure endured during solder assembly and solder rework operations.

71.8.3 Prestress Evaluation Requirements for Flexible Circuits

The following points are evaluated before exposure to solder stress, to screen the product for the presence of defects in the product as received. Major faults detected here may preempt the need for further testing:

- *Lands or pads:* Checked to ensure that they have good adhesion to the substrate before stress testing. Land lifting is usually the result of thermal stress, where expansion of the heated laminate can cause lands to lose adhesion and lift from the surface of the circuit.
- *Plating integrity evaluation:* Checked to ensure that plating quality, uniformity, and thickness all meet specification requirements and that no cracks are present in the through-hole in order to ensure through-hole plating reliability.

- *Layer to layer registration evaluation:* Checked to ensure that minimum requirements for the given class of product are met. This is primarily a concern for multilayer and rigid flex constructions, but it can be a concern with double-sided flex as well.

71.8.4 Poststress Evaluation Requirements for Flexible Circuits

The following checks are performed after required thermal tests. Microscopic evaluation of plated-through-hole cross-sections after thermal stress testing is the approved method for determining ultimate plated-through-hole quality.

- *Thermal stress testing:* A particularly aggressive test developed to assess the effects of assembly simulation, thermal stress testing is a benchmark test within the industry when determining plated-through-hole quality. Historically the test involves placing a flux coated circuit coupon on a bath of molten solder held at a temperature of 289°C (550°F). It is a much more punishing test than typical assembly that is used to weed out marginal quality product. Other tests may be used including ones which simulate the actual manufacturing process such as passing the assembly through a conveyorized oven to simulate assembly conditions or the so-called interconnect stress test (IST), which involves passing a current through a daisy chain of plated-through holes, the current being sufficiently high to achieve temperatures proximate to those seen in a solder flow test.
- *Rework simulation testing:* Another challenging test of plated-through-hole reliability involves the soldering and desoldering of a component lead five times in the plated through-hole. The test was designed and is performed to simulate field repair and evaluate its effects on the flex

circuit’s plated-through-hole integrity. The test must be performed by a skilled operator because an uncontrolled soldering iron could cause significant damage.

- *Lifted lands:* The presence of lifted lands after eight thermal stress test is evaluated to try and determine the circuit construction’s capability in the field. The phenomenon is more common where outer layer circuits are built on materials having a high coefficient of thermal expansion which caused the pads to lift and rotate. Excessive incidents of lifted lands may require a redesign with new materials.

71.9 ELECTRICAL REQUIREMENTS FOR FLEXIBLE CIRCUITS

Finished flexible circuits are required to meet certain electrical requirements to ensure their performance in the field. The specific electrical requirements for the flex circuit are identified and specified to ensure proper electrical performance of the finished product. While the tests outlined below are ones most often called out for circuit acceptance, other tests such as time domain reflectometry (TDR) testing of controlled-impedance circuits may also be required under contract provisions.

- *Circuit continuity and shorting:* Flexible circuits should be electrically tested to make certain that no opens or shorts are present in the board. This testing will ensure conformance to design, and proper circuit performance in the field. Test conditions such as test voltage and minimum resistance between conductors should be called out on the master drawing. There are a range of different tools available for performing this type of testing which include both fixtured tooling systems as well as flying

probe heads. The choice of method is typically a function of volume and complexity.

- *Insulation resistance testing of flexible circuits:* A test which duplicates the raw material test and verifies that circuit manufacture processing has not degraded the insulation resistance of the material beyond customer-specified requirements.
- *Conductive anodic filament evaluation:* Conductive anodic filaments (CAF) are seen as fine conductive paths that form between two adjacent interconnects (e.g., PTH to ground plane). These filaments tend to develop over time in the end-use environment. The filaments have some common attributes. The growth is found between two conductive features that exhibit an electrical bias. It requires a source of moisture and a source of ionic contamination. The fiber grows down a path between the glass fiber and the epoxy matrix. This is obviously of greater concern with rigid flex where glass-reinforced epoxy laminates are made into hybrid structures with homogeneous flex circuit materials which are immune. The concern is that occasionally a conductive pathway is formed down cracks caused by delamination or cohesive failure. The filament growth is from the anodic circuit to the adjacent cathode. Frequently, the fiber shorts to the adjacent structure (e.g., through-hole) and, in the process of shorting, are destroyed by the electric potential, only to then grow again. This may produce an intermittent electrical short that is vexingly difficult to find. CAF testing has been limited to testing a specific coupon in an isotherm with constant humidity. No thermal cycling is employed during the test. The circuits are tested in a humidity chamber typically set to 65°C with 85°C relative humidity.

71.10 ENVIRONMENTAL RESISTANCE REQUIREMENTS

Flexible circuits are used in an ever broadening array of applications so understanding their performance under different environmental conditions is important. Thus certain environmental tests are performed to simulate, in a practical fashion, the effects of various environmental conditions on flex circuit quality, performance and reliability.

- *Moisture an insulation resistance testing:* In the performance of this test, circuits are cyclically exposed to hot, moist air (from 80 percent relative humidity at 25°C to 98 percent relative humidity at 65°C). This is to ensure that no damaging effects occur in the laminate and that undesirable degradation of the insulation resistance of the flex circuit has not occurred. Some variations to the test exist.
- *Thermal shock and thermal cycling:* A number of different types of tests and test conditions have been developed over the years all of which have some measure of acceptance under the broader heading of thermal shock and thermal cycle testing. Most tests consist of exposing the device to temperature extremes to induce thermal-cycle strain-related failures. Thermal cycling is meant to be representative of the temperature extremes a circuit might be exposed to during its lifetime. Cycling conditions range from −65°C to +150°C, with prescribed dwells at anywhere from 10 min to 1 h. Shock testing normally employs short dwell times. The most common temperature conditions for bare-board testing range from −55°C to +125°C. However, with the introduction of product-specific reliability testing by some manufacturers, several new thermal-cycling tests are becoming more common.

- *Cleanliness testing of flexible circuits:* Finished flex circuits must be tested to ensure that the circuits do not carry an excessive amount of ionic or organic contaminants with them. Surface contaminants both ionic and organic have been shown to have a negative effect on long-term reliability.
- *Ionic contamination testing:* It is commonly performed to determine the level of ionic material left on the board. Method most commonly employed is one called solvent extract resistivity testing. It is performed by washing the board using a pure alcohol/water solvent, collecting the solvent and measuring its change in resistance. Ionic contaminants, if left on the board, are capable of causing latent failures due to corrosion and current leakage or shorting.
- *Organic contaminant testing:* Organic contaminants are another potential source of problems that should not remain on the circuit. The contamination can be detected by flushing the surface of a small sample of the circuit with chemically pure acetonitrile onto a clean glass surface and allowing the solvent to evaporate. Residue on the slide may indicate the presence of organic contaminants.

71.11 SOLDERABILITY REQUIREMENTS

A subject unto itself measure of solderability of all circuit substrates is considered vital. Tests for solderability of the finished circuit are performed to ascertain that the flexible circuit will not experience or create problems in assembly operations due to a nonwetting condition. This is normally accomplished by checking that proper wetting of solderable surfaces is present after testing in accordance with an approved test method. EIA/IPC-J-Standard-001 is the

reference standard for all electronic applications across the industry and around the globe. A more detailed discussion of this topic can be found elsewhere in this book.

71.12 STANDARDS AND SPECIFICATIONS FOR FLEXIBLE CIRCUITS

There are a wide array of different standards from different parts of the world which have been promulgated to serve the needs of flexible circuits. Most of the major standards associations have generated new standards or upgraded existing ones for flexible circuits. Following is a listing of some of the most prominent flexible circuit standards developers and custodians.

ANSI (American National Standards Institute)

ANSI-Y-145: Dimensioning and Tolerancing

IEC (**International Electrotechnical Commission)**

IEC 249-2-15: Flexible copper-clad polyimide film of defined flammability grade

IEC 326-7: Specification for single- and double-sided flexible printed boards without through-hole connections

IEC 326-8: Specification for single- and double-sided flexible printed boards with through-hole connections

IEC 326-9: Specification for multilayer flexible printed boards with through-hole connections

IEC 326-10: Specification for flex/rigid double-sided printed boards with through-hole connections

IEC 326-11: Specification for flex/rigid multilayer printed boards with through-hole connections

IPC (Association Connecting Electronics Industries)

2221B: Generic Standard on Printed Board Design

2223C: Sectional Design Standard for Flexible Printed Boards (Formerly IPC-D-249)

2611: Generic Requirements for Electronic Product Documentation

2614: Sectional Requirements for Board Fabrication Documentation

4202A: Flexible Base Dielectrics for Use in Flexible Printed Circuitry (Formerly IPC-FC-231)

4203A: Cover and Bonding Material for Flexible Printed Circuitry (Formerly IPC-FC-232)

4204A: Flexible Metal-Clad Dielectrics for Use in Fabrication of Flexible Printed Circuitry (Formerly IPC-FC-241

4412B: Specification for Finished Fabric Woven from “E” Glass for Printed Boards

4562A: Metal Foil for Printed Board Applications (Formerly IPC-MF-150)

6011: Generic Performance Specification for Printed Boards

6013C: Qualification and Performance Specification for Flexible Printed Boards

9252A: Requirements for Electrical Testing of Unpopulated Printed Boards

A-600H: Acceptability of Printed Boards

DR-572A: Drilling Guidelines for Printed Boards

FC-234A: Pressure Sensitive Adhesive (PSA) Assembly Guidelines for Flexible, Rigid or Rigid-Flex Printed Boards

J-STD-001 Requirements for Soldered Electrical and Electronics Assemblies

J-STD-002 Solderability Tests for Component Leads, Terminations, Lugs, Terminals and Wires

J-STD-003 Solderability Tests for Printed Boards

J-STD-004 Requirements for Soldering Fluxes

J-STD-005 General Requirements and Test Methods for Electronic Grade Solder Paste

J-STD-006 General Requirements and Test Methods for Soft Solder Alloys and Fluxed and Non-Fluxed Solid Solder for Electronic Soldering Applications.

JIS (Japanese Industrial Standards)

JIS-C 5016: Test methods for flexible printed wiring boards

JIS-C 5017: Flexible printed wiring boards, single-sided and double-sided

JIS-C 6471: Test methods for copper-clad laminates of flexible printed wiring boards

JIS-C 6472: Copper-clad laminates for flexible printed wiring boards (polyester film, polyimide film)

JPCA (Japanese Printed Circuit Association)

JPCA-BM 01: Copper-clad laminates of flexible printed circuits, polyester films, and polyimide films

JPCA-FC 01: Single-sided flexible printed circuits

JPCA-FC 02: Double-sided flexible printed circuits

JPCA-FC 03: Visual defect criteria for flexible printed circuits

MIL (US Military Standard)

MIL-STD-2118: Flexible and rigid-flex printed-wiring for electronic equipment

MIL-C-28809: Circuit card assemblies, rigid, flexible and rigid-flex

MIL-P-50884C: Printed wiring, flexible, and rigid-flex

MIL-STD-105 Sampling Procedures and Inspection Tables

MIL-STD-129 Marking for Shipment and Storage

MIL-STD-130 Identification for Marking

MIL-STD-202 Test Methods for Electronic Equipment

MIL-STD-2000 Soldering and Assembly

MIL-STD-45662 Calibration System Requirements

DOD-D-1000 Engineering Drawings

DOD-STD-100 Engineering Drawing Practices

MIL-S-13949 Plastic Sheet, Laminate, Metal Clad (for PWBs)

MIL-C-14550 Copper Plating (Electrodeposited)

MIL-I-43553 Ink Marking, Epoxy Base

MIL-G-45204 Gold Plating (Electrodeposited)

MIL-I-45208 Inspection System Requirements

MIL-Q-9858 Quality Program Requirements

MIL-P-81728 Plating Tin Lead (Electrodeposited)

MIL-P-55110 Printed Wiring Boards

QQ-N-290 Nickel Plating (Electrodeposited)

UL (Underwriters Laboratories)

UL796F: Flexible materials interconnect constructions

71.13 SUMMARY

There are many tests and inspection steps employed to ensure the reliability of flexible and rigid flex circuits. It is important to note that not all tests are required for every lot. Testing is typically split into two levels: tests required for qualification and tests required for acceptance. Of these two, acceptance testing is more limited in scope, which helps to reduce some of the testing requirements. An effectively run

manufacturing operation is one that rigorously employs statistical process control (SPC) methods. The use of statistical process control, by a quality assurance department, can significantly reduce the need for formal inspection operations by keeping the processes under constant control. Using SPC, it is possible to achieve desired levels of performance and reliability at no extra cost, or even at a reduced cost. Employment of SPC methods is becoming a customer requirement for an increasing number of flex circuit users and is a key conceptual foundation for the ISO-9000 certification program, which is becoming a de facto standard for the world market.

71.14 ACKNOWLEDGMENTS

The author extends his appreciation to the industry and the many who contributed to the progress of flexible circuit activities. Sincere thanks also goes to Dominique K. Numakura, at DKN Research, for his authorship of this chapter in the previous (6th) edition of *Printed Circuits Handbook*.

APPENDIX

SUMMARY OF KEY COMPONENT, MATERIAL, PROCESS, AND DESIGN STANDARDS

Marc Carter

IPC—Association Connecting Electronics Industries, Bannockburn, Illinois

Appropriately selected, properly applied standards are the one of the keys to a globally successful electronics community. They serve as a common “language” between the various participants in the supply chain from early concept, through final delivery, and commercial and technical conflict resolution. By using mutually accepted preexisting standards, two parties to a contract need not recreate every technical definition or requirement for every transaction, greatly facilitating commerce.

The following documents emphasize surface-mount technology. These documents have been developed by standards organizations around the world. The letters in

each document designation indicate the organization that has responsibility for the document. Current details (abstracts, publication revisions, additional supporting documents, etc.) should be obtained at the organization's website/online store. As this is a "living" body of documents and organizations that support them, some documents may become unavailable after this list was compiled.

The reader may also note some apparent overlap where two organizations provide standards for the what appears to be the same entity or process. In some cases, that may reflect historical separation, or a simple failure to coordinate activities. In other cases, the two standards legitimately exist to address different needs, or different markets. It is important for the parties in a supply chain to reach agreement on what standards are most appropriate for their marketplace. In recent years, there has been some increase in communication and coordination between Standards Development Organizations (SDOs) to reduce wasteful overlap, though improvements are still needed.

DoD: Documents prepared by the Department of Defense.

ECA: Documents prepared by the Electronic Components, Assemblies, Equipment and Supplies Association (ECA) of the Electronic Industries Alliance (EIA). EIA ceased operations in 2011 but standard activities under the EIA Standards Council (ESC) continue under the auspices of the Electronic Components Industry Association (ECIA).

IEC: Documents prepared by the IEC—International Electrotechnical Commission.

IECQ: Documents prepared for Quality Assessment System for Electronic Components supported through the IEC.

IPC: Documents prepared by the IPC—Association Connecting Electronics Industries.

JEDEC: Documents of the Solid State Technology Association of the Electronic Industries Alliance (EIA).

JESD: Standards prepared by JEDEC.

JPCA: Standards prepared by JPCA.

J-STD: Joint industry standards (standards followed by more than one association).

MIL: Documents prepared by the military.

COMPONENTS—GENERAL

EIA-186-E: Standard Test Methods for Passive Electronic Component Parts—General Instructions and Index

EIA-481-2-A: Embossed Carrier Taping of Surface Mount Components for Automatic Handling (16, 24, 32, 44, and 56 mm)

EIA-944: Surface Mount Ferrite Chip Bead Qualification Specification

EIA-945: Surface Mount Inductor Qualification Specification

EIA/IS-47: Contact Termination Finish Standard for Surface Mount Devices

EIA/IS-760: Surface Mount Wirewound Inductor Qualification Specification

EIA-JEP-95: JEDEC Registered and Standard Outlines for Solid State and Related Products

EIA-JESD30B: Descriptive Designation System for Semiconductor Device Packages

EIA-PDP-100: Registered and Standard Mechanical Outlines for Electronic Parts

JESD-625A: Requirements for Handling Electrostatic-Discharge-Sensitive (ESDS) Devices

PASSIVE COMPONENTS

Capacitors

ECA SP 4984: Surface Mount Aluminum Electrolytic Chip Capacitor with Polymer Cathode

EIA-198-E: Ceramic Dielectric Capacitors Classes I, II, III, and IV

EIA-469-C: Standard Test Method for Destructive Physical Analysis of High Reliability Ceramic Monolithic Capacitors

EIA-479A: Film-Paper, Film Dielectric Capacitors for 50/60 Hz Voltage Doubler Power Supplies

EIA-535: Series of Detail Specifications on Fixed Tantalum Capacitors

EIA-595: Visual and Mechanical Inspection Multilayer Ceramic Chip Capacitors

EIA/IS-35: Two-Pin Dual In-Line Capacitors

EIA/IS-36: Chip Capacitors, Multilayer (Ceramic Dielectric)

EIA/IS-37: Multiple Layer High Voltage Capacitors (Radial Lead Chip Capacitors)

EIA/IS-717: Surface Mount Tantalum Capacitor Qualification Specification

IEC-384-3: Sectional Specification, Tantalum Chip Capacitors

IEC-384-10: Sectional Specification, Fixed Multilayer Ceramic Chip Capacitors

IECQ Draft: Blank Detail Specification, Fixed Multilayer Ceramic Chip Capacitors

IECQ-PQC-31: Sectional Specification, Fixed Tantalum Chip Capacitors with Solid Electrolyte

IECQ-PQC-32: Blank Detail Specification, Fixed Tantalum Chip Capacitor

Resistors

ECA SP 5052: Resistors, Rectangular, Surface Mount, General Purpose

ECA SP 5053: Resistors, Rectangular, Surface Mount, Precision

EIA/ECA-575: Thick Film Resistor Specification

EIA/ECA-576: Resistors, Rectangular, Surface Mount Precision

EIA/IS-30: Resistors, Rectangular Surface Mount Thick Film

EIA/IS-34: Leaded Surface Mount Resistor Networks, Fixed Film

EIA/RS-344: Low Power, Insulated Fixed Wirewound Resistors

EIA/RS-345: Resistors, Variable, Wirewound (Lead-Screw Actuated)

EIA/RS-360: Resistors, Variable (Lead-Screw Actuated) Nonwirewound

EIA/RS-396: Resistors, Fixed Film Microelement

EIA/RS-451: Resistor Networks—Fixed Film

EIA/RS-452: Fixed Film Resistors—High Resistance/High Voltage

EIA/RS-460: Fixed Film Resistors—General Purpose

ACTIVE COMPONENTS

EIA-JEP-95: JEDEC Registered and Standard Outlines for Solid State and Related Products

EIA-JESD11: Chip Carrier Pinouts Standardized for CMOS 4000, HC, and HCT Series of Logic Circuits

EIA-JESD21-C: Configurations for Solid State Memories

EIA-JESD22-B: Test Methods and Procedures for Solid State Devices Used in Transportation/Automotive Applications (series format—consists of over 16 different test procedure documents)

EIA-JESD-26A: General Specification for Plastic Encapsulated Microcircuits for Use in Rugged Applications

EIA-JESD-30: Descriptive Designation System for Semiconductor Device Packages

EIA SP 4251 Detail Specification for Production Ball Grid Array (BGA), High Pin Count (1089 Pins and Greater) Socket for Use in Electronic Equipment

ELECTROMECHANICAL COMPONENTS

Connectors

EIA-364-C: Electrical Connector/Socket Test Procedures Including Environmental Classifications

EIA/IS-47: Contact Termination Finish Standard for Surface Mount Devices

IPC-CI-408: Design and Application Guidelines for the Use of Solderless Surface Mount Connectors

Sockets

EIA-5400000: Generic Specification for Sockets for Use in Electronic Equipment

EIA-540H000: Sectional Specification for Burn-In Sockets Used with Ball Grid Array Devices for Use in Electronic Equipment

Switches

EIA-448-23: Surface Mountable Switches, Qualification Test

EIA-520AAAD: Detail Specification for Single Pole, Single Throw, Surface Mount Pushbutton Switches

EIA-520DAAD: Detail Specification for Single Pole, Double Throw, Surface Mount Subminiature Size Toggle Switches

EIA-5200000-C: Generic Specification for Special-Use Electromechanical Switches of Certified Quality

EIA-SP-2186: Detail Specification for Single Pole, Double Throw, Surface Mount Subminiature Size Toggle Switches

EIA-SP-3162: Detail Specification for Single Pole, Single Throw, Surface Mount Pushbutton Switches

IECQ-PQC-41: Detail Specification, Dual-in-Line Switch, Surface Mountable, Slide Actuated US0003

Printed Boards

IPC-6011: General Performance Requirements for Printed Boards

IPC-6012: Performance Specification for Rigid Printed Boards

IPC-6013: Performance Specification for Flexible Printed Boards

IPC-6015: Performance Specification for Organic Multichip Module Structures (MCM-L)

IPC-6016: Qualification and Performance Specification for High-Density Interconnect (HDI) Layers or Boards

IPC-6017: Qualification and Performance Specification for Printed Boards Containing Embedded Passive Devices

IPC-6018: Microwave End Product Board Inspection and Test

JPCA DG-04: Flexible Printed Wiring Boards and Material for Flexible Printed Wiring Boards Integrated Standard

MIL-P-50884: Military Specification for Printed Wiring, Flexible, and Rigid Flex

MIL-P-55110: Printed Wiring Boards, Rigid General Specification for Performance

MIL-PRF-31032: Printed Circuit Board/Printed Wiring Board Manufacturing, General Specification

Materials

IPC-3406: Guidelines for Electrically Conductive Surface Mount Adhesive

IPC-3407: General Requirements for Isotropically Conductive Adhesives

IPC-3408: General Requirements for Anisotropically Conductive Adhesive Films

IPC-4101: Specification for Base Materials for Rigid and Multilayer Boards

IPC-4103: Specification for Plastic Substrates, Clad or Unclad, for High-Speed/High-Frequency Interconnection

IPC-4110: Specification and Characterization Methods for Nonwoven Cellulose Based Paper for Printed Boards

IPC-4121: Guidelines for Selecting Core Constructions for Multilayer Printed Wiring Board Applications

IPC-4130: Specification and Characterization Methods for Nonwoven “E” Glass Mat

IPC-4202: Flexible Base Dielectrics for Use in Flexible Printed Wiring

IPC-4203: Adhesive Coated Dielectric Films for Use as Cover Sheets

IPC-4204: Flexible Metal-Clad Dielectrics for Use in Fabrication of Flexible Printed Circuitry

IPC-4411: Specification and Characterization Methods for Nonwoven Para-Aramid Reinforcement

IPC-4412: Specification for Finished Fabric Woven form “E” Glass for Printed Boards

IPC-4552: Specification for Electroless Nickel/Immersion Gold (ENIG) Plating for Printed Circuit Boards

IPC-4553: Specification for Immersion Silver Plating for Printed Circuit Boards

IPC-4562: Metal Foil for Printed Wiring Applications

IPC-CC-830A: Qualification and Performance of Electrical Insulation Compounds for Printed Board Assemblies

IPC-CF-148: Resin Coated Metal for Multilayer Printed Boards

IPC-CF-152A: Metallic Foil Specification for Copper/Invar/Copper (CIC) for Printed Wiring and Other Related Applications

IPC/JPCA-4104: Specification for High-Density Interconnect (HDI) and Microvia Materials

IPC-SM-840C: Qualification and Performance of Permanent Solder Mask for Printed Boards

J-STD-004: Requirements for Soldering Fluxes

J-STD-005: General Requirements and Test Methods for Electronic Grade Solder Paste

J-STD-006: General Requirements and Test Methods for Soft Solder Alloys and Fluxed and Non Fluxed Solid Solders for Electronic Soldering Applications

DESIGN ACTIVITIES

IPC-1902: Grid Systems for Printed Circuits (equivalent to IEC 60097)

IPC-2141: Controlled Impedance Circuit Boards and High-Speed Logic Design

IPC-2221: Generic Standard on Printed Board Design

IPC-2222: Sectional Design Standard for Rigid Organic Printed Boards

IPC-2223: Sectional Design Standard for Flexible Printed Boards

IPC-2224: Sectional Standard for Design of PWBs for PC Cards

IPC-2225: Sectional Design Standard for Organic Multichip Modules (MCM-L) and MCM-L Assemblies

IPC-2226: Design Standard for High-Density Array or Peripheral Leaded Component Mounting Structures

IPC-2251: Design Guidelines for Electronic Packaging Utilizing High-Speed Techniques

IPC-2252: Design and Manufacturing Guide for RF/Microwave Circuit Boards

IPC-2615: Printed Board Dimensions and Tolerances

IPC-7351: Generic Requirements for Surface Mount Design and Land Pattern Standard

IPC-7525: Guidelines for Stencil Design

IPC-7530: Guidelines for Temperature Profiling for Mass Soldering (Wave and Reflow) Processes

IPC-C-406: Design and Application Guidelines for Surface Mount Connectors

IPC-D-279: Reliability Design Guidelines for Surface Mount Technology Printed Board Assemblies

IPC/JPCA-2315: Design Guide for High-Density Interconnects (HDI) and Microvia

JPCA DG-01: Multilayer Printed Wiring Board Design Guide

JPCA DG-02: Double-Sided and Single-Sided Design Guide Manual, Flexible Printed Wiring Board

JPCA DG-04: Flexible Printed Wiring Boards and Material for Flexible Printed Wiring Boards Integrated Standard

J-STD-026: Semiconductor Design Standard for Flip Chip Applications

J-STD-027: Mechanical Outline Standard for Flip Chip or Chip Scale Configurations

COMPONENT MOUNTING

EIA-CB-11: Guidelines for the Surface Mounting of Multilayer Ceramic Chip Capacitors

IPC-4104: Specification for High-Density Interconnect (HDI) and Microvia Materials

IPC-6016: Qualification and Performance Specification for High-Density Interconnect (HDI) Layers or Boards

IPC-7093: Design and Assembly Process Implementation for Bottom Termination Components

IPC-7094: Design and Assembly Process Implementation for Flip Chip and Die Size Components

IPC-7095: Design and Assembly Process Implementation for BGAs

IPC-CM-770D: Guidelines for Printed Board Component Mounting

IPC/JPCA-2315: Design Guide for High-Density Interconnects (HDI) and Microvias

IPC-MC-790: Guidelines for Multichip Module Technology Utilization

IPC-SM-780: Electronic Component Packaging and Interconnection with Emphasis on Surface Mounting

IPC-SM-784: Guidelines for Direct Chip Attachment

J-STD-032: Performance Standard for Ball Grid Array Bumps and Columns

SOLDERING AND SOLDERABILITY

EIA-448-19: Method 19: Test Standard for Electromechanical Components, Environmental Effects of Machine Soldering Using a Vapor Phase System

EIA-534: Applications Guide, Soldering and Solderability Maintenance of Leaded Electronic Components

EIA-638: Surface Mount Solderability Test

EIA/IS-46: Test Procedure for Resistance to Soldering (Vapor Phase Technique) for Surface Mount Devices

EIA/IS-86: Surface Mount Solderability Test

EIA SP 3408: Surface Mount Solderability Test

IPC-AJ-820: Assembly and Joining Handbook

IPC-HDBK-001: Handbook and Guide to the Requirements for Soldered Electrical and Electronic Assemblies

IPC-S-816: Troubleshooting for Surface Mount Soldering

IPC-TR-460A: Troubleshooting Checklist for Wave Soldering Printed Wiring Boards

IPC-TR-462: Solderability Evaluation of Printed Boards with Protective Coatings over Long-Term Storage

IPC-TR-464: Accelerated Aging for Solderability Evaluations

JESD22: B102C Solderability Test Methods

J-STD-001: Requirements for Soldered Electrical and Electronic Assemblies

J-STD-002: Solderability Tests for Component Leads, Terminations, Lugs, Terminals, and Wires

J-STD-003: Solderability Tests of Printed Boards

QUALITY ASSESSMENT

IPC-7912: Calculation of DPMO and Manufacturing Indices for Printed Wiring Assemblies

IPC-9191: General Guideline for Implementation of Statistical Process Control (SPC)

IPC-9194: Implementation of Statistical Process Control (SPC) Applied to Printed Board Assembly Manufacture Guideline

IPC-9199: SPC Quality Rating

IPC-9201: Surface Insulation Resistance Handbook

IPC-9251: Test Vehicles for Evaluating Fine Line Capability

IPC-9252: Guidelines and Requirements for Electrical Testing of Unpopulated Printed Boards

IPC-9261: In-Process DPMO and Estimated Yield for PWAs

IPC-A-20/21: Stencil Pattern for Solder Paste Slump Test

IPC-A-24: Flux/Board Interaction Board

IPC-A-36: CFC Cleaning Alternatives Artwork

IPC-A-38: Fine Line Round Robin Test Pattern

IPC-A-48: Surface Mount Airforce Mantech Artwork

IPC-A-600: Acceptability of Printed Boards

IPC-A-610: Acceptability of Printed Board Assemblies

IPC/JEDEC-033: Standard for Handling, Packing, Shipping and Use of Moisture Reflow Sensitive Surface Mount Devices

IPC/JEDEC J-STD-020: Moisture/Reflow Sensitivity Classification for Plastic Integrated Circuits Surface Mount Devices

IPC/JEDEC J-STD-035: Acoustic Microscopy for Nonhermetic Encapsulated Electronic Components

JEDEC JEP-150: Stress-Test-Driven Qualification of and Failure Mechanisms Associated with Assembled Solid State Surface Mount Components

JEDEC JEP-179: Stress-Test-Driven Qualification of and Failure Mechanisms Associated with Assembled Solid State Surface Mount Components

JEDEC JESD-51-3: Low Effective Thermal Conductivity Test Board for Leaded Surface Mount Packages

JEDEC JESD-51-5: Extension of Thermal Test Board Standards for Packages with Direct Thermal Attachment Mechanisms

JEDEC JESD-51-7: High Effective Thermal Conductivity Test Board for Leaded Surface Mount Packages

JEDEC JESD-51-9: Test Boards for Area Array Surface Mount Package Thermal Measurements

JEDEC JESD-51-10: Test Boards for Through-Hole Perimeter Leaded Package Thermal Measurements

JEDEC JESD 51-11 Test Boards for Through-Hole Area Array Leaded Package Thermal Measurements

J-STD-028: Performance Standard for Flip Chip/Chip Scale Bumps

MIL-STD-883: Methods and Procedures for Microelectronics

SURFACE MOUNT PROCESS

IPC-5701: Users Guide for Cleanliness of Unpopulated Printed Boards

IPC-AC-62: Post Solder Aqueous Cleaning Handbook

IPC-CH-65: Guidelines for Cleaning of Printed Boards and Assemblies

IPC-SA-61: Post Solder Semi Aqueous Cleaning Handbook

IPC-SC-60: Post Solder Solvent Cleaning Handbook

RELIABILITY

IPC-9151: Printed Board Capability, Quality and Relative Reliability ($PCQR^2$) Benchmark Test Standard and Database

IPC-D-279: Design Guidelines for Reliable Surface Mount Technology Printed Board Assemblies

IPC-SM-785: Guidelines for Accelerated Surface Mount Attachment Reliability Testing

JEDEC JESD 22-A113: Preconditioning of Nonhermetic Surface Mount Devices Prior to Reliability Testing

JEDEC JESD 22-B113: Board Level Cyclic Bend Test Method for Interconnect Reliability Characterization of Components for Handheld Electronic Products

DATA TRANSFER STANDARDS

EIA-267-C: Axis and Motion Nomenclature for Numerically Controlled Machines

EIA-274-D: Interchangeable Variable Block Data Contouring, Format for Positioning and Contouring/Positioning Numerically Controlled Machines

EIA-358-C: ANSI X3.4 American National Standard Code for Information Interchange for Numerical Machine Control Perforated Tape

EIA-408: Interface between Numerical Control Equipment on Data Terminal Equipment Employing Parallel Binary Data Interchange

EIA-431: Electrical Interface between Numerical Control and Machine Tools

EIA-441: Operator Interface Function of Numerical Controls

EIA-484-A: Electrical and Mechanical Interface Characteristics and Line Control Protocol Using Communication Control Characters for Serial Data Link between a Direct Numerical Control System and Numerical Control Equipment Employing Asynchronous Full Duplex Transmission

EIA-494-B: 32 Bit Binary CL (BCL) and 7 Bit ASCII CL (ACL) Exchange Input Format for Numerically Controlled Machines

IPC-2511: Generic Requirements for Implementation of Product Manufacturing Description Data and Transfer Methodology

IPC-2512: Sectional Requirements for Implementation of Administrative Methods for Manufacturing Data Description

IPC-2513: Sectional Requirements for Implementation of Drawing Methods for Manufacturing Data Description

IPC-2514: Sectional Requirements for Implementation of Printed Board Manufacturing Data Description

IPC-2515: Sectional Requirements for Implementation of Bare Board Product Electrical Testing Data Description

IPC-2516: Sectional Requirements for Implementation of Assembled Board Product Manufacturing Data Description

IPC-2517: Sectional Requirements for Implementation of Assembly Circuit Testing Data Description

IPC-2518: Sectional Requirements for Implementation of Bill of Material Product Data Description

IPC-2581 Generic Requirements for Printed Board Assembly Products Manufacturing Description Data and Transfer Methodology

TEST METHODS

EIA-469-C: Standard Test Method for Destructive Physical Analysis of High Reliability Ceramic Monolithic Capacitors

EIA-638: Surface Mount Solderability Test

EIA/IS-722: Fixed Capacitors for Use in Electronic Equipment; Part 1: Generic specification

EIA IS 46: Test Procedure for Resistance to Soldering (Vapor Phase Technique) for Surface Mount Devices

IPC-9501: PWB Assembly Process Simulation for Evaluation of Electronic Components

IPC-9502: PWB Assembly Soldering Process Guidelines for Non-IC Electronic Components

IPC-9503: Moisture Sensitivity Classification for Non-IC Components

IPC-9504: Assembly Process Simulation for Evaluation of Non-IC Components

IPC-9701: Qualification and Performance Test Methods for Surface Mount Solder Attachments

IPC-9850: Surface Mount Equipment Performance Characterization

IPC/JEDEC-9702: Monotonic Bend Characterization of Board-Level Interconnects

IPC/JPCA-6801: Terms & Definitions, Test Methods, and Design Examples for Build-Up/High-Density Interconnection

IPC-TM-650: Test Methods Manual

JEDEC JESD 22-A111: Evaluation Procedure for Determining Capability to Bottom Side Board Attach by Full Body Solder Immersion of Small Surface Mount Solid State Devices

JEDEC JESD 22-A112: Test Method A112, Moisture-Induced Stress Sensitivity for Plastic Surface Mount Devices

JEDEC JESD 22-B105-B: Test Method Lead Integrity

JEDEC JESD 22-B106: Test Method B106c, Resistance to Soldering Temperature for Through-Hole Mounted Devices

JEDEC JESD 22-B108: Coplanarity Test for Surface Mount Semiconductor Devices

JEDEC JESD 22-B117: BGA Ball Shear

JEDEC JESD 51-8: Integrated Circuit Thermal Test Method Environmental Conditions Junction-to-Board

JEDEC Standard 22 Series: Test Methods

REPAIR

IPC-7711A/7721A: Rework, Repair and Modification of Electronic Assemblies

TERMS AND DEFINITIONS

IPC-T-50F: Terms and Definitions for Interconnecting and Packaging Electronic Circuits

JEDEC JEP 99: Glossary of Microelectronic Terms, Definitions, Symbology

JEDEC JESD 12-1: Terms and Definitions for Gate Arrays and Cell-Based Integrated Circuits

JEDEC JESD 77: Terms, Definitions, and Letter Symbols for Discrete Semiconductor and Optoelectronic Devices

JEDEC JESD 99: Terms, Definitions, and Letter Symbols for Microelectronic Devices

JEDEC JESD 100: Terms, Definitions, and Letter Symbols for Microcomputers, Microprocessors, and Memory Integrated Circuits

HOW TO OBTAIN THESE DOCUMENTS

Following are the addresses of the IPC and ECIA, as well as other sources for documents shown in this SMT listing:

IPC—Association Connecting Electronics Industries

3000 Lakeside Drive #309S

Bannockburn, IL 60015

Phone: (847) 615-7100

Electronic Components Industry Association (ECIA)

1111 Alderman Drive, Suite 400

Alpharetta, GA 30005
Phone: (678) 393-9998

JEDEC
3103 North 10th Street, Suite 240-S
Arlington, VA 22201-2017
Phone: (703) 624-9230

Global Engineering Documents
15 Inverness Way
East Englewood, CO 80112
Phone: (800) 854-7179

Military documents are available from the following address:

Standardization Documents Order Desk
Building 4D, 700 Robbins Avenue
Philadelphia, PA 19111-5094

Central office address of the IEC is as follows:

International Electrotechnical Commission (IEC)
3 Rue de Varembe
1211 Geneva 20, Switzerland

IEC documents are available from the following address:

American National Standards Institute (ANSI)
11 West 42nd Street
New York, NY 10036

GLOSSARY[a]

ACCELERATOR: A chemical that is used to speed up a reaction or cure, as cobalt naphthenate is used to accelerate the reaction of certain polyester resins. It is often used along with a catalyst, hardener, or curing agent. The term “accelerator” is often used interchangeably with the term “promoter.”

ACCURACY: The ability to place the hole at the targeted location.

ADDITIVE PROCESS: A process for obtaining conductive patterns by the selective deposition of conductive material on an unclad base material.

ADHESIVE: Broadly, any substance used in promoting and maintaining a bond between two materials.

AGING: The change in properties of a material with time under specific conditions.

ANNULAR RING: The circular strip of conductive material that completely surrounds a hole.

ARC RESISTANCE: The time required for an arc to establish a conductive path in a material.

ARTWORK MASTER: An accurately scaled configuration used to produce the production master.

BACKUP MATERIAL: A material placed on the bottom of a laminate stack in which the drill terminates its drilling stroke.

BASE MATERIAL: The insulating material upon which the printed wiring pattern may be formed.

BASE MATERIAL THICKNESS: The thickness of the base material excluding metal foil cladding or material deposited on the surface.

BLIND VIA: Conductive surface hole that connects an outerlayer with an innerlayer of a multilayer PWB without penetrating the entire board.

BLISTERING: Localized swelling and separation between any of the layers of the base laminate or between the laminate and the metal cladding.

BONDING LAYER: An adhesive layer used in bonding other discrete layers during lamination.

BOND STRENGTH: The force per unit area required to separate two adjacent layers by a force perpendicular to the board surface; usually refers to the interface between copper and base material.

BOW: A laminate defect in which deviation from planarity results in a smooth arc.

B-STAGE: An intermediate stage in the curing of a thermosetting resin. In it a resin can be heated and caused to flow, thereby allowing final curing in the desired shape.

B-STAGE LOT: The product from a single mix of B-stage ingredients.

B-STAGE RESIN: A resin in an intermediate stage of a thermosetting reaction. The material softens when heated and swells when in contact with certain liquids, but it may not entirely fuse or dissolve.

BURIED VIA: Conductive surface hole that connects one innerlayer to another innerlayer of a multilayer PWB without having a direct connection to either the top or bottom surface layer.

BURR: A ridge left on the outside copper surfaces after drilling.

CAPACITANCE: The property of a system of conductors and dielectrics which permits the storage of electricity when

potential difference exists between the conductors.

CAPACITIVE COUPLING: The electrical interaction between two conductors caused by the capacitance between the conductors.

CARBIDE: Tungsten carbide, formula WC. The hard, refractory material forming the drill bits used in PWB drillings.

CATALYST: A chemical that causes or speeds up the cure of a resin but does not become a chemical part of the final product.

CERAMIC LEADED CHIP CARRIER (CLCC): A chip carrier made from ceramic (usually a 90 to 96 percent alumina or beryllia base) and with compliant leads for terminations.

CHIP CARRIER (CC): An integrated circuit package, usually square, with a chip cavity in the center; its connections are usually on all four sides. (See *leaded chip carrier* and *leadless chip carrier*.)

CHIP LOAD (CL): The movement of the drill downward per revolution; usually given in mils (thousandths of an inch) per revolution.

CHLORINATED HYDROCARBON: An organic compound having chlorine atoms in its chemical structure. Trichloroethylene, methyl chloroform, and methylene chloride are chlorinated hydrocarbons.

CIRCUIT: The interconnection of a number of electrical devices in one or more closed paths to perform a desired electrical or electronic function.

CLAD: A condition of the base material, to which a relatively thin layer or sheet of metal foil (cladding) has been bonded on one or both of its sides. The result is called a metal-clad base material.

CNC: Computer numerically controlled. Refers to a machine with a computer which stores the numerical information about location, drill size, and machine parameters, regulating the machine to carry out that information.

COAT: To cover with a finishing, protecting, or enclosing layer of any compound.

COLD FLOW: The continuing dimensional change that follows initial instantaneous deformation in a nonrigid material under static load. Also called creep.

COLLIMATION: The degree of parallelism of light rays from a given source. A light source with good collimation produces parallel light rays, whereas a poor light source produces divergent, nonparallel light rays.

COMPONENT HOLE: A hole used for the attachment and electrical connection of a component termination, including pin or wire, to the printed board.

COMPONENT SIDE: The side of the printed board on which most of the components will be mounted.

COMPOUND: A combination of elements in a stable molecular arrangement.

CONDUCTIVE FOIL: The conductive material that covers one side or both sides of the base material and is intended for forming the conductive pattern.

CONDUCTIVE PATTERN: The configuration or design of the electrically conductive material on the base material.

CONDUCTOR LAYER 1: The first layer having a conductive pattern, of a multilayer board, on or adjacent to the component side of the board.

CONDUCTOR SPACING: The distance between adjacent edges (not centerline to centerline) of conductors on a single layer of a printed board.

CONDUCTOR THICKNESS: The thickness of the copper conductor exclusive of coatings or other metals.

CONDUCTOR WIDTH: The width of the conductor viewed from vertically above, that is, perpendicularly to the printed board.

CONFORMAL COATING: An insulating protective coating which conforms to the configuration of the object coated and is applied on the completed printed board assembly.

CONNECTOR AREA: The portion of the printed board that is used for providing external (input–output) electrical connections.

CONTACT BONDING ADHESIVE: An adhesive (particularly of the nonvulcanizing natural rubber type) that bonds to itself on contact, although solvent evaporation has left it dry to the touch.

CONTROLLED IMPEDANCE: The matching of substrate material properties with trace dimensions and locations to create a specific electric impedance as seen by a signal on the trace.

COPOLYMER: See *polymer*.

CORE MATERIAL: The fully cured inner-layer segments, with circuiting on one or both sides, that form the multilayer circuit.

CORNER MARKS: The marks at the corners of printed board artwork, the inside edges of which usually locate the borders and establish the contour of the board.

COUPON: One of the patterns of the quality conformance test circuitry area. (See *test coupon*.)

CRAZING: A base material condition in which connected white spots or crosses appear on or below the surface of the base material. They are due to the separation of fibers in the glass cloth and connecting weave intersections.

CROSS-LINKING: The forming of chemical links between reactive atoms in the molecular chain of a plastic. It is cross-linking in the thermosetting resins that makes the resins infusible.

CROSS TALK: Undesirable electrical interference caused by the coupling of energy between signal paths.

CRYSTALLINE MELTING POINT: The temperature at which the crystalline structure in a material is broken down.

CTE: Coefficient of thermal expansion. The measure of the amount a material changes in any axis per degree of temperature change.

CURE: To change the physical properties of a material (usually from a liquid to a solid) by chemical reaction or by the action of heat and catalysts, alone or in combination, with or without pressure.

CURING AGENT: See *hardener*.

CURING TEMPERATURE: The temperature at which a material is subjected to curing.

CURING TIME: In the molding of thermosetting plastics, the time in which the material is properly cured.

CURRENT-CARRYING CAPACITY: Maximum current which can be carried continuously without causing objectionable degradation of electrical or mechanical properties of the printed board.

DATUM REFERENCE: A defined point, line, or plane used to locate the pattern or layer of a printed board for manufacturing and/or inspection purposes.

DEBRIS: A mechanically bonded deposit of copper to substrate hole surfaces.

DEBRIS PACK: Debris deposited in cavities or voids in the resin.

DEFINITION: The fidelity of reproduction of the printed board conductive pattern relative to the production master.

DELAMINATION: A separation between any of the layers of the base laminate or between the laminate and the metal cladding originating from or extending to the edges of a hole or edge of the board.

DIELECTRIC CONSTANT: The property of a dielectric which determines the electrostatic energy stored per unit volume for a unit potential gradient.

DIELECTRIC LOSS: Electric energy transformed into heat in a dielectric subjected to a changing electric field.

DIELECTRIC LOSS ANGLE: The difference between 90° and the dielectric phase angle. Also called the dielectric phase difference.

DIELECTRIC LOSS FACTOR: The product of dielectric constant and the tangent of dielectric loss angle for a material.

DIELECTRIC PHASE ANGLE: The angular difference in phase between the sinusoidal alternating potential difference applied to a dielectric and the component of the resulting alternating current having the same period as the potential difference.

DIELECTRIC POWER FACTOR: The cosine of the dielectric phase angle (or sine of the dielectric loss angle).

DIELECTRIC STRENGTH: The voltage that an insulating material can withstand before breakdown occurs, usually expressed as a voltage gradient (such as volts per mil).

DIMENSIONAL STABILITY: Freedom from distortion by such factors as temperature changes, humidity changes, age, handling, and stress.

DIRECT IMAGING: The exposure of photo resist material with a laser without the use of positive or negative photo tool.

DISSIPATION FACTOR: The tangent of the loss angle of the insulating material. Also called loss tangent or approximate power factor.

DRILL FACET: The surface formed by the primary and secondary relief angles of a drill tip.

DRILL WANDER: The sum of accuracy and precision deviations from the targeted location of the hole.

DUMMY: A cathode with a large area used in a low-current-density pulsating operation for the removal of metallic impurities from solution. The process is called “dummying.”

DWELL POINT: The bottom of the drilling stroke before the drill bit ascends.

EDGE-BOARD CONTACTS: A series of contacts printed on or near an edge of a printed board and intended for mating with a one-part edge connector.

EDX: Energy dispersive x-ray fluorescent spectrometer

ELASTOMER: A material which at room temperature stretches under low stress to at least twice its length but snaps back to its original length upon release of the stress. Rubber is a natural elastomer.

ELECTRIC STRENGTH: The maximum potential gradient that a material can withstand without rupture. It is a function of the thickness of the material and the method and conditions of test. Also called dielectric strength or disruptive gradient.

ELECTROLESS PLATING: The controlled autocatalytic reduction of a metal ion on certain catalytic surfaces.

EMULSION SIDE: The side of the film or glass on which the photographic image is present.

ENTRY MATERIAL: A material placed on top of a laminate stack.

EPOXY SMEAR: Epoxy resin which has been deposited on edges of copper in holes during drilling either as a uniform coating or as scattered patches. It is undesirable because it can electrically isolate the conductive layers from the plated-through-hole interconnections.

ETCHBACK: The controlled removal of all the components of the base material by a chemical process acting on the sidewalls of plated-through holes to expose additional internal conductor areas.

ETCH FACTOR: The ratio of the depth of etch to lateral etch.

EXOTHERM: A characteristic curve which shows heat of reaction of a resin during cure (temperature) versus time. The peak exotherm is the maximum temperature on the curve.

EXOTHERMIC REACTION: A chemical reaction in which heat is given off.

FIBER EXPOSURE: A condition in which glass cloth fibers are exposed on machined or abraded areas.

FILLER: A material, usually inert, added to a plastic to reduce cost or modify physical properties.

FILM ADHESIVE: A thin layer of dried adhesive. Also, a class of adhesives provided in dry-film form with or without reinforcing fabric and cured by heat and pressure.

FLEXURAL MODULUS: The ratio, within the elastic limit, of stress to corresponding strain. It is calculated by drawing a tangent to the steepest initial straight-line portion of the load deformation curve and using the equation $EB = L3m/4bd3$, where EB is the modulus, L is the span (in inches), m is the slope of the tangent, b is the width of beam tested, and d is the depth of the beam.

FLEXURAL STRENGTH: The strength of a material subjected to bending. It is expressed as the tensile stress of the outermost fibers of a bent test sample at the instant of failure.

FLUOROCARBON: An organic compound having fluorine atoms in its chemical structure, an inclusion that usually lends stability to plastics. Teflon[b] is a fluorocarbon.

GEL: The soft, rubbery mass that is formed as a thermosetting resin goes from a fluid to an infusible solid. It is an intermediate state in a curing reaction, and a stage in which the resin is mechanically very weak.

GEL POINT: The point at which gelation begins.

GLASS TRANSITION POINT: The temperature at which a material loses properties and becomes a semiliquid.

GLASS TRANSITION TEMPERATURE: The temperature at which epoxy, for example, softens and begins to expand independently of the glass fabric expansion rate, usually symbolized as T_g.

GLUE-LINE THICKNESS: Thickness of the fully dried adhesive layer.

GRID: An orthogonal network of two sets of parallel lines for positioning features on a printed board.

GROUND PLANE: A conducting surface used as a common reference point for circuit returns, shielding, or heat

sinking.

GULL WING LEAD: A surface mounted device lead which flares outward from the device body.

HALOING: A light area around holes or other machined areas on or below the surface of the base laminate.

HARDENER: A chemical added to a thermosetting resin for the purpose of causing curing or hardening. A hardener, such as an amine or acid anhydride for an epoxy resin, is a part of the chemical reaction and a part of the chemical composition of the cured resin. The terms “hardener” and “curing agent” are used interchangeably.

HEAT-DISTORTION POINT: The temperature at which a standard test bar (ASTM D 648) deflects 0.010 in under a stated load of either 66 or 264 psi.

HIGH-DENSITY INTERCONNECT (HDI): Ultrafine-geometry multilayer PWB constructed with conductive surface microvia connections between layers. (Microvia is usually defined as a hole with a diameter less than 0.006 in.) These boards also usually include buried and/or blind vias and are made by sequential build-up lamination.

HOLE PULL STRENGTH: The force, in pounds, necessary to rupture a plated-through hole or its surface terminal pads when loaded or pulled in the direction of the axis of the hole. The pull is usually applied to a wire soldered in the hole, and the rate of pull is given in inches per minute.

HOOK: A geometric drill bit defect of the cutting edges.

HOT-MELT ADHESIVE: A thermoplastic adhesive compound, usually solid at room temperature, which is heated to fluid state for application.

HYDROCARBON: An organic compound containing only carbon and hydrogen atoms in its chemical structure.

HYDROLYSIS: The chemical decomposition of a substance involving the addition of water.

HYGROSCOPIC: Tending to absorb moisture.

I-LEAD: A surface mounted device lead which is formed such that the end of the lead contacts the board land pattern at a 90° angle. Also called a butt joint.

IMPREGNATE: To force resin into every interstice of a part, as of a cloth for laminating.

INHIBITOR: A chemical that is added to a resin to slow down the curing reaction and is normally added to prolong the storage life of a thermosetting resin.

INORGANIC CHEMICALS: Chemicals whose molecular structures are based on other than carbon atoms.

INSULATION RESISTANCE: The electrical resistance of the insulating material between any pair of contacts, conductors, or grounding devices in various combinations.

INTERNAL LAYER: A conductive pattern contained entirely within a multilayer board. IPC: Institute for Interconnecting and Packaging Electronic Circuits. A leading printed wiring industry association that develops and distributes standards as well as other information of value to printed wiring designers, users, suppliers, and fabricators. IR: Infrared heating for solder-reflow operation.

J-LEAD: A surface mounted device lead which is formed into a “J” pattern folding under the device body.

JUMPER: An electrical connection between two points on a printed board added after the printed wiring is fabricated.

KIRKENDALL VOIDS: In Cu-Au or Cu-Au-Sn systems, pores in the older joint, or at copper interfaces occur through solid-state diffusion. Copper which has a relatively high solubility and solid-state mobility in gold diffuses into the gold. Transported by grain boundry diffusion at temperatures below 150°C, and by bulk diffusion above that temperature. Au-Sn regions result along with atomic vacancies. Then lattice vacancies are in profusion. Pours (voids) can be observed and this material depletion weakens the solder joint.

LAMINATE: The plastic material, usually reinforced by glass or paper, that supports the copper cladding from which circuit traces are created.

LAMINATE VOID: Absence of epoxy resin in any cross-sectional area which should normally contain epoxy resin.

LAND: See *terminal area*.

LANDLESS HOLE: A plated-through hole without a terminal area.

LASER PHOTOPLOTTER (LASER PHOTO GENERATOR, OR LPG): A device that exposes photosensitive material, usually a silver halide or diazo material, subsequently used as the master for creating the circuit image in production.

LAYBACK: A geometric drill bit defect of the cutting edges.

LAYER-TO-LAYER SPACING: The thickness of dielectric material between adjacent layers of conductive circuitry.

LAY-UP: The process of registering and stacking layers of a multilayer board in preparation for the laminating cycle.

LCCC: Leadless ceramic chip carrier.

LEADED CHIP CARRIER: A chip carrier (either plastic or ceramic) with compliant leads from terminations.

LEAD-FREE: Referring to solder alloys made without lead, to conform with the requirements of the European Union directive on the Restriction of Hazardous Substances (RoHS), the most important of which, to the printed circuit industry, is lead. Often used to refer to any process that is designed to be compatible with “lead-free” alloys.

LEADLESS CHIP CARRIER: A chip carrier (usually ceramic) with integral metallized terminations and no compliant external leads.

LEGEND: A format of lettering or symbols on the printed board, for example, part number, component locations, or patterns.

LOOSE FIBERS: Supporting fibers in the substrate of the laminate which are not held in place by surrounding resin.

MAJOR WEAVE DIRECTION: The continuous-length direction of a roll of woven glass fabric.

MARGIN RELIEF: The area of a drill bit next to the cutting edge is removed so that it does not rub against the hole as the drill revolves.

MASTER DRAWING: A document that shows the dimensional limits or grid locations applicable to any or all parts of a printed wiring or printed circuit base. It includes the arrangement of conductive or nonconductive patterns or elements; size, type, and location of holes; and any other information necessary to characterize the complete fabricated product.

MEASLING: Discrete white spots or crosses below the surface of the base laminate that reflect a separation of fibers in the glass cloth at the weave intersection.

MICROSTRIP: A type of transmission line configuration which consists of a conductor over a parallel ground plane separated by a dielectric.

MICROVIA: Usually defined as a conductive hole with a diameter of 0.006 in or less that connects layers of a multilayer PWB. Often used to refer to any small-geometry connecting hole the creation of which is beyond the practical capabilities of traditional mechanical drilling processes.

MINOR WEAVE DIRECTION: The width direction of a roll of woven glass fabric.

MIXED ASSEMBLY: A printed wiring assembly that combines through-hole components and surface mounted components on the same board.

MODULUS OF ELASTICITY: The ratio of stress to strain in a material that is elastically deformed.

MOISTURE RESISTANCE: The ability of a material not to absorb moisture either from air or when immersed in water.

MOUNTING HOLE: A hole used for the mechanical mounting of a printed board or for the mechanical attachment of

components to a printed board.

MULTILAYER BOARD: A product consisting of layers of electrical conductors separated from each other by insulating supports and fabricated into a solid mass. Interlayer connections are used to establish continuity between various conductor patterns.

MULTIPLE-IMAGE PRODUCTION MASTER: A production master used to produce two or more products simultaneously.

NAILHEADING: A flared condition of internal conductors.

NC: Numerically controlled. Usually refers to a machine tool, in this case a drilling machine. The most basic type is one in which a mechanical guide locates the positions of the holes. NC machines are usually controlled by punched tape.

NEMA STANDARDS: Property values adopted as standard by the National Electrical Manufacturers Association.

NOBLE ELEMENTS: Elements that either do not oxidize or oxidize with difficulty; examples are gold and platinum.

OILCANNING: The movement of entry material in the *z* direction during drilling in concert with the movement of the pressure foot.

ORGANIC: Composed of matter originating in plant or animal life or composed of chemicals of hydrocarbon origin, either natural or synthetic.

PAD: See *terminal area*.

PADS ONLY: A multilayer construction with all circuit traces on inner layers and the component terminal area only on the surface of the board. This construction adds two layers but may avoid the need for a subsequent solder resist, and since inner layers usually are easier to form, this construction may lead to higher overall yields. PH: A measure of the acid or alkaline condition of a solution. A pH of 7 is neutral (distilled water); pH values below 7 represent increasing acidity as they go toward 0; and pH

values above 7 represent increasing alkalinity as they go toward the maximum value of 14.

PHOTOMASTER: An accurately scaled copy of the artwork master used in the photo fabrication cycle to facilitate photo processing steps.

PHOTOPOLYMER: A polymer that changes characteristics when exposed to light of a given frequency.

PINHOLES: Small imperfections which penetrate entirely through the conductor.

PINK RING: The appearance of a halo of copper around the hole of a multilayer.

PLASTICIZER: Material added to resins to make them softer and more flexible when cured.

PLASTIC LEADED CHIP CARRIER (PLCC): A chip carrier packaged in plastic, usually terminating in compliant leads (originally "J" style) on all four sides.

PLATED-THROUGH HOLE: A hole in which electrical connection is made between printed wiring board layers with conductive patterns by the deposition of metal on the wall of the hole. (See *PTH*.)

PLATING VOID: The area of absence of a specific metal from a specific cross-sectional area: (1) When the plated-through hole is viewed as cross-sectioned through the vertical plane, it is a product of the average thickness of the plated metal times the thickness of the board itself as measured from the outermost surfaces of the base copper on external layers. (2) When the plated-through hole is viewed as cross-sectioned through the horizontal plane (annular method), it is the difference between the area of the hole and the area of the outside diameter of the through-hole plating.

PLOWING: Furrows in the hole wall due to drilling.

POLYMER: A high-molecular-weight compound made up of repeated small chemical units. For practical purposes, a polymer is a plastic. The small chemical unit is called a

mer, and when the polymer or mer is cross-linked between different chemical units (e.g., styrene-polyester), the polymer is called a copolymer. A monomer is any single chemical from which the mer or polymer or copolymer is formed.

POLYMERIZE: To unite chemically two or more monomers or polymers of the same kind to form a molecule with higher molecular weight.

POTLIFE: The time during which a liquid resin remains workable as a liquid after catalysts, curing agents, promoter, etc. are added. It is roughly equivalent to gel time.

POWER FACTOR: The cosine of the angle between the applied voltage and the resulting current.

PRECISION: The ability to repeatedly place the hole at any location.

PREPRODUCTION TEST BOARD: A test board (as detailed in IPC-ML-950) the purpose of which is to determine whether, prior to the production of finished boards, the contractor has the capability of producing a multilayer board satisfactorily.

PRESS PLATEN: The flat heated surface of the lamination press used to transmit heat and pressure to lamination fixtures and into the lay-up.

PRESSURE FOOT: The tube like device on the drilling machine that descends to the top surface of the stack, holding it firmly down, before the drill descends through the center of the pressure foot. The vacuum system of the drilling machine separates through the pressure foot to remove chips and dust formed in drilling.

PRINTED WIRING ASSEMBLY DRAWING: A document that shows the printed wiring base, the separately manufactured components which are to be added to the base, and any other information necessary to describe the joining of the parts to perform a specific function.

PRINTED WIRING LAYOUT: A sketch that depicts the printed wiring substrate, the physical size and location of electronic and mechanical components, and the routing of conductors that interconnect the electronic parts in sufficient detail to allow for the preparation of documentation and artwork.

PRODUCTION MASTER: A 1:1 scale pattern used to produce one or more printed wiring or printed circuit products within the accuracy specified on the master drawing.

PROMOTER: A chemical, itself a feeble catalyst, that greatly increases the activity of a given catalyst.

PTH: Plated-through holes. Also refers to the technology that uses the plated-through hole as its foundation.

QUADPACK: Generic term for surface mount technology packages with leads on all four sides. Commonly used to describe chip carrier-like devices with gull wing leads.

QUALITY CONFORMANCE CIRCUITRY AREA: A test board made as an integral part of the multilayer printed board panel on which electrical and environmental tests may be made for evaluation without destroying the basic board.

RAW MATERIAL PANEL SIZE: A standard panel size related to machine capacities, raw material sheet sizes, final product size, and other factors.

REGISTER MARK: A mark used to establish the relative position of one or more printed wiring patterns, or portions thereof, with respect to desired locations on the opposite side of the board.

REGISTRATION: The relative position of one or more printed wiring patterns, or portions thereof, with respect to desired locations on a printed wiring base or to another pattern on the opposite side of the base.

REPAIR: The correction of a printed wiring defect after the completion of board fabrication to render the board as functionally good as a perfect board.

RESIN: High-molecular-weight organic material with no sharp melting point. For current purposes, the term “resin,” “polymer,” and “plastic” can be used interchangeably.

RESIST: A protective coating (ink, paint, metallic plating, etc.) used to shield desired portions of the printed conductive pattern from the action of etchant, solder, or plating.

RESISTIVITY: The ability of a material to resist passage of electric current through its bulk or on a surface.

RIFLING: Spiral groove or ridge in the substrate due to drilling.

RIGID/FLEX: A PWB construction combining flexible circuits and rigid multilayer PWBs, usually either to provide a built-in connection or to make a three-dimensional form that includes components.

ROCKWELL HARDNESS NUMBER: A number derived from the net increase in depth of an impression as the load on a perpetrator is increased from a fixed minimum load to as higher load and then returned to minimum load.

RoHS: Acronym for “Restriction of Hazardous Substances.” The name given to a directive of the European Union meant to reduce certain materials considered detrimental to the environment.

ROUGHNESS: Irregular, coarse, uneven hole wall on copper or substrate due to drilling.

SCHEMATIC DIAGRAM: A drawing which shows, by means of graphic symbols, the electrical interconnections and functions of a specific circuit arrangement.

SEM: Scanning electron microscope.

SEQUENTIAL BUILD-UP: A process for making multilayer PWBs in which already finished multilayers are laminated together to form a higher-layer-count final board, or in which additional outerlayers are added to finished multilayer PWBs.

SHADOWING: Etchback to maximum limit without removal of dielectric material from conductors.

SINGLE-IN-LINE PACKAGE (SIP): Component package system with one line of connectors, usually spaced 0.100 in apart.

SMC: Surface mounted component. Component with terminations designed for mounting flush to printed wiring board.

SMD: Surface mounted device. Any component or hardware element designed to be mounted to a printed wiring board without penetrating the board.

SMEAR: Fused deposit left on copper or substrate from excessive drilling heat.

SMOBC: Solder mask over bare copper. A method of fabricating a printed wiring board which results in the final metallization being copper with no other protective metal; but the nonsoldered areas are coated by a solder resist, exposing only the component terminal areas. This eliminates tin-lead under the solder mask.

SMT: Surface mount technology. Defines the entire body of processes and components which create printed wiring assemblies without components with leads that pierce the board. Sn-Au-Cu: An alloy used as a replacement for eutectic tin-lead (Sn-Pb) in “lead-free” solders (often referred to, and pronounced as “snack”).

SOI: SOIC package with J-leads rather than gull wing leads.

SOIC: Small-outline integrated circuit. A plastic package resembling a small dual-in-line package (DIP) with gull wing leads on two sides for surface mounting.

SOT: Small outline transistor. A package for surface-mounting transistors.

SPINDLE RUNOUT: The measure of the wobble present as the drilling machine spindle rotates 360°.

STORAGE LIFE: The period of time during which a liquid resin or adhesive can be stored and remain suitable for use. Also called shelf life.

STRAIN: The deformation resulting from a stress. It is measured by the ratio of the change to the total value of

the dimension in which the change occurred.

STRESS: The force producing or tending to produce deformation in a body. It is measured by the force applied per unit area.

SUBSTRATE: A material on whose surface an adhesive substance is spread for bonding or coating. Also, any material which provides a supporting surface for other materials used to support printed wiring patterns.

SURFACE RESISTIVITY: The resistance of a material between two opposite sides of a unit square of its surface. It may vary widely with the conditions of measurement.

SURFACE SPEED: The linear velocity of a point on the circumference of a drill. Given in units of surface feet per minute—sfm.

TERMINAL AREA: A portion of a conductive pattern usually, but not exclusively, used for the connection and/or attachment of components.

TEST COUPON: A sample or test pattern usually made as an integral part of the printed board, on which electrical, environmental, and micro sectioning tests may be made to evaluate board design or process control without destroying the basic board.

TETRA-ETCH[c]: A nonpyrophoric (will not ignite when exposed to moisture) proprietary etchant.

TETROFUNCTIONAL: Describes an epoxy system for laminates that has four cross-linked bonds rather than two and results in a higher glass transition temperature, or T_g.

T_g: Glass transition temperature. The temperature at which laminate mechanical properties change significantly.

THERMAL CONDUCTIVITY: The ability of a material to conduct heat; the physical constant for the quantity of heat that passes through a unit cube of a material in a unit of time when the difference in temperatures of two faces is 1°C.

THERMOPLASTIC: A classification of resin that can be readily softened and resoftened by repeated heating.

THERMOSETTING: A classification of resin which cures by chemical reaction when tested and, when cured, cannot be resoftened by heating.

THIEF: An auxiliary cathode so placed as to divert to itself some current from portions of the work which would otherwise receive too high a current density.

THIXOTROPIC: Said of materials that are gel-like at rest but fluid when agitated.

THROUGH-HOLE TECHNOLOGY: Traditional printed wiring fabrication where components are mounted in holes that pierce the board.

THROWING POWER: A measure of the degree of uniformity with which metal is deposited on an irregularly shaped cathode. Often refers to the ratio of amount of plated metal on the surface of a copper-clad board to the amount plated on a side of a hole through the same board.

TWIST: A laminate defect in which deviation from planarity results in a twisted arc.

UNDERCUT: The reduction of the cross-section of a metal foil conductor caused by the etchant removing metal from under the edge of the resist.

VAPOR PHASE: The solder-reflow process that uses a vaporized solvent as the source for heating the solder beyond its melting point, creating the component-to-board solder joint.

VIA: A metallized connecting hole that provides a conductive path from one layer in a printed wiring board to another. (1) *Buried via*—connects one inner layer to another inner layer without penetrating the surface. (2) *Blind via*—connects the surface layer of a printed wiring board to an internal layer without going all the way through the other surface layer.

VOID: A cavity left in the substrate.

VOLUME RESISTIVITY: The electrical resistance between opposite faces of a 1-cm cube of insulating materials, commonly expressed in ohm-centimeters. The recommended test is ASTMD 256 51T. Also called the specific insulation.

VULCANIZATION: A chemical reaction in which the physical properties of an elastomer are changed by causing the elastomer to react with sulfur or some other cross-linking agent.

WATER ABSORPTION: The ratio of the weight of water absorbed by a material to the weight of the dry material.

WEAVE EXPOSURE: A condition in which the unbroken woven glass cloth is not uniformly covered by resin.

WEAVE TEXTURE: A surface condition in which the unbroken fibers are completely covered with resin but exhibit the definite weave pattern of the glass cloth.

WETTING: Ability to adhere to a surface immediately upon contact.

WICKING: Migration of copper salts into the glass fibers of the insulating material.

WORKING LIFE: The period of time during which a liquid resin or adhesive, after mixing with catalyst, solvent, or other compounding ingredients, remains usable. (See *potlife*.)
