Printed Circuits Handbook

50th Anniversary Edition!

SEVENTH EDITION

- Printed Circuit Supply Chain Management
- Lead-Free Materials and Processes
- Printed Circuit Reliability
- Printed Circuit Design and Layout Processes

Clyde F. Coombs, Jr., and Happy T. Holden

Mc Graw Hill Education

ABOUT THE EDITORS-IN-CHIEF

Clyde F. Coombs, Jr., joined Hewlett-Packard in 1959, where he developed the plated-through-hole process that became the basis for printed circuit production for the next 40+ years. He was the editor-in-chief of all six previous editions of *Printed Circuits Handbook*.

Happy T. Holden is the retired director of electronics engineering and innovations at Gentex Corporation, and has worked with printed circuits in various capacities since 1970. Previously, he was the CTO for Foxconn's MIP Business Group (supplier of mechanical components, flexible circuits, and rigid PCBs), a senior PCB technologist for Mentor Graphics' System Design Division, and an advanced technology manager at Westwood Associates (Nan Ya PCB) and Merix Corporation, and he worked for Hewlett-Packard for 28 years in various engineering and marketing roles.

PRINTED CIRCUITS HANDBOOK

CONTENTS

Contributors

Preface

Part 1 Printed Circuit Technology Drivers

Chapter 1. Electronic Packaging and High-Density Interconnectivity *Clyde F. Coombs, Jr., and Happy T. Holden*

1.1 Introduction
1.2 Measuring the Interconnectivity Revolution
1.3 Hierarchy of Interconnections
1.4 Factors Affecting Selection of Interconnections
1.5 ICs and Packages
1.6 Density Evaluations
1.7 Methods to Increase PWB Density
1.8 References

Chapter 2. Types of Printed Wiring Boards *Hayao Nakahara*

2.1 Introduction
2.2 Classification of Printed Wiring Boards
2.3 Organic and Nonorganic Substrates
2.4 Graphical and Discrete-Wire Boards
2.5 Rigid and Flexible Boards
2.6 Graphically Produced Boards
2.7 Molded Interconnection Devices
2.8 Plated-Through-Hole Technologies
2.9 Summary
2.10 References

Part 2 Managing the Printed Circuit Supply Chain

Chapter 3. Basics of Printed Circuit Supply Chain Management *Tim Rodgers*

3.1 Introduction
3.2 General Business Considerations
3.3 Contract Manufacturers
3.4 Criteria for Evaluating Suppliers
3.5 Supplier Selection Criteria Example

Chapter 4. Design for Manufacturability *Tim Rodgers*

4.1 General Principles
4.2 PCB/PCA Pricing Models
4.3 Process Cost Drivers
4.4 Production Yield and Design for Manufacturability
4.5 DFM Complexity Models

Chapter 5. Manufacturing Information, Documentation, Formatting, and Exchange *Happy T. Holden*

5.1 Introduction
5.2 Manufacturing Information
5.3 Fabrication Information Exchange
5.4 Data Exchange Formats
5.5 Initial Design Review
5.6 Design Input
5.7 Design Analysis and Review
5.8 Acknowledgments
5.9 References

Chapter 6. Supplier Selection and Qualification *Tim Rodgers*

6.1 Introduction
6.2 Evaluating Suppliers
6.3 Supplier Selection
6.4 Supplier Qualification

Chapter 7. Process Control, Monitoring, and Incoming Inspection *Tim Rodgers*

7.1 Introduction
7.2 Process Capability and Process Control
7.3 Process Monitoring and Troubleshooting
7.4 Assessing a PCB Fabricators Capability
7.5 Testing and Inspection
7.6 Incoming Inspection

Chapter 8. Product Acceptance and Feedback *Tim Rodgers*

8.1 Introduction
8.2 Design Qualification
8.3 Incoming Inspection and Lot Acceptance
8.4 Supplier Performance Management
8.5 Business Reviews
8.6 Strategic Supplier Management

Part 3 Materials

Chapter 9. Introduction to Base Materials *Edward Kelley and Douglas Trobough*

9.1 Introduction
9.2 Grades and Specifications
9.3 Properties Used to Classify Base Materials

9.4 Types of FR-4
9.5 Laminate Identification Scheme
9.6 Prepreg Identification Scheme
9.7 Laminate and Prepreg Manufacturing Processes
9.8 References

Chapter 10. Base Material Components *Edward Kelley and Douglas Trobough*

10.1 Introduction
10.2 Other Resin Systems
10.3 Legislative Issues
10.4 Additives
10.5 Reinforcements
10.6 Conductive Materials
10.7 References

Chapter 11. Properties of Base Materials *Edward Kelley and Douglas Trobough*

11.1 Introduction
11.2 Thermal, Physical, and Mechanical Properties
11.3 Electrical Properties
11.4 Other Test Methods
11.5 References

Chapter 12. Base Material Performance in PCBs *Edward Kelley*

and Douglas Trobough

12.1 Introduction
12.2 Methods of Increasing Circuit Density
12.3 Copper Foil
12.4 Laminate Constructions
12.5 Prepreg Options and Yield-per-Ply Values
12.6 Dimensional Stability
12.7 High-Density Interconnect/Microvia Materials
12.8 Conductive Anodic Filament Growth
12.9 Electrical Performance
12.10 Electrical Performance of Lower D_k/D_f Lead-Free Compatible Materials
12.11 Resin and Glass Micro-D_k Effects
12.12 References

Chapter 13. The Impact of Lead-Free Assembly on Base Materials *Edward Kelley and Douglas Trobough*

13.1 Introduction
13.2 RoHS Basics
13.3 Base Material Compatibility Issues
13.4 The Impact of Lead-Free Assembly on Base Material Components
13.5 Critical Base Material Properties
13.6 Impact on Printed Circuit Reliability and Material Selection
13.7 Summary
13.8 Further Reading

Chapter 14. Selecting Base Materials *Edward Kelley and Douglas Trobough*

14.1 Introduction
14.2 Selecting Materials for Thermal Reliability
14.3 Selecting a Base Material for Thermal Reliability
14.4 Selecting Materials for Electrical Performance
14.5 CAF Resistance
14.6 References

Chapter 15. Laminate Qualification and Testing *Michael Roesch and Sylvia Ehrler*

15.1 Introduction
15.2 Industry Standards
15.3 Laminate Test Strategy
15.4 Initial Tests
15.5 Full Material Characterization
15.6 Characterization Test Plan
15.7 Manufacturability in the Shop

Part 4 Engineering and Design

Chapter 16. Planning for Design, Fabrication, and Assembly *Happy T. Holden*

16.1 Introduction
16.2 General Considerations
16.3 New Product Design
16.4 Specification: Capture of System Description
16.5 Layout Trade-Off Planning
16.6 PWB Fabrication Trade-Off Planning
16.7 Assembly Trade-Off Planning
16.8 References

Chapter 17. Physical Characteristics of the PCB *Lee W. Ritchey*

17.1 Introduction
17.2 Types of PCBs or Substrates
17.3 Methods of Attaching Components
17.4 Component Package Types
17.5 Materials Choices
17.6 Fabrication Methods

Chapter 18. Electronic Design Automation and Printed Circuit Design Tools *Andy Shaughnessy*

18.1 Description of PCB Design Tools
18.2 Using PCB Design Tools
18.3 Major PCB Design Tools
18.4 Lower-Cost PCB Design Tools
18.5 Free PCB Design Tools
18.6 Signal Integrity and EMC Tools
18.7 Key Questions to Consider
18.8 Further Reading

Chapter 19. The PCB Design Process *Lee W. Ritchey*

19.1 Introduction
19.2 The Virtual Prototyping Process
19.3 Making the Conversion from Hardware Prototyping to Virtual Prototyping

Chapter 20. Electrical and Mechanical Design Parameters *Bill Hargin and Mark I. Montrose*

20.1 Electrical and Mechanical Design Parameters Overview
20.2 Introduction to Digital Signal Integrity
20.3 Which Nets to Terminate and What Type of Termination to Use
20.4 Introduction to Differential Signaling
20.5 Introduction to Power Integrity
20.6 Introduction to Electromagnetic Compatibility
20.7 Introduction to Mechanical Design Requirements
20.8 Types of Edge Mounting for Circuit Boards
20.9 Acknowledgments
20.10 References

Chapter 21. The Basics of Printed Circuit Board Design *Susy Webb*

21.1 Software Selection
21.2 Standards
21.3 The Schematic

21.4 Parts
21.5 Padstacks
21.6 Starting a New Board
21.7 Placement
21.8 Planes
21.9 Stackup
21.10 Routing
21.11 Finishing
21.12 Saving
21.13 Conclusion

Chapter 22. Current Carrying Capacity in Printed Circuits *Mike Jouppi*

22.1 Introduction
22.2 Conductor (Trace) Sizing Charts
22.3 Baseline Charts
22.4 Summary
22.5 References

Chapter 23. PCB Design for Thermal Performance *Mike Jouppi*

23.1 Introduction
23.2 The PCB as a Heat Sink Soldered to the Component
23.3 Optimizing the PCB for Thermal Performance
23.4 Conducting Heat to the Chassis
23.5 PCB Requirements for High-Power Heat Sink Attach
23.6 Modeling the Thermal Performance of the PCB
23.7 Heat Sources

23.8 Acknowledgment
23.9 References

Chapter 24. Embedded Components *Vern Solberg*

24.1 Introduction
24.2 Definitions and Example
24.3 Applications and Trade-Offs
24.4 Designing for Embedded Component Applications
24.5 Materials
24.6 Material Supply Types
24.7 Conclusion
24.8 Acknowledgment

Part 5 High-Density Interconnection

Chapter 25. Introduction to High-Density Interconnection Technology *Happy T. Holden*

25.1 Introduction
25.2 Definitions
25.3 HDI Structures
25.4 Design
25.5 Dielectric Materials and Coating Methods
25.6 HDI Manufacturing Processes
25.7 Appendix
25.8 References
25.9 Further Reading

Chapter 26. Advanced High-Density Interconnection Technologies *Happy T. Holden*

26.1 Introduction
26.2 Definitions of HDI Process Factors
26.3 HDI Fabrication Processes
26.4 Next-Generation HDI Processes
26.5 References
26.6 Further Reading

Part 6 Fabrication

Chapter 27. CAM Tooling for Fab and Assembly *Happy T. Holden*

27.1 Introduction
27.2 Manufacturing Information
27.3 Design Analysis and Review
27.4 The CAM-Tooling Process
27.5 Additional Processes
27.6 Acknowledgments

Chapter 28. Drilling Processes *Matthias Stickel*

28.1 Introduction
28.2 Materials
28.3 Machines
28.4 Methods

28.5 Hole Quality
28.6 Troubleshooting
28.7 Postdrilling Inspection
28.8 Drilling Cost per Hole
28.9 Acknowledgment

Chapter 29. Precision Interconnect and Laser Drilling *Matthias Stickel*

29.1 Introduction
29.2 Factors Affecting High-Density Drilling
29.3 Laser versus Mechanical
29.4 Factors Affecting High-Density Mechanical Drilling
29.5 Depth-Controlled Drilling Methods
29.6 Controlled Depth Via Drilling
29.7 Innerlayer Registration of Multilayer Boards
29.8 Laser Drilling
29.9 Laser Via Formation
29.10 Laser Tool Types
29.11 Acknowledgment
29.12 Further Reading

Chapter 30. Imaging and Automated Optical Inspection *Gareth Parry*

30.1 Introduction
30.2 Photosensitive Materials
30.3 Dry-Film Resists
30.4 Liquid Photoresists
30.5 Electrophoretic Depositable Photoresists
30.6 Resist Processing
30.7 Design for Manufacturing

30.8 Inkjet Imaging
30.9 Automatic Optical Inspection
30.10 References

Chapter 31. Multilayer Materials and Processing *C. D. (Don) Dupriest and Happy T. Holden*

31.1 Introduction
31.2 Multilayer Construction Types
31.3 ML-PWB Processing and Flows
31.4 Lamination Process
31.5 Lamination Process Control and Troubleshooting
31.6 Lamination Overview
31.7 ML-PWB Summary
31.8 Acknowledgment
31.9 Further Reading

Chapter 32. Preparing Boards for Plating *Michael Carano*

32.1 Introduction
32.2 Process Decisions
32.3 Process Feedwater
32.4 Multilayer PTH Preprocessing
32.5 Electroless Copper
32.6 Acknowledgments
32.7 References

Chapter 33. Electroplating *George Milad*

33.1 Introduction
33.2 Electroplating Basics
33.3 Acid Copper Electroplating
33.4 Tin Electroplating
33.5 Nickel Electroplating
33.6 Gold Electroplate

Chapter 34. Direct Plating *Hayao Nakahara*

34.1 Direct Metallization Technology
34.2 References

Chapter 35. Printed Circuit Board Surface Finishes *George Milad*

35.1 Introduction
35.2 PWB Surface Finishes
35.3 Hot Air Solder Level
35.4 Electroless Nickel Immersion Gold
35.5 Nickel Palladium Gold
35.6 Organic Solderability Preservatives
35.7 Immersion Silver
35.8 Immersion Tin
35.9 Other Surface Finishes

Chapter 36. Solder Mask *David A. Vaughan*

36.1 Introduction
36.2 Trends and Challenges for Solder Mask
36.3 Types of Solder Mask
36.4 Solder Mask Selection
36.5 Solder Mask Application and Processing
36.6 Via Protection
36.7 Solder Mask Final Properties
36.8 Legend and Marking (Nomenclature)

Chapter 37. Etching Process and Technologies *Gareth Parry*

37.1 Introduction
37.2 General Etching Considerations and Procedures
37.3 Resist Removal
37.4 Etching Solutions
37.5 Other Materials for Board Construction
37.6 Metals Other than Copper
37.7 Basics of Etched Line Formation
37.8 Equipment and Techniques
37.9 Acknowledgment
37.10 References

Chapter 38. Routing and V-Scoring *Matthias Stickel*

38.1 Introduction
38.2 The Routing Operation

38.3 Materials
38.4 Machines
38.5 Routers
38.6 Parameters
38.7 Depth Controlled Routing
38.8 V-Scoring
38.9 References

Part 7 Bare Board Test

Chapter 39. Bare Board Test Objectives and Definitions *David J. Wilkie*

39.1 Introduction
39.2 The Impact of HDI
39.3 Why Test?
39.4 Circuit Board Faults

Chapter 40. Bare Board Test Methods *David J. Wilkie*

40.1 Introduction
40.2 Nonelectrical Testing Methods
40.3 Basic Electrical Testing Methods
40.4 Specialized Electrical Testing Methods
40.5 Data and Fixture Preparation
40.6 Combined Testing Methods

Chapter 41. Bare Board Test Equipment *David J. Wilkie*

41.1 Introduction
41.2 System Alternatives
41.3 Universal Grid Systems
41.4 Flying-Probe/Moving-Probe Test Systems
41.5 Verification and Repair
41.6 Test Department Planning and Management

Chapter 42. HDI Bare Board Special Testing Methods *David J. Wilkie*

42.1 Introduction
42.2 Fine-Pitch Tilt-Pin Fixtures
42.3 Bending Beam Fixtures
42.4 Flying Probe
42.5 Coupled Plate
42.6 Shorting Plate
42.7 Conductive Rubber Fixtures
42.8 Optical Inspection
42.9 Noncontact Test Methods
42.10 Combinational Test Methods

Part 8 Assembly, Soldering Materials, and Processes

Chapter 43. Assembly Processes *Happy T. Holden*

43.1 Introduction
43.2 Through-Hole Technology
43.3 Surface-Mount Technology
43.4 Odd-Form Component Assembly
43.5 Process Equipment Selection
43.6 Conformal Coating, Encapsulation, and Underfill Materials
43.7 Acknowledgments

Chapter 44. Conformal Coating *Jason Keeping*

44.1 Introduction
44.2 Types of Conformal Coatings
44.3 Product Preparation
44.4 Application Processes
44.5 Cure, Inspection, and Demasking
44.6 Repair Methods
44.7 Design for Conformal Coating
44.8 References

Chapter 45. Fluxes and Cleaning *Gregory C. Munie and Laura J. Turbini*

45.1 Introduction
45.2 Assembly Process
45.3 Surface Finishes
45.4 Soldering Flux
45.5 Flux Form versus Soldering Process
45.6 Rosin Flux

45.7 Water-Soluble Flux
45.8 Low Solids Flux
45.9 Cleaning Issues
45.10 Summary
45.11 References

Chapter 46. Soldering Fundamentals *Gary M. Freedman*

46.1 Introduction
46.2 Elements of a Solder Joint
46.3 Solder Overview
46.4 Soldering Basics
46.5 References

Chapter 47. Soldering Materials and Metallurgy *Gary M. Freedman*

47.1 Introduction
47.2 Solders
47.3 Solder Alloys and Corrosion
47.4 Pb-Free Solders: Alternatives and Implications
47.5 Board Surface Finishes
47.6 References

Chapter 48. Solder Fluxes *Gary M. Freedman*

48.1 Introduction to Fluxes
48.2 Flux Functions
48.3 Flux Delivery Methods

48.4 Flux Activity and Attributes
48.5 Flux: Ideal versus Reality
48.6 Flux Types
48.7 Soldering Atmospheres
48.8 References

Chapter 49. Soldering Techniques *Gary M. Freedman*

49.1 Introduction
49.2 Mass Soldering Methods
49.3 Oven Reflow Soldering
49.4 Wave Soldering
49.5 Wave Solder Defects
49.6 Vapor-Phase Reflow Soldering
49.7 Laser Reflow Soldering
49.8 Hot-Bar Soldering
49.9 Hot-Gas Soldering
49.10 Ultrasonic Soldering
49.11 References

Chapter 50. Soldering Repair and Rework *Gary M. Freedman*

50.1 Introduction
50.2 Hot-Gas Repair
50.3 Manual Solder Fountain
50.4 Automated Solder Fountain (Single-Point Soldering)
50.5 Laser
50.6 Considerations for Repair
50.7 Reference

Part 9 Nonsolder Interconnection

Chapter 51. Press-Fit Interconnection *Gary M. Freedman*

51.1 Introduction
51.2 The Rise of Press-Fit Technology
51.3 Compliant Pin Configurations
51.4 Press-Fit Considerations
51.5 Press-Fit Pin Materials
51.6 Surface Finishes and Effects
51.7 Equipment
51.8 Assembly Process
51.9 Rework for Press-Fit Connectors
51.10 PCB Design and Board Procurement Tips
51.11 Press-Fit Process Tips
51.12 Further Reading

Chapter 52. Pressure-Interconnect Land Grid Array Systems *Gary M. Freedman*

52.1 Introduction
52.2 LGA and the Environment
52.3 Elements of the LGA System
52.4 Assembly
52.5 PCA Rework
52.6 Design Guidelines
52.7 Reference

Part 10 Quality

Chapter 53. Acceptability and Quality of Fabricated Boards *Robert (Bob) Neves*

53.1 Introduction
53.2 Specific Quality and Acceptability Criteria by PCB Type
53.3 Methods for Verification of Acceptability
53.4 Inspection Lot Formation
53.5 Inspections Categories
53.6 Acceptability and Quality After Simulated Solder Cycle(s)
53.7 Nonconforming PCBs and Material Review Board Function
53.8 The Cost of the Assembled PCB
53.9 How to Develop Acceptability and Quality Criteria
53.10 Class of Service
53.11 Inspection Criteria
53.12 Reliability Inspection Using Accelerated Environmental Exposure

Chapter 54. Acceptability of Printed Circuit Board Assemblies *Mel Parrish*

54.1 Understanding Customer Requirements
54.2 Handling to Protect the PCBA
54.3 PCBA Hardware Acceptability Considerations
54.4 Component Installation or Placement Requirements
54.5 Component and PCB Solderability Requirements

54.6 Solder-Related Defects
54.7 PCBA Laminate Condition, Cleanliness, and Marking Requirements
54.8 PCBA Coatings
54.9 Solderless Wrapping of Wire to Posts (Wire Wrap)
54.10 PCBA Modifications
54.11 References

Chapter 55. Asssembly Inspection *Stacy Kalisz Johnson and Stig Oresjo*

55.1 Introduction
55.2 Definition of Defects, Faults, Process Indicators, and Potential Defects
55.3 Reasons for Inspection
55.4 Lead-Free Impact on Inspection
55.5 Miniaturization and Higher Complexity
55.6 Visual Inspection
55.7 Automated Inspection
55.8 Three-Dimensional Automated Solder Paste Inspection
55.9 Pre-Reflow AOI
55.10 Post-Reflow Automated Inspection
55.11 Implementation of Inspection Systems
55.12 Design Implications of Inspection Systems
55.13 References

Chapter 56. Design for Testing *Kenneth P. Parker*

56.1 Introduction
56.2 Definitions
56.3 Ad Hoc Design for Testability
56.4 Structured Design for Testability
56.5 Standards-Based Testing
56.6 References

Chapter 57. Loaded Board Testing *Kenneth P. Parker*

57.1 Introduction
57.2 The Process of Test
57.3 Definitions
57.4 Testing Approaches
57.5 In-Circuit Test Techniques
57.6 Alternatives to Conventional Electrical Tests
57.7 Tester Comparison
57.8 References

Chapter 58. Failure Modes and Effects Analysis *Happy T. Holden*

58.1 Prognostics and Health Management
58.2 Theory
58.3 What Is Process FMEA?
58.4 Reference
58.5 Further Reading

Part 11 Reliability

Chapter 59. Conductive Anodic Filament Formation *Laura J. Turbini and Antonio Caputo*

59.1 Introduction
59.2 Electrochemical Migration
59.3 Developing a Quantitative Copper Corrosion Test
59.4 Understanding CAF Formation
59.5 Factors That Affect CAF Formation
59.6 Test Method for CAF-Resistant Materials
59.7 Manufacturing Tolerance Considerations
59.8 References

Chapter 60. Reliability of Printed Circuit Boards *Reza Ghaffarian*

60.1 Introduction
60.2 PCB and Microelectronics Trends and Reliability
60.3 PCB Fabrication and Failure Mechanisms
60.4 PTH Thermal Cycle Reliability and Projections Methods
60.5 Acknowledgments
60.6 References
60.7 Further Reading

Chapter 61. Reliability of Microvia Printed Circuit Boards *Reza Ghaffarian*

61.1 Microvia Fabrication
61.2 Summary

61.3 List of Acronyms
61.4 Acknowledgments
61.5 References
61.6 Further Reading

Chapter 62. Component-to-PWB Reliability: The Impact of Design Variables and Lead Free *Mudasir Ahmad and Mark Brillhart*

62.1 Introduction
62.2 Packaging Challenges
62.3 Variables That Impact Reliability
62.4 References

Chapter 63. Lead-Free Solder Joint Reliability: Fundamentals and Design-for-Reliability Rules *Jean-Paul Clech*

63.1 Introduction
63.2 Reliability Definition and Goals
63.3 Why Do Solder Joints Fail?
63.4 Main Effects and Basic Rules-of-Thumb
63.5 Parameters That Affect Solder Joint Reliability Under Thermal Cycling Conditions
63.6 Significance of Board Parameter Effects
63.7 Lead-Free Reliability Trends
63.8 Conclusions
63.9 Further Reading

Chapter 64. Component-to-PWB Reliability: Estimating Solder Joint Reliability and the Impact of Lead-Free Solders *Mudasir Ahmad and Mark Brillhart*

64.1 Introduction
64.2 Thermomechanical Reliability
64.3 Mechanical Reliability
64.4 Finite Element Analysis
64.5 References

Part 12 Flexible Circuits

Chapter 65. Flexible Circuit Applications and Materials *Happy T. Holden*

65.1 Introduction to Flexible Circuits
65.2 Applications of Flexible Circuits
65.3 High-Density Flexible Circuits
65.4 Materials for Flexible Circuits
65.5 Substrate Material Properties
65.6 Conductor Materials
65.7 Copper-Clad Laminates
65.8 Coverlay Materials
65.9 Stiffener Materials
65.10 Adhesive Materials
65.11 Restriction of Hazardous Substances Issues
65.12 Acknowledgments

Chapter 66. Design of Flexible Circuits *Happy T. Holden*

66.1 Introduction
66.2 Types of Flexible Circuits
66.3 Multilayer Rigid Flex (Multilayer Flex)
66.4 Circuit Designs for Flexibility
66.5 Electrical Design of the Circuits
66.6 Design of Flexible Printed Wiring with Transmission Line Properties
66.7 Circuit Designs for Higher Reliability
66.8 Acknowledgments

Chapter 67. Manufacturing Flexible Circuits *Joseph Fjelstad*

67.1 Introduction
67.2 Fundamental Flex Circuit Processing Steps
67.3 Equipment for Wet Processing of Flexible Materials
67.4 Coverlayer/Cover-Coating Methods
67.5 Interconnection Surface Treatments
67.6 Depanelization of Flexible Circuits
67.7 Stiffener Processes
67.8 Packaging for Flex
67.9 High-Density Flexible Circuit Manufacturing
67.10 Acknowledgments

Chapter 68. Termination Options for Flexible Circuits *Joseph Fjelstad*

68.1 Introduction
68.2 Wirebonding Technology

68.3 Solutions Where the Flex Circuit Is Half of the Mated Pair
68.4 Summary
68.5 Acknowledgments

Chapter 69. Multilayer Flex and Rigid Flex *Joseph Fjelstad*

69.1 Introduction
69.2 Multilayer Flex versus Rigid Flex
69.3 Aluminum Rigid Flex Circuit—Prospective Structure for the Future
69.4 Summary
69.5 Acknowledgments

Chapter 70. Special Constructions of Flexible Circuits *Dominique K. Numakura*

70.1 Introduction
70.2 Flying-Lead Construction
70.3 Tape Automated Bonding
70.4 Microbump Arrays
70.5 Thick-Film Conductor Flex Circuits
70.6 Shielding of the Flexible Cables
70.7 Functional Flexible Circuits

Chapter 71. Flexible Circuit Quality Assurance: Principles and Practices *Joseph Fjelstad*

71.1 Introduction
71.2 Basic Concepts in Flexible Circuit Quality Assurance
71.3 Raw Material Testing
71.4 Electrical Performance Tests
71.5 General Testing Requirements for Flexible Circuit Materials
71.6 Flexible Circuit Visual Evaluation
71.7 Flexible Circuit Dimensional Requirements
71.8 Physical Testing Requirements for Flexible Circuits
71.9 Electrical Requirements for Flexible Circuits
71.10 Environmental Resistance Requirements
71.11 Solderability Requirements
71.12 Standards and Specifications for Flexible Circuits

PREFACE

This book provides the reader with the tools to be successful in the printed circuit world of today, and of the foreseeable future. A world where, increasingly, the designer/user organizations are not only different from the manufacturing organizations, they are separated by geography and language, and, perhaps most importantly, one where there is great opportunity for serious disconnect between the understanding of what is required by the user and what can be accomplished by the manufacturer. The term “supply chain” has been used to define these issues in general for non-vertically integrated organizations, but here, for the first time, we have focused specifically on those supply chain elements that relate to printed circuits. This includes design, specification, supplier identification and qualification, and process understanding and control, as well as quality and reliability specification and assurance. When a user organization entrusts its present, as well as its future, success to an outside manufacturing organization, the need for care and clarity cannot be overstated. Chapters, written by authors with experience in these issues, have been specifically developed to provide the reader with usable information on dealing with them, and will help guide the development of these relationships, for the benefit of all.

In addition, with the continued, and increasing, importance of printed circuits as the basic building block of all electronic devices, issues associated with them can be found throughout the engineering and manufacturing organizations, rather than in just design and layout in engineering and purchasing and product assembly in manufacturing. Knowledge of printed circuits, at some level, is needed by many staff members who find they have a need to understand the issues of a technology and industry that did not previously concern them. This book provides a reference, for those who are not printed circuit professionals, to find information on, and answers to, questions on process issues. It also helps define the appropriate questions to pose to either members of their own organization or the potential supplier, while developing the entire range of relationships.

From its beginning, the printed circuit has not only been one of the most important technology developments ever made, but one of the least understood and appreciated. It has often been mistakenly considered a “commodity” and purchased on the basis of board, or assembly, initial cost. In fact, there is no such thing as a “standard” or “generic” printed circuit. Every board is actually an “application-specific interconnection system” that can have immense impact on the performance, quality, reliability, and cost of the final product in which it is used. A problem that could have been resolved in the early design and acquisition processes may not be evident until the product is in use, when it is the most difficult and expensive to resolve. This book helps the reader deal with these issues at each step of the supply chain, which includes those inside the user organization as well as the supplier organizations. Specifically, these have brought about a new part entirely devoted to the understanding of, and working with, the printed circuit supply chain itself. The generic issues of

supply chain management have been well documented; however, applying them to the specific problems created by printed circuits requires specialized understanding and is addressed only in this book.

While introducing new tools to address the supply chain issues, the book remains committed to its historical role of providing detailed descriptions of the technology and processes of printed circuits that have evolved over the years, and brought up to date in this edition. It remains the only single reference on all aspects of printed circuit technology. At the same time, when revising process chapters, we have included, where possible, a discussion of issues that the reader should consider when dealing with suppliers that are involved in making boards using these processes by addressing such questions as: What are the things that help the reader know if a supplier, in fact, has the capabilities to provide what is needed? What is unreasonable to expect? How can the desired result be demonstrated initially, and maintained over time?

In using contract manufacturing to fabricate and assemble boards, the user gives up the ability to define the design rules. Success will come by having a partnership with the supplier that reconciles the needs of the user with the capabilities of the manufacturing organization. To make the communications on printed circuit issues between the designer/user and the manufacturer clearer and more efficient, the book also contains new chapters, and expanded revisions of existing chapters on design and layout of boards and assemblies. These include additional information on design and layout basics, high-performance boards, CAD tools, design for manufacturing, and information exchange systems and standards.

As electronic products have become more complex, with higher levels of performance expected, volumes never seen before, and new process and material challenges, such as

“lead-free” soldering, the using organization has had to delegate more responsibility for much of the quality and reliability of the product to the supplier organization. In response, this book also contains critical new material on the reliability of boards and assemblies, with consideration for new base materials, and assembly processes. These chapters were developed specifically for this book, and much of their contents is not available anywhere else, and will allow the user to reach reasonable agreements on process controls and acceptance criteria that ensure the needs are met.

With the continuing concern over the impact on the global environment of printed circuit wet and fabrication processes, as well as assembled boards at the end of their useful life, the issue of RoHS (Restriction of Hazardous Substances), and specifically “lead free” has caused a revolution in the industry unprecedented in its history. Specific information on the impact of the resulting changes in materials and processes is documented and described. For example, for lead-free solders, we start with the Periodic Table and define what is even possible for an alternate alloy. Thus physics and material science are used to describe alternatives available.

The end result of these additions is essentially the creation of a new book, not just a new edition. Twenty-five percent of the chapters are new to this edition, while only 16 percent are reprinted from previous editions.

The publication of this book coincides with the 50th anniversary of the publication of the first edition. That book had 16 chapters, contributed by 11 authors. This edition, the seventh, has 71 chapters contributed by 38 authors. This clearly reflects the development of the level of the technology, as well as the expansion of the user base for printed circuits over time. The fact that this book has maintained a high position of usefulness and importance to

those in the printed circuit field for this length of time must really be attributed to the skills of the authors who have contributed chapters developed from their considerable knowledge and expertise in their respective areas and at considerable time expense. It has been said that the author list for this book reads like a “who’s who” in the printed circuit industry. This has resulted in information the reader can actually use to solve problems.

We also thank the IPC—Association Connecting Electronics Industries, which has given this book total cooperation and support for every edition. We would especially like to acknowledge the active help and encouragement of IPC managers Anne Marie Mulvihill, David Bergman, and Greg Munie (who also authored a chapter). Their efforts were a great contribution to our ability to accomplish the development of a project of this size and complexity.

1.1 INTRODUCTION

All electronic components must be interconnected and assembled to form a functional and operating system. The design and the manufacture of these interconnections have evolved into a separate discipline called *electronic packaging*. Since the early 1950s, the basic building block of electronic packaging is the printed wiring board (PWB), and it will remain that into the foreseeable future. This book

outlines the basic design approaches and manufacturing processes needed to produce these PWBs.

This chapter outlines the basic considerations, the main choices, and the potential trade-offs that must be accounted for in the selection of the interconnection methods for electronic systems. Its main emphasis is on the analysis of potential effects that the selection of various printed wiring board types and design alternatives could have on the cost and performance of the complete electronic product.

1.2 MEASURING THE INTERCONNECTIVITY REVOLUTION

The continuing increase in component performance and lead density, along with the reduction in package sizes, has required that PWB technology find corresponding ways to increase the interconnection density of the substrate. With the introduction and continued refinement of such packaging techniques as the ball grid array (BGA), chip-scale packaging (CSP), and chip-on-board (COB), traditional PWB technology has approached a point where alternative ways of providing high-density interconnection have had to be developed.

This has been called at times high-density interconnects (HDI), the interconnection revolution, or the density revolution, because doing the same things in the same way, only smaller, was no longer sufficient.

1.2.1 Interconnect Density Elements

The extent of these interconnect density issues is not always observable, but the chart[1] in Figs. 1.1 and 1.2 can help one define and understand it. The chart portrays the interrelationship between component packaging, surface-

mount technology (SMT) assembly, and PWB density. As can be seen, these three elements are interlinked. A change in one has a significant effect on the overall interconnection density. The metrics are as follows:

- *Assembly complexity*. The measure of the difficulty of assembling surface-mounted components in parts per square inch and leads per square inch.
- *Component packaging complexity*. The degree of sophistication of a component, measured by its average leads (I/Os) per part.
- *Printed wiring board density*. The amount of wiring a PWB has as measured by the average length of traces per square inch or the area of that board, including all signal layers. The metric is inches per square inch.

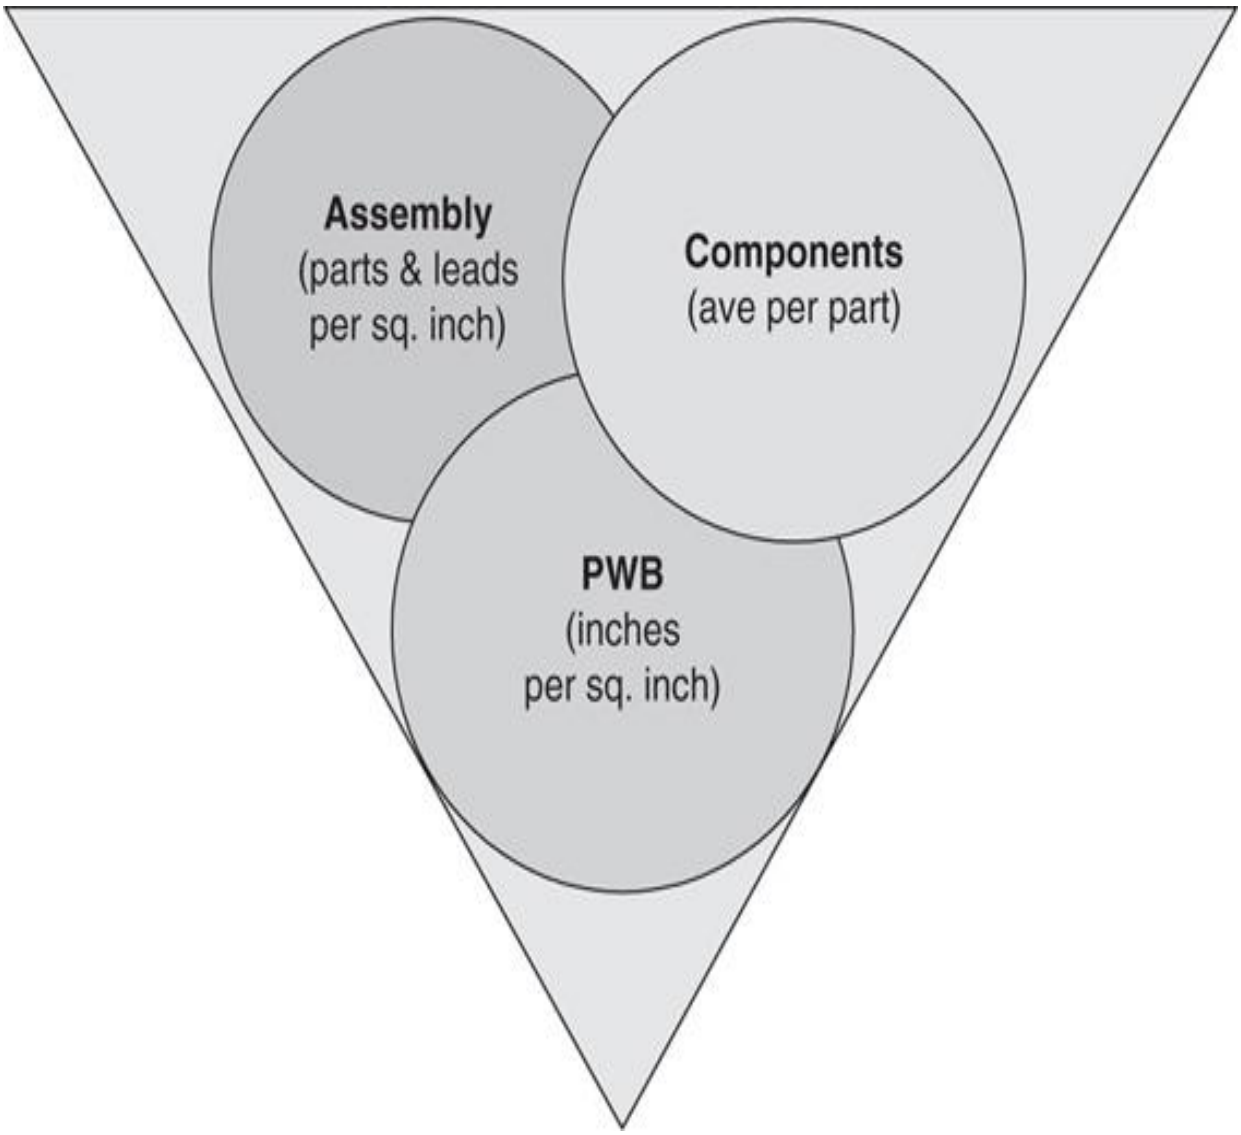

FIGURE 1.1 Representation of the metrics of assembly, component, and PWB technologies and their general relationship to each other.

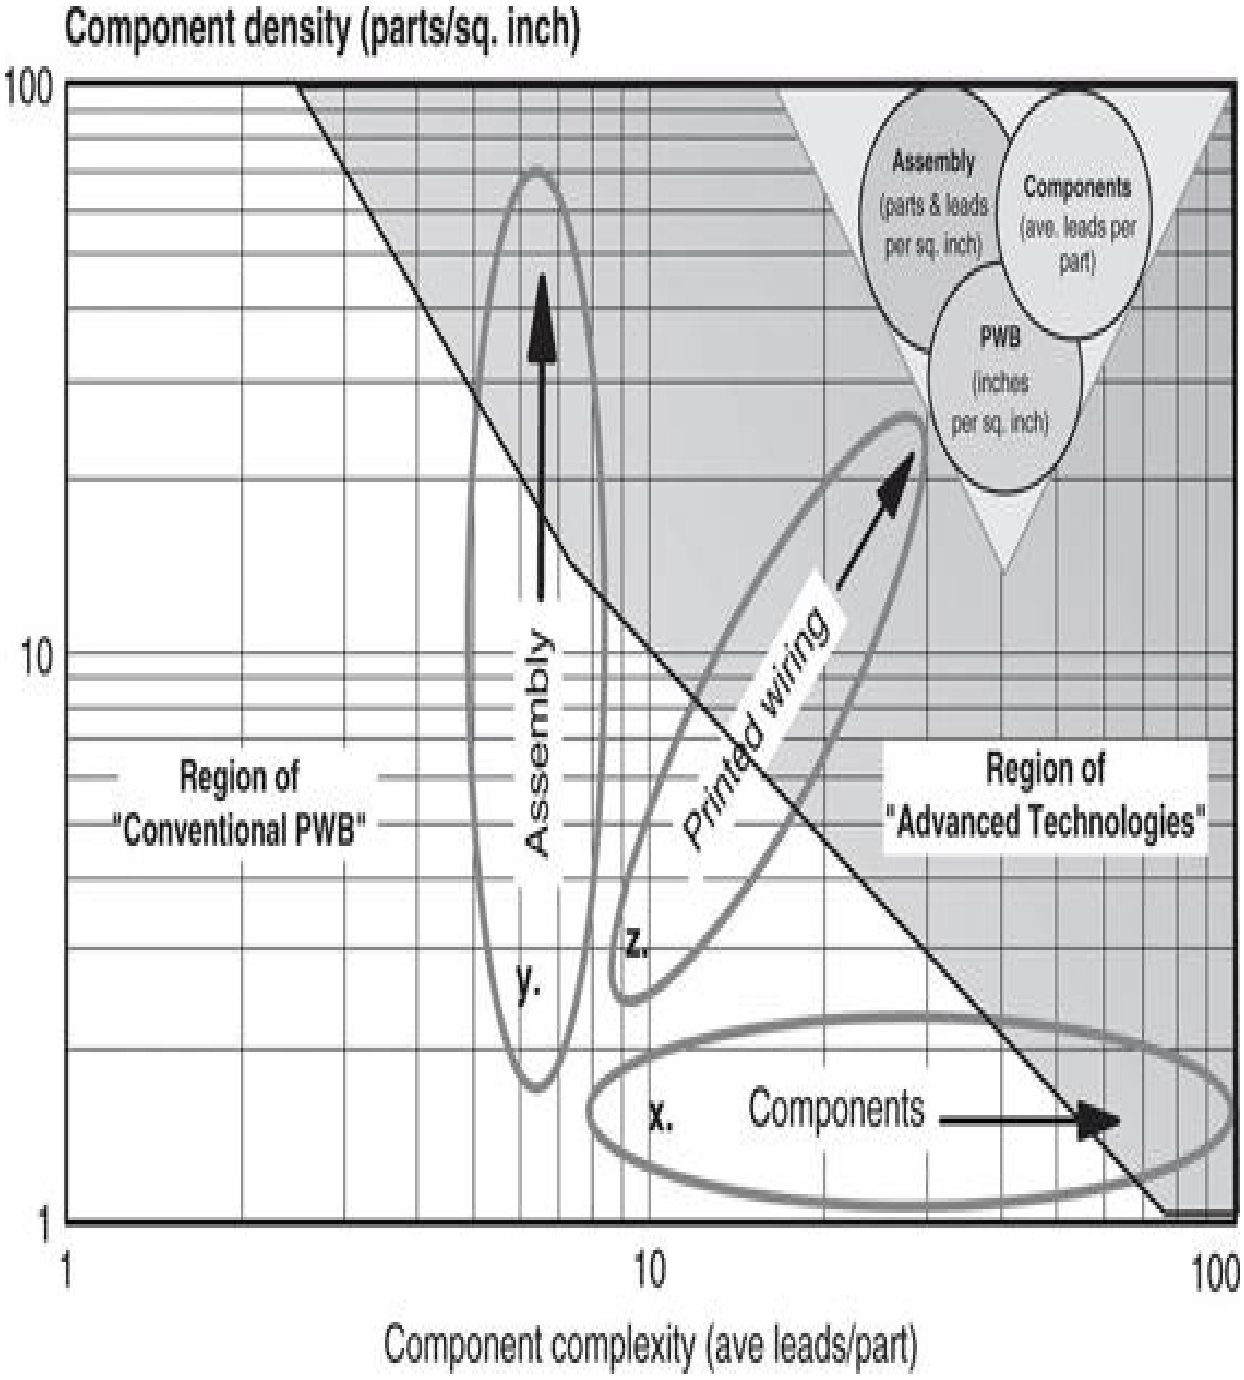

FIGURE 1.2 Component technology map, showing the relationship of assembly, PWB, and component technologies on overall package density and technology.

1.2.2 Interconnect Technology Map

To visualize the interrelationships of the three elements, see Fig. 1.2.[1] It shows these elements as axes of a three-dimensional technology map that defines the passage from conventional PWB structures to advanced technologies and shows how changes in just one of the elements can increase or decrease the total density of the entire electronic package.

To describe the component complexity of an assembly, the total component connections (I/Os) include both sides of an assembly, as well as edge fingers, or contacts, which are divided by the total number of components on the assembly. The resulting average leads (I/Os) per part provides the *x* axis of Fig. 1.1. The horizontal oval shape shows how the component complexity can vary from two leads per part in discrete circuit elements to the very large numbers seen on BGA and application-specific integrated circuits.

When Fig. 1.2 is used to describe surface-mount assemblies, the vertical (*y* axis) dimension (shown as a vertical oval) indicates how complex it is to assemble the board by number of components per square inch or square centimeter for the surface area of the PWB. This vertical oval can vary from 1 to over 100 parts per square inch. As the parts become smaller and closer together, this number naturally goes up. A second assembly measure is average leads (I/Os) per square inch or square centimeter. This is the *x*-axis value multiplied by the *y*-axis value. (For a further description of these issues, and equations for quantifying them, see Chap. 16.)

The *z*-axis oval in Fig. 1.2 describes the printed wiring board's density. This is the wiring required to connect all the I/Os of the components at the size of the assembly specified, assuming three nodes per net. This axis has the units inches per square inch, or centimeters per square centimeter. A further description of this metric is provided in this chapter and in more detail in Chap. 16.

1.2.3 An Example of the Interconnect Revolution

By charting products of a particular type over time, an analysis will show how the interconnect technology has changed and continues to change, its rate of change, and the direction of these changes. An example is given in Fig. 1.3. This shows how component technology, assembly technology, and PWB technology have led to the evolution of the same computer CPU from:

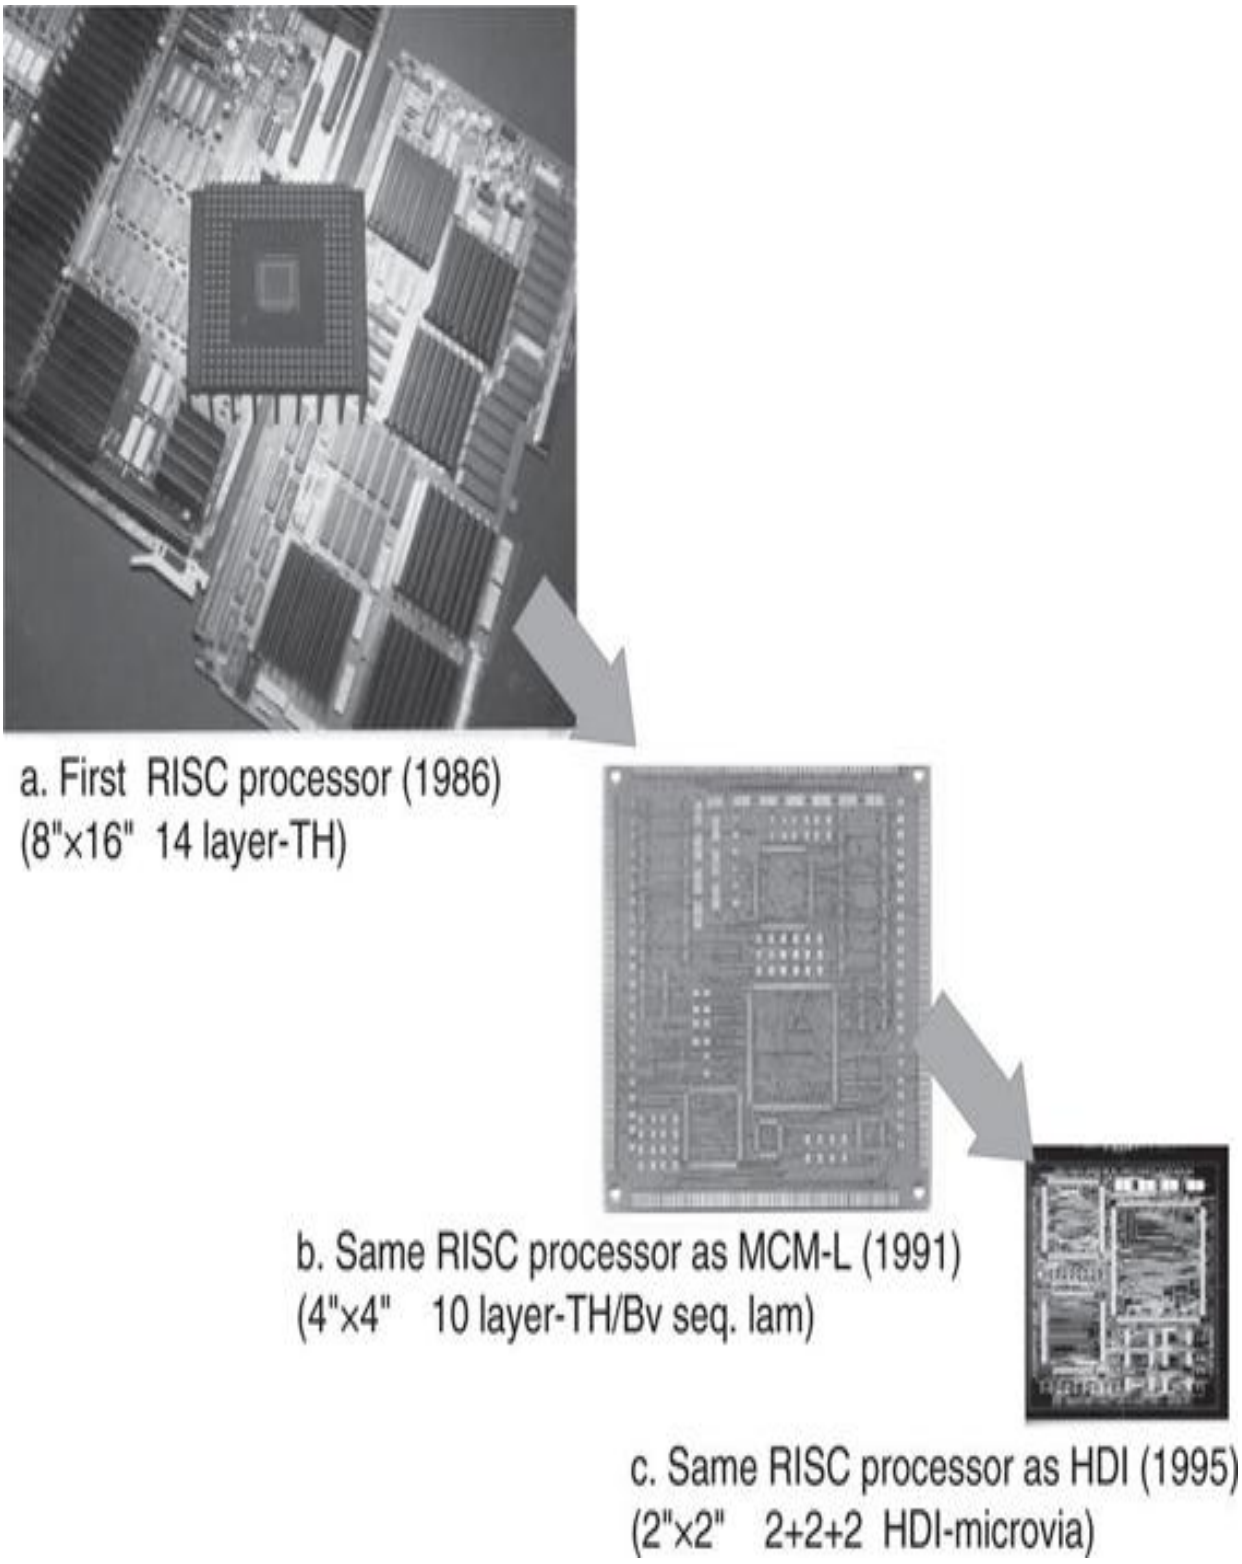

FIGURE 1.3 Example of the same computer CPU board as it used alternative component, assembly, and PWB technologies. (*a*) Size and appearance of each generation. (*b*) Movement of total board density from traditional to HDI. (*c*) HDI.

A 14-layer board through-hole with a surface area of 128 in^2 in 1986 (Fig. 1.3*a*) to a 10-layer surface-mount technology board with a surface area of 16 in^2 in 1991 (Fig. 1.3*b*) to a high-density interconnect board with sequential build-up microvias, buried and blind vias, and a surface area of 4 in^2 in 1995 (Fig. 1.3*c*).

1.2.4 Region of Advanced Technologies

A second valuable feature of the chart in Fig. 1.2 is the area identified as the region of advanced technologies. This is where calculations and data have shown that it is necessary to have an HDI structure. Therefore, this is the barrier, or wall of HDI: on one side it is most cost effective to use traditional PWB technologies; on the other side it becomes cost effective to use HDI technologies. Continuing beyond this point, HDI becomes necessary.

1.3 HIERARCHY OF INTERCONNECTIONS

To have the proper perspective on where PWBs fit into electronic systems, it will be helpful to describe briefly the packaging hierarchy of electronic systems. Some time ago, the Institute for Interconnecting and Packaging Electronic Circuits (IPC)[2] proposed eight categories of system elements in ascending order of size and complexity, which will be used here to illustrate typical electronic packaging structures. These are as follows:

Category A consists of fully processed active and passive devices. Bare or uncased chips and discrete capacitors,

resistors, or their networks are typical examples of this category.

Category B comprises all packaged devices (active and passive) in plastic packages, such as DIPs, TSOPs, QFPs, and BGAs, as well as those in ceramic packages, such as PGAs, and connectors, sockets, and switches. All are ready to be connected to an interconnecting structure.

Category C is substrates that interconnect uncased or bare chips (i.e., the components of category A) into a separable package. Included here are all types of multichip modules (MCMs), chip-on-boards (COBs), and hybrids.

Category D covers all kinds of substrates that interconnect and form assemblies of already packaged components, that is, those from categories B and C. This category includes all types of rigid PWBs, flexible and rigid-flexible, and discrete-wiring boards.

Category E covers the back planes made by printed wiring and discrete-wiring methods or with flexible circuits, which interconnect PWBs, but not components, from the preceding groups.

Category F covers all intraenclosure connections. Included in this category are harnesses, ground and power distribution buses, RF plumbing, and coax or fiberoptic wiring.

Category G includes the system assembly hardware, card racks, mechanical structures, and thermal control components.

Category H encompasses the entire integrated system with all its bays, racks, boxes, and enclosures and all auxiliary and support subsystems.

As seen from the preceding list, PWBs are exactly in the center of the hierarchy and are the most important and universally used element of electronic packaging.

The packaging categories F, G, and H are used mainly in large mainframes, supercomputers, central office switching, and some military systems. Since there is a strong trend toward the use of miniaturized and portable electronic products for the majority of electronic packaging designs, trade-offs are made in the judicious application and selection among the elements of the first five categories. These are discussed in this chapter.

1.4 FACTORS AFFECTING SELECTION OF INTERCONNECTIONS

Selection of the packaging approaches among the various aforementioned elements is dictated not only by the system function, but also by the component types selected and by the operating parameters of the system, such as the clock speeds, power consumption, and heat management methods, and the environment in which the system will operate. This section provides a brief overview of these basic constraints that must be considered for proper packaging design of the electronic system.

1.4.1 Speed of Operation

The speed at which the electronic system operates is a very important technical factor in the design of interconnections. Many digital systems operate at close to 100 MHz and are already reaching beyond that level. The increasing system speed is placing great demands on the ingenuity of packaging engineers and on the properties of materials used for PWB substrates.

The speed of signal propagation is inversely proportional to the square root of the dielectric constant of the substrate

materials, requiring designers to be aware of the dielectric properties of the substrate materials they intend to use. The signal propagation on the substrate between chips, the so-called *time of flight*, is directly proportional to the length of the conductors and must be kept short to ensure the optimal electrical performance of a system operating at high speeds.

For systems operating at speeds above 25 MHz, the interconnections must have transmission line characteristics to minimize signal losses and distortion. Proper design of such transmission lines requires careful calculation of the conductor and dielectric separation dimensions and their precise manufacture to ensure the expected accuracy of performance. For PWBs, there are two basic transmission line types:

1. Stripline
2. Microstrip (for details, see Chap. 20)

1.4.2 Power Consumption

As the clock rates of the chips increase and as the number of gates per chip grows, there is a corresponding increase in their power consumption. Some chips require up to 30 W of power for their operation. With that, more and more terminals are required to bring power in and to accommodate the return flow on the ground planes. About 20 to 30 percent of chip terminals are used for power and ground connections. With the need for electrical isolation of signals in high-speed systems operation, the count may go to 50 percent.

Design engineers must provide adequate power and ground distribution planes within the multilayer boards (MLBs) to ensure efficient, low-resistance flow of currents, which may be substantial in boards interconnecting high-speed chips consuming tens of watts and operating at 5 V,

3.3 V, or lower. Proper power and ground distribution in the system is essential for reducing *di/dt* switching interference in high-speed systems, as well as for reducing undesirable heat concentrations. In some cases, separate bus-bar structures have been required to meet such high power demands.

1.4.3 Thermal Management

All the energy that has been delivered to power integrated circuits (ICs) must be efficiently removed from the system to ensure its proper operation and long life. The removal of the heat from a system is one of the most difficult tasks of electronic packaging. In large systems, huge heat-sink structures, dwarfing the individual ICs, are required to air-cool them, and some computer companies have built giant superstructures for liquid cooling of their computer modules. Some computer designs use liquid immersion cooling. Still, the cooling needs of large systems tax the capabilities of existing cooling methods.

The situation is not that severe in smaller, tabletop or portable electronic equipment, but it still requires packaging engineers to ameliorate the hot spots and ensure longevity of operation. Since PWBs are notoriously poor heat conductors, designers must carefully evaluate the method of heat conduction through the board, using such techniques as heat vias, embedded metal slugs, and conductive planes.

1.4.4 Electronic Interference

As the frequency of operation of electronic equipment increases, many ICs, modules, or assemblies can act as generators of radio frequency (RF) signals. Such electromagnetic interference (EMI) emanations can seriously

jeopardize the operation of neighboring electronics or even of other elements of the same equipment, causing failures, mistakes, and errors, and must be prevented. There are specific EMI standards defining the permissible levels of such radiation, and these levels are very low.

Packaging engineers, and especially PWB designers, must be familiar with the methods of reducing or canceling this EMI radiation to ensure that their equipment will not exceed the permissible limits of this interference.

1.4.5 System Operating Environment

The selection of a particular packaging approach for an electronic product is also dictated by its end use and by the market segment for which that product is designed. The packaging designer has to understand the major driving force behind the product use. Is it cost driven, performance driven, or somewhere in between? Where will it be used—for instance, under the hood of a car, where environmental conditions are severe, or in the office, where the operating conditions are benign? The IPC[2] has established a set of equipment operating conditions classified by the degree of severity, which are listed in Table 1.1.

TABLE 1.1 Realistic Representative-Use Environments, Service Lives, and Acceptable Cumulative-Failure Probabilities for Surface-Mounted Electronics by Use Categories

Use category	Worst-case use environment					Years of service	Acceptable failure risk, %
	T_{min}, °C	T_{max}, °C	ΔT,* °C	t_D, h	Cycles/year		
1—Consumer	0	+60	35	12	365	1–3	~1

			&140	2	40		

& = in addition.

*ΔT represents the maximum temperature swing, but does not include power dissipation effects; for power dissipation, calculate ΔT_c.

1.4.5.1 Cost. The universal digitization of most electronic functions led to the merger of consumer, computer, and communication technologies. This development resulted in the increased appeal of electronics and the need for mass production of many electronic products. Thus, product cost has become the most important criterion in any design of electronic systems. While complying with all the aforementioned design and operation conditions, the design engineer must keep cost as the dominant criterion, and must analyze all potential trade-offs in light of the best cost/performance solution for the product.

The importance of the rigorous cost trade-off analysis during the design of electronic products is underscored by the fact that about 60 percent of the manufacturing costs are determined in the first stages of the design process, when only 35 percent of the total design effort has been expended.

Attention to manufacturing and assembly requirements and capabilities [so-called design for manufacturability and assembly (DFM/A)] during product design can reduce assembly costs by up to 35 percent and PWB costs by up to 25 percent.

The elements that must be considered for the most cost-effective electronic packaging designs are

- Optimization of the PWB design and layout to reduce its manufacturing cost
- Optimization of the PWB design to reduce its assembly cost
- Optimization of the PWB design to reduce testing and repair costs

The following sections provide some guidelines on how to approach such optimization of PWB designs. Basically, the costs of the electronic assemblies are directly related to their complexity and there are a number of measurements

relating the effects of various PWB design elements to their costs to guide the design engineer in selection of the most cost-effective approach.

1.5 ICs AND PACKAGES

The most important factors influencing PWB design and layout are the component terminal patterns and their pitches, especially those of ICs and their packages, since these dictate the density of the interconnecting substrates. Thus, this element will be considered first.

Driven by the need for improved cost and performance, the complexity of ICs is constantly increasing. Due to relentless progress in IC technology, the gate density on a chip is increasing by about 75 percent per year, resulting in the growth of IC chip I/O terminals by 40 percent per year, which places ever increasing demands on the methods of their packaging and interconnection.

As a result, the physical size of electronic gears keeps shrinking by 10 to 20 percent per year, while the surface area of substrates is being reduced by about 7 percent per year. This is accomplished by continuously increasing wiring densities and reducing line widths, which has severely stressed PWB manufacturing methods, reduced processing yields, and increased the costs of the boards.

1.5.1 IC Packages

Since their inception, IC chips have been placed within ceramic or plastic packages. Until about 1980, all IC packages had terminal leads that were soldered into plated through-holes (PTHs) of the PWBs. Since then, an increasing number of IC packages have their terminals made in a form

suitable for surface-mounting technology (SMT), which has become the prevailing method of component mounting.

There has been a proliferation of IC package types, both for through-hole assembly as well as for surface mounting, varying in their lead configurations, placement, and pitches. Also, IPC-SM-782[3] provides a good catalog of the available SMT packages and of the PWB footprint formats they require for their assembly.

Basic I/O termination methods of IC packages include the following:

- *Peripheral*, where the terminations are located around the edges of the chip or package
- *Grid-array*, where the terminations are located on the bottom surface of the chip or package

1.6 DENSITY EVALUATIONS

1.6.1 Component Density Analysis

Because the components and their terminations exert a major effect on the design of the PWB, a number of metrics have been developed to establish the relationships between component density and PWB density. A major analysis of these relationships has been made by H. Holden[4] and some of his charts and derivations are provided here to guide the design engineers during the development of a rational PWB design.

This information is very useful in determining where the designed product will fit in the component density spectrum and what, therefore, is to be expected for PWB density.

Figure 1.4 provides a generalized view of the relationships among the component density, their terminal density, and the necessary wiring density that will be required to

accommodate the selected degree of component complexity. The definition of the wiring connectivity W_f is provided.

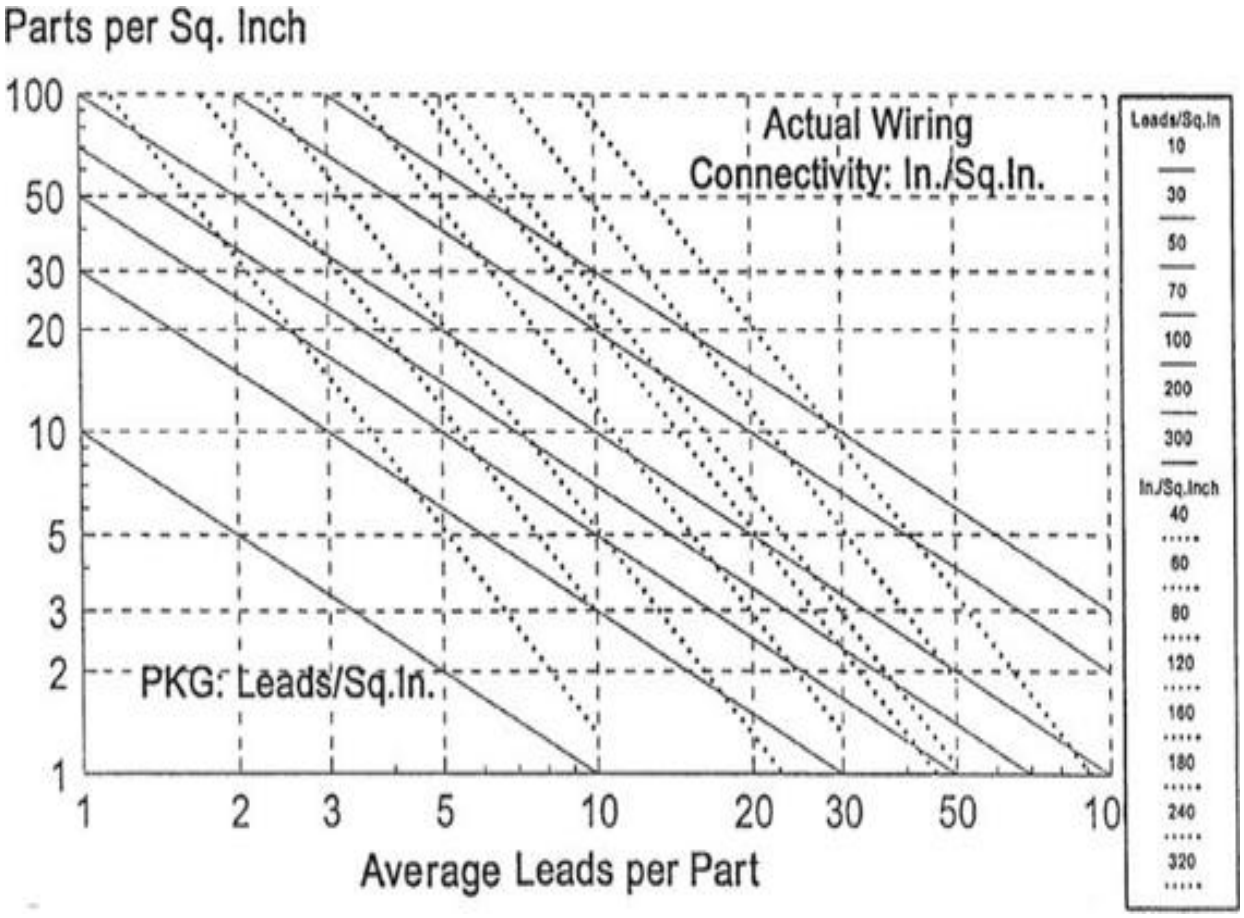

FIGURE 1.4 Plot of general relations between component and wiring density.

1.6.2 PWB Density Metrics

It is essential for the proper design of PWBs to determine the density requirements and then analyze alternative methods of board construction for the most cost-effective design. There are a number of basic terms and equations used for the calculation and analysis of PWB wiring density.

$$W_c = \frac{T * L}{G} \text{ in/in}^2 \qquad (1.1)$$

where W_c = wiring capacity
T = tracks per channel
L = number of signal layers
G = channel width

But it is more important to determine the required wiring density that will be sufficient to interconnect all the components on the desired board size. There have been a number of empirically developed equations that permit the calculation of such a wiring demand. The simplest has been developed by Dr. D. Seraphim[5]:

$$W_d = 1.25\, N_t * P \tag{1.2}$$

where W_d = wiring demand
N_t = number of I/Os
P = pitch between packages

1.6.3 Special Metrics for Direct Chip Attach

The assembly of uncased or bare chips on substrates has become popular mostly due to the ability of such assemblies to reduce the area of interconnections. The ideal limit for such assembly would be to place all the chips tightly together, without any space in between. This would result in 100 percent packaging efficiency, a metric measuring the ratio of silicon area to the substrate area. Naturally, such 100 percent efficiency is not achievable, but this metric is still useful in ranking various substrate construction or bare chip attachment methods, as shown in Fig. 1.5.

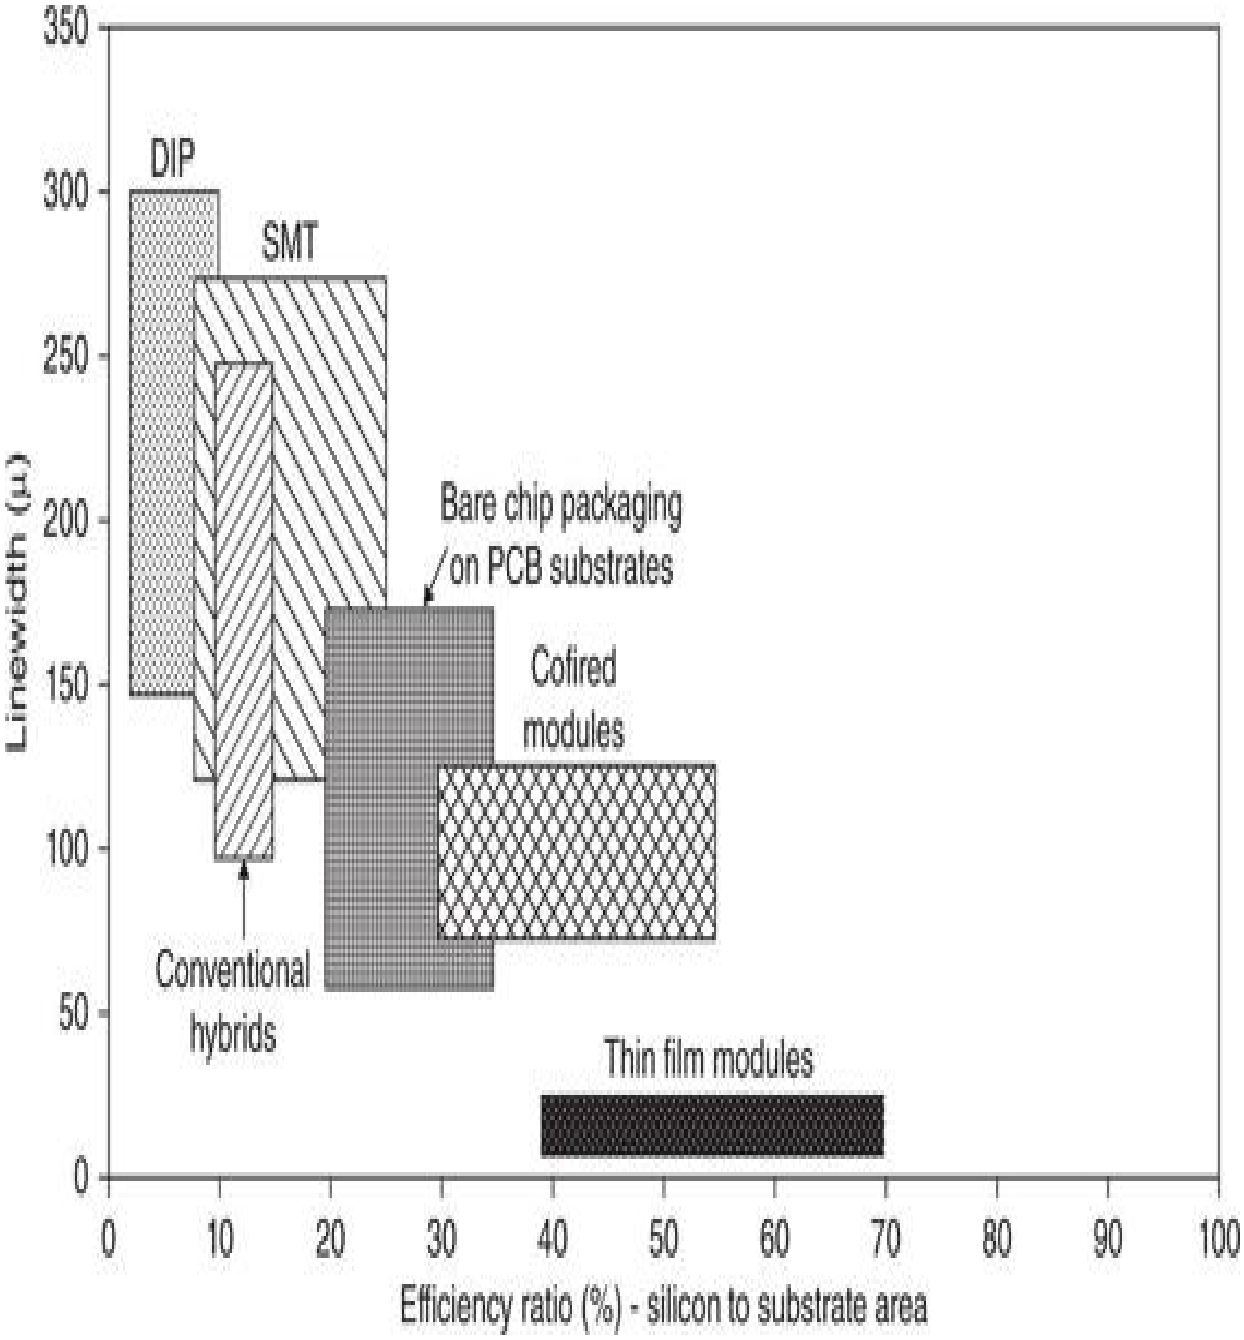

FIGURE 1.5 Packaging efficiency. (*Courtesy of BPA, used with permission*.)

Packaging efficiency of 100 percent is impossible to achieve because all chip-mounting methods require some space around the chips. Even with flip-chips, there must be a distance left between the chips to permit room for the placement tool.

Dr. H. Charles[6] of Johns Hopkins University has listed the dimensions in Table 1.2 for the necessary spacing between the chips (or the total width of the frame around the chips) for various chip attachment methods. These or very similar distances have also been cited by a number of other sources.

TABLE 1.2 Spacing Required between Chips

Attachment Method	Chip Spacing, mils
Flip-chip	15–20
Wire-bonding	70–80
Flip TAB	100–120
Regular TAB	150–400

Even with the flip-chip mounting, packaging efficiency must be derated to about 90 percent, for wire-bonding to 70 percent and for TABs to about 50 percent, and in some cases much more. A very similar situation is shown graphically in Fig. 1.6. The packaging efficiency deratings, shown in Fig. 1.6, are required to accommodate only the wiring bond pads on the substrates. But the mounting of bare chips on PWBs requires additional signal redistribution area to permit placement of larger-diameter PTHs farther out for communication with internal layers. It is evident that the packaging efficiencies on PWBs could be reduced to the range of only 20 to 30 percent, unless special surface signal redistribution layers (as previously mentioned) are used, which are made of unreinforced dielectric material. In such cases, packaging efficiency and the chip-to-chip distances will again be similar to the values cited in Table 1.2.

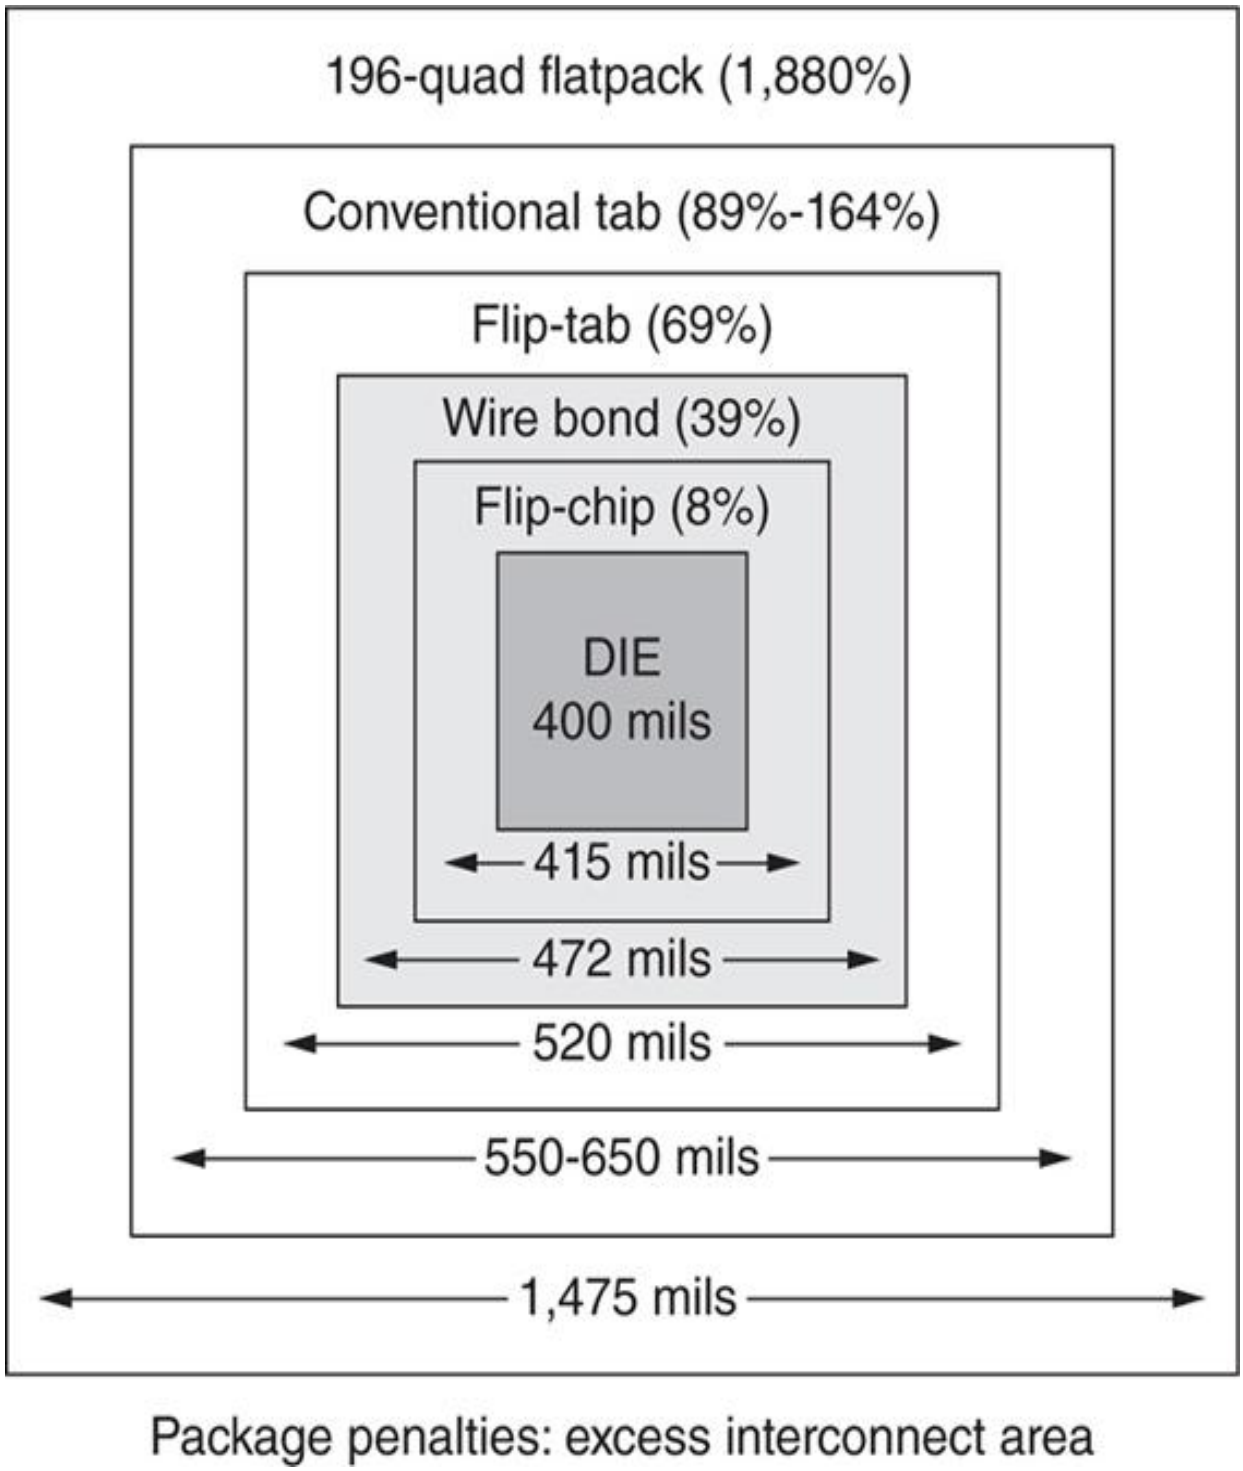

FIGURE 1.6 Chip area required to accommodate bonding methods.

It is apparent that direct chip attach on PWBs will result in the significant reduction of the packaging efficiency of such assemblies, except for the fact that components can be

mounted on both sides of the PWB substrate. It has been shown that wire-bonding can be done on both sides of a PWB with some special fixturing; also, outer lead bonding (OLB) of TABs can be done on both sides of the PWB substrate. Thus, while single-sided bare chip assembly on PWBs reduces its packaging efficiency to about half that of other types of substrate constructions, the ability to place components on both sides of PWBs brings it back to the same packaging efficiency level as others.

1.7 METHODS TO INCREASE PWB DENSITY

There are four basic ways to increase the connectivity or available conductor capacity of PWBs[7]:

- Reduce hole and pad diameters
- Increase the number of conductive channels between pads by reducing the widths of the conductors
- Increase the number of signal planes
- Add blind or buried via structures

The effect of each approach on manufacturing yields, and thus on board costs, will be discussed in sequence. It should be noted that the last option is the simplest but the most costly solution, and thus should be used only after the methods suitable for resolving the first two conditions have been proven inadequate for achieving the desirable board density.

1.7.1 Effect of Pads on Wiring Density

The major obstacles preventing increase of conductor channel capacity are large pad diameters around the plated through-holes (PTHs), since, at the present state of technology, PWBs still require pads wider than the conductors at their location. These pads reduce the obtainable connectivity of PWB boards and must be accounted for in a proper analysis of interconnection density I_d. For instance, in one design, the reduction of pad diameters from 55 to 25 mils (by 55 percent) doubled the interconnection density, while the reduction in conductor pitch C_p from 18 to 7 mils (by 61 percent) increased it only by 50 percent. It is obvious that the reduction of pad diameters, or their total elimination, could be a more efficient way to increase the wiring capacity of complex PWBs.

The purpose of copper pads surrounding the drilled holes in PWBs is to accommodate any potential layer-to-layer or pattern-to-hole misregistrations and thus prevent any hole breakout outside the copper area of the pads. This misregistration is caused mainly by the instability and movement of the base laminate during its processing through the PWB or multilayer board (MLB) manufacturing steps.

The base material standards specify that such movement be limited to a maximum of 300 ppm, but the actual base material excursions are closer to 500 ppm, producing 10 mils of layer movement within a 20-in distance. For many applications this tolerance is too wide, as it requires at least a 10-mil-wide annular ring around drilled holes, resulting in considerable conductor channel blockage.

Another cause of material instability in MLBs is the excessive material movement that occurs if the laminating temperature exceeds the glass transition temperature T_g of the laminate resin. On the other hand, if the laminating temperature remains below the T_g of the resin, there is

minimal dimensional variation of the base material, as the resin is still in its linear expansion phase. This explains the need for use of high-T_g resins in the PWB industry.

The data obtained from the performance of new, more stable unidirectional laminates indicate that the base material movement is reduced, for instance to 200 from 500 ppm, and the requirements for the annular ring width will be reduced to 4 from 10 mils.

Table 1.4 illustrates the connectivity gains made possible when a more stable laminate material is used, permitting a reduction in the initial diameters of the pads (as given in the first column) spaced at 1.5 mm (0.100 in) while keeping the conductor pitches constant. The most effective use of the signal plane area is achieved when the pads are eliminated and the *z*-axis interconnects are confined within the width of the conductors forming the invisible vias.

This derivation is based on actual data obtained from the performance of new, more stable, unidirectional laminates. While MLBs using these new, more dimensionally stable, unidirectional laminates with reduced pad diameters could be manufactured by conventional manufacturing methods, the production of MLBs with invisible vias requires the use of a sequential manufacturing process similar to the SLC process previously described.

PWB manufacturers are reasonably comfortable with the production of boards with 4- or 5-mil-wide conductors, but they still require large pads around plated holes to ensure against hole breakout. This limits the currently available wiring density to about 40 to 60 in/in^2 per plane, as seen from Table 1.3. A technology that will permit PWB manufacturers to fabricate invisible vias could increase the connectivity per PWB signal plane from this current range to the level of 100 to 140 in/in^2. Conductor widths of 0.002 in will offer a PWB of 200 to 250 in/in^2 per signal plane.

TABLE 1.3 Effect of Pad Diameters on Interconnectivity Density

Pad dia, in	Cond Pitch, in	I_d @ 500 ppm, in/in^2	I_d @ 200 ppm, in/in^2	I_d @ Invisible via, in/in^2
0.055	0.010	20	37	55
0.036	0.018	30	48	55
0.025	0.009	40	96	100
0.025	0.007	60	130	143

Table 1.4 illustrates the most important result of increased connectivity per layer: a reduction in the number of signal layers needed to provide the same wiring density W_d. Table 1.4 was constructed by applying connectivity data from Table 1.3 to a 50-in^2 MLB with total wiring length of 10,000 in. Note also that the layer count in Table 1.3 has been brought up to the next higher full-layer value, that is, the calculated 1.4 layers have been recorded as 2 layers.

TABLE 1.4 Effect of Increased Connectivity on Reduction of Layers

Pad dia, in	Cond Pitch, in	I_d @ 500 ppm, layers	I_d @ 200 ppm, layers	I_d @ Invisible via, layers
0.055	0.010	10	6	4
0.036	0.018	7	4	4
0.025	0.009	5	2	2
0.025	0.007	4	2	2

The major benefit of such a reduction in the layer count is that it can result in a significant reduction of the manufacturing cost while providing the same total interconnection length.

1.7.2 Reduction of Conductor Width

An obvious method of increasing the connectivity of PWBs is to reduce the widths of conductors and spaces and thus increase the number of available wiring channels on each signal plane, as described previously. This is the direction that has been used in the IC and PWB industries for many years. However, it is impossible to decrease conductor widths or spaces indefinitely. The reduction of the conductor width is limited by the current-carrying capacity of thin, small conductors, especially when these conductors are long, as they frequently are on PWBs. There are processing limits to this conductor reduction, since manufacturing yields may plummet if the reduction stretches the process capabilities beyond their normal limits.

There is also a limit to the reduction of the spaces between the conductors, governed mainly by electrical considerations, that is, by the need to prevent excessive cross talk, to minimize noise, and to provide proper signal propagation conditions and characteristic impedance.

Still, such conductor reductions, if achieved within the described limits, can be an effective path for increasing the PWB density and the reduction of PWB manufacturing costs. As seen from Table 1.5, constructed from cost data derived from the Columbus program of BPA, the reduction of conductor widths from 6 to 3 mils halves the number of signal layers necessary to ensure the same connectivity (while their yields, interconnection density, and board area were kept constant). This reduction in the number of layers

can significantly reduce the manufacturing costs of PWB boards.

TABLE 1.5 Effect of Conductor Widths on Number of Layers and Board Cost for a 6-in × 8-in MLB, with I_d = 450 in/in^2, 65 to 68 Percent Yields

Line-Space	Total No. of Layers	No. of Signal Layers	Board Cost, %
3–3	8	4	55
4–4	10	6	64
5–6	12	7	77
5–7	14	8	87
6–6	16	8	90
7–8	20	10	100

1.7.3 Effect of Conductor Widths on Board Yields

It is obvious that any successful increase of conductor density I_d in PWBs would be effective only if the processes exist that permit manufacture with reasonable yields. Unfortunately, the yields of thin conductors in PWBs fall rapidly as their widths are reduced below 5 mils, as shown in Fig. 1.7. Therefore, the understanding of manufacturing yields is very important for analysis of the most cost-effective manufacturing process, because the process yields have a major effect on the cost of interconnection substrates.

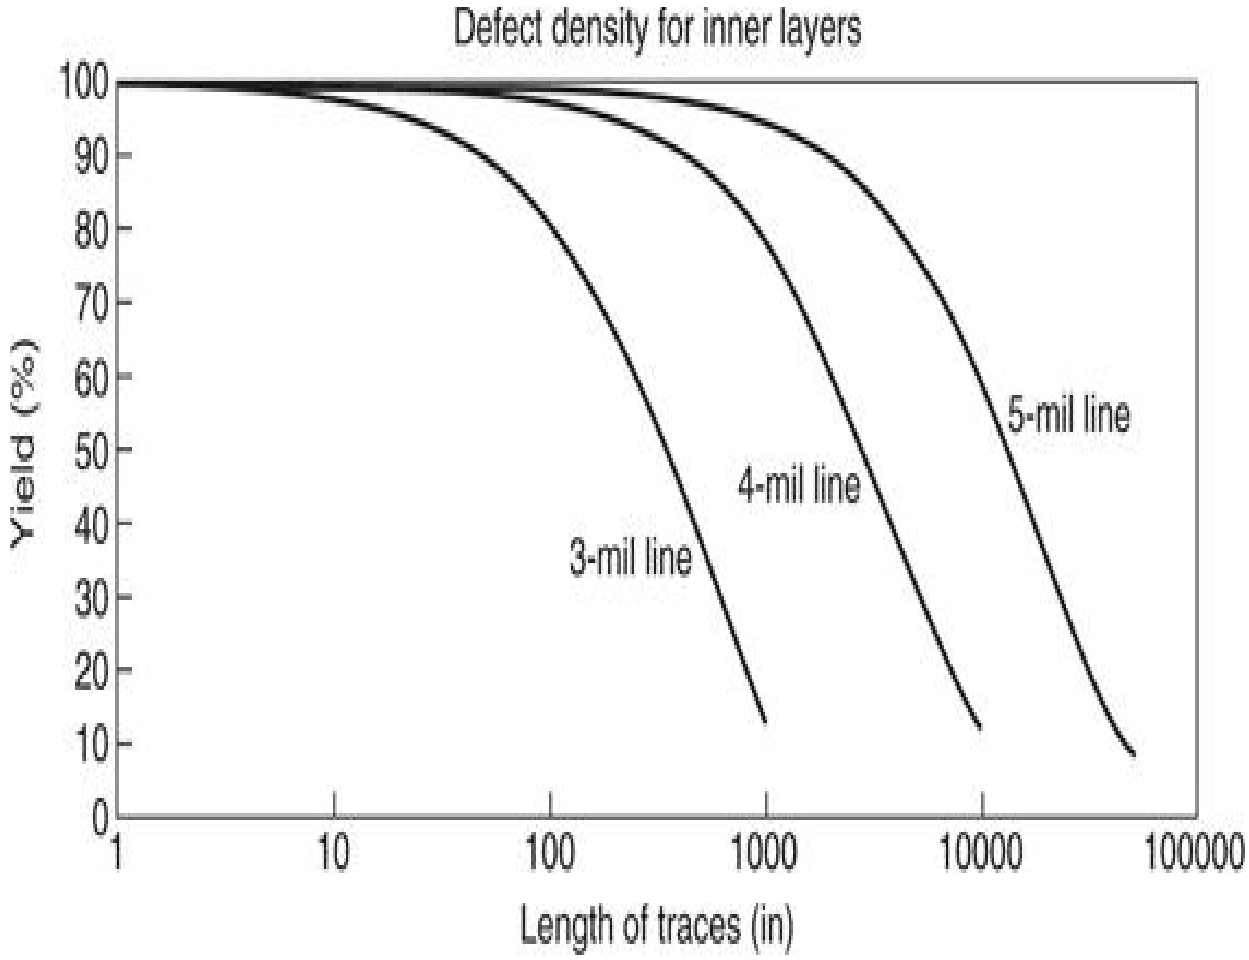

FIGURE 1.7 Board yields versus conductor width.

A useful empirical equation for calculating the manufacturing cost is

$$\text{Cost } C = \frac{(\text{material} + \text{process cost})}{\text{yield } Y} \tag{1.3}$$

To establish the effect of the interconnection density I_d on the final yield of substrates, the total processing yield can be split into two components: one that depends on the conductor density, that is, Y_{Id}, and the second, which is a function of the combined yields of the rest of the manufacturing processes:

$$Y_{\text{total}} = Y_{ld} * Y_{\text{proc}} \tag{1.4}$$

In a well-controlled manufacturing operation, the process-dependent yields (such as plating) remain fairly constant for a given technology, permitting the yield function to be based solely on the changes in the conductor widths.

As seen from Fig. 1.8, the defects that affect this density-dependent yield function Y_{ld} are conductor opens and shorts between them. It would be reasonable to assume that such defects have a Poisson distribution over the total length TL of conductors of a substrate, with an average defect frequency of v. The yield is the probability of zero defects ($n = 0$) in the total conductor length TL. Thus,

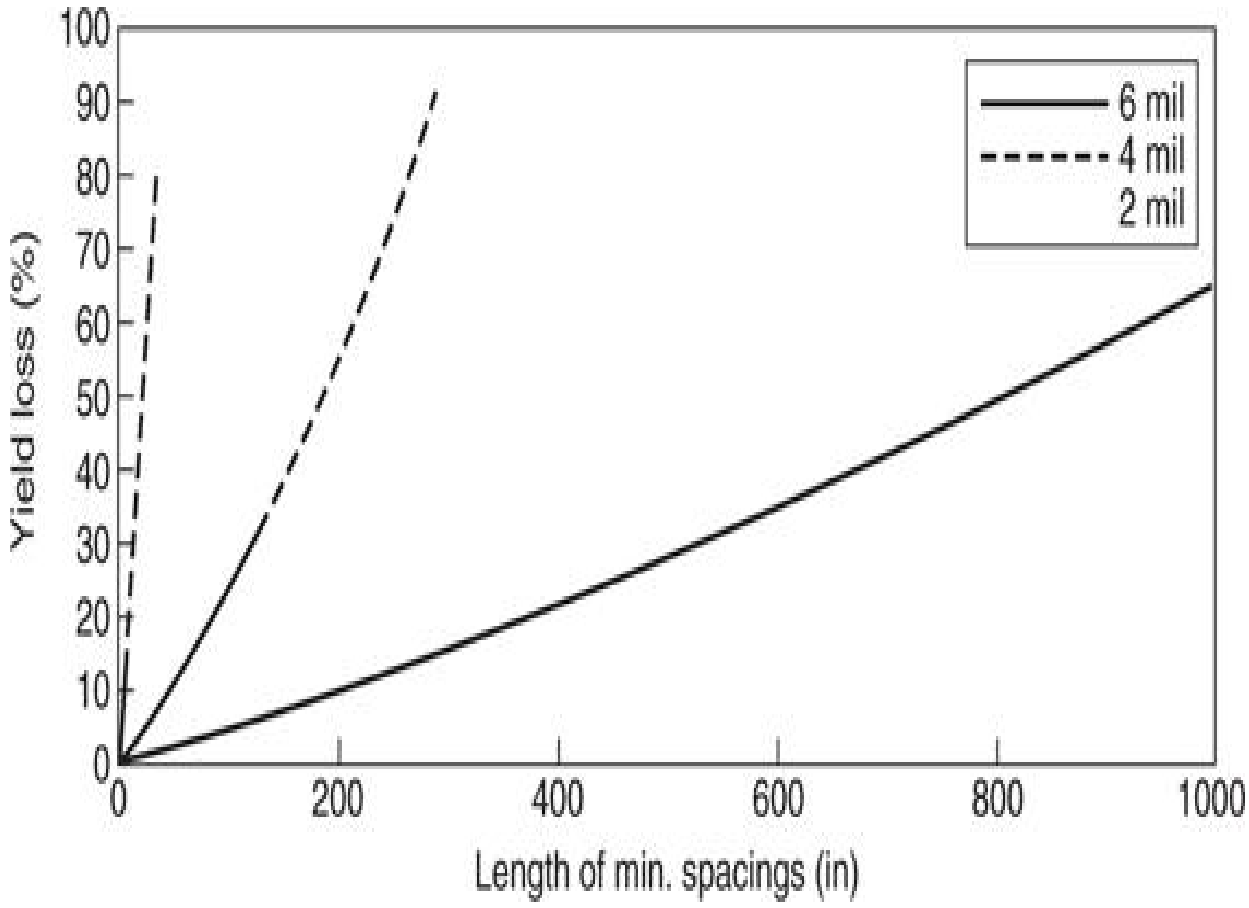

FIGURE 1.8 Yield loss from shorts.

$$Y = (\text{at } n = 0) = e^{(-\nu * \text{TL})} \text{ (Poisson distribution)} \quad (1.5)$$

As seen from Figs. 1.7 and 1.8, the defect frequency ν depends also on the widths of lines and spaces, that is, on the conductor pitch C_p. With a decrease of C_p, ν will increase, but for very large C_p, ν should be 0, since Y_{ld} will be 100 percent.

For instance, in the case of a design using invisible pads, where $C_p = 2w$, the interconnection density I_d can be expressed as I_d = TL/A, and I_d is proportional to C_p, that is, $I_d * C_p = 1$, and TL = A/C_p. Therefore, ν in this equation can be empirically expressed as:

$$\nu = -\ln \frac{Y_0}{\text{TL}_0} * \left(\frac{C_{p0}}{C_p} \right)^b \quad (1.6)$$

where b is an exponent dependent on the technology or process used to form the conductors. This exponent b varies considerably from facility to facility and among various pattern formation methods, and must be empirically determined for each case.

1.7.4 Increase in Number of Conductor Layers

This is the simplest and most straightforward solution: when there is insufficient room on existing layers to place all the necessary interconnecting paths, add a layer. This approach has been widely practiced in the past, but when cost effectiveness of the substrates is of paramount importance, a very careful design analysis must be made to minimize layer counts in MLBs, because there is a significant cost

increase with every additional layer in the board. As seen from Table 1.5, calculated for 6-in × 8-in MLBs produced in large quantity with yields and conductor density kept constant, there is almost a linear relationship between board costs and layer count.

Table 1.5 also shows that any increase in the number of signal layers in boards operating at frequencies requiring transmission line characteristics will double the total number of layers, due to the need to interleave ground or DC power planes between signal planes.

A typical example of the effect of layer count on the finished MLB yield can be seen from Fig. 1.9, prepared some years ago by BPA. We can see that there is a definite decrease in the manufacturing yields with an increased number of layers in any of the line width categories. This is rather a typical situation in board manufacturing because increased complexity and thickness of MLB with a higher number of layers usually leads to a larger number of problems on the production floor.

1.7.5 Add Blind or Buried via Structures

By adding blind or buried vias to a board, additional routing channels and routing space can be achieved. Later chapters will detail more on blind and buried vias, especially the small vias called "*microvias*" or HDI technologies[8].

CHAPTER 2

TYPES OF PRINTED WIRING BOARDS

Hayao Nakahara
N.T. Information Ltd., Huntington, New York

2.1 INTRODUCTION

Since the invention of printed wiring technology by Dr. Paul Eisner in 1936, several methods and processes have been developed for manufacturing printed wiring board (PWBs) of various types. Most of these have not changed significantly over the years; however, some specific trends continue to exert major influences on the types of PWBs required and the processes that create them:

1. Computers and portable telecommunications equipment require higher-frequency circuits, boards, and materials, and also use more functional components that generate considerable amounts of heat that need to be extracted.
2. Consumer products have incorporated digital products into their design, requiring more functionality at ever-lower total cost.

3. Products for all uses continue to get smaller and more functional, driving the total circuit package itself to become more dense, causing the PWBs to evolve to meet these needs.

These trends have led to the larger use of nonorganic base substrates, such as aluminum and soft iron. In addition, alternate ways to create boards have been developed. These will be discussed in this chapter, along with the traditional board structures and processes. The terms *printed wiring board, PWB*, and *board* will be used synonymously. Also, the words *laminate, substrate*, and *panel* will be used interchangeably.

2.2 CLASSIFICATION OF PRINTED WIRING BOARDS

PWBs may be classified in many different ways according to their various attributes. One fundamental structure common to all of them is that they must provide electrical conductor paths which interconnect components to be mounted on them.

2.2.1 Basic PWB Classifications

There are two basic ways to form these conductors:

1. *Subtractive:* In the subtractive process, the unwanted portion of the copper foil on the base substrate is etched away, leaving the desired conductor pattern in place.
2. *Additive:* In the additive process, formation of the conductor pattern is accomplished by adding copper to a bare (no copper foil) substrate in the pattern and places desired. This can be done by plating copper, screening

conductive paste, or laying down insulating wire onto the substrate on the predetermined conductor paths.

The PWB classifications given in Fig. 2.1 take into consideration all these factors, i.e., fabrication processes as well as substrate material. The use of this figure is as follows:

- Column 3 shows the classification of PWBs by their physical nature.
- Column 4 shows the classification of PWBs by the method of actual conductor formation.
- Column 5 shows the classification of PWBs by the number of conductor layers.
- Column 6 shows the classification of PWBs by the existence or absence of plated-through-holes (PTHs).
- Column 7 shows the classification of PWBs by production method.

2.3 ORGANIC AND NONORGANIC SUBSTRATES

One of the major issues that has arisen with the ever-higher speed and functionality of components used in computers and telecommunications is the availability of materials for the PWB substrate that are compatible with these product and process needs. This includes the stresses on substrate material created by more and longer exposure to soldering temperatures during the assembly process, as well as the need to match the coefficient of thermal expansion for components and substrate. The resultant search has found new materials, both organic and nonorganic based. The details of these materials are explained in Chaps. 6 through 11, but this outlines the basic character of the two types of substrate.

2.3.1 Organic Substrates

Organic substrates consist of layers of paper impregnated with phenolic resin or layers of woven or nonwoven glass cloth impregnated with epoxy resin, polyimide, cyanate ester, BT resin, etc. The usage of these substrates depends on the physical characteristics required by the application of the PWB, such as operating temperature, frequency, or mechanical strength.

2.3.2 Nonorganic Substrates

Nonorganic substrates consist mainly of ceramic and metallic materials such as aluminum, soft iron, and copper-invar-copper. The usage of these substrates is usually dictated by the need of heat dissipation, except for the case of soft iron, which provides the flux path for flexible disk motor drives.

2.4 GRAPHICAL AND DISCRETE-WIRE BOARDS

Printed wiring boards may be classified into two basic categories, based on the way they are manufactured:

1. Graphical
2. Discrete-wire

2.4.1 Graphical Interconnection Board

A *graphical PWB* is the standard PWB and the type that is usually thought of when PWBs are discussed. In this case, the image of the master circuit pattern is formed photographically on a photosensitive material, such as treated glass plate or plastic film. The image is then transferred to the circuit board by screening or photoprinting the artwork generated from the master. Due to the speed and economy of making master artwork by laser plotters, this master can also be the working artwork.

Direct laser imaging of the resist on the PWB can also be used. In this case, the conductor image is made by the laser plotter, on the photoresistive material, which is laminated to the board, without going through the intermediate step of creating a phototool. This tends to be somewhat slower than using working artwork as the tool and is not generally applied to mass production. Work continues on faster resists, as well as exposure systems, and this method will undoubtedly continue to emerge.

2.4.2 Discrete-Wire Boards

Discrete-wire boards do not involve an imaging process for the formation of signal conductors. Rather, conductors are formed directly onto the wiring board with insulated copper wire. Wire-wrap® and Multiwire® are the best known discrete-wire interconnection technologies. Because of the allowance of wire crossings, a single layer of wiring can match multiple conductor layers in the graphically produced boards, thus offering very high wiring density. However, the wiring process is sequential in nature and the productivity of discrete-wiring technology is not suitable for mass production. Despite this weakness, discrete-wiring boards are in use for some very high density packaging applications. See Fig. 2.2 for an example of a discrete-wiring board.

FIGURE 2.2 Example of discrete-wiring board.

2.5 RIGID AND FLEXIBLE BOARDS

Another class of boards is made up of the *rigid* and *flexible* PWBs. Whereas boards are made of a variety of materials, flexible boards generally are made of polyester and polyimide bases. *Rigi-flex boards*, a combination of rigid and flexible boards usually bonded together, have gained wide use in electronic packaging (see Fig. 2.3). Most rigi-flex boards are three-dimensional structures that have flexible parts connecting the rigid boards, which usually support components; this packaging is thus volumetrically efficient.

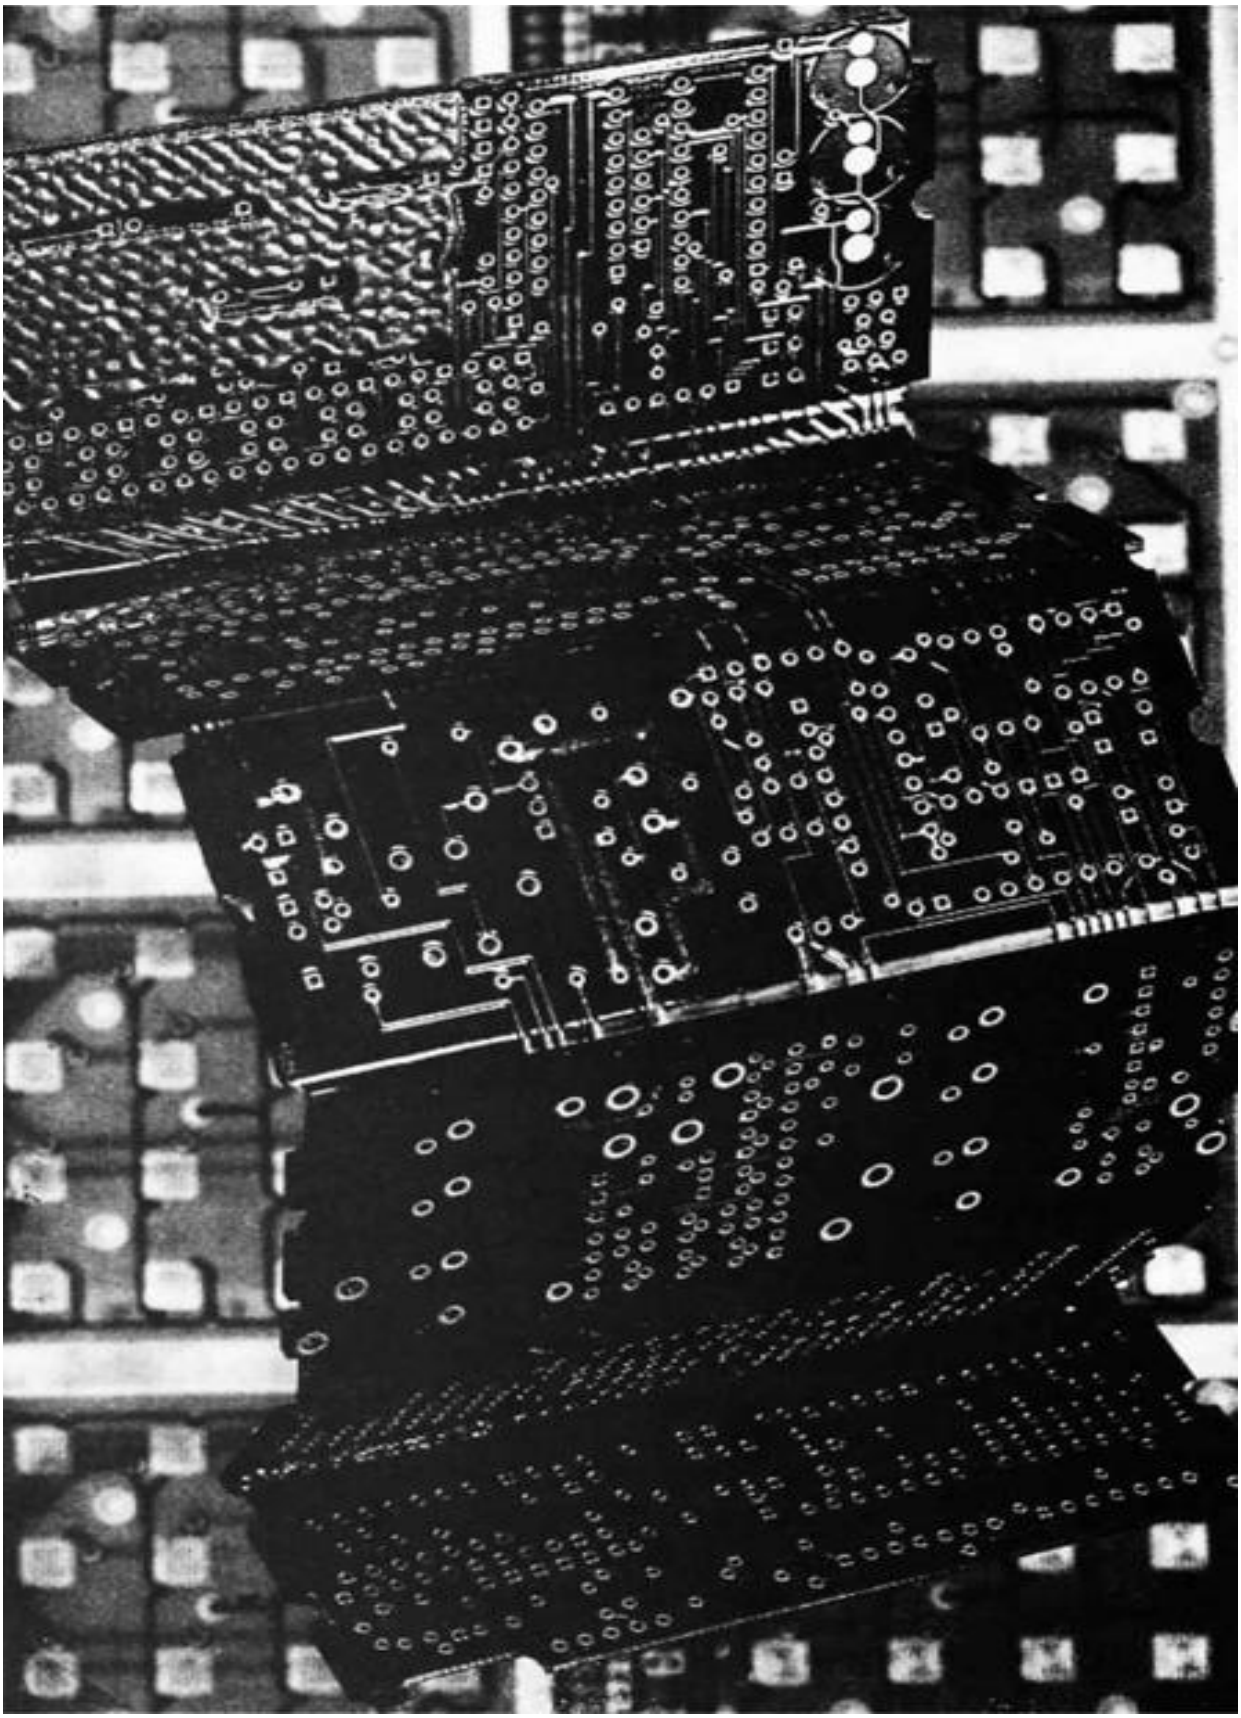

FIGURE 2.3 Rigi-flex printed wiring board.

2.6 GRAPHICALLY PRODUCED BOARDS

The majority of boards produced in the world are graphically produced. There are three alternative types:

1. Single-sided boards
2. Double-sided boards
3. Multilayer boards

2.6.1 Single-Sided Boards

Single-sided boards (SSBs) have circuitry on only one side of the board and are often referred to as print-and-etch boards because the etch resist is usually printed on by screen-printing techniques and the conductor pattern is them formed by chemically etching the exposed, and unwanted, copper foil.

2.6.1.1 Typical Single-Sided Board Materials. This method of board fabrication is generally used for low-cost, high-volume, and relatively low functionality boards. In the Far East, for example, the majority of SSBs are made of paper-based substrates for lowest cost, with the most popular grade of paper-based laminate being XPC-FR, which is a flame-retardant phenolic material that is also highly punchable. In Europe, FR-2 grade paper laminate is the most popular substrate for SSBs because it emits less odor than XPC-FR when placed in high-voltage, high-temperature environments, such as inside a television set chassis. In the United States, CEM-1 material, which is a composite of paper and glass impregnated with epoxy resin, is the most popular

substrate for SSBs. While not as low cost as XPC-FR or FR-2, CEM-1 has gained popularity because of its mechanical strength and also because of the relative unavailability of paper phenolic laminates.

2.6.1.2 Single-Sided Board Fabrication Process.

Given the emphasis on cost and low complexity, SSBs are generally produced in highly automated, conveyorized print-and-etch lines, using the following basic process flow.

Step 1: Cut substrate into appropriate panel size by either sawing or shearing.

Step 2: Place panel in loader which feeds them into the line.

Step 3: Clean panels.

Step 4: Screen panel with ultraviolet curable etch-resist ink.

Step 5: Cure the etch-resist ink.

Step 6: Etch exposed copper.

Step 7: Strip the resist.

Step 8: Apply solder resist.

Step 9: Screen legend.

Step 10: Form holes by drilling or punching.

Step 11: Test for shorts and opens.

The conveyor speed of automated print-and-etch lines ranges from 30 to 45 ft/min. Some lines are equipped with an online optical inspection which enables the elimination of the final electrical open/short test.

As previously noted, after the conductor pattern is generated in the print-and-etch line, holes for component insertion are formed on the panel by punching when the

panel is made of paper-based substrate, but must be formed by drilling when the panel is made of glass-based substrate.

2.6.1.3 Process Variations. In some variations, the conductor surface of the PWB gets insulated, exposing only pads, and then conductive paste is screened to form additional conductors on the same side of the board, thus forming double conductive layers on a single side.

Most metal-core PWB consumer applications are made of aluminum substrate, which comes as a copper-clad material. PWBs made of such material do not have through-holes, and components are usually surface-mount types. These circuits are frequently formed into three-dimensional shapes.

2.6.2 Double-Sided Boards

By definition, double-sided boards (DBs) have circuitry on both sides of the boards. They can be classified into two categories:

1. Without through-hole metallization
2. With through-hole metallization

The category of through-hole metallization can be further broken into two types:

1. Plated-through-hole (PTH)
2. Silver-through-hole (STH)

2.6.2.1 Plated-Through-Hole Technology. PTH technology is discussed in some detail in Sec. 2.7; however, some comments are appropriate here.

Metallization of holes by copper plating has been practiced since the mid-1950s. Since PWB substrate is an insulating material, and therefore nonconductive, holes must be metallized first before subsequent copper plating can take

place. The usual metallization procedure is to catalyze the holes with palladium catalyst followed by electroless copper plating. Then, thicker plating is done by galvanic plating. Alternately, electroless plating can be used to plate all the way to the desired thickness, which is called *additive plating*.

The biggest change in the manufacturing process of double-sided PTH boards, and also of multilayer boards (MLBs), is the use of *direct metallization* technologies. (See Chap. 34 for full discussion of electroless and direct metallization for through-hole boards.) Here, simply, it eliminates the electroless copper process. The hole wall is made conductive by palladium catalyst, carbon, or polymer conductive film, then copper is deposited by galvanic plating. The elimination of electroless copper, in turn, allows the elimination of environmentally hazardous chemicals, such as formaldehyde, and EDTA, which are two main components of electroless copper-plating solutions.

2.6.2.2 Silver-Through-Hole Technology. STH boards are usually made of paper phenolic materials or composite epoxy paper and glass materials, such as CE-1 or CE-3. After double-sided copper-clad materials are etched to form conductor patterns on both sides of the panel, holes are formed by drilling. Then the panel is screened with silver-filled conductive paste. Instead of silver, copper paste can also be used.

Since STHs have a relatively high electrical resistance compared with PTHs, the application of STH boards is limited. However, because of their economic advantage (the cost of STH boards is usually one-half to two-thirds that of functionally equivalent PTH boards), their application has spread to high-volume, low-cost products such as audio equipment, floppy disk controllers, car radios, remote controls, etc.

2.6.3 Multilayer Boards

By definition, multilayer boards (MLBs) have three or more circuit layers (see Fig. 2.4). Main applications of MLBs used to be confined to sophisticated industrial electronic products. Now, however, they are the mainstream of all electronic devices, including consumer products such as portable video cameras, cellular phones, and audio discs.

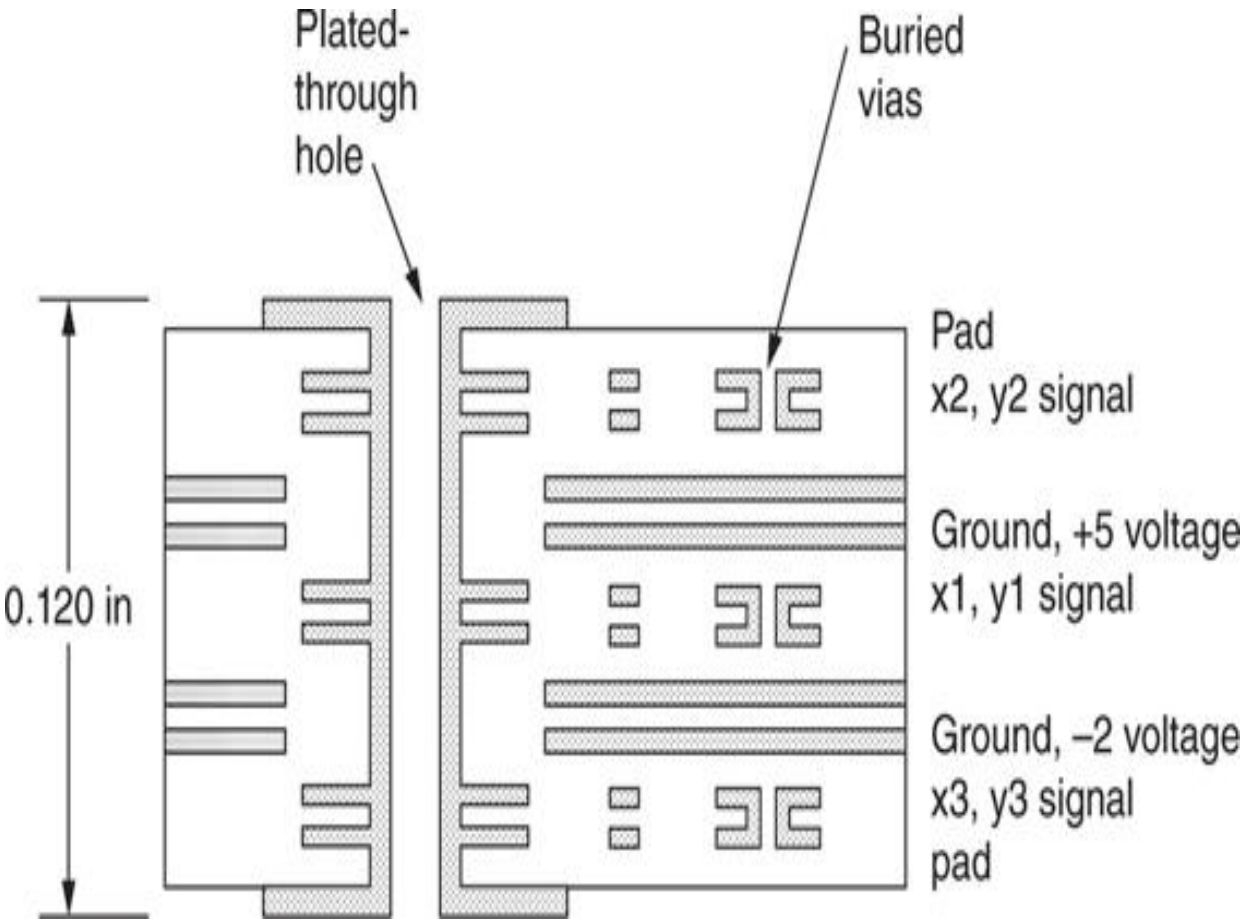

FIGURE 2.4 Cross-section multilayer board with buried via holes. Buried vias are built into each of the double-sided boards that make up the final multilayer structure.

2.6.3.1 Layer Count. As personal computers and workstations become more powerful, mainframe computers and supercomputers are being replaced in many applications by these smaller machines. As a result, the use of highly

sophisticated MLBs, which have layer counts over 70, are being reduced, but the technology to produce them is proven. At the other end of the layer-count spectrum, thin and high-density MLBs with layer counts between 4 and 8 are mainstream. The drive toward thinner MLBs will continue and is made possible by the continuing concurrent advancement of materials and equipment to handle thin core materials.

2.6.3.2 Via and Via Production Technologies. As PWBs have had to address the issues of higher speed, higher density, and the rise of surface-mount components that use both sides, the need to communicate between layers has increased dramatically. At the same time, the space available for vias has decreased, causing a continuing trend toward smaller holes, more holes on the board, and the decline of the use of holes that penetrate the entire board, which use space on all layers. As a result, the use of buried and blind vias has become a standard part of multilayer board technology, driven by the need for this increased package density (Fig. 2.4).

One of the immediate issues that arise from these trends is the problems of drilling and the associated cost of this fabrication step. Printed wiring boards, which once were stacked three high on a drilling machine, must be drilled individually, and the number of holes per board has risen, to accommodate the need for vias. This has caused a major problem for fabricators, who find that a lack of drilling capacity is creating a big demand on funds for additional machines, while the cost of drilling continues to increase dramatically. Therefore, alternate methods for creating vias are being developed. These pressures will be ongoing, and therefore the process listed here, or some equivalent, will undoubtedly become more important as the drive to miniaturization continues and drilling individual holes becomes less and less practical.

These processes have been developed to mass-produce vias without drills.

2.6.3.2.1 Surface Laminar Circuits (SLCs). The most notable MLB technology developed to form vias is the *sequential* fabrication of multilayers without press operations. This is particularly important for surface blind via holes.

The process for fabricating a board using surface laminar circuits is as follows (see Fig. 2.5):

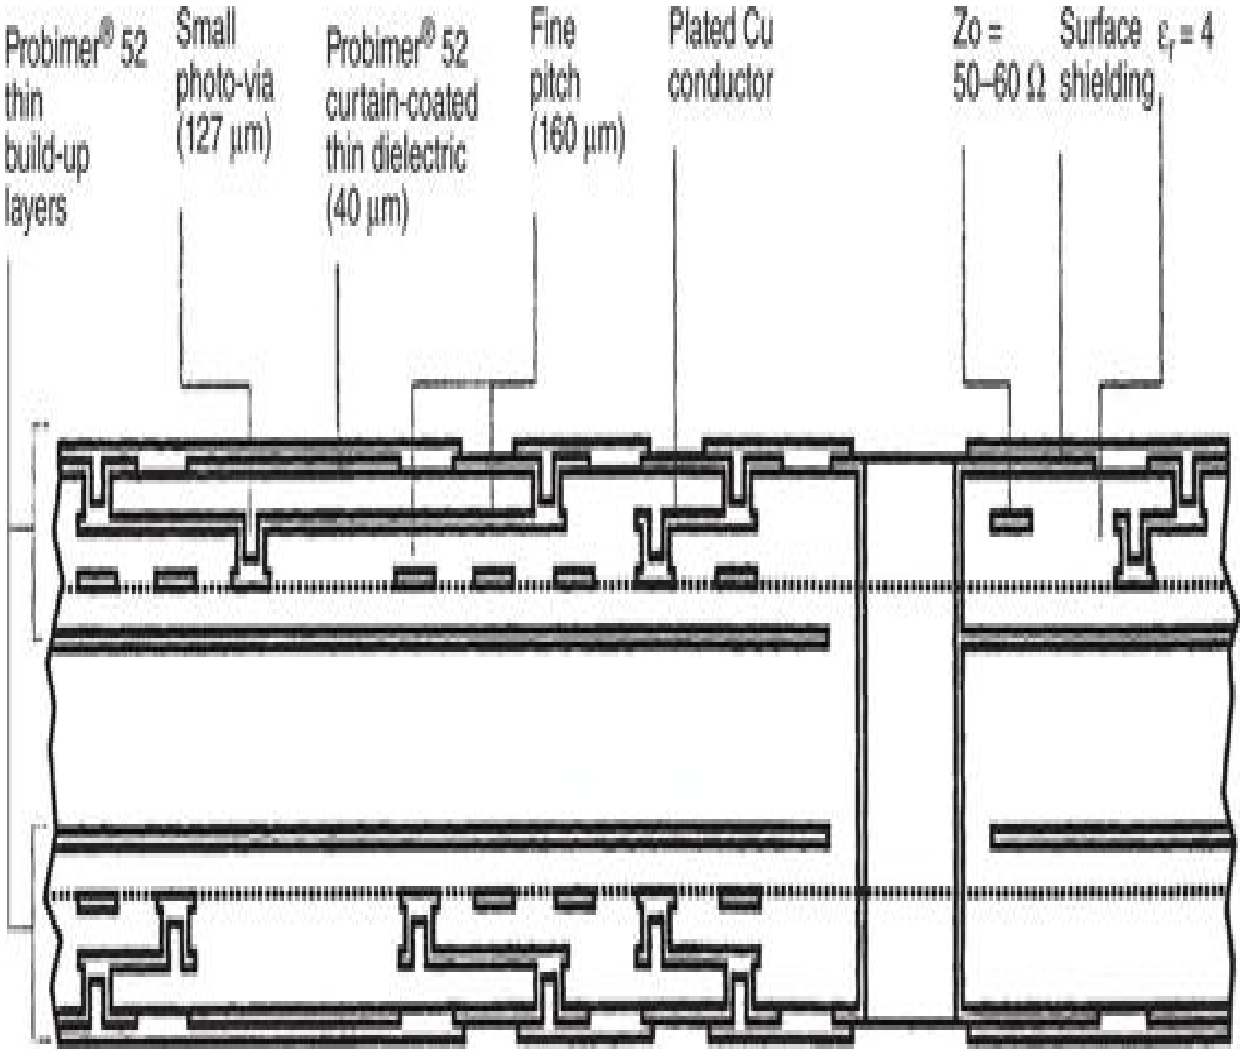

FIGURE 2.5 Example of surface laminar circuit (SLC) board cross section. (*Courtesy IBM Yasu and Ciba-Geigy Limited*.)

1. Innerlayer ground and power distribution patterns are formed.
2. Panel receives an oxide treatment.
3. Insulating photosensitive resin is coated over the panel by curtain or screen-coating methods.
4. Holes are formed by photoexposure and development.
5. Panel is metallized by usual copper reduction process (consisting of catalyzing and electroless copper plating or by direct metallization process).
6. Thicker deposition of copper is made by continuation of electroless copper plating or galvanic plating.
7. Circuit patterns are formed by dry film tenting process.

2.6.3.2.2 DYCOstrate®. A different approach to small via creation has been taken by Dyconex AG of Switzerland. After ground and power patterns are formed on the panel, and the panel is oxide-treated, polyimide-backed copper foil is laminated on the panel. Holes in the copper are formed by a chemical etching process, and the insulating polyimide material underneath the holes is removed by plasma etching. PWBs made in such a way are called DYCOstrate. In other, similar technologies, different dielectric materials are used, and they are removed by alkaline solutions. The rest of the process is similar to that for SLC; that is, holes are metallized and a thick copper deposition is made by electroless or galvanic plating, and the circuit pattern is formed by a tent-and-etch process (see Fig. 2.5).

2.6.3.2.3 Drilled Vias. In both SLC and DYCOstrate cases, through-holes can also be made by conventional drilling and plating processes, in addition to the surface blind via holes.

2.6.3.2.4 Cost Impact. The manufacturing cost of these sequential technologies is not necessarily directly cheaper than conventional MLB technology, which depends on a laminating press operation. However, since the cost of making standard holes in a board can be as high as 30

percent of the total manufacturing cost, and the creation of holes in these processes is comparatively inexpensive, the overall cost for equivalent functionality can be less. In addition, the fine pattern capability for this process is excellent. For example, an eight-layer conventional structure can often be reduced to a four-layer structure, reducing the total cost for the same packaging density.

2.7 MOLDED INTERCONNECTION DEVICES

Three-dimensional circuit technology was of great interest in the early to mid-1980s. The proponents for this technology, however, realized the mistake of trying to make it directly competitive with conventional flat circuits and have developed a niche where the substrate also offers other functional uses, such as structural support for the product.

Manufacturers of three-dimensional circuits prefer to call them *molded interconnection devices* (MIDs). In many applications of MIDs, the number of components to interconnect the electronic and electrical components can be reduced, thus making the total assembly cost cheaper and the final structure more reliable.

2.8 PLATED-THROUGH-HOLE TECHNOLOGIES

In 1953, the Motorola Corporation developed a plated-through-hole (PTH) process called the *Placir* method,[1] in which the entire surface and hole walls of an unclad panel are sensitized with $SnCl_2$ and metallized by spraying on silver with a two-gun spray. Next, the panel is screened with

a reverse conductor pattern, using a plating resist ink, leaving metallized conductor traces uncovered. The panel is then plated with copper by an electroplating method. Finally, the resist ink is stripped and the base silver removed to complete the PTH board. One problem associated with the use of silver is the migration caused by silver traces underneath the copper conductors.

The Placir method was the forerunner of the semiadditive process, which is discussed in Chap. 32.

In 1955, Fred Pearlstein[2] published a process involving electroless nickel plating for metallizing nonconductive materials. This catalyzer consists of two steps. First, the panel is sensitized in $SnCl_2$ solution, and then it is activated in $PdCl_2$ solution. This process presented no problem for metallizing nonconductive materials.

At the same time that Pearlstein's paper was published, copper-clad laminates were starting to become popular. Manufacturers of PWBs applied this two-step catalyzing process to making PTHs using copper-clad laminates. This process, however, turned out to be incompatible with the copper surface. A myriad of black palladium particles called *smads* were generated between copper foil and electrolessly deposited copper, resulting in poor adhesion between the electroless copper and the copper foil. These smads and electroless copper had to be brushed off with strong abrasive action before the secondary electroplating process could begin. To overcome this smad problem, around 1960 researchers began attempting to develop better catalysts; the products of their research were the predecessors of modern palladium catalysts.[3]

The mid-1950s was a busy time in the area of electroless copper-plating solutions. Electrolessly deposited nickel is difficult to etch. But since it adheres somewhat better to the base than does electroless copper, research for the development of stable electroless copper-plating solutions

was quite natural. Many patent applications for these solutions were filled in the mid-1950s. Among the applicants were P. B. Atkinson, Sam Wein, and a team of General Electric engineers, Luke, Cahill, and Agens. Atkinson won the case, and a patent[4] teaching the use of Cu-EDTA as a complexing agent was issued in January 1964 (the application had been filed in September 1956).

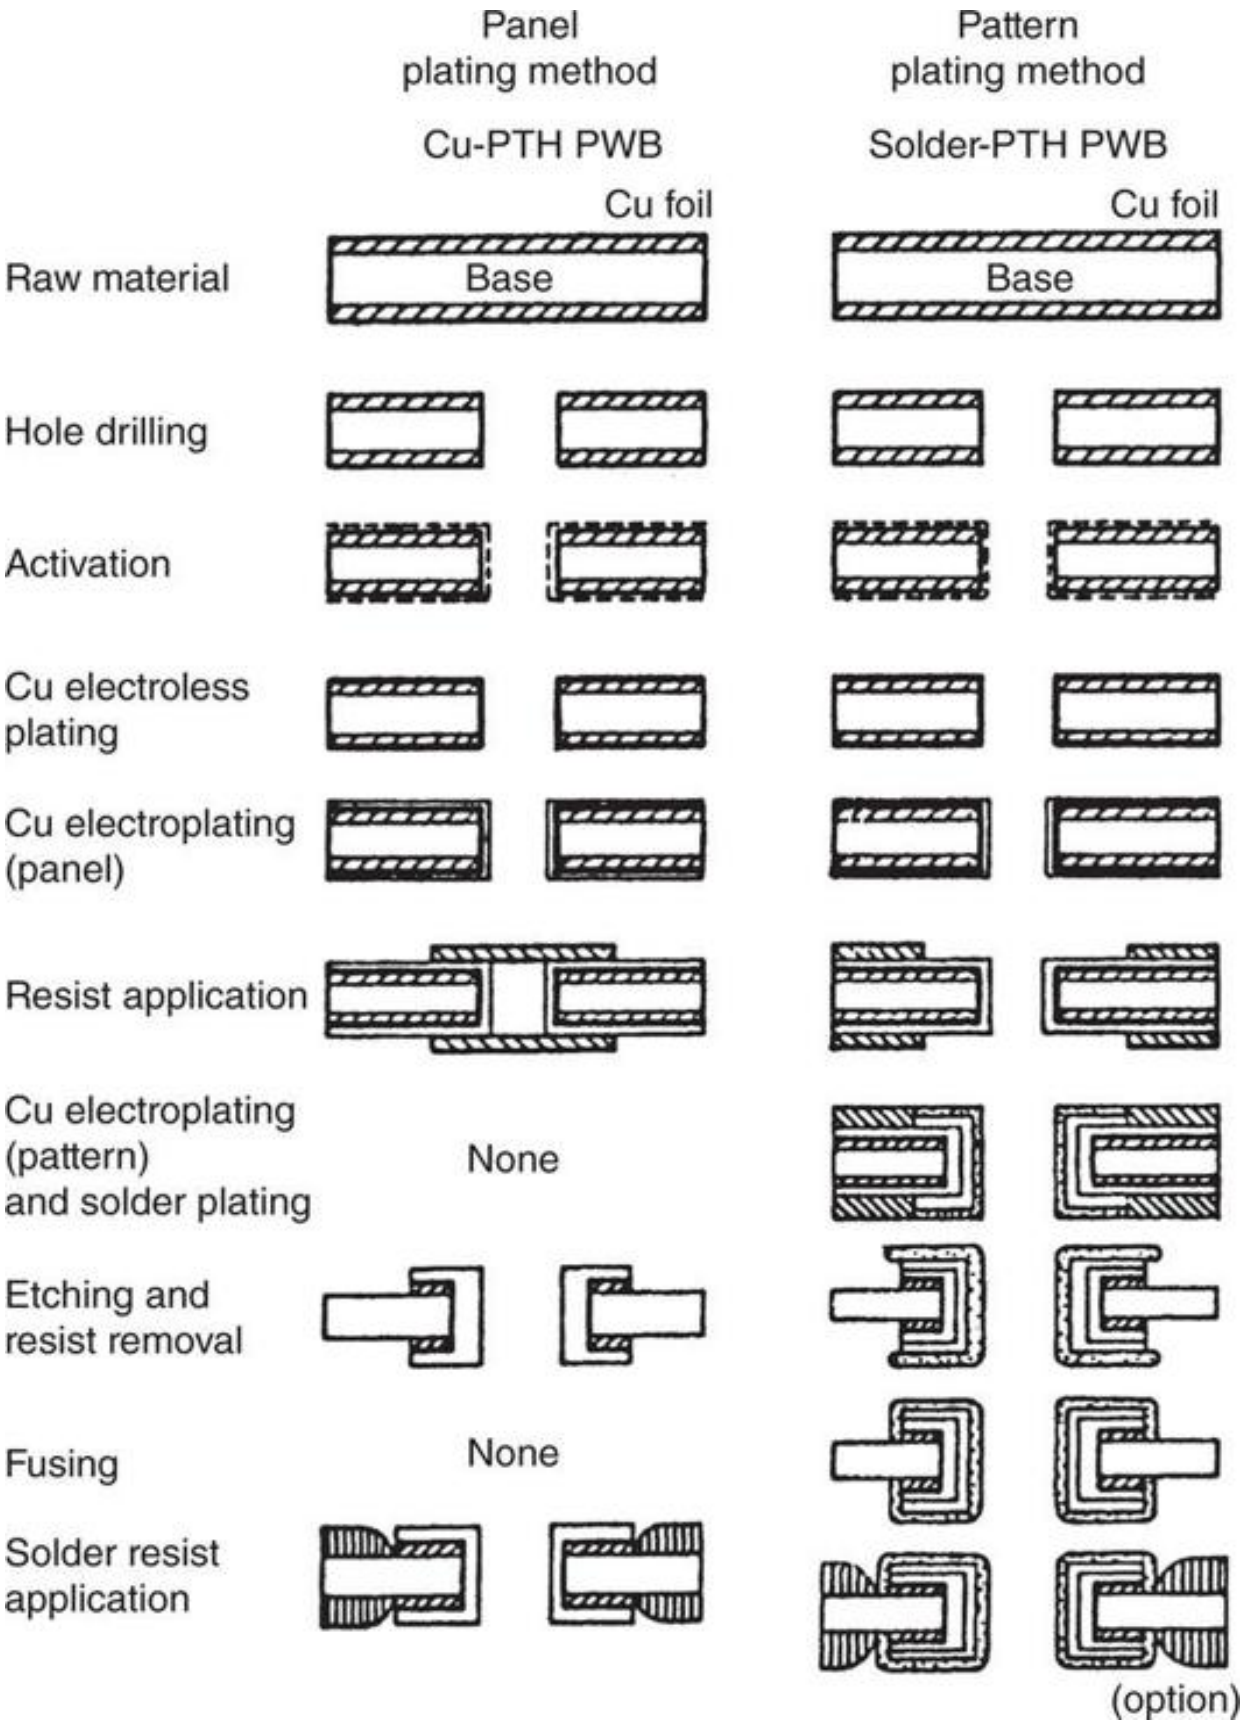
2.8.1 Subtractive and Additive Processes

Photocircuits Corporation was another company engaged throughout the 1950s in the development of chemicals for PTH processes. Copper-clad laminates were expensive, and a major portion of expensive copper foil had to be etched (*subtracted*) to form the desired conductor pattern. The engineers at Photocircuits, therefore, concerned themselves with plating (*adding*) copper conductors wherever necessary on unclad materials for the sake of economy. Their efforts paid off. They were successful in developing not only the essential chemicals for reliable PTH processes but also the fully additive PWB manufacturing technology known as the CC-4[a] process.

With the use of $SnCl_2$-$PdCl_2$ catalysts and EDTA-base electroless copper-plating solutions, the modern PTH processes became firmly established in the 1960s. The process of metallizing hole walls with these chemicals for the subsequent formation of PTHs is commonly called the *copper reduction process*. In the subtractive method, which begins with copper-clad laminates, pattern plating and panel plating are the two most widely practiced methods of making PTH boards. These methods are discussed in the following subsections.

2.8.2 Pattern Plating

In the pattern-plating method, after the copper reduction process, plating resist layers of the reverse conductor image are formed on both sides of the panel by screening resist inks. In most fineline boards, photosensitive dry film is used instead. There are some minor variations in the pattern-plating method (see Fig. 2.6):



Panel plating method
Pattern plating method
Cu-PTH PWB
Solder-PTH PWB
Cu foil
Cu foil
Raw material
Base
Base
Hole drilling
Activation
Cu electroless plating
Cu electroplating (panel)
Resist application
Cu electroplating (pattern) and solder plating
None
Etching and resist removal
Fusing
None
Solder resist application
(option)

FIGURE 2.6 Key manufacturing steps in panel plating and pattern-plating methods.

1. Catalyzing (preparing the nonconductive surface to cause copper to come out of solution onto that surface)
2. Thin electroless copper (0.00001 in) followed by primary copper electroplating; thick electroless copper (0.0001 in)
3. Imaging (application of a plating resist in the negative of the desired finished circuit)
4. Final electroplating copper
5. Solder plating (as etching resist) 0.0002 or 0.0006 in
6. Stripping plating resist
7. Etching of base copper
8. Solder etching (0.0002-in case); solder reflow (0.0006-in case)
9. Solder mask followed by hot-air solder coater leveler if solder etching is used
10. Final fabrication and inspection

Most manufacturers of DSBs with relatively wide conductors employ thick electroless copper plating. However, thin electroless copper followed by primary electroplating is preferred for boards having fine-line conductors, because a considerable amount of surface is brushed off for better adhesion of dry film. This provides a higher reliability for PTHs. Solder reflow boards had been preferred by many customers, particularly in military and telecommunications applications, until the emergence of hot-air solder coater levelers. Although the solder-over-copper conductors protect the copper from oxidization, solder reflow boards have some limitations. Solder mask is hard to apply over reflowed solder, and it tends to wrinkle and peel off in some areas when the boards go through component soldering. A more serious problem is the solder bridging that occurs when the conductor width and clearance become very small.

In step 9, the entire surface of the board except for the pads is covered by solder mask, and then the board is immersed into the hot-air solder coater leveler, resulting in a thin coating of solder over the pads and the hole walls. The operation sounds simple, but it requires constant fine-tuning and maintenance of the hot-air solder coater leveler; otherwise, some holes may become heavily clogged with solder and are then useless for component insertion.

One advantage of the pattern-plating method over the panel-plating method is in etching. The pattern-plating method needs to etch only the base copper. The use of ultrathin copper foil (UTC), which is usually ⅛ or ¼ oz thick, offers a real advantage. However, as long as electroplating is used, the pattern-plating method cannot escape from a current distribution problem, regardless of the thickness of the base foils. The panel-plating method by electroplating suffers from the same problem but to a lesser degree. Good current distribution is very difficult to achieve when the boards are not of the same size or type, and particularly if some have large ground planes on the outer faces being plated. When the board has a few holes in an isolated area remote from the bulk of the circuitry, these tend to become overplated, making component lead insertion difficult during assembly. To minimize this current distribution problem, various countermeasures are practiced, such as special anode position, anode masking, agitation, and plating thieves. But none of these offers a decisive solution to the distribution problem, and they are extremely difficult to implement flexibly and effectively in a large plating operation, where a large number of product mixes have to be handled all the time.

Another advantage of the pattern-plating method is its ability to form padless micro-via holes of a diameter ranging from 0.012 to 0.016 in. Micro-via holes enable better usage of conductor channels, thereby increasing the connective capacity of the board.

2.8.3 Panel Plating

In the panel-plating method, there are two variations for finishing the board after the panel is plated with electrolytic copper to the desired thickness. In the *hole-plugging* method, the holes are filled with alkaline-etchable ink to protect the hole walls from being etched; this is used in conjunction with screened etch resist. In the other method, called *tent-and-etch* or simply *tenting*, the copper in the hole is protected from etching by covering the hole or tenting with dry film, which is also used as an etch resist for conductors on the panel surface. The simplified sequence of the panel-plating method is as follows (see Fig. 2.6):

1. Catalyzing
2. Thin electroless copper deposition (0.0001 in)
3. Electroplating copper (0.001 to 0.0012 in)
4. Hole plugging with alkaline-resolvable ink; tenting (dry film lamination)
5. Screen-print etching resist (conductor pattern); photoexpose the panel for conductor pattern
6. Etching copper
7. Stripping etching resist
8. Solder mask
9. Solder coater leveler (optional)
10. Final fabrication and inspection

The panel-plating method is ideal for bare copper board. However, it is a difficult way to make padless via holes, which are becoming more popular. Generally, the conductor width of 0.004 in is considered to be the minimum realizable by this method for mass production.

Although the use of the panel-plating method in the United States and western Europe is limited, nearly 60 percent of the PTH boards in Japan are manufactured by this method.

2.8.4 Additive Plating

Plated-through holes can be formed by additive (electroless) copper deposition, of which there are three basic methods: fully additive, semiadditive, and partially additive. Of these, semiadditive involves pattern electroplating for PTHs with very thin surface copper, but the other two form PTHs solely by electroless copper deposition. The additive process has various advantages over the subtractive process in forming fineline conductors and PTHs of high aspect ratio.

2.9 SUMMARY

Modern electronic packaging has become very complex. Interconnections are pushed more into lower levels of packaging. The choice of which packaging technology to use is governed by many factors: cost, electrical requirements, thermal requirements, density requirements, and so on. Material also plays a very important role. All things considered, PWBs still play important roles in electronic packaging.

PART 2

MANAGING THE PRINTED CIRCUIT SUPPLY CHAIN

CHAPTER 3

BASICS OF PRINTED CIRCUIT SUPPLY CHAIN MANAGEMENT

Tim Rodgers
University of Colorado, Boulder, Colorado

3.1 INTRODUCTION

Printed circuit boards (PCBs) and printed circuit assemblies (PCAs) are often the most technically complex components that are purchased for electronic assemblies and products. This complexity leads to a number of challenges for a supply chain management (SCM) team that may be significantly different when compared with the other parts and commodities that the team manages.

3.1.1 Examples of Printed Circuit Supply Chain Issues

- PCBs and PCAs are custom-designed and therefore cannot simply be purchased from a catalog. There are many suppliers, but their capabilities and performance varies

widely, requiring more attention to supplier selection and qualification.

- A wide variety of manufacturing processes are used to create PCBs and PCAs, ranging from precise photoimaging and component placement, mechanical presses for lamination and ovens for solder reflow, wet chemical plating and etching, and high-speed drilling and routing. Buyers don't have to become expert in these processes; however, they can be intimidating.
- PCBs and PCAs are required to perform as part of an electrical circuit and that performance is critical to the success of the final product. The PCB obviously provides electrical interconnections between components attached to the board, but in some cases it operates as an active component in its own right. It may not be possible to determine whether the PCA works correctly until your design team has evaluated its performance as part of the final product.
- Although components on a PCA can be replaced, traces cut, and jumpers added, PCBs and PCAs cannot be easily reworked, returned, or recycled if the product requirements change. This can lead to additional cost and unwanted inventory.

The next several chapters are intended to guide experienced or new SCM professionals who may be unfamiliar with PCBs and PCAs and are looking for help. Figure 3.1 gives an overview of Part 2 of *Printed Circuits Handbook*.

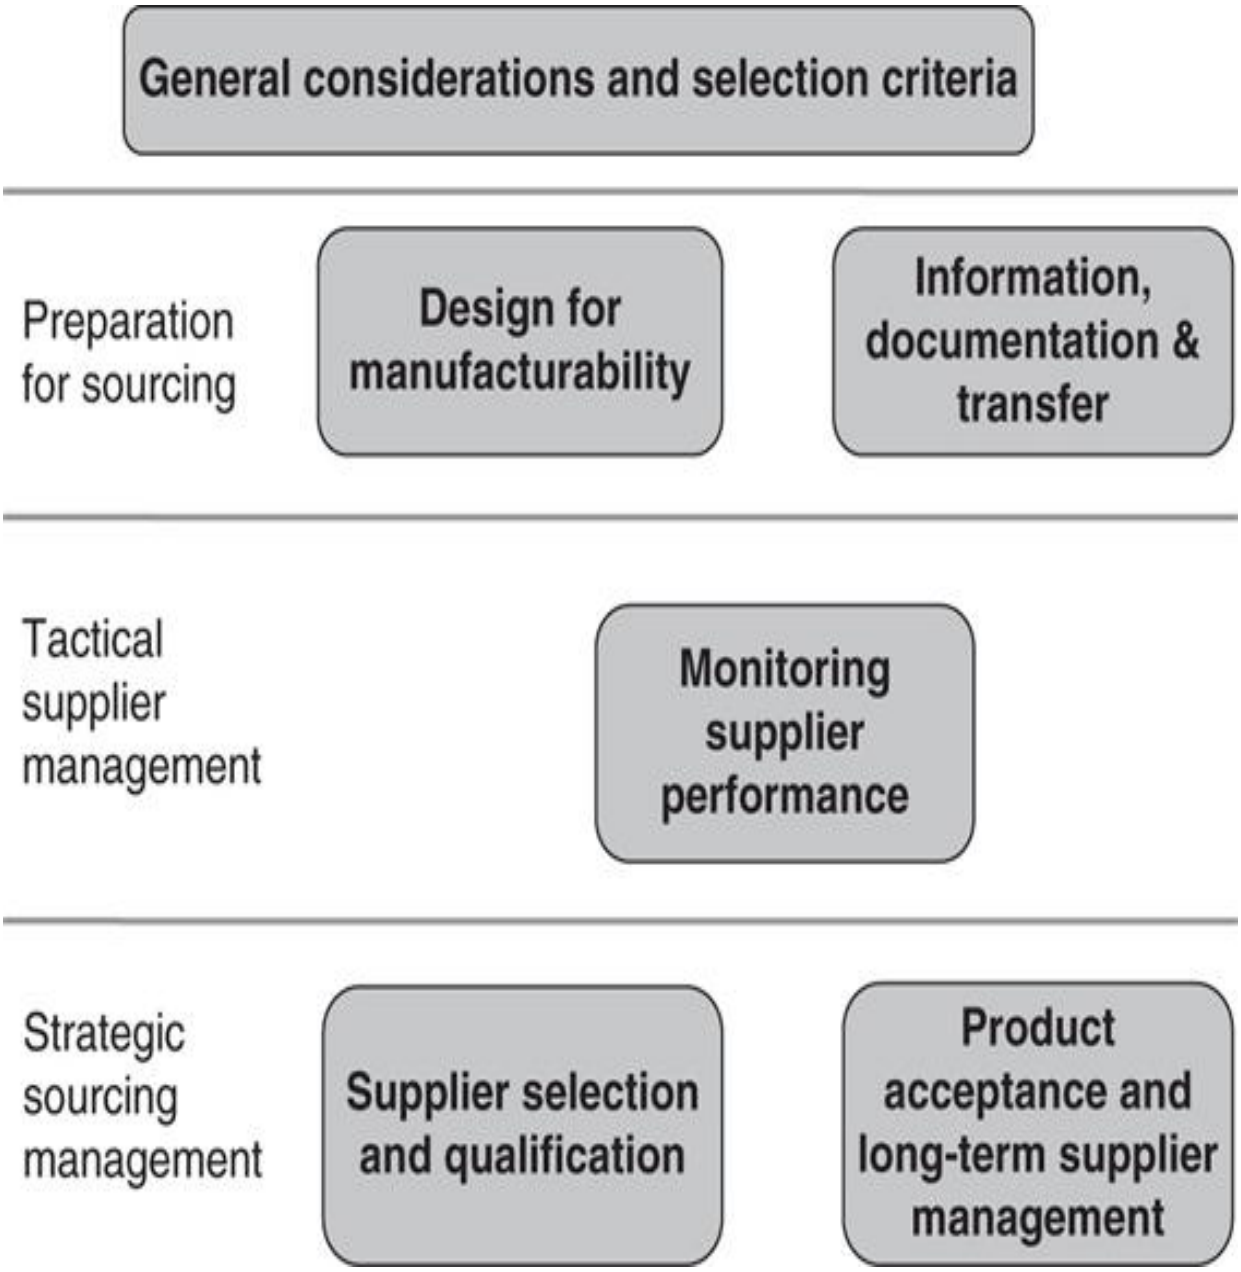

FIGURE 3.1 Supply chain management focus.

3.1.2 Overall Printed Circuit Supply Chain Management Chapters

- *Basics of Printed Circuit Supply Chain Management (Chap. 3)*. This chapter includes some general considerations for

PCB and PCA sourcing decisions, and the criteria that should be used to evaluate and select suppliers.

- *Design for Manufacturability (Chap. 4)*. This chapter explains the importance of DFM as a way of optimizing performance and cost, reviews the major contributors to cost and manufacturability, and provides some practical examples.
- *Managing Information, Documentation, Formatting, and Exchange (Chap. 5)*. This chapter outlines the recommended steps for creating documentation and drawings in order to specify the design requirements and other expectations for the suppliers.
- *Supplier Selection and Qualification (Chap. 6)*. This chapter applies the business considerations and selection criteria described in Chap. 3 to evaluate and qualify suppliers, including processes to perform technical assessments of samples provided by the supplier.
- *Process Control, Monitoring, and Incoming Inspection (Chap. 7)*. This chapter gives a brief introduction to quality assurance methodology based on six sigma principles, with specific recommendations for process control, testing, and inspection of PCBs and PCAs at the supplier.
- *Product Acceptance and Feedback (Chap. 8)*. The final chapter in Part 2 provides guidelines for design qualification, lot acceptance, and ongoing inspection of received PCBs and PCAs. It also includes recommendations for long-term supplier management that minimize the internal management cost while maintaining a high level of performance.

3.2 GENERAL BUSINESS CONSIDERATIONS

Before choosing a supplier it is important to understand where the PCBs and PCAs fit in the overall value delivery system for an electronic assembly (see Fig. 3.2). This is because the incoming requirements for the next, downstream step in the value chain, whether component assembly or top-level assembly, will dictate many of the requirements for the upstream suppliers. The key questions are

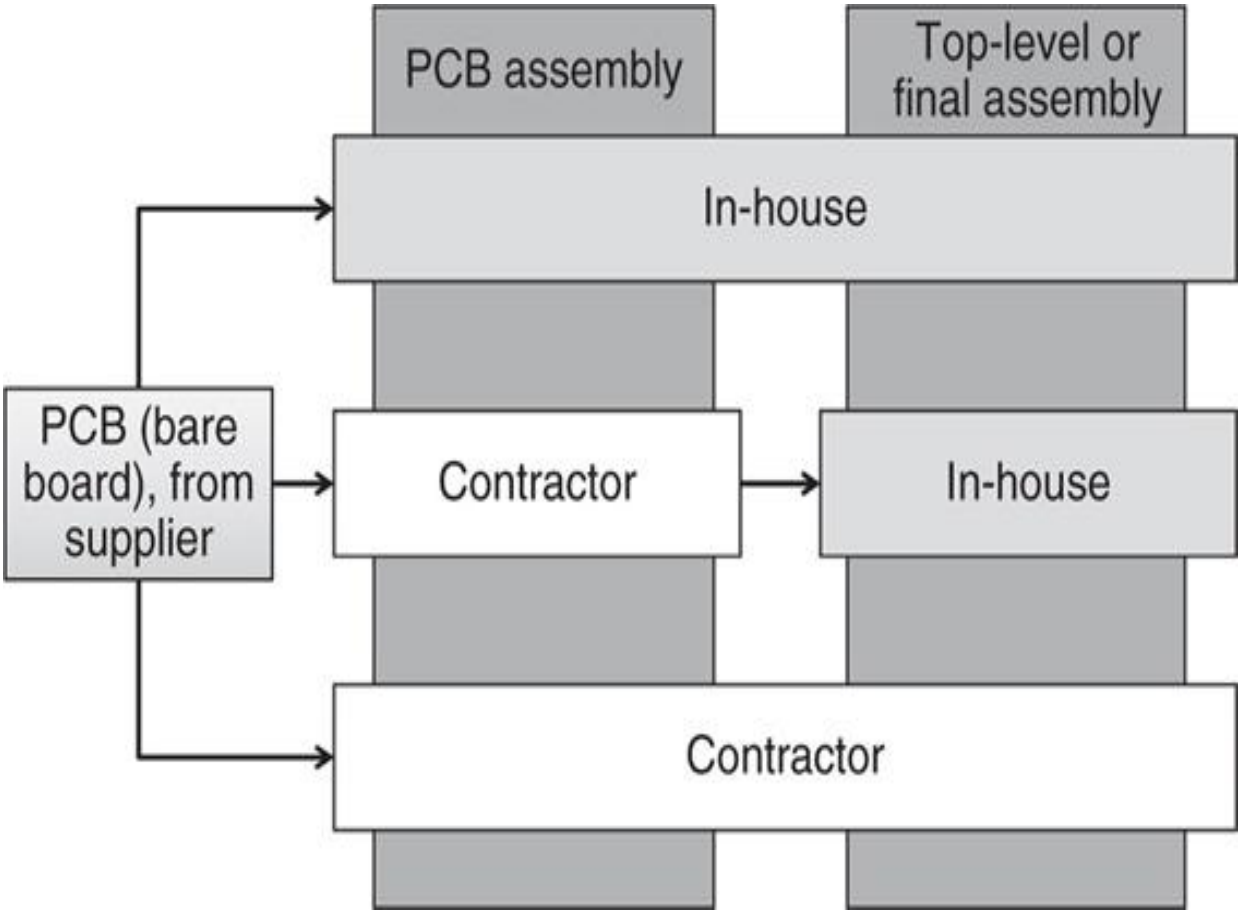

FIGURE 3.2 PCB and PCA value delivery system.

- Where are the PCBs or PCAs going after they are obtained from the supplier?
- Will they be assembled on-site at an in-house, captive factory?

- Or, will they be sent to another contractor for component assembly, and possibly final assembly as well?

3.3 CONTRACT MANUFACTURERS

Contract manufacturers who provide assembly services often have their own preferred list of qualified suppliers that can be used to greatly simplify the sourcing decision. Regardless of whether the PCBs/PCAs go next, whether to an internal or external factory, that facility must be included in sourcing decisions to ensure that manufacturability is taken into account. The supplier evaluation team will be discussed in more detail later in this chapter.

If the firm has its own internal capability to assemble PCBs and create PCAs, the sourcing strategy must include a discussion of whether it is better to make or buy the PCAs.

3.3.1 Sourcing Factors That Should Be Considered

- Are there special technology requirements? The internal factory may not currently have the capabilities that are required to support the design. If that is the case, then the design must be outsourced.
- What is the capacity of the internal factory? Outsourcing may be the only option if the internal factory cannot meet the required delivery time. The internal “make” option may be expected to be more responsive; however, this is not always the case.
- What is the cost of internal assembly versus outsourcing? Note that it may be possible to find an external supplier that can provide lower unit cost, but unused internal capacity is also a cost to the business.

3.4 CRITERIA FOR EVALUATING SUPPLIERS

The choice of a specific supplier depends on the relative importance of several different dimensions of supplier performance (see Table 3.1). Suppliers have inherent capabilities and strengths that are based on their own strategic decisions about how they choose to compete. Those capabilities will determine how well they fit the sourcing strategy and how they are likely to perform as an ongoing business partner. Understanding what is most important to the business will guide initial supplier selection and determine whether the supplier's performance continues to meet your requirements.

TABLE 3.1 PCB Supplier Performance Criteria

Category	Examples
Technology	Electrical (thick copper, dielectric) Thermal (low TCE) Dimensional (flexible or molded circuit) Assembly (surface finish, tolerances)
Responsiveness	On-time delivery Rapid prototyping Lead time
Quality	Conformance to industry standards Conformance to internal specifications Order completeness Accuracy of required documentation
Cost and price	Price per unit Supplier management costs
Other services	Design support Locally-based sales or technical staff

3.4.1 Supplier Performance Requirements

- *Technology*. The PCB or PCA is expected to perform in the final service environment, both as a mechanical platform for other components, and as an element in the electrical circuit. Suppliers must be able to provide the chosen combination of design elements (e.g., conductors, layers), surface finishes, dielectric materials, dimensions, and other technical specifications as required.

- *Responsiveness*. This category includes the supplier's ability to achieve on-time delivery, and the lead time that the supplier requires for orders and design changes, both of which must be consistent with the requirements of the downstream assembly and production processes.
- *Quality*. The PCB or PCA must conform consistently to industry standard, and also any unique internal specifications and requirements for the design. This category also includes order completeness and the accuracy of any required documentation provided by the supplier.
- *Cost and price*. Obviously the price paid to the supplier per unit is an important factor. However, there are other cost elements that should be considered, including any internal staff and other expenses required for ongoing supplier management, and inventory holding costs due to fixed order quantities or slow response to design changes.
- *Other services*. PCB and PCA suppliers may offer other services that may be valuable to the business, including design support, or locally based sales or technical staff to help address issues.

Each of these categories will be described in more detail later in this chapter.

3.4.2 The Sourcing Strategy Team

Because PCBs and PCAs are a custom-designed component with significant implications for a successful product, a cross-functional sourcing team is strongly recommended to review the business requirements, determine how to prioritize and assign weighting factors to these requirements, and subsequently evaluate and qualify potential suppliers.

The sourcing strategy team should be led by a commodity manager or senior buyer in the SCM organization, and at

minimum the team should include representatives from design engineering and the manufacturing group that will use the PCB or PCA, whether internal or outsourced. Representatives from the quality and finance functional groups may also be added to the team, if available.

The team's initial responsibility is to develop a sourcing strategy that is aligned with the needs and priorities of the business. It is possible that a single supplier can meet all of these needs, but it is more likely that compromises and trade-offs will have to be made. The sourcing strategy team needs to determine which performance characteristics are "musts" or "wants," and what can be traded for higher performance in a different area. Note that over time the needs and priorities of the business may change, and this requires a reevaluation of the sourcing strategy.

3.4.3 Technology

At a fundamental level, suppliers must be able to provide a PCB or PCA that meets certain performance requirements, and their inability to do so will typically eliminate them from further consideration. For PCBs these include electrical, thermal, dimensional, and assembly requirements.

The most common materials used to fabricate rigid PCBs are FR-4 laminate with ½-oz copper conductors. SCM professionals should consult with the electrical engineers on the design team to understand whether the PCB is required to provide specific performance characteristics as part of the circuit. Examples include thicker copper for current carrying capacity, or a material with a different dielectric constant between conductive layers.

Other applications may require laminate materials with a low coefficient of thermal expansion to reduce strain on solder joints and improve reliability. The physical dimensions and size constraints of the finished product can limit the use

of a rigid board, making it necessary to opt for a flexible or molded circuit. Non-standard technical requirements such as these may significantly limit the supply base; however, there are still many suppliers who can meet the need.

Suppliers who can offer narrow conductor widths, small-diameter through vias, blind or buried vias, and high layer counts give designers more options for circuit layout, although these options can add significant cost due to the special processing required and lower production yields. Chapter 4, “Design for Manufacturability,” describes some of the more common technology trade-offs and their relative costs.

Printed circuit assembly operations have standard requirements for surface finishes, and location and dimensional tolerances for holes, pads, and fiducials. The electronics manufacturing industry generally follows IPC standards and specifications, and any reputable PCB supplier will be familiar with IPC-A-600 Acceptance of Printed Wiring Boards. Other standards may be specified by the assembly operation and these should be clearly communicated to the supplier, and ideally the supplier’s performance should be verified independently before selection.

Table 3.2 summarizes the key questions for determining the technology requirements for PCBs.

TABLE 3.2 PCB Technology Considerations

Technology	Consideration
What is the laminate material?	Dielectric constant Low thermal expansion
What are the required characteristics of the conductors?	Conductor width and spacing Through via diameter Copper thickness
Any constraints on the physical dimensions of the board	Overall board thickness, length, width and tolerances Flexible or molded substrate
What are the requirements for the assembly operation?	Surface finish Dimensional and location tolerances Other requirements

The technology considerations for suppliers of PCAs include the following:

- Single- versus double-sided assembly
- Restrictions on back-side active components
- The ability to accurately place fine pitch components (e.g., QFP, BGA, COB)
- The ability to handle non-standard components requiring manual placement
- Support of non-lead soldering

PCB and PCA suppliers will provide a detailed list of their capabilities, materials, and processes on request. However, for most applications, it is important to verify those capabilities with samples, prototypes, or first articles. Chapter 6, “Supplier Selection and Qualification,” provides a

review of the common methods used to evaluate samples for supplier qualification.

3.4.4 Responsiveness

Supplier responsiveness considerations should be familiar to any experienced SCM team, regardless of the commodity:

- On-time delivery
- Rapid prototyping capability
- Lead time for production orders
- Minimum order quantity

PCB and PCA suppliers obviously must be able to meet your technology requirements, but it is also important that the boards or assemblies arrive when they are needed. You can measure a supplier's on-time delivery performance over time; however, this is difficult to assess before placing the initial order with a new supplier. The sourcing strategy team should determine the business requirements for rapid and reliable on-time delivery and ask potential suppliers how they can support those needs.

Despite the availability of simulation tools, PCB and PCA design performance typically cannot be verified without the actual hardware. Electrical engineers and board designers value rapid turn-around time for prototype boards to test performance, and suppliers who can provide this service have an advantage.

Many businesses use different suppliers for prototype and production boards, with the prototype supplier located geographically close to the design team to reduce the delivery time and facilitate communication. A single supplier who can offer a local quick-turn prototype facility that is associated with a higher-volume production facility (typically in a region with lower labor and production costs) offers the

best of both worlds. (See Fig. 3.3.) This model also reduces the need to communicate design and manufacturability information from the prototype supplier to the production supplier.

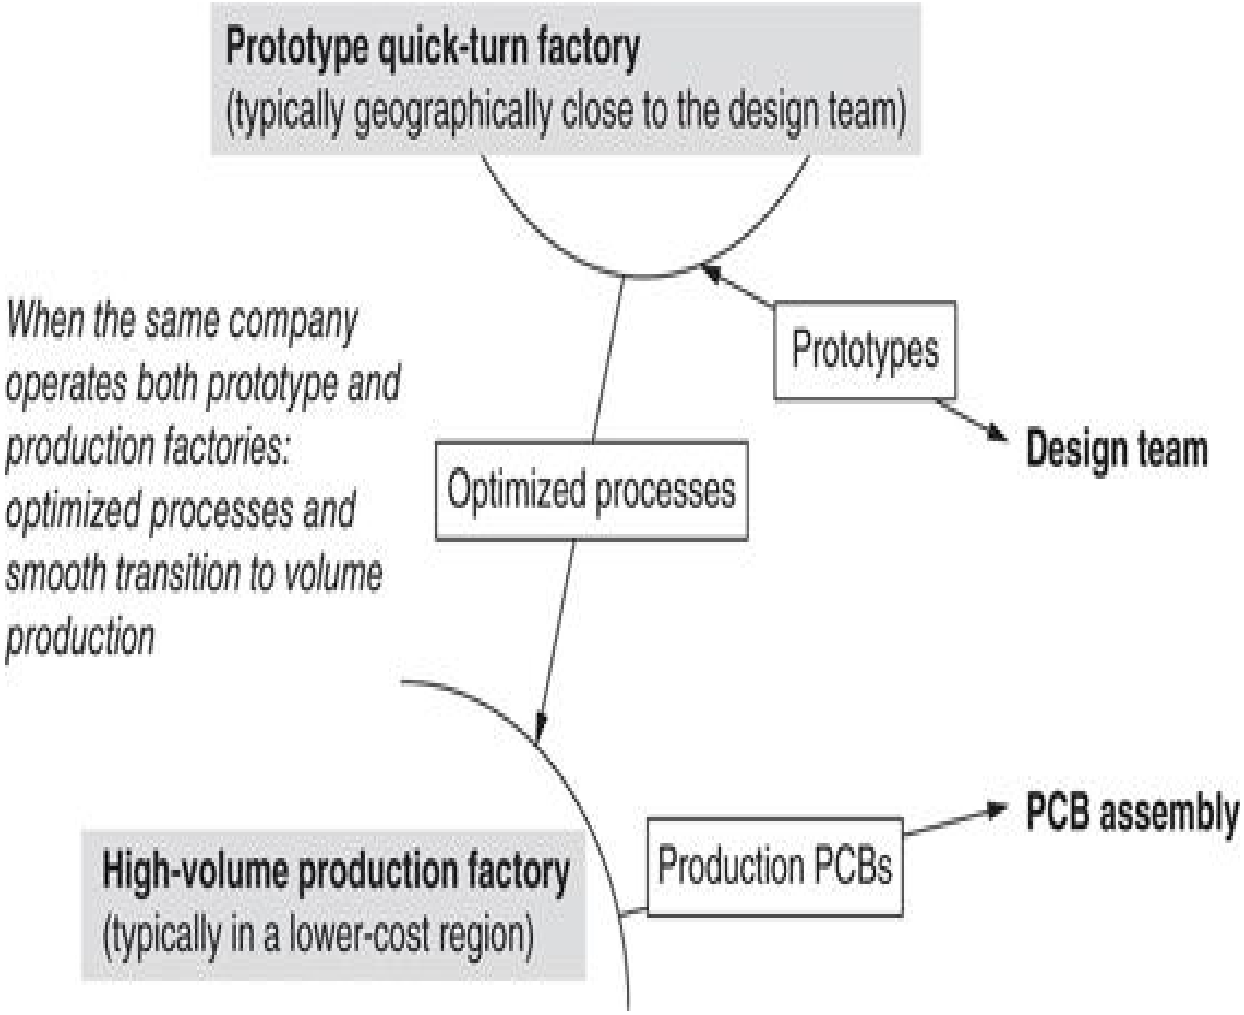

FIGURE 3.3 Prototype and production factories.

Suppliers will typically advertise a standard lead time for order completion and delivery of production boards, but most will also usually offer a faster turn-around time option to expedite the order at a higher price. The sourcing strategy team should consider the likelihood of design changes or other engineering change orders that require a quick change from one PCB or PCA version to another. A slow response

here could mean a large quantity of obsolete inventory in-house or in-transit, particularly for a large minimum order quantity. If changes are likely and frequent, a supplier who can provide expedited orders at a manageable cost will be valuable.

Inventory buffer and safety stock management also depends on the likelihood of late deliveries and the supplier's minimum order quantity. Supply chain professionals should audit a supplier's fulfillment and shipping processes, and estimate the business's sensitivity to delays in order to optimize buffers.

Table 3.3 summarizes the key questions for determining the responsiveness requirements for PCBs or PCAs.

TABLE 3.3 PCB/PCA Responsiveness Considerations

What is the acceptable range of delivery time vs. plan?
Is late delivery acceptable?
How early?
What is the expected quantity of parts per order?
What is the expected frequency of orders?
What is the standard lead time for production orders?
Is shorter lead time valuable to the business?
Does the engineering team need rapid prototyping capability?

3.4.5 Quality

As with delivery performance and responsiveness, it is very difficult to assess a supplier's quality performance in advance. All reputable suppliers should be familiar with the IPC standards for PCBs and PCAs (see summary in Table 3.4). These define the minimum specifications; however, downstream assembly and production sites may have

additional and more-stringent requirements, for example, for dimensional tolerances or more-detailed inspection reports.

TABLE 3.4 Subset of IPC Standards for PCBs and PCAs

Standard	Title
IPC-2615	Printed Board Dimensions and Tolerance
IPC-D-325	Documentation Requirements for Printed Boards
IPC-ET-652	Guidelines and Requirements for Electrical Testing of Unpopulated Printed Boards
IPC-7351B	Generic Requirements for Surface Mount Design and Land Pattern Standards
IPC-4652	Metal Foil for Printed Wiring Applications
IPC-4101	Laminate Prepreg Materials Standard for Printed Boards
IPC-A-600	Acceptance of Printed Wiring Boards
IPC-6011	Generic Performance Specification for Printed Boards
IPC-6013	Specification for Printed Wiring, Flexible and Rigid-Flex
IPC-TF-870	Qualification and Performance of Polymer Thick Film Printed Boards
IPC-FA-251	Assembly Guidelines for Single and Double Sided Flexible Printed Circuits

All PCB suppliers should have the capability to perform visual inspection and simple electrical continuity testing for opens and shorts, and the sourcing strategy team should consider whether this should be done on all boards or an audit sample. For PCAs, in-circuit testing is typically performed on 100 percent of all assemblies. Customers can also request functional testing of the PCAs; however, this will require a dedicated test fixture that must be designed and provided by the customer, or designed and purchased separately from the supplier.

Suppliers can ensure that all shipped PCBs pass required testing and inspection; however, a supplier with a high-production yield will operate at lower costs. A low production yield is often an indicator of manufacturing process problems that can lead to low reliability of the final product in the field. The sourcing strategy team should consider a site audit to assess the effectiveness of the supplier's internal quality processes to meet specifications on a consistent basis. Chapter 7, "Process Control, Monitoring, and Incoming Inspection," provides specific guidelines and recommendations for process monitoring and inspection.

It is important to determine the response and level of engagement that is expected from the supplier when there is a quality issue with received PCBs. The supplier should actively participate in troubleshooting and root cause analysis, and may be asked to inspect and sort boards in any suspect lot received. SCM commodity managers should also clearly communicate their warranty expectations in their contract terms and conditions, including processes for returning defective boards to the supplier for rework or scrap.

Table 3.5 summarizes the key questions for determining the quality requirements for PCBs or PCAs.

TABLE 3.5 PCB/PCA Quality Considerations

Does downstream assembly have special quality needs beyond IPC standards?	
What are the production testing and inspection requirements?	Additional testing Sampling and audit frequency Reports
Do PCAs require functional testing?	
What is the expected supplier response to quality issues?	Returns, rework and scrap On-site lot inspection Warranty for field failures due to bad parts

3.4.6 Cost and Price

Obviously the supplier who offers the lowest quoted price per unit will get the attention of the SCM team. However, the profit margins at the average PCB or PCA supplier are typically very small. The lowest-cost supplier will not make much profit on your business and they are unlikely to freely offer other capabilities and services that may be needed or desired. It is important to understand the impact of PCB or PCA price on the total material cost of the final product to determine the overall sensitivity to price changes.

Also, as mentioned above, price is something that may be traded for other considerations, such as expedited delivery or rapid prototyping. Poor supplier performance in these other areas can lead to additional costs that may not be immediately apparent. For example, a long delivery pipeline from the supplier will contribute to inventory costs, which can be particularly expensive following a design change.

Note that the supplier’s cost to produce the PCB or PCA is the most important factor in determining the price that is quoted to a customer, and that cost is almost entirely due to

decisions made by the PCB or PCA designer. Chapter 4 provides details about the most common cost models and drivers used by suppliers. Understanding these models will help designers make decisions that optimize performance and cost. Actual pricing may vary according to market conditions.

Table 3.6 summarizes the key questions for determining the cost and price requirements for PCBs or PCAs.

TABLE 3.6 PCB/PCA Cost and Price Considerations

Is there a material cost budget that limits the maximum price per unit?
What is the overall sensitivity to PCB/PCA price?
Is the business willing to pay more to receive other services?
Shorter lead time or smaller lot sizes for production orders
Faster prototype turn-around time

3.4.7 Other Supplier Services

The availability of other engineering, design, and sales support services may be an additional consideration in choosing a supplier. As mentioned above, many major PCB and PCA suppliers offer local prototyping services that are associated with a separate high-volume production facility. This capability enables the supplier to quickly transfer knowledge about the PCB or PCA design from the early prototypes, which should mean a smoother ramp to higher production quantities. Suppliers may also be able to provide support to assist designers and electrical engineers, including board layout, schematic capture, and performance simulation tools.

The sourcing strategy team should also consider the value of having a locally based sales and technical staff that can quickly respond to questions, quality and delivery issues,

and other routine communication needs. All of these services certainly add to the supplier's operating costs; however, the value of the services can greatly outweigh any incremental increase in board or assembly price.

3.4.8 Other Supplier Management Considerations

PCBs and PCAs may be different than other commodities in some ways, but in many other ways standard supplier management principles apply. Here are a few additional considerations when formulating a sourcing strategy:

- *Supplier management costs*. It may be possible or even necessary to assign dedicated staff to manage PCB or PCA suppliers, but typically this is a shared responsibility within the SCM team. There is an incremental cost associated with each supplier, including time and travel, and businesses should take that into account when deciding on the number and geographic location of their PCB or PCA suppliers.
- *Sole sourcing versus multiple suppliers*. One way to minimize supplier management costs is to choose a single supplier to meet all of your needs. However, sole sourcing significantly increases supply risk. The supplier strategy team should consider the cost and benefit of maintaining multiple suppliers who actively compete against each other and reduce the risk of supply interruptions.
- *Managing poor performance*. Poor supplier performance over a period of time may ultimately lead to a discussion about changing suppliers. However, there is a switching cost associated with starting a new business relationship with a supplier, or ending a relationship with an existing supplier. Working to improve an underperforming supplier also has a cost, and there is no assurance of success. At

some point it may be better to end the relationship. Chapter 8, “Product Acceptance and Feedback,” includes additional guidelines regarding long-term supplier performance management and options for correcting poor performance.

- *Intellectual property protections*. Because PCBs and PCAs are custom-designed, drawings, schematics, and other documents are confidential information that must be kept secret and secure at the supplier. Chapter 5, “Manufacturing Information, Documentation, Formating, and Exchange,” provides more details about protecting sensitive and confidential information. All suppliers should be regularly audited to ensure that the appropriate protections are in-place and effective, and a supplier who cannot provide these protections with confidence should not be selected.
- *Business stability and environmental stewardship*. As with any commodity, buyers should consider whether or not the supplier has the financial stability to remain a long-term business partner. Suppliers should also maintain processes and business records that support the buyer’s goals for environmental stewardship and sustainability.

3.5 SUPPLIER SELECTION CRITERIA EXAMPLE

The specific needs of each business will determine the relative importance of all the performance characteristics of suppliers, and what trade-offs can be made to optimize the mix of suppliers and capabilities. Before investigating and evaluating suppliers, the sourcing strategy team should review the business needs for technology, responsiveness, quality, cost and price, and other service requirements. Note that it is unlikely that each of these requirements will be

equally important. Some requirements may be “musts,” meaning the team will not consider a supplier who cannot provide that requirement. Other requirements are “wants” that are desired but would not eliminate a supplier from consideration.

A common approach is to assign weighting factors to indicate the relative importance of each requirement. This makes it possible to evaluate suppliers based on their ability to meet those requirements using a weighted criteria analysis. Table 3.7 shows an example of how one sourcing strategy team might prioritize their needs for a PCB supplier. This decision-making methodology will be revisited in Chap. 6.

TABLE 3.7 Supplier Selection Criteria Weighting Example

Selection Criteria	"Must" Requirement?	Relative Weight (1 to 5)
Technology		
• Standard FR-4 laminate	Yes	
• Minimum conductors 4 mils	No	2
• Minimum via diameter 12 mils	No	4
• Pb-free surface finish	Yes	
Responsiveness		
• 6 week lead time for production	No	3
• 0 days late, no more than 3 days early	Yes	
Quality		
• 100% opens/shorts testing	Yes	
• Defective boards returned to supplier	Yes	
Cost and Price		
• No more than $X per square inch	No	5
Other Services		
• Prototypes within one week	No	2
• Local sales and technical support	No	4

CHAPTER 4

DESIGN FOR MANUFACTURABILITY

Tim Rodgers
University of Colorado, Boulder, Colorado

4.1 GENERAL PRINCIPLES

The design process for an electronic system requires decisions that will influence the cost and performance of the printed circuit assembly (PCA).

4.1.1 Examples That Influence Cost and Performance

- Product architecture and circuit design assigns the partitioning of functions between component-level and board-level, and this determines the approximate size and number of PCAs that are required.
- In many cases, a previously defined standard card cage or other form factor constraint leads to a maximum board

length and width requirement.

- Electrical performance characteristics such as timing requirements, controlled impedance, and maximum current or voltage determine allowable combinations of trace width, trace length, and dielectric thickness.
- High I/O components will dictate local connectivity requirements for successful circuit routing.
- The board layout designer may be given some flexibility in determining component placement, conductor width, and layer count during schematic capture and routing.

Not surprisingly, it is usually possible to create more than one PCB or PCA design that meets the specified performance requirements. Figure 4.1 gives three possible design solutions for a single circuit schematic and set of components. When faced with equivalent design alternatives, how does one decide which is “best”? Most people would agree that it is the one that results in the lowest overall cost. If the number of design alternatives is small, it may be possible to obtain a price quote for each one. However, price quotes from suppliers can be misleading. Price is often based on prevailing market conditions or the desire of a supplier to attract or discourage business.

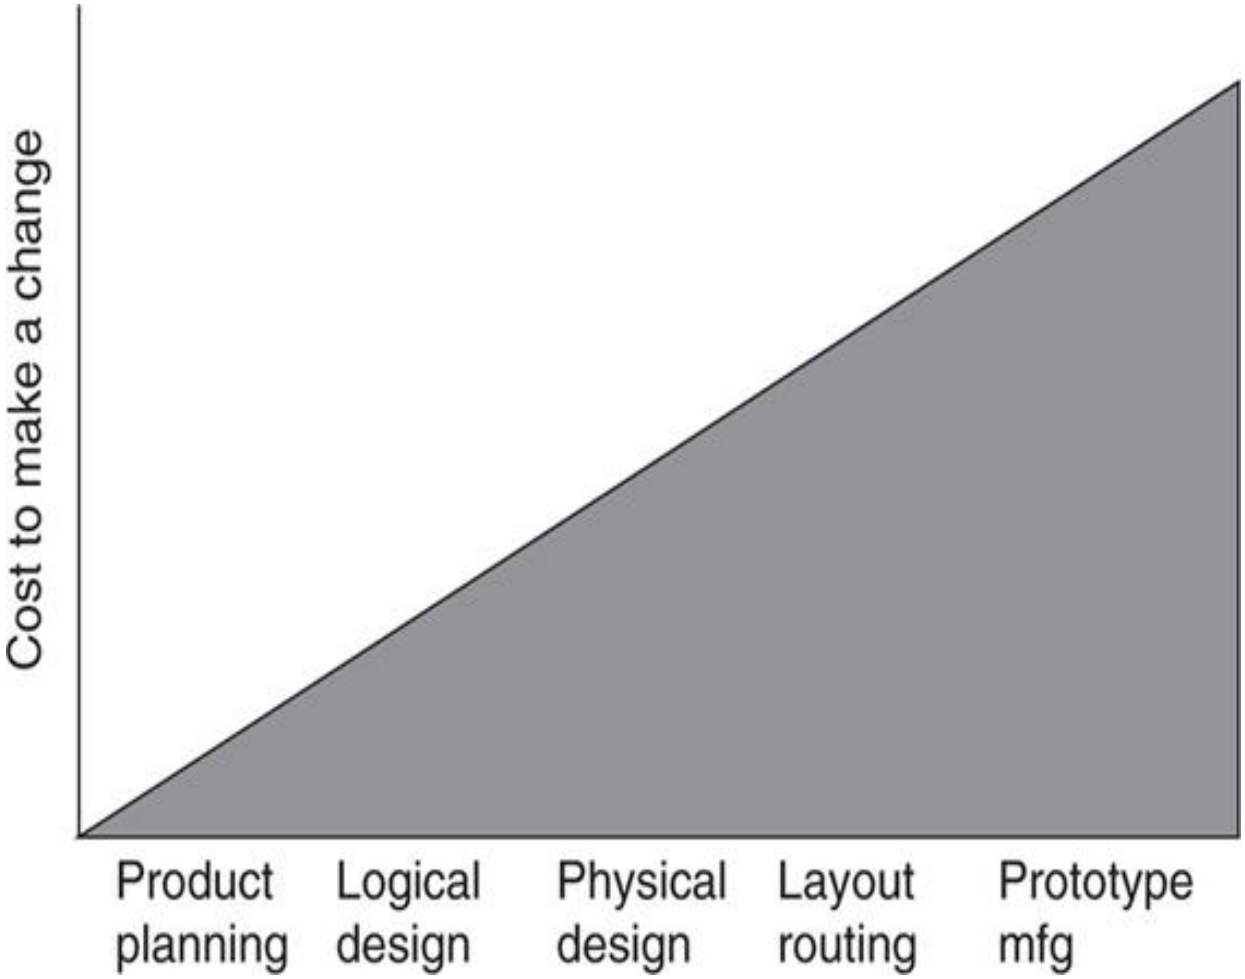

FIGURE 4.1 Cost opportunity at different design stages.

There is also value in being able to quickly estimate the impact of design on cost. Because of the increasing pressure to shorten time-to-market, design engineers may not have the luxury of using trial-and-error and price quotes to fine tune a new design. In addition, the farther down the development cycle for a new product, the greater the difficulty in introducing a design change for any reason. Decisions made during the early phases of product planning and logical design have a greater impact on final cost than is often realized (see Fig. 4.2).

56 gates

Minimum trace width / space width	12/12 mils	8/7 mils	6/6 mils
Totalholes	791	931	895

FIGURE 4.2 Alternative PCB design for a single schematic.

When engineers and designers understand what contributes to the cost of the printed circuit board (PCB) or PCA, and how their decisions can optimize both performance and cost, they not only save money for the immediate purchase order, but also over the entire life of the product.

4.2 PCB/PCA PRICING MODELS

PCB fabricators and PCA assemblers are in business to make money, and they expect to recover their expenses of doing business with at least some profit. While many elements

contribute to those expenses, designers, engineers, and supply chain management professionals are most interested in the things they can directly control through their own design choices.

The operating cost of any manufacturing facility will include overhead for such things as administration and sales and marketing. However, these are usually considered design-independent and outside the control of the customer. Similarly, the mark-up for profit depends less on the design, and more on how badly the supplier wants to win this business, the competitive environment, and other strategic considerations.

Design-dependent costs can be estimated by looking at the cost of the materials used in production plus the allocated cost of any processes that are used, adjusted for any yield losses that are incurred due to failures at inspection or test. Figure 4.3 illustrates this relationship.

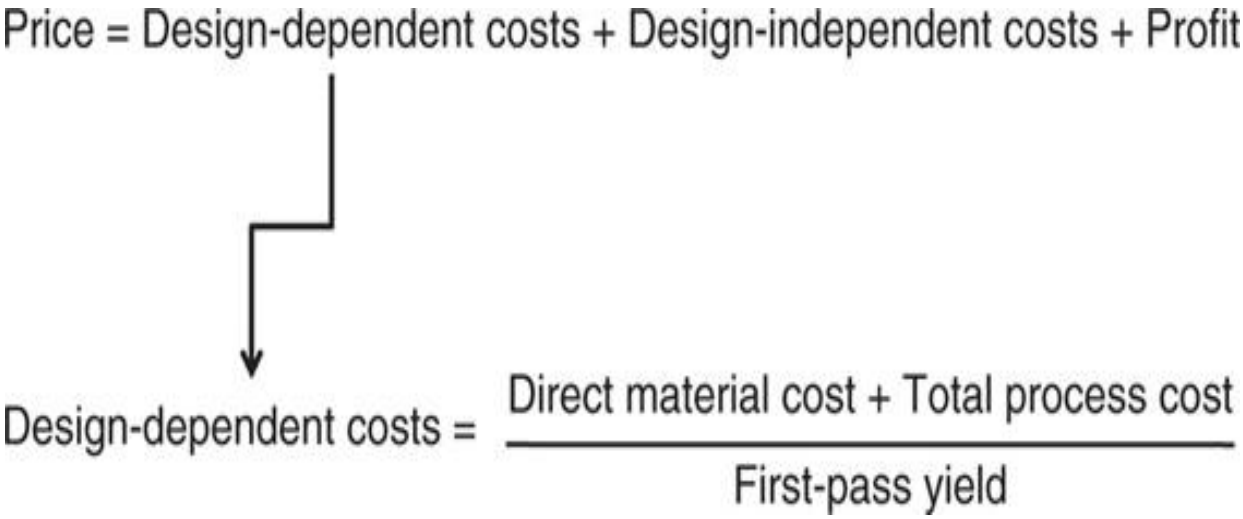

FIGURE 4.3 Contributions to design-dependent costs.

The materials used to construct a PCB are the source of the *direct material cost*. This includes copper foil, prepreg, copper clad core laminate, and soldermask. The material cost can be easily determined from board area and details about the board construction, such as laminate type, number

of layers, and number of prepreg plies. It also includes any deposited metal layer, although with the exception of gold this cost is negligible. For a PCA this would certainly include any attached components in the bill of materials.

Manufacturing processes are characterized by variable costs that depend on the number of units that are produced, and fixed costs that do not. Variable costs include indirect consumables, labor, and maintenance. Fixed costs are incurred regardless of whether the process is used, such as depreciation on capital equipment. From the standpoint of design-dependent costs these can be lumped together as the *total process cost*.

The specific cost model for PCB or PCA suppliers can vary; however, many operations use the concept of a cost center with a specific allocation applied to each unit that passes through the center. For example, if it costs a total of $100,000 per year to operate and maintain a process (or, cost center), and recent history indicates that 10,000 units per year will be processed, then the allocation for the process is $10 per unit. Note that in this model a process that is rarely used will have a smaller basis for cost allocation and therefore a higher rate. This will become important when we look at nonstandard PCB and PCA production.

The internal, *first-pass yield* at a supplier must also be factored into the cost for several reasons. PCBs are difficult to rework, and because of the risk to long-term reliability many customers prefer to have suppliers scrap any boards that fail testing. Production scheduling must compensate for yield loss by increasing the number of panels launched for a given purchase order. PCAs can be reworked by replacing components, but this adds both labor and component cost. Note that the cost of rework is usually passed to customers as an additional process cost, or appears as a yield variance.

Rather than calculate a bottoms-up cost for each new design, PCB fabricators typically create a standard pricing

matrix that provides a basis for quoting. This matrix assumes a standard set of design characteristics that includes laminate material, outerlayer surface finish, minimum conductor width, and minimum hole size, and estimates the cost for a given board size and layer count. Any characteristics of the board design that deviate from standard materials and processing adds cost and is accounted for as either a price adder, or its own pricing model. PCA assemblers use the component bill-of-materials and a similar matrix for quoting purposes.

While each factory or supplier may have their own internal and confidential cost model, we can infer the relative cost contributions of different design features from average market price data. Figure 4.4 shows the results of a survey of Chinese PCB suppliers taken in July 2012 with a range of prices (in cents per square inch) for PCBs with different layer counts. Where absolute price data are unavailable, it is still possible to compare design options using a ratio, or relative price compared to a standard. See, for example, Fig. 4.5 for a price comparison of different types of FR-4 laminate.

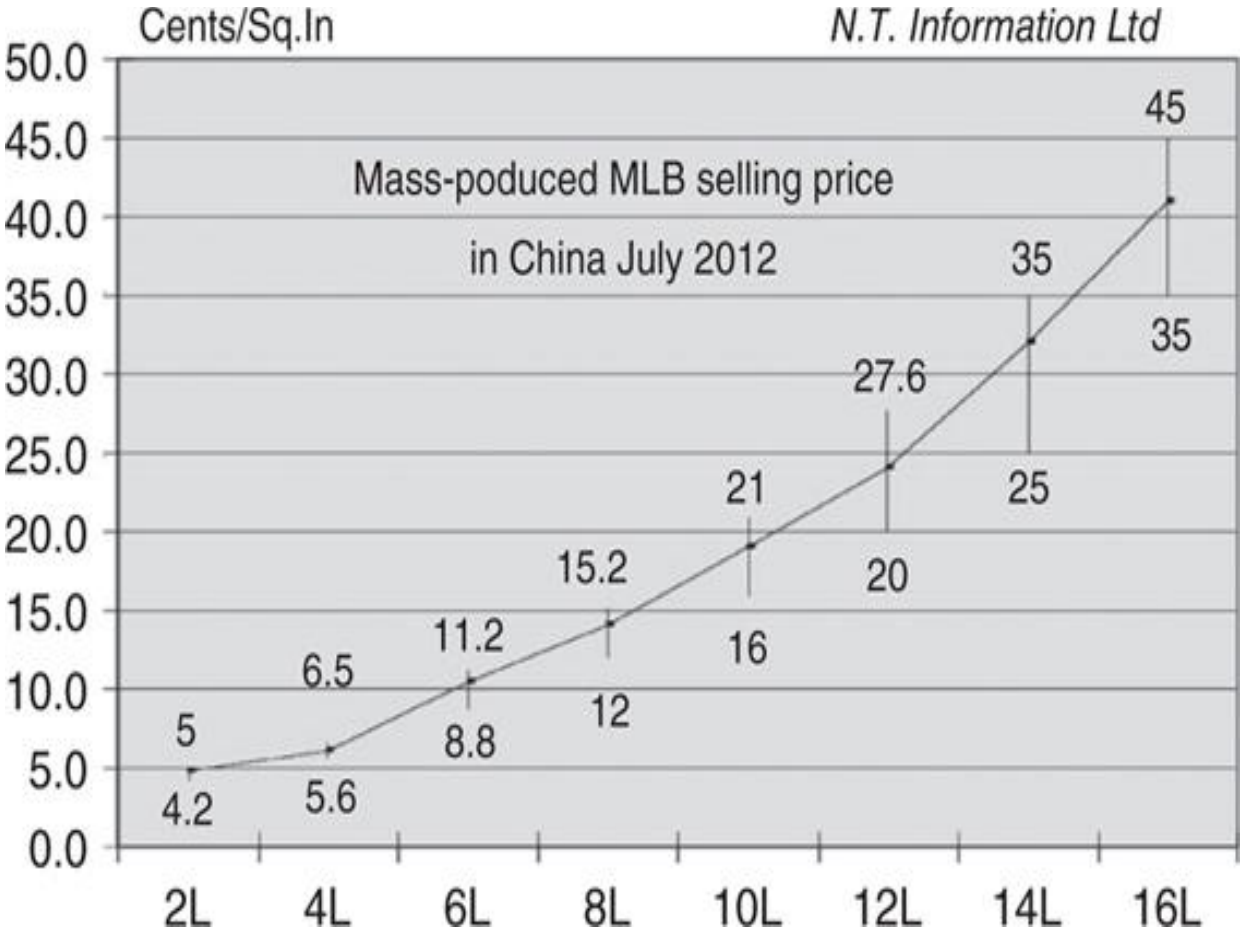

FIGURE 4.4 Market price survey data for PCBs.

4.2.1 Material Cost Drivers

For PCBs the predominant driver of material cost is the dielectric laminate, including copper-clad core and prepreg. Design decisions that relate to laminate cost include the type of material itself, the board size, and the number of layers.

4.2.1.1 Material Type. Glass-reinforced FR-4 certainly remains the default choice for PCBs, and DiCY-free or halogen-free varieties are currently available with a variety of thermal characteristics (see Fig. 4.5). There are cheaper materials such as paper phenolic, but their performance may not meet the electrical and thermal requirements for the finished PCA. At the other end of the spectrum are more

expensive and exotic materials using different resins and reinforcements for high speed or low thermal expansion applications. Figure 4.6 shows some of these materials and their associated permittivity and dissipation factor. The effect of laminate type on board cost for a double sided and a multilayer board is illustrated in Figs. 4.7 and 4.8.

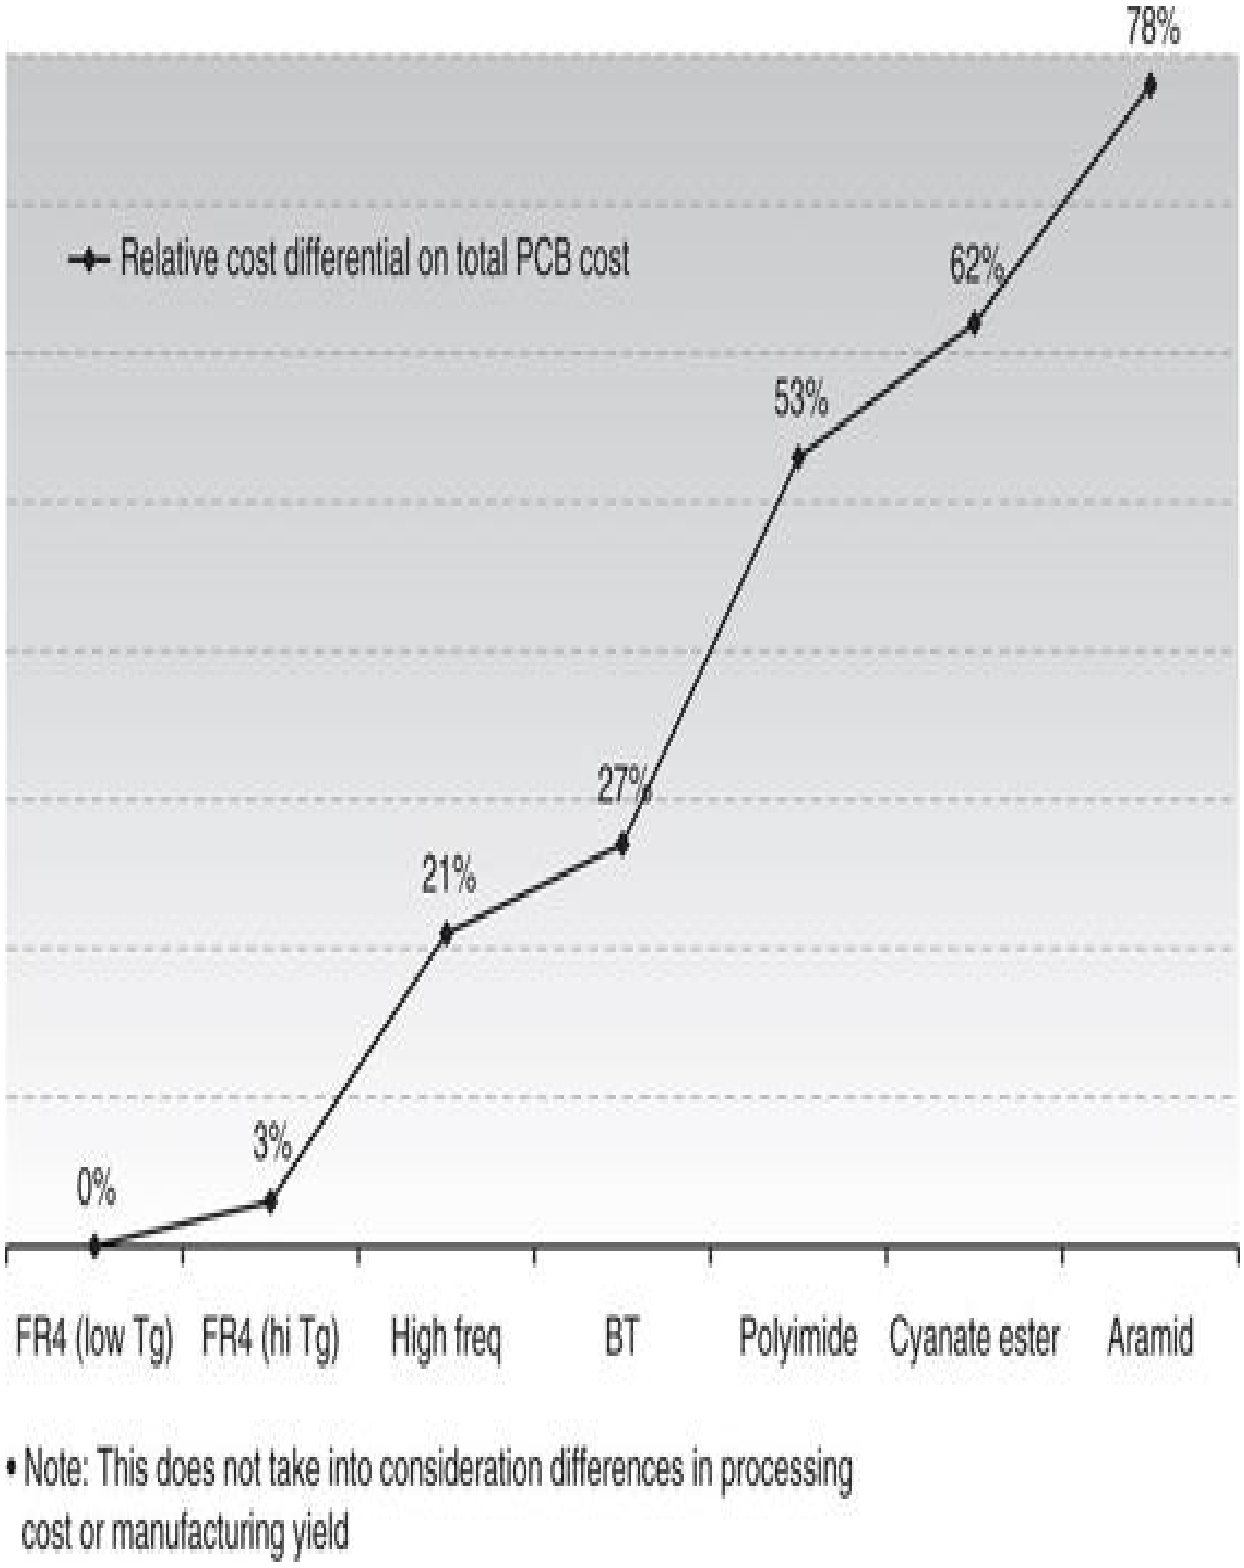

FIGURE 4.8 Effect of laminate type on multilayer PCB cost.

4.2.1.2 Board Size and Layer Count. These design elements determine how much material is used, and suppliers use these as the starting point for any price quote. PCB fabricators build panels and then cut them (depanelize) into individual boards, so there is an obvious advantage to maximize panel utilization since the customer is paying for the entire panel (see Fig. 4.9). Suppliers will work with their customers to optimize board dimensions, spacing between boards, and panel layouts using nesting and rotation to minimize unused space.

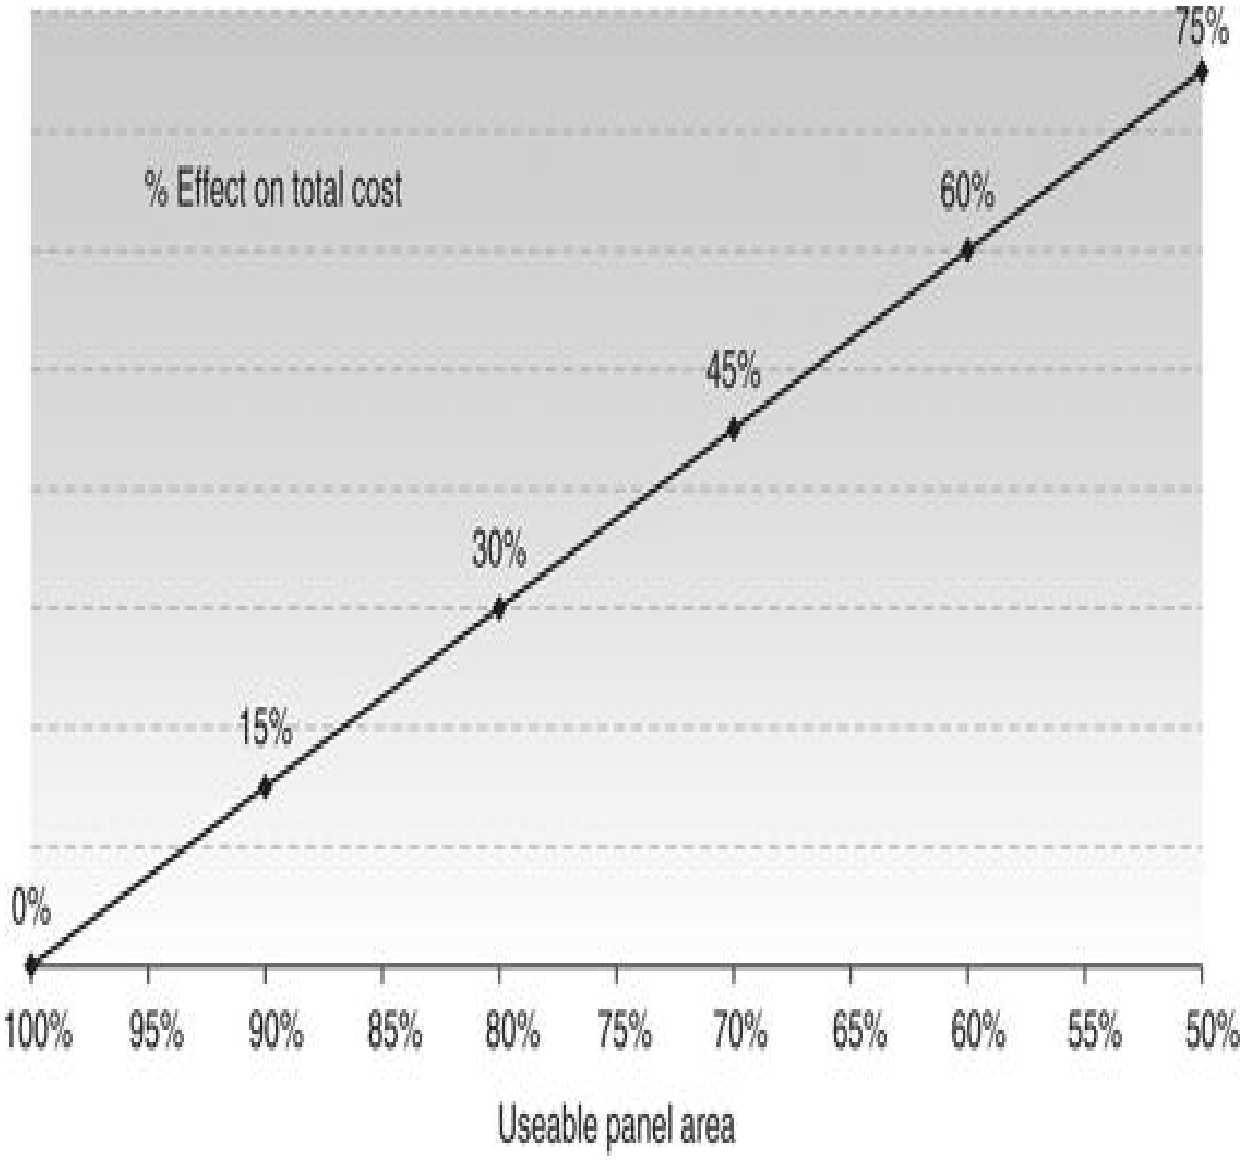

FIGURE 4.9 Effect of panel utilization on relative PCB cost.

Designers add layers to provide more area for signal routing, especially when overall board size is constrained.

Figures 4.4, 4.10, and 4.11 show the effect of layer count on price and the differential cost of adding two more layers.

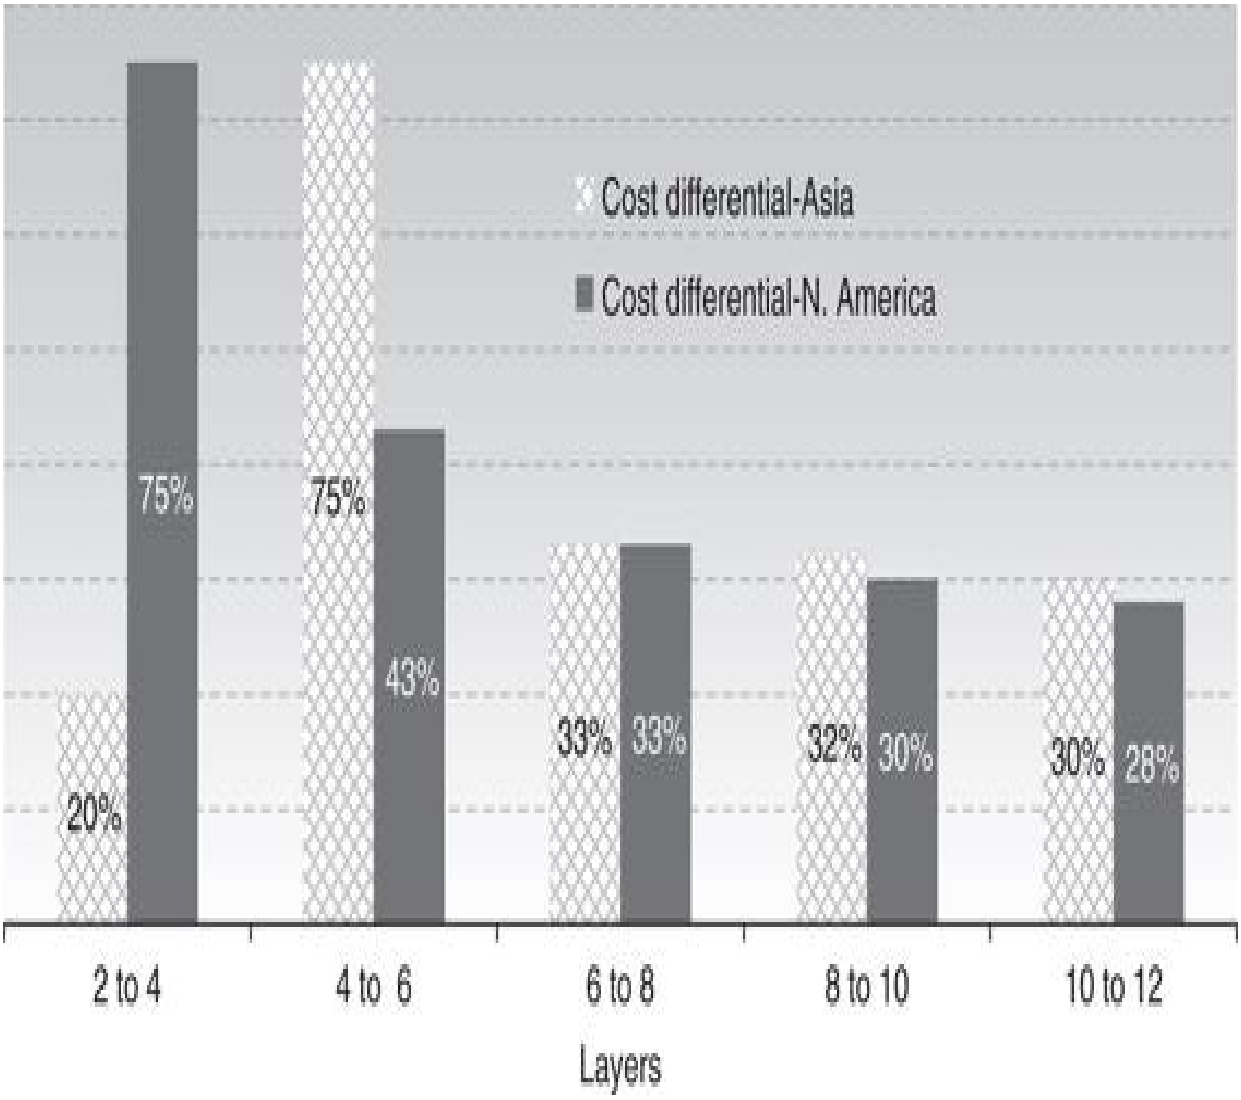

FIGURE 4.10 Cost differential for two additional layers.

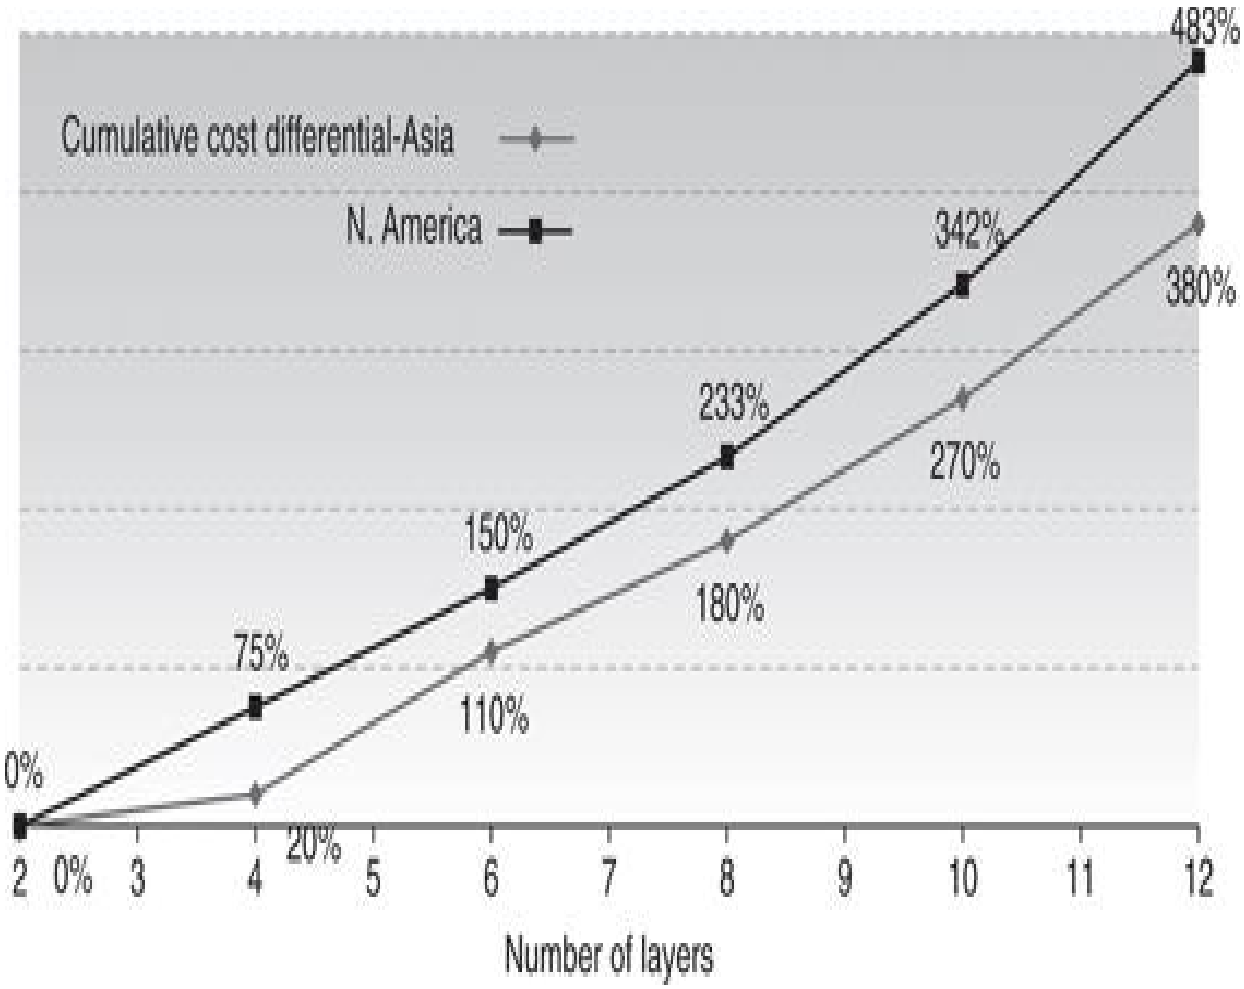

FIGURE 4.11 Cumulative cost differential compared to two-sided board.

Higher *board thickness* can contribute to higher PCB cost, in part because of the slightly greater amount of laminate required, but also because of the requirement of nonstandard thicknesses of copper-clad core material. See Fig. 4.12.

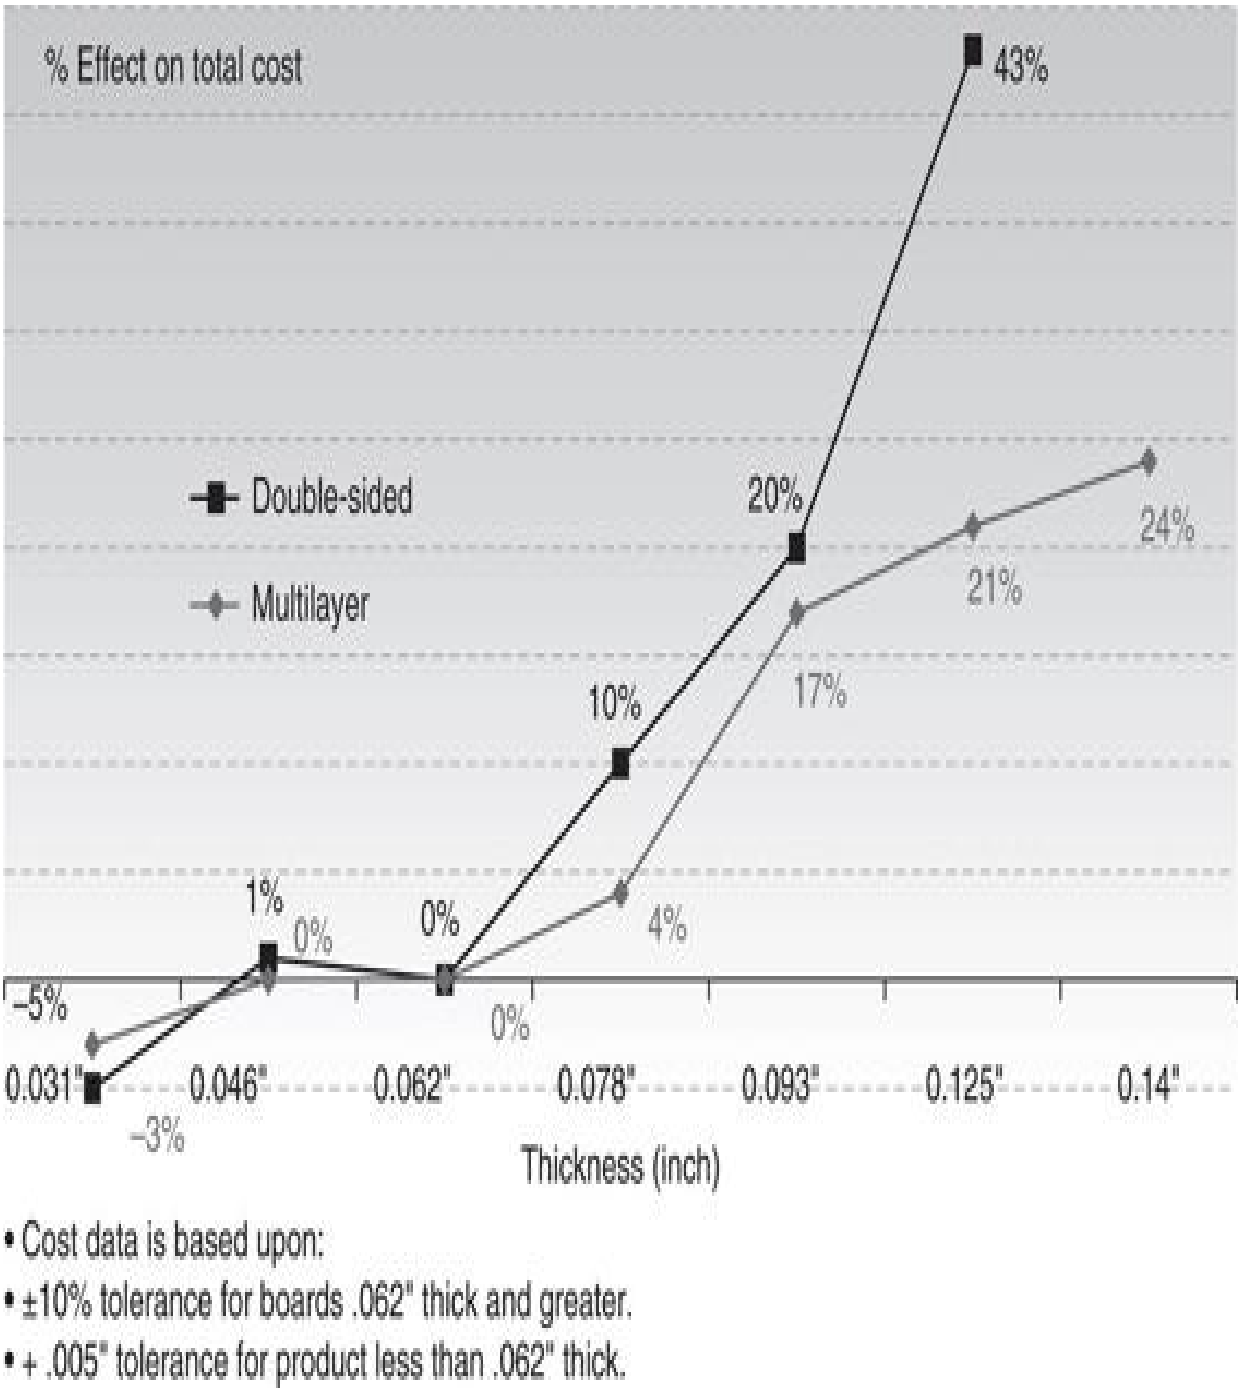

FIGURE 4.12 Effect of PCB thickness on relative cost.

Standard PCBs use copper as the primary conductive medium, but copper is relatively cheap and is rarely a material cost consideration, even for the thicker copper-clad materials used for high-current applications. The bigger impact of thick copper is to etching tolerance for smaller

features (see the discussion of production yield in Sec. 4.4). Common *surface finishes* have a slight impact on board cost compared with tin/lead solder applied by HASL, with the notable exception of gold (Figs. 4.13 and 4.14).

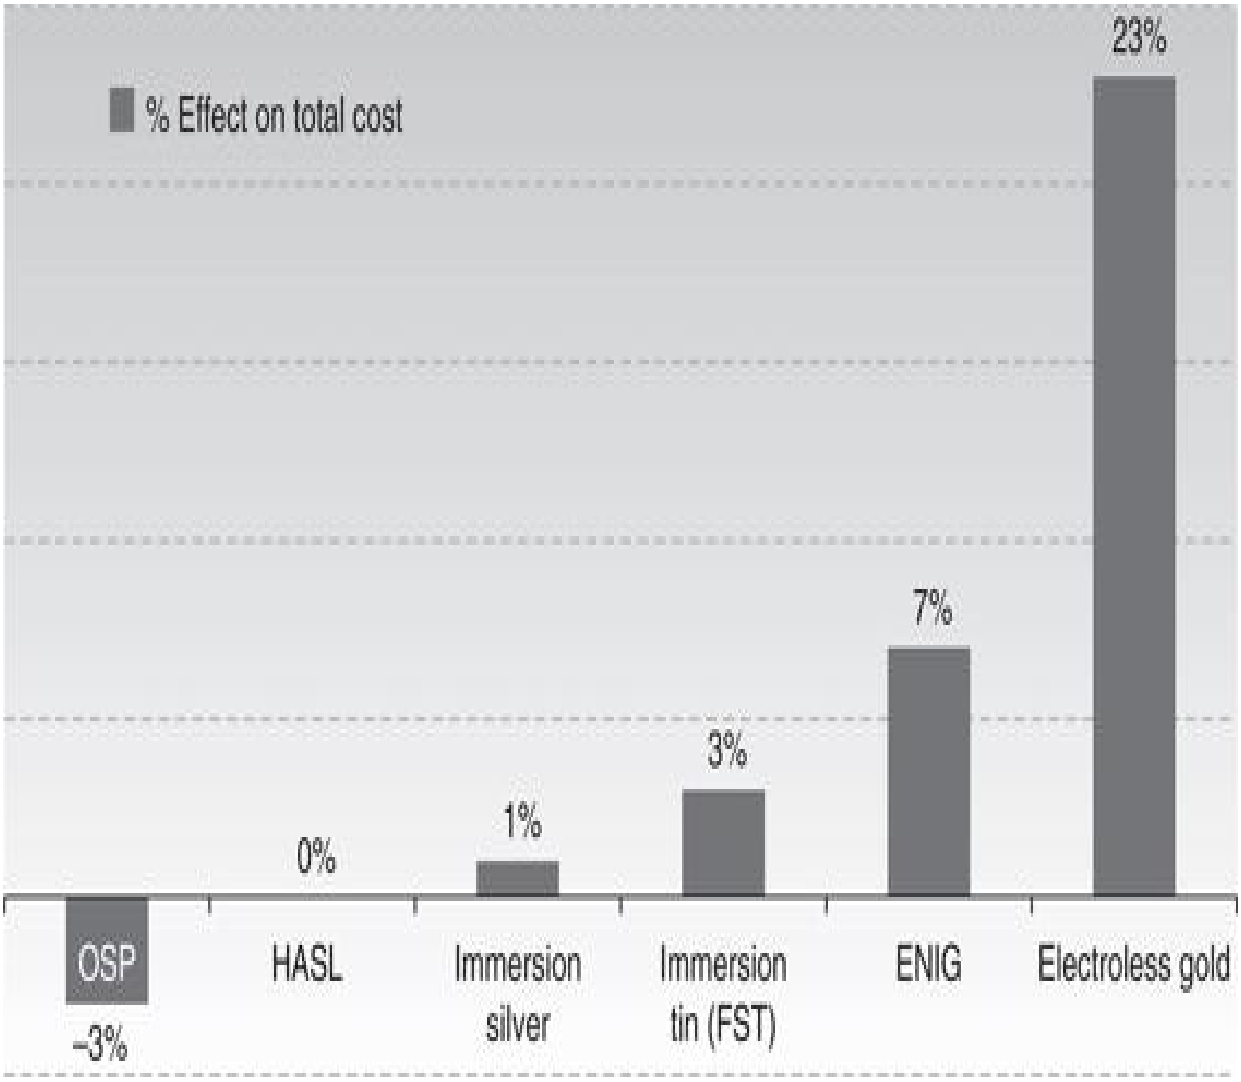

FIGURE 4.13 Effect of surface finish on relative PCB cost.

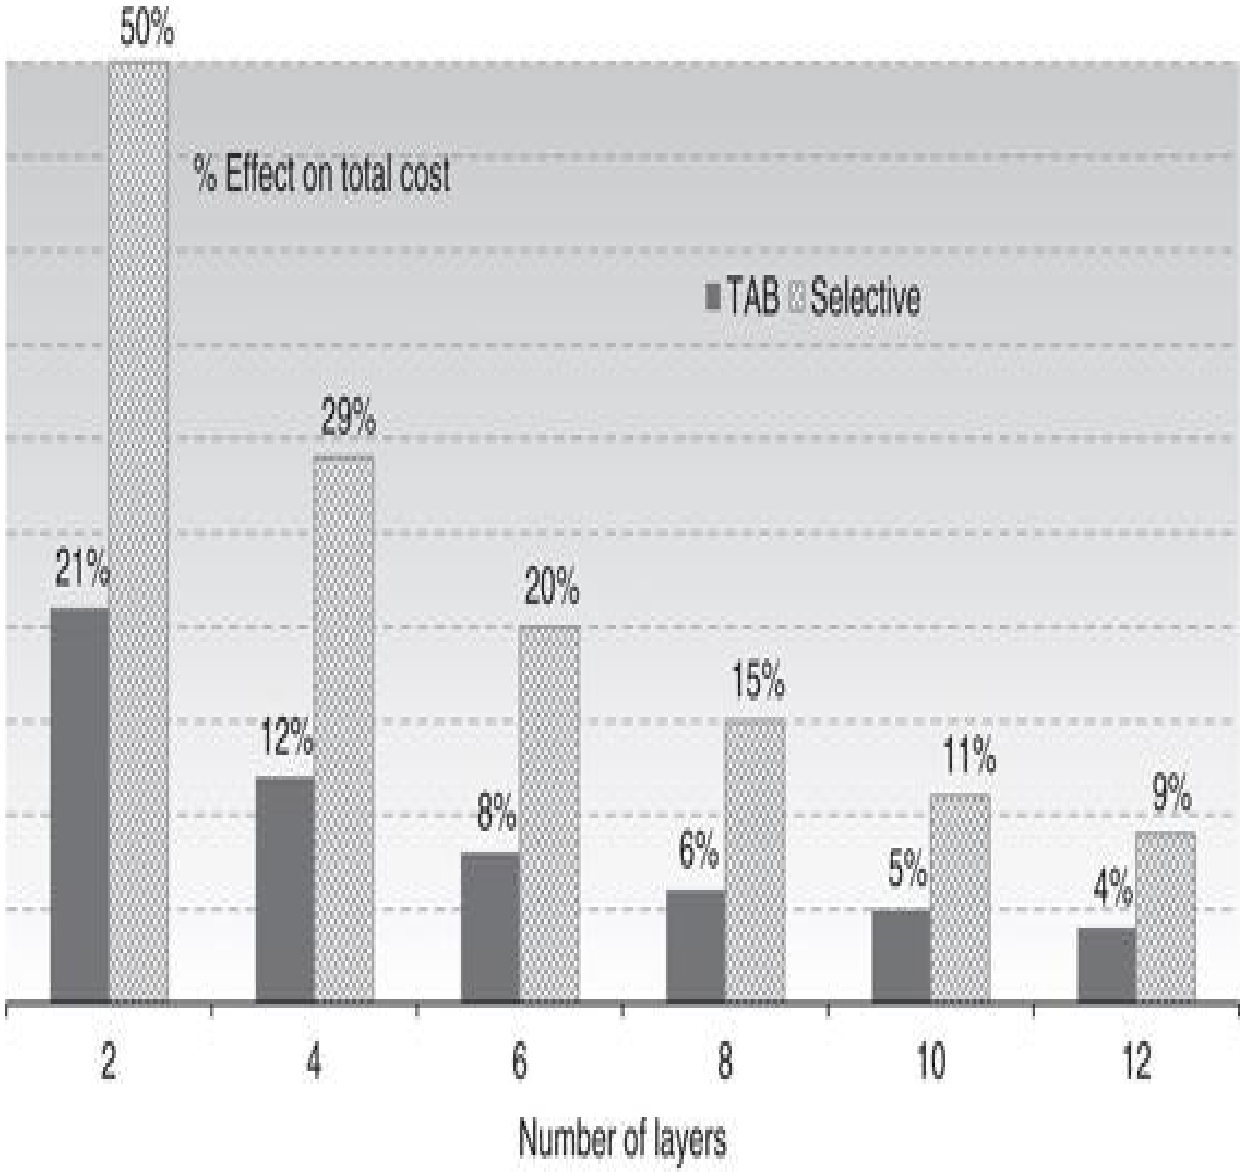

FIGURE 4.14 Effect of gold-plated fingers on relative PCB cost.

4.3 PROCESS COST DRIVERS

For a PCB factory, the logical production cost centers include

- Innerlayer processing (imaging, etching, inspection)
- Lamination
- Drilling
- Outerlayer processing (plating, etching, final surface finish)
- Soldermask
- Graphics printing
- Depanelization
- Final inspection and electrical test
- Other special processes (e.g., gold connector fingers)

For a PCA factory these are

- Solder paste printing
- Surface mount component placement
- Thermal reflow
- Through-hole component placement
- Wave solder
- Manual component placement
- Final inspection and electrical test

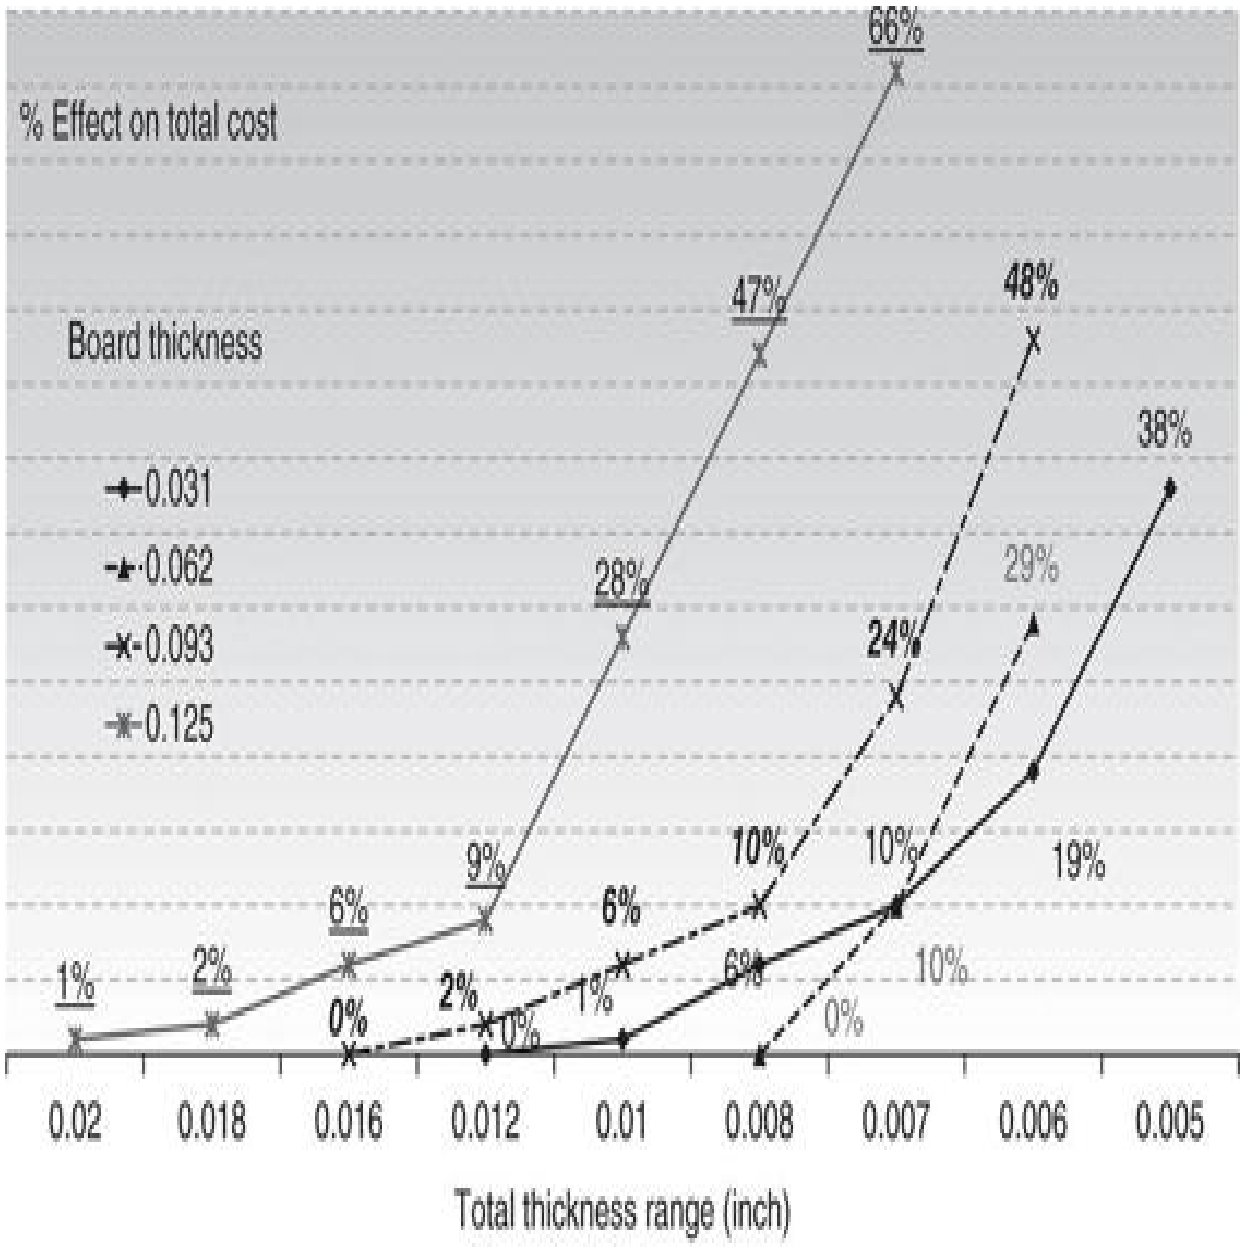
Standard processing defines a baseline for board pricing and is automatically accounted for in quoting models that use board area and layer count. Here are some examples of how the design contributes to total process cost for a PCB or PCA:

- Some board designs have to go through processes more than once. In the simplest case, the number of layers will determine how many times the innerlayer processing rate is applied. Double-sided surface mount assembly will require at least two passes through component placement and reflow. Buried or blind vias typically require sequential lamination.

- Since the drilling process cost is often expressed per hole, this cost will depend on the stack height, or the number of panels that can be drilled at one time, which in turn is based on the board thickness and minimum hole diameter.
- Most cost centers process full panels, so the more images or boards that can be designed on a single panel, the smaller the per-board process cost.

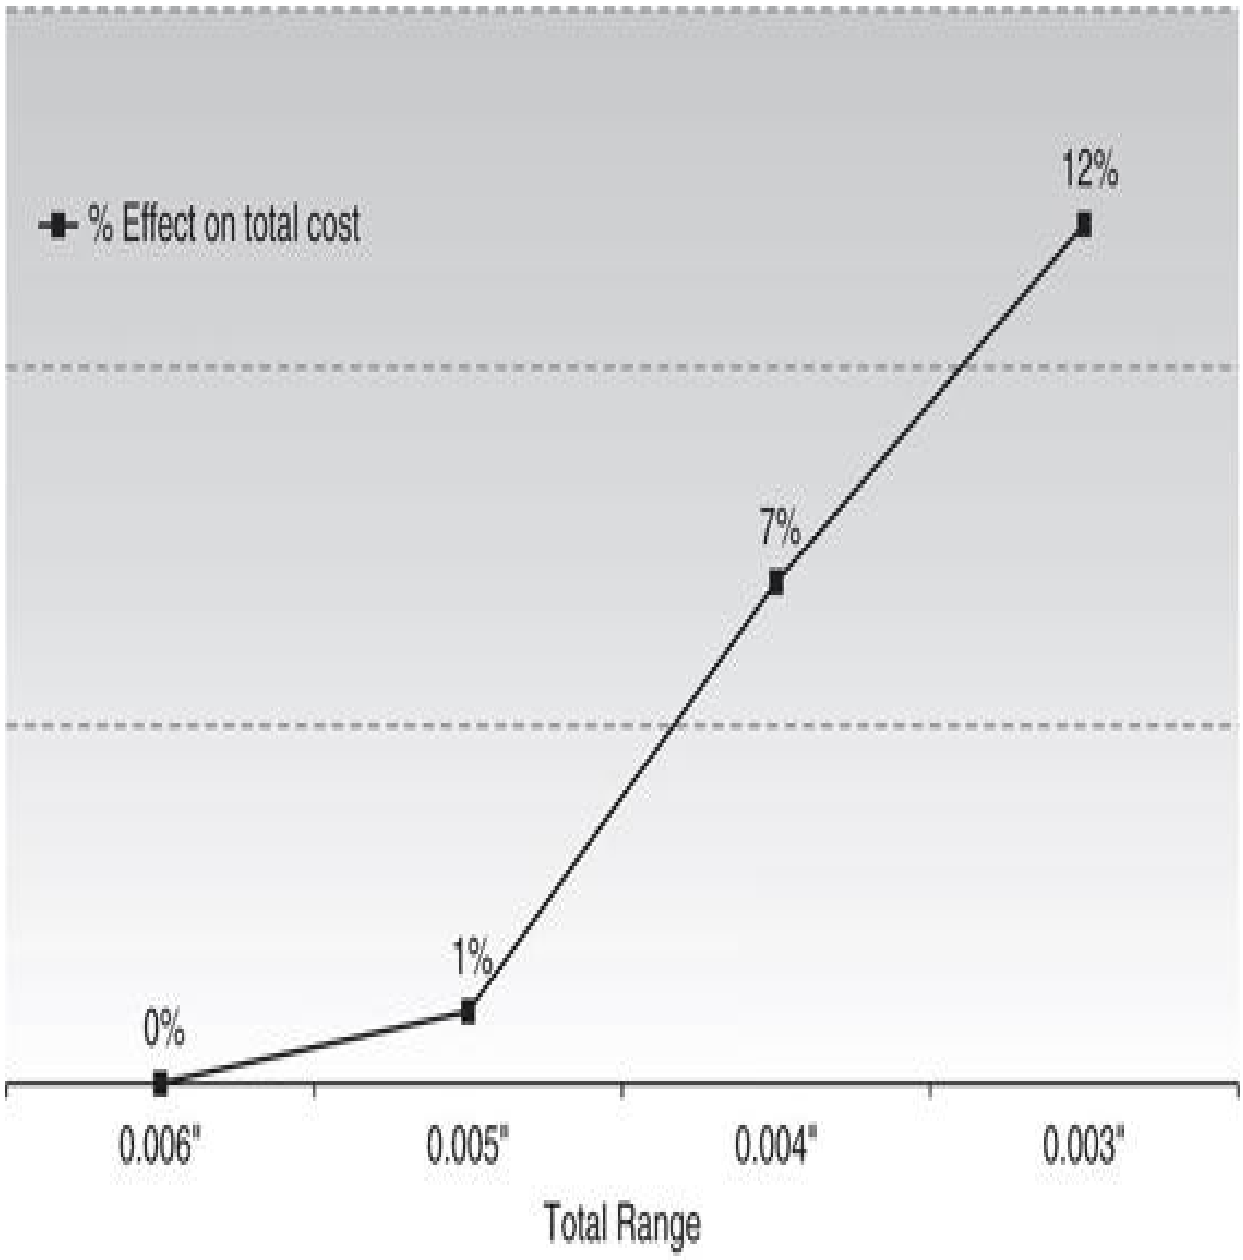
Note that one-time processes such as initial set-up and prints for soft tooling may be added as a charge to the first purchase order, or distributed over several orders.

Any additional PCB or PCA process steps that are not included in the standard pricing model will add to the cost, such as hole plugging, beveling, or plated edges or slots. This includes special processes that require greater control in order to achieve the required tolerances, such as board thickness, hole size, and controlled impedance applications (see Figs. 4.15, 4.16, and 4.17). Manual processes are obviously more expensive than automated ones because of the labor required. This includes manual taping or masking, manual depanelization, and manual placement of components that cannot be loaded into a pick-and-place machine.



- Thickness tolerance is based on the sum of the plus and minus tolerances.
- Ex: + .004/–.003 has a total thickness range of .004. "This data is derived from 4 layer product. The cost impact is more dramatic as the layer count increases.

FIGURE 4.15 Effect of board thickness tolerance on relative PCB cost.



• Total range is the sum of the plus and minus tolerances. Ex: +.002"/-.003" has a total range of .005". A .004" range and less require panel plating to ensure compliance to the tight finished hole size requirements. Cost data is based on a final board thickness of .062" and a maximum aspect ratio of 3:1.

FIGURE 4.16 Effect of finished hole size tolerance on relative PCB cost.

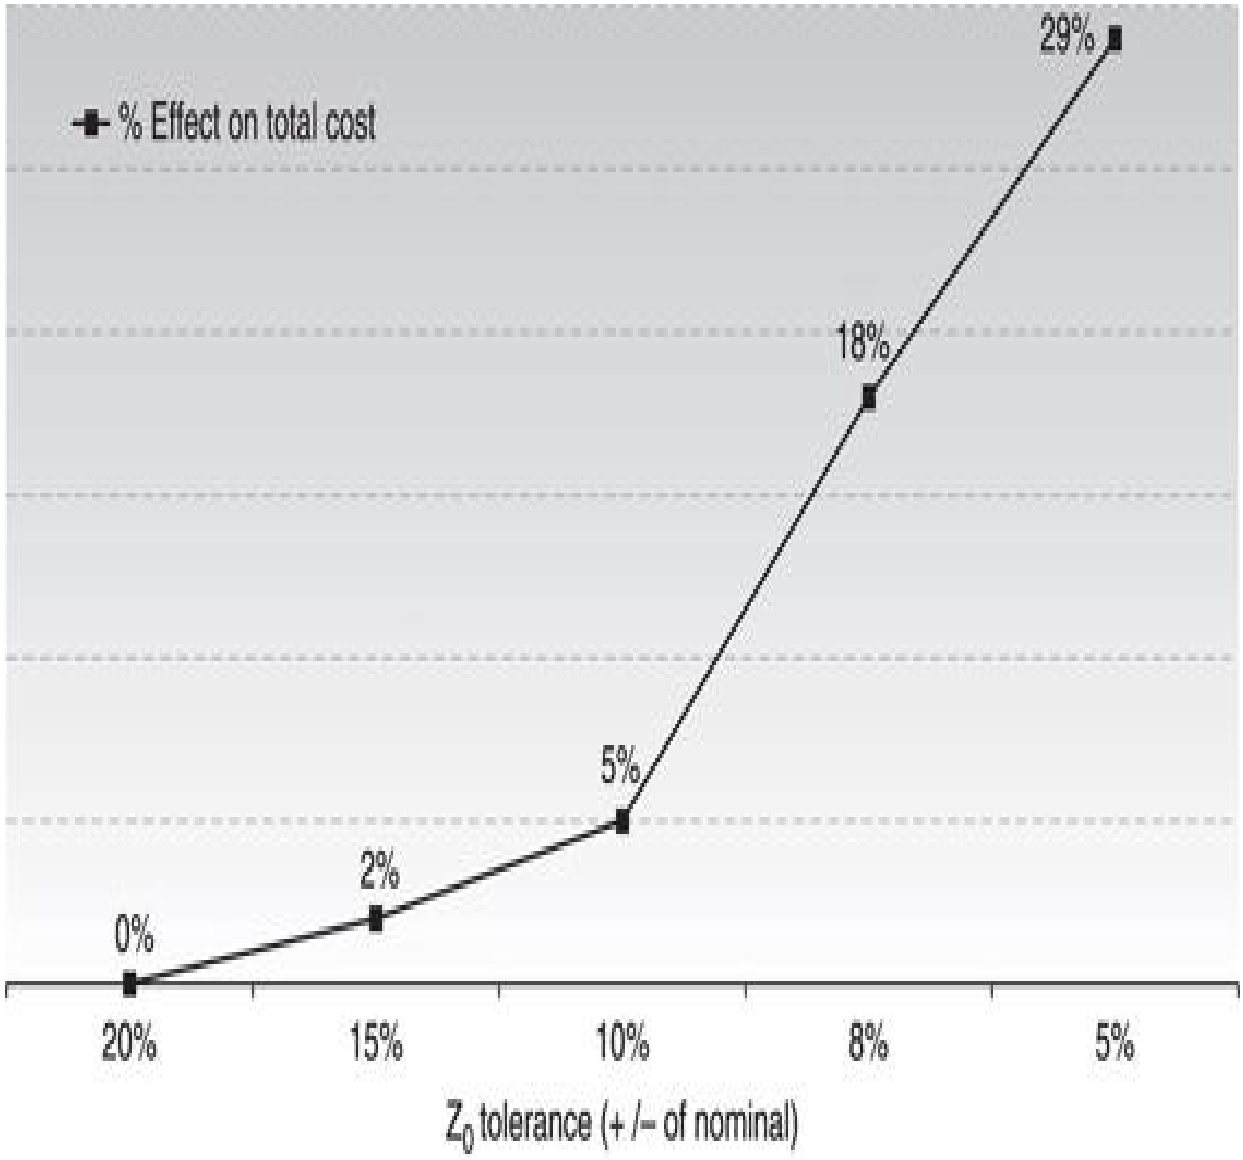


FIGURE 4.17 Effect of impedance tolerance on relative PCB cost.

4.4 PRODUCTION YIELD AND DESIGN FOR MANUFACTURABILITY

The concept of design for high-production yield or design for manufacturability (DFM) is not new, but early programs consisted of a collection of recommendations or best practices based on the experience of senior experts. The beginning of a more systematic approach to DFM can be traced to the pioneering work in the early 1980s by Geoffrey Boothroyd from the University of Rhode Island and Peter Dewhurst from the University of Massachusetts.[a,b] Their system analyzed each part in a mechanical assembly from the standpoint of

1. The necessity of its existence as a separate part (fewer parts are better)
2. Ease of handling, feeding, and orienting the part
3. Ease of securing the part to the base assembly

The results of this analysis were an estimate of assembly time and a rating for overall design efficiency, with the implication that higher design efficiency provides not just higher productivity, but also higher production yield.

Based on Boothroyd's seminars and studies on the cost of motions and joining methods, Hitachi's Production Engineering Research Laboratory (PERL) developed an Assemblability Evaluation Method (AEM) that rates the ease of assembly to get a quantitative score. General Electric obtained a license from Hitachi and added improvements.

The Hitachi/GE studies led to an assembly model that examines the manufacturing processes as a series of individual steps. The probability of introducing a fatal defect at each step is determined by the nature of the process and specific design elements. Penalty points are assessed to processes and elements that introduce difficulty, such as an operation that requires registration and alignment of several parts at once. A high final score suggests a low assembly yield, and multiple design options can be objectively compared.

Without DFM models, design engineers work independently to create specifications and requirements without regard for the capabilities of the intended manufacturing site. By the time problems are discovered it is often too late in the launch schedule to make changes, leaving the production team to struggle to meet yield, quality, cost, or delivery targets, and possibly risking field failures and long-term reliability issues.

With DFM, the design can be optimized for manufacturing without sacrificing performance, which leads to higher production yields, lower cost for the supplier (which usually means lower price to the customer), and a lower probability of defect escapes.

Unfortunately, while the Hitachi/GE models work well with mechanical assemblies and even PCAs, they are not very applicable to PCB fabrication. Summed algorithms are inappropriate for PCBs because of the statistical uncertainty associated with the individual process steps. Each step has a probability of introducing a fatal defect that depends on not only the design elements but also the result of previous steps.

Also, interactions and trade-offs between PCB design elements are difficult to characterize. For example, the diameter of drilled holes should be large to avoid the mass transfer limits of electroplating and the higher cost of reduced drill stack height. On the other hand, for a fixed pad size, a smaller via results in a larger hole-to-pad annular ring, which provides a margin for drilled hole breakout or reduced conductor width that can result from extreme misregistration (see Fig. 4.18).

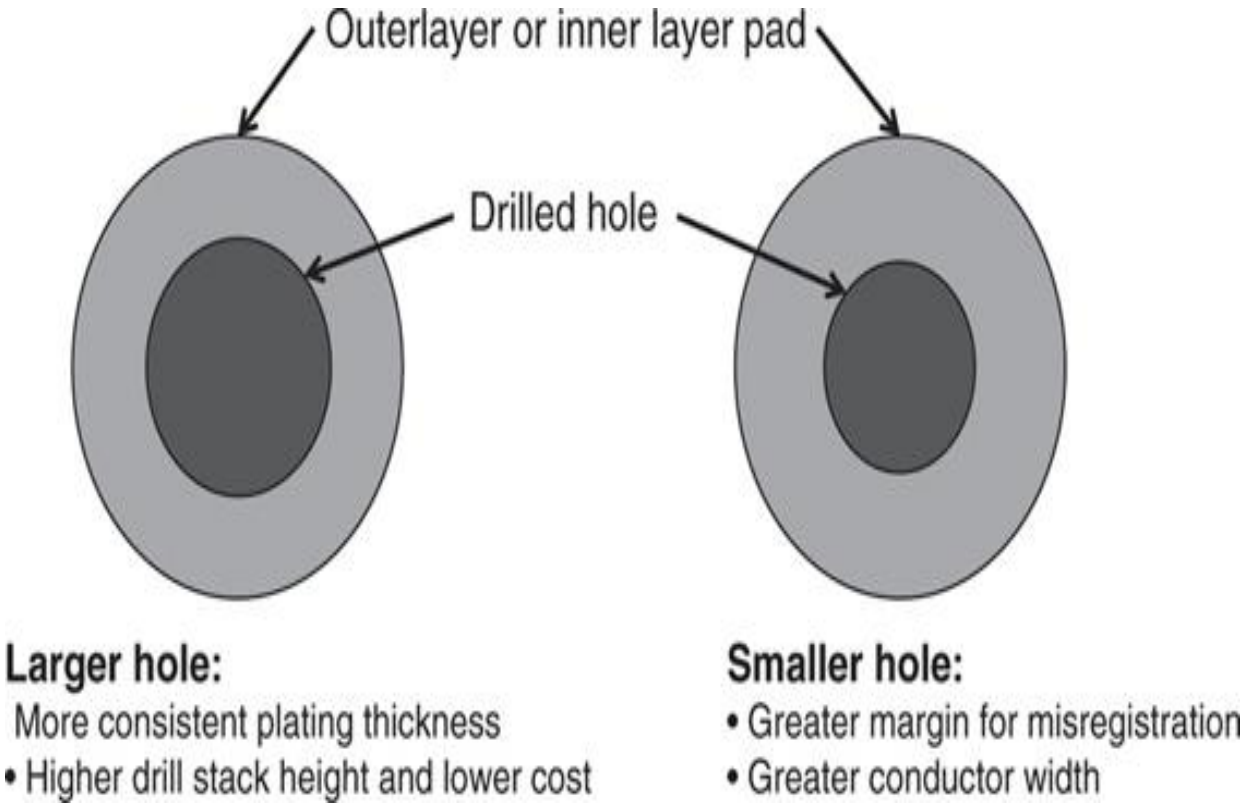

FIGURE 4.18 Bigger holes or smaller holes?

In this environment PCB designers and manufacturers use their intuition and judgment based on experience with similar boards, usually provided as best practices. These may take the form of a company-wide design standard, but most designers rely on IPC Standards to guide their decisions. See Fig. 4.7 for a list of some of the more common IPC Standards.

4.4.1 Design for Manufacturability Guidelines

Manufacturing yield depends entirely on the performance of the PCB or PCA supplier, which in turn depends both on both (1) the inherent capability of the production processes, and (2) the ability of the supplier to monitor and control those processes. Chapter 7, “Process Control, Monitoring, and

Incoming Inspection," provides details about what suppliers should be expected to do to manage their processes. However, because the predominant majority of PCB and PCA suppliers use the same basic manufacturing processes, it's possible to create a general set of guidelines that will maximize yield and thereby reduce cost, regardless of the supplier's quality management system.

PCBs and PCAs are typically inspected for cosmetic defects and rejected at the factory, but the most common reason for yield loss is failure at electrical test due to opens or shorts.

4.4.2 Design Decisions That Contribute to Manufacturing Yield Loss

- *Conductors*. A design with narrow lines and spaces requires better control over imaging and etching processes to maintain the required conductor cross section and remove all copper between conductors. This is a bigger problem with thick copper layers because the etching process may not be able to guarantee both (Figs. 4.19, 4.20, and 4.21). The probability of an open or short increases with the length of the minimum width conductor, so designers are advised to use narrow conductors only where necessary, and increase conductor width in areas of lower wiring density. (See Figs. 4.22, 4.23, and 4.24.)

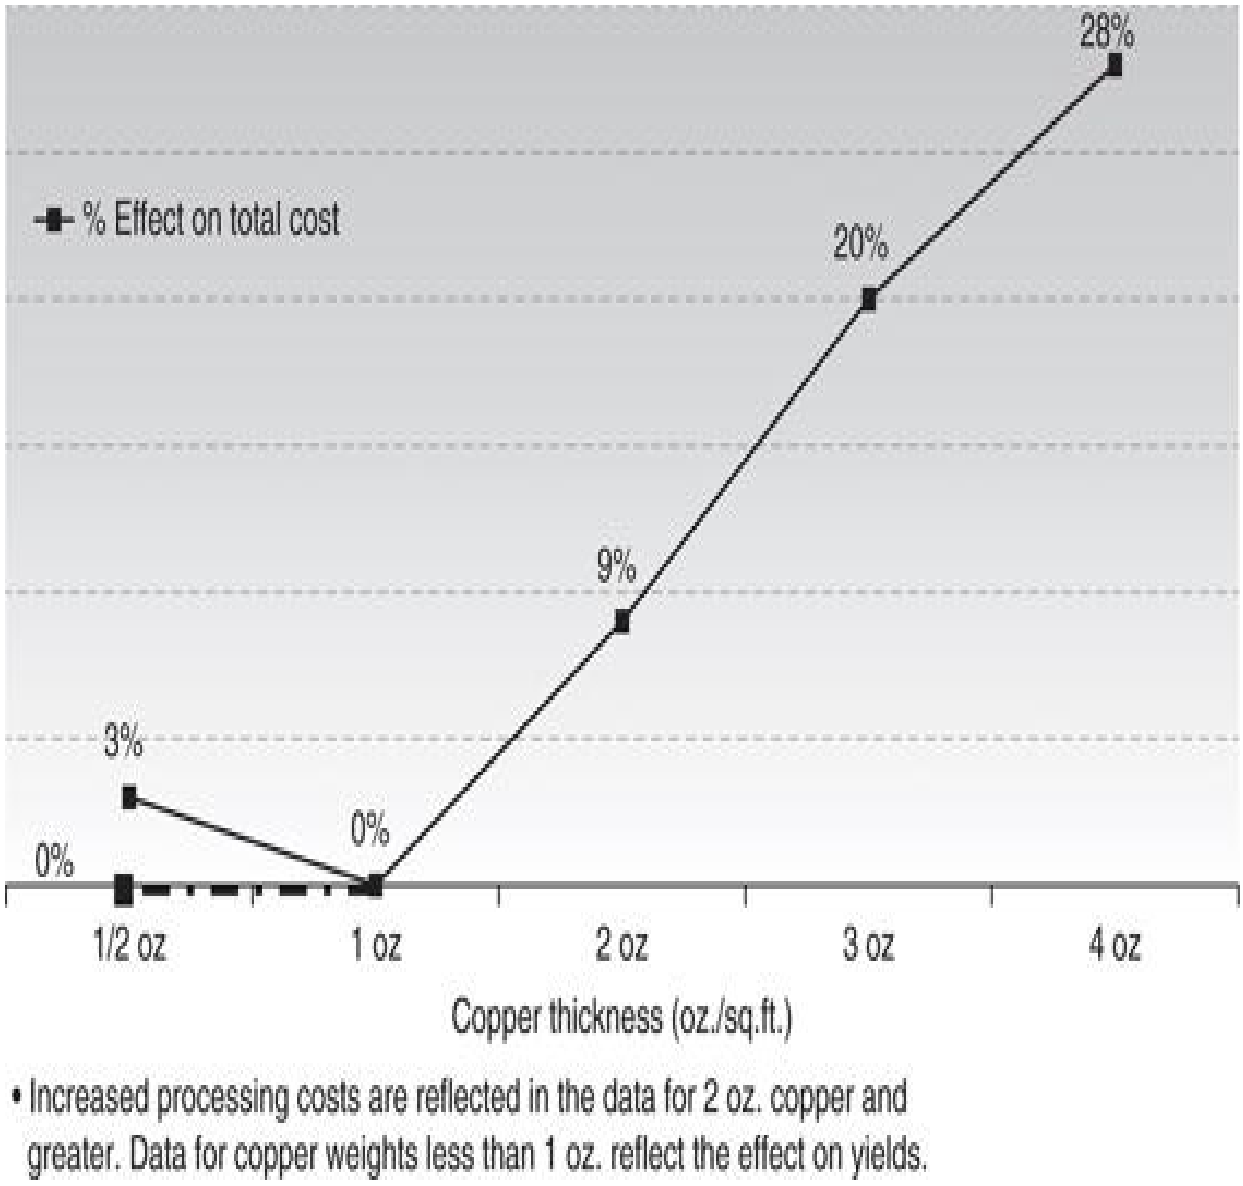

FIGURE 4.19 Effect of innerlayer copper thickness on relative PCB cost.

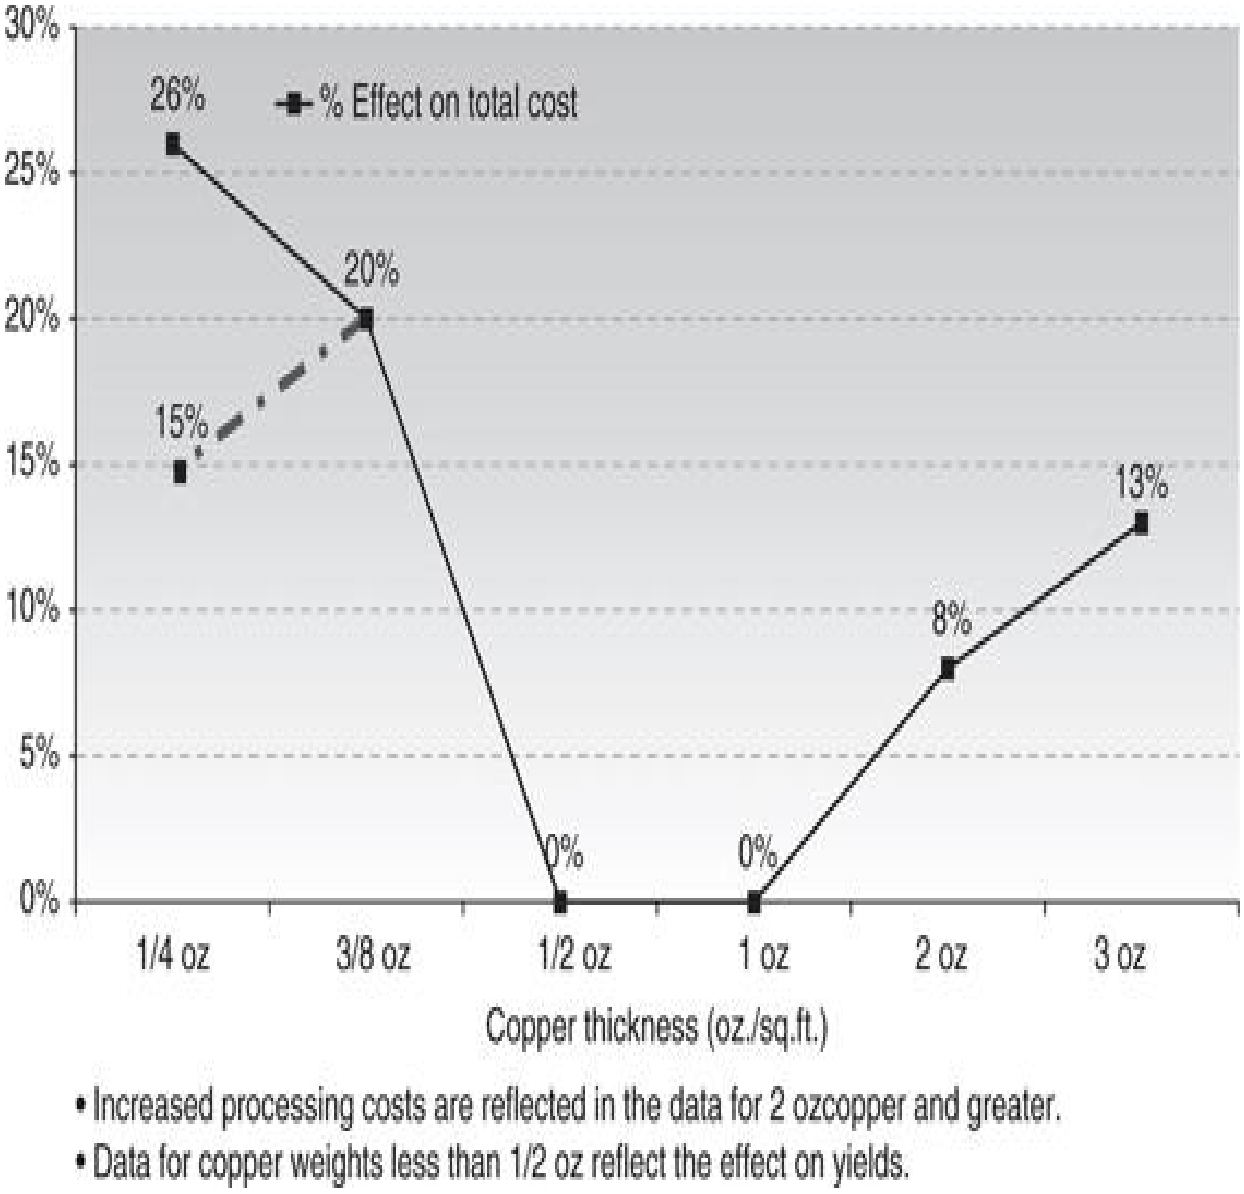

FIGURE 4.20 Effect of outerlayer copper thickness on relative 2-S PCB cost.

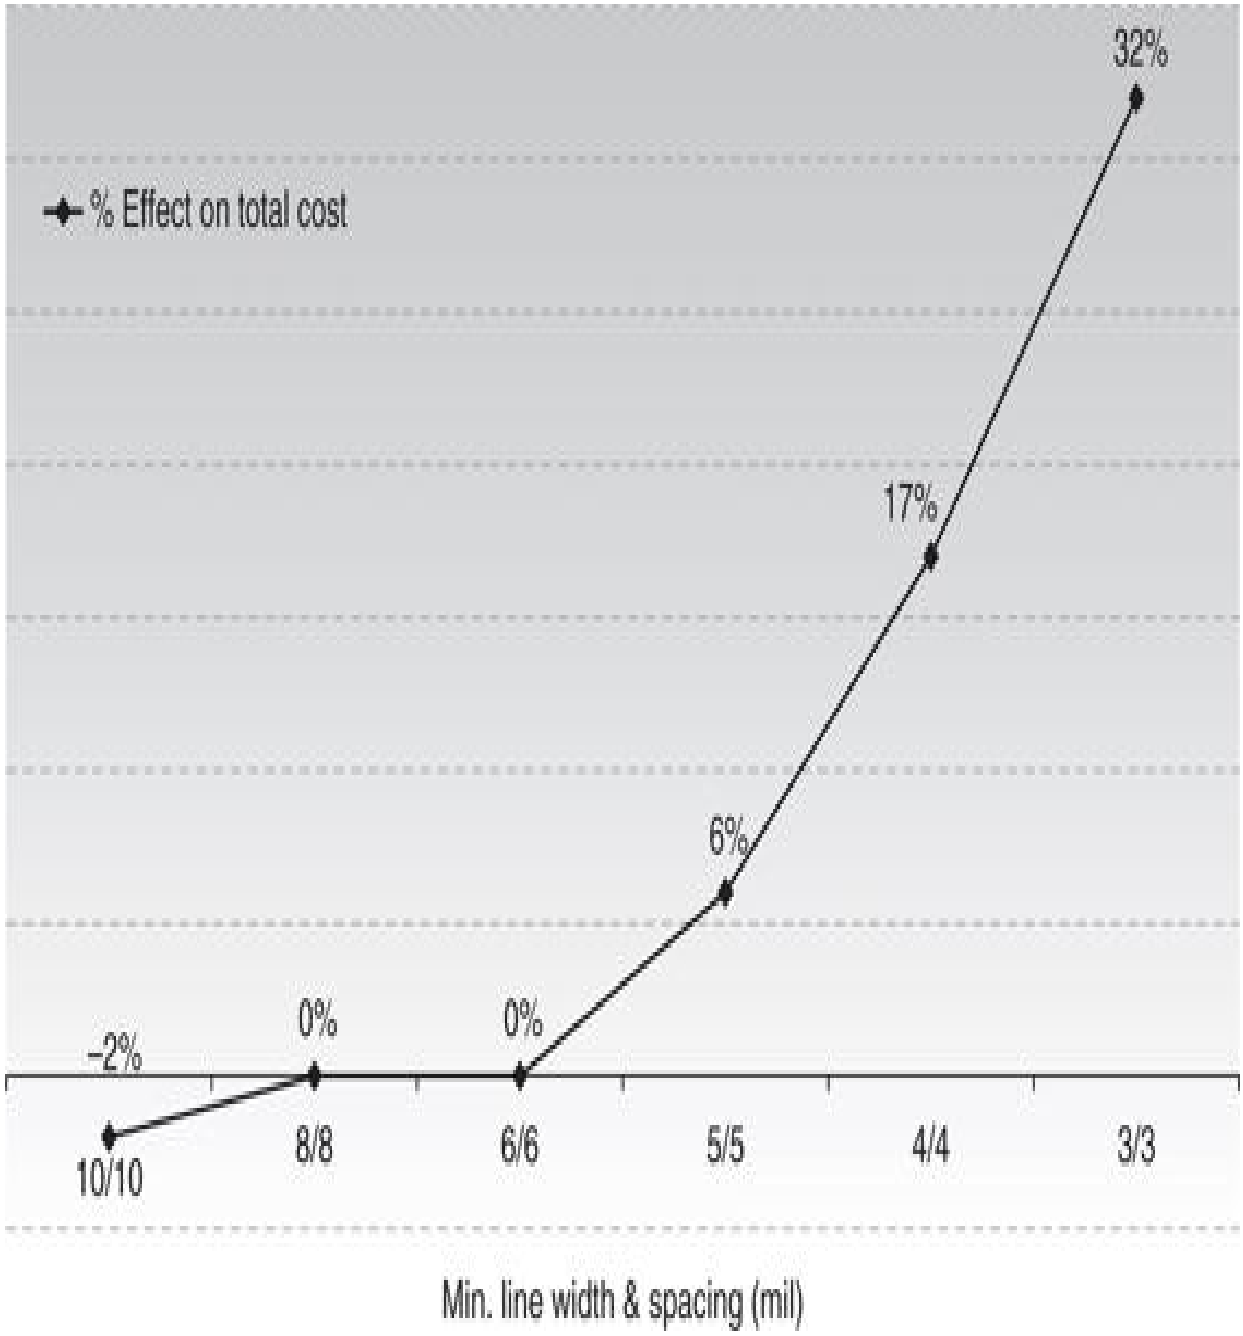

FIGURE 4.23 Effect of outerlayer line width on relative PCB cost for multilayer board.

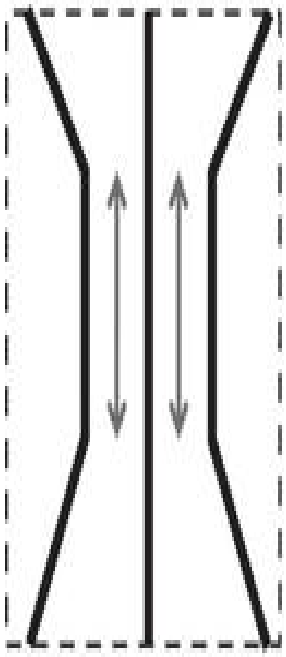
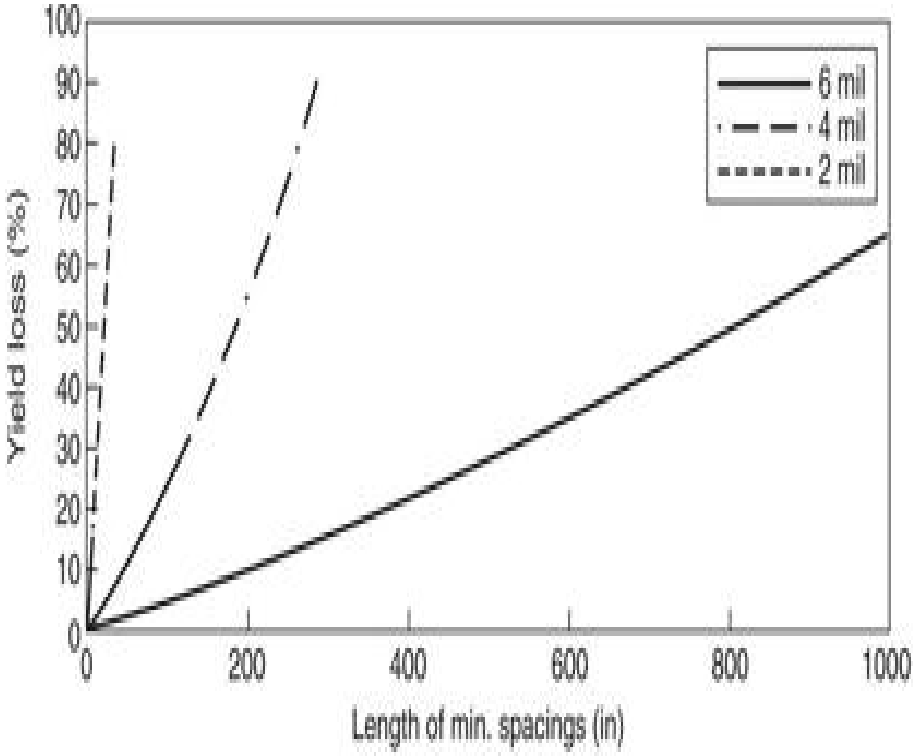
Finer traces and spaces will be a cost driver



Length of minimum spacing



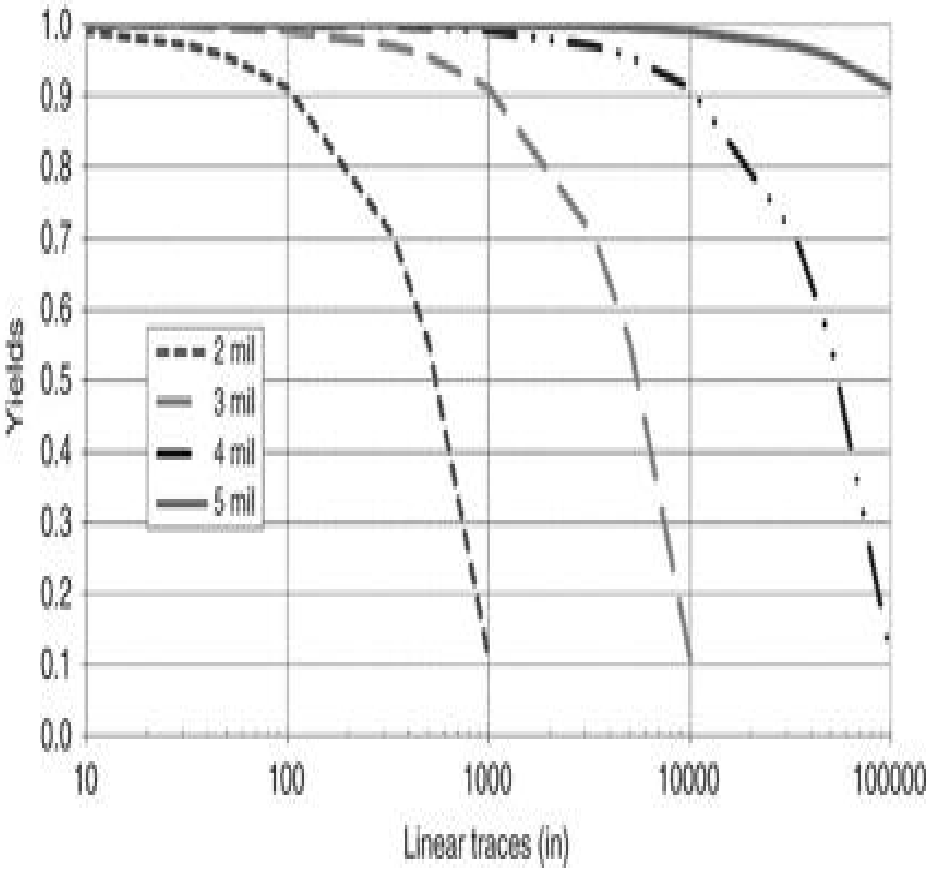


FIGURE 4.24 Effect of minimum trace length on relative PCB cost.

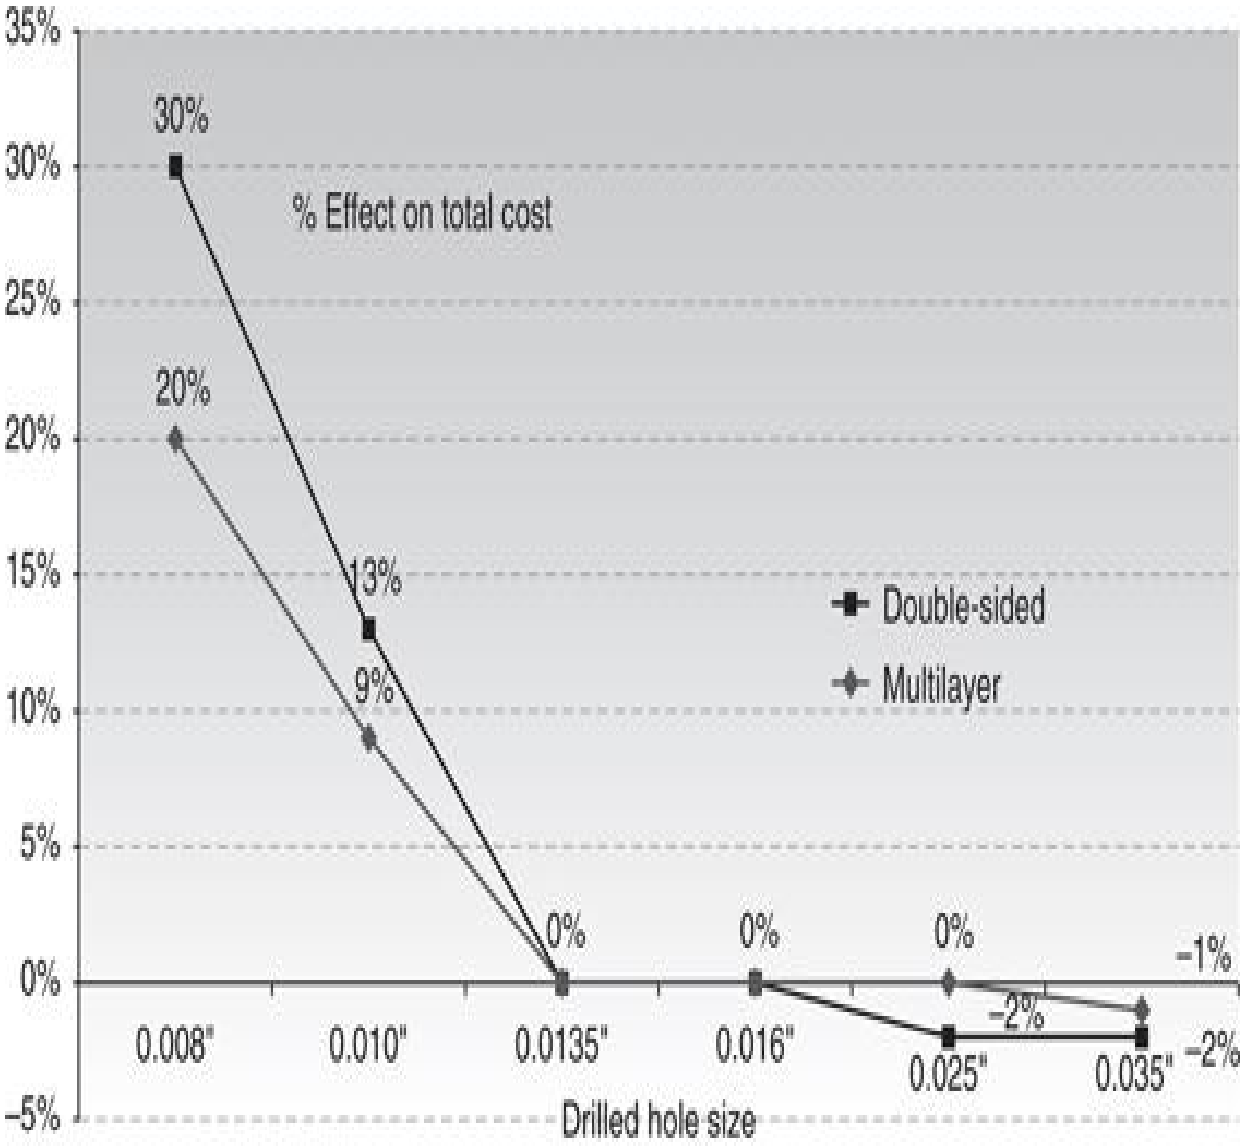
- *Vias and through holes*. Every drilled hole is a potential open or short, so designers are often cautioned to minimize total hole count. Smaller-diameter vias can provide more wiring density; however, it is more difficult to achieve the required plating thickness due to mass transfer limitations, especially for thicker boards (high aspect ratio). Drill bits for smaller holes are fragile and broken bits can damage the PCB. (See Figs. 4.25 and 4.26.)



• This data reflects the minimum drilled hole size in boards .062" thick.

FIGURE 4.25 Effect of minimum drilled hole size on relative PCB cost.

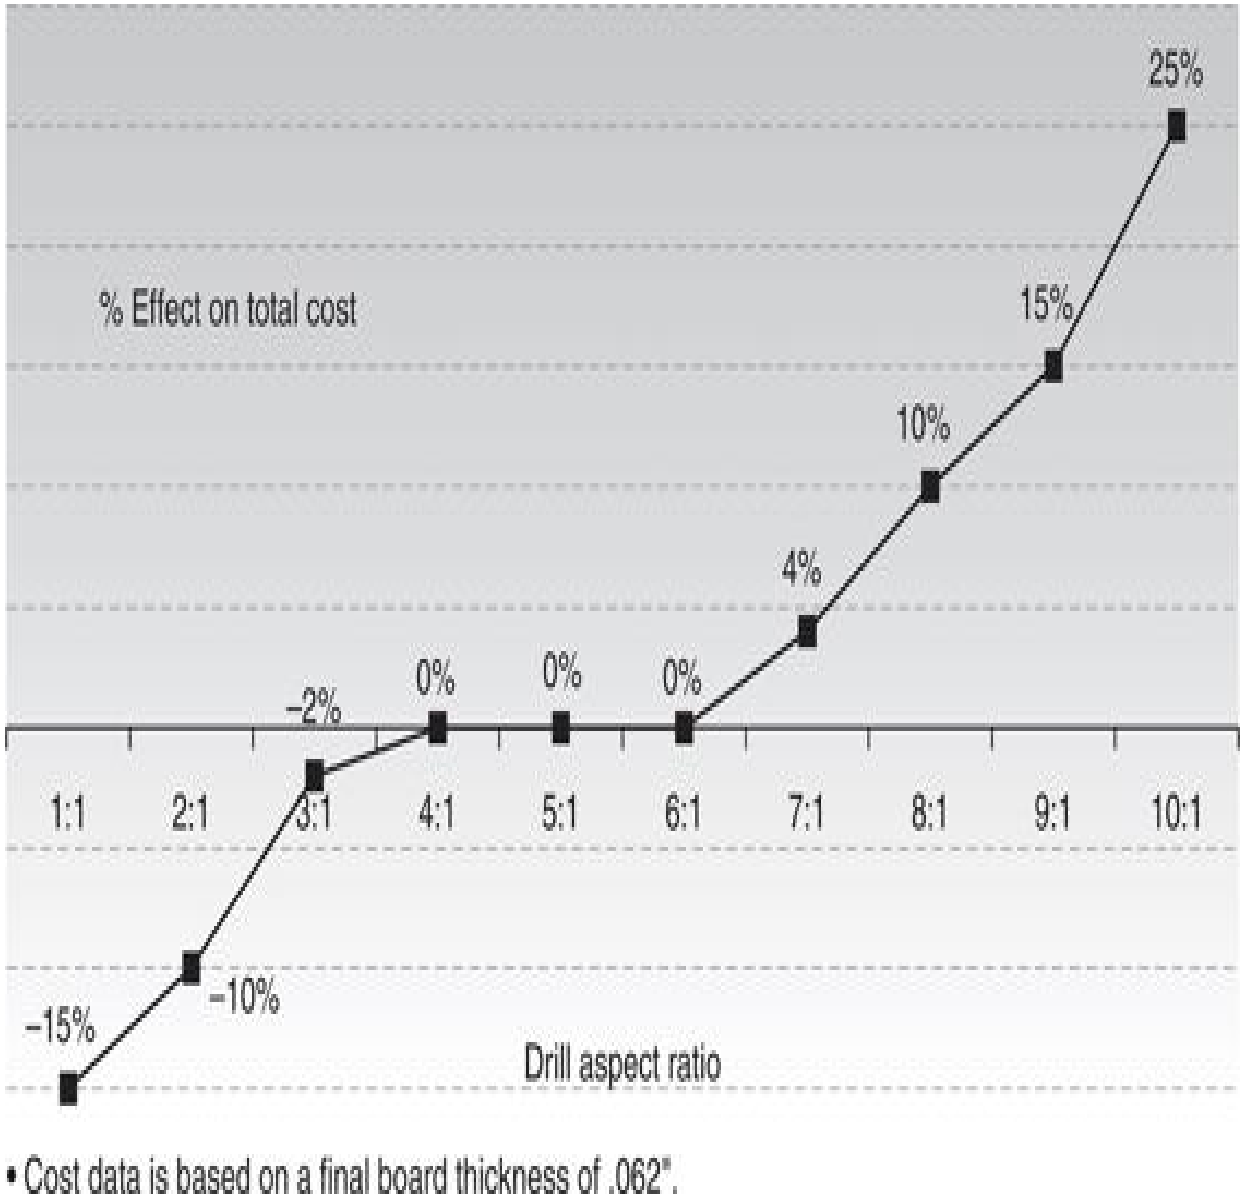


FIGURE 4.26 Effect of hole aspect ratio on relative PCB cost.

- *Via and through hole annular ring*. The pad surrounding a via or through hole needs to be big enough to maintain sufficient conductor width and allow some variation in positional tolerance for drilling and imaging. However, pads also take up valuable space on the PCB so there is a desire to minimize the annular ring around the drilled hole (Fig. 4.27).

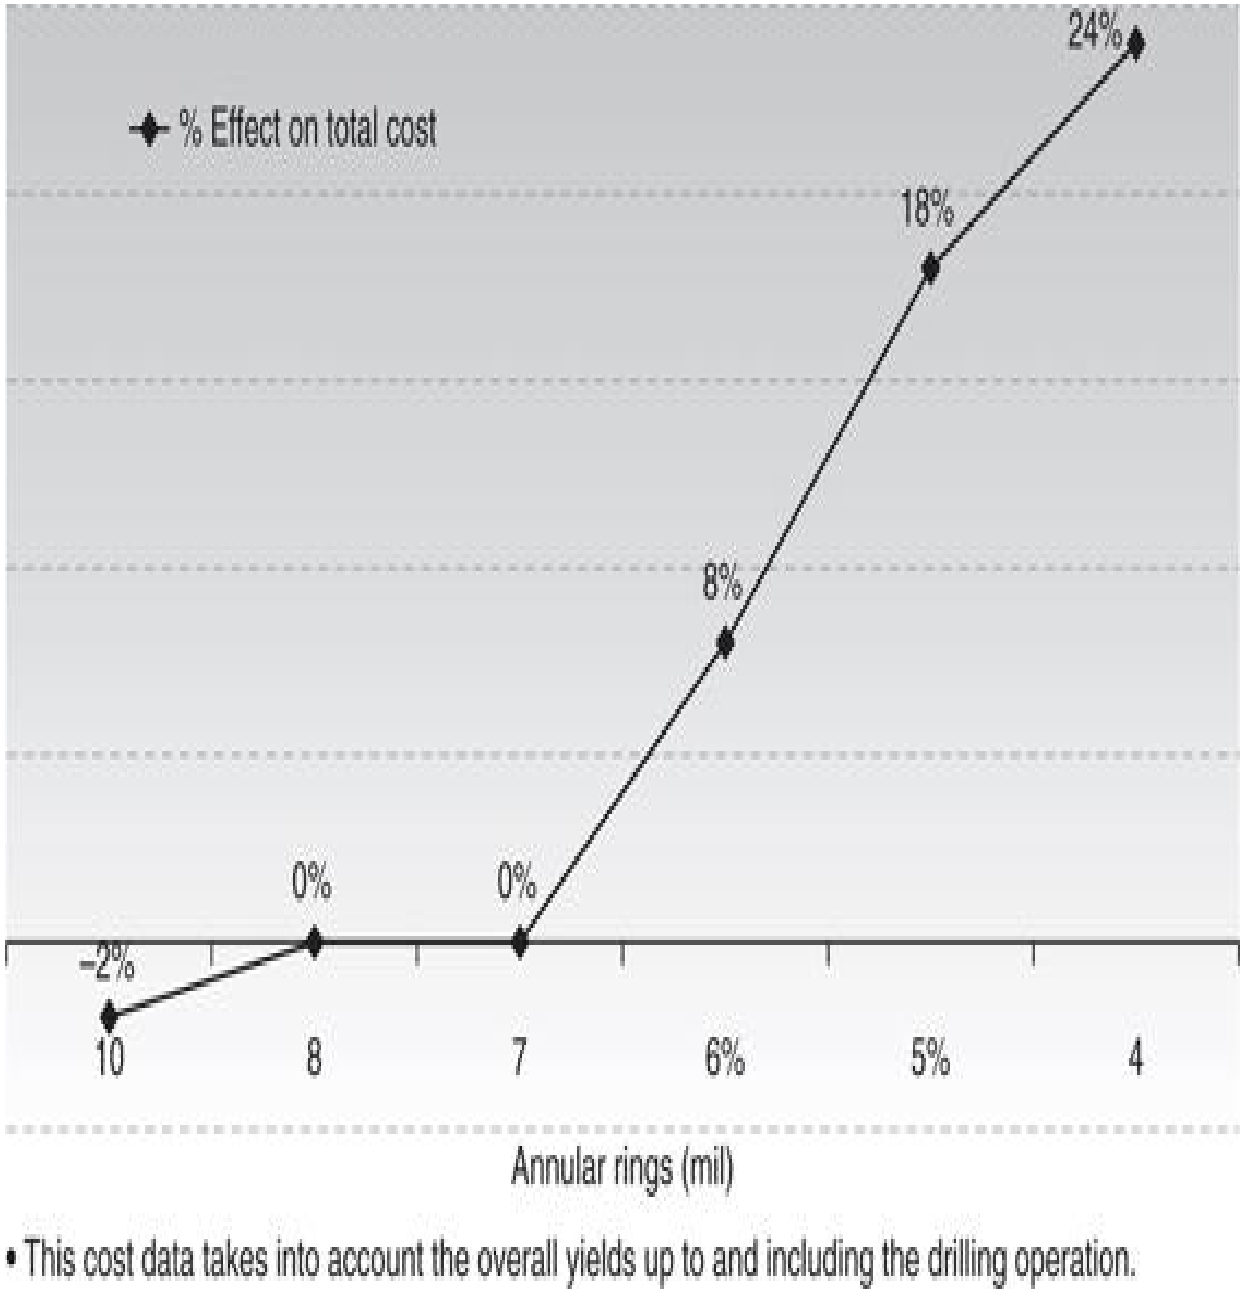

FIGURE 4.27 Effect of hole annular rings on relative PCB cost.

- *Fine pitch surface mount components*. Automated pick and place relies on fiducials to optimize location, but the narrower pads for fine pitch components means higher risk for misplacement and lead offset, which can lead to yield loss at the PCA assembler, or a less reliable solder joint in the field.

4.4.3 Common Examples of the Use of DFM and Cost Models to Optimize Designs

There are many scenarios that illustrate the use of DFM and cost models to optimize design for performance and cost. These include:

- *More layers versus larger PCB*. If the board size is not constrained by a standard card cage or other physical limitation, then the designer can provide more real estate for circuit routing either by adding more signal layers or increasing the size of the PCB. In most cases the added material and processing cost per layer is greater than the cost of the larger board area. This is particularly true if the PCB fabricator can offer multiple panel sizes to optimize material utilization.
- *Double-sided assembly versus larger PCB*. Board size can be significantly reduced if double-sided assembly is an option. In this case the cost of the larger PCB is compared with the additional processing cost for a second pass through the solder paste printing and reflow processes. These processes are generally highly automated with low operating costs, so double-sided assembly is usually the right choice here, assuming that the selected components are amenable to backside attachment on the PCA assembly line.
- *More layers versus higher wiring density per layer*. This is a trade-off between the higher material and processing cost per layer and the probability of higher scrap at the supplier due to failures at electrical test. The answer depends on the PCB supplier's process capability to deliver small features and narrow conductors at high yield. Production yield for a given minimum conductor width falls off sharply beyond the limit of the supplier's capability. If

the designer can stay within that “sweet spot,” it is better to increase wiring density than to add more layers.

- *Dedicated signal layers versus mixed signal/power/ground layers*. The standard for PCBs is ½ oz copper for outerlayers and 1 oz copper for innerlayers, but engineers and designers typically choose thicker copper for power and ground layers in high current applications. To minimize the total layer count, designers may use power/ground layers for signal routing, but production yields are lower when trying to etch small features with thick copper. Once again, the best solution is determined by the supplier’s optimum range of conductor width that matches their process capability.

4.5 DFM COMPLEXITY MODELS

In the late 1980s, Happy Holden, then with Hewlett-Packard, led a research study to create a model for predicting PCB first-pass production yield based on a set of design characteristics, including board area, layer count, minimum conductor width, and minimum via diameter. Rather than an additive model such as the ones based on the Hitachi/GE assembly studies, the PCB yield model recognized the cumulative and weighted interactions between design elements, expressed as a single “Complexity Index” metric. Designs with higher complexity would be expected to have a lower production yield. However, the yield for any given lot or order quantity could vary widely depending on factors such as handling, operator training, equipment maintenance, or other special causes of variability. *Complexity Index* will be defined in Chap. 16, “Planning for Design, Fabrication, and Assembly.”

The HP team measured actual first-pass production yields for a variety of PCB designs and developed a best-fit

regression model using the complexity index metric (see Fig. 4.28). The model predicts the highest-probability value of the production yield at a given manufacturing site that has a specific set of process capabilities. A different PCB fabricator with different capabilities would have its own regression model to predict yield for a given complexity index (see Fig. 4.29), which could be determined from actual yield data or parametric test coupons. Chapter 6, “Supplier Selection and Qualification,” describes some of these techniques in more detail.

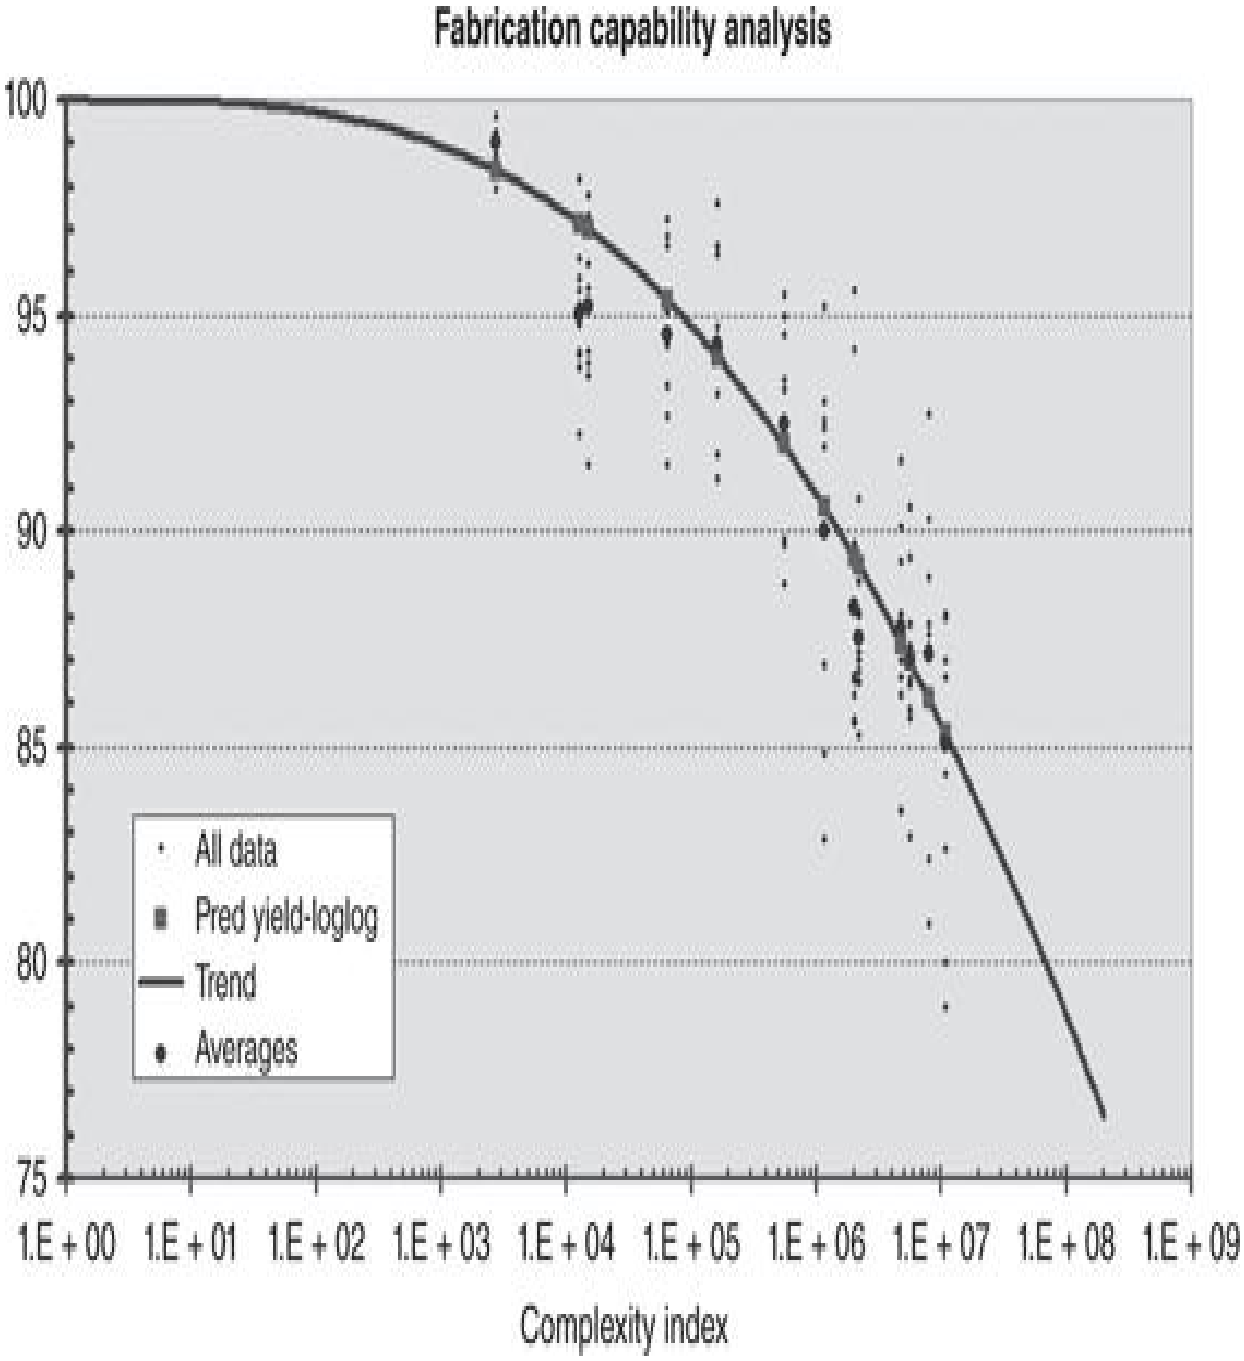

FIGURE 4.28 Example of predicted yield versus complexity index.

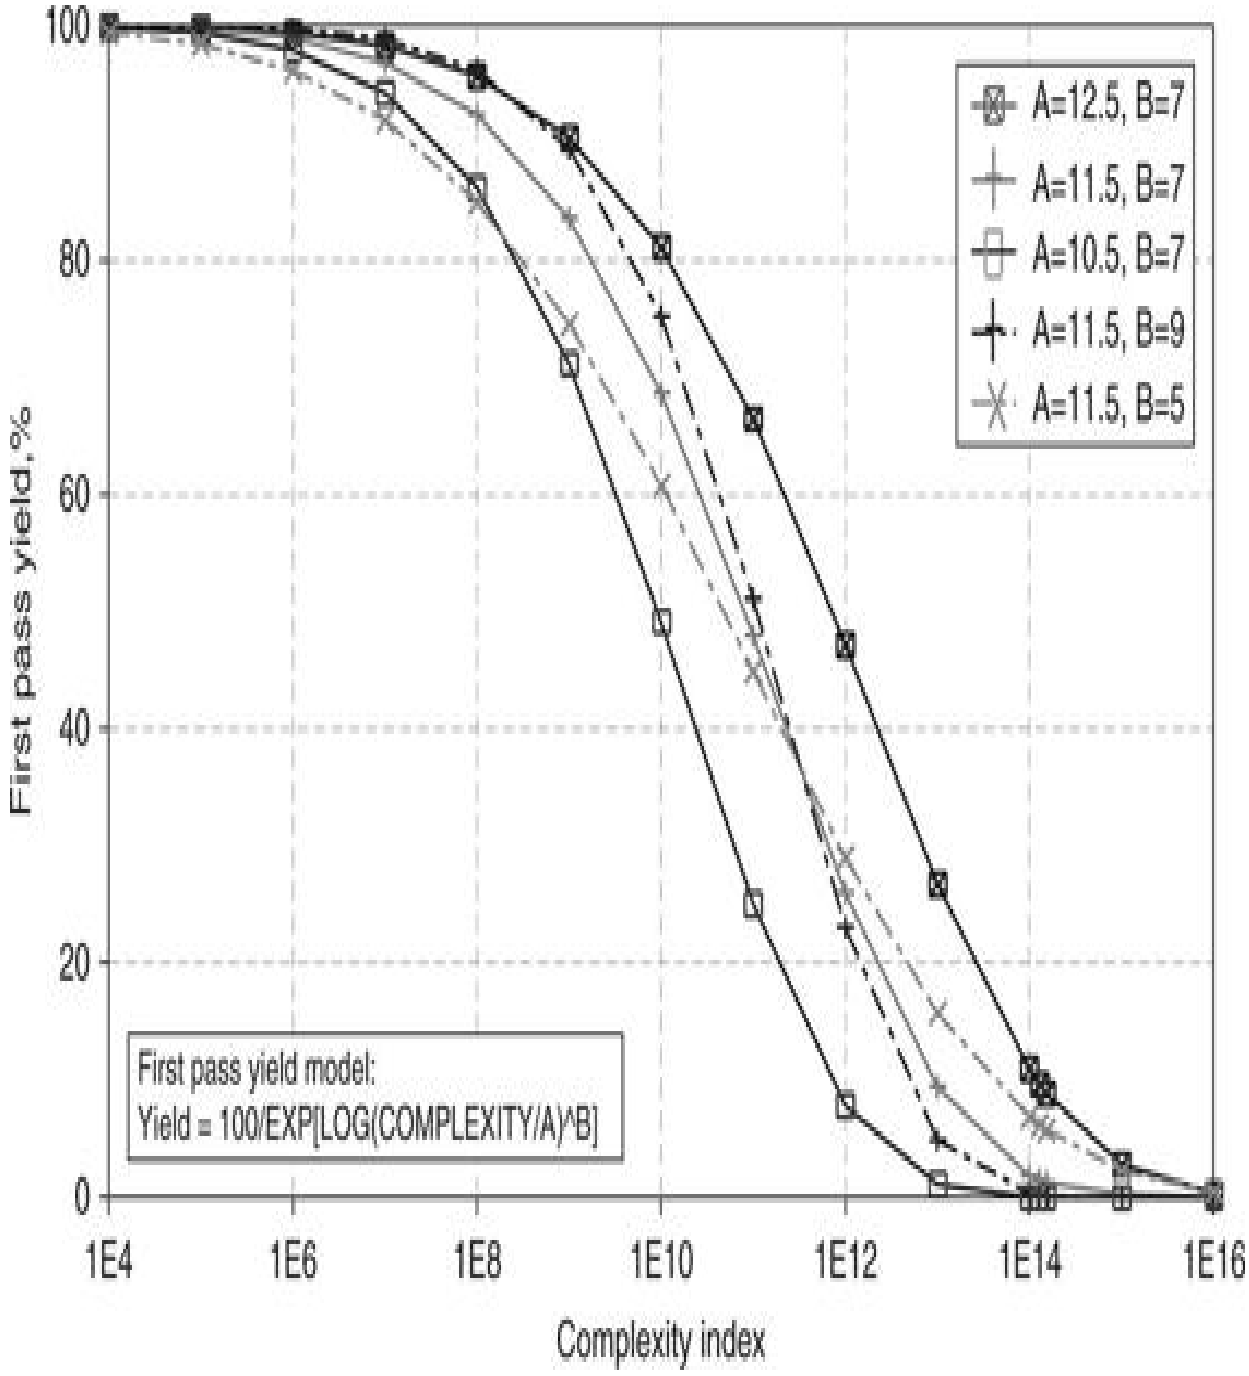

FIGURE 4.29 Yield-complexity models for different PCB fabricators.

4.5.1 Technology and Assurance of Supply

Some suppliers may be able to offer uncommon materials or manufacturing processes that provide desirable performance. However, optimizing the PCB or PCA design for a single supplier or a small subset of suppliers is potentially dangerous and places the sourcing strategy at risk. A more robust strategy includes an “open source” design with generally available materials and processes. This makes it easier to transfer to an alternate supplier if necessary.

At the same time, it is important for sourcing teams to follow the development and growth of new PCB/PCA technology. What is uncommon and exotic today may become mainstream tomorrow. Those who can successfully anticipate the broader availability of advanced interconnect technology will be able to give design teams high-performance options while protecting assurance of supply.

CHAPTER 5

MANUFACTURING INFORMATION, DOCUMENTATION, FORMATTING, AND EXCHANGE[a]

Happy T. Holden
Co-Editor-in-Chief, Printed Circuits Handbook, *and PCB Technologist, Zeeland, Michigan*

5.1 INTRODUCTION

This chapter presents the elements of needed manufacturing information, documentation, data exchange, the data exchange process, its pitfalls and best practices, the most widely used data exchange formats and their main characteristics, and evolution drivers in data exchange.

The electronics manufacturing marketplace is a dynamic domain where supply chains of trading partners compete in a global economy in which time to market and efficiency are key factors for success. Data communication is a vital key to supply chain management. Efficient and accurate data exchange is an extremely important factor in customer supply networks.

The challenge of more efficient and accurate data exchange has only recently begun to be addressed and the future for data exchange improvements holds much potential.

The manufacturing of printed circuit boards (PCBs) and assemblies (PCAs) begins with the soft PCB information process. This process is the transformation of customer computer-aided design (CAD) data and specifications into the necessary tools required for manufacturing the bare PCB and populating the assembly. The typical tools required for manufacturing PCBs include artwork for photo printing of inner conductive layers, outer conductive layers, and solder mask patterns. Artwork is also created for screen-printing patterns for nomenclature and via plugging layers. Additional tools required include drill and routing numerical controlled (NC) programs, electrical testing netlists and fixtures, and CAD reference soft tools.

The PCB Information process for assembly requires assembly drawings, bills of materials (BOM), and schematic or logic diagrams, and includes the solder-paste stencil design, assembly array layout, and the resulting computer numeric control (CNC) programs for component placement, in-circuit test program creations, and possibly the creation of a functional test program. Many of these procedures will be covered in subsequent chapters in Part 8 “Assembly, Soldering Materials, and Processes” of this handbook.

During the PCB information process, the customer part numbers are analyzed to determine the compatibility of the design features with the manufacturing process capabilities. Additionally, attempts to optimize the manufacturing of the product at the lowest cost are a primary goal. However, the majority of the costs have been defined before the design is transmitted to the manufacturing site by the PCB designer. An early investment in time by the PCB design team and the manufacturing PCB information team can result in the most significant savings in overall product cost.

This chapter describes the PCB information exchange process, as defined in Fig. 5.1, including the transfer of information, design reviews, optimization of materials, definition of BOM and routings, tool creation, and additional processes that are required.

FIGURE 5.1 The soft-PCB information process (computer-aided manufacturing [CAM]) for PCB fabrication and assembly).

5.2 MANUFACTURING INFORMATION

The information process begins with the receipt of information from the design department. Unfortunately, although the time required to send information to the manufacturer has decreased to minutes or hours from day(s), a significant issue with the provision of packages to manufacturers is the completeness of the information provided.

The Institute for Interconnecting and Packaging Electronic Circuits (IPC) has a new document, IPC-2610, that defines a complete documentation package, including the following:

- IPC-2611, “Generic Requirements for Electronic Product Documentation”
- IPC-2612, “Sectional Requirements for Electronic Diagramming Documentation (Schematic and Logic Descriptions)”
- IPC-2613, “Sectional Requirements for Assembly Documentation (Electronic Printed Board and Module Assembly)
- IPC-2614, “Sectional Requirements for Board Fabrication Documentation (Printed Circuit Board Description Including Embedded Passives)”
- IPC-2615, “Sectional Requirements for Dimensions and Tolerances”
- IPC-2616, “Sectional Requirements for Electrical and Mechanical Part Descriptions (Specification and Source Control Part Descriptions)”
- IPC-2617, “Sectional Requirements for Discrete Wiring Documentation (Wire Harness, Point to Point and Flexible

Cable Descriptions)”

IPC-2618, “Sectional Requirements for Bill of Material Documentation (Complete Listing of Parts, Materials, and Procurement Documents)”

Timely PCB Information of a part number depends on having the correct information. All features required to exist on the PCB must be defined for the manufacturer. The information is defined via design data, drawings, and textual information. Automated data are encouraged whenever possible.

5.2.1 Required Information

In addition to PCB design data, copious information pertinent to board manufacture is exchanged between partners in the manufacturing and assembly process. Such information can include standard compliance requirements (e.g., UL) statements of workmanship (SOW), and delivery and packaging instructions. Modern data exchange formats address some of these comprehensive data exchange issues. The design-to-manufacturing data exchange process should ideally progress to become online collaboration. The drivers of this progression are globalization, the supply chain, and time-to-market pressure.

Historically, the PCB design-to-manufacturing flow began with manually laid-out artworks whose images were printed on copper-clad laminates and developed, etched, and stripped within the same vertically integrated organization. Advances in miniaturization and multilayer board technology led to the need for specialization, and outsourcing of bare board fabrication became the norm. Together with advances in PCB fabrication tools and digital communication, the outsourcing supplier communication advanced from courier delivered artwork to data tapes and disks and later to

electronic transfer over modems and finally over the Internet. Globalization and outsourcing continue to push the envelope of electronic business communication in the PCB industry as well as everywhere around us.

The PCB fabrication tools driving the history of data exchange are mostly imaging tools and placement machines. PCB lithography began with hand-routed artworks and continued with photo plotters, aperture wheels, and computerized numerical control (CNC). Gerber Scientific was the most successful of the early photo-plotter vendors, and hence the Gerber 274D format caught on.[1] Later these were replaced with laser plotters without aperture wheels, but the Gerber data format remained the "lowest common denominator" format. In the PCB assembly arena, robotic assembly machines of varying complexities succeeded hand assembly. This trend led to the need for electronic assembly data, just as the artwork-to-laserplotter development in board fabrication led to the need for electronic fabrication data.

Bare board fabrication and board assembly share some common data elements but also have distinct data needs. Examples of common elements are the outer circuit and mask layers and through-drill information. Unique data elements are, for example, inner layers for board fabricators and component placement locations and functional component descriptions for assembly houses. All these data elements are described in the next section.

The information and common data formats required to permit the PCB information of the PCB include the following:

- *Part number information*

  Information: This information defines the part number to be built, including revision number, releases, dates, etc.

  Format: This information is typically provided in the part drawing or may be provided as an additional text file.

- *Fabrication drawing*
  Information: This drawing describes the unpopulated printed board and all features that become part of the board. It may contain specific design requirements such as material requirements, multilayer stack-up diagram, dielectric separation between layers, controlled impedance requirements, solder mask type, nomenclature color, location, size requirements for the fabricator's ID, Underwriter's Laboratories (UL), electrostatic discharge (ESD), country of origin, and dimensional tolerances, as well as testing and electrical performance expectations. The dimensional datum (see Fig. 5.2) should be clearly identified.

FIGURE 5.2 Datum identification examples.

Format: Common formats for drawings are Adobe PDF, HP-GL, HP-GL-II, and PostScript.

- *Drill drawing*
  Information: Although the drill data are provided via data files, this information typically contains only the location of holes and the tool number. The drill drawing identifies the location of the datum reference planes and the coordinate dimensioning system of the board (see Fig. 5.2). The tool number is referenced against the drill drawings to determine the required sizes, plating status, size tolerances, and the total count for verification. This is for plated (TH), nonplated (NPTH), blind/buried vias, and countersink holes.

  Format: Common formats for drawings are Adobe PDF, HP-GL, HP-GL-II, and PostScript.
- *Subpanel drawing*
  Information: Many assembly operations require boards to be provided in a subpanel form (many parts on one shippable unit). The drawing defines the orientation and position of each part, the subpanel dimensions, PCB information hole information, special markings, and specific manufacturing processes and tolerances.

  Format: Common formats for drawings are Adobe PDF, HP-GL, HP-GL-II, and PostScript.
- *Manufacturing notes*
  Information: Manufacturing information is usually included on the fabrication drawing or attached documents. This document details the following:
  - Board details: The type, size and shape of the printed board, bow and twist allowances, overall board thickness requirements including tolerances, PCB information hole information, special markings, and specific manufacturing processes and tolerances.

- Materials: Type class and grade of materials, including color if applicable. Plating and coating material(s), type, thickness, and tolerances. Solder mask and marking inks type, minimum thickness, and permanency.
- Conductors: Shape and arrangement of both conductors and nonconductor patterns, thickness, dimensions, and tolerances, including conductor width and spacing allowances.
- Acceptability: Location of quality conformance coupons or circuitry, control documents for acceptability, X-OUTs accepted and assembly-panel concerns.

Format: Common formats for drawings are Adobe PDF, HP-GL, HP-GL-II, and PostScript.

- *Artwork data*

  Information: These data consist of files for each circuit layer, coating (e.g., solder mask), marking (i.e., nomenclature), solder paste, hole plugging, and possible test-probing layer.

  Format: The data required are usually RS-274X, commonly called Gerber data or ODB++ (Orbitech Data Base). Gerber and ODB++ data are provided as a standard output from most PCB CAD systems. Other possible formats include GenCAM and the new IPC2581 (see Sec. 5.4.5 “Modern Data Exchange Formats” for more details).

- *Aperture list files*

  Information: The definitions of the shapes used for drawing are required for each layer provided of artwork data. Special shapes such as thermal pads should specifically define their method of construction.

  Format: This information is usually provided as a text file, although the information may also be defined in the beginning of the individual artwork files, including constructions of complex apertures.

- *Drill data*

Information: This information may consist of a single or multiple file(s), and defines the location and tool number used for each hole in the PCB. The files required should define all plated, unplated (which can be combined with plated if fully defined), buried via, and blind via layers.

Format: Common data files provided are in Excellon format.

- *Drill tool files*

  Information: This information describes the size, plating status, layer-from, and layer-to (in the case of buried and blind vias) drill-data format and filenames. This information is referenced against the drill drawing.

  Format: This information is usually provided as a text file, although the information may also be defined in the beginning of the individual drill files.

- *Special requirements information*

  Information: The drawing or a file should describe any special requirements not defined in other information. Typical of such requirements would be the details and image enlargement of “break-away” tabs on a subpanel or details of “hole-plugging” requirements. It is important for the PCB designer not to assume that requirements are understood, but to refer to specifications or clearly define the requirements.

  Format: This information is typically provided in the part drawing or may be provided as an additional text or drawing file.

- *Netlist data*

  Information: Netlist data define the connectivity of the circuitry.

  Format: This information can be provided from the CAD systems in various formats, or it can be extracted from the drill and artwork data. Contact the PCB manufacturer for compatible formats if the netlist data are to be provided

directly. The IPC has defined a neutral format, IPC356, that provides all the information necessary for netlist and electrical test fixture creation.

In addition, the IPC has defined an alternative neutral standard format for most of the previously defined data. These formats provide simpler processing at the manufacturer. They include IPC-D-350, IPC-2511 (GenCAM), and IPC-2581 (the offspring of ODB++ and GenCam). These formats can be generated by most PCB CAD systems and processed by most PCB CAM/PCB Information systems. The PCB customer should review the compatibility of these formats with the PCB manufacturer prior to sending data formatted with them.

5.3 FABRICATION INFORMATION EXCHANGE

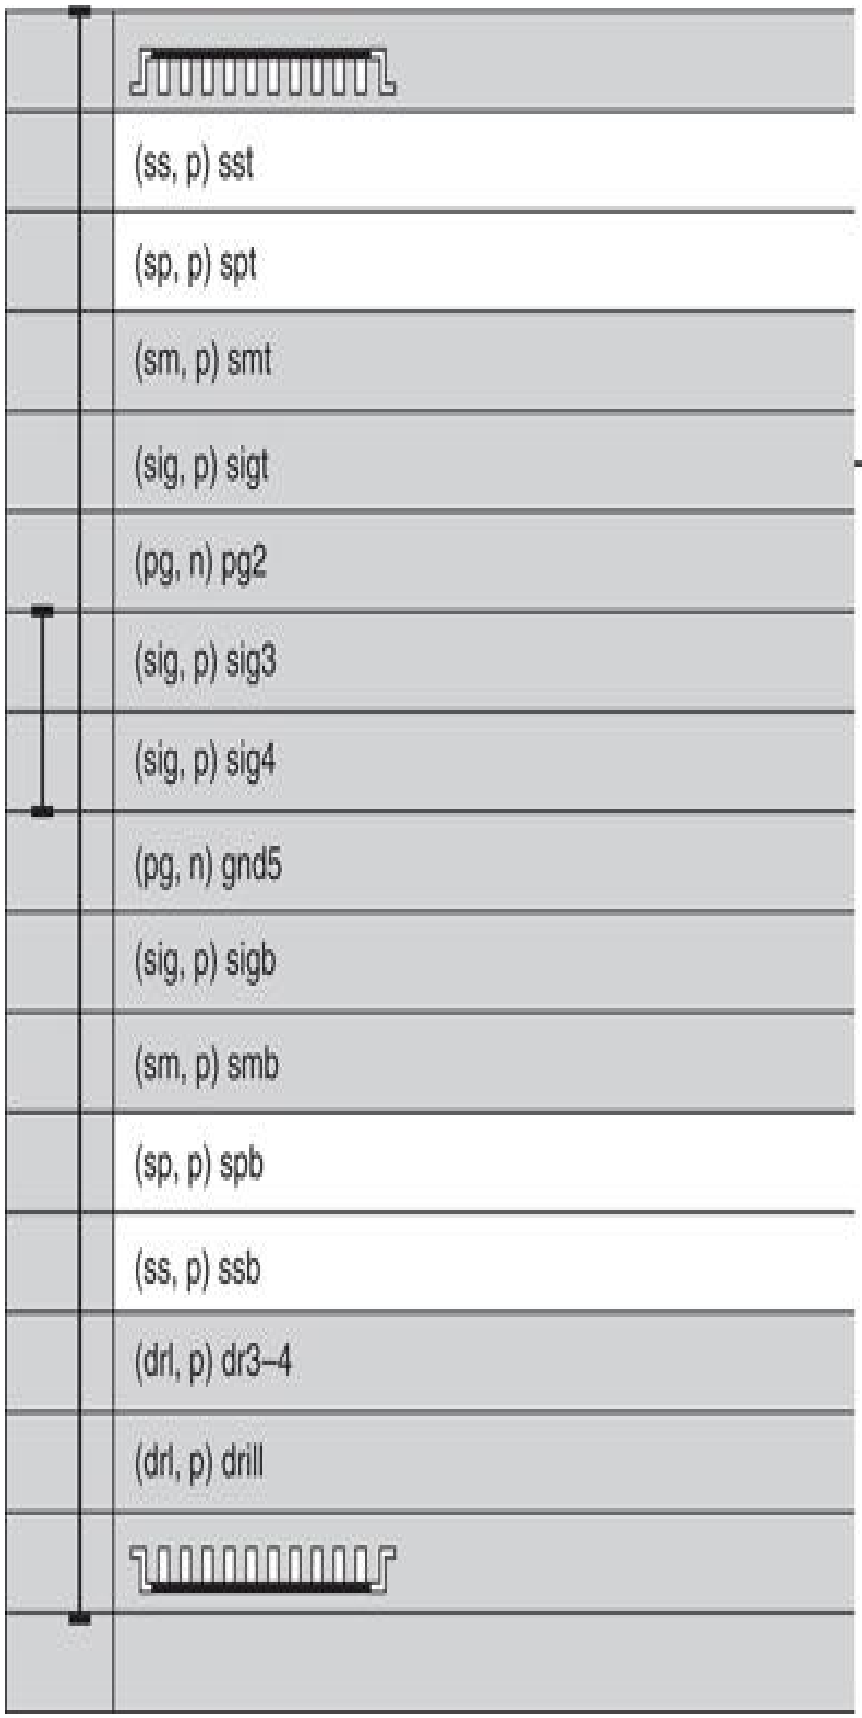
When a printed circuit assembly (PCA) design (layout, routing, and verification) is complete, the board data must be sent to the PCB manufacturer. An output format is chosen to export the data from the computer-aided design (CAD) system. Historically, the output to bare board manufacturing was in Gerber data format and drill information was accompanied by some textual “readme” files. (These files did not contain precise definition of layer stack-up, drill span, or component outlines). These files would be sent—or rather, “thrown over the wall”—to the fabricator, sometimes without even being checked. When the board reached the assembly stage, the board assembler would receive Gerber images of the outer layers, *x, y* locations of the components and a BOM file. These methods were recognized as troublesome because errors and lack of communication necessitated

many clarification calls, faxes, and e-mails, and slowed down the process.

5.3.1 Assessing Quality of Data Exchange Formats

Designers and editors, forced to verify the data after output for correctness and manufacturability, began to work with CAD and computer-aided manufacturing (CAM) tool vendors and industry consortia to develop better formats and methods for data exchange. They sought a data exchange format that was explicit, intelligent, optimized, and bidirectional:

Explicit. There should be no need for guesswork or reverse engineering of design and no need for external files (see Fig. 5.3).



(ss, p) sst
(sp, p) spt
(sm, p) smt
(sig, p) sigt
(pg, n) pg2
(sig, p) sig3
(sig, p) sig4
(pg, n) gnd5
(sig, p) sigb
(sm, p) smb
(sp, p) spb
(ss, p) ssb
(drl, p) dr3–4
(drl, p) drill
Top Cu. Layer is a positive signal layer named "sigt"

FIGURE 5.3 A CAM system view of a typical six-layer PCA after input from an "intelligent" format that defines the layers' order and characteristics explicitly and unambiguously. If Gerber files were used it would take some time to arrange the layers' order and characteristics manually. The example includes the following:

Silk screen legend files: sst (for top) and ssb (for bottom)
Solder paste stencil aperture layers: spt and spb
Solder mask images: smt and smb
Outer copper layers: sigt and sigb
Second layer: pg2 (power layer, which is negative)
Fifth layer: gnd5 (ground layer, which is also negative)
Inner circuit layers: sig3 and sig4
Drill layers: drill (through drill layer) and dr3-4 (buried via connecting sig3 and sig4)

Intelligent. The format retains CAD information that may help the manufacturer (see Fig. 5.4).

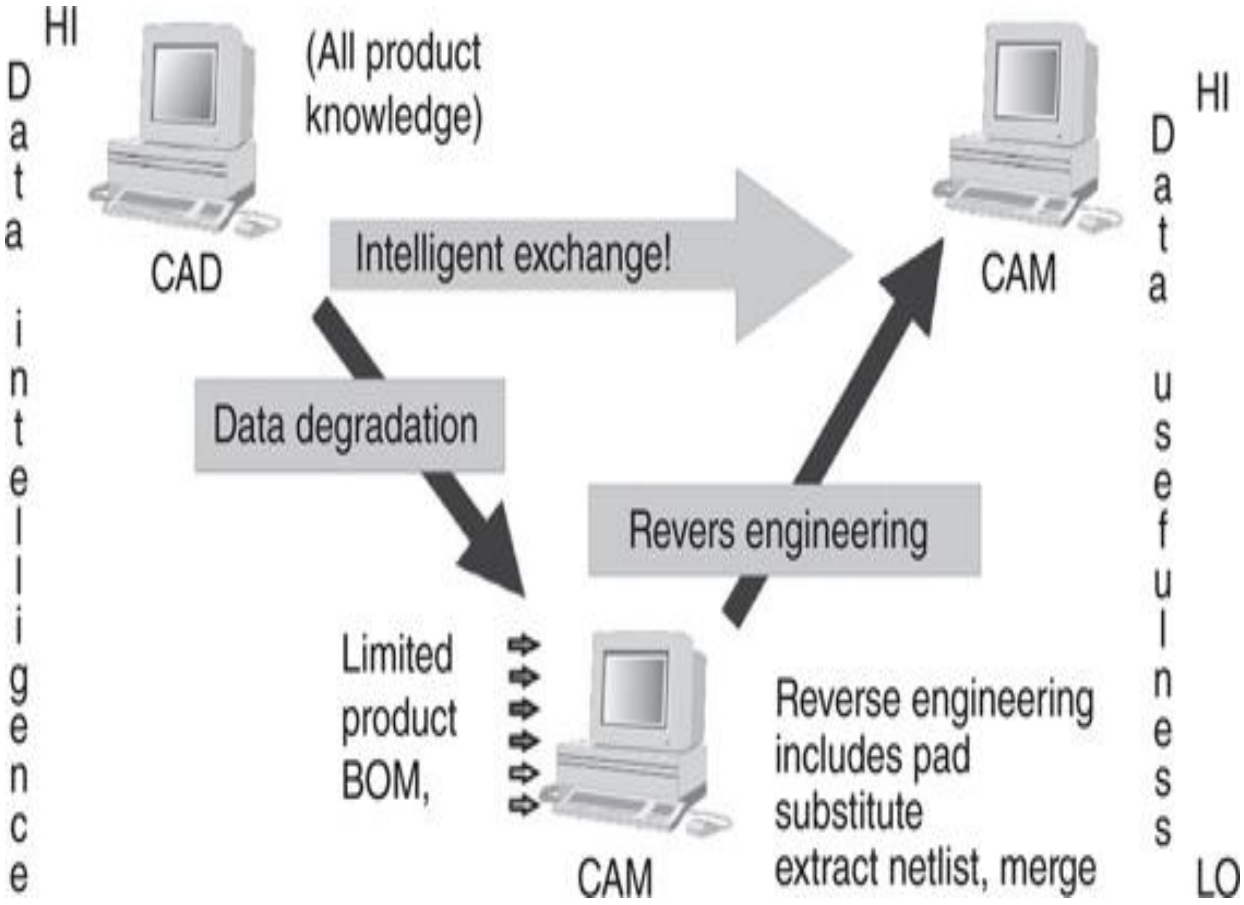


FIGURE 5.4 OEM, CEM, and Fab communication levels. In this figure the *y* axis denotes the level of intelligence and the *x* axis denotes the data exchange process progression over time. When the formats used carry less design intelligence, it is lost (data degradation). Non-value-added reverse engineering (such as manually rebuilding the board stack-up) is required to rebuild intelligence that is required for manufacturing. If an intelligent exchange format is used, no design data are lost and no reverse engineering is required, resulting in a faster, more accurate, and more efficient process.

Optimized. A surface should be represented by a clear outline and not drawn with overlapping vectors (see Fig. 5.5).

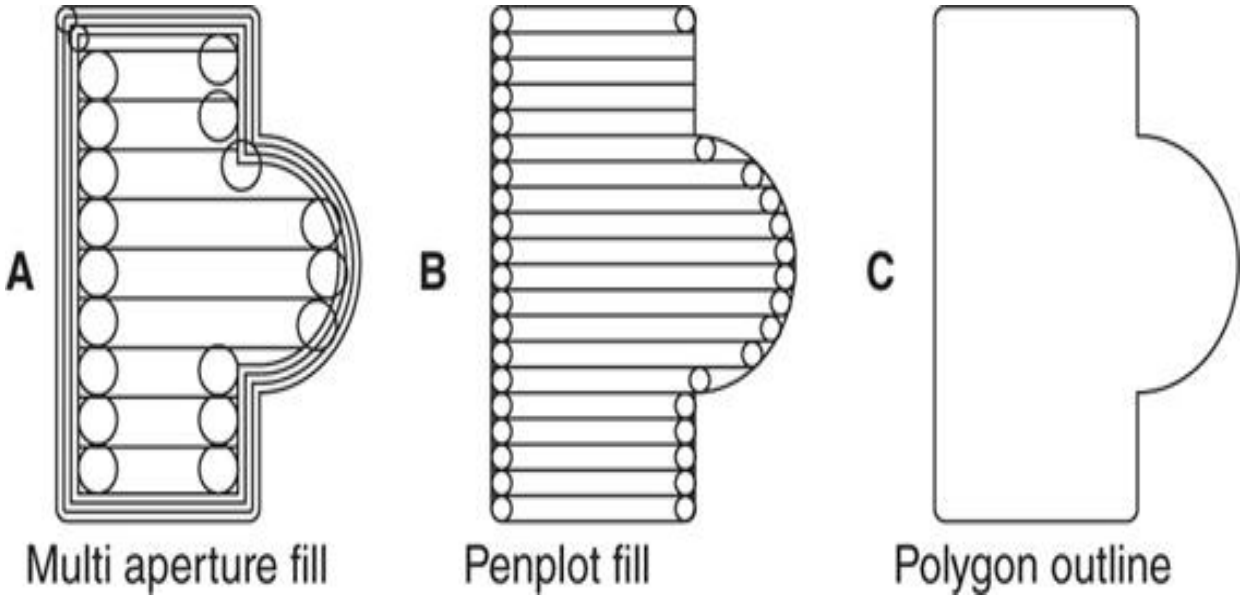

FIGURE 5.5 Optimizing surfaces: (*a*) a polygon filled by different vector widths; (*b*) the same polygon as drawn by a pen plotter; (*c*) the polygon as defined by its external outline. Option *c* is clearly much more efficient and economical. The outline in (*c*) is the actual outline of the polygon, whereas (*a*) and (*b*) represent approximations.

Bidirectional. The format should be inherently capable of passing data back and forth, not just passing them one way. This can be achieved through free viewers, annotations tools, and so on.

Other important issues to consider in the context of data exchange are the following:

Accountability. Who is responsible if something is misunderstood? If the exchange always succeeds, it is easier to differentiate between design and manufacturing errors.

Data ownership. Who can authorize changes? If reverse engineering is performed, subtle design changes may be introduced without OEM authorization.

Trust. Is the supplier an ally to whom all available data are provided, or are some design details withheld to protect intellectual property rights?

The next section details all the data elements that designers and manufacturers need to pass among each other.

5.3.2 Elements of Data Exchange: Intelligent Design Data

The goal of a supply chain is short time to market, high quality, and lowest cost, and achieving this goal requires high clarity, efficient communication, and not just a bare-bones data hand-over.

Although a PCB can be manufactured from supplied artworks and drill tapes alone, it is much more efficient to send accurate and verifiable electronic data. The data can include information elements beyond the graphic image and component location information that form the minimum "pure" design data required for improved manufacturing. Among these elements are

- Mechanical specifications
- Component geometry
- Component tolerances and vendor information
- Standards that the product has to meet

Some of the information belongs in an SOW and need not be repeated in the case of an established partnership. Included may be marking instructions, packaging instructions, and information needed to ensure conformance to standards.

This section lists the information required for data exchange for fabrication.

5.3.2.1 Minimum Requirements. These are the minimum required elements of data needed for fabrication:

- Layer graphics (see Fig. 5.6)

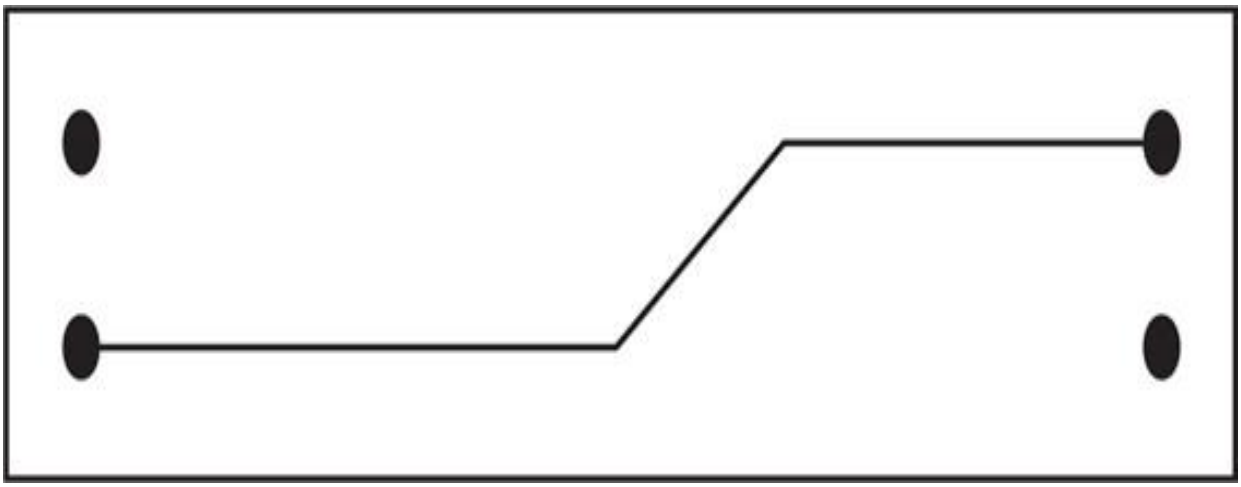

FIGURE 5.6 A layer graphic represents—board outline and rout informing the features of a circuit (or a document) layer represented by computer-readable geometric entities involving *x* and *y* coordinates and geometric objects—lines, arcs, circles, and so on.

- Drill data: locations, spans (for blind and buried vias), tolerances, and plating thickness
- Board outline and rout information
- Stack-up requirements (layer order)

5.3.2.1.1 Important Additional Information. These elements are important but not absolutely required for fabrication:

- Netlist information is required to verify that the graphic and drill data truly represent the design. It is highly advisable always to include netlist data so that the graphics can be verified.
- Assembly panelization definition is required to deliver multiple PCBs in a ready-to-assemble array form (four or more cell phone boards can be assembled together due their small dimensions).

5.3.2.1.2 Extra Information. This extra information is not covered by computerized formats, but is useful in fabrication:

- Electrical (impedance) and material requirements (solder mask, legend, etc.). (Impedance requirements refer not only to line width and tight tolerances thereof but also the actual impedance value, in ohms, and the frequency and impedance model to use.) Fabrication drawing (extra instructions, dimensions)
- Type of finish and quality requirements [hot air solder leveling (HASL) versus organic solderability preservative (OSP), solder mask]
- Packaging and delivery instructions
- Testing coupon requirements
- These additional information elements can be provided as well:
- Design for manufacturing (DFM) analysis results and criteria (e.g., spacing criteria and violations thereof)
- Component placement information, which can help the manufacturer create solder mask clearances that provide a good fit for soldering

5.3.3 Elements of Data Exchange for Assembly

This section lists the data elements to consider for assembly processes.

***5.3.3.1 Common to Fabrication and Assembly*.** These elements are common to fabrication and assembly:

- Outer layer graphics (for circuit, solder mask, and legend images)

- Drill information (especially through drills and mechanical drills)
- Board dimensions and outline

5.3.3.2 Required for Assembly. These elements are required specifically for assembly:

- Component placement information, including rotations.
- BOM and approved vendor list (AVL) information (AVL is not required if parts are supplied by consignment).
- Mechanical assemblies and their locations (screws, shields and heat sinks, etc.).
- Board electrical schematics for testing (see Fig. 5.7). This information is usually transferred either as an element of a CAD database or as a human- and machine-readable drawing format [usually as a Hewlett Packard Pen Plotter (HPGL) or Data eXchange Format (DXF) file]. [Machine-readable in this context means identification of textual labels for nets (signals) and pin and component names. The computer programs cannot understand the connectivity symbolism of the line drawings within schematic drawings.]

- Test requirements
- Material instructions
- Delivery and packaging instructions

5.4 DATA EXCHANGE FORMATS

This section describes the most widely used data exchange formats in the electronics industry according to a common list of characteristics. Advantages and disadvantages of each format are discussed.

5.4.1 Format Types and Their Characteristics

There are several format families differentiated by their origins, properties, and usage. They fall into four categories:

1. Historical file collections
2. Full-design databases
3. Component information (BOM and AVL)
4. Formats that support full design to manufacturing

5.4.1.1 Historical File Collections. The historical file collection that is used to transfer design data is composed of

three file types:

5.4.1.1.1 Graphic Image Formats. Gerber 274D and 274X[2] belong to this group (see Sec. 5.3.2.1). (There are other formats in this group, most of which are used internally within CAM systems and as archive formats within bare-board fabrication facilities. Pentax format, DaiNippon Screen, and MDA Autoplot belong to this group.) Most of these formats originated as a photo-plotter machine language; they describe single-graphic (drill, drawing), two-dimensional layers. They are usually accompanied by drill files indicating drill locations and diameters. The main drawbacks to graphic image formats are that they represent single layers rather than whole PCBs and that they cannot be verified unless accompanied by a netlist file.

5.4.1.1.2 Netlist. A netlist presents a list of net numbers, and for each net a list of points by their x and y coordinates, and the surface upon which they can be found (see Fig. 5.8). This is the basic information representing PCB connectivity against which PCB graphics can be verified and from which a test program for an electrical test machine can be constructed. One type of netlist identifies the locations of the nets that the PCB is designed to implement. Another type of netlist is a CAD software design package schematic netlist that identifies connectivity between components [by component and pin number as an input/output (I/O) pin identifier], but does not identify their physical location.

```
327LDIN_47          IC52  -U5        A01X+110078Y+030997X0200Y    R180
317LDIN_47          VIA   -    MD0100PA00X+110274Y+031194X0230Y    R180
327LDIN_47          IC10  -J2        A01X+134371Y+039414X0200Y
317LDIN_47          VIA   -    MD0100PA00X+134174Y+039217X0230Y
```

(a)

```
Signal LDIN_47
IC52 U5

```

(b)

FIGURE 5.8 Example of a netlist: (*a*) this part represents a physical netlist with *x* and *y* coordinates [the first line translates as “Pin U5 of component IC52 is connected to net LDIN_47 and is at location (11.0078, 3.0997)”]; (*b*) this part represents the same netlist but at schematic stage with only component and pin names; the electric signal identified as LDIN_47 connects IC52 pin V5 to IC10 pin J2 through two vias.

5.4.1.1.3 Component Information. In addition to being part of the historical file collection, BOM and AVL files are also part of an independent file class that is required even when the more advanced formats are used (see Sec. 5.3.5).

***5.4.1.2 Full-Design Database: CAD Formats*.** Full-design databases, which are formatted using either the CAD system database format or American Standard Code for Information Interchange (ASCII)[b] extracts thereof, represent information for the component and their connectivity through the board as hierarchical arrangements of nets and subnets broken into traces, vias, and planes. They are transferred for board assembly and test but not for board fabrication. Because OEMs consider these formats to present

a proprietary information security risk, they often prefer to convey inferior quality information using other formats in order to preserve privacy.

5.4.1.3 Explicit Design for Manufacturing Formats.

Formats for full design for manufacturing were explic itly built for design-to-manufacturing data exchange and contain nearly all of the required computer-readable data elements in a well-designed, explicit, intelligent layout. Some of these formats originated as DFM/CAM vendor formats whereas others were designed by an industry association committee.

5.4.1.4 Component Information: BOM and AVL.

A PCA may be designed for more than one product variant and to support future functionality. Therefore, for almost all designs, some of the reference designators (or actual bare board footprints on which components can be placed) will not be populated for all assembled board orders. BOM files are used to tell the assembler which reference designators should actually be placed on a given board for a specific order.

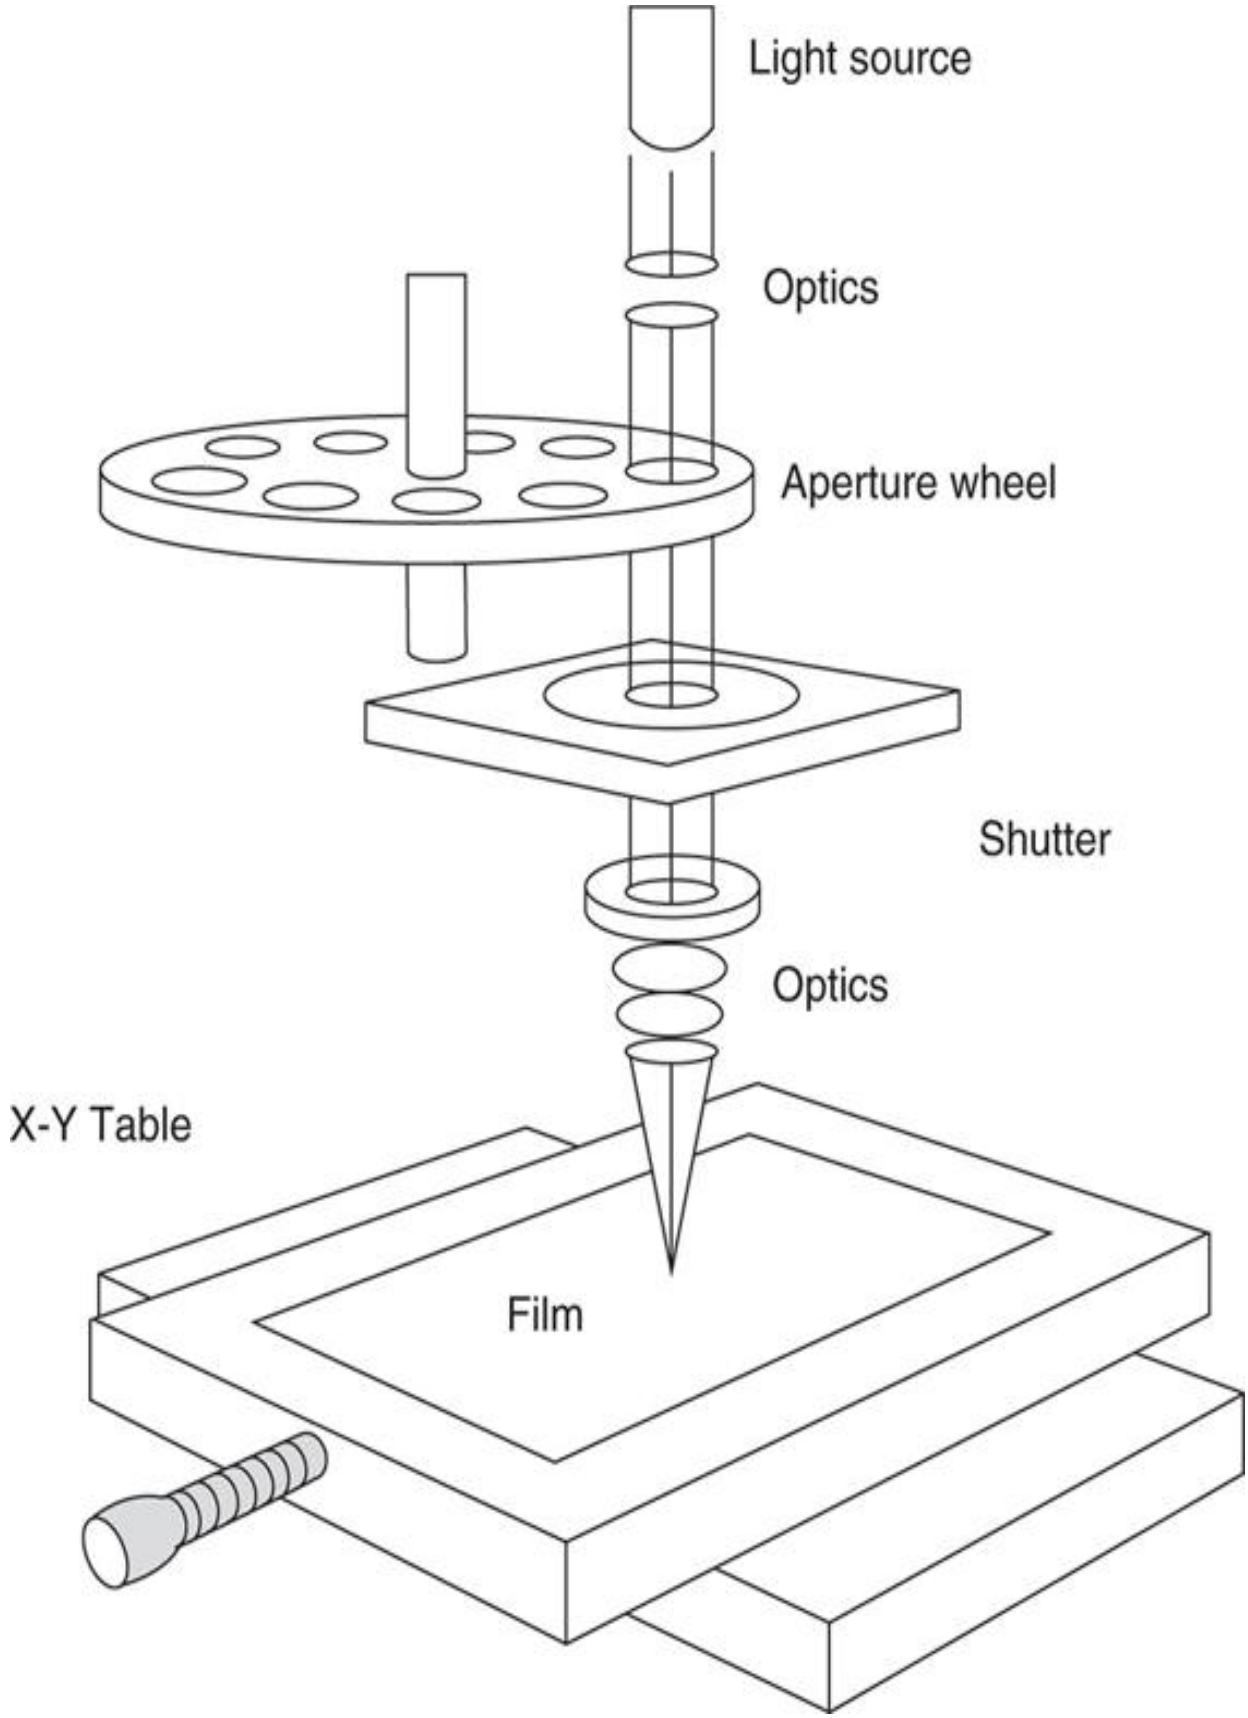
The separation between electrical functionality of components and their actual procurement leads to the need for an AVL file. CAD databases usually contain part numbers that represent functionality and are internal to the design organization rather than part numbers (including the vendor and catalog number) that customers can order. Component engineers are charged with finding true part numbers to implement the internal ones, and this information is usually organized in spreadsheets or text files called AVLs or approved component lists (ACLs).

5.4.2 Historical File Formats Descriptions

Each format description that follows includes its domain (the elements that are covered), its history and expected future path, distinctive characteristics, and a short example. Format description references can be found at the end of the chapter.

5.4.2.1 Gerber (274D and 274X), Drill and "Readme." Gerber formats are the "lowest common denominator" for passing bare-board fabrication information. They are composed of one file per graphic layer, one file for each drill layer, text files that list the PCB stack-up, and optional drawing files that list critical dimensions and requirements. Inclusion of a netlist file with each Gerber transfer is imperative to ensure correct board fabrication.

A common problem with both Gerber 274D and drill formats (usually Excellon I and II) is the lack of definition of both units and scale factor of numbers (Excellon is a precision drill machines manufacturer). Each coordinate is given as a collection of digits, and the translator, or user, must define the units (in in. or mm) and the location of the decimal points in the format. Another problem stems from the use of arbitrary numbers ("Dcodes" for aperture numbers on an aperture wheel) to describe the width of lines and size of pads. Accurate translation of these files depends on the correct definition of an aperture wheel, which is described separately. Figure 5.9 shows a photo-plotter schematic that explains the source of the terminology.



Light source
Optics
Aperture wheel
Shutter
Optics
X-Y Table
Film

FIGURE 5.9 A photo plotter uses a stationary light source to deliver light through a rotating variable size aperture wheel (which determines the size of the light spot on the table) onto a table that can move in the *x* and *y* directions. A shutter shuts or allows light passage as required. Precision optics control the focus of the light spot.

The commands that drive this mechanism are *x* and *y* coordinate movement commands to position the table, those that turn the shutter on and off, and Dcode commands that rotate the aperture wheel to the required position.

Gerber 274X was designed in the early 1970s (by a team of two engineers—one from Gerber Scientific and another from what used to be the biggest PCB factory in the United States, the AT&T plant in Richmond, Virginia) to overcome some Gerber 274D problems. Gerber 274X permeated slowly at first, but its adoption accelerated and Gerber 274D is now used less frequently.

Both 274D and 274X are used to transfer graphic images of circuit and mask layers and images of documentation layers used for instructions. Other graphic drawing formats are occasionally used to transfer board and drawing data. The most common formats are HPGL (the format of HP pen plotters) and DXF (the AutoCAD exchange format).

Several drill formats originating from drill machine makers other than Excellon (Sieb and Mayer, Posalux, etc.) are sometimes used to transfer drill data or to archive old drill data. They suffer from the same problems of Dcode (explained in Fig. 5.9) and unit definition.

5.4.2.1.1 Gerber 274D. Gerber RS-274-D has been the most common format for describing PCB plot data. This format was originally intended to drive vector photo plotters (see Fig. 5.8), produced by Gerber Systems Corporation (see Fig. 5.10 for an annotated snapshot section of a Gerber file).

Example	
G90*	G90 indicates absolute coordinates.This means that that each set of coordinates is referenced to the table's origin (0,0).The converse to absolute is incremental;each coordinate is measured relative the previous coordinate value and is set by issuing the G91 command.
G70*	G70 indicates inch units.
G54D10*	G54,tool select (line 3),is the most commonly encountered Gcode and instructs the plotter to rotate the aperture wheel to the position described by Dxx immediately following the G54 command. If this code is omitted,the the photo plotter then identifies the next Dxx command as telling it to select a tool.
G01X0Y0D02*	Dcodes are instructions to the photo plotter that, naturally, include the letter *D*. The first three Dcodes control the movement of the x,y table.D02 (D2) tells the plotter to move to the x,y location specified with the shutter closed.
X450Y330D01*	D01 (D1):This command tells the plotter to move with the shutter open to the x,y location specified.
.X455Y300D03*	D03 (D3):This command tells the plotter to move with the shutter closed to the x,y location specified, then open and close the shutter—known as flashing the exposure.
G54D11*	
Y250D03*	
Y200D03*	
Y150D03*	
X0Y0D02*	
M02*	The *M* in Mcommands stands for miscellaneous; in this case, M02 means stop or end of file.

FIGURE 5.10 An annotated section of a Gerber file.

The basic commands of this format include the following:

- Selecting the aperture
- Opening and closing the aperture shutter
- Moving the head to a given *x, y* coordinate

Typically, commands are separated by the asterisk character (*).[3]

5.4.2.1.2 Gerber 274X. Gerber RS-274-X is a common format in use today for describing PCB plot data. The format can be divided into two parts:

1. The Gerber part
2. The extended part, which includes commands for the following:
   - Standard aperture definition
   - Aperture Macro definition (special symbols)
   - Layer polarity selection

Typically, extended commands begin with % and end with *%.

Unlike Gerber 274D format, Gerber 274X includes definition of coordinates using the FS command (see Fig. 5.11). Reading software uses this information when reading Gerber parts.

Example

%FSLAX23Y23*%	This command indicates (L)eading zero suppression,(A)bsolute, 2.3, or xx.xxx and yy.yyy decimal point location
%MOIN*%	This command specifies inches
%SFA1.000B1.000*%	
%ADD11C,0.00500*%	These are aperture definition commands defining various diameter circles (5, 8, 10, 20, and 25 mil, respectively)
%ADD13C,0.00800*%	
%ADD14C,0.01000*%	
%ADD70C,0.02000*%	
%ADD71C,0.02500*%	
G54D11*	Here the Gerber part begins.
%LPD*%	This command indicates that digitized data is dark. However, when the entire film is reversed, the digitized data will be clear.

```
G11*G70*G01*D02*G54D10*X-0020000Y-0250000D02*X-0020000Y-0265200D01*
X0010000Y-0255000D02*X0010000Y-0250000D01*X0025200Y-0344800D02*
X0025200Y-0285000D01*X0022800Y-0265200D02*X0022800Y-0270000D01*
```

This is straight Gerber code with multiple commands on a line.

FIGURE 5.11 An annotated Gerber 274X section.

The most serious limitation of Gerber 274X is polygon representation. No solution was provided for describing internal cutouts or clearances. Each implementation of Gerber 274X-based CAD output deals with these in its own way. The most problematic way is to use self-intersecting polygons (SIPs) where the “pen” does not leave the board

while drawing the internal cutouts, but “swerves” to the inside of the external outline to draw the internal cutout and then returns (see Fig. 5.11).

An SIP is a polygon with two nonconsecutive edges (segments or curves) touching each other. SIPs are illegal in CAM systems that define legal polygons as those whose edges intersect only at endpoints of consecutive edges.

Translation of 274X data into a CAM system might fail with a “Self Intersecting Polygon” error because some CAD systems create surfaces using self-intersecting polygons.

SIPs are not mathematically robust, and the following SIP operations are problematic:

- Resizing (enlarge, shrink, scale—especially with differing *x* and *y* values)
- Accurate copper calculations (these require unambiguous definition of the copper location)

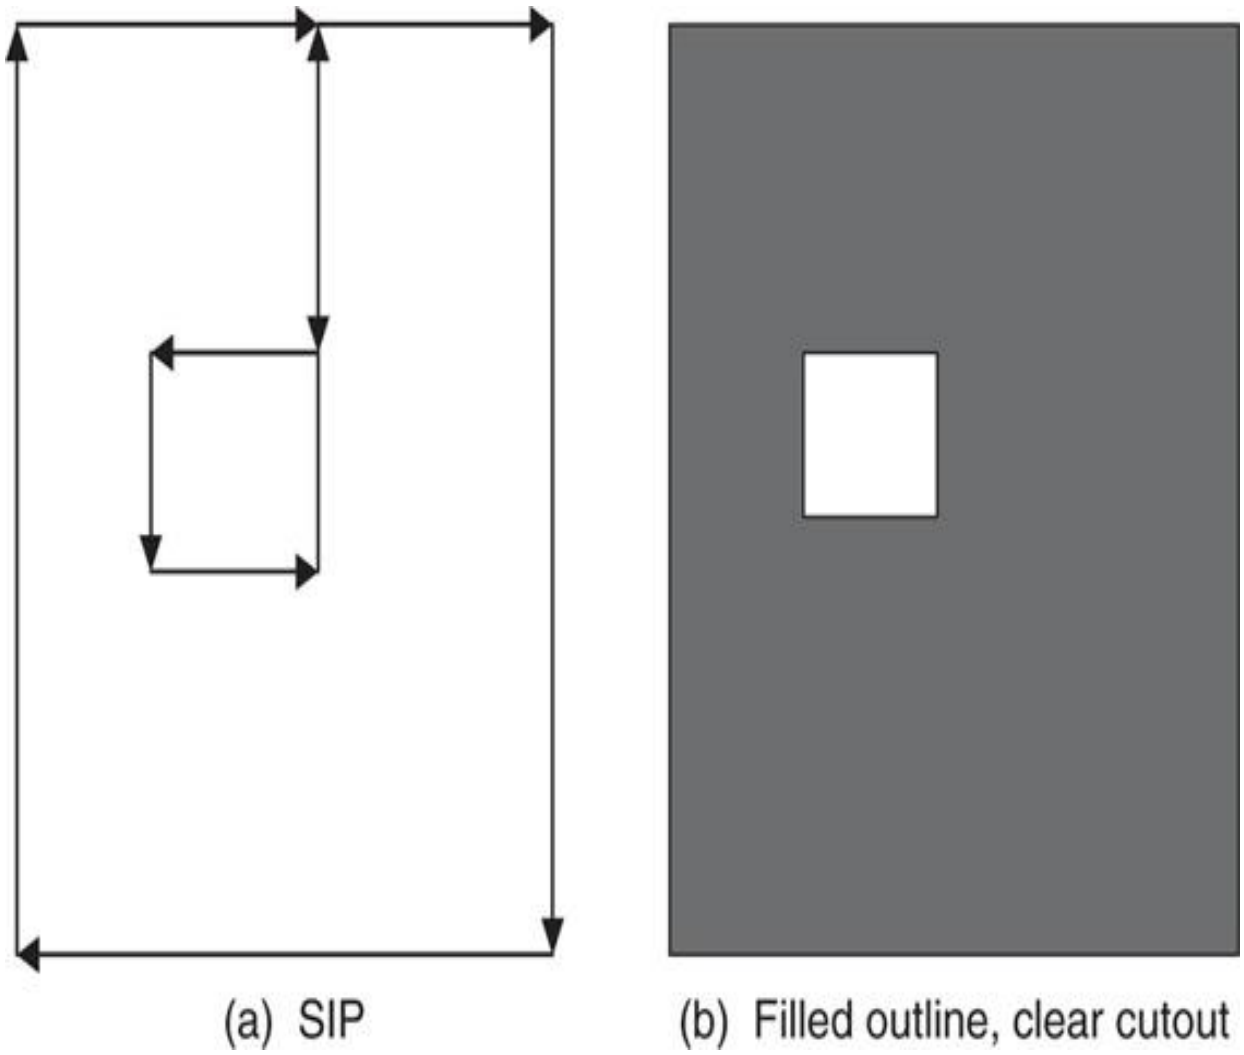


FIGURE 5.12 An SIP: (*a*) as drawn by self-intersection, with a single path and the pen not removed from the paper; (*b*) with a filled rectangle as an outline and a clear rectangle as the cutout.

In most CAM systems, a surface is a mathematical entity that describes planes. It can contain islands (positive polygons) and holes (negative polygons). If the layer is positive, islands represent copper, whereas holes represent non-copper (see Fig. 5.13). Copper planes usually implement power or ground connections, where the clearances provide spacing for data signal vias that pass through the plane but must be electrically disconnected from it.

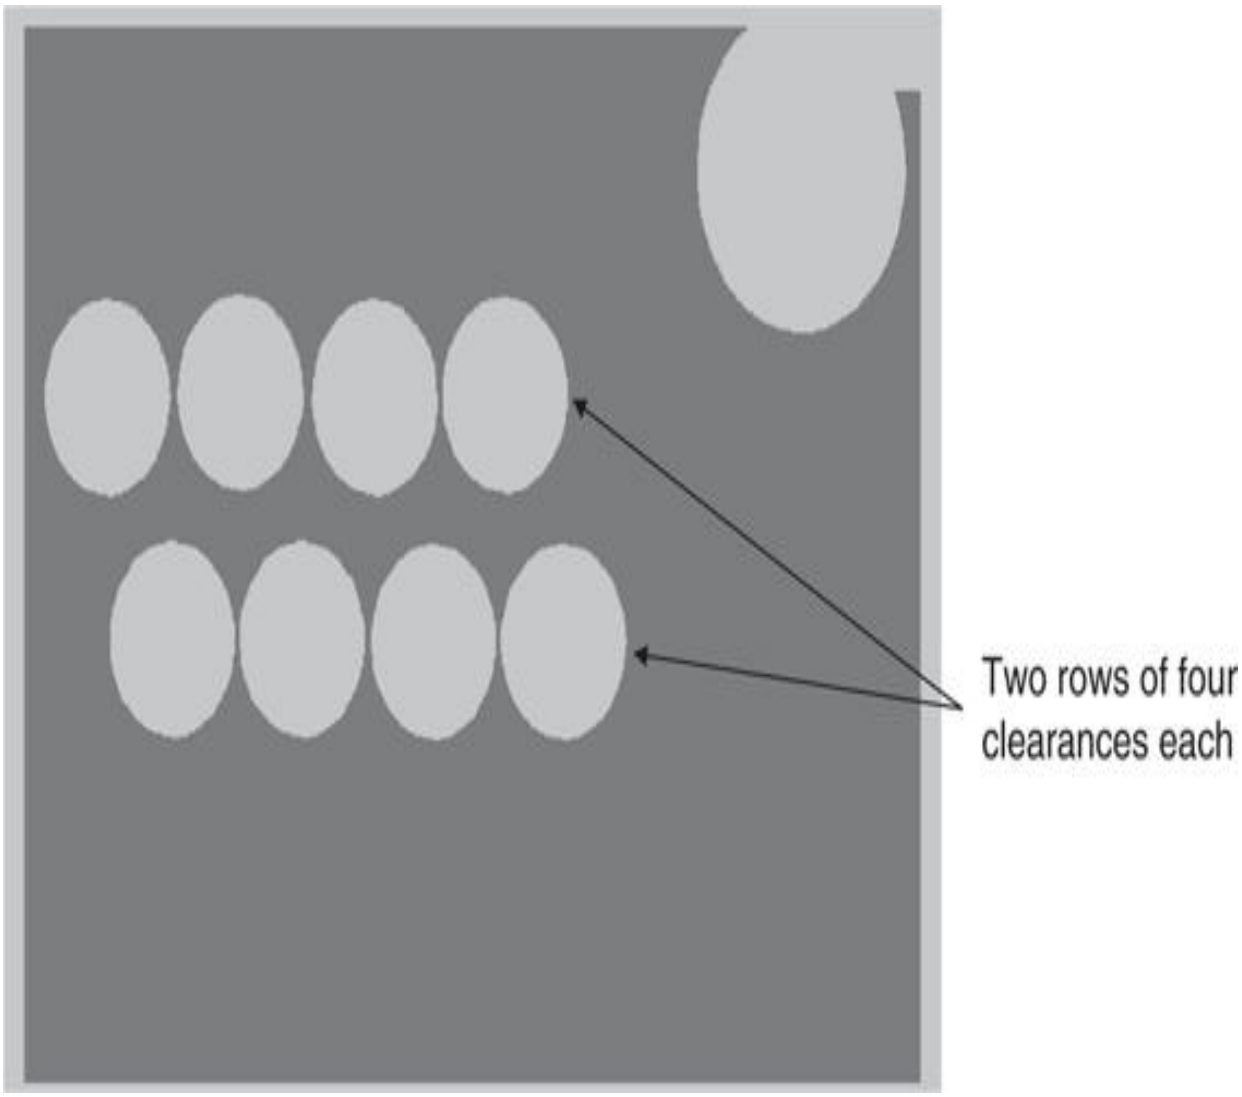

FIGURE 5.13 This surface is composed of one rectangular island, with a circular cutout in the top-right corner representing copper and eight round holes representing clearances.

There are two non-ambiguous ways of drawing planes with cutouts in 274X. The first is to use positive polarity for the islands and negative polarity for the holes. The second is to decompose the plane into positive surfaces that, when combined, yield the outline with the holes.

5.4.2.2 Netlist Formats. A netlist is a set of connection points joined together to form networks. Each point represents a contact point on the surface of a bare board. A

connection point can be either a drilled hole or a surface mount pad. All points belonging to one network should be connected to each other through PCB layer circuitry and/or power and ground planes.

5.4.2.2.1 Gerber Data. Gerber data format is the oldest artwork format. It was developed with the first NC photo plotters in the early 1970s. It is the "least complete" of data formats in that it consists of an aperture wheel definition, an x-y starting coordinate, an "open shutter" command, an x-y ending coordinate, and a "close shutter" command. The aperture wheel must also be defined. Figure 5.14 shows a typical Gerber format program.

```
*                (Always a good idea to start a plot with an asterisk)
04 *             (Comment; Date: Sun Feb 26 16:48:19 2006)
G04 *            (Comment; Layer 1: Layer_1.gbr )
G54D12*          (G54, tool select Aperture number D12)
D2*              (D02: move to the x-y location specified with the shutter closed.)
X40000Y30000D03* (Go to X-4.0000", Y-3.0000, D03 (D3): move to the x-y location specified
                 with the shutter closed; then open and close the shutter-known as flashing
                 the exposure.)
G54D10*          (Select Aperture number D10)
X10000Y10000D02* (Go to X-1.0000", Y-1.0000, not drawing a line)
G01X50000D01*    (Go to X-5.0000", Y-1.0000, drawing the base of the triangle)
Y60000*          (Go to X-5.0000", Y-5.0000, still drawing)
X10000Y10000*    (Go to X-1.0000", Y-1.0000, drawing the hypotenuse)
M02*             (End of plot)
```

FIGURE 5.14 Example of a Gerber format program.

The Gerber 274-X is the preferred version today, as the apertures are embedded in the format. Figure 5.15 shows the RS-274X 2.5 leading absolute format.

FIGURE 5.15 Example showing RS-274D 2.5, the leading absolute format.

5.4.2.2.2 GenCAM. Developed by IPC to improve data transfer for manufacturing in the 1980s, GenCAM is an ASCII-based, English-readable, and universal vendor-independent data exchange format. IPC-D-350 was the first such format in the 1970s, followed by IPC2511/GenCAM in the 1990s, and in the new millennium IPC-2581 evolved.

5.4.2.2.3 IPC-D-356.[c] IPC-D-356 is an ANSI-accepted standard that has become the most widely used standard for transferring netlist information. The IPC-D-356 format is used to transfer netlist information within the PCB design and fabrication community. This information can be used to verify the integrity of the design by netlist extraction from the Gerber graphics and comparison with the IPC-D-356 CAD reference. The information is also used within both the bare board and the assembled board test domains.

Most data in the IPC-D-356 file (see Fig. 5.16) consist of electrical test records of two types:

FIGURE 5.16 A section of an IPC-D-356 file. It contains two drill records (“317”) and six surface mount records (“327”). The four bottom solder mask (SMT) points

should not be connected, hence their “net name” fields contain “N/C,” indicating “Not connected.”

1. Drill records (starting with “317”)
2. Surface mount pad records (starting with “327”)

There are also other general parameter records.

Each IPC-D-356 record consists of one line and (for historic reasons) is of a fixed length with a maximum of 80 characters.

The information extracted from translation of IPC-D-356 files to an internal netlist might include solder mask coverage and midpoint flags, along with the dimensions and location of connection points and their groupings into networks. Information in component and pin identification fields is not necessarily extracted for comparison purposes.

There are two amendments to IPC-D-356: IPC-D-356A and IPC-D-356B. Most of the extra information included in these formats is important for bare-board electrical testing and, unless buried passives are used, the information is generally not needed for CAD-to-CAM data consistency verification. If buried passives are used, it is better to transfer IPC-D-356A after verifying readability by the supplier.

5.4.3 Mentor Graphics Neutral File[4]

Several nonstandard netlist formats can be output by various CAD software suites. All such formats contain connection point records and their grouping into nets. American designers and fabricators occasionally used a stripped-down version of the Mentor CAD format Neutral File to transfer netlist information, and thus it is described here.

The Mentor Graphics Board Station Fablink application produced the Mentor Graphics Neutral File format. It has

several sections, each describing one aspect of a board (components, netlist, holes, etc.).

A full neutral file contains these information sections:

- BOARD: board attributes
- NET: net points
- GEOM: packages and pins
- COMP: components and “toeprints”—another name for a pad pattern outline
- HOLE: drilled holes
- PAD: approximate shape of pads

The BOARD and NET sections contain sufficient information to derive a netlist. If the file includes all sections, it is possible to derive components and drills but not full routing (trace) information.

The Fablink user can control which sections are included in the file (see Fig. 5.17).

5.4.3.1 Component Placement List.

Component placement lists (CPL) are ASCII or spreadsheet files used to transfer component *x, y* locations if CAD data files are not sent. CPL files are usually minimally formatted into columns. Required columns are the reference designator, *x, y* locations, and component rotation. In Fig. 5.15, the example CPL file also includes CAD package information.

FIGURE 5.18 An example of a typical simple text tabulated CPL file. The first line translates as “Place resistor R101 at $x = 5.065$, $y = 0.88$ at 90°. Use part number 10467C. For information, see CAD package R0805. The mounting process is SMT.” This example is just a text file listing.

5.4.4 CAD Formats

The leading CAD system vendors have created several formats. When there is a high level of cooperation between customer and supplier, the design customer can send the whole design database from the CAD system on which it was created (and achieve the goal of intelligent exchange as depicted in Fig. 5.3). CAD formats are excellent for testing assembled boards because they include the schematic information. In addition, they include component locations and packages, as well as enough data to derive the graphics of any board layer. They must be accompanied by BOM information and also AVL information (unless parts are consigned) to define which components to place for each board variant and which components to procure.

CAD formats are less suitable for board fabrication, because they lack a flattened WYSIWYG ("what you see is what you get") representation of the circuit layers. Examples of CAD formats include Mentor's Board Station Neutral and Geoms files [4], as well as Cadence or ORCAD layout files.

When CAD formats are used for data exchange, their format is, by definition, the format of the specific CAD system that was used for layout and routing. The designer must therefore verify that the supplier can read it or use some translation tool to convert the data to a format readable by the supplier, risking conversion errors.

5.4.5 Modern Data Exchange Formats

5.4.5.1 ODB Format. Orbitech developed ODB++ as a "complete" data description format used for design to manufacturing (DFM) and CAD/CAM data exchange. It contains all the relevant design data for manufacturing and assembly. Section 5.4.1 provides details.

ODB++ and IPC-2581 are examples of formats that were explicitly designed for the purpose of CAD to CAM data exchange. ODB++ is the internal format for Valor's[5] tools and was developed early as an exchange format. IPC-2581 is a vendor-independent format developed as a joint effort by Valor and an IPC-sponsored committee to correct the historical problems associated with data exchange.

ODB++ and IPC-2581 are the only formats that can include all the data needed for manufacturing, including BOM and AVL information. They come closest to the idea of intelligent exchange depicted in Fig. 5.3.

5.4.5.2 ODB++. The ODB++ data format is a common language used for DFM and CAD/CAM data exchange. It overcomes many data communication obstacles within design/manufacturing supply chains. Data in this powerful open database impart an integrated and accurate physical model of all bare-board, component, and test-related information. It is designed as a simple yet comprehensive description of all entities used in the manufacture and assembly of a PCB.

The Valor Universal Viewer (VUV) is free software that enables ODB++ design data to be viewed graphically on Windows, Sun, or HP-UX workstations.

ODB++ uses a standard file system structure.[5] ODB++ denotes a job using a simple directory tree that can be transferred between systems with no loss of data (see Fig. 5.19).

FIGURE 5.19 ODB++ job tree—the left-hand side of the figure describes the top-most elements under the job level and the right-hand side describes the top-most elements under the step level.

The advantages of a directory tree compared to one large file are apparent when a job is being read or saved. The flexible tree structure allows only selected parts of the job to be read or saved, avoiding the overhead of reading and writing a large file.

When a job must be transferred, standard compression utilities can be used to convert a directory tree into a single file.

ODB++ is widely used in the PCB industry and many vendor tools support it, including some CAD systems that offer output to ODB++ format. Description of all ODB++ format elements is beyond the scope of this chapter, but a small excerpt from a layer features file, shown in Fig. 5.20, can exemplify its explicitness and its clarity.

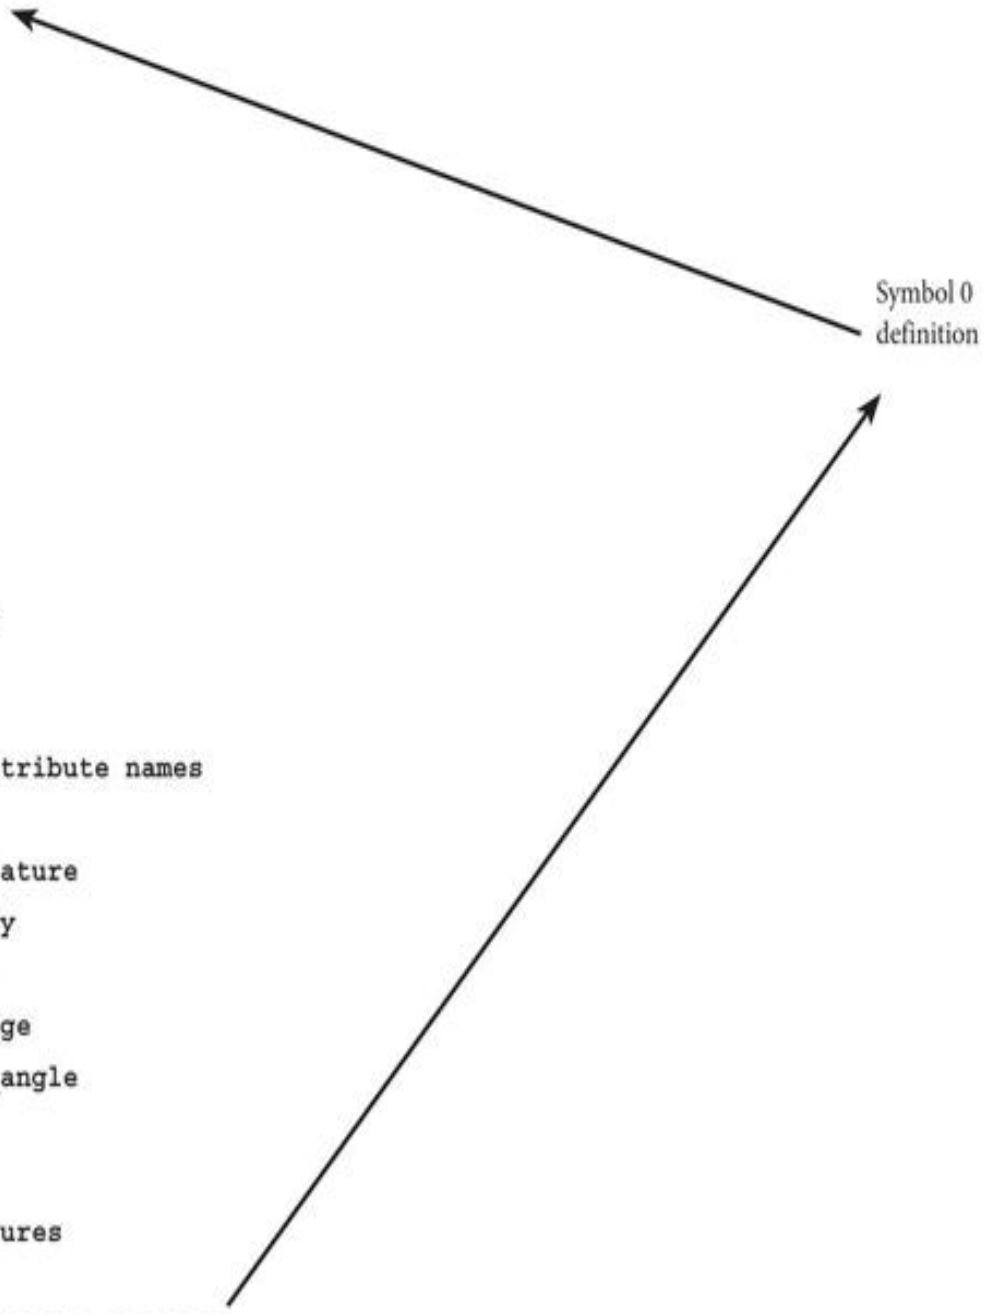

FIGURE 5.20 An ODB++ feature file with annotations. “P 5.3145669 3.215 0 P 0 0” indicates a pad at (5.314, 3.215) with a 3.937 mil diameter. (The first 0 points to symbol 0, clearly represented by “$0 r3.937” in the symbols section. “P 0 0” indicates that the pad has “P” (positive polarity), is not rotated 0°, and has zero attribute values.

5.4.5.3 IPC-2581. IPC-2581, on the part of the IPC and the electronics industry, is a universal vendor-independent data exchange format.[6] IPC-D-350 was the first such format in the 1970s, followed by IPC-2511 GenCAM in the 1990s; in the new millennium, IPC-2581 evolved.

IPC-2581 (nicknamed “Offspring”) is based on ODB++ and is the culmination of the ODB++ and GenCAM convergence project sponsored by the National Electronics Manufacturing Initiative (NEMI). IPC-2581 has inherited some of IPC-2511 GenCAM characteristics.

IPC-2581 is actually a series of IPC-258*x* documents, where *x* represents 1–9; IPC-2581 consists of the generic requirements (or, in this case, the full format description), whereas IPC-2582 and above are sectional requirements. IPC-2584, for example, contains the sectional requirements for fabrication and explains which generic IPC-2581 elements are required for bare-board fabrication and which elements are optional.

IPC-2581 is an all-inclusive, explicit, accurate, and intelligent format containing all data needed for both manufacturing and assembly. The following data elements can be described in a full-mode IPC-2581 file:

- Original schematic capture files
- Original layer/stack instance files
- Original conductor routing files
- BOM and AVL
- Component packages and logical Nets
- Outerlayer copper lands
- Solder mask, solder paste, and legend layers

- Drilling and routing layers
- Documentation layers
- Physical nets
- Outer copper layers (nonlands)
- Innerlayers
- Nondocument miscellaneous layers
- Instructions and specifications
- Component tuning and programming instructions, program files, and/or references thereof

This format contains information not available in the earlier formats (including details about personnel and the enterprise, material requirements, and component tuning and programming). Most industry tools lack these items in their internal formats, so at this point these sections are usable primarily in human-readable form.

Future evolution and market acceptance of IPC-2581 depend on committee work and vendor implementation and could well take several more years.

5.4.5.4 Component Information. BOM and AVL files do not usually follow any global standard, but rather conform to the internal standards of each organization. Their format may be simple ASCII or a spreadsheet (see Fig. 5.21). Interpretation of BOM and AVL files requires either manual or semi-automatic parsing followed by conversion into a known supported format. This process might entail creation of templates that recognize various types of BOM and AVL files and translate them semi-automatically.

ITEM	CPN	GEOM	COUNT	DESCRIPTION	REFERENCE

FIGURE 5.22 Typical simple text tabulated AVL file excerpt.

The line numbers are not part of the file. Lines 1 through 5 are header lines and lines 6 through 15 are data lines. There are two types of data lines; line 1 contains column headers for the first line type, and line 3 contains column headers for the second line type. Lines 6 and 12 are lines of the first type, representing functional devices [usually referred to as customer part numbers (CPNs)]. Lines 8 through 10 and 14 and 15 are of the second type and represent alternative orderable part numbers [usually referred to as manufacturer part numbers (MPNs)].

Line 6 translates as “Part number XYZ00001 is a 1 Pico Farad chip capacitor of description ‘CAP CHIP 1PF 0.25PF 50V COG 0402,’” whereas line 8 translates as “to get the XYZ00001 functionality from Kemet Electronics Corporation, specify catalog number C0402C109C5GACTU.”

5.5 INITIAL DESIGN REVIEW

The purpose of the initial design review is to determine the potential fit of the product to the manufacturing facility, determine general cost information, and prepare for PCB information. Proper upfront analysis of a product prior to manufacturing or PCB information saves time and materials.

It is the responsibility of the manufacturing site to determine the fit of a given product to its capabilities. PCB manufacturing sites should monitor and maintain a list of manufacturing capabilities and a technology roadmap of where the facility is developing additional process capabilities. This list of capabilities defines the acceptability of a product for manufacturing or whether the product is a research and development project.

5.5.1 Design Review

Reviewing the incoming package for design and performance requirements (e.g., line width and spacing, impedance) versus the PCB manufacturing capabilities will define the capability for manufacturing and provide a prediction of the resulting yield. Among the design characteristics that should be reviewed against process capabilities are the following:

Item	Issue
Maximum number of layers	Higher-layer-count products require greater control of processes and PCB information tolerances.
Board thickness	Some process or handling equipment may have limitations on board thickness (either too thin or too thick).
Minimum feature width	Finer line widths require better control of artwork and process tolerances. In addition, the relationship of line width to copper weight is significant in providing a well-defined line. Fine lines with lower copper weights are easier to manufacture than fine lines with higher copper weights. For normal impedances, like 50 ohm, thinner lines will require thinner dielectrics.
Minimum feature spacing	Finer feature spacing requires better control of artwork and process tolerances. In addition, the relationship of feature spacing to copper weight is significant. Fine spaces with lower copper weights are easier to manufacture than fine spaces with higher copper weights.
	Minimum feature spacings affect electrical cross-talk. Closer spacing to reference ground will minimize this cross-talk.
Minimum finished hole size	Smaller holes require higher manufacturing process capabilities and imply (due to design characteristics) finer tolerances on PCB Information and internal registration systems. The aspect ratio (AR) of diameter to board thickness is a major process concern.
Maximum aspect ratio	Small holes and thick boards result in difficulty during the plating processes and can result in defective products that may or may not pass electrical testing. Plating high-AR holes requires chemistry and process parameter enhancements.
PCB dimensional tolerances	Fine PCB profile or cutout tolerances may result in punching/blanking requirements versus routing, or changes in the routing parameters or programming.
Feature-to-feature tolerances	The location of features on the PCB relative to other features may require alternative materials or process changes to reduce the tolerances.
Hole size tolerances	Consistency in the plating process versus selected drilling hole size and plating densities has significant impact on the capability to control hole tolerances. Adjustments to the PCB design, drill hole size selection, or process parameters may be required to produce an acceptable product with tighter tolerances.
Impedance requirements	The multilayer stack-up thicknesses and tolerances, along with the copper thickness and line widths, must match the nominal impedance and the upper- and lower-acceptability limit. Often, various impedances cannot be fabricated on the same layer.

5.5.2 Material Requirements

Determination of the bill of materials is required during the initial analysis of the design. The determination of the BOM and other material-processing requirements will define the manufacturing facility's capability to produce and its material cost structure. In addition, the definition of the material requirements will be the basis for the generation of the process traveler requirements.

The primary materials requiring definition are those included in the BOM, including laminates, prepregs, copper foil, solder mask, and gold. The materials may be explicitly defined by the PCB customer (e.g., usage of a specific solder mask), or may be implied in the drawings or specifications provided with the PCB Information package.

Several factors impact the selection of the raw materials, including the following:

- Customer-defined physical constraints, for example, the definition of the physical dimensions between conductive layers
- Customer specification of electrical properties, for example, the definition of the impedance requirements on certain layers
- Manufacturing process capabilities related to lamination thicknesses and tolerances
- Specification of material dielectric requirements, for example, the usage of FR-4 or polyimide
- Specifications of physical operating parameters, for example, the minimum requirements of the glass transition temperature

The determination of the laminates, prepregs, and copper foils are based on the following:

- Standard constructions for the PCB manufacturer of a defined PCB layer count, final thickness, copper weight, and dielectric spacing.
- Custom constructions based on defined physical constraints (e.g., minimum dielectric spacing). These custom constructions are defined through knowledge of the lamination pressing thickness of materials versus copper circuitry densities and the availability of materials from suppliers.
- Custom constructions based on defined electrical property constraints, such as controlled impedances, crosstalk, or capacitance. These custom constructions are typically defined via equations or software models provided with certain product parameters.

The determination of solder mask is based on the customer specifications and drawings. Once the acceptability of the solder masks is defined, the PCB manufacturer selects the acceptable masks based on either preferred process (due to volume or cost) or the design characteristics' interaction with the solder mask. These design characteristics include the following:

- *Tenting or plugging of vias*. A hole plugging epoxy may be preferred over liquid photoimageable solder mask with a secondary via plugging process.
- *Platable area densities/higher external copper weights*. Thin solder masks may not be able to ensure coverage of high plating.
- *Secondary processes*. Post-solder-mask processes may chemically or mechanically alter the appearance of certain solder masks.

The determination of gold requirements is based on the thickness and area of the gold. These factors can be used to calculate the requirement of gold per PCB product.

5.5.3 Process Requirements

The selection of the proper product routing (or traveler) is critical to the upfront analysis of the product acceptability to manufacturing. Considering a typical multilayer PCB product, the product routings can be broken into two parts: the innerlayer pieces and the outerlayer piece.

The product routings of the innerlayer pieces are fairly standard, and are typically as follows:

Step	Typical process requirements
Layer cleaning	Cleaning of the laminate surface via either mechanical or chemical cleaning processes
Imaging	Coating of the laminate with photoresist material and the exposure of the photoresist with artwork defining the innerlayer pattern
Develop-etch-strip (DES)	Developing of the photoresist, etching of the exposed copper, and stripping of the remaining photoresist
Innerlayer inspection	Inspection of the innerlayer piece to the PCB design intent
Oxide	Coating of the innerlayer piece with an oxide layer prior to lamination

One of the few decision points in innerlayer manufacturing is whether the product will require inspection. This decision can be based on the manufacturing facility's process capabilities and the design of the specific innerlayer piece. For example, if the process capability for innerlayer manufacturing of designs at 0.008 in lines and spaces is 100 percent yield, and the product has been designed at or above 0.008 in lines and spaces, then the product may not require inspection. Typically, the design package will identify the design technologies (e.g., line width and spacing);

however, these should be confirmed during the design analysis and review stage.

The product routings of the outerlayer pieces define the finished product appearance and, as a result, are more complex. Assuming a pattern plating process, the typical outerlayer process routings for a solder-mask-over-bare-copper (SMOBC)/hot-air-solder-level (HASL) product is as follows:

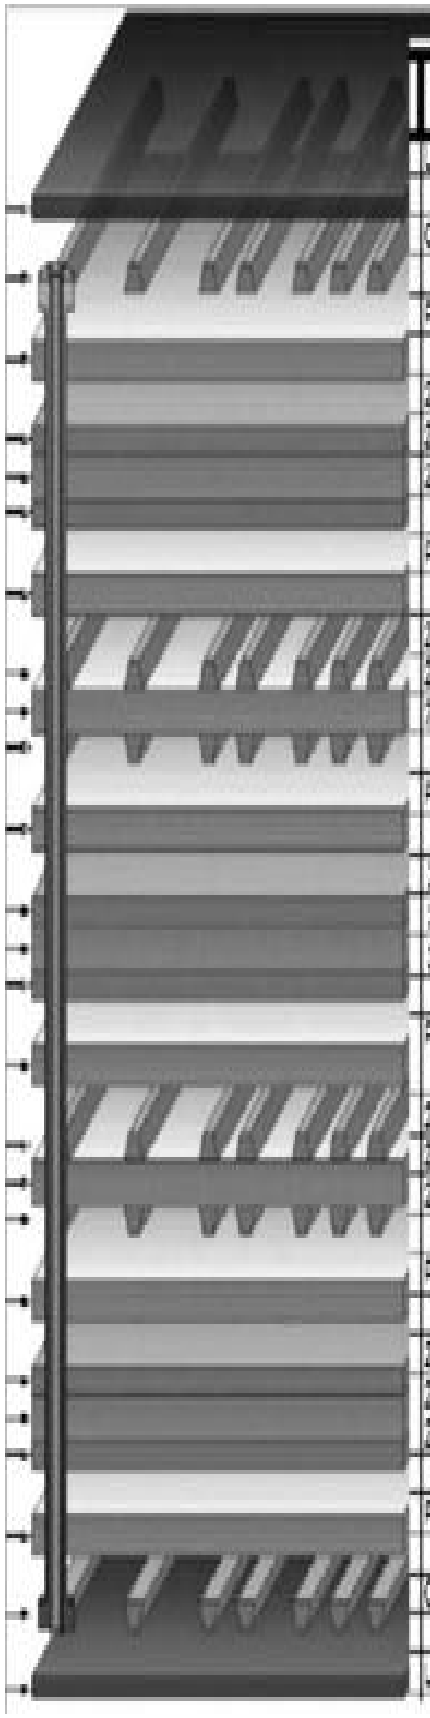
Step	Typical process requirements
Lamination	Lamination of innerlayer pieces with prepreg and copper foils to create the outerlayer piece
Drilling	Addition of the holes providing pathways for electrical conductivity between outer layer and innerlayer pieces and for other PCB design purposes
Electroless copper plating	Deposition of copper on the surface and in the holes of the product, providing the conductivity necessary for electroplating
Imaging	Coating of the panel with photoresist material, the exposure of the photoresist with artwork defining the outerlayer pattern, and the developing of the outerlayer pattern
Electroplate copper	The plating of the final circuitry of the product
tin plating	Sacrificial plating over the final circuitry of the product
Strip-etch-strip (SES)	Stripping of the remaining photoresist, etching of the exposed copper, and stripping of the sacrificial plating
Solder mask	Coating of the bare copper product with either dry film or liquid photoimageable solder mask, exposing of the panel with the PCB customer-supplied artwork pattern, developing of the pattern (exposing the sites requiring solder), and curing of the solder mask
Nomenclature	Screening of the nomenclature onto the panel and curing
HASL	Coating of the exposed copper sites with solder, leveling to the customer's requirements of thickness
Depanelization	NC routing of the PCB products from the manufacturing panel
Electrical testing	Electrical testing of the product for conformance to the PCB design
Inspection	Verification of product conformance to specifications prior to shipment to the PCB customer

After the electroplate copper operation, the process may change to meet the surface finish requirements. Some of the alternative steps affecting the outerlayer product routing include the following:

Item	Typical process requirements
Selective gold plating	Before the SES process, the panel is coated with additional resist and the selective sites are exposed. These exposed sites are then plated with nickel and gold. The panel will then proceed through the SES process. The HASL step would be omitted.
NPTH in planes without annular ring	A secondary drilling operation will be required to drill the holes, if the hole is to be located through the copper or the hole/feature size is beyond the process capabilities of tenting. This step may occur at the depanelization step.
Scoring	Additional PCB Information holes may be required to register the panel to the scoring machine blades. Programming of the scoring machine will be required to set the locations and depth of the cuts. This step may occur prior to NC routing of the product.
Countersink holes	The countersinking process is normally performed prior to depanelization.
Gold finger plating	Nickel and gold are plated over the finger area on connectors. This process typically requires shearing/NC routing separation of the panel to place the fingers at the edge of the remaining pieces, taping the product to expose only the fingers, stripping the solder, plating nickel, plating gold, and removing the tape. These operations occur prior to the depanelization process. Finger-plated products usually require chamfering of the fingers.
Via plugging	Plugging of vias may occur prior to solder mask or after the HASL operations.
Chamfer	After depanelization of the products from the manufacturing panel, the PCB products are processed through a machine to add an angle to the edge of the part or fingers.
Organic coating	Products requiring organic coating would omit the HASL step and be coated prior to inspection.

5.5.4 Multilayer Stack-Up

Multilayer stack-up, defined in Sec. 17.2.2 and Chap. 31, must be carefully specified. This is the function of the stack-up definition (see Fig. 31.2), which is usually part of the fabrication drawing. Impedance specifications (from the electrical performance data block) should be compatible with the materials stack-up. Figure 5.23 shows a cross-sectional view of the finished multilayer. Figure 5.24 shows the stack-up code.



Description	Stock No	Usage	Base	Finish	Er

5.5.5 Panelization

The selection of the manufacturing panel is one of the most important steps in achieving product profitability. Several factors affect the selection of panel sizes to produce a specific product. These include

- Material utilization
- Process-specific constraints
- Process limitations

All of these factors impact the selection of the manufacturing panel size and the profitability of the product.

5.5.5.1 Material Utilization. The material manufacturing costs, which correspond to 30 to 40 percent

of total costs, are directly related to the square inches of material processed. The material costs can include the following: laminate, prepreg, copper foil, solder mask, photoresists, drill bits, chemicals, and so on. Generally, these materials are consumed relative to the panel area manufactured.

The appropriate manufacturing panel size (see Fig. 5.25) should be selected such that the shippable product consumes the highest percentage of the manufactured panel as possible, thus reducing waste material and product costs.

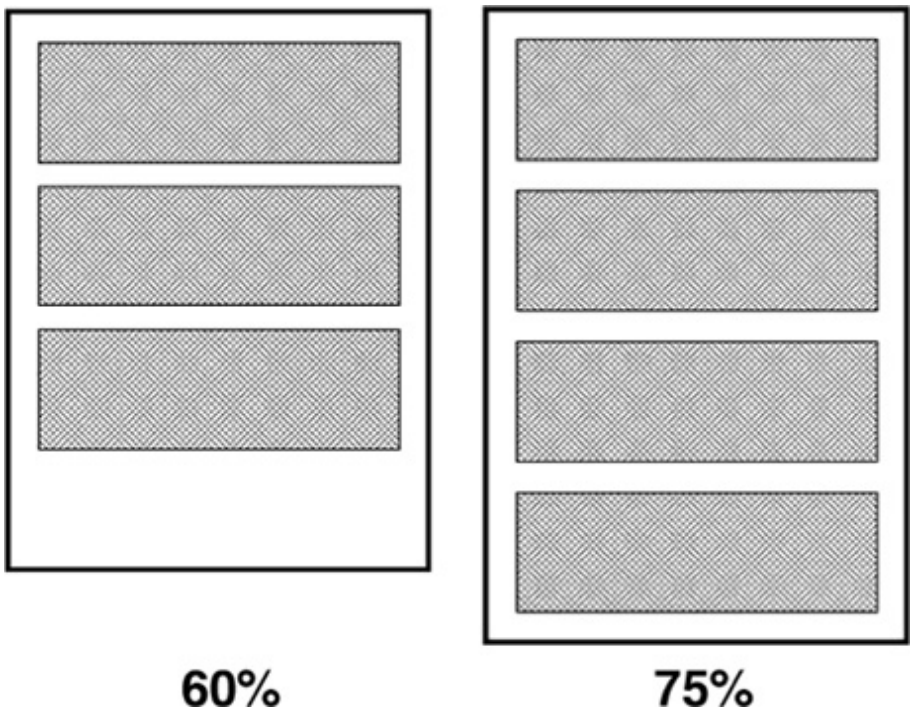

FIGURE 5.25 Selection of the best panel to increase the material utilization of the shippable product.

During the design phase of the PCB, the board profile is defined. If the profile's design results in poor manufacturing panel utilization, it will significantly impact the cost of the product. When defining the PCB board profile, the PCB designer should ask the manufacturing site to provide DFM feedback. Oddly shaped PCB profiles can still result in good material utilization, through nesting of the PCB on the panel.

General limitations in the selection of appropriate panel sizes include the following: minimum spacing between products for depanelization processes (typically 0.100 in) and minimum panel border-to-product spacing to permit PCB information and registration systems (typically 1.0 in).

In Asia, minimizing materials to minimize costs plays a much more important role than in North America or Europe, where rapid turnaround time may be the singular focus. Table 5.1 shows a typical set of multilayer panel sizes for a large Asian PCB manufacturer.

TABLE 5.1 Typical Multilayer Panel Sizes for a PCB

Type	Panel Size (in)	Useable Area (with soldermask)
Standard	12 × 14	10.2" × 12.2"
Standard	12 × 16	10.2" × 14.2"
Standard	12 × 20	10.2" × 5.2"
Standard	13 × 16	11.2" × 14.2"
Standard	13 × 20	11.2" × 5.2"
Standard	14 × 16	12.2" × 14.2"
Standard	14 × 20	12.2" × 5.2"
Standard	14 × 21	12.2" × 19.2"
Standard	14 × 22	12.2" × 5.2"
Standard	14 × 23	12.2" × 21.2"
Standard	14 × 24	12.2" × 22.2"
Standard	16 × 20	14.2" × 5.2"
Standard	16 × 21	14.2" × 19.2"
Standard	16 × 22	14.2" × 5.2"
Standard	16 × 23	14.2" × 21.2"
Standard	16 × 24	14.2" × 22.2"
Standard	17 × 14	15.2" × 12.2"
Standard	18 × 14	15.2" × 12.2"
Standard	18 × 16	15.2" × 14.2"
Standard	18 × 20	15.2" × 5.2"
Standard	18 × 22	15.2" × 5.2"
Standard	18 × 23	15.2" × 21.2"
Standard	18 × 24	15.2" × 22.2"
Chip packaging	12 × 18	10.0" × 15.0"
HDI-microvia Optional	16 × 18	14.0" × 15.0"

5.5.5.2 Product Process-Specific Constraints. In the selection of manufacturing panel sizes, there may be processing constraints that restrict the usage of specific panels or limit the method of placing the shippable product on the panel. For example, the manufacturing of products with gold tab plating may require additional spacing between products and restrictions on the rotation and nesting of products. These constraints may force the usage of panel sizes below the optimal material utilization.

5.5.5.3 Process Limitations. Process limitations may require the usage of nonoptimal panel sizes. For example, due to a product's registration requirements, additional PCB Information may be required, thus reducing the available area for shippable product and reducing the material utilization. Another example is the limitations of some processes to permit larger panel sizes due to the physical processing constraints of the equipment.

The panelization process results in the placement of the PCB single images in the locations defined in the panelization definition step during the initial design review. In addition to the placement of the PCB single images and rotated/nested images (Fig. 5.26), the following features may be added to the panel for manufacturing.

FIGURE 5.26 Nesting and rotation of a multi-image panel.

5.5.6 Initial Design Analysis

After the initial design review, the basics of the design are known and a decision on whether to manufacture the design has to be made. If it is decided to proceed with manufacturing, the cost of the product must be determined. Once the cost has been determined, the product price can be provided to the PCB customer.

The material and process requirements with the manufacturing panel selection, combined with the prediction of yield based on the design review, define the basics of the product costs.

5.5.6.1 Automated Design Analysis. Many automated design analysis software systems exist. You can find them on the Internet by searching on key words such as “Automated Design Analysis,” “Computer Aided Manufacturing,” or “Design Validation.” Figure 5.27 shows a report resulting

from a CAM macro executed on an ODB++ design file, “8-Layer.”

5.6 DESIGN INPUT

The input of the design into the CAM system is primarily performed by defining the apertures and shapes to be used and then loading Gerber data into the PCB CAM system. Alternatively, most PCB CAM systems accept the IPC-350 format.

The information loaded into the PCB CAM systems includes all artwork layers (e.g., circuitry layers and solder mask layers) and the drill files. Although some PCB CAM systems can accept NC routing files (i.e., board profiling), these files are normally not part of the PCB design system's capabilities to create, and therefore are not provided to the PCB manufacturer.

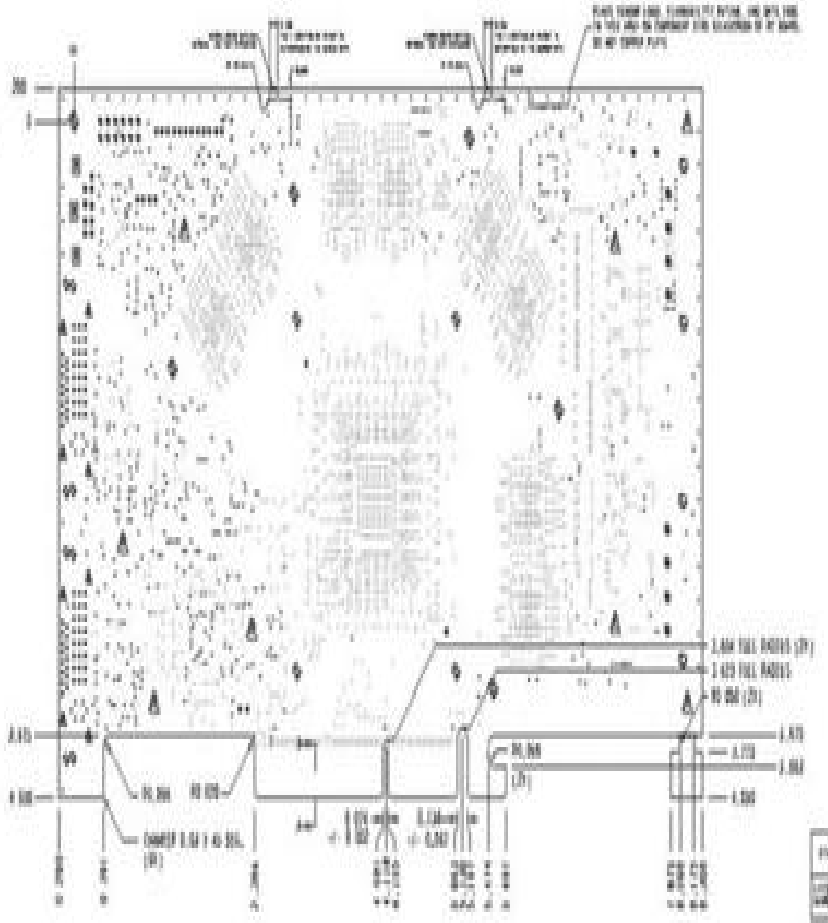
Before loading the PCB design files, the PCB CAM operator must relate the aperture codes within the design file to physical shapes within the PCB CAM system. These shapes are usually round, square, and rectangular, but may also include complex shapes (e.g., thermal relief pads for innerlayer planes). The complex shapes may need to be created on the CAM system from information provided by the PCB designer. The complete definition of these complex shapes by the PCB designer is critical to the success of the resulting design. Incomplete descriptions could result in nonfunctional designs.

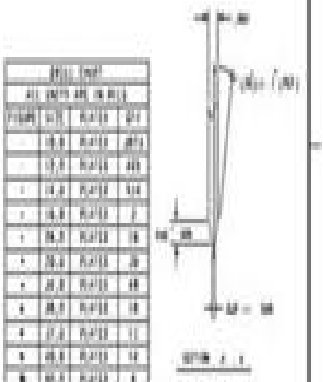
During the loading process of the design files, it is important to review any log files and screen messages for missing aperture definitions or damaged design files. After loading the files, the PCB CAM operator should review the design for any problems with the interpretation of the data or apertures while aligning the data for further processing. The PCB CAM operator also must ensure that the apertures

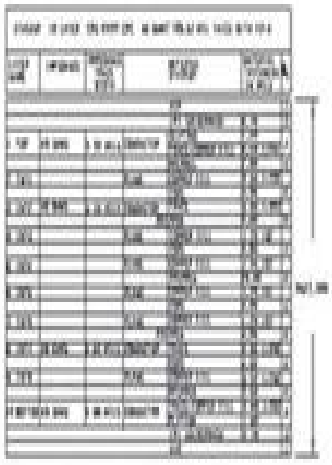
match those defined by the PCB designer and that the design input process has proceeded without failure, since subtle errors may not be discovered within the manufacturing site but only at the PCB customer site, and such errors could result in nonfunctional designs.

5.6.1 Documentation

5.6.1.1 Drill Drawing Example. Figure 5.29 shows an example of a drill drawing.







NOTES: UNLESS OTHERWISE SPECIFIED:

1. MATERIAL : GLASS-EPOXY RESIN SHEET, MEETING REQUIREMENTS OF NEMA GRADE FR-4 OR EQUIVALENT.
2. FINISH: COPPER, MACROETCH 120 MICROINCHES MINIMUM. SOLDER MASK OVER BARE COPPER, BLACK, MATTE FINISH.
3. EDGE FINGERS: ELECTROPLATING: 50 MICROINCHES GOLD OVER 100 MICROINCHES NICKEL.
4. FINISH: SOLDERMASK OVER BARE COPPER (ALSO ON UNUSED AREAS) THICKNESS: 1000 MIN. SOLD MASK THICKNESS COLOR - GREEN.
5. CONNECTOR HOLES: TOLERANCE: .002 MIN UNLESS OTHERWISE STATED. CONNECTOR HOLES: SMOOTH, BREAK ALL SHARP EDGES AND CORNERS.
6. SILKSCREEN LEGEND TO BOARD USING WHITE, NON-CONDUCTIVE, EPOXY BASED. REMOVE SILKSCREEN FROM PADS.
7. TOLERANCES: MACHINING: .010 / INCH MIN ALONG CONNECTOR EDGE. ETCHING: +/- 20% OF MASTER PATTERN. HOLE DIAMETER: + .003 +/-.002, -.003 +/-.002 HOLE DIAMETER + .004 - .002 - (HOLE DIAMETER)
8. ACCEPTABILITY BASED ON [illegible] SPEC 6012-0010 (LATEST REV.) AND IPC-A-600 CLASS 2, (LATEST REV.) REFER TO [illegible] SPEC FOR ORDER OF PRECEDENCE.
9. TEST ALL BOARDS FOR OPENS AND SHORTS.
10. DO NOT SOLDER MASK OVER BY-PASS PAD.

5.7 DESIGN ANALYSIS AND REVIEW

Design analysis and review is a refinement of the initial design review performed earlier but is the first step in the CAM (soft-PCB Information) process. This step focuses on the actual design data submitted for fabrication and assembly. The design analysis and review step consists of the following tasks:

- Design rule checking
- Manufacturability analysis
- Single-image edits
- DFM enhancements
- Panelization
- Fabrication parameters extraction

These tasks provide the final checking of the PCB design requirements against the capabilities of the PCB manufacturer and preparation of the design for manufacturing.

Most fabrication problems occur or are discovered during the initial PCB Information (CAM) phase. The following are among the causes of such problems:

- Poorly documented designs
- Improperly formatted drill files
- Use of 274-D Gerber with separate aperture tables
- Lack of proper clearance on solder mask openings
- Inadequate drill-to-copper clearance
- Misaligned layers
- Inadequate manufacturing clearances
- Lack of an IPC-D-356 netlist
- Use of positive plane layers instead of negative ones

- Minimal communication between the designer and the fabricator

The best advice for these problems is to fix them during the design phase. Consider the following precautions and considerations:

- Try not to use 274-D with separate aperture tables.
- Because there are no standards for aperture tables, the fabricator must do extra work to accommodate the tables, with increased opportunity for error.
- Use 274-X whenever possible. The apertures are embedded and files are easier for the fabricator to work with. This provides better support for special aperture shapes.
- Better yet, if possible, use “intelligent” formats like GenCAM, DirectCAM, or ODB++. These formats should enable the fabricator to better understand your design. Also, such formats have the netlist information embedded.
- Design rules can be embedded in some formats.

5.8 ACKNOWLEDGMENTS

Portions of this chapter were taken from Chap. 18, “Information Formating and Exchange,” written by Bini Elhanan for the *Printed Circuits Handbook*, 6th ed. (Coombs), 2008.

I would like to thank Jeff Miller, WISE Software Solutions (www.wssi.com); DownStream Technologies (www.downstreamtech.com); and Julian Coates of Valor, Inc. (www.valor.com) for their invaluable contributions to this chapter.

CHAPTER 6

SUPPLIER SELECTION AND QUALIFICATION

Tim Rodgers
University of Colorado, Boulder, Colorado

6.1 INTRODUCTION

In this chapter the business considerations and selection criteria initially described in Chap. 3, “Basics of Printed Circuit Supply Chain Management,” will be applied to evaluate and select printed circuit board (PCB)/printed circuit assembly (PCA) suppliers. The chapter also includes recommendations and benefits for creating a formal supplier qualification program and approved vendor list (AVL).

Whether a business is looking for a supplier that will only be used for a single purchase order, or a long-term partner that will become a key element in the value delivery system, it’s important to have a methodology for assessing supplier capabilities and performance. It is very likely that there will be multiple suppliers who can meet the needs of the business, some possibly better than others. It’s not a good idea to choose any random supplier for such an important

component, especially if the customer expects to place multiple purchase orders over the life of a single product. The time and cost required to change suppliers because of poor performance can be significant.

Chapter 3 provided a framework for considering how PCBs and PCAs fit into the overall new product design and development process, and how they ultimately support the business's supply chain strategy. The cross-functional sourcing strategy team must understand the needs of the business and the relative importance of supplier performance characteristics, including technology, responsiveness, quality, cost, and the availability of other services. See Table 6.1 for a summary of the common considerations for evaluating PCB/PCA suppliers:

TABLE 6.1 PCB Supplier Performance Criteria

Category	Examples
Technology	Electrical (thick copper, dielectric) Thermal (low TCE) Dimensional (flexible or molded circuit) Assembly (surface finish, tolerances)
Responsiveness	On-time delivery Rapid prototyping Lead time
Quality	Conformance to industry standards Conformance to internal specifications Order completeness Accuracy of required documentation
Cost and Price	Price per unit Supplier management costs
Other Services	Design support Locally-based sales or technical staff

- Technology
- Responsiveness
- Quality
- Price and cost

While it’s easy to ask suppliers about their capabilities, it can be difficult to objectively determine whether a supplier can sustain the required performance and meet the needs of the business over the long term. This chapter provides a review of some of the more common methods used to

evaluate supplier processes and work products that will give the sourcing team more confidence in selecting a supplier.

Finally, many companies use a formal supplier qualification program that includes an AVL. Suppliers on the AVL are favored for new purchase orders, and teams may require special approval to use a supplier that is not on the AVL. This chapter describes some of the benefits that can be realized by both the supplier and the customer with such a program.

6.2 EVALUATING SUPPLIERS

It has become quite easy to find suppliers today by using standard Internet search methods. The Institute of Printed Circuits (IPC) maintains a database of member manufacturers and suppliers for both PCBs and PCAs with links to their respective websites. Suppliers will typically advertise their standard capabilities, and they often include their target markets and a list of some of their major, current customers. If the supplier is already working with customers in your market segment, then they should be familiar with the technology and quality requirements.

A supplier capability matrix is very commonly used to present the standard product and service offerings, and this can also make it convenient to quickly compare the standard offerings from different suppliers. Table 6.2 is an example of a capability matrix that uses readily available information from supplier websites, sales brochures, and other sources.

TABLE 6.2 Example of a Supplier Capability Matrix

Inner Layer Feature	Standard	Special/Premium
Minimum conductor width		
• 0.5 oz or 1 oz copper	0.1 mm (0.004")	0.075 mm (0.003")
• 2 oz copper	0.15 mm (0.006")	0.125 mm (0.005")
Minimum spacing width		
• 0.5 oz or 1oz copper	0.125 mm (0.005")	0.1 mm (0.004")
• 2 oz copper	0.15 mm (0.006")	0.125 mm (0.005")
Tolerances		
• 0.5 oz copper	±0.01 mm (0.0004")	
• 1 oz copper	±0.015 mm (0.0006")	
• 2 oz copper	±0.035 mm (0.0014")	
Copper foil thickness, 2-sided core	0.5/0.5 oz	2/2 oz with less than
	1/1 oz	0.15 mm conductor width
	2/2 oz	1/2 oz with less than
	1/2 oz	0.15 mm conductor width
Minimum pad size	Finished hole size +0.013"	Finished hole size +0.010"
Minimum plane clearance	Finished hole size +0.030"	Finished hole size +0.022"

A capability matrix may provide a quick way of determining whether a supplier should be considered further, but a supplier's advertising does not necessarily give a complete picture of how they will perform on a consistent basis. Wherever possible, sourcing teams should measure actual performance or audit processes to evaluate suppliers and substantiate marketing claims.

The following sections include recommended methods that can be used by sourcing teams to assess the capabilities of suppliers and ultimately select the ones that can best meet their requirements.

6.2.1 Technology

The simplest way to determine whether a supplier can provide a given set of technology requirements is by checking their advertised capabilities or sending a formal request for information (RFI) to the supplier. For a PCB the RFI should describe the dielectric material, surface finish, minimum conductor widths and spacings, minimum via diameter, essential tolerances, specific workmanship requirements or quality standards, and any other characteristics that are critical to the performance of the board. Similarly, for a PCA the RFI should specify single- or double-sided assembly, minimum component lead pitch, unusual components requiring manual placement, and lead-free requirements.

Note that for unusual, non-standard laminate materials and manufacturing processes it’s important to know how much experience the supplier has. If the supplier has limited or infrequent experience, there’s a greater risk of delay and quality issues. When the volume of work is low, a supplier will typically subcontract nonstandard technology to a nearby facility with specialized capabilities. In this case, the sourcing team should consider both *how long* the supplier has built production orders with the nonstandard technology, and *how often* they run these processes.

However, a match between the business’s technology requirements and a supplier’s advertised offerings does not guarantee a good long-term fit. This is especially true for requirements such as minimum conductor width that are dependent on a supplier’s ability to manage and control their

production processes. While it's standard for suppliers to perform 100 percent electrical test on all production units, a supplier with high first-pass yield will have lower costs due to less scrap and rework, and their boards will have higher reliability in the field.

Sourcing teams should consider whether to perform an objective, independent assessment of the supplier's ability to meet technology requirements over time, particularly for repeat orders of the same part number, or additional part numbers with similar requirements.

6.2.1.1 Two Common Techniques to Assess Suppliers' Technologies

1. Ask the supplier that's being considered to build a small quantity of boards using a new design. These "first articles" can be inspected, tested, and subjected to destructive analysis by the buyer's engineering team. Note, however, that it's very risky to add supplier evaluation to the development schedule for a new product.
2. Use a design that is already in production at a different supplier. This removes the schedule risk from new product development, and provides an opportunity to compare performance with a "known good" standard.

Unfortunately, both of these approaches have limited effectiveness because of the very small sample size. It's hard to draw general conclusions about long-term process capability from selective visual inspection or destructive analysis of a few boards.

The recommended alternative for evaluating PCB suppliers is the program described in the document IPC-9151D (May 2012) Process Capability and Relative Reliability ($PCQR^2$) Benchmark Test Standard and Database and at www.pcbquality.com. This methodology is based on test modules and procedures developed by Conductor Analysis

Technology, Inc. (CAT) and sponsored by the IPD-D-36 PCQR^2 Subcommittee. CAT has created 1- × 1-in test patterns that are arranged on a standard PCB panel (see Figs. 6.1 and 6.2) and are provided under license to IPC. These patterns include a range of conductor widths and spacings, via and pad diameters, soldermask clearances, and other design features.

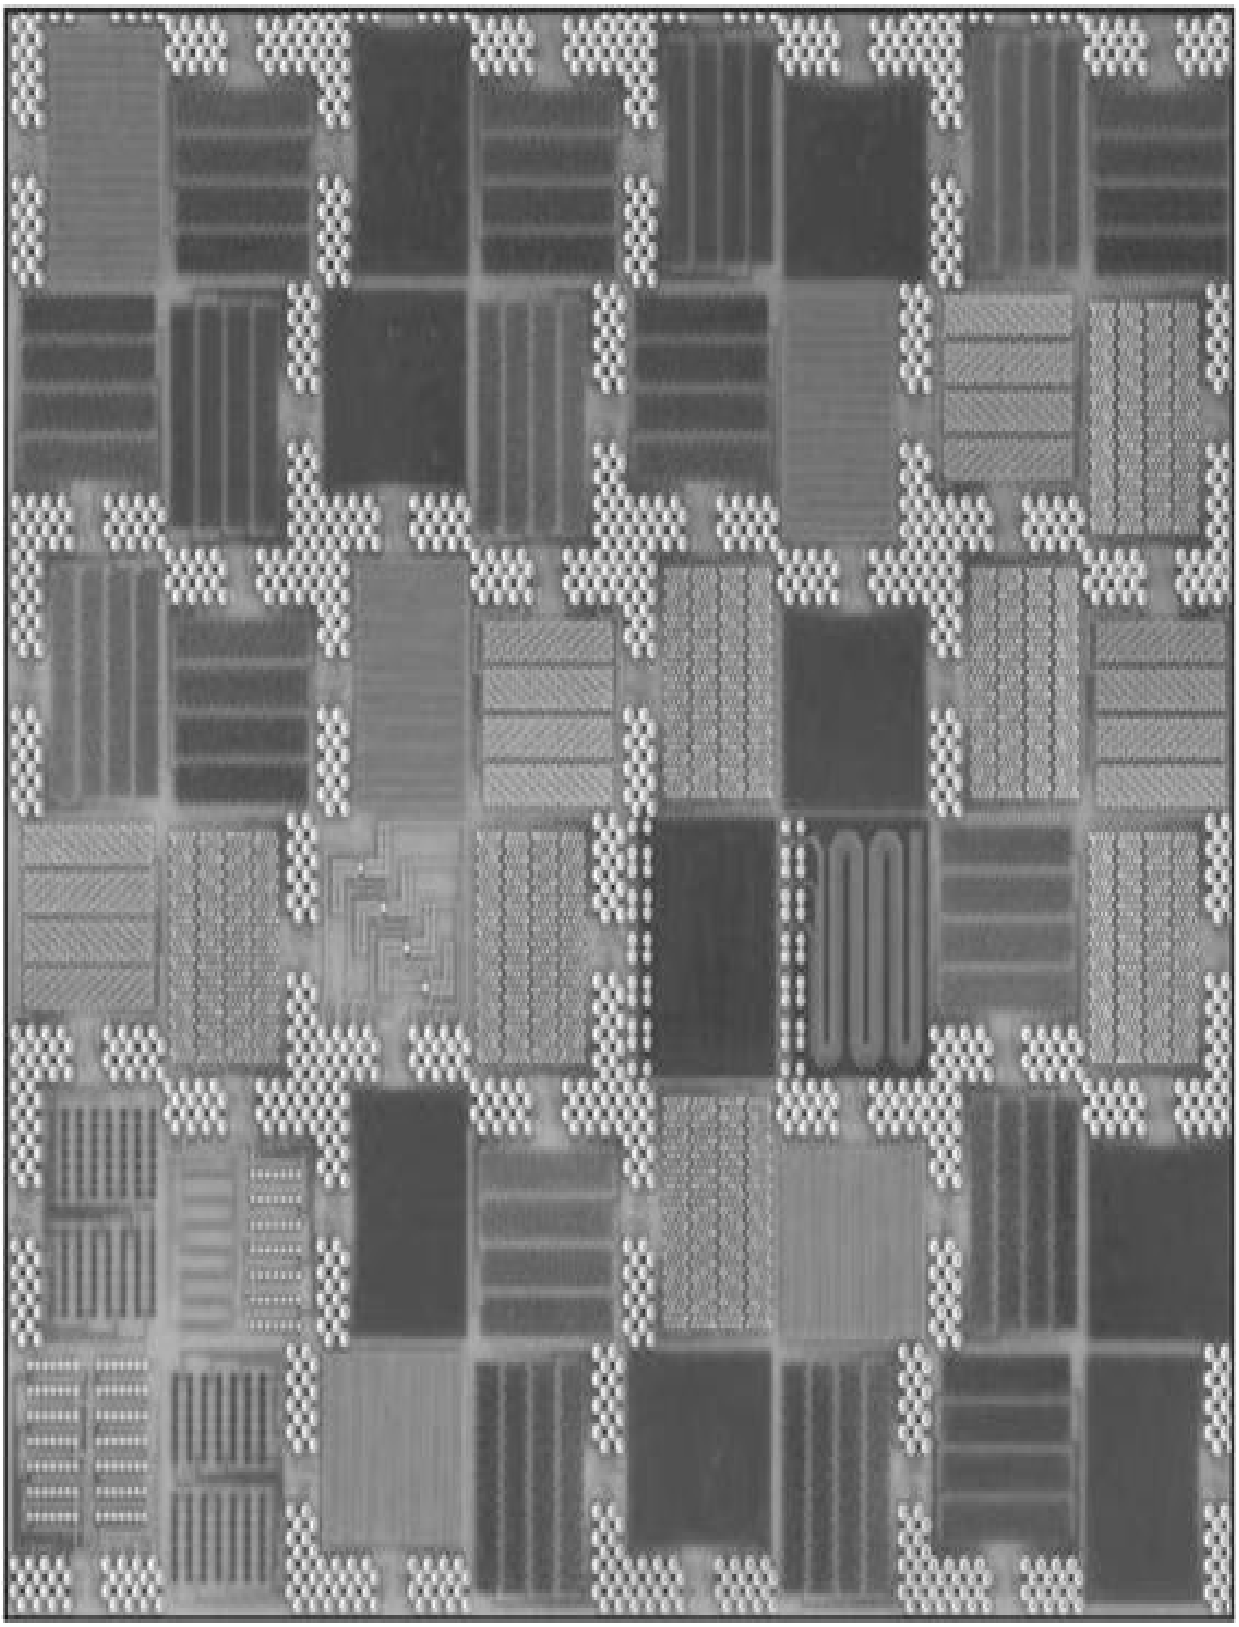

FIGURE 6.2 IPC-9151D PCQR2 benchmark design, full panel layout.

In this program, the supplier fabricates panels with the test patterns using artwork provided by CAT, and the panels are then submitted directly to CAT for testing using electrical measurements, optical analysis (including x-ray and cross-sections) and other techniques. CAT performs additional data analysis and adds the results to a shared database of supplier capabilities. The database, which includes the identity of the participating PCB suppliers, is available through an annual subscription from IPC.

The CAT analysis uses panel measurements to estimate defect density, predicted yields, and process capability. Figures 6.3 through 6.10 illustrate the range and detail of information that is available in the database.

FIGURE 6.9 Conductor height versus panel number.

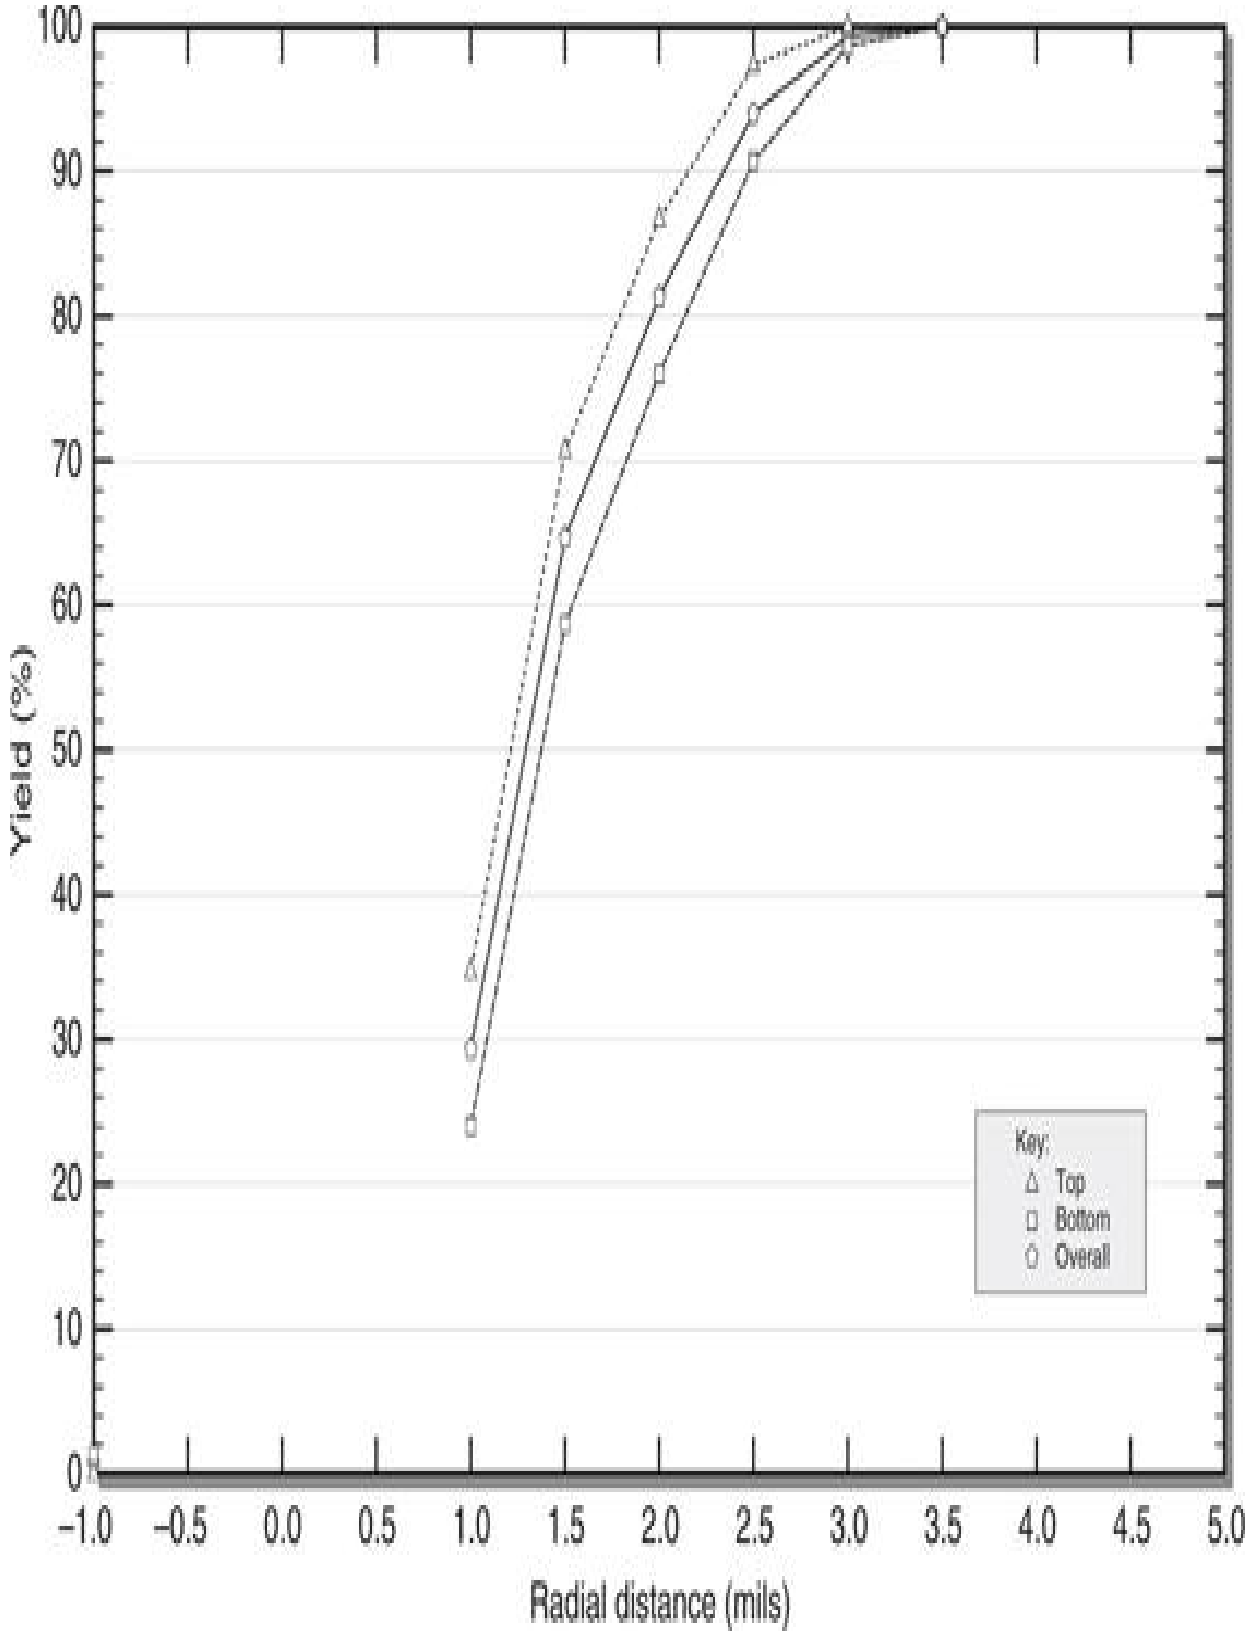

FIGURE 6.10 Conductor height versus panel number.

While it is possible for a company to create unique test patterns and conduct their own analysis, there’s tremendous value in participating in the IPC and CAT program. Database subscribers have the ability to review detailed results from individual suppliers and compare their capabilities across the industry. As of July 2014, a total of 72 PCB production facilities are included in the database, including suppliers in the US, China, Taiwan, South Korea, Canada, France, and Austria. Program subscribers include Dell, GE, Honeywell, Intel, Lockheed-Martin, Raytheon, and Sandia National Laboratories.

Because the test patterns are repeated over an entire panel, it is possible to collect a lot of data from a small number of panels (as few as 10) and produce statistically significant results. Subscribers can use the database not only to benchmark supplier capabilities, but also to establish design rules and guidelines for their board designers. The information provided by CAT can also be used to measure supplier performance improvement over time, and isolate specific production processes that need attention.

6.2.2 Responsiveness

It’s difficult to independently verify supplier claims about responsiveness characteristics such as percent on-time delivery and production order lead time. Generally speaking, however, the greater the geographic distance between the supplier and the customer, the greater the probability of transportation and logistics issues that will increase the variability of delivery time. Or, to put it a different way, delays are more likely when there are more hand-offs in the delivery chain, and these potential delays make it harder for anyone to accurately predict when a shipment will actually arrive.

Rather than simply accept the assurances provided by a supplier, sourcing teams can audit production and fulfillment processes to help determine whether the supplier can consistently meet the business's responsiveness requirements. Listed below are some questions that can be included in a supplier request for information (RFI) and verified during an on-site audit.

6.2.2.1 Responsiveness Questions for a Supplier

- Does the supplier have a dedicated outbound shipping department that handles bills of lading, customs, and other required documentation?
- Does the supplier have long-standing relationships with shipping and logistics service providers with experience delivering in your region?
- What contingency plans has the supplier used to help guarantee on-time delivery in case of shipment interruptions or delays?
- Does the supplier have a local or regional office that can monitor shipments from the factory and expedite as necessary? Can customers track shipments as well?
- What processes does the supplier use to facilitate fast turn production orders in the factory? How are expedited orders prioritized, tracked, and managed?
- How does the supplier manage design changes requested by the customer, including version control processes and disposition of work-in-progress?

The answers to these questions will lead to either greater confidence or greater concern regarding a supplier's responsiveness, and provide a basis to compare the likely performance of different suppliers.

6.2.3 Quality

Sourcing teams should only consider PCB and PCA suppliers whose quality management systems (QMS) have received an ISO 9001:2008 compliance certificate from an accredited external auditor. The certificate must be renewed at regular intervals, generally once every 3 years. The supplier should also be able to show evidence of recent internal audits of the quality management system. See Fig. 6.11.

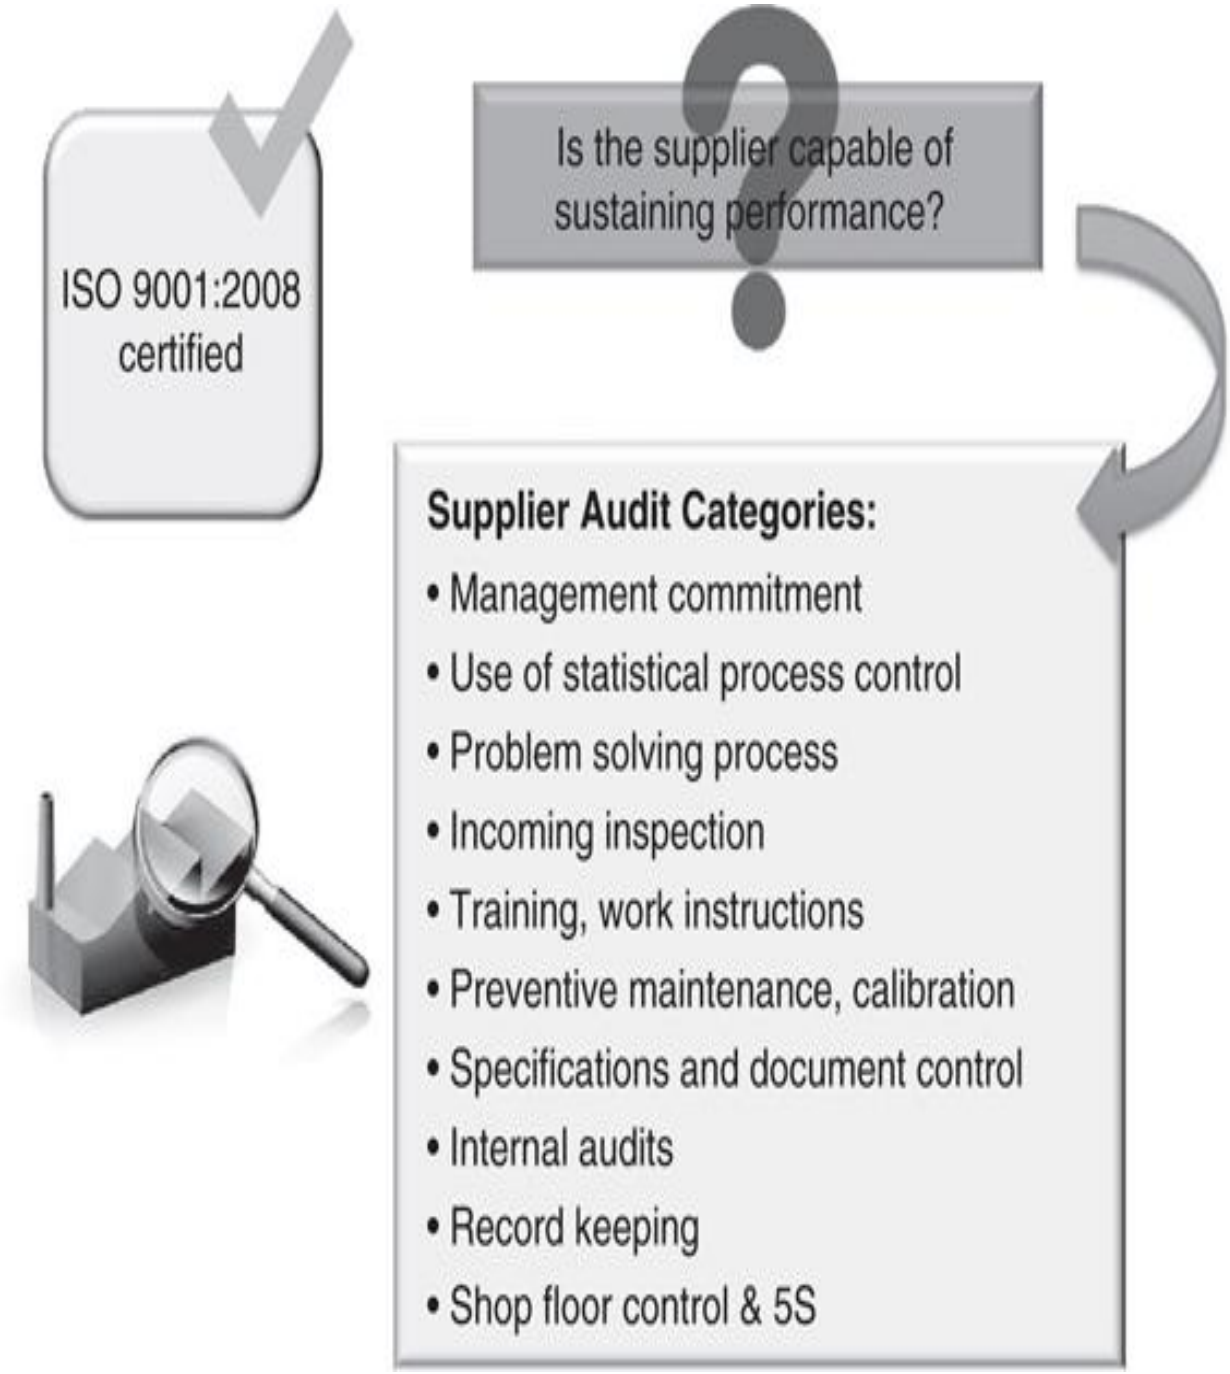

FIGURE 6.11 Supplier quality audit.

Potential customers can request a review of a supplier's QMS. It should include clear statements of commitment from the management team, and processes for traceability, communicating with customers, testing to confirm that a product meets customer requirements, control and

disposition of nonconforming product, and reviewing past results to support continuous improvement. The sourcing team should also inquire about the results and corrective actions from the most recent external audit, including nonconformities, observations, and opportunities for improvement.

The ISO 9001 certificate indicates that the supplier has a documented QMS that met the standard's requirements with no major nonconformities at the time of an external audit. However, because a company is unlikely to win business or contracts without the certificate, there is a risk that a supplier may be putting more emphasis on passing the audit than on sustaining quality performance over time. Also, the auditor only certifies that the processes in the QMS are being followed, but not whether following those processes actually ensures product quality.

While it is reassuring that PCB and PCA suppliers perform 100 percent electrical test on their finished products, and nothing should be shipped that does not pass, customers should nevertheless insist on sound operating processes that reduce the likelihood of nonconforming product. A higher first-pass yield means lower production costs for the supplier, which should in turn lead to lower price per unit. When the supplier's processes are capable and in-control, the PCBs and PCAs that do pass final test and inspection are better suited for downstream production and more reliable in the field. Chapter 7, "Process Control, Monitoring, and Incoming Inspection," provides recommendations for both customers and suppliers.

Sourcing teams should consider performing their own on-site audit to assess a supplier's internal processes and how they contribute to product quality (see Fig. 6.11). Some teams may prefer sending the supplier a request for information (RFI) with audit questions, but there is no substitute for a site visit and tour of the production facility, and the cost of the trip is a small price to pay for greater

confidence. Figure 6.12 is a sample agenda for a 2-day quality audit of a PCB supplier, and Table 6.3 shows some specific questions that might be asked during an inspection of the drilling operation.

FIGURE 6.12 Sample quality audit for PCB supplier.

TABLE 6.3 Sample Audit Questions: Drilling Process

- What is the inspection process for drill bits (incoming, repainted, and during use)?
- What is the frequency for repainting? When is the drill discarded?
- How is drill use and wear measured?
- What is the drill entry and back-up material?
- How are panels kept clean in the drill room?
- What are the temperature and humidity controls in the drill room?
- Are the drill machines isolated from vibration?
- Do the drill machines have isolated power and grounding?
- Is the actual rpm and feed rate independently determined?
- What is the inspection process for drilled holes? Test pattern? Cross-sections?
- How are accuracy and precision determined?
- Check the drill machine maintenance log
- X-ray verification after drill?

In addition to the audit, the sourcing team should ask the supplier to provide examples of their commitment to customer quality objectives. Figure 6.13 shows different levels of supplier quality maturity from the standpoint of the customer. A supplier who works on behalf of their customer is a valuable partner who helps reduce overall cost. This includes providing DFM feedback to the customer's design, proactively warning the customer of potential quality issues, preventive action to eliminate the root cause of problems, and a focus on process management and control instead of testing and inspection.

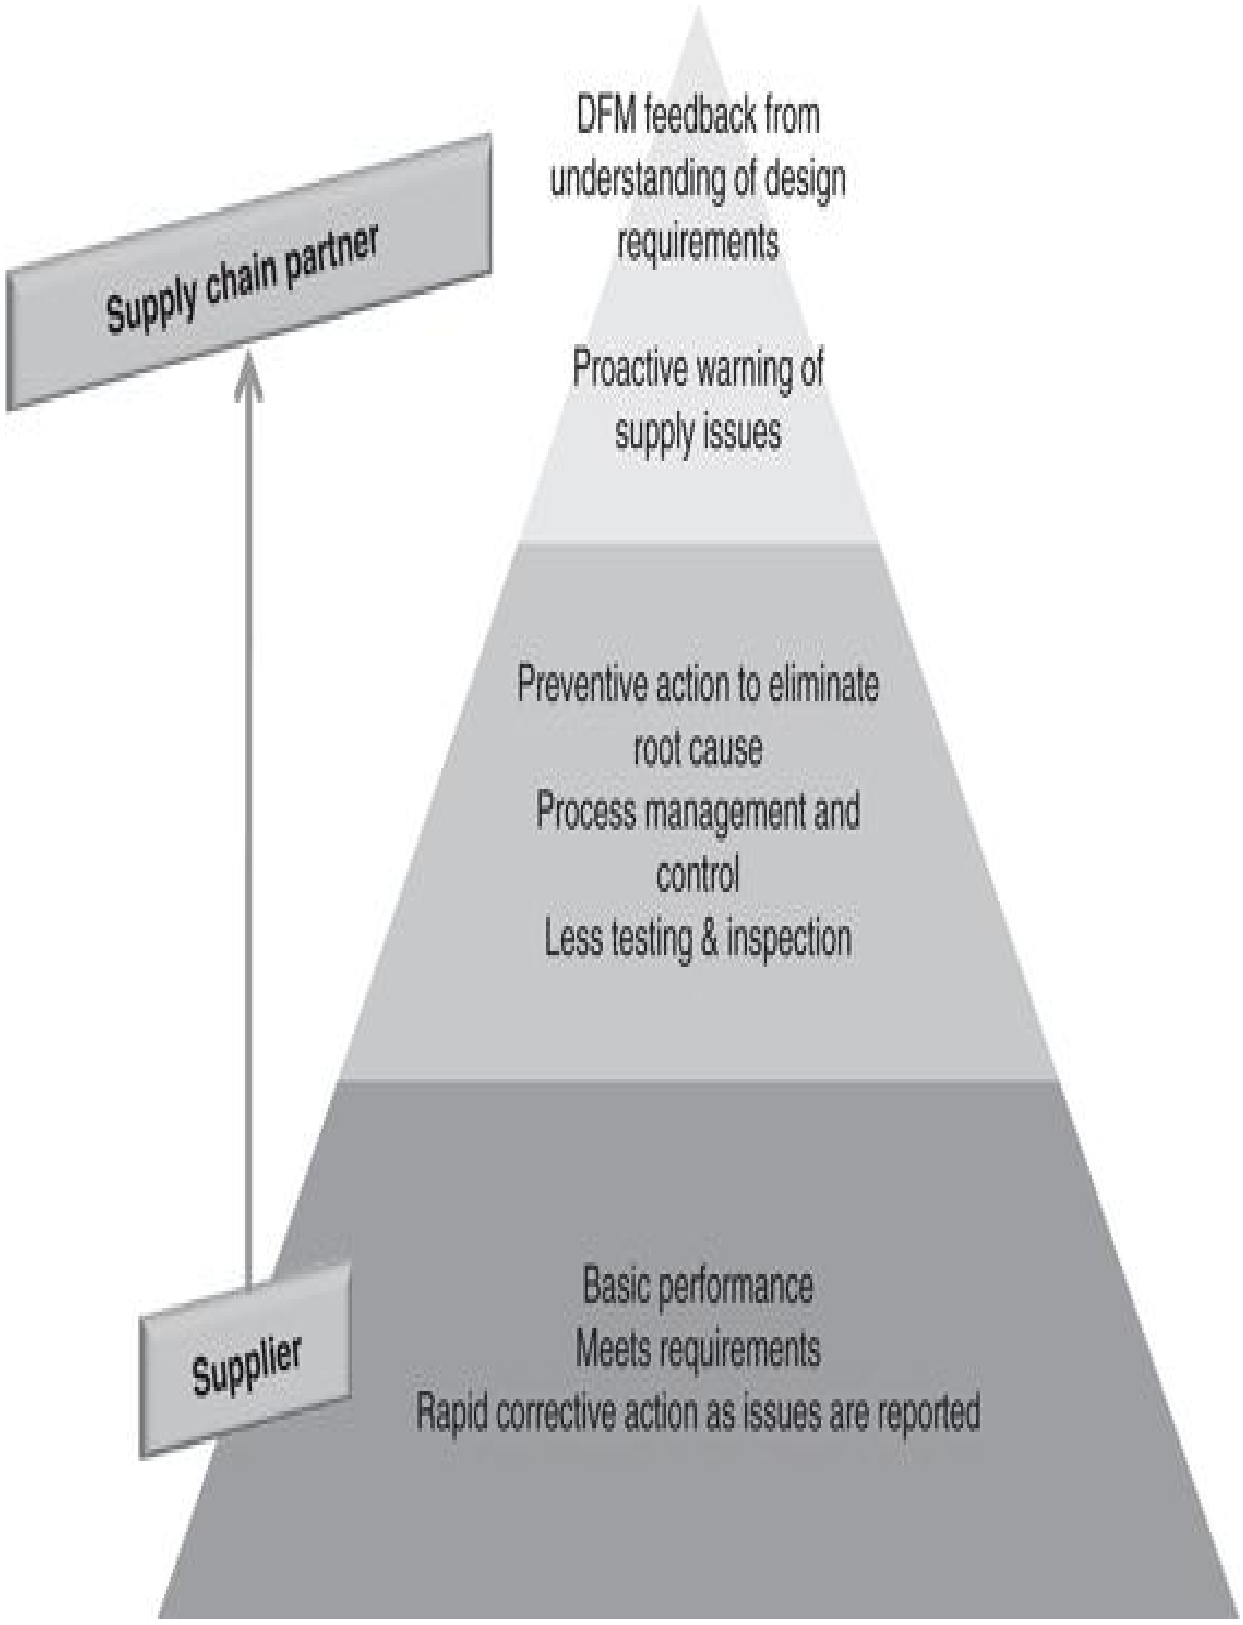

FIGURE 6.13 Supplier quality maturity model.

Depending on the final service environment for the finished PCA, the engineering design team may require that PCB and PCA suppliers routinely submit test results from coupons subjected to accelerated service life conditions and destructive analysis. Of course this can also be used to evaluate the processes of a new supplier. There are many coupon systems that can be used for reliability testing of PCBs. Most of these designs use daisy-chained vias since these sites usually provide the greatest risk of failure. The coupons can be arranged on test panels that are fabricated at the supplier and later subjected to conditioning and thermal stress before they are evaluated using destructive or nondestructive methods.

6.2.3.1 Typical Test Procedures for Coupons

- Normal and accelerated thermal cycling
- Thermal shock
- Surface insulation resistance
- Resistance at high humidity
- Solderability
- Peel strength
- Glass transition temperature
- High pot testing

Note that many suppliers can provide reliability test results from their own in-house testing or from independent laboratories.

6.2.4 Cost and Price

Unlike the other dimensions of supplier performance, PCB/PCA price is an objective and measurable characteristic that is relatively easy to obtain and easy to compare from one supplier to another. Sourcing teams can send a request-

for-quote document, or RFQ, that includes details about the board design, order quantity, standard or rush delivery options, quality expectations, documentation requirements, and any other information that the supplier may need to prepare an estimated price, or bid. If multiple suppliers are presented with an RFQ at the same time, their replies provide a useful basis for comparison.

Unfortunately there are caveats and limitations to RFQ responses:

- A price quote from a supplier is usually only valid for a specific period of time, typically 30 days or less. The actual board price when the production order is placed may be higher than the earlier RFQ response, and may in fact change from one order to the next over the life of the design, unless the supplier has agreed to a contracted price.
- While PCB/PCA price is based on the supplier's internal cost, it can vary depending on how badly the supplier wants the business. A supplier may quote more aggressively in order to help fill their factory and improve asset utilization, or attract a high-profile customer.
- The overwhelming majority of PCB and PCA suppliers use basically the same manufacturing processes for production orders, and it's unlikely that price differences between suppliers for the same design are due to some underlying breakthrough in process cost or yield, particularly for suppliers in the same labor market.

Note that although it's tempting to always choose the supplier that offers the lowest price, "leaving some money on the table" makes it much more likely that a supplier will be cooperative and responsive. PCB and PCA suppliers typically operate with very small profit margins and may not be very accommodating or flexible with a customer who has already won significant price concessions.

The sourcing strategy team should also consider the total cost of supplier management when comparing prices. A supplier who offers the lowest price per unit may require a disproportionate amount of attention from internal purchasing and engineering departments due to documentation errors, quality problems, or inconsistent delivery performance. This added cost-of-management is often overlooked and can be hard to measure, but it effectively increases the price per unit and is a very common reason for switching suppliers. While these costs are difficult to anticipate at the beginning of a new relationship with a supplier, they should be included in routine supplier performance reviews (see Chap. 8, “Product Acceptance and Feedback”).

6.3 SUPPLIER SELECTION

The results from the testing of sample boards, site audits, RFIs, and RFQs are all important inputs for comparing suppliers and determining how likely they are to perform consistently over time. Figure 6.14 shows a suggested sequence of steps for collecting and evaluating these inputs.

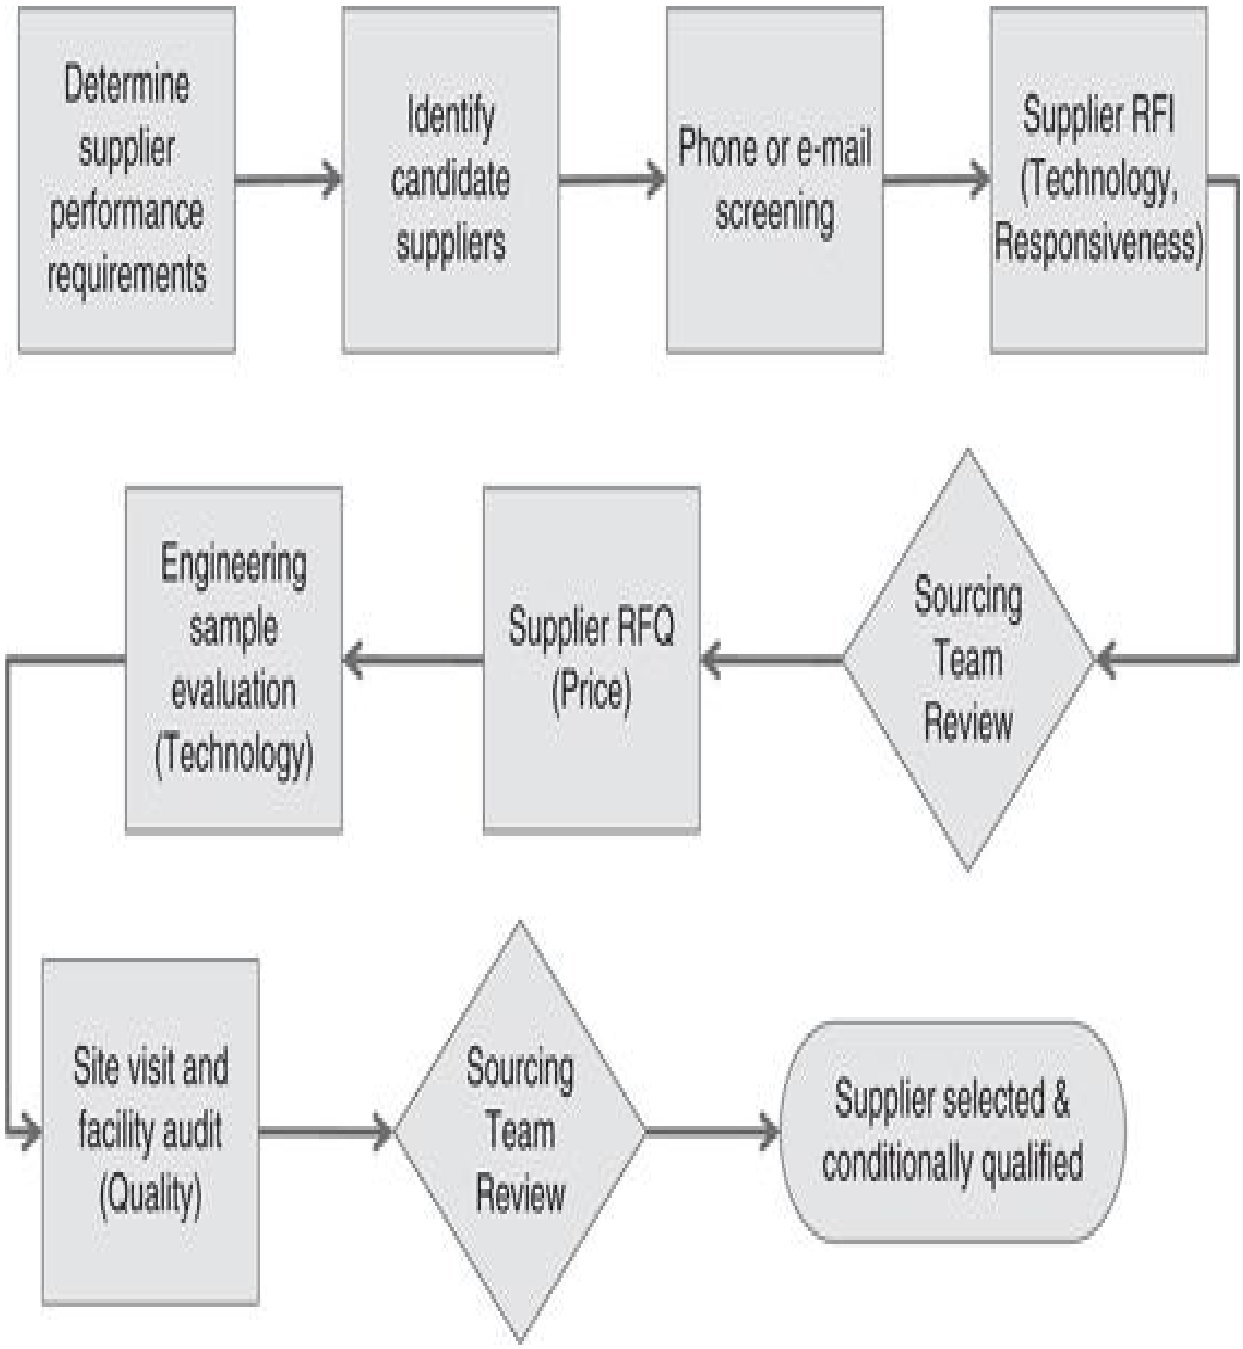

FIGURE 6.14 New supplier selection and qualification process.

It may seem that the best supplier is the one that provides the best overall combination of performance across all categories. However, the sourcing team should base their recommendation on the specific needs of the business that have been weighted to indicate relative importance. See Fig.

3.10 for an example. The more information that the sourcing team can obtain from stakeholders regarding what the business requires and the relative importance of each factor, the more likely that the best supplier will be chosen.

Some suppliers may be eliminated from further consideration because they cannot provide a “must” requirement. The remaining suppliers can be evaluated using a weighted criteria or similar decision-making process that applies factors to a qualitative ranking of each supplier’s assessment. Table 6.4 illustrates this technique.

TABLE 6.4 Supplier Selection Criteria Weighting Example

Selection Criteria	Must Requirement?	Relative Weight	Supplier A Rating	Supplier A Weighted	Supplier B Rating	Supplier B Weighted
Technology						
• Standard FR-4 laminate	Yes		Yes		Yes	
• Minimum conductors 4 mils	No	2	3	6	5	10
• Minimum via diameter 12 mils	No	4	3	12	5	20
• Pb-free surface finish	Yes		Yes		Yes	
Responsiveness						
• 6 week lead time for production	No	3	4	12	3	9
• 0 days late, no more than 3 days early	Yes		Yes		Yes	
Quality						
• 100% opens/shorts testing	Yes		Yes		Yes	
• Defective boards returned to supplier	Yes		Yes		Yes	
Cast and Price						
• No more than $X per square inch	No	5	2	10	1	5
Other Services						
• Prototypes within one week	No	2	2	4	4	8
• Local sales and technical support	No	4	5	20	4	16
TOTAL WEIGHTED SCORE				64		68

6.3.1 Techniques for Evaluating Suppliers

- In this case both Supplier A and Supplier B meet all of the "must" requirements and will be evaluated further.

- The sourcing team has used information gathered from their technical evaluations, RFIs, RFQs and on-site audits to give the two suppliers a qualitative rating for each of the remaining selection criteria.
- The weighted score for each supplier is obtained by multiplying the qualitative rating by the relative weight previously determined (based on the importance to the business).
- The total weighted score is the sum of the individual weighted scores for each selection criteria. Supplier B has a slightly higher score because it provides a better fit to the business requirements.

6.4 SUPPLIER QUALIFICATION

A supplier who has been selected for a specific purchase order is typically placed on a company's approved vendor list (AVL). Because the sourcing team has already evaluated the suppliers on the AVL, they are generally preferred for future business. Companies often have policies that restrict the use of non-AVL suppliers without explicit management approval. AVL suppliers are easier to do business with because they are already familiar with the customer's requirements and documentation. This means they are less likely to have quality issues because of errors or misunderstandings. Since they have more experience with the customer's designs, AVL suppliers are also better able to offer DFM feedback that will reduce cost and increase first-pass yield.

6.4.1 Additional Considerations

- Supplier selection is usually determined by the capabilities and performance of a factory at a single

location. If the supplier proposes to transfer production to a different location with different physical processes, operators, and management team, the sourcing team should reevaluate.

- The steps described in this chapter can be used by the sourcing team to choose suppliers that are likely to perform well and meet the needs of the business. However, additional steps should be taken to qualify and approve production of a **specific part number** by an approved supplier. Chapter 8 provides guidelines for design qualification, lot acceptance and ongoing inspection.

In addition to the AVL, some companies have a more formal qualification program that provides additional benefits for preferred suppliers. Because of their consistently high performance, these suppliers are identified as strategic partners who have an important role to play in the overall value delivery system.

A preferred supplier may receive better pricing and payment terms, participate in long-range capacity planning, and collaborate with the customer's design and engineering teams. Other benefits for a preferred supplier include an advertised relationship with a well-known customer (especially valuable for smaller suppliers), and predictable and consistent demand for better asset utilization. For the customer, a preferred supplier can help reduce inventory and testing costs, and enable faster time-to-market by rapid qualification of new part numbers.

Finally, it should be remembered that supplier capabilities and performance can change over time, as can the technology and business needs of the customer. Sourcing teams should routinely audit and assess qualified suppliers to ensure that they are still able to meet the technology, responsiveness, quality and cost requirements. Suppliers should also be given regular feedback on their performance,

and encouraged to address areas of concern and proactively implement improvements. Chapter 8 includes recommendations for long-term supplier management.

CHAPTER 7

PROCESS CONTROL, MONITORING, AND INCOMING INSPECTION

Tim Rodgers
University of Colorado, Boulder, Colorado

7.1 INTRODUCTION

Chapter 6, “Supplier Selection and Qualification,” provided detailed recommendations for a printed circuit board (PCB) or printed circuit assembly (PCA) sourcing team to evaluate alternate suppliers and choose those that best meet their business needs. If the supplier is only required for a single purchase order or transaction, then the team can immediately shift their focus to design qualification and lot acceptance, which is described in Chap. 8, “Product Acceptance and Feedback.”

However, if the relationship with the supplier is expected to continue over an extended period of time that includes multiple purchase orders and part numbers, the sourcing team should understand whether the supplier has the

production processes and management systems to *sustain* the required performance with a minimum of oversight. This chapter includes information that can help a sourcing team assess a supplier's processes and determine the likelihood of consistently receiving PCBs or PCAs that conform to the design requirements.

There may be several testing or inspection steps in the overall supply chain for a product that contains electronic assemblies (see Fig. 7.1). PCBs are typically visually inspected before they are loaded with components, and the PCAs may be inspected again before being assembled into the final product. Functional testing of the final product before shipping often detects defective PCAs. Some production designs may include accelerated reliability testing for a sample of the finished products. However, it's important to find defective or nonconforming parts as early as possible, and ideally prevent them from being produced in the first place.

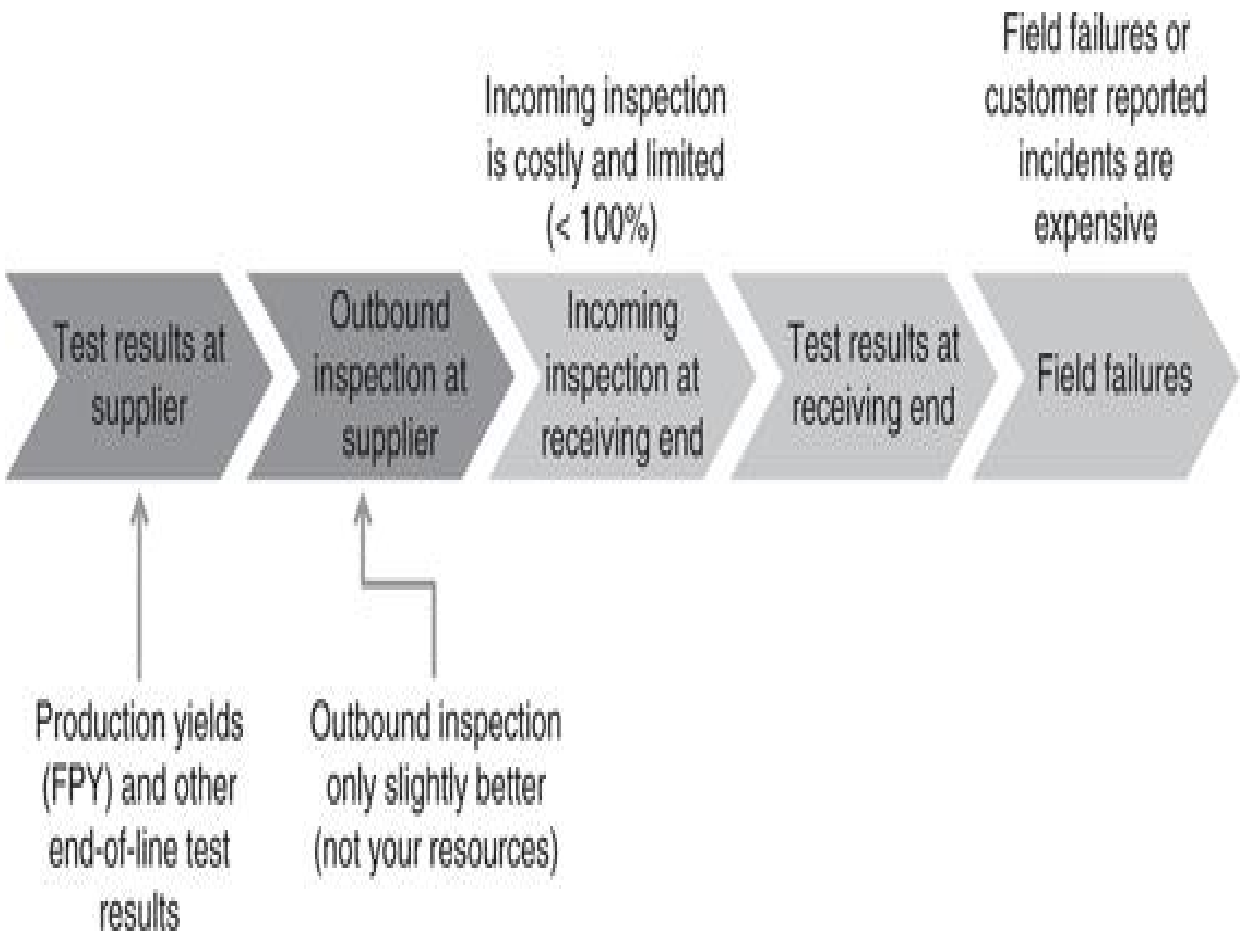

FIGURE 7.1 Quality checks at supplier and receiving end.

Figure 7.2 illustrates the relative cost of finding defects through the PCA supply chain. When defective PCAs are found during final assembly, the engineering, manufacturing, and quality teams must consider whether to scrap or rework by replacing components, which adds significant cost and possibly delays production. Defective PCBs that are found before component loading are somewhat less costly, but manual rework by cutting traces or adding jumpers adds a reliability risk, and scrap PCBs have become a major worldwide environmental concern.

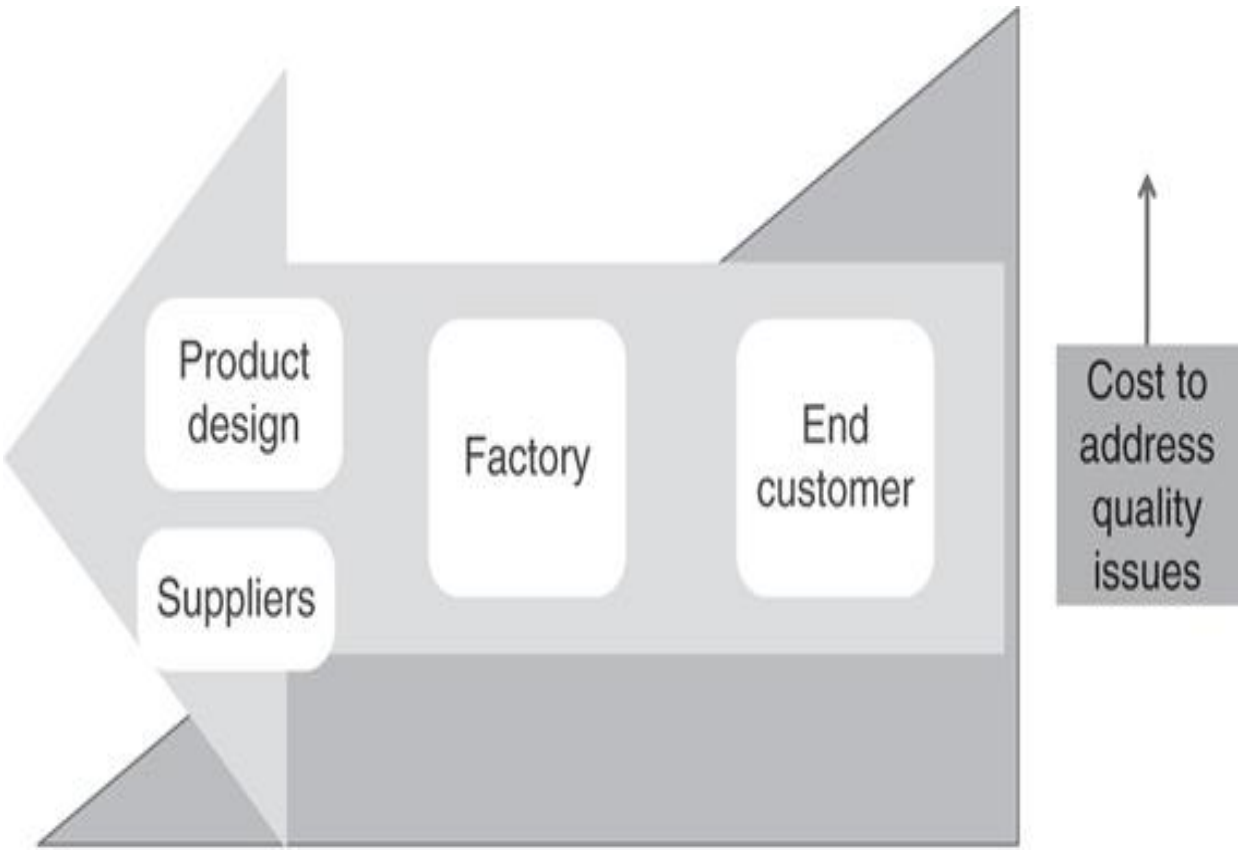

FIGURE 7.2 Improving quality at the supplier.

Because of these added expenses, and the risks to production schedules, long-term reliability, and environmental stewardship, businesses should insist that their suppliers do everything possible to prevent shipping nonconforming parts. Sourcing teams should routinely monitor their suppliers' ability to manage and control their production processes.

7.2 PROCESS CAPABILITY AND PROCESS CONTROL

A supplier will routinely subject 100 percent of their PCBs or PCAs to continuity testing ("opens and shorts"), and PCAs may also have to pass functional testing before shipment.

Any PCB or PCA that fails this testing may be scrapped or reworked, depending on the authorization given by the customer. Suppliers typically report first-pass yield (FPY) before rework as an indicator of the overall performance of their production processes.

A supplier with a low FPY can correctly claim that all of their shipped boards pass testing; however, this is an indicator that the supplier's processes are fundamentally less able to deliver conforming product. This requires the supplier to start more panels in order to complete their order, and figure out what to do with the boards that failed, both increasing their costs. Low FPY also suggests the possibility of lower long-term reliability for boards that pass continuity testing before leaving the factory, but are susceptible to failure after field use or environmental exposure, especially for narrow conductor widths and spacings.

In addition to passing continuity testing or functional testing, there may be other characteristics of the PCB or PCA that are critical to the performance of the final product.

7.2.1 Characteristic Performance for the Product

- Board width and length
- Pad height
- Plating thickness
- Through hole diameter and location relative to a datum
- Fiducial location relative a datum
- Trace impedance

The sourcing team should consult with electrical engineers, PCB/PCA designers, and downstream production engineers to identify the critical performance parameters (CPPs) for the

finished board or assembly. Often critical-to-function or critical-to-assembly dimensional requirements and tolerances are explicitly called out on CAD drawings that accompany the design. The performance of a supplier is determined by how well they can consistently deliver boards or assemblies that not only pass continuity or functional testing, but also meet the CPP requirements.

To understand the role that suppliers play in meeting the CPP requirements, it's necessary to review some of the basic concepts behind statistical process control, process capability, and the six sigma methodology for process improvement.

If a physical process is repeated many times and the output of the process is measured, the results are often found to follow a normal distribution, commonly referred to as a bell curve (see Fig. 7.3). This distribution of the process outputs can be described by the mean, or average of the measured values, and the standard deviation, which characterizes the variability of the distribution. The mean and standard deviation are usually taken to be fundamental characteristics of the process, also known as statistics of the *population* of an infinite number of outputs. The mean and standard deviation of a subset of measured outputs are statistics of a *sample* from that population, and are used to approximate the population statistics. The more samples are taken, the better the approximation.

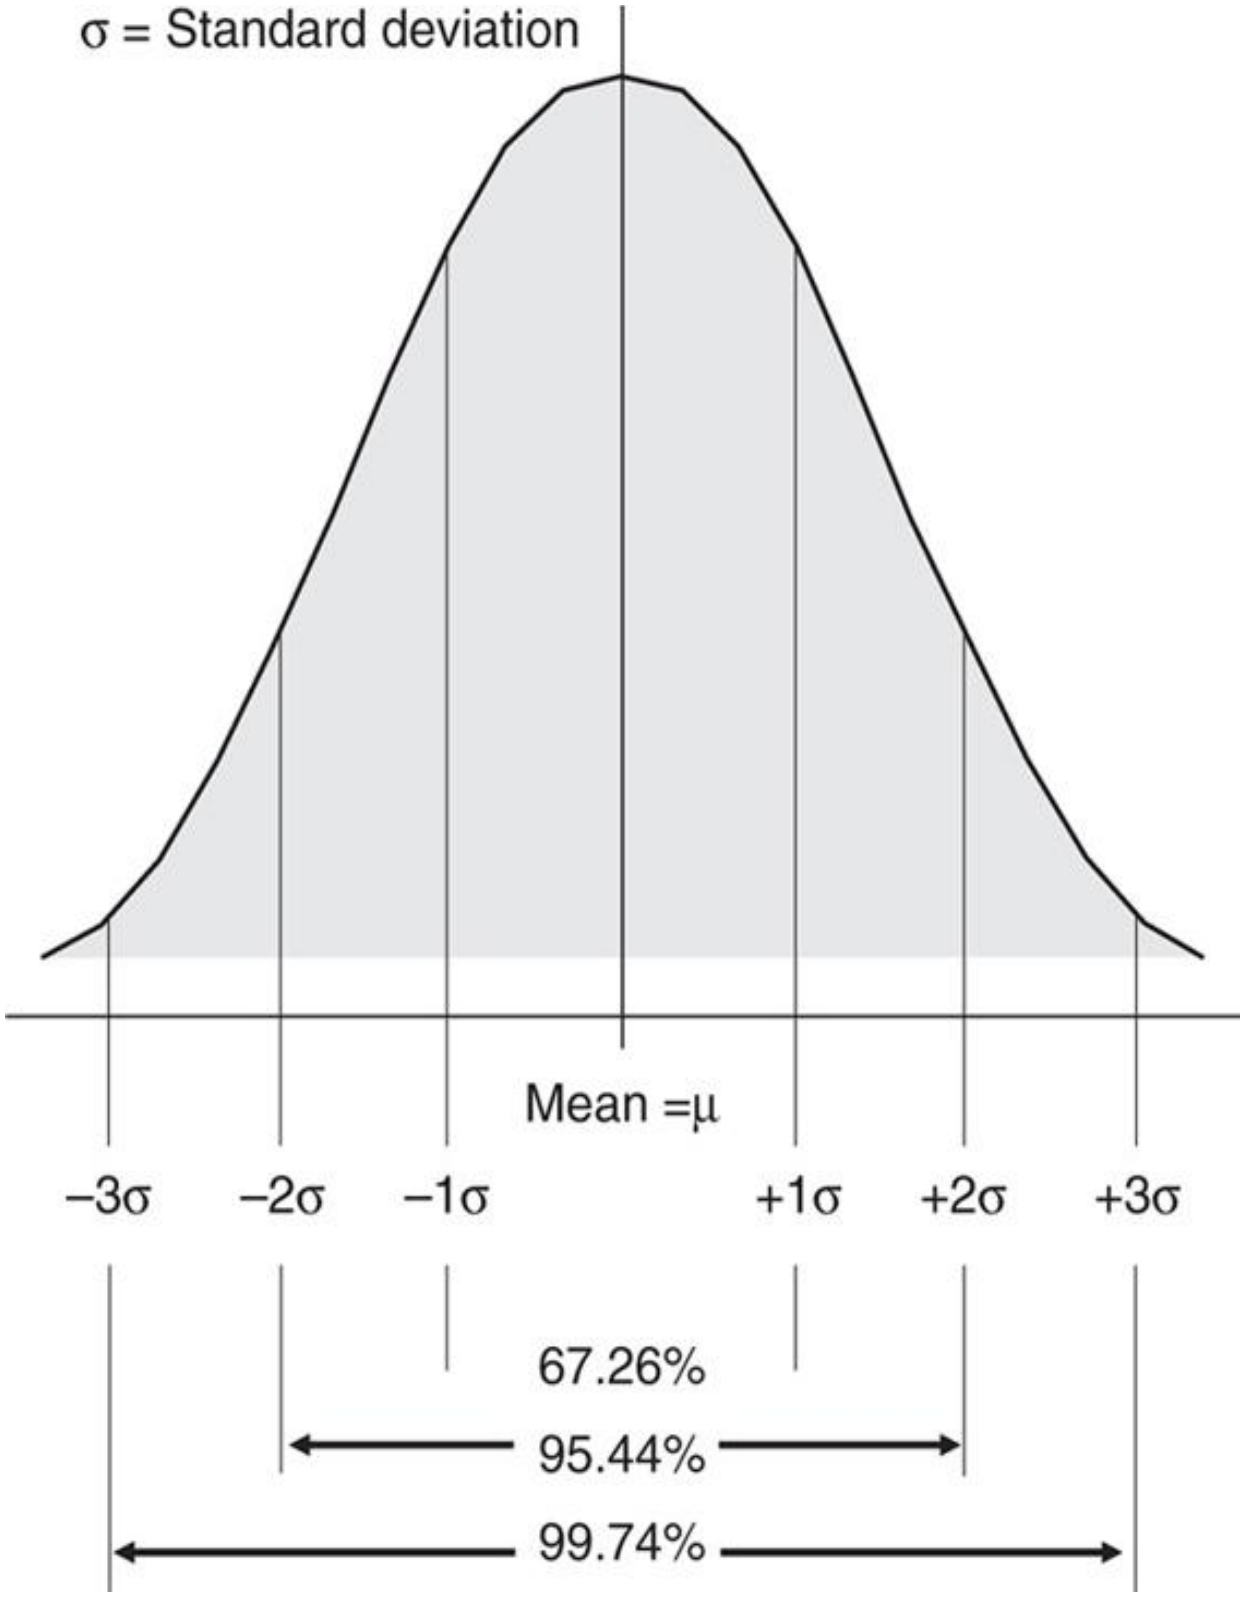

FIGURE 7.3 Normal distribution.

The distribution is valuable because it shows the probability of a particular output occurring. For example, there's a 67.26 percent probability that the output will occur within 1 standard deviation above and below the mean, and a 99.74 percent probability that the output will occur within 3 standard deviations from the mean.

The normal distribution model assumes that the output is determined only by the inherent randomness of the process itself, which is referred to as the *common causes* of variability. *Special causes* are events that are external to the usual, expected functioning of the process. When special causes are present, the process output may not follow any expected pattern or distribution and are unpredictable. A process that is governed only by common causes is said to be "in control" and provides outputs that can be predicted using the process mean and standard deviation. A process with special causes is "out of control."

Some suppliers may use a monitoring tool called a *control chart* to determine whether a process is in control (see Fig. 7.4). A control chart plots the average of a sample of measured outputs collected over a period of time. If only common causes are present, these data points will be randomly distributed on either side of the process mean. A data point that falls outside the control limits is considered to be an unexpected and very low-probability event for a process that is governed only by common causes. This indicates the presence of special causes that must be identified and eliminated in order to bring the process under control. Note that there are other low-probability events and patterns in the control chart that indicate special causes. Figure 7.5 shows several examples of special causes that may be present in a typical factory environment.

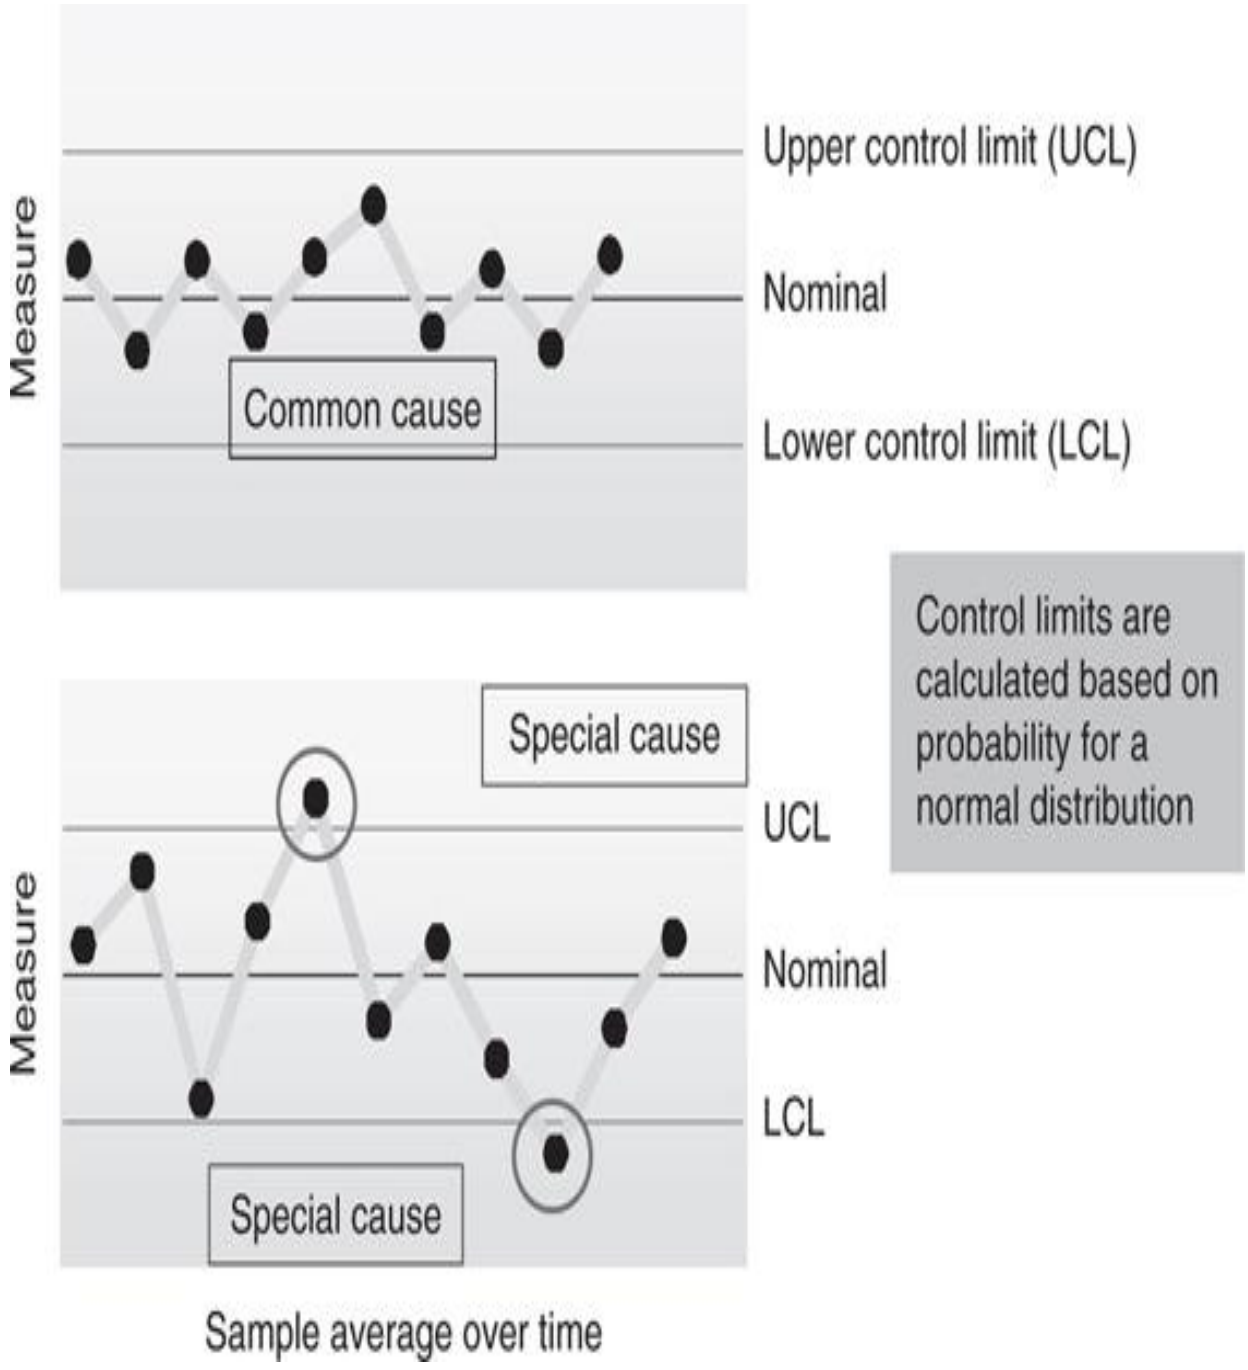

FIGURE 7.4 Process control chart example.

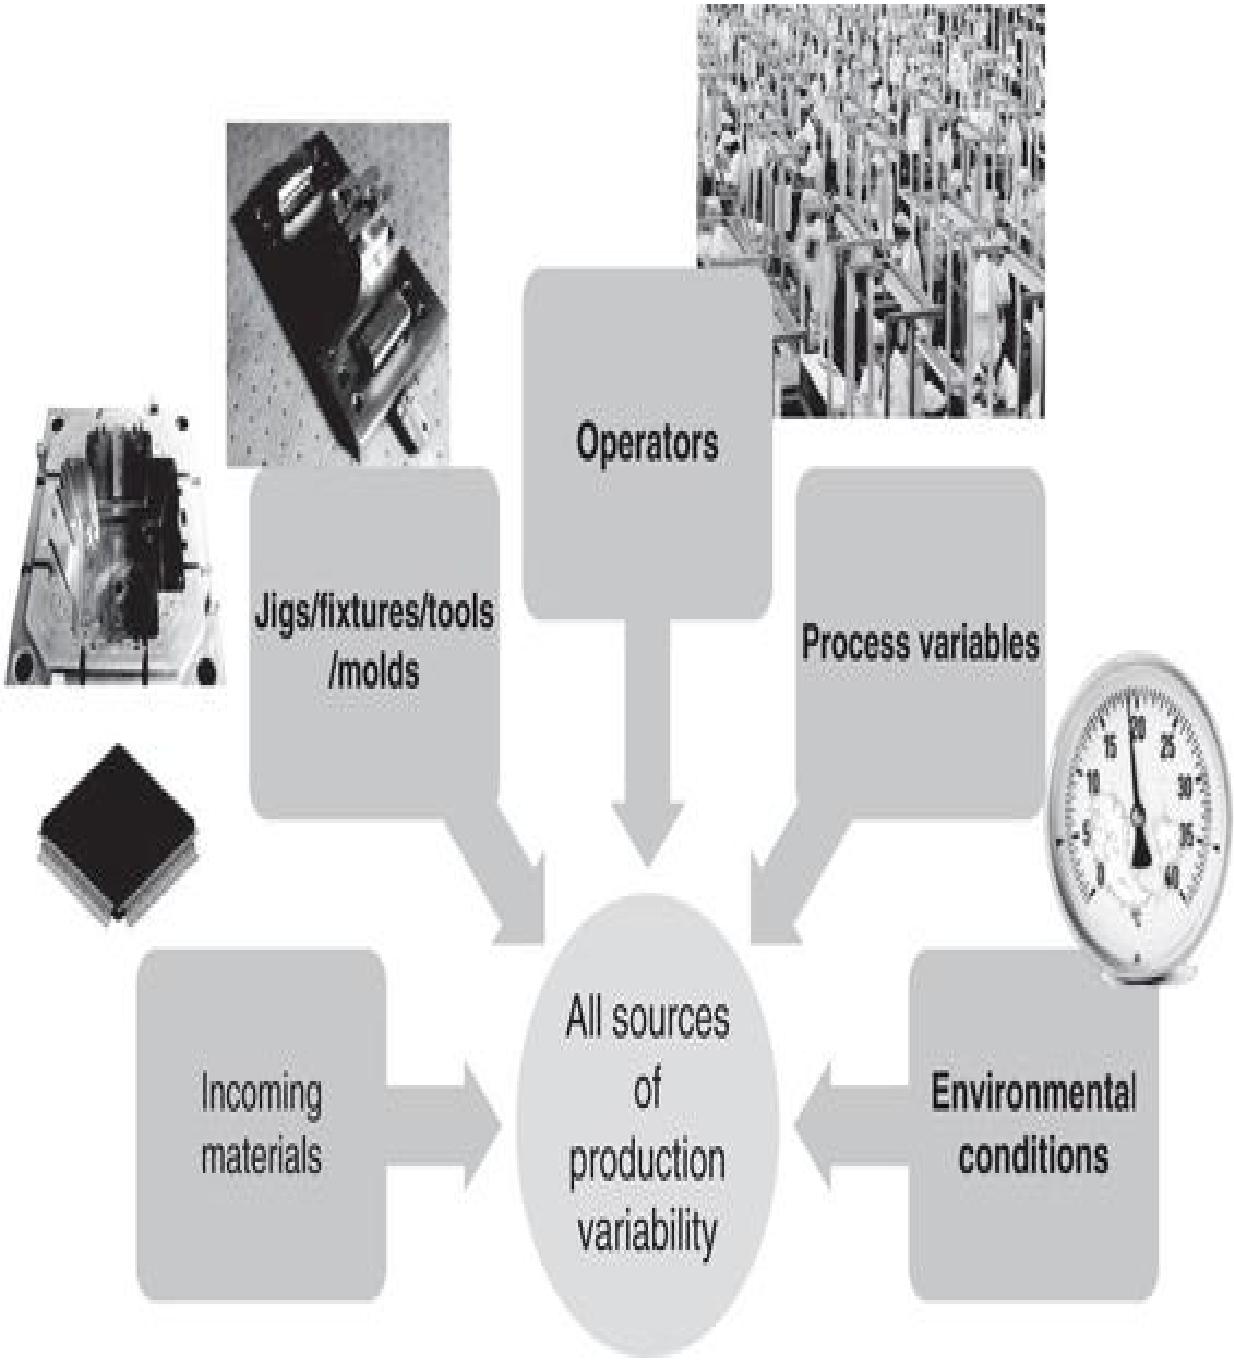

FIGURE 7.5 Special causes in a factory environment.

Obviously both the customer and the supplier benefit from manufacturing processes that are in control and provide predictable outputs. However, a process that is in control does not necessarily produce outputs that meet the customer's requirements. Suppliers often use *process*

capability studies to determine the probability of producing nonconforming parts. These studies use a sample of process outputs to create an estimated distribution, then compares that distribution to the specification limits defined by the customer (see Fig. 7.6). The most common process capability metric is C_{pk}. If the C_{pk} is 1.0 or greater, this means that there is a 99.73 percent probability that a process output will be within the defined specification limits. Or, to say it a different way, there is a 0.27 percent chance that the output will be outside the specification limits. Note that a six sigma process has a C_{pk} of 2.0 or greater, which corresponds to only two nonconforming parts per billion.

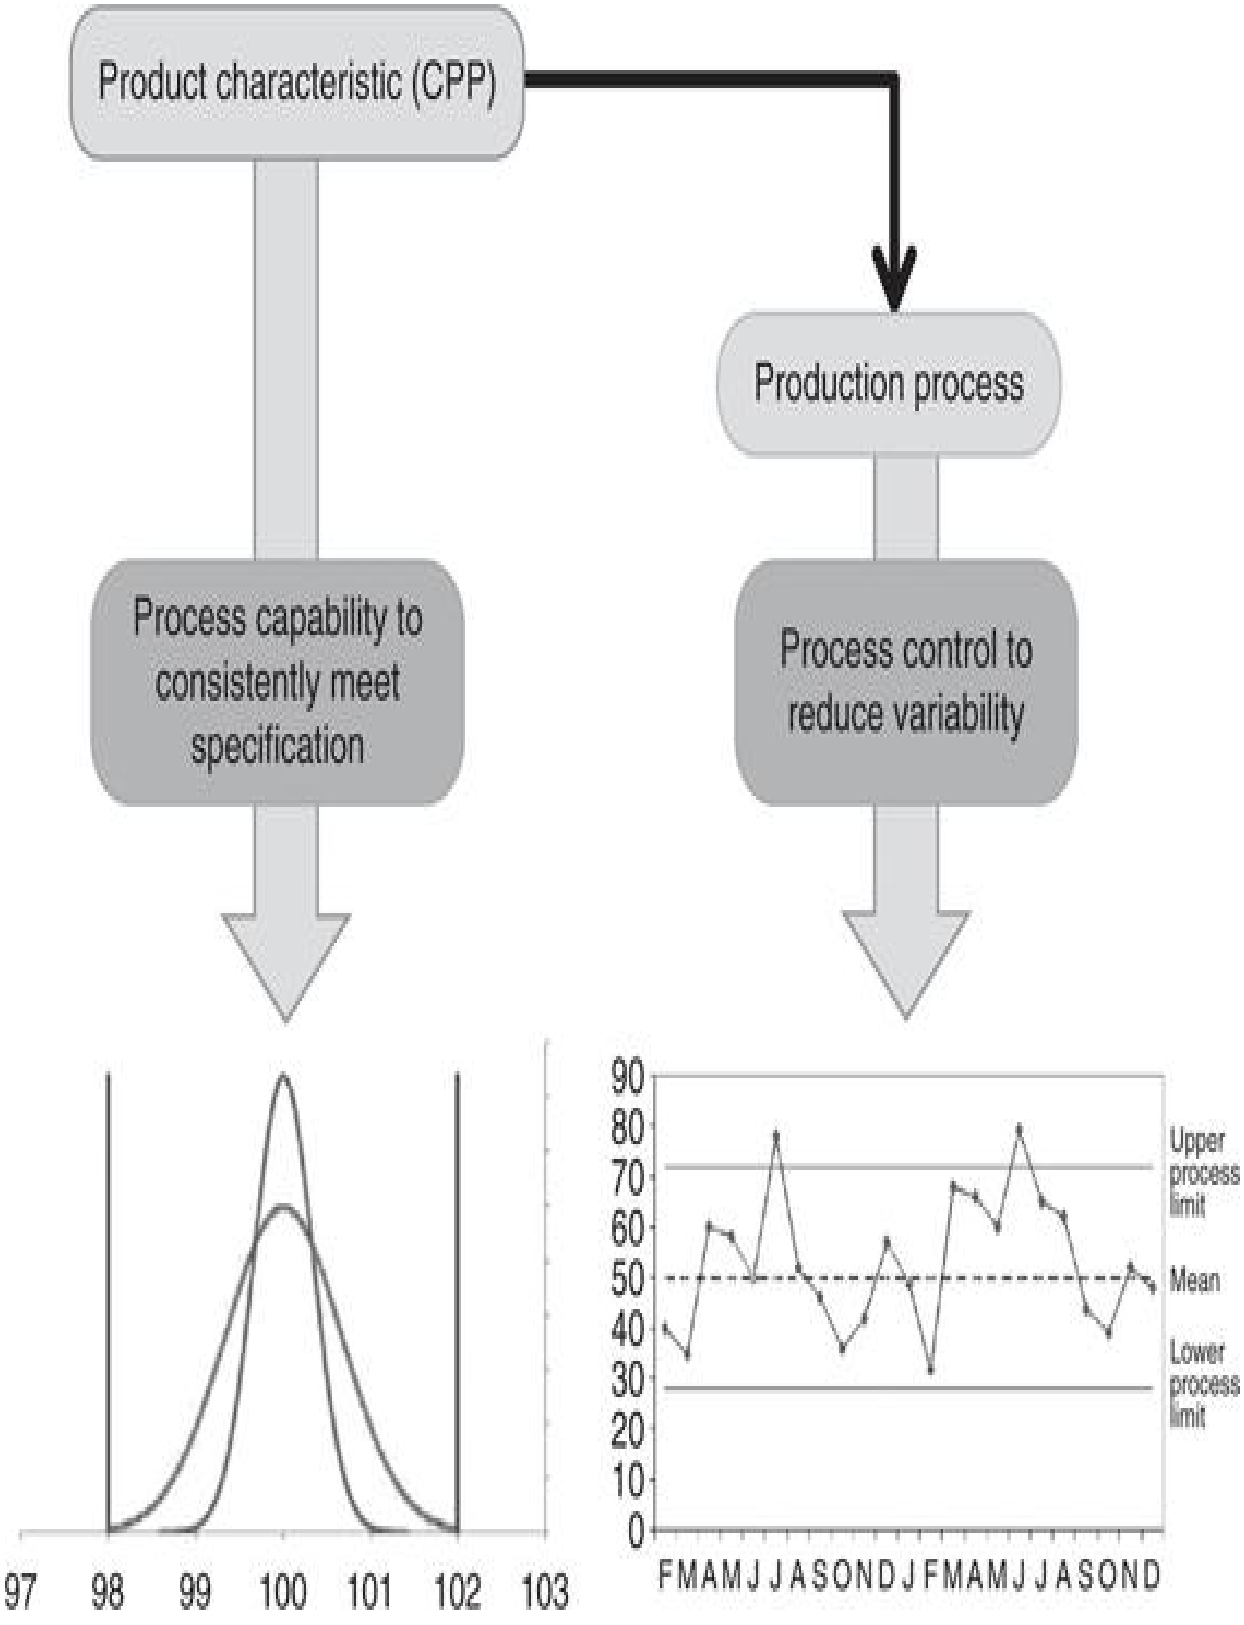

FIGURE 7.6 Process capability index.

After the sourcing team has identified the CPPs and their specification limits, they should ask the supplier to perform a process capability study to determine how well the production facility can meet those requirements, and how many nonconforming parts are predicted for a given lot size. Depending on the result, it may be necessary to implement short-term testing or inspection until the supplier can improve the process capability and reduce the probability of nonconformance.

A supplier may be able to improve process capability by either shifting or “centering” the process mean, or reducing the variability of the process. However, before making any change to the process to improve its performance, the supplier should verify that the process is in control, and eliminate any special causes (see Fig. 7.7).

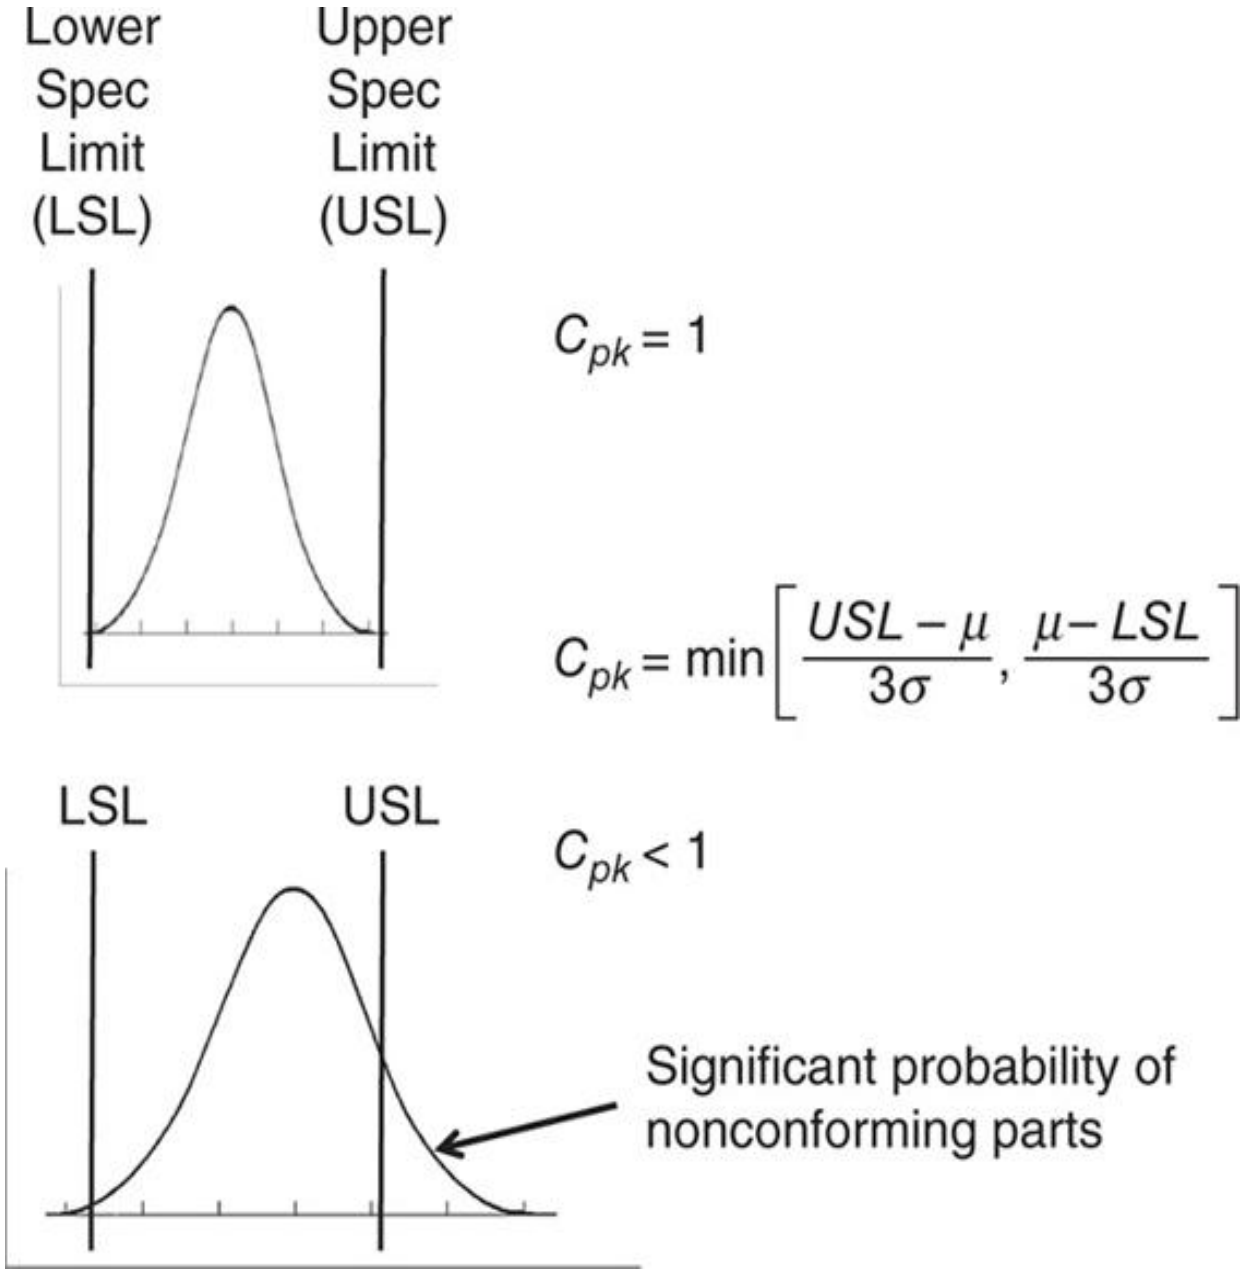

FIGURE 7.7 Process capability and process control.

7.3 PROCESS MONITORING AND TROUBLESHOOTING

A supplier and the sourcing team can use process control and process capability reports to measure the output of a

process. Control charts help determine whether special causes of variability are present that could lead to unpredictable output.

Process capability studies determine the likelihood that the output of the process will be outside the specification limits defined by the customer. However, the goal of a supplier should not only be to prevent nonconforming parts from being sent to the customer, *it should also be to prevent nonconforming parts from being built in the first place*.

The most effective and lowest cost way to assure quality is to define and implement a process that enables a high probability of conforming parts, and then manage the process to identify and systematically eliminate special causes of variability. Active process management leads to higher first pass yields at the factory and higher reliability product in the field.

Once a process is established, it's important to be able to monitor the inputs and operations of the process to determine whether it is being managed effectively. A supplier with an experienced engineering and management team will perform regular internal audits and checks to monitor their processes. However, when a process is not performing well it may be difficult and time consuming to troubleshoot and identify the source of the problem.

7.4 ASSESSING A PCB FABRICATORS CAPABILITY

Chapter 6, "Supplier Selection and Qualification," provides a brief introduction to supplier quality audits and a framework for inspection of production processes to help the sourcing team assess the quality system of a supplier. A more detailed methodology for assessing and troubleshooting PCB

fabrication processes is presented in Tables 7.1 through 7.21. This includes the following focus areas:

1. Engineering and artwork generation
2. Receiving and incoming inspection
3. Innerlayer processing
4. Innerlayer automated optical inspection (AOI)
5. Lamination
6. Drilling
7. Deburr and electroless
8. Outerlayer processing
9. Outerlayer AOI
10. Plating
11. Soldermask and via plugging
12. Hot air leveling
13. Organic surface protection (OSP)
14. Final fabrication and routing
15. Electrical test
16. Final inspection and impedance test
17. Laboratory processes
18. Waste treatment and chemical storage processes
19. Packaging and outgoing quality assurance (OQA)
20. Electroless nickel and immersion gold
21. Maintenance processes

TABLE 7.1 Engineering Process Audit

Item	Audit Criteria
1.00	Are the front-end engineering processes documented, and are the latest revision work instructions, PM, calibration & inspection procedures for all front-end processes in place for operators to follow?
1.01	Does evidence exist that process capability studies have been performed for the artwork generation, i.e., processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp and Cpk reporting?
1.02	Is the overall appearance of the area and equipment condition adequate?
1.03	Does traceability exist that permits tracking the artwork and tool generation to the PCB manufacturing lot numbers and process equipment (CAD station, plotters, exposure machines, etc.)?
1.04	Is there a continuous improvement team in place for the front-end engineering with documented action plans?
1.05	Are the laboratory records for artwork processes complete and up-to-date?
1.06	Are the operator and maintenance PMs documented and objective evidence exists that they are performed?
1.07	Are the calibration labels on critical equipment current?
1.08	Do training records exist for front end personnel and are they current?
1.09	Do health and safety procedures exist and are they being followed?
1.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling artwork?
	Product Engineering
1.11	Is there a formal pre-production design review of product designs with Quality, Engineering, Materials, and Manufacturing involvement for each new part number?
1.12	Is there a procedure in place and objective evidence that pre-production design review is compared to the current volume manufacturing capability matrix before accepting an order?

1.13 Is there objective evidence that a formal review of the customer specification has been performed and that necessary information has been included in all required documentation (traveler, inspection documents, etc.)?

1.14 Is it understood that subcontracting on the product is not allowed without written permission?

1.15 Does the PCB manufacturing site have a current valid ISO certification?

1.16 Is a checklist used to determine all items required for product engineering and tool planning? If so, is there objective evidence that they are used 100% of the time?

1.17 Is there a closed loop system to ensure that all items on the tooling checklist were performed before the tooling is released to production?

1.18 Are the design packages checked and reviewed by authorized personnel prior to being released to production?

1.19 Are there comprehensive design rules for creating tools based on process requirements and customer acceptance criteria?

1.20 Is there an electronic ECO process for all changes made to tooling?

1.21 Is there a process to ensure written approval from the customer prior to making manufacturing, inspection, or test process changes?

1.22 Is there objective evidence that a pre-production lot was run for all new part numbers and revisions before production lots were issued?

1.23 Is the DFM review report signed off by Quality, Production, ME, and TE?

1.24 Is there a log for DFM non-compliance found in pilot run and mass production?

1.25 Is there evidence that Engineering has taken action to all the DFM non-compliance?

1.26 Is there evidence that Engineering has enhanced its design guidelines based on experience?

1.27 Is there a procedure in place and objective evidence for revision controls for traveler, tooling, etc.?

1.28 Is there a procedure in place for the addition of fileting/teardrop to outerlayer trace to pad for PTH, BGA's and SMD's for immersion silver product?

1.29 Is it documented to perform a DRC after the fileting/teardrop addition for spacing violations and other design concerns?

1.30 Does impedance modeling capability exist with a continuous feedback loop from production lots?

1.31 Is there a revision control system in place for all tooling?

	Artwork Generation
1.32	Is the artwork generated in a controlled temperature ± 2.0° C and humidity environment ± 5%?
1.33	Does the temperature and relative humidity in AW generation equivalent to the imaging areas where the film will be used?
1.34	Is the artwork 100% AOI inspected and the data used for continuous improvement?
1.35	Are the artwork dimensions verified and used for SPC and improvement plans?
1.36	Is the artwork Dmin and Dmax measured?
1.37	Has a gage R&R been performed on the artwork dimensional measurement system?
1.38	Does a formalized artwork compensation feedback loop exist with objective evidence?
1.39	Is there an established hold time after the application of artwork protective film coating before artwork dimensional measurements?
1.40	Is a photoplotter registration lines & spacing accuracy check performed every two days and monitored via SPC?
1.41	Is there a separate storage area for artwork not currently in production use? Is it temperature and humidity controlled?
1.42	Is there a documented artwork inventory system that controls artwork revision, film hit count, etc.?
1.43	Is the compare method used to make sure no pattern is missing?
	Drill & Rout Tooling
1.44	Are the drill programs verified against customer data prior to releasing to production?
1.45	Is there a procedure/system in place to verify items not in the drill program supplied: i.e., tooling holes in arrays, slots, etc.?
1.46	Are the rout programs verified against customer data prior to releasing to production?
	Electrical Test Fixtures
1.47	Are electrical test fixtures and programs designed and fabricated in-house?
1.48	Are the electrical test fixtures set-up and verification performed by engineers or engineering technicians?

TABLE 7.2 Receiving and Incoming Process Audit

Item	Audit Criteria
2.00	Are the Receiving & Incoming Inspection processes documented and are the latest revision work instructions, PM, calibration, and inspection procedures in place for operators to follow?
2.01	Does evidence exist for process capability for the incoming processes, i.e., processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp and Cpk reporting?
2.02	Is the overall appearance of the area and equipment condition adequate?
2.03	Does lot traceability exit that permits tracking the raw material lot numbers to the manufacturing lot number?
2.04	Is there a continuous improvement team in place for the Receiving & Incoming Inspection with documented action plans?
2.05	Are the laboratory records for Receiving & Incoming Inspection (bulk chemicals, laminates & prepregs, etc.) processes complete an up to date?
2.06	Are the operator and maintenance PMs documented and objective evidence exist that they are performed?
2.07	Are the calibration labels on critical equipment current?
2.08	Do training records exist for Receiving & Incoming personnel and are they correct?
2.09	Do health and safety procedures exist and are they being followed?
2.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

	Incoming Inspection
2.11	Are general storage conditions acceptable, with appropriate temperature and humidity control with automatic alarms or notification systems for out of control excursions?
2.12	Are the storage conditions (temperature, humidity, etc.) based on the raw material suppliers recommendations and do they meet those requirements?
2.13	Is the incoming inspection procedure in place which provides the accept criteria for raw material?
2.14	Is incoming inspection performed with actual physical verification of material? If not, do you have a documented ship-to-stock vendor program that includes Certificate of Compliance, periodic inspection plan, documented vendor audit program, vendor process capability program, vendor scorecard, and quarterly vendor review?
2.15	For non-inspection materials or ship-to-stock, is there any evidence of supplier inspection/control plan, and results shown except for collecting C of C, documented vendor audit program, vendor scorecard and quarterly vendor review?
2.16	Are inspected materials and waiting for inspection materials properly labeled, easily identified, and segregated to insure that waiting for inspection materials are not mistakenly used before the inspections have been completed?
2.17	Are all chemical and raw material containers/cartons, etc. properly identified with accept (pass) or reject (fail) labels, with traceability information?
2.18	Are all chemical and raw material containers/cartons, etc. that are identified as received/passed/rejected properly segregated to avoid missing incoming inspection or mistakenly used for production?
2.19	Are all passed lots transferred from the inspection area to parts warehouse within 2 working days?
2.20	Is the shelf like properly defined and identified on material/chemical containers?
2.21	Is there a documented procedure to verify that the material expirations date (shelf life) of all critical materials/chemicals are within the expiration dates in all warehouses and storage areas? Is it audited on a weekly basis?
2.22	Is there a documented procedure for first-in/first-out for materials and chemicals?
2.23	Is there evidence that only passed lots are in the warehouse and production lines?
2.24	Do all failed lots go through the MRB process?
2.25	Do all rework/screen/waive disposition require Engineering and Quality approval?
2.26	Are all material sorts, reworks, and screens performed in a designated area to insure defective materials are not mistakenly mixed with production material?
2.27	Is there a documented Supplier Quality Management system and are the individual suppliers' performance monitored internally on a weekly basis?
2.28	Is there objective evidence that each supplier's quality, cost, and delivery performance is reviewed with the supplier on at least a quarterly basis?

2.29	Are there written procedures which require material and chemical supplier audits? Are they up to date?
2.30	Is there a documented SCAR procedure for material and chemical suppliers?
2.31	Is there objective evidence that SCARs have been issued for rejected lots and parts found?
2.32	Is there a SCAR closure tracking procedure and is it current?
2.33	Are the material suppliers' corrective action responses checked and verified for effectiveness?
2.34	Is the incoming/line/feed quality of major suppliers tracked and feedback to procurement and the suppliers?
2.35	Is there objective evidence that the incoming inspection information is used to rate and disqualify suppliers?
2.36	Is all in-process WIP and materials properly identified and controlled in designated areas?

TABLE 7.3 Innerlayer Fabrication Process Audit

Item	Audit Criteria
3.00	Are the Innerlayer processes documented and are the latest revision work instructions, PM, calibration & inspection procedures for all innerlayer processes in place for operators to follow?
3.01	Does evidence exist that process capability have been performed for the innerlayer processes i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
3.02	Is the overall appearance of the area and equipment condition adequate?
3.03	Does lot traceability exist that permits tracking the I/L lot number to all major equipment, laminate material, artwork and resist lot used to fabricate the product?
3.04	Is there a continuous improvement team in place for the Innerlayer process area with documented actions plans?
3.05	Are the laboratory records for Innerlayer processes complete and up to date?
3.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
3.07	Are the calibration labels on critical equipment current?
3.08	Do training records exist for front end personnel and are they current?
3.09	Do health and safety procedures exist and are they being followed?
3.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

	CCL Shearing
3.11	Is there an evidence that CCL feed speed and cutting direction are well listed in WI?
3.12	Is there a system in place to insure the material grain direction is maintained during the shearing routing operation
	Pre-Clean
3.13	Is the innerlayer preclean process being run per the current documentation?
3.14	Is there a pre-startup checklist for the preclean line? Is it current (completely filled in)?
3.15	Is there a system to identify uneven copper weights on a core and a method to insure that the uneven copper weight cores are imaged correctly?
3.16	Is there objective evidence that the scrub/preclean chemistries are being analyzed by the laboratory on the documented frequency?
3.17	Is the microetch rate monitored? Is it under SPC control with calculated control limits and are the charts & actions current?
3.18	Are dump and remake schedules documented for the preclean line and objective evidence exist that they are being adhered too?

3.19	Are there documented maximum final rinse water contamination levels, rinse flow rates and are these verified by conductivity measurements?
3.20	Is there an evidence to demonstrate that all chemicals are monitored and controlled as listed in WI?
3.21	Is all in-process WIP and materials properly identified and controlled in designate area?
3.22	Is a water break test performed every shift to ensure quality of pre-clean?
3.23	Is there positive air pressure from the cleanroom at the preclean line entrance into the cleanroom?

Imaging

3.24	Is the cleanroom positive pressure monitored on a regular basis with alarms for out of control notification?
3.25	Is the cleanroom well controlled by temperature, humidity and particles which meet 10K Max. requirement and out of control notification? Review objective evidence.
3.26	Are the resist lamination and exposure areas in the cleanroom utilizing yellow lighting and do all exterior windows have UV blocking film?
3.27	Is there a defined specification for the rubber durometer hardness for the lamination rollers and is it checked?
3.28	Is there a documented maintenance replacement schedule for the laminator resist cutter?
3.28	Is there objective evidence to demonstrate that all dry films and/or liquid resist are stored in temperature and humidity control environment? Also, inventoried under FIFO with expired date control?
3.29	Are there tacky roller clean machines in front of the laminator?
3.30	For dry film lamination, is the temperature of the lamination roller checked and verified using an infrared meter?
3.31	Is there a documented resist inspection criteria with pass/fail guidelines?
3.32	Is there an evidence to demonstrate that all chemicals are monitored and controlled as listed in WI?
3.33	Is all in-process WIP and materials properly identified and controlled in designate area? Including expiration date on age sensitive material?

3.34 Is there a documented resist strip/rework procedure with the maximum number of reworks identified?

3.35 Are resist defective cores due to the lamination or coating process fully exposed before resist removal i.e. stripped?

3.36 Is there evidence to demonstrate that exposure energy and vacuum are well controlled? Step tabs/wedges for exposure.

3.37 Is the exposure uniformity monitored across the exposure area with a radiometer and are exposure uniformity limits established and adhered too?

3.38 Is there a latest revision control on working film?

3.39 Is there appropriate verification of artworks before use to check for damage, eg AOI? Is there a stablization process in place before film is used?

3.40 Is there an evidence that working film and T/C are well controlled at cleanning room?

3.41 Is there an evidence that a maximum number of exposures has been established and the number of exposure times of working film is monitored?

3.42 Is the artwork cleaned after defined exposure times using tacky roller? Review the condition of the tacky rollers.

3.43 Are there tools and procedures with tolerance limits in place for front-to-back registration verification during the artwork setup?

3.44 Are first articles processed through DES & AOI prior to exposing the remainder of the lot? Is the front to back verified during this process?

3.45 Is process capability for front-to-back registration on layers measured and controlled? Is it identified as a critical SPC parameter?

3.46 Is the maximum number of permissible exposures documented with a system to track the number of exposures?

3.47 Is the artwork segregated and destroyed after the maximum number of exposures have been reached?

3.48	Is there an evidence that the number of exposure times of working film is monitored and the artwork is not being used beyond documented useful life?
3.49	Is the artwork stored appropriately to prevent damage and ensure the consistent scaling?
3.50	Is the max holding time between expose and develop documented and followed?

Develop-Etch-Strip

3.51	Is there a pre-startup checklist for the DES line? Is it current (completely filled in)?
3.52	Is there an evidence to demonstrate that all chemicals are monitored and controlled as listed in WI?
3.53	Are all in-process WIP and materials properly identified and controlled in designate area?
3.52	Are dump and remake schedules documented for the DES line and objective evidence exist that they are being adhered too?
3.53	Is the developer chemistry analyzed by the laboratory and is it on a feed & bleed pH controller?
3.54	Is "break point " testing performed on the developer for both top and bottom of the core with documented frequency, percent limits & test records?
3.55	Is a first article run prior to etching the lot to confirm etcher settings and linewidths?
3.56	Is there an established frequency that the operator inspects the line for plugged nozzles, conveyor problems and adherences to process parameters?
3.57	Is there a manifold nozzle layout & conveyor schedule available and is it used to validate correct equipment setup?
3.58	Is the etch unifomity checked at least monthly and records maintained as a quality document?

3.59	Are the etcher conveyor speeds defined and documented by copper weight/thickness?
3.60	Is "break point" testing performed on the stripper for both top and bottom of the core with documented frequency, percent limits & test records?
3.61	Is the filtration system adequate? What's the clean frequency and renew frequency?
3.62	Is the stripper chemistry analyzed by the laboratory and is it on a feed & bleed controller?
3.63	Are there documented maximum final rinse water contamination levels, rinse flow rates and are these verified by conductivity measurements?
3.64	Are the cores observed coming off the DES line clean, dry and stain free?
3.65	Is there a documented I/L strip/rework procedure with proper quality controls and traceability?
3.66	Are slip sheets used to separate each core (signals & power/grounds) to prevent scratches?
3.67	Is there a system in place to identify the linewidths to be measured on a core?
3.68	Are gage R&R's performed on a routine basis for the linewidth measurement system? Is it current?
3.69	Are the linewidths measured after develop/etch/strip in each lot using equipment of adequate accuracy (eg. Scope has graduations $\leq$0.001"?
3.70	Are linewidth measurement frequency documented and is the frequency at a minimum of the first core, middle and last core off the line in the lot?

TABLE 7.4 Innerlayer AOI Inspection Process Audit

Item	Audit Criteria
4.00	Are the Innerlayer AOI processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all AOI & PEP processes in place for operators to follow?
4.01	Does evidence exist that process capability studies have been performed for the innerlayer AOI processes i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
4.02	Is the overall appearance of the area and equipment condition adequate?
4.03	Does lot traceability exist that permits tracking the I/L lot number to AOI machine/verification station and rework/repair used in inspection or repair?
4.04	Is there a continuous improvement team in place for the Innerlayer AOI Process Area with documented actions plans?
4.05	Are the laboratory records for Innerlayer processes complete and up to date?
4.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
4.07	Are the laboratory records for Innerlayer processes complete and up to date?
4.08	Do training records exist for Front End personnel and are they current?
4.09	Do health and safety procedures exist and are they being followed?
4.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?
	AOI
4.11	Is 100% AOI performed on signal layers? Are all AOIs operated under a controlled environment? (Humidity, Temperature,...etc)
4.12	Are all in process WIP and materials properly identified and controlled in designate area?
4.13	Are the power and ground layers either AOI inspected or electrical tested based on a statistically valid sampling plan?
4.14	Are the AOI programs data driven using the customer's data and are all the critical AOI settings and programs established by Engineering?
4.15	Does the AOI program have appropriate parameters programed to cover minimum linewidths, minimum spacing, dishdowns, etc?

4.16	Is a standard defect board used to verify each AOI machine is catching all defects at the beginning of each shift?
4.17	Is there a system in place to notify the Image Area for first articles with repeat defects?
4.18	If excess random defects are detected on a lot is this information immediately fed back to the DES operation for review and action? i.e. excess copper, nicks, shorts, opens?
4.19	Is the AOI defect verification performed on separate verification stations and defect data collected and reported in a meaningful manner?
4.20	Is there a limit established for the maximum number of false hits before a lot is reviewed by a MRB/DRB team?
4.21	Are repaired panels re-AOI'd to confirm all defects were found and repaired?
4.22	Are yields tracked daily at AOI and feedback loop to I/L process improvement team established? Are first pass yield and final yield targets defined?
4.23	Are corrective actions taken if yields fall below target?
4.24	Is Pareto analysis used to determine the top defects? Is effective continuous improvement used to eliminate top defects?
	Post-Etch Punch
4.25	Is rivet or pin lamination used?
4.26	Are all in process WIP and materials properly identified and controlled in designate area?
4.27	Is the imaged feature to tooling hole location verified on each lot? Have tolerance limits been established to insure registration for this technology level?
4.28	Is the front to back registration verified based on a sampling plan for each lot?
4.29	For post-etch-punch, Is the offset measured each shift and plotted on SPC? Are there established SPC actions for offset adjustments?
4.30	Does post-etch-punch tooling pattern have non-symmetrical holes to prevent panel being laminated upside down?
4.31	Is the post etch punch calibration and punch sharpening set-up on a routine maintenace schedule and is it current?
4.32	Is there a comprehensive PEP Preventative Maintenance plan with current updated records?

TABLE 7.5 Lamination Process Audit

Item	Audit Criteria
5.00	Are the Oxide, Layup & Lamination processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
5.01	Does evidence exist that process capability studies have been performed for the Oxide, Layup & Lamination processes i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
5.02	Is the overall appearance of the area and equipment condition adequate?
5.03	Does lot traceability exist that permits tracking the I/L lot numbers to the O/L lot number and to all major equipment and materials i.e. prepreg, laminate, copper foil used to fabricate the product?
5.04	Is there a continuous improvement team in place for the Oxide & Lamination Process Area with documented actions plans?
5.05	Are the laboratory records for Oxide process complete and up to date?
5.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
5.07	Are the calibration labels on critical equipment current?
5.08	Do training records exist for Front End personnel and are they current?
5.09	Do health and safety procedures exist and are they being followed?
5.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?
	Pre-Lamination
5.11	Does evidence exist that the Oxide Chemistry supplier has audited the line in the previous three months? If so, were actions taken?
5.12	Have DOEs been conducted to verify the optimum oxide thickness to ensure no delamination after thermal stress test?
5.13	Are all in-process WIP and materials properly identified and controlled in designate area?
5.14	Is the microetch rate monitored? Is it under SPC control with calculated control limits and are the charts & actions current?
5.15	For horizontal oxide lines, is there an established frequency that the operator inspects the line for plugged nozzles, conveyor problems and adherences to process parameters? How are nozzles checked for plugs and proper spray pattern

5.16	Are oxide bond strength test performed for all material types for each oxide line used on the product on a weekly basis?
5.17	Are the oxide chemistries on a auto-dosing system?
5.18	Is DI water used for rinses?
5.19	Are the cores exiting the machine dry and stain free?
5.20	Is the 5% HCL or 10% Sulfuric acid spot test performed and are the results greater than 10 minutes?
5.21	Is the Weight gain test performed for Black Oxide and Weight Loss test for Brown Oxide process? SPC Chart
5.22	Is there an evidence that black oxide thickness is well controlled?
5.23	Are the oxided panels uniform in color, appearance and free of scratches/handling damage?
5.24	Are cores reworked at oxide? If so, is there a documented rework procedure with the maximum number of reworks established?

Lamination

5.25	Is the lay-up done in a clean room with adequate temperature and humidity control?
5.26	Are there established hold-times for oxide cores in the layup operation?
5.27	Are all in-process WIP and materials properly identified and controlled in designate area?
5.28	Are prepreg types and MFG date identified during lay-up? Are material types tracable to incoming and is recorded on work order?
5.29	Has adequate testing and DOE's been performed insure the dielectric and board press out thickness for all copper weights, signal, P/G layers and degree of cure have been optimized?
5.30	Are the lamination programs defined depending on the different stack ups? How to select the lamination program?
5.31	Are Rivet process or Pin-lamination used to hold stacks to ensure the registration?

5.32	Is the material profile done regularly to ensure the actual cooldown rate not exceed 5 deg C/minute? What is the heat rise and cool down rate?
5.33	Are steel plates cleaned for each cycle and polished periodically? Is the thickness of the steel plate checked regularly?
5.34	Is there an evidence that lamination press platen flatness/parallelism is checked minimum once per six months ?
5.35	Is the temperature uniformity for each press opening monitored using thermocouples each shift?
5.36	Are the laminated panels inspected for resin spots?
5.37	Is board thickness measured after lamination on all panels or on appropriate sample size at a min 5 points on each panel?
5.38	Is SPC used to track the board thickness by part number and does a action plan exist for out of control points?
5.39	Does a feedback loop exist for dielectric and PCB thickness to Front-End Engineering for continuous improvement and out of control situations?
5.40	Is there X-ray punch with accuracy compensation design for registration control?
5.41	Is there a documented quality conformance procedure with accept/reject criteria for lamination press malfuctions (temperature, pressure, etc. interuptions) to insure the quality of the product in the press?
5.42	Is there a lamination repair document that prevents re-lamination and abrasive techniques for the removal of epoxy spots or board thickness violations?
5.43	Are procedures in place for inspecting and testing lamination integrity?
	Pre-Drill X-ray
5.44	Does there exist a documented accept/reject criteria at pre-drill x-ray for misregistration?
5.45	Are all in-process WIP and materials properly identified and controlled in designate area?
5.46	Is there a documented routine dimensional measurement confirmation performed on the x-ray pre-drill measurement system?
5.47	Is there on-going feedback mechanism to use X-ray drill measurements to optimize artwork scaling factor?

TABLE 7.6 Drilling Process Audit

Item	Audit Criteria
6.00	Are the Drill & Resharpening processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
6.01	Does evidence exist that process capability studies have been performed for the Drill & Resharpening processes i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
6.02	Is the overall appearance of the area and equipment condition adequate?
6.03	Does lot traceability exist that permits tracking the O/L lot number to all major equipment and materials i.e. drill machine, drill bits, etc. used to fabricate the product?
6.04	Is there a continuous improvement team in place for the Drill Process Area with documented actions plans?
6.05	Are the laboratory records (i.e. Cross-sections for hole roughness, etc.) for Drill process complete and up to date?
6.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
6.07	Are the calibration labels on critical equipment current?
6.08	Do training records exist for the Drill & Resharpening operators and are they current?
6.09	Do health and safety procedures exist and are they being followed?
6.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

6.11 Does the traveller clearly define all the drilling parameters including stack height?

6.12 Is the stack height, maximum hit per drill bit, and feeds and speeds as a function of laminate type, board thickness, layer count and hole size controlled properly?

6.13 Is the drilling program checked prior to being released for production?

6.14 Is there evidence to demonstrate that spindle run-out is well controlled?

6.15 Does the drilling machine have broken bit and wrong bit size detection capability?

6.16 Is drilled hole registration checked by cross-section or X-ray? What is the frequency?

6.17 Is true position monitored monthly for each spindle and controlled to +/–3 mils?

6.18 Do action plans exist for investigating and reducing broken bits? Does objective evidence exist that this is in control?

6.19 Is there a documented drill rework/repair procedure with quality checks?

6.20 Are PCB's with missing holes placed back on the drill machine and drilled?

6.21 Are resharpened drill bit inspected and identified prior to use?

6.22 Are the maximum number of re-sharpens documented & controlled?

6.23 Is the inspection of new or resharpened drill bits flute length, diameter performed with non-contact method?

6.24 Are Aluminum plates inspected for dents and scratches before use?

6.25 Are output boards at the bottom of each spindle inspected on the hole size & location, hole registration and hole quantity etc?

6.26 Is there an effective process for removing surface debris after drilling?

6.27	Are collets PM(ed) periodically?
6.28	Is there a general inspection procedure with drilling positional accuracy, hole size, hole quantity, hole location and copper surface appearance defined?
6.29	Are drill machines capability data for hole position accuracy traceable for each machine and spindle?
6.30	Are drill machines capability data for runout traceable for each machine and spindle?
6.31	Is the stroke height checked & pressure foot inspected weekly?
6.32	Is the depth into the back-up material checked for each spindle weekly?
6.33	Is there a documented quality conformance procedure with accept/reject criteria for drill machine malfuctions (vacuum, air pressure, etc. interuptions) to insure the quality of the product in the press?
6.34	Is registration monitored by Perfect Test machine or X-ray check after Drilling?
6.35	Is the hole roughness monitored as part of the cross-section evaluations and is this information feedback to the drill process and quality engineer?
6.36	Is SPC used in Drilling process?
6.37	Are all passed/rejected boards properly labeled and segregated to avoid mixing or missing?
6.38	Does all in process WIP and materials be properly identified and controlled?
6.39	Is there a SPC control implemented and control chart updated for critical parameters?
6.40	Are relevant corrective actions taken toward all the out of control points?

TABLE 7.7 Deburr & Electroless Process Audit

Item	Audit Criteria
7.00	Are the Deburr & Electroless Copper Plating processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
7.01	Does evidence exist that process capability studies have been performed for the Electroless Copper Plating process i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
7.02	Is the overall appearance of the area and equipment condition adequate?
7.03	Does lot traceability exist that permits tracking the O/L lot number to all major equipment and materials i.e. deburr machine, plating line, plating tanks, etc. used to fabricate the product?
7.04	Is there a continuous improvement team in place for the Electroless Process Area with documented actions plans?
7.05	Are the laboratory records (i.e. Chemical Analysis, Backlight, X-sections, etc.) for Deburr & Electroless Copper Plating process complete and up to date?
7.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
7.07	Are the calibration labels on critical equipment current?
7.08	Do training records exist for the Deburr & Electroless Copper Plating operators and are they current?
7.09	Do health and safety procedures exist and are they being followed?
7.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

	Deburring
7.11	Is there a pre-startup checklist for the Deburr line? Is it current(completely filled in)?
7.12	Are there air knives, fluid heads & ultrasonics on the deburr machine?
7.13	Is there a wet course-grit scrubber ~180-330grit in the deburr line?
7.14	Are all in-process WIP and materials properly identified and controlled in designate area?
7.15	Is there an established frequency that the operator inspects the line for plugged nozzles, conveyor problems and adherences to process parameters?
7.16	Is a hole inspection/checker used after deburr for plugged holes? If so, are the data used for continuous improvement activities.
7.17	Is there evidence to demonstrate that good control of scrubbing rollers - bristle check?
7.18	Is the Ultrasonic vibration check with a meter each shift and data included in the shift check list?
7.19	Does the process documentation cover the procedures to be used for different technology PCBs i.e. standard lower technology versus high aspect ratio, thick PCB's? Are they passed through multiple times?
7.20	Is the uniformity of the pressure checked as part of startup checklist?
7.21	After the deburr operation are the exterior of the boards and holes completely dry?
7.22	Are footprints performed as part of the startup procedure and when board thickness changes?

	Desmear
7.23	Is there a pre-startup checklist for the Desmear line? Is it current?
7.24	Were the pre-startup checklist, process documentation, rework and inspection procedures based on the chemisry suppliers recommendations?
7.25	Are Dump and Remake schedules documented for the Desmear line and objective evidence exist that they are being adhered too?
7.26	Are all in-process WIP and materials properly identified and controlled in designate area?
7.27	Is the permanganate electrolytically regenerated?
7.28	Are the temperatures, pumps, bath condition, tanks/sumps and process times on the line within the process specifications?
7.29	Is the weight loss checked regularly to verify the effective of the desmear?
7.30	Is there an evidence that chemical analysis is performed periodically?

	Electroless
7.31	Is a standard electroless copper process utilized for the product?
7.32	Is there a pre-startup checklist for the electroless line? Is it current (completely filled in)?
7.33	Are the pre-startup checklist, process documentation, rework and inspection procedures based on the chemistry suppliers recommendations?
7.34	Are all in-process WIP and materials properly identified and controlled in designate area?
7.35	Does the chemical area have negative pressure or a ventilization design that provide adequate ventilation in the process area?
7.36	Is the incoming process water tested for pH, ionic and organic contaminants?
7.37	Is all process chemistries utilizing deionized (DI) or reverse osmosis (RO) water?
7.38	Is the microetch rate monitored? Is it under SPC control with calculated control limits and are the charts & actions current?
7.39	Is the deposition rate (weight gain) of electroless copper tank performed regularly?
7.40	Is backlight inspection performed to check the coverage of the electroless copper including both sides of the hole?
7.41	Is dummy-plating performed as part of the start-up procedure before electroless copper plating product?
7.42	Is auto-dosing utilized on the electroless copper bath?
7.43	For vertical electroless copper lines, is the overall basket conditions good and panel spacing greater than 0.5 inches?
7.44	Do the elecroless copper tanks have vibration? Are they in good condition and on a preventative maintenance schedule?
7.45	For horizontal electroless copper platers, is there an established frequency that the operator inspects the line for plugged nozzles, conveyor problems and adherences to process parameters? How are nozzles checked for plugs and proper spray pattern?
7.46	Are the panels as observed coming off the plating line clean, dry and stain free?
7.47	Is there chemical filtration used in support tanks?
7.48	Are the temperatures, pumps, bath condition, tanks/sumps and process times on the line within the process specifications?
7.49	Is there a documented allowable rework procedure with appropriate quality checks?
7.50	Are Dump and Remake schedules documented for the electroless line and objective evidence exist that they are being adhered too?
7.51	Is there a documented line down procedure that clearly identifies the appropriate steps for the product in the line?
7.52	Is there a documented quality conformance procedure with accept/reject criteria for electroless plating line malfuctions (hoist, time, temperature, etc. interuptions) to insure the quality of the product in the line at the time of malfunction?
7.53	Is there an active continuous improvement team for plating voids in the electroless copper operation?
7.54	Is there a documented clearly defined cleaning procedure for the electroless tanks?
7.55	Is SPC used for Desmear and Electroless process ? Is the corrective action taken for the out of control status?

TABLE 7.8 Outerlayer Process Audit

Item	Audit Criteria
8.00	Are the Outerlayer Preclean & Imaging processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
8.01	Does evidence exist that process capability studies have been performed for the Outerlayer Preclean & Imaging process i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
8.02	Is the overall appearance of the area and equipment condition adequate?
8.03	Does lot traceability exist that permits tracking the O/L lot number to all major equipment and materials i.e. process lines, resist lot number, etc. used to fabricate the product?
8.04	Is there a continuous improvement team in place for the Outerlayer Process Area with documented actions plans?
8.05	Are the laboratory records (i.e. Chemical Analysis, etc.) for Outerlayer Preclean & Imaging process complete and up to date?
8.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
8.07	Are the calibration labels on critical equipment current?
8.08	Do training records exist for the Outerlayer Preclean & Imaging operators and are they current?
8.09	Do health and safety procedures exist and are they being followed?
8.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

Pre-Clean	
8.11	Is there a pre-startup checklist for the preclean line? Is it current(completely filled in)?
8.12	If the preclean line is a scrub, is the footprint inspection procedure documented and performed for different thickness product?
8.13	If the outerlayer preclean inludes a microetch, is the microetch rate monitored and is the electroless copper thickness compensated for the copper removal?
8.14	Is there objective evidence that the scrub/preclean chemistries are being analyzed by the laboratory on the documented frequency?
8.15	If a scrub preclean is used, is there an established brush - bristle maintenance schedule?
8.16	Are all in-process WIP and materials properly identified and controlled in designate area?
8.17	Are Dump and Remake schedules documented for the preclean line and objective evidence exist that they are being adhered too?
8.18	Are the final rinses deionized or RO water?
8.19	Are the panels as observed coming off the preclean line clean, dry and stain free?

	Imaging
8.20	Is the cleanroom well controlled by temperature, humidity and particles which meet 10K Max. requirement and out of control notification? Review objective evidence.
8.21	Is the cleanroom positive pressure monitored on a regular basis with alarms for out of control notification?
8.22	Are the process documentation, rework and inspection procedures based on the resist suppliers recommendations?
8.23	Are all in-process WIP and materials properly identified and controlled in designate area?
8.24	Are the resist lamination and exposure areas in the cleanroom utilizing yellow lighting and do all exterior windows have UV blocking film?
8.25	Is there objective evidence to demonstrate that all dry films and/or liquid resist are stored in temperature and humidity control environment? Also, inventoried under FIFO with expired date control?
8.26	Is there a defined specification for the rubber durometer hardness for the lamination rollers and is it checked?
8.27	Is there a documented maintenance replacement schedule for the laminator resist cutter?
8.26	Are tack roller clean machines used in front of the laminator?
8.27	Is the temperature of the lamination roller checked and verified using the infrared meter?

8.28 Is there inspection criteria applied for dry film lamination with documented pass/fail criteria? (eg, bubble, tension force)

8.29 Is there a documented resist strip/rework procedure with the maximum number of reworks identified?

8.30 Are resist defective panels due to the lamination or coating process fully exposed before resist removal i.e. stripped?

8.31 Is there a latest revision control on working film?

8.32 Is there appropriate verification of artworks before use to check for damage, eg AOI? Is there a stablization process in place before film is used?

8.33 Is the artwork cleaned after defined exposure times using tacky roller? Review the condition of the tacky rollers.

8.34 Is there evidence to demonstrate that exposure energy and vacuum are well controlled? Step tabs/wedges for exposure.

8.35 Is the exposure uniformity monitored across the exposure area with a radiometer and are exposure uniformity limits established and adhered too?

8.36 Are first articles processed through Outerlayer Develop & AOI prior to exposing the remainder of the lot? Is the front to back verified during this process?

8.37 Is process capability for front-to-back registration on layers measured an controlled?

8.38 Is the maximum number of permissible exposures documented with a system to track the number of exposures?

8.39 Is the artwork segregated and destroyed after the maximum number of exposures have been reached?

8.40 Are artworks stored appropriately to prevent damage and ensure the consistent scaling?

8.41 Is the max holding time between expose and develop documented and followed?

Outerlayer Develop–Panel Plating Process–DES Line	
8.42	Is there a pre-startup checklist for the develop line? Is it current(completely filled in)?
8.43	Are Dump and Remake schedules documented for the developer and objective evidence exist that they are being adhered too?
8.44	Are all in-process WIP and materials properly identified and controlled in designate area?
8.45	Is the developer chemistry analyzed by the laboratory and is it on a feed & bleed pH controller?
8.46	Is "break point" testing performed on the developer for both top and bottom of the core with documented frequency, percent limits & test records?
8.47	Is a first article run prior to developing the lot to confirm developer settings and linewidths?
8.48	Is there an established frequency that the operator inspects the line for plugged nozzles, conveyor problems and adherences to process parameters?
8.49	Is there a manifold nozzle layout & conveyor schedule available and is it used to validate correct equipment setup?
8.50	Are there documented maximum final rinse water contamination levels, rinse flow rates and are these verified by conductivity measurements?
8.51	Are the panels observed coming off the developer line clean, dry and stain free?
8.52	Is there a documented allowable rework procedure with appropriate quality checks?
8.53	Is there a documented O/L strip/rework procedure with proper quality controls and traceability?
8.54	Is there a system in place to identify the linewidths to be measured on a panel?
8.55	Are Gage R&R's performed on a routine basis for the linewidth measurement system? Is it current?
8.56	Are all repaired boards identified for traceability?
8.57	Is there a documented maximum hold time for panels with laminated photoresist before copper plating?

TABLE 7.9 Outerlayer AOI Inspection Process Audit

Item	Audit Criteria
9.00	Are the Outerlayer AOI & Repair processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
9.01	Does evidence exist that process capability studies have been performed for the Outerlayer AOI & Repair process i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
9.02	Is the overall appearance of the area and equipment condition adequate?
9.03	Does lot traceability exist that permits tracking the O/L lot number to all major equipment and materials i.e. AOI machine, verification station, operator, welder, etc. used to fabricate the product?
9.04	Is there a continuous improvement team in place for the Outerlayer AOI & Repair Process Area with documented actions plans?
9.05	Are the laboratory records for Outer Layer AOI processes complete and up to date?
9.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
9.07	Are the calibration labels on critical equipment current?
9.08	Do training records exist for the Outerlayer AOI & Repair operators and are they current?
9.09	Do health and safety procedures exist and are they being followed?
9.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

Outerlayer AOI	
9.11	Is 100% AOI performed on outlayer? If No, what's the sample size?
9.12	Are the AOI programs data driven using the customer's data and are all the critical AOI settings and programs established by Engineering?
9.13	Are all in-process WIP and materials properly identified and controlled in designate area?
9.14	Does the AOI program have appropriate parameters programed to cover minimum linewidths, minimum spacing, dishdowns, etc?
9.15	Is there a system in place to notify the Image Area for first articles with repeat defects?
9.16	If excess defects are detected on a lot is this information immediately fed back to the previous operation for review and action? i.e. excess copper, nicks, shorts, opens?
9.17	Is the AOI defect verification performed on separate verification stations and defect data collected and reported in a meaningful manner?
9.18	Is there a documented procedure identifing the maximum number of repairs allowed, including but not limited too welding opens, cutting out shorts and excess copper spots, etc?
9.19	Is there a limit established for the maximum number of false hits before a lot is reviewed by a MRB/DRB team?
9.20	Are repaired panels re-AOI'd to confirm all defects were found and repaired?
9.21	Are all repaired boards identified for traceability?
9.22	Are yields tracked daily at AOI and feedback loop to O/L process improvement team established? Are first pass yield and final yield targets defined?
9.23	Does the In-process Inspection check the boards after AOI/verification on sampling basis? Is the loss rated of AOI monitored?
9.24	Are corrective actions taken if yields fall below target?
9.25	Is golden boards used to check the AOI machine before the inspection of each shift?
9.26	Is Pareto analysis used to determine the top defects? Is effective continuous improvement used to eliminate top defects?

TABLE 7.10 Plating Process Audit

Item	Audit Criteria
10.00	Are the Electrolytic Copper Plating processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
10.01	Does evidence exist that process capability studies have been performed for the Electrolytic Copper Plating process i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
10.02	Is the overall appearance of the area and equipment condition adequate?
10.03	Does lot traceability exist that permits tracking the O/L lot number to all major equipment and materials i.e. Plating chemistry, plating line, plating tank, etc. used to fabricate the product?
10.04	Is there a continuous improvement team in place for the Electrolytic Copper Plating Process Area with documented actions plans?
10.05	Are the laboratory records (i.e. Chemical Analysis, Cross-sections, etc.) for Electrolytic Copper Plating process complete and up to date?
10.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
10.07	Are the calibration labels on critical equipment current?
10.08	Do training records exist for the Electrolytic Copper Plating operators and are they current?
10.09	Do health and safety procedures exist and are they being followed?
10.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

Copper Plating	
10.11	Is there a pre-startup checklist for the electrolytic copper plating line? Is it current (completely filled in)?
10.12	Are the pre-startup checklist, process documentation, rework and inspection procedures based on the chemistry suppliers recommendations?
10.13	Do the plating current and program used match the design and traveler? What is the ASF range used during plating? Who determines ASF? How?
10.14	Is the copper plating process an electrolytic acid copper plating system?
10.15	Is dummy-plating performed as part of the start-up procedure before plating product?
10.16	Is all in-process WIP and materials properly identified and controlled in designate area?
10.17	Is chemical area with good ventilization design for operation enviroment control?
10.18	Is incoming water tested with PH and organics?
10.19	Is all chemistry utilizing (DI) water?
10.20	Is the operation conducted in a enclosed and controlled environment?
10.21	Are organic & inorganic contaminants in the plating tank analyzed and monitored?
10.22	Is vibration used? How often is the vibration checked?
10.23	Is a CVS used for additive analysis?
10.24	Are Hull Cells performed on a routine frequency?
10.25	Is there an established schedule for the anode, buss bars, and cables maintenance? Is it current?
10.26	Are the anodes at a satisfactory level in the anode baskets based on the date of the last anode maintenance?
10.27	Are the buss bars clean, insulation on the cables in good condition, and are the cables connections free of corrosion?
10.28	Is the resistance of the of the buss bars and cables checked as part of the weekly maintenace?
10.29	Is there an documented rectifier calibration procedure and is it current?
10.30	Is the filter bag cleaned and checked periodically to ensure no plugging and broken?
10.31	Are filters managed properly? Clean frequency, renew frequency?
10.32	Is there an established carbon treatment schedule with a maximum frequency of treating each plating tank every six months?
10.33	Is PTH and small via hole wall quality checked by cross-section and followed by a closed loop corrective action?
10.34	Are cross-sections frequency performed per GNTX-7000?

10.35 Is the customer specification for copper thickness documented on the traveler and other quality documents?

10.36 Is a Caviderm used for copper thickness process control? If so, has a copper thickness coorelation to cross-sections been performed and smallest via on the panel?

10.37 Is there a documented procedure to verify hole size for press-fit and other tight toleranced plated through holes at the electroplating operation using pin gages?

10.38 Is there a feedback loop to pre-production engineering to provide hole size data to insure the hole sizes are centered on nominal and have a good Cpk?

10.39 Is there a documented quality conformance procedure with accept/reject criteria for electrolytic plating line malfuctions(hoist, time, temperature, etc. interuptions) to insure the quality of the product in the plating line?

10.40 Is there an evidence that the elongation and tensile strength test is conducted on a frequency of once per month per copper plating tank?

10.41 Are plating distributions performed each plating tank on a monthly basis?

10.42 Is the tin thickness and uniformity monitored regularly to ensure the quality?

10.43 Are thermal stressed cross-sections performed as an in-process plating control?

10.44 Is there an evidence that expiration date of all wet materials are well controlled?

10.45 Is pure tin used as etch resist in plating ?

10.46 Is there a documented allowable rework procedure with appropriate quality checks?

10.47 If product is reworked, is the rework documented on the traveler, and does the reworked product receive appropriate re-inspection and testing?

Strip-Etch-Strip	
10.48	Is there a pre-startup checklist for the strip-etch-strip line? Is it current(completely filled in)?
10.49	Are Dump and Remake schedules documented for the strip-etch-strip and objective evidence exist that they are being adhered too?
10.50	Is there an established frequency that the operator inspects the line for plugged nozzles, conveyor problems and adherences to process parameters?
10.51	Is there a manifold nozzle layout & conveyor schedule available and is it used to validate correct equipment setup?
10.52	Are all in-process WIP and materials properly identified and controlled in designate area?
10.53	Is "break point " testing performed on the stripper for both top and bottom of the panel with documented frequency, percent limits & test records?
10.54	Is the filtration system adequate? What's the clean frequency and renew frequency?
10.55	Are the etchant, stripper and tin strip chemistries analyzed by the laboratory and are they on a feed & bleed controller?
10.56	Is a first article run prior to etching the lot to confirm etcher settings and linewidths?
10.57	Are the etcher conveyor speeds defined and documented by external copper weight/thickness?
10.58	Is the etch unifomity checked at least monthly and records maintained as a quality document?
10.59	Are there documented maximum final rinse water contamination levels, rinse flow rates and are these verified by conductivity measurements?
10.60	Are slip sheets used to separate each panel to prevent scratches?
10.61	Is there a system in place to identify the linewidths to be measured on a panel?
10.62	Are fine pitch SMT pad size measured and SPC utilized?
10.63	Are Gage R&R's performed on a routine basis for the linewidth measurement system? Is it current?
10.64	Is there evidence that the impedance is being monitored/checked as part of the SES first article on controlled impedance product?
10.65	Is "break point " testing performed on the strip tin for both top and bottom of the panel with documented frequency, percent limits & test records?
10.66	Are the panels observed coming off the SES line clean, dry and stain free?

TABLE 7.11 Soldermask & Via Plugging Process Audit

Item	Audit Criteria
11.00	Are the Soldermask, Legend & Via Plugging processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
11.01	Does evidence exist that process capability studies have been performed for the S/M process i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
11.02	Is the overall appearance of the area and equipment condition adequate?
11.03	Does lot traceability exist that permits tracking the O/L lot number to all major equipment and materials i.e. Soldermask coaters, developers, Imaging equipment etc. used to fabricate the product?
11.04	Is there a continuous improvement team in place for the Soldermask Process Area with documented actions plans?
11.05	Are the laboratory records (i.e. Chemical Analysis, S/M Thickness, etc.) for Soldermask process complete and up to date?
11.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
11.07	Are the calibration labels on critical equipment current?
11.08	Do training records exist for the Soldermask operators and are they current?
11.09	Do health and safety procedures exist and are they being followed?
11.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

	Pre-Clean
11.11	Is there a pre-startup checklist for the preclean lines? Is it current (completely filled in)?
11.12	Is there objective evidence that the scrub/preclean chemistries are being analyzed by the laboratory on the documented frequency?
11.13	If the preclean is a scrub, are footprints performed and is this requirement documented?
11.14	If the preclean is a microetch, is the microetch rate monitored and is this requirement documented?
11.15	Is the soldermask preclean/scrub process being run per the current documentation?
11.16	If a scrub preclean is used, is there an established brush—bristle maintenance schedule?
11.17	Is all in-process WIP and materials properly identified and controlled in designate area?
11.18	Are Dump and Remake schedules documented for the preclean line and objective evidence exist that they are being adhered too?
11.19	Are the final rinses deionized or RO water?
11.20	Is there positive air pressure from the cleanroom at the preclean line entrance into the cleanroom?
11.21	Are the panels completely dry (esp. in the holes) upon exit?

Soldermask Printing

11.22 Is there a pre-startup checklist for the soldermask coaters? Is it current (completely filled in)?

11.23 Are the panels racked or stacked before coat?

11.24 Is all in-process WIP and materials properly identified and controlled in designate area?

11.25 Is the viscosity of the solder mask after preparation checked to ensure the quality?

11.26 Is the date and time that the soldermask expires after preparation specified on its container?

11.27 Is there objective evidence to demonstrate that all soldermasks are stored in temperature and humidity control environment? Also, inventoried under FIFO with expired date control?

11.28 Is there evidence to demonstrate that the cleaness is well controlled of solder mask coating room?

11.29 Are the soldermask coaters cleaned and maintained to a documented procedure?

11.30 If soldermask screen printers are used, is the silk-screen stencil life cycle controlled?

11.31 If soldermask screen printers are used, are the silk-screen stencils identified with labels or plates which as visible when the stencil is in its racks or mounted in the printer?

11.32 Is there a documented requirement to inspect a stencil once cleaned?

11.33 Is the screen tension checked before each use?

11.34 Are the squeegees controlled properly, such as the width, angle, resharpen freq?

11.35 Is there a system in place to determine the S/M coated weight or coated thickness and tack dry weight loss? Is it under SPC control?

11.36 Is there a documented allowable rework procedure with appropriate quality checks?

11.37 Are thermal profiles performed on the tack dry ovens on a documented schedule? Is there objective evidence that it is being performed?

11.38 Are thermal profiles performed on the tack dry ovens when fully loaded?

Soldermask Exposure	
11.39	Is there a pre-startup checklist for the exposure units? Is it current(completely filled in)?
11.40	Is imaging done in a clean room with the parameters tracked effectively (temperature, humidity, particulate counts)?
11.41	Are the working films clearly defined the P/N REV and No. of exposure?
11.42	Are all in-process WIP and materials properly identified and controlled in designate area?
11.43	Is the cleanroom positive pressure monitored on a regular basis with alarms for out of control notification?
11.44	Are the soldermask coating and exposure areas in the cleanroom utilizing yellow lighting and do all exterior windows have UV blocking film?
11.45	Is there appropriate verification of the artwork before use to check for damage, eg AOI?
11.46	Is there inspection criteria applied for S/M with documented pass/fail criteria?
11.47	Is there a documented S/M strip/rework procedure after coat or expose with the maximum number of reworks identified?
11.48	Are defective S/M coated panels due to S/M misregistration or other coating problems fully exposed before S/M removal i.e. stripped?
11.49	Is there appropriate verification of artworks before use to check for damage? Is there a stablization process in place before film is used?
11.50	Is there a documented process for requesting compensated S/M artwork for registration problems?
11.51	Are artworks cleaned after defined exposure times using tacky roller? Review the condition of the tacky rollers.
11.52	Is there evidence to demonstrate that exposure energy and vacuum are well controlled? Step tabs/wedges for exposure.
11.53	Is the exposure uniformity monitored across the exposure area with a radiometer and are exposure uniformity limits established and adhered too?
11.54	Is there a documented procedure to monitor exposure machine lamp life based on power output measurements (i.e. mW/cm^2)?
11.55	Are first articles processed through S/M Develop & Inspection prior to exposing the remainder of the lot? Is the registration verified during this process?
11.56	Is process capability for registration measured and controlled?
11.57	Is the maximum number of permissible exposures documented with a system to track the number of exposures? Also, are the artworks segregated and destroyed after the maximum number has been reached?
11.58	Is the artwork segregated and destroyed after the maximum number of exposures have been reached?
11.59	Is there a documented allowable rework procedure with appropriate quality checks?
11.60	Is the artwork stored appropriately to prevent damage and ensure the consistent scaling?
11.61	Is the max holding time between expose and develop documented and followed?

Developing

11.62 Is there a pre-startup checklist for the Develop line? Is it current (completely filled in)?

11.63 Is development tank filtration checked before each shift operation?

11.64 Are all in-process WIP and materials properly identified and controlled in designate area?

11.65 Are Dump and Remake schedules documented for the developer and objective evidence exist that they are being adhered too?

11.66 Is the developer chemistry analyzed by the laboratory and is it on a feed & bleed pH controller?

11.67 Is "break point" testing performed on the developer for both top and bottom of the core with documented frequency, percent limits & test records?

11.68 Is a first article run prior to developing the lot to confirm developer settings, registration and soldermask clearances?

11.69 Is there an established frequency that the operator inspects the line for plugged nozzles, conveyor problems and adherences to process parameters?

11.70 Is there a manifold nozzle layout & conveyor schedule available and is it used to validate correct equipment setup?

11.71 Are there documented maximum final rinse water contamination levels, rinse flow rates and are these verified by conductivity measurements?

11.72 Are the panels observed coming off the developer line clean, dry and stain free?

11.73 Is there a documented S/M strip/rework procedure with proper quality controls and traceability?

11.74 Are Gage R&R's performed on a routine basis for the S/M defined pad size measurement system? Is it current?

11.75 Are S/M defined pads & registration measured after develop on min first, middle, and last panel in each lot using equipment of adequate accuracy (eg. Scope has graduations <0.005"

11.76 Are Panels inspected after developing?

	Soldermask Cure
11.77	Are all in-process WIP and materials properly identified and controlled in designate area?
11.78	Is there a pre-startup checklist for the S/M cure ovens/line? Is it current(completely filled in)?
11.79	Is the solder mask thickness effectively monitored?
11.80	Is a S/M cure monitored on a routine/documented procedure? Does objective evidence exist?
11.81	Is the same S/M material used for touch-up & repair as was originally coated on the PCB?
11.82	Is there a S/M strip operation after final cure? Is it a documented & controlled process?
11.83	Does the first pass yields for soldermask include the soldermask strip data/quantity?
11.84	Are cross-sections taken to monitor the S/M sidewall for undercut, etc. Are these reviewed by Engineering?
11.85	Is there a documented allowable rework procedure with appropriate quality checks?
11.86	Are tack dry/final cure ovens cleaned & calibrated as part of the routine maintenance?
11.87	Are thermal profiles performed on the final cure ovens on a documented schedule? Is there objective evidence that it is being performed?
11.88	Are thermal profiles performed on the final cure ovens when fully loaded?

Via Plugging/Cap & Legend

11.89 Are all in-process WIP and materials properly identified and controlled in designate area?

11.90 Does the current process documentation cover screen preparation, screen cleaning, emulsion coating/application, exposure, development and baking conditions?

11.91 Is the screen exposure performed in an environmentally controlled area with the relative humdity controlled to with +/−5% and temperature control of +/−2 degrees C?

11.92 Has the via plugging and legend process capabilities i.e. DOE's, etc been performed to optimize the screen mesh used, ink viscosity, blotting frequency (absorption paper), registration to prevent via plug or legend ink on SMT pads for the tightest tolerance designs?

11.93 Are there sufficient controls for ensuring via fill requirements are met?

11.94 Is the viscosity of the via plug ink checked after preparation to ensure that it mets documented requirements?

11.95 Is there objective evidence to demonstrate that all via plug ink are stored in temperature and humidity control environment? Also, inventoried under FIFO with expired date control?

11.96 Is the date and time that the via plug ink expires after preparation specified on its container?

11.97 Are the screen printers cleaned and maintained to a documented procedure?

11.98 Is blotter paper (screen cleaning absorption paper) used to remove excess ink on the legend & via plugging screens on a 10-20 panel frequency while screening product? Was this frequency based on engineering tests?

11.99	Has the via plug ink curing parameters been established and are they re-verified on a quarterly basis?
11.A0	Is the screen developing performed in a clean area with adequate ventilation?
11.A1	Are the squeegees controlled properly, such as the width, angle, resharpen freq?
11.A2	Are the screen frames routinely inspected for squareness, twisted rails, broken corners and other similar defects that would interfere with properly tensioned screens?
11.A3	Is there a documented closed loop system to verify the silk-screen stencil life cycle is controlled?
11.A4	Are silk-screen stencils identified with labels or plates which are visible when the stencil is in its racks or mounted in the printer
11.A5	Is there a documented requirement to inspect a stencil after it is cleaned?
11.A6	Is the screen tension checked during screen stretching, after develop & prior to use in manufacturing?
11.A7	Are the screens cleaned on a defined frequency?
11.A8	Is there a documented allowable via plugging & legend rework procedure with appropriate quality checks?

TABLE 7.12 Hot Air Leveling Process Audit

Item	Audit Criteria
12.00	Are the Hot Air Leveling processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
12.01	Does evidence exist that process capability studies have been performed for the Hot Air Leveling process i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
12.02	Is the overall appearance of the area and equipment condition adequate?
12.03	Does lot traceability exist that permits tracking the O/L lot number to all major equipment and materials i.e. HAL line, XRF, etc. used to fabricate the product?
12.04	Is there a continuous improvement team in place for the Hot Air Leveling Process Area with documented actions plans?
12.05	Are the laboratory records (i.e. Chemical Analysis, Solder Impurities etc.) for Hot Air Leveling process complete and up to date?
12.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
12.07	Are the calibration labels on critical equipment current?
12.08	Do training records exist for the Hot Air Leveling operators and are they current?
12.09	Do health and safety procedures exist and are they being followed?
12.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

Pre-Clean	
12.11	Is there a pre-startup checklist for the preclean lines? Is it current?
12.12	Is there objective evidence that the preclean chemistries are being analyzed by the laboratory on the documented frequency?
12.13	Is the microetch rate monitored? Is it under SPC control with calculated control limits and are the charts & actions current?
12.14	Are Dump and Remake schedules documented for the preclean line and objective evidence exist that they are being adhered too?
12.15	Are the final rinses deionized or RO water?
12.16	Is there evidence to demonstrate that all chemicals are monitored and controlled as listed in WI?
12.17	Are all in-process WIP and materials properly identified and controlled in designate area?
12.18	Is the specific gravity of the flux controlled?
12.19	Is there an evidence to demonstrate that the PCB surface cleanliness is monitored and controlled?

Hot Air Solder Leveling

12.20 Is there a pre-startup checklist for the HASL lines? Is it current(completely filled in)?

12.21 Are all in-process WIP and materials properly identified and controlled in designate area?

12.22 Is a pilot run to set HASL conditions such as Dip-in speed, dwell, withdraw speed, Hot air Temperature and pressure, Knife angle and gap to ensure the required solder thickness for each P/N to fine tune the setting to get uniform tin thickness and minimum plugged vias?

12.23 Is the angle and Gap of air knife verified regularly?

12.24 Is air knife distance checked with V-block as part of start-up checklist?

12.25 Did the supplier perform measurement verification and GR&R for air knife angle and air knife distance?

12.26 Is the Temperature and Pressure of Hot air verified regularly?

12.27 Are panels washed right after HASL to prevent flux drying?

12.28 Did the supplier ilnclude specific gravity and viscosity as flux process control parameters?

12.29 Does the supplier analyze the nickel and copper concentration in tin pot twice per week and establish SPC charts for each element?

12.30 When the nickel conc or copper conc out of spec, does the supplier do alloy adjustment to make sure the nickel and copper conc are within the spec? Do they reanalyze the nickel conc and copper conc after adjustment? Documented procedure and proof of training with sign-off by manufacturing manager?

12.31 Did the supplier document adjusting the alloy to maintain the nickel & copper concentrations within the Nihon specfication? Is there any proof of training with sign-off by manufacturing manager?

12.32 Does the supplier standardize the copper removal frequency? Is the carbonization removed thouroughly? What's the frequency?

12.33 Does the supplier document the air knife replacement frequency based on the production panels? Is the air knife blade smooth and will not impact the tin uniformity after HASL?

12.34 Are panels placed in slotted racks after HASL?

12.35 Did the supplier implement 20-40X stereo microscope inspection methodology for visual inspection for solder uniformity and solder plugged holes?

12.36 Is the lighting at LF HASL inspection area adequate?

12.37 Are the inspectors provided the visual aids for determining preferred and unacceptable uniformity conditions?

12.38 On-site check the LF HASL boards using 20~40X microscope, are the uniformity of tin is acceptable and solder plugged via hole less than 5%?

12.39 Does the supplier monitor one and two pass LF-HASL trends and set one pass 30-day goal of 95%.

12.40 Does the supplier have the log sheet to record the LF HASL parameters setting for each Lot according to the customer's requirement?

12.41 Is solder thickness & composition checked on sampling basis after HASL?

12.42 Does the supplier measure the tin thickness on BGAs, QFP, SMT & 3mm X 3mm pad sizes? Sample size is 5 panels/lot min?

12.43 Does the traveler or other process documentation specify the solder thickness that meets HOLDEN CONSULTING PCB Specification GNTX-7000 criteria?

12.44 Is the solder purity checked and monitored? Is this requirement documented in the standard operating procedure?

12.45 Does the supplier send the solder sample to 3rd party for analysis for the nickel concentration and copper concentration in the solder pot, did they do correlation study with internal analysis? Did the supplier document this? Is there any proof of training with sign-off by manufacturing manager?

12.46 Is the X-ray used for solder thickness measurement? What's the frequency?

12.47 Is there a documented procedure to verify hole size for press-fit and other tight toleranced plated through holes at the HASL operation using pin gages?

12.48 Is there a feedback loop to pre-production engineering to provide hole size data to insure the hole sizes are centered on nominal and have a good Cpk?

12.49 Does the supplier perform 6X thermal stress test and do horizontal & vertical cross-section to verify the hole wall quality?

12.50 Does the supplier check the intermetallic thickness 1/week?

12.51 Have the supplier establish computer system for the LF HASL setting for each P/N?

12.52 Is there objective evidence to demonstrate that the PM's are being performed?

12.53 Are the panels in-time/on line inspected to prevent the volume defect

12.54 Is there a procedure to define the Rework of the defective boards after HASL?

12.55 Does the rework procedure defines the allowed maximum number of passes at 2 or less (first HASL & one re-HASL)?

12.56 Are the customer's fab print requirements for LF HASL copper thickness documented in the traveler and verified by cross section analysis?

12.57 For LF HASL applications, are analysis performed verifying LF HASL deposits are free of lead?

12.58 Are waste treatment manifests filed demonstrating HASL preclean, HASL/LFHASL and post clean chemistries/materials are properly disposed?

Post-Clean

12.59 Is there a pre-startup checklist for the postclean lines? Is it current?

12.60 Is the horizontal cooling system well maintained and set up and the boards can be held up (no scratch on solder surface will be caused)

12.61 Does the supplier add conductivity measurements to final DI rinse water on LF-HASL post treatment line?

12.62 Are the boards rinsed by warm water?

12.63 Are the boards rinsed by High pressure water/scrubbing?

12.64 Are Dump and Remake schedules documented for the postclean line and objective evidence exist that they are being adhered too?

12.65 Are the final rinses deionized or RO water?

12.66 Is there an evidence to demonstrate that the PCB surface cleanliness is monitored and controlled?

TABLE 7.13 OSP Process Audit

Item	Audit Criteria
13.00	Are the OSP processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
13.01	Does evidence exist that process capability studies have been performed for the OSP process i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
13.02	Is the overall appearance of the area and equipment condition adequate?
13.03	Does lot traceability exist that permits tracking the O/L lot number to all major equipment and materials i.e. OSP line used to fabricate the product?
13.04	Is there a continuous improvement team in place for the OSP Process Area with documented actions plans?
13.05	Are the laboratory records (i.e. Chemical analysis, etc.) for OSP process complete and up to date?
13.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
13.07	Are the calibration labels on critical equipment current?
13.08	Do training records exist for the OSP operators and are they current?
13.09	Do health and safety procedures exist and are they being followed?
13.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

OSP

13.11 Does the traveler or other process documentation specify the OSP coating thickness?

13.12 Is the OSP thickness specification per the suppliers recommendation?

13.13 Is the OSP thickness determined per the OSP suppliers recommended procedure?

13.14 Is the OSP thickness verified at start-up and checked twice per shift while processing PCB's?

13.15 Are all in-process WIP and materials properly identified and controlled in designate area?

13.16 Are the chemicals analyzed per supplier recommendation and is SPC implemented where applicable?

13.17 Is there objective evidence that the microetch (microinches of copper) is being performed per the suppliers recommendation? Is it under SPC control?

13.18 What is the max. allowable Cu limit in the microetch?

13.19 Is there objective evidence to demonstrate that the PM's are being performed?

13.20 Is the OSP line free of crystallization build-up?

13.21 Is there an documented squeegee (squeezing) roller inspection and cleaning procedure?

13.22 Is there a documented process to insure that there is no OSP residue present on the gold fingers for all PCB's with G/F connectors?

	Ionic Contamination
13.23	Is ionic contamination testing performed prior to OSP application on the product per the customer's specification?
13.24	Is the ionic contamination test frequency being performed at a minimum of once per lot?
	Quality Inspections
13.25	Are the latest visual inspection work instructions with defect photos posted for operator use?
13.26	Are visual inspections being performed using 1.75× magnification per IPC-A-600 and verifications being performed at 30× magnification?
13.27	Is 100% visual inspection being performed?
13.28	Is the plated copper thickness verified after the OSP operation?
13.29	Are random samples pulled to verify the presence of OSP before they are packaged?
	Rework
13.30	Is there a documented allowable rework procedure based on the OSP process supplier recommendations?
13.31	Are the OSP re-coats limited to only one complete cycle through the OSP line?
13.32	Are all repaired boards identified for traceability?
13.33	Is testing performed after all rework to validate conformance to HOLDEN CONSULTING PCB Specification requirements?
13.34	Is the Cu thickness in PTHs validated as part of the testing after rework to ensure no issues due to additional exposure to microetch chemistries?

	Handling
13.35	Have standard handling procedures been established based on OSP supplier handling requirements and put on-site for operator use?
13.36	After OSP coating, are all output boards protected by sulfur free slit paper?
13.37	Are the boards kept in a non-corrosive environment after the application of OSP while still in the manufacturing facility?
13.38	Is there a documented maximum hold time for unpackaged OSP boards?
13.39	Are the operators wearing gloves to help prevent tarnish when handling boards after ImAg has been applied?
13.40	Are the PCBs handled by the edges?
	OSP Packaging
13.41	Does the OSP finished PCBs packaging conform to the standards and procedures provided by the OSP process supplier?
13.42	Is the OSP finished PCBs using vacuum packaging?
13.43	Have all packaging materials (including slip sheets if used) been verified sulfur-free?
13.44	Are the sealed packages stored below 86°F (30°C)?
13.45	Since dessicants can contain sulfur, are they not used in packing the OSP PCBs?
13.46	Since rubber bands, adhesive tapes, labels, stamps can contain sulfur, are they not used on packing materials or boards?

TABLE 7.14 Final Fabrication Process Audit

Item	Audit Criteria
14.00	Are the FAB processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
14.01	Does evidence exist that process capability studies have been performed for the FAB process i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
14.02	Is the overall appearance of the area and equipment condition adequate?
14.03	Does lot traceability exist that permits tracking the O/L lot number to all major equipment and materials i.e. rout & scoring machines, etc. used to fabricate the product?
14.04	Is there a continuous improvement team in place for the FAB Process Area with documented actions plans?
14.05	Are the laboratory records (i.e. Chemical analysis, etc.) for the process complete and up to date?
14.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
14.07	Are the calibration labels on critical equipment current?
14.08	Do training records exist for the FAB operators and are they current?
14.09	Do health and safety procedures exist and are they being followed?
14.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

	Routing
14.11	Is the routing program checked prior to being released to production?
14.12	Are panels fixtured with locked pins during routing?
14.13	Are all in-process WIP and materials properly identified and controlled in designate area?
14.14	Is first article dimension checked on the bottom panel from each spindle before production start-up and on each subsequent rout machine setup?
14.15	Is stack height controlled properly based on pinning and abrasive used?
14.16	Is there evidence to demonstrate that all routing bits, V-cut/Beveller knives are well controlled? Such as the life control?
14.17	Is mechanical dimension PCB specification available at inspection station under document control?
14.18	Is there evidence to demonstrate that V-cut depth and board dimension are well controlled?
14.19	Is there process documentation in place to identify the customer's V-groove requirements? Is it verified during setup and lot inspection?
14.20	Are output boards at the bottom of each spindle inspected the dimension?

TABLE 7.15 Electrical Test Process Audit

Item	Audit Criteria
15.00	Are the Electrical Test processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
15.01	Does evidence exist that process capability studies have been performed for the Electrical Test process i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
15.02	Is the overall appearance of the area and equipment condition adequate?
15.03	Does lot traceability exist that permits tracking the O/L lot number to all major equipment and materials i.e. Test Fixture, Tester, Operator, etc. used to fabricate the product?
15.04	Is there a continuous improvement team in place for the Electrical Test Process Area with documented actions plans?
15.05	Are the laboratory records (i.e., etc.) for the process complete and up to date?
15.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
15.07	Are the calibration labels on critical equipment current?
15.08	Do training records exist for the Electrical Test operators and are they current?
15.09	Do health and safety procedures exist and are they being followed?
15.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

	Electrical Test
15.11	Are boards separated in a fool proof manner after test to avoid mixing passed and failed boards?
15.12	Are temperature and humidity monitored to optimized test conditions?
15.13	Are all in-process WIP and materials properly identified and controlled in designate area?
15.14	Does the test fixture passed the incoming inspection before they are used?
15.15	Are the tools and fixtures associated with P/N and REV clearly identified?
15.16	Is full open and full short test by Aluminum foils and back up routinely before testing every shift?
15.17	Are all open/short test machine grounded?
15.18	Is testing machine having self-check function before each shift machine start-up?
15.19	Is there procedure in place that clearly defines the ET fixture set up? Is there objective evidence that it is followed?
15.20	Are the test fixtures for the product capable of simultaneously contacting all assigned points? No flip testing allowed.
15.21	Are the tools and fixture checked at the start of each shift?
15.22	Is Debug performed in an isolated area to avoid mixing passed and failed boards?
15.23	Are boards re-tested after verification?
15.24	Are repaired PCB's subjected to a complete electrical test after repair?
15.25	Are false defect rate tracked with defined target?
15.26	Are the PCBs properly identified by their P/N, status, and traceability information?
15.27	Are all passed/rejected boards properly labeled and segregated to avoid mixing or missing?
15.28	Is the 100% electrical test requirement documented and performed per customer specification?
15.29	Are the electrical testers capable of testing open circuit resistance threshold of 10 ohms as described in the customer specification?
15.30	Are the electrical testers capable of testing isolation resistance threshold of at least 10 Megaohms with a voltage of at least 100 volts as described in the customer specification?
15.31	Do the electrical testers have a means of limiting the energy delivered to failing (shorted) networks so that tested products are not damaged?
15.32	Is the open and short repair procedures documented and operators trained and certified?
15.33	Is the same S/M material used for touch-up & repair as was originally coated on the PCB?
15.34	Are the soldermask touch-ups tape tested?
15.35	Is there documentation that identifies traces that can and cannot be repaired?
15.36	Is the baking oven well calibrated?
15.37	Are the passed boards marked properly with an electrical test stamp?
15.38	Are the electrical test equipment capabilities evaluated regularly?
15.39	Is the Dielectric Withstanding voltage 500V AD/DC +0.15/−0 for spacing over .003 in and 250V AC/DC +0.15/-0 for spacing under .003 in?

TABLE 7.16 Final Inspection/Impedance Process Audit

Item	Audit Criteria
16.00	Are the Final Inspection processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
16.01	Does evidence exist that process capability studies have been performed for the Final Inspection process i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
16.02	Is the overall appearance of the area and equipment condition adequate?
16.03	Does lot traceability exist that permits tracking the O/L lot number to all major equipment and inspectors?
16.04	Is there a continuous improvement team in place for the Final Inspection Area with documented actions plans?
16.05	Are the laboratory records for Final Inspection Certificates of Conformance & FAI's complete and up to date?
16.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
16.07	Are the calibration labels on critical equipment current?
16.08	Do training records exist for the Final Inspection operators and are they current?
16.09	Do health and safety procedures exist and are they being followed?
16.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

Final Inspection	
16.11	Are customer specifications readily accessible, clearly legible, and understood in the inspection area?
16.12	Are inspection stations equipped with magnified ring lights or stereo microscopes (10× min)?
16.13	Is there adequate lighting in the inspection area and at inspection stations?
16.14	Do the final QC inspectors have access to 40× magnification or greater for defect verification?
16.15	Are all in-process WIP and materials properly identified and controlled in designate area?
16.16	Is there a workmanship standard for touch up of final QC?
16.17	Is there the standard handling work instruction put on site? Are the inspectors handling the board properly to avoid damage or mixing?
16.18	Is there a nonconforming procedure that clearly define the disposition of nonconforming boards?
16.19	Are all of the nonconforming boards sufficiently segregated and identified?
16.20	Is there a documented system to track the performance i.e. number of inspection escapes to the customer for each inspector? If the inspectors performance is poor, is there any re-training or job transition?
16.21	Are previous quality issues and customer complaints highlighted in inspection records for a given part number?
16.22	Is there a feedback loop to pre-production engineering to provide hole size data to insure the hole sizes are centered on nominal and have a good Cpk?
16.23	Are inspection tools/gages (pin gages, calipers, etc) and test equipment on a defined calibration frequency? Does objective evidence exist that it is being performed?
16.24	Are the rejected PCB properly identified by their P/N, reject status, and reject information?
16.25	Does the final QC documentation have inspection guidelines for soldermask interface attack (SMIA) and have the operators been trained to identify this defect?
16.26	Are requirements documented, procedures established and methods adhered too for soldermask repairs?
16.27	Is the same S/M material used for touch-up & repair as was originally coated on the PCB?
16.28	Are all in-process and final inspection reworks and touch-ups cross checked by final QC inspectors?
16.29	Are soldermask touchups adhesion tape tested per IPC (IPC-TM-650, Method 2.4.28.1)?

	Impedance Test
16.30	Are controlled impedance boards/coupons tested in accordance with customer's spec and drawing?
16.31	Is there a documented system in place to convey the customer's impedance measurement requirements on the PCB fab drawing?
16.32	Is the impedance equipment separated in ESD room so that there is no influence on test?
16.33	Are all in-process WIP and materials properly identified and controlled in designate area?
16.34	Is there a work instruction for impedance test?
16.35	Are TDR probes inspected regularly for wear and replaced as needed? Are the machines calibrated periodically?
16.36	Is the impedance equipment utilized have accuracy, repeatability and reproducibility of 10% or less of the impedance range being verified?
16.37	Are impedance measurement records maintained for a minimum of two years?
16.38	Is the impedance test using automated fixture?

TABLE 7.17 Laboratory Process Audit

Item	Audit Criteria
17.00	Are the Laboratory Procedures documented and are the latest revision Work Instructions, PM, Calibration, Inspection procedures and all wet and dry lab procedures in place for the laboratory technicians to follow?
17.01	Does evidence exist for process capability for the Packaging & OBE processes i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
17.02	Is the overall appearance of the area and laboratory equipment condition adequate?
17.03	Does lot traceability exist that permits tracking the O/L lot and to all major equipment and materials i.e., etc. used to fabricate the product?
17.04	Is there a continuous improvement team in place for the Laboratory Area with documented actions plans?
17.05	Are the laboratory records (i.e. Cross-sections for hole roughness, etc.) for the process complete and up to date?
17.06	Are the technician and Maintenance PM's documented and objective evidence exist that they are performed?
17.07	Are the calibration labels on critical equipment current and current?
17.08	Do training records exist for the Laboratory Technicians and are they current?
17.09	Do health and safety procedures exist and are they being followed?
17.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?
	Cross-Section Laboratory
17.11	Are the requirements documented, procedures established and methods adhered too for microsection evaluations?
17.12	Is there a documented system for customer fab drawing requirements (dielectric thickness, copper weights, surface copper, plating thickness, etc.) for microsection verification?
17.13	Is there a formal system to provide feedback to Product Engineering, Process Engineering and Operations for microsection failures?
17.14	Are structural integrity microsection coupons prepared per IPC-TM-650, Method 2.1.1 or 2.1.1.2 with acceptability verified per IPC-6012, Class 2?
17.15	Are thermal stressed samples prepared for microsection coupon per IPC-TM-650, Method 2.6.8 and microsectioned per IPC-TM-650, Method 2.1.1.2 with acceptability verified per IPC-6012, Class 2?
17.16	Is the structural integrity verified at 1X and 3X thermal shocks?

17.17	Are thermal stressed microsection performed at the rate of at least one coupon per 100 customer panels produced?
17.18	Is the temperature verified on the solder pot before coupons are thermal stressed?
17.19	Is the microscope measurement system validated against a standard daily before microsection measurements?
17.20	Has a Gage R & R been performed on the microsection measurement system?
17.21	Are microsection coupons retained for six months with an adequate index system for locating archived microsections?
17.22	Are the archived microsection coupons and documents traceable to manufacturing lots and shipping lots?
17.23	Is there a system in place to archive microsection results and coupons for six months?
17.24	Are plating adhesion tests performed per IPC-6012, Class 2 Section 3.3.7 at the customer's prescribed frequency?
17.25	Are solderability test performed per IPC-6012, Class 2 and method D of J-STD-003, Category 2?
17.26	Are solderability test samples archived for six months?

Reliability & Wet Laboratory

17.27	Is there a documented analytical sampling plan with a closed loop system to insure that all chemical analysis are performed per either the laboratory procedure or manufacturing SOP?
17.28	Is there a documented traceable closed loop system to insure that identified adds to wet processes are made?
17.29	Have guard band limits been established for all critical process chemistries to insure chemical processes stay in control between analysis?
17.30	Is there a documented procedure to make chemical adds based on action limits to prevent chemistries from going outside the specification limits between analysis?
17.31	Are chemical process Cpk reports for critical chemistries generated, monitored and have continuous improvement plans for any Cpk less than 1.5?
17.32	Is there a system in place to monitor chemical reagent expiration date?
17.33	Is there an archived traceable system to find historical analytical results for all chemical laboratory analysis?
17.34	Are the analytical reagents certified standards or are they verified against known standards?
17.35	Are the analytical instruments standardized against know standards prior to performing chemical analysis?
17.36	Are all tests performed in a safe manner with proper protective gloves, face shield, clothing and ventilation?
17.37	Is S.I.R testing performed at least once per quarter on inner layers after oxide, prior to soldermask and after finishing (each soldermask type)?

TABLE 7.18 Waste Treatment & Chemical Storage Process Audit

Item	Audit Criteria
18.00	Are the waste treatment procedures, purified water (deionized or reverse osmosis) and chemical storage procedures documented and are the latest revision Work Instructions, PM, Calibration, Inspection procedures & all wet lab procedures in place for the laboratory technicians to follow?
18.01	Does evidence exist that the Waste Treatment processes have been characterized and the capabilities and treatment capacities are fully understood and documented?
18.02	Is the overall appearance of the area and waste treatment equipment condition adequate?
18.03	Are the waste treatment discharge records traceable to dates treated and treatment equipment?
18.04	Is there a continuous improvement team in place for the Waste Treatment operation with documented actions plans?
18.05	Are the laboratory records for waste treatment process complete and up to date?
18.06	Are the waste treatment technician/operators and maintenance PM's documented and objective evidence exist that they are performed?

18.07 Are the calibration labels on critical equipment current and current?

18.08 Do training records exist for the Waste Treatment Technicians/Operators and are they current?

18.09 Do health and safety procedures exist and are they being followed?

18.10 Have standard chemical handling procedures been established and put on-site for the operators to follow? Are the operators wearing appropriate safety equipment while handling chemicals or waste?

Chemical Storage

18.11 Are bulk storage tanks located in area that has adequate containment for spills?

18.12 Are bulk storage tanks connected to segregated waste streams to avoid cross contamination, noncompatible chemicals from coming into contact with each other and contamination of the environment?

18.13 Is there a system in place to monitor the level (quantity) in the bulk tanks to insure additional chemistry is ordered to prevent running out?

18.14 Are bulk chemicals analyzed or certifications verified before pumping from the delivery tanker into the bulk storage tank?

18.15 Are drummed chemicals stored in a warehouse with temperature control and stored per the chemical suppliers recommendation?

18.16 Are drummed chemicals labeled with a legible label with adequate information to insure that the appropriate chemical is issued to the floor when a request is submitted?

18.17 Are drummed chemicals stored in a warehouse utilizing a first-in first-out system?

18.18 Are drummed chemicals managed under inventory control to insure that additional chemistries are ordered in time to prevent running out?

18.19 Are there documented water quality levels established for the deionized water and/or reverse osmosis water systems?

18.20 Are there established maintenace schedules for the deionized or reverse osmosis systems based on water quality (purification) levels?

18.21 Is there a documented system for the deionized water and/or reverse osmosis water systems to insure water quality levels are maintained?

18.22 Are drummed chemicals managed under inventory control to insure that additional chemistries are ordered in time to prevent running out?

	Waste Treatment
18.23	Are all hazardous chemical manufacturing process waste streams segregated (i.e. chelated metals, etc.) and processed through the waste treatment operation before discharging to the environment?
18.24	Do the hazardous chemical process equipment equipped with containment vessels to help control/manage spills and are they piped to the appropriate waste stream for the waste treatment operation?
18.25	Are there documented reaction plans in place for spills in the manufacturing areas to insure the waste treatment treating capacity is not exceeded and resulting in an discharge excursion?
18.26	Are the waste streams analyzed to confirm conformance to governmental treated waste regulatory requirements?
18.27	Are waste treatment discharge levels reviewed by upper management during operation reviews?
18.28	Is there a documented reaction plan for waste treatment excursions that exceed internal and external (governmental) regulatory requirements?
18.29	Are hazardous waste and spent solids removed from the premises by government approved agencies or licensed companies?
18.30	Is waste water treatment in accordance with government standards?
18.31	Are records of compliance to government standards for waste water current?
18.32	How often is the waste water tested? Does the company check this regularly or wait for the government agency to test the waste water?
18.33	Are all manifests and transactions records of hazardous waste and spent solids removal current?
18.34	Are hazardous waste and spent solids picked up on a scheduled basis or an "on-call" basis?
18.35	Have any of the waste streams exceeded governmental regulatory requirements in the past twelve months?
18.36	Is there a waste minimization project team in place with active actions?

TABLE 7.19 Packaging & OQA Process Audit

Item	Audit Criteria
19.00	Are the Packaging & OBE processes documented and are the latest revision Work Instructions, Calibration & Inspection procedures for all processes in place for operators to follow?
19.01	Does evidence exist for process capability for the Packaging & OBE processes i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
19.02	Is the overall appearance of the area and equipment condition adequate?
19.03	Does lot traceability exist that permits tracking the O/L lot and to all major equipment and materials i.e., etc. used to fabricate the product?
19.04	Is there a continuous improvement team in place for the Packaging & OBE Process Area with documented actions plans?
19.05	Are the laboratory records (i.e. Cross-sections for hole roughness, etc.) for Packaging & OBE process complete and up to date?
19.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
19.07	Are the calibration labels on critical equipment current?
19.08	Do training records exist for the Packaging & OBE operators and are they current?
19.09	Do health and safety procedures exist and are they being followed?
19.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

	Packaging
19.11	Is the work instruction for packaging in place and under document control?
19.12	Are lots properly separately part number to avoid mixing parts during packaging?
19.13	Are parts vacuum packaged?
19.14	Are proper methods used to prevent moisture absorption?
19.15	Are weight restriction defined for boxes?
19.16	Are customers requirements for packaging accessible?
19.17	Does the suppliers have bar code capability?
19.18	Are boxes properly labeled on outside with date code, qty, x-out, inspection reports?
	Outgoing Quality Audit (OQA)
19.19	Is there an inspection Instruction for the specific product being audited?
19.20	Is the sampling plan set with consideration of existing outgoing quality level and target?
19.21	Is the OQA defective level tracked as an index to predicted the outgoing quality level?
19.22	Does the OQA test and inspection has good coverage? Such as check the packaging, labeling, quality of PCB and the attachments etc?
19.23	Do all units of the reject lot go through all the final test and inspection, and not just for the failed test and inspection?
19.24	Are the rejected PCB properly identified by their P/N, reject status, and reject information?
19.25	Is CAR issue for the failure found?

TABLE 7.20 Electroless Nickel/Immersion Gold Process Audit

Item	Audit Criteria
20.00	Are the Electroless Nickel—Immersion Gold processes documented and are the latest revision Work Instructions, PM, Calibration & Inspection procedures for all processes in place for operators to follow?
20.01	Does evidence exist that process capability studies have been performed for the Electroless Nickel—Immersion process i.e. processes characterized, critical parameters identified, FMEA, SPC, gage R&R, and Cp & Cpk reporting?
20.02	Is the overall appearance of the area and equipment condition adequate?
20.03	Does lot traceability exist that permits tracking the O/L lot number to all major equipment and materials i.e. Plating line, XRF, etc. used to fabricate the product?
20.04	Is there a continuous improvement team in place for the Electroless Nickel—Immersion Gold Process Area with documented actions plans?
20.05	Are the laboratory records (i.e. Chemical analysis, cross-sections, etc.) for Electroless Nickel—Immersion Gold process complete and up to date?
20.06	Are the operator and maintenance PM's documented and objective evidence exist that they are performed?
20.07	Are the calibration labels on critical equipment current?
20.08	Do training records exist for the Electroless Nickel—Immersion Gold operators and are they current?
20.09	Do health and safety procedures exist and are they being followed?
20.10	Have standard handling procedures been established and put on-site for the operators to follow? Are the operators wearing gloves when handling product?

Electroless Nickel/Immersion Gold (ENIG)

20.11 Has the ENIG chemical supplier audited and approved process. Provide date of last audit?

20.12 Is there a pre-startup checklist for the plating line(s)? Is it current (completely filled in)?

20.13 Is the line an automated with an established timeway?

20.14 Is there objective evidence that the chemistries are being analyzed by the laboratory on the documented frequency?

20.15 Are all in-process WIP and materials properly identified and controlled in designate area?

20.16 During production runs, are additional checks of controllers, pumps, bath levels, temperatures, agitation, and rinses performed every two hours?

20.17 Are the chemical controls based on the process chemistry suppliers TDS?

20.18 Are the rinses DI water? Clean and algae free?

20.19 Are the maximum nickel and gold bath turnover before dump documented? Does objective evidence exist?

20.20 Is a first article checked performed on the first basket or rack to confirm process parameter to insure meeting nickel and gold thickness and other quality parameters?

20.21 Are liners, or anodic protection used in the nickel & gold bath?

20.22 Is the maximum idle time at temperature established for the plating line?

20.23 Is air agitation used in critical tanks i.e. microetch, rinses, nickel bath?

20.24 Is the microetch rate monitored on a daily basis?

20.25 Is the nickel tank on an automatic controller and do controller calibration records exist?

20.26 Is the stabilizer added separately to the electroless nickel bath?

20.27 Are the process rack/baskets coating in good condition, free of plate-up and on an documented recoating schedule?

20.28 Is there a documented quality conformance procedure with accept/reject criteria for gold finger plating line malfuctions(chemistries out of spec. time, temperature, etc. interuptions) to insure the quality of the product in the plating line?

20.29 Does the traveler or other process documentation specify the Nickel/Gold thickness?

20.30 Is the nickel and gold plating rates documented and objective evidence exist that they are being monitored?

20.31 Is rework performed for ENIG? If so, what type of rework?

20.32 Is the IPC tape test performed on each lot for plating adhesion?

20.33 Are the customer specific ENIG thickness requirements documented on the traveler?

20.34 Are the XRF calibration records current and are appropriate XRF standards used to verify calibration?

20.35	Is X-ray measurement for Au/Ni/thickness performed on every production rack?
20.36	Are the deposition rates microinches/minute for the nickel & gold plating calculated and confirmed to meet the chemical supplier's recommended deposition rate each shift?
20.37	Is the solderability test being performed per J-STD-003, Category 2 to evaluate surface and hole solderability per IPC 6012 class 2 requirements?
20.38	Is the solderability test frequency being performed at a minimum of once per lot?
20.39	Have interactive influences for corrosion of nickel & gold peel been studied and findings implemented? Identify black pad precautions taken.
20.40	Have critical process parameter been identified on SPC and Cpk values monitored?
20.41	Is there a documented shutdown procedure for the entire plating line(s) that includes the critical steps for the nickel plating bath (temperature & nickel controller flushing)?

TABLE 7.21 Maintenance Process Audit

Item	Audit Criteria
	Equipment Maintenance
21.00	Is there a documented maintenance schedule for all critical equipment?
21.01	Do the maintenance records indicte the maintenance is being performed at the documented frequency?
21.02	Is there a closed-loop system to verify the maintenance occurs on the prescibed frequency?
21.03	Is there a valid spare parts inventory control system?
21.04	Are key spare part components identified and replenishment min/max. levels established?
21.05	Are worn/used parts disposed of properly to ensure they are not re-used?
	D.I. Water Maintenance
21.06	Are sand bed pre-filters used before Activated Carbon, RO and/or Ion-Exchange filters?
21.07	Is there a scheduled frequency to replace the media?
21.08	Is there an Activated Carbon prefiltration to block bacteria from entering the main filtration system?
21.09	Is an RO system or ion-exchanger used to prefilter the water before mixed bed or resin polishers?
21.10	Is there a scheduled frequency to service the RO or ion-exchange units?
21.11	Is the DI water resistivity electronically monitored? M ohms or u-Siemens?
21.12	Is D.I. Water process rating acceptability at (4)18 to 15 meg, (3)15 to 10 meg, (2)10 to 5 meg or (1-0)less? Or in micro Siemens: (4).055 to .065 uS, (3).065 to .100 uS, (2).100 to .200 uS, greater?
21.13	At what resistance is an emergency filter change required? Less than 5Meg? Greater than .200uS?
21.14	Is there an Ultra-Violet final filtration to kill bacteria, which may be growing in the DI filter system, and prevent live bacteria from entering the factory DI water plumbing system?
21.15	How often is the factory plumbing (DI water pipes) cleaned to remove/purge algae? Is this maintenance on a scheduled basis? Semi-Annual or Annual?
21.16	Is the status of DI water plumbing cleanliness (bacteria & algae level) verified by TSS (total suspended solids) testing? Is this test performed on a monthly or semi-annual basis? Most TDS (total disolved solids) can be detected by resistivity meter, but is TDS tester also utilized to detect PPM?
21.17	At what TSS level is an emergency Plumbing System Cleaning required?
21.18	Is the Plumbing System Cleaned with H_2O_2 and peracitic acid? Other?
21.19	Are all water pipes throughout the factory labeled DI (for de-ionized water) and CITY or CW (for city water)?
21.20	Do all DI water rinse processes have resistivity meters at the input to the equipment?

Sourcing teams or suppliers can use the in-depth audit questions provided in each focus area to

- Troubleshoot PCB fabrication processes
- Eliminate special causes of variability
- Quickly identify areas for process improvement that will significantly reduce the likelihood of nonconforming product

The questions can be submitted as a written questionnaire, but it's generally much more effective to conduct an on-site audit of the suspect processes, ideally by a senior process engineer with expertise in PCB fabrication.

7.5 TESTING AND INSPECTION

Sound processes that are well managed are more likely to consistently produce good parts and minimize nonconformance, but testing nevertheless plays an important role in electronics manufacturing. Generally, it's better to insist that suppliers perform this testing on behalf of the customer rather than ship PCBs or PCAs for incoming inspection and disposition at the customer's site.

Suppliers are able to conduct testing and visual inspection at different stages of production. The sourcing team needs to consider *what specific testing is necessary* to support the overall quality strategy, and *how many parts should be tested* (the sampling frequency).

7.5.1 Testing and Inspection Commonly Performed at Suppliers

7.5.1.1 Incoming

- Lot check and inspection of incoming materials, chemicals, and components to verify what was ordered from their own suppliers
- Visual inspection of copper-clad laminate for physical damage, such as dents, scratches, or discoloration
- Inspection and verification of electrical test fixtures

7.5.1.2 In-process

- Automated optical inspection (AOI) for imaging artwork, finished innerlayers, and finished laminate after outerlayer processing to verify dimensions of etched features
- Visual inspection of laminated panels for physical damage, dents, scratches and other imperfections
- Visual inspection of hole positional accuracy, hole size, hole quantity, hole location, and surface appearance after drilling
- Backlight inspection of electroless copper coverage
- Visual inspection of soldermask coverage
- Visual inspection of solder uniformity and solder plugged holes after hot air leveling
- Visual inspection of solder joints after reflow and wave soldering

7.5.1.3 Outbound

- Coordinate measuring machine—measurements of critical dimensions and locations relative to datum
- Continuity testing (“opens and shorts”)
- Functional testing of PCAs using dedicated test fixtures
- Visual inspection versus workmanship standards, such as IPC-A-600 Acceptance of Printed Wiring Boards
- Controlled impedance measurements using time-domain reflectometry
- Inspection of cross-sections to check dielectric thickness or plating thickness

- Other destructive analysis and reliability testing, following procedures in IPC-TM-650, Test Methods Manual
- Cross-sections and x-ray analysis of solder joints

The sourcing team should review the standard test and inspection processes that are routinely conducted at the supplier, and review with internal engineering and quality teams to decide whether those processes will provide adequate coverage, particularly for the CPPs. The customer can certainly specify additional product-specific testing and inspection, either on finished boards or test coupons. If requested, inspection reports should be available from the supplier for each lot or work order.

The other decision that the sourcing team needs to make is the sampling frequency for supplier PCB/PCA testing or inspection. The team can insist on 100 percent inspection for in-process panels and boards; however, outbound audits that require destructive analysis of boards can add significant cost without improving quality. A common approach is to randomly select a small sample of boards for audit testing, based on acceptable quality level (AQL) tables (see Table 7.22). These tables provide the size of a random sample for a given lot size and desired quality level, and the maximum number of defects permitted in that sample in order to accept the lot.

TABLE 7.22 AQL Table Example

Lot size			Inspection Level		
			I	II	III
2	To	8	A	A	B
9	To	15	A	B	C
16	To	25	B	C	D
26	To	50	C	D	E
51	To	90	C	E	F
91	To	150	D	F	G
151	To	280	E	G	H

Maximum number of defects allowed

Inspection Levels:

- Level I: High confidence in supplier
- Level II: Default
- Level III: Low confidence in supplier

Lot size = 400, Inspection Level II -> Code H
Sample size = 50, Maximum of 3 defects for AQL of 2.5%

7.6 INCOMING INSPECTION

As mentioned above, it's better to identify nonconforming PCBs or PCAs at the supplier rather than at the receiving end. This means that only boards that pass testing and inspection are shipped to the customer, and any nonconforming boards can be immediately analyzed for root cause and dispositioned at the supplier. Note that there may be exceptions where specialized testing can only be performed at the customer site, for example if other elements of the final product are required to verify system functionality.

Chapter 8 describes the recommended procedures for qualifying a supplier for a specific part number and authorizing production. After the supplier has been approved for the part number, incoming inspection at the customer site can be reduced to a low-frequency audit as a confidence check of the supplier's overall quality system. If failures are found at incoming inspection, the sourcing team can recommend the following actions:

- Increase the frequency of incoming inspection at the receiving end until the supplier has demonstrated quality improvement. Use Inspection Level III in Table 7.22 as a guide.
- Meet with the supplier to review the defective boards, and return the boards to the supplier for root cause analysis and corrective action.
- Conduct a follow-up audit of the supplier's quality system, focusing on process management in the production areas that are implicated in the root cause analysis.
- Add more testing or increase the frequency of testing at the supplier, but only as a temporary measure. Improved quality comes from improved processes, not more testing.

- Consider passing the cost of the additional incoming inspection back to the supplier, if this is permitted in the terms and conditions of the supplier contract.

A decline in the quality performance from an approved supplier should also be addressed at regular business reviews with supplier management. Chapter 8 provides more details on this topic.

CHAPTER 8

PRODUCT ACCEPTANCE AND FEEDBACK

Tim Rodgers
University of Colorado, Boulder, Colorado

8.1 INTRODUCTION

The previous chapters in this part include processes and recommendations for determining the criteria that should be used to evaluate and select printed circuit board (PCB) or printed circuit assembly (PCA) suppliers, qualifying these suppliers, and monitoring their performance. This final chapter provides guidelines for design qualification, lot acceptance, and ongoing inspection of received boards and assemblies. It also gives some suggestions for long-term supplier management that minimizes the customer's internal expenses while maintaining a high level of supplier performance.

8.2 DESIGN QUALIFICATION

Chapter 6, “Supplier Selection and Qualification,” describes a general process for selecting a PCB or PCA supplier and adding them to an approved vendor list (AVL). Most companies establish guidelines for purchasing that favor AVL suppliers, including special approvals that are required in order to use a supplier that is not on the AVL. Some customers may consider a supplier on the AVL to be automatically qualified to build any design ordered by the customer. This general or “blanket” qualification would be based on the information and performance data collected during the initial supplier evaluation and selection process.

However, if the technology or quality requirements for a new design are significantly different or more challenging, the sourcing team should consider a design qualification process to verify that the approved supplier can meet the new requirements. Design-specific qualification is less risky, but it requires fabricating and inspecting additional boards, usually referred to as first articles, before authorizing full production at the supplier. Note that a customer can decide to accept first articles as incoming material if they pass inspection. The sourcing team can require design qualification for each new design, but if the new design is not significantly different they may choose to waive this requirement. Table 8.1 compares the pros and cons of general versus design qualification.

TABLE 8.1 Comparison of Product Qualification Strategies

	Pros	Cons
General Qualification (applies to all boards and assemblies)	• Based on information already collected during supplier assessment and selection processes • Eliminates delays and costs due to additional qualification testing and inspection	Risk of supplier using non-standard processes and special handling that does not represent actual production conditions
Part Qualification only for new technology	Focuses qualification activities on higher risk technology not previously used (e.g., new materials and processes)	Additional time and expense for qualification testing and inspection
Part Qualification for each new part number or design	Lowest risk	Additional time and expense for qualification testing and inspection

	Pros	Cons
First article inspection (FAI) as a separate order before authorizing production	Higher confidence that subsequent production will meet customer requirements	• Additional expense for separate order, although boards that pass may be approved for use • Risk of supplier using non-standard processes and special handling that does not represent actual production conditions
FAI using a sample of boards from the first production lot	• Boards that pass FAI can be immediately used in production • Standard production conditions at the supplier	If the lot is rejected at inspection, significant delays until corrective action is implemented

The benefit of first article inspection (FAI) before approving production is based on the assumption that the samples provided by the supplier are representative of the fabrication processes that will be used for later purchase orders. It’s important that the sourcing team makes this clear to the supplier. Any special handling of the FAI order or nonstandard processing can render the results meaningless because any subsequent production orders may not follow these same processes.

The number of boards in the FAI order depends on the level of confidence required to proceed. The AQL table in Table 8.2 provides a useful guide for selecting a sample size given the quality level and maximum number of defective boards permitted.

TABLE 8.2 AQL Table Example

Lot size			Inspection Level		
			I	II	III
2	To	8	A	A	B

Acceptable quality level

Maximum number of defects allowed

Inspection Levels:

- Level I: High confidence in supplier
- Level II: Default
- Level III: Low confidence in supplier

Lot size = 400, Inspection Level II -> Code H

Sample size = 50, Maximum of 3 defects for AQL of 2.5%

A popular alternative to inspecting a separate order of first articles is to take a sample of boards from the first lot received, again using Table 8.2. This ensures that the boards used to approve production came from the same fabrication processes. However, this is a risky approach. If defects are found during inspection, this could mean discarding or reworking the entire order, and delaying subsequent production until corrective action is taken and a new shipment is received.

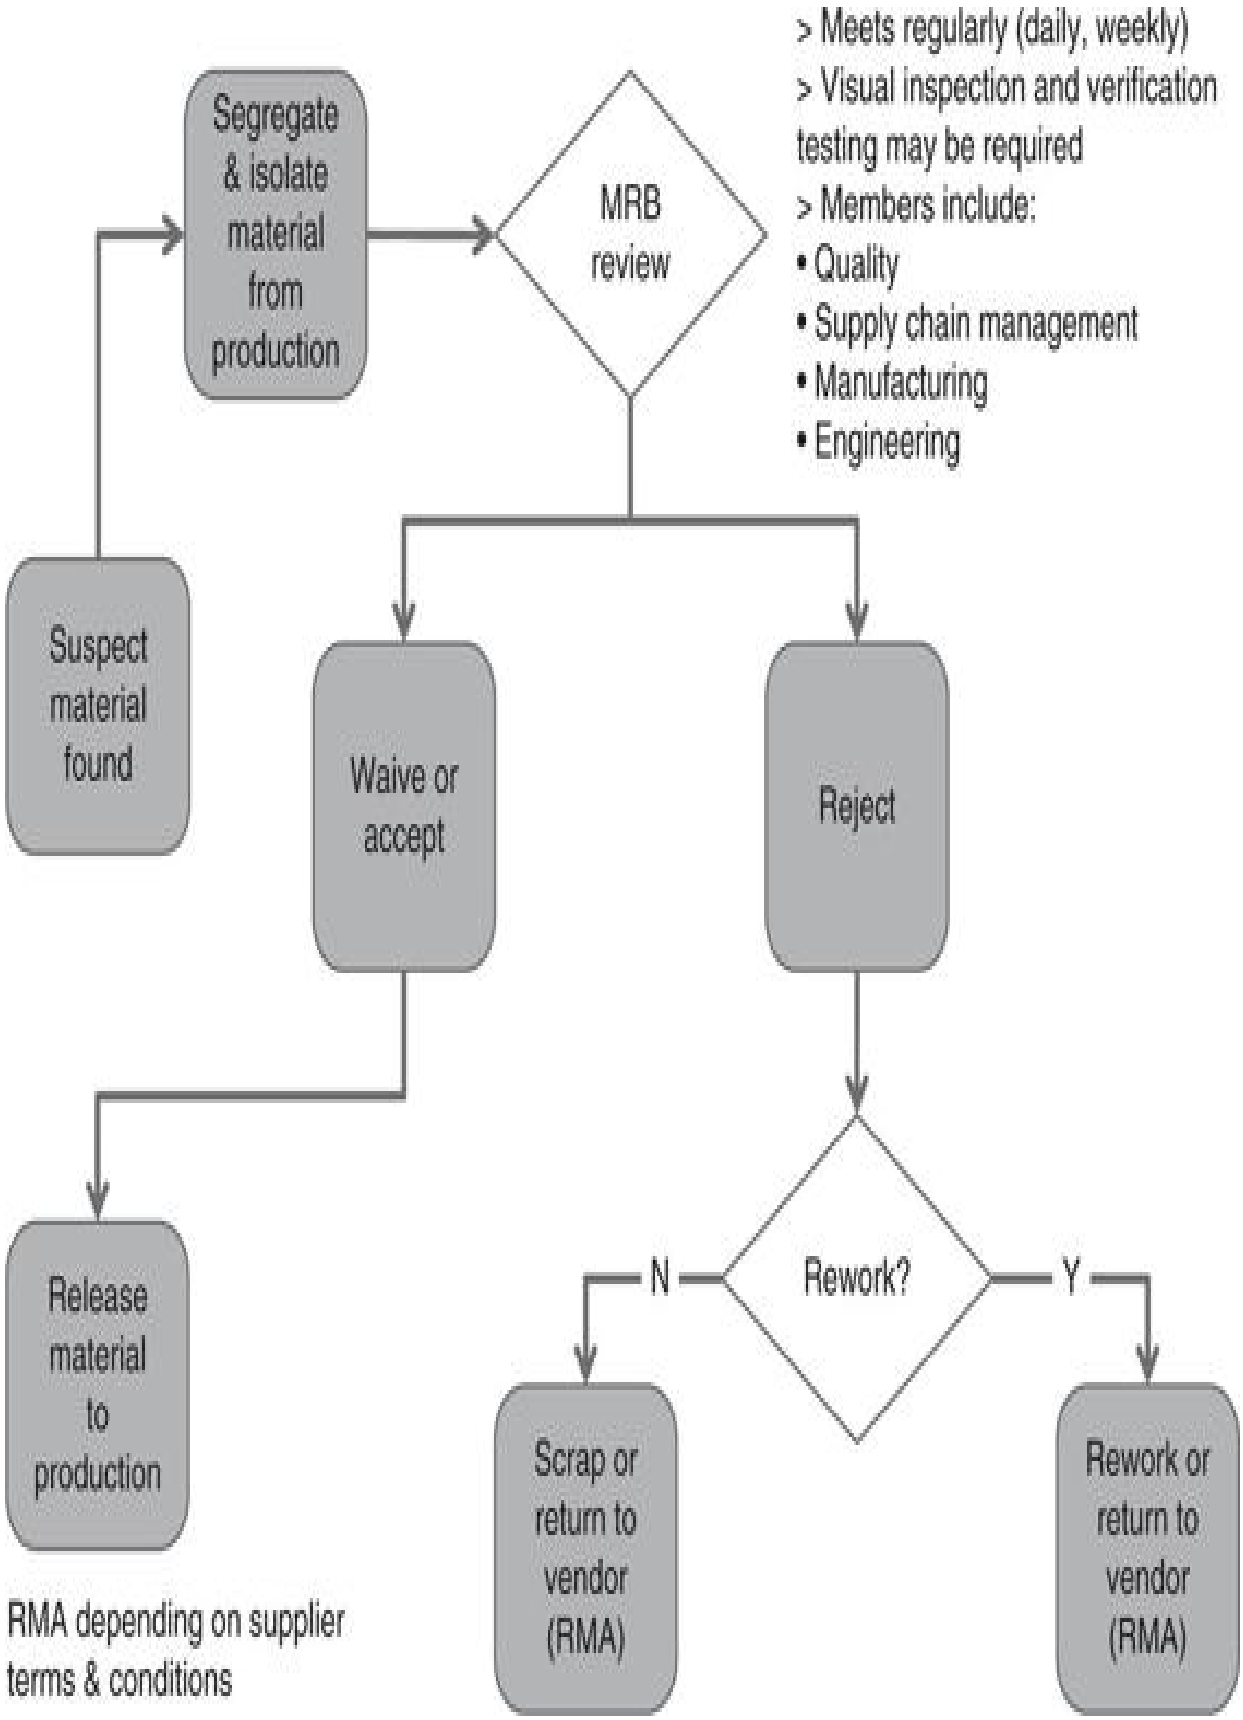
8.3 INCOMING INSPECTION AND LOT ACCEPTANCE

Chapter 7, “Process Control, Monitoring, and Incoming Inspection,” explains how to assess a supplier’s production processes and identify opportunities for improvement that will help reduce or possibly eliminate the need for incoming inspection. While it may be a useful check of quality performance when the customer has little experience with a new supplier, incoming inspection adds time and expense on the customer side. It also creates a lengthy feedback loop for any failures or discrepancies. It’s much better to “drive quality upstream” and insist on defect prevention through stable and robust processes, and early defect detection through in-process checks.

If the sourcing team decides to conduct incoming inspection on a short-term basis to determine whether to accept a lot of boards, the sampling plan provided in Table 8.2 is recommended. The table on the right shows the maximum number of defects that are permitted in the sample in order to achieve the required quality level. If more than that number of defects is found, then the entire lot should be rejected, and the supplier should be notified immediately to initiate a corrective action plan (see below).

Note that incoming inspection should be focused on the critical performance parameters (CPPs) previously identified by the engineering and production teams.

Boards that are rejected at incoming inspection, or elsewhere in subsequent processing or testing at the customer site should be immediately segregated from other boards in a separate physical location so they cannot be used in production. The recommended procedure is to use a cross-functional *material review board (MRB)* to regularly inspect segregated boards to determine an appropriate disposition. Figure 8.1 provides an overview of a typical MRB process.



> Meets regularly (daily, weekly)
> Visual inspection and verification testing may be required

Scrap or return to vendor (RMA)
Rework or return to vendor (RMA)
RMA depending on supplier terms & conditions

FIGURE 8.1 Basic material review board (MRB) process.

8.3.1 Possible Actions by the MRB

- Recommend the board for *rework*, followed by testing and inspection. Rework for a PCB may include manually cutting a trace or soldering a jumper wire, or replacing a component for a PCA. Reworked boards are less reliable than a good board and the decision to use reworked boards in the final product should be discussed with the appropriate engineering teams. The supplier must also be consulted to determine whether the rework should be done at the customer or at the supplier. In some cases a supplier may send authorized personnel to perform the rework at the customer's location. Regardless of where the rework occurs, the terms and conditions of the supplier contract should be consulted to determine who bears the expense of rework.
- Recommend the board for *scrap*. This may be appropriate if any attempted rework would create an unacceptable risk to product reliability, or is not economically feasible. Note that suppliers are typically reluctant to declare a board to be a bad candidate for rework. Scrapped boards are usually returned to the supplier for root cause analysis and replacement using a return merchandise authorization (RMA) process. As before, the terms and conditions of the supplier contract will determine any financial adjustments.
- Recommend the board for *use as-is*. This action essentially waives or overrules the finding of the previous test or inspection, determining after closer examination that the board can be accepted for subsequent production. This may be appropriate if there is some confusion or disagreement about acceptance criteria. It may also be taken as a calculated risk if the nonconformance is not critical to the function or reliability of the final product, or

if the factory needs the boards to avoid a more serious disruption in production.

If any nonconforming boards are discovered at incoming inspection or during later assembly or test operations, the sourcing team should discuss whether to increase the sample size and/or increase the scope of testing. To increase the sample size, refer to Table 8.2 and Inspection Level III. Additional testing or inspection may also be appropriate in order to check for similar dimensional or workmanship defects elsewhere on the same board.

8.4 SUPPLIER PERFORMANCE MANAGEMENT

It is important to notify suppliers promptly regarding any performance issue, specifically for quality or delivery problems discovered at the customer:

- For high-volume production, the supplier may have work-in-progress (WIP) that requires immediate intervention to address quality or delivery issues and prevent shipping more boards with the same defects or nonconformances.
- For new suppliers on the AVL, early feedback will enable the supplier to quickly address any misunderstandings or confusion regarding customer expectations before starting work on the next purchase order.

The timing of this communication depends on how quickly the supplier is expected to correct the issue. Feedback should be specific and detailed, including part number, lot number, invoice, date received, and supporting evidence such as photographs and test results if available. The supplier will need this information to conduct an

investigation of root cause and develop an appropriate corrective action plan.

For serious quality problems that require scrap or rework, customers should insist that the supplier submit a written document that describes the investigation and corrective actions, or a corrective action report (CAR). The purpose of the document is to provide a record of the problem solving activities, and establish confidence that the supplier has successfully addressed the issue and that the issue will not recur. A common methodology used by many suppliers is *Eight Disciplines Problem Solving (8D)* created by the U.S. Department of Defense and popularized by Ford (see Table 8.3), and the CAR based on this process is sometimes referred to as an *8D report*.

TABLE 8.3 8D Problem Solving and Report Elements

	Discipline	Description
D1	Use a team approach	Identify a team with technical expertise, product and process knowledge, and decision making authority; and provide their names
D2	Describe the problem	Use specific terms, photographs, and test or inspection results to explain the nature of the problem, including who, what, where, when, why, how, and how many.
D3	Develop interim containment plan	Define the plan that will be used to isolate the problem from the customer
D4	Determine, identify and verify root causes	Brainstorm possible causes, verify that they could be the cause of the problem, and identify the most likely root cause
D5	Choose and verify permanent corrections for the problem	Verify that the correction will actually solve the problem, using quantitative evidence
D6	Implement and validate corrective actions	Implement process changes and present evidence that those changes have eliminated the root cause
D7	Take preventive measures	Modify systems, practices, and procedures to prevent reoccurrence of this problem and any similar problems
D8	Congratulate the team	Recognize the efforts of the team

Another popular methodology is the *7-Step Problem Resolution Process*, attributed to Toyota and described in Table 8.4. Both 8D and the 7-Step Process emphasize the need to understand why the issue is occurring under one set of circumstances but not another, and to consider more than one possible root cause. Regardless of which process is used,

the customer should require a systematic approach to problem solving at the supplier that avoids these pitfalls:

TABLE 8.4 7-Step Problem Resolution Process

Step	Purpose	Output	Key Questions
1. Define Problem	Identify the problem and the importance of working on it. Usually a short title that best describes the problem	• Problem statement • Project owner • Business priority • Stakeholders (customers, suppliers, team members)	• What is the problem or gap to be addressed? • Why is this a customer / business priority? • Who are the key players associated with the project?
2. Current Situation	Clarify the problem area(s) as the situation exists today. Describe what is known about the problem	• Identification of where the problem is and is-not • Supporting information to help focus the root cause analysis	• What data do you have about the problem? • Are there trends in this data? • Is there other data that you need? • What key areas does the data tell you to focus on?
3. Cause Analysis	Identify and verify the root causes of the problem	• Causes of the the problem • Data and analysis verifying root causes	• Why is the problem occurring? • What are possible root causes based on data collected and analyzed in Step 2? • What causes have the greatest impact on the problem?
4. Solutions	Develop plans to eliminate the root causes of the problem	• Documentation of proposed solutions • Plan for implementing and monitoring results	• What possible solutions would eliminate the causes identified in Step 3? • What are the recommended solutions? • Who is impacted by the solutions? • What is the implementation plan? • What monitors have been established to measure improvements?
5. Check Results	Implement plans, confirm they have impacted the root causes and that goals for improvement have been met	• Data confirming that the solutions eliminated the root causes • Decision on whether to standardize the improvement	• To what extent have the solutions eliminated the root causes? • Have the desired goals been achieved? • Were there deviations from the planned improvement? • Should the improvements be standardized?
6. Standardization	Modify process/system to ensure that the improvements are sustained over time	• Documented plan for communicating, integrating and monitoring the change • Implementation of the plan	• What does the new process look like? • How will you integrate changes into the organization?
7. Future Plans	Evaluate	• Data and documentation showing the effect of the improvement effort • Summary of remaining problems and a plan for addressing them	• To what extend did the solution improve the problem? • Does the problem require further investigation? • What issues were uncovered during the problem solving? • What other areas should the process changes be applied to? • What did the team learn during the problem solving?

- Problem poorly defined and characterized
- Rapid convergence on a single root cause without considering others
- Unclear ownership for problem resolution
- Failure to segregate suspect material
- Poor verification of root cause or solution
- No schedule to track deliverables for verification
- No leverage of knowledge, defects discovered on similar products

There is often some urgency to find and resolve the issue, and the sourcing team should be wary of quick solutions proposed by the supplier without thorough analysis. The supplier may propose additional testing and inspection on their side to check for defects and prevent future escapes, but the sourcing team should push for permanent process changes to prevent defects from occurring in the first place. Finally, the corrective action request should not be considered closed until improvement has actually been measured and noted by the customer. A corrective action plan is not the same thing as the successful implementation of that plan.

Failure to promptly or successfully resolve an issue is a serious matter that could jeopardize the relationship between a supplier and a customer, particularly for repeat occurrences of the same issue. The sourcing team should closely monitor supplier investigations and their implementation of corrective action plans. Although any failure to meet customer requirements is a concern, issues will happen from time to time, and a supplier who takes swift and effective action on behalf of the customer can still be considered a valued partner.

8.5 BUSINESS REVIEWS

In addition to real-time notification about issues discovered by the customer, the sourcing team should also schedule periodic, formal reviews of supplier performance, including AVL suppliers who are well established. These meetings are often combined with on-site supplier factory audits and customer demand forecasts. The frequency of these business reviews may depend on the volume of shipments and the timeliness of the information that will be shared with the supplier, but should be at least once per year. A sample agenda for a supplier business review is shown in Table 8.5.

TABLE 8.5 Supplier Business Review Sample Agenda

Presentation from the customer's sourcing team:
➢ Review of supplier performance requirements and targets
➢ Production and delivery metrics
➢ Quality metrics and corrective action results
➢ Comparison of supplier performance vs. competitive benchmarks
➢ Future technology requirements
➢ Projected demand
Presentation from the supplier:
➢ Update on corrective action plans and open CARs
➢ Cost reduction plans, including yield improvement
➢ Other process improvements underway

8.5.1 Agenda Items for a Supplier Business Review Meeting

- General customer performance requirements and business priorities, emphasizing the elements of technology, responsiveness, quality, and cost (or price)

previously established by the sourcing team (see Chap. 3, “Basics of Printed Circuit Supply Chain Management”)

- Quantitative data based on the supplier’s performance during the previous review period, focused on the critical needs of the customer
- Supplier performance goals for the upcoming review period
- A look ahead to upcoming technology and demand requirements
- Any changes in the customer’s business that could impact the supplier relationship

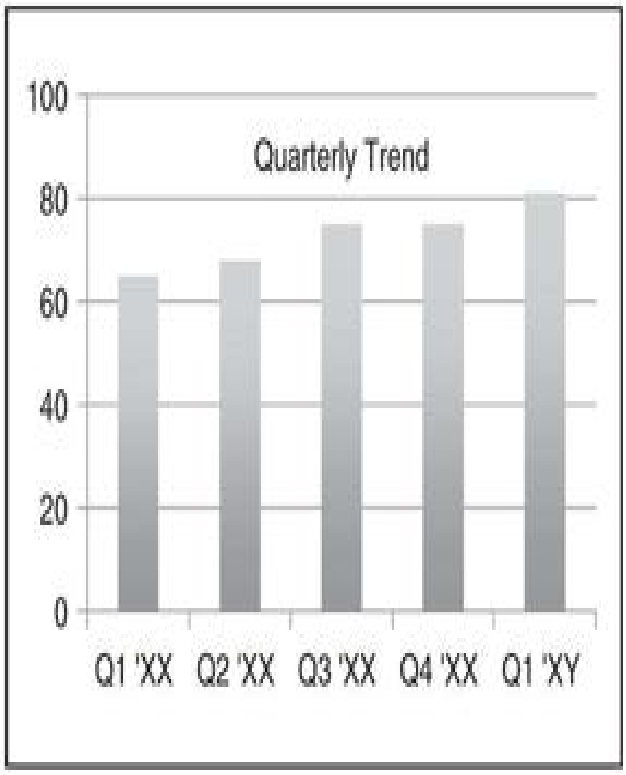
The specific supplier performance metrics will vary depending on the customer’s business priorities, but here are some examples used by sourcing teams:

- Percent of on-time deliveries (typically within a range of the commit date, such as from 3 days early to 0 days late)
- Lots rejected due to nonconforming or defective boards
- Score from a factory quality audit conducted by the customer
- Number and status of CARs
- Board price versus price reduction goals

A recommended way of presenting this information is a *supplier scorecard* or dashboard that includes a high-level summary of performance and trends over time. The sourcing team can assign a numerical score for each performance category, depending on how well the supplier meets the needs of the business, with the number of possible points in each category based on the importance of that category to the business. Figure 8.2 shows an example of a supplier scorecard and a plot of the supplier’s quarterly performance over time.

Category	Target	Max score	Supplier score
Minimum conductor width	4 mil	10	5 (8 mil)
On-time deliveries	95%	20	18 (90%)
Lead time for design changes	1 week	5	2 (2.5 weeks)
Rejected lots	0 lots	20	15 (1 lot)
Quality audit score	90	10	8 (75)
Open CARs	None > 1 month	15	15
First-pass yield	85%	10	10
Price reduction	5%	10	8 (4%)
TOTAL		100	81

Scorecard



Spider Diagram vs. Competition

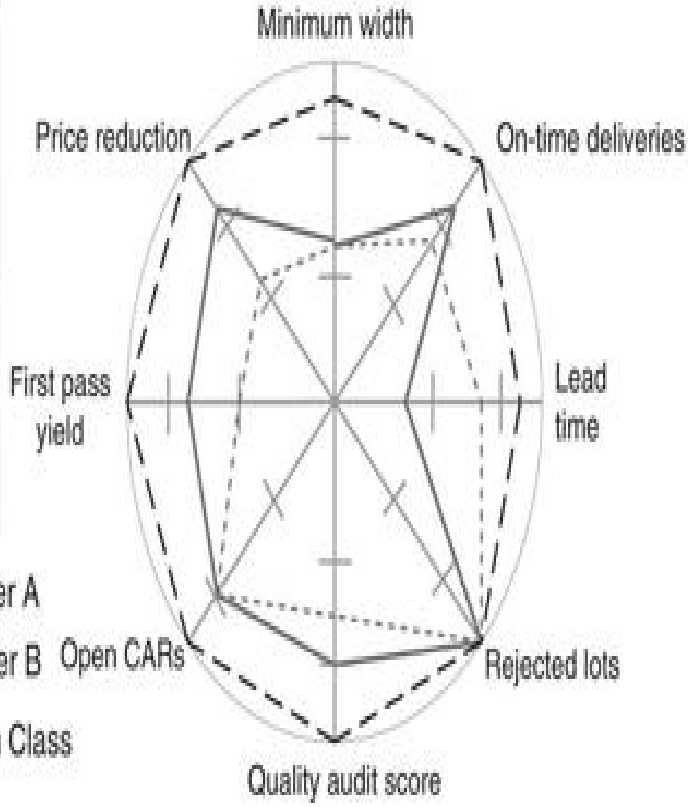


FIGURE 8.2 Supplier performance scorecard.

Also, if the customer uses more than one supplier for PCBs or PCAs, it can be useful to compare a supplier's performance against its competitors and identify gaps that can inspire improvement. A popular way of comparing suppliers is a *spider diagram*, shown in Fig. 8.2. Each supplier's performance level or score is plotted on axes radiating from the center and the points connected by a series of lines. Each axis represents a category in the scorecard. The resulting polygon provides a visual representation of overall performance and how that compares with other suppliers. Generally, the sourcing team should make sure their suppliers understand the need to improve over time in order to remain competitive and support the changing needs of the customer. The team should also regularly review supplier performance goals to determine if it's appropriate to raise the bar and demand higher performance.

The supplier should be invited to present at the business review as well. Possible topics of interest to the sourcing team include updates on new technology development, cost reductions and yield improvements, status reports on unresolved CARs, and any other planned process changes that could impact the customer.

If a supplier's performance consistently fails to meet expectations, or the sourcing team believes that the supplier is not making a good faith effort to improve, it may be necessary to switch suppliers for future production. Some companies will designate an under-performing supplier as "on probation" and restrict their use until improvement plans are successfully implemented within a designated period (see Fig. 8.3). The loss of future business needs to be a credible threat to be effective, and the sourcing team must weigh the switching cost and supply disruption against the

confidence level of better performance from a different supplier.

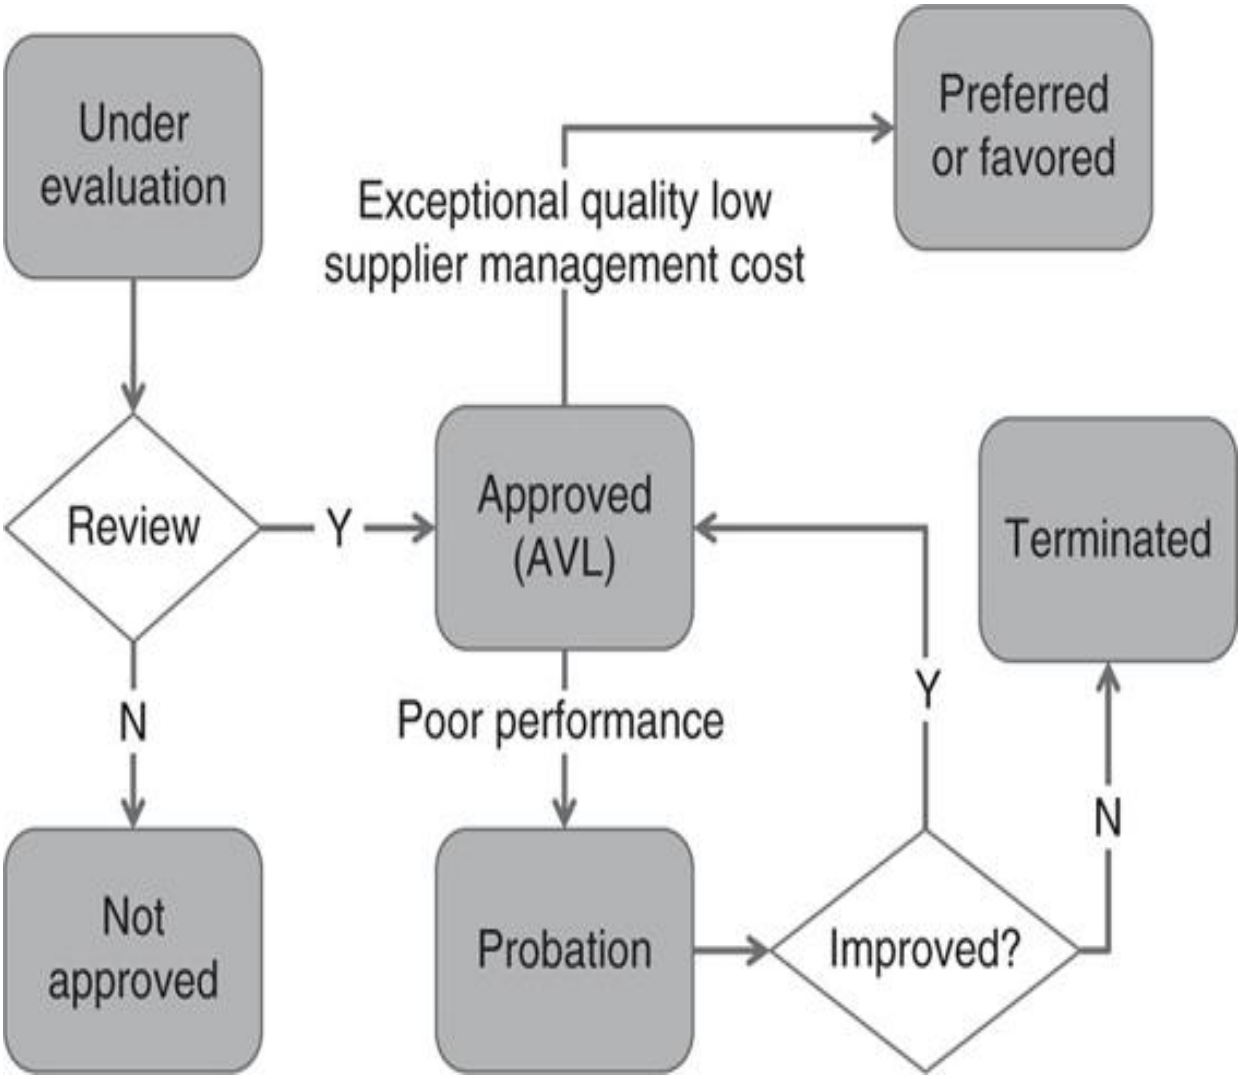

FIGURE 8.3 Supplier categories and transitions.

8.6 STRATEGIC SUPPLIER MANAGEMENT

In the case of a single transaction between a supplier and a customer there's little incentive for the supplier to provide exceptional performance that exceeds expectations. Most

suppliers operate with very small profit margins, and higher levels of service do not necessarily command a higher price. However, when a supplier believes there is a high probability of repeated transactions over an extended period, there are opportunities for mutual collaboration and partnership that supports strategic business objectives on both sides of the relationship.

From the standpoint of the customer, a supplier requires less time and cost to manage if they consistently provide high quality boards and deliver within the expected window. For example, high quality means the customer can consider a ship-to-stock program that eliminates incoming inspection or reduces it to a low-frequency audit. New designs can be rapidly qualified, which could translate into faster time-to-market. Similarly, a supplier can reduce or avoid cost when they are given the opportunity to provide design feedback to improve manufacturability, quality, and reliability.

Many companies have established a *preferred or favored supplier program* that recognizes the contribution of these suppliers to expense management and customer satisfaction (see Fig. 8.3). Preferred suppliers may receive a plaque, certificate, or other award from their customer that they can display in their lobby or promote on their website, but more importantly they may be eligible for considerations such as favorable pricing and payment terms. A customer might also agree to commit to pay for a fixed level of manufacturing capacity at a preferred or favored supplier, thereby providing predictable demand for better asset utilization.

The sourcing team should consider inviting a preferred supplier to participate in long-term planning discussions. Sharing this information helps the supplier understand the customer's future technology requirements and decide whether to add these capabilities. This works the other way as well: the customer's design team can capitalize on the supplier's technology that is currently available or in development. The customer can also provide insights about

other changes in the business that could have an impact on the supplier, such as emerging markets and the optimum geographic location of the supply chain. Generally, the better a supplier understands the customer’s business, the better they can represent the customer’s interests. Figure 8.4 summarizes the potential benefits of a closer partnership.

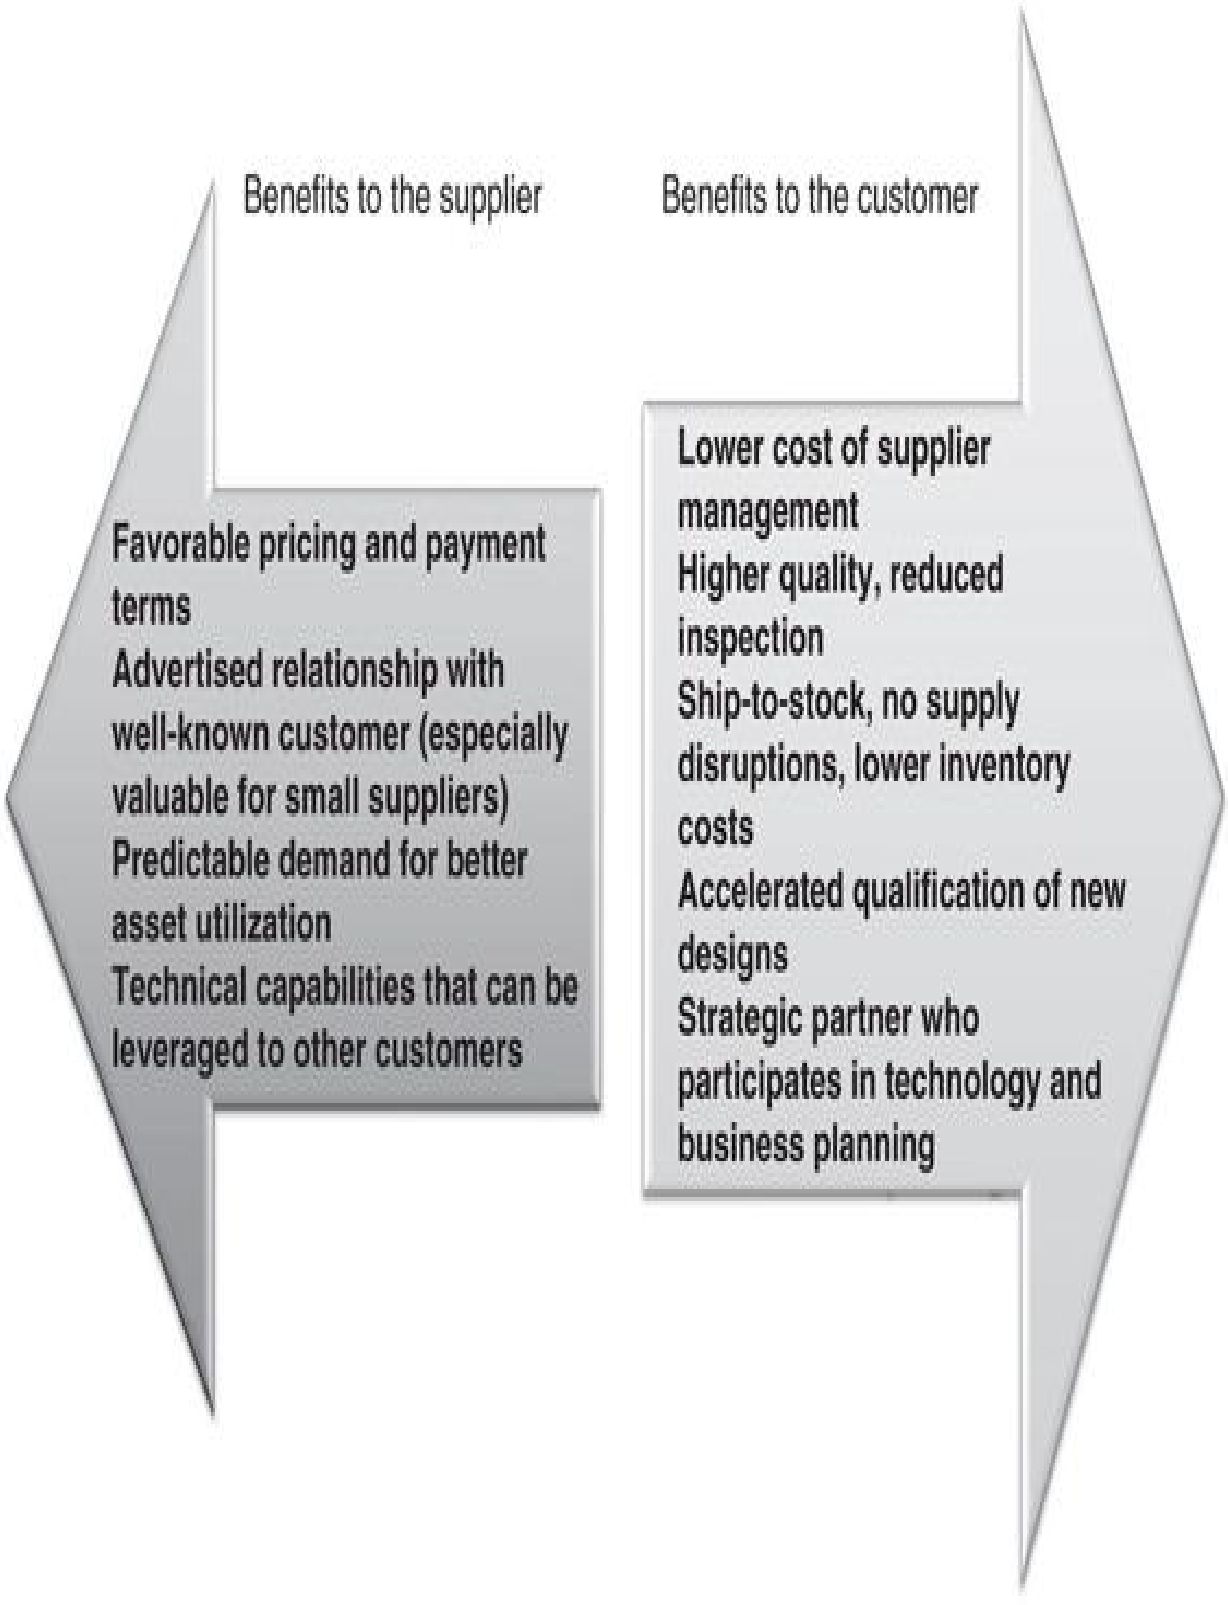

FIGURE 8.4 Advantage of a preferred supplier program.

8.6.1 Circumstances That Make It Necessary to Terminate a Supplier Relationship

- Persistent quality or responsiveness problems, and failure to successfully manage corrective actions
- Customer's cost to manage the supplier is excessive (e.g., number of resources and time required, including additional inspection or other quality incidents)
- Lower pricing from an alternate supplier
- Changing technology requirements that cannot be met by the supplier, such as high density interconnect technology or advanced materials and processes
- Changing business requirements that cannot be met by the supplier, such as shorter lead time or more consistent delivery time

Note that there is a cost for switching suppliers, particularly if this means starting a new relationship with a supplier that has no previous experience with the customer. The sourcing team should not overreact to supplier performance problems. It's important to assess these problems to determine whether the supplier is actually at fault, and assess whether a different supplier would be a net improvement. The timing of switching suppliers is also a consideration. Moving production of an active part number can create confusion in ordering and inventory management. It may be better to start production at the new supplier for the next new design or design revision.

If the decision is made to terminate the relationship, the sourcing team should give early notice to the supplier to prevent incurring additional cost for incoming materials. The customer is certainly not required to give a reason, but it is good business practice. A transition plan is necessary to determine the schedule for ramping down production,

managing remaining inventory and work-in-process, and returning all intellectual property that is owned by the customer.

PART 3

MATERIALS

CHAPTER 9

INTRODUCTION TO BASE MATERIALS

Edward Kelley
Douglas Trobough
Isola Group, Chandler, Arizona

9.1 INTRODUCTION

Just as printed circuits are a basic building block of electronic devices, base materials are a fundamental building block of printed circuits. But while the field of base materials can appear simple, variants in the building blocks used to make the base materials add significant complexity when deciding what material to use. In simple terms, base materials consist of just three components: the resin system (including any fillers used), the reinforcement, and the conductive foil. However, combinations of the available materials in each of these component categories require the user to make several important decisions. The best decision often depends on the end use application, which drives decisions on electrical performance, reliability and of course cost.

Also, because base materials are the most fundamental component of the printed circuit, they interact with critical printed circuit manufacturing processes. Therefore, not only are the physical and electrical properties of the material critical, but their compatibility with manufacturing processes used is also of great importance.

The advent of the European Union's Restriction of Hazardous Substances (RoHS) directive and the lead-free assembly processes that resulted, redefined the requirements for base materials. The impact of lead-free assembly on base materials and a method of selecting materials for lead-free assembly are discussed in Chap. 14 Requirements to support circuit densification, reliability, and electrical performance are also critical and will be discussed in Chap. 12. This chapter discusses grades and specifications of base materials, as well as the manufacturing processes used to make them.

9.2 GRADES AND SPECIFICATIONS

The various types of base materials can be classified by the reinforcement type, the resin system used, the glass transition temperature (T_g) of the resin system, as well as many other properties of the material. With the advent of lead-free assembly processes, properties other than T_g have become as important, if not more important when selecting a base material. The decomposition temperature (T_d) is one of these properties and will be defined shortly.

The most commonly referenced specification for base materials is IPC-4101, "Specification for Base Materials for Rigid and Multilayer Printed Boards." In the past, the National Electrical Manufacturers Association (NEMA) has also been used in specifying base materials.

9.2.1 NEMA Industrial Laminating Thermosetting Products

One of the first classifications of base materials for printed circuits (and other electrical components) was completed by the NEMA. NEMA's industrial laminating thermosetting products standard documents many of the materials used in printed circuits as well as specifications for some of their properties. Historical NEMA grades are outlined in Table 9.1 and cross-referenced with IPC-4101 in Table 9.2. Some of the commonly used materials have been FR-2, CEM-1, CEM-3, and, of course, FR-4.

TABLE 9.1 NEMA Base Material Grades

Grade	Resin	Reinforcement	Flame Retardant
XXXPC	Phenolic	Cotton paper	No
FR-2	Phenolic	Cotton paper	Yes
FR-3	Epoxy	Cotton paper	Yes
FR-4	Epoxy	Woven glass	Yes
FR-5	Epoxy	Woven glass	Yes
FR-6	Polyester	Mat glass	Yes
G-10	Epoxy	Woven glass	No
CEM-1	Epoxy	Cotton paper/woven glass	Yes
CEM-2	Epoxy	Cotton paper/woven glass	No
CEM-3	Epoxy	Woven glass/mat glass	Yes
CEM-4	Epoxy	Woven glass/mat glass	No
CRM-5	Polyester	Woven glass/mat glass	Yes
CRM-6	Polyester	Woven glass/mat glass	No
CRM-7	Polyester	Mat glass/glass veil	Yes
CRM-8	Polyester	Mat glass/glass veil	No

*ANSI, NEMA, and/or MIL-S-13949 grade. Note that MIL-S-13949 is not an active specification.

FR-2 is comprised of multiple plies of paper impregnated with a flame-resistant phenolic resin. It possesses good punching characteristics and is relatively low in cost. It has typically been used in simple applications such as radios, calculators, and toys, where dimensional stability and high performance are not required. FR-3 is also paper based, but uses an epoxy resin system.

CEM-1 uses a paper-based core with woven glass cloth on the surfaces, both impregnated with an epoxy resin. This enables the material to be punched while realizing improved electrical and physical properties. CEM-1 has been used in both consumer and industrial electronics.

CEM-3, a composite of dissimilar core materials, uses an epoxy resin impregnated, nonwoven fiberglass core with epoxy resin impregnated, woven fiberglass cloth surface sheets. It is higher in cost than CEM-1, but is more suitable for plated through holes. CEM-3 had been used in early home computers, automobiles, and home entertainment products.

FR-4, by far the most commonly used material for printed circuits, is constructed of woven fiberglass cloths impregnated with an epoxy resin or epoxy resin blend. The outstanding electrical, mechanical, and thermal properties of FR-4 have made it an excellent material for a wide range of applications including computers and peripherals, servers and storage networks, telecommunications, aerospace, industrial controls, and automotive applications. FR-4 will be discussed in more detail later.

9.2.2 IPC-4101 Specification for Base Materials for Rigid and Multilayer Printed Boards

The most commonly used specification for base materials is IPC-4101. This specification presents a classification scheme and specification sheets for the various materials in use. Table

9.2 summarizes the various materials by specification sheet number. Each specification sheet in IPC-4101[1] includes property requirements for that particular material type. It is recommended that the latest revision of this document be reviewed, although it is possible to specify materials based on past revisions of this document. Table 9.2 is presented for reference only and may not be all-inclusive as new specification sheets can be added periodically, so the user should consult this document when reviewing requirements. UL94 comments in Table 9.2 reference the minimum flammability requirements for that material. Materials may be more flame retardant than these minimum ratings. Also note that materials with halogen-free flame retardants are noted as such in the resin system column. Definitions of the UL flammability ratings are given in Chap. 11.

Some of the properties documented in the specification sheets of IPC-4101 include T_g, copper peel strengths at different conditions, volume resistivity, surface resistivity, moisture absorption, dielectric breakdown voltage, permittivity, loss tangent, flexural strengths and arc resistance. These properties will be discussed further in Chap. 11. In some cases the specification is listed as AABUS. AABUS is an acronym for "as agreed between user and supplier," meaning there is not currently an agreed upon industry specification value for that property.

It is also important to understand that the specification sheets may be used as a general starting point, and that the user and supplier are free to agree upon exceptions to certain values when sourcing the material. For example, there is a growing desire for lower and lower copper roughness profiles for signal integrity reasons. As the copper roughness decreases, the copper peel strength will generally decrease as well, and may fall below the values in the specification sheet. In this case, the user and supplier could reference a particular specification sheet and make an exception for the peel strength value. This could be done for other properties as well.

It should also be noted that the properties covered by these specification sheets refer to copper clad laminate and prepreg as noted on these sheets. Base material suppliers generally develop corresponding data sheets with typical material properties for the laminate and prepreg. Properties of actual printed circuits may vary from the values listed on the laminate and prepreg specification and data sheets. There can be multiple reasons for this, including property variation based on the actual construction and resin content of the materials used, as well as the influence of the printed circuit manufacturing process.

9.2.3 IPC-4103 Specification for Base Materials for High-Speed/High-Frequency Applications

There are additional specifications related to materials depending on the application. One of these is IPC-4103, which is for high-speed/high-frequency applications. As stated in the scope of this specification, it is for high-speed/high-frequency materials used for fabrication of printed circuits for microstrip, stripline, high-speed digital and RF/microwave electrical and electronic circuits. In general, laminates controlled by this specification usually have a dissipation factor of less than 0.005.

IPC-4103 parallels IPC-4101 in many ways, with the obvious increased emphasis on electrical properties. Like IPC-4101, IPC-4103 maintains specification sheets for different materials. Tables 9.3 and 9.4 are the summaries of specification sheets contained in IPC-4103. Note that there can be differences in the designations for metal cladding, as well as the overall designation scheme used in IPC-4103 compared to IPC-4101. The latest revisions of these specifications should be referenced when using these designations.

TABLE 9.3 Summary of Legacy Specification Sheets in IPC-4103

Specification Sheet #	Reinforcement	Resin System	Filter	Permittivity Range	ID Reference

9.2.4 IPC/JPCA-4104 Specification for High-Density Interconnect and Microvia Materials

In addition to IPC4101 and IPC-4103, IPC/JPCA-4104[3] is also used, and pertains to additional materials used for high-density interconnect (HDI) and microvia designs, particularly for thin multilayer PCBs used in such applications as mobile phones, smartphones and tablet computers. It contains information on the general classification and characteristics of HDI materials. Like the other specifications, it provides a designation scheme specific to the HDI materials as well as conformance and quality assurance requirements. The designation system for IPC-4104 is also different than for materials covered by IPC-4101, so it is recommended to refer to IPC-4104 when it is desired to use this system.

Figure 9.1 provides a very simple illustration of HDI with microvias, and Fig. 9.2 provides an illustration of various methods that can be used to manufacture HDI circuits with microvias. Currently, laser drilled microvias are the most common method used to make microvias, although there are specific applications and design types that use other methods. For many of the printed circuits manufactured today with microvias, conventional glass reinforced materials are used, albeit mostly with thin fiberglass cloth styles. These materials will be discussed further in Chap. 11, covering base material components. In addition, Chaps. 25 and 26 focus specifically on HDI.

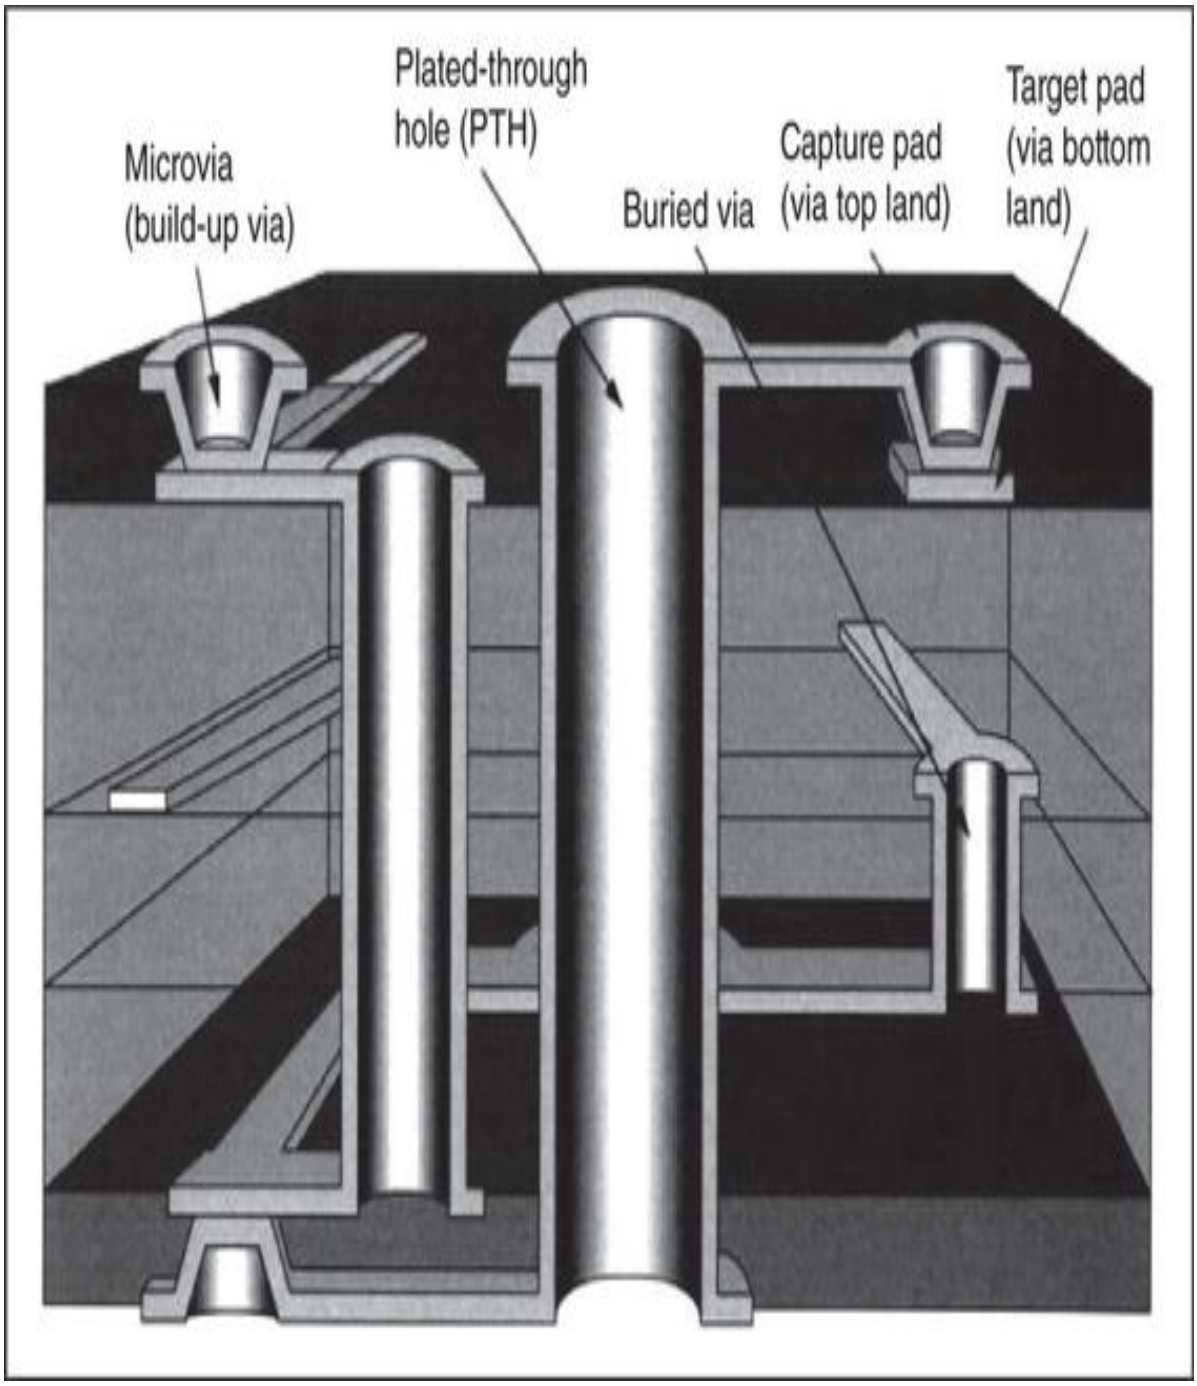

FIGURE 9.1 General illustration of HDI with microvias. (*From IPC-4104*.)

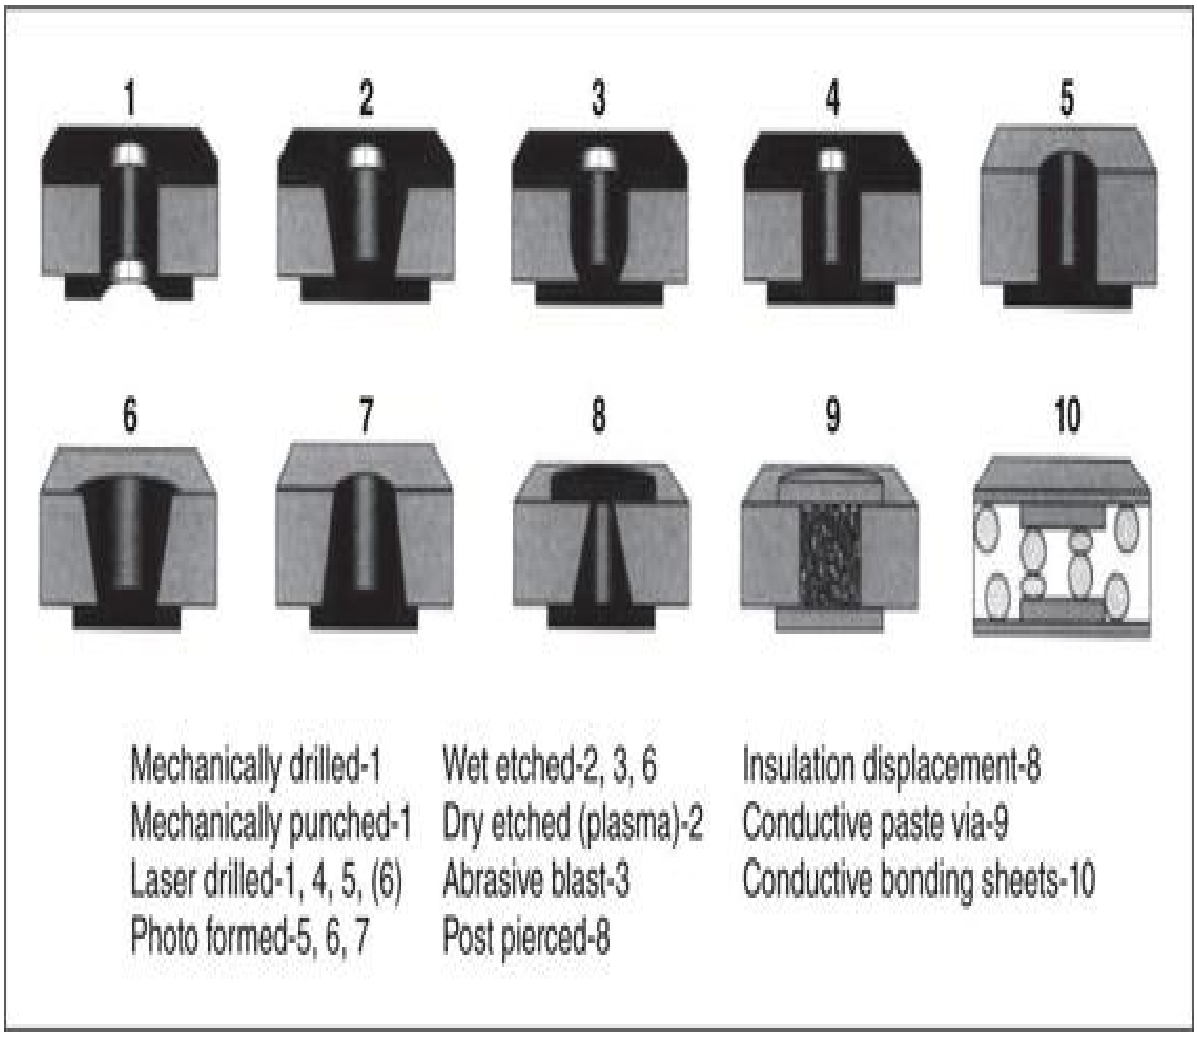

FIGURE 9.2 Methods used to form microvias. (*From IPC-4104*.)

9.3 PROPERTIES USED TO CLASSIFY BASE MATERIALS

Historically, the T_g had been the most common property used to classify FR-4 base materials, and this is one of the primary properties documented in IPC-4101. Materials with high T_g values were generally viewed as being more reliable. While this question was never as simple as specifying only the T_g, the move toward lead-free assembly has caused a fundamental redefinition of what properties are needed to ensure a given

level of reliability. The reason is that the alloys used in lead-free assembly require higher peak temperatures than those used in tin-lead assembly. These higher peak temperatures can approach the point where many base materials begin to decompose. For this reason, the decomposition temperature has become important, along with thermal expansion properties, modulus, moisture absorption as well as adhesion characteristics often measured by using time-to-delamination tests such as the T260 test.

The T_g and its impact on *z*-axis expansion are summarized below along with the decomposition temperature. The other properties will be discussed in Chaps. 11 and 12.

9.3.1 Glass Transition Temperature, T_g

The T_g of a resin system is the temperature at which the material transforms from a relatively rigid or "glassy" state, to a more deformable state with a significant drop in modulus. This is a thermodynamic change in the material which is reversible as long as the resin system has not been degraded. This is to say that when a material that has been heated above its T_g is cooled back below the T_g, it returns to a more rigid state with essentially the same properties as before. However, if the material is heated to too high a temperature beyond T_g, irreversible changes in properties may result. The temperature at which this will happen varies by material type and is related to resin decomposition, discussed later.

A material is not in a liquid state when it is above the T_g. It is a temperature at which physical changes take place due to the weakening of molecular bonds within the material. It is important to understand T_g since the properties of base materials are different above T_g than below T_g. While the T_g is typically described as being a very precise temperature, this is somewhat misleading, because the physical properties of the

material can begin to change as the T_g is approached and some of the molecular bonds are affected. As the temperature increases, more of the bonds become weakened until the material reaches a steady state with new properties. This explains the curved line in Fig. 9.3, which is discussed in the following text.

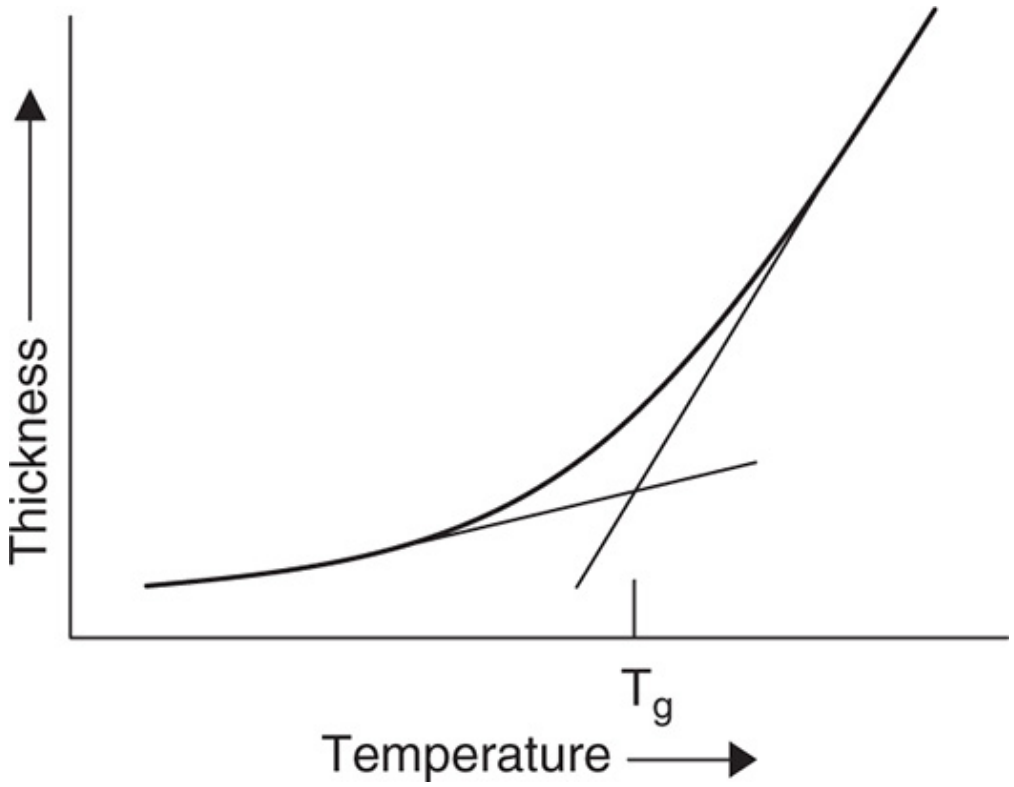

FIGURE 9.3 Glass transition temperature by TMA.

The T_g of a resin system has several important implications. These include

- The impact on thermal expansion.
- The temperature at which the materials' modulus properties decrease.
- A measure of the degree of cure of the resin system.

9.3.1.1 Thermal Expansion. All materials will undergo changes in physical dimensions in response to changes in

temperature. The rate at which the material expands is much lower below the T_g than above. Thermomechanical analysis (TMA) is a procedure used to measure dimensional changes versus temperature. Extrapolating the linear portions of the curve to the point at which they intersect provides a measure of the T_g (see Fig. 9.3). The slopes of the linear portions of the curve above and below the T_g represent the respective rates of thermal expansion, or as they are typically called, the coefficients of thermal expansion (CTEs). CTE values are important since they influence the reliability of the finished circuit. Other things being equal, less total thermal expansion will result in greater circuit reliability as less stress is applied to plated holes. With a higher T_g value, the onset of more rapid thermal expansion is delayed.

9.3.1.2 Modulus Decrease. Modulus can be defined as the ratio of stress-to-strain in a material. A high modulus material would exhibit little strain even at high levels of stress. In the discussion of T_g, a materials' modulus is relatively high below T_g, and decreases rapidly as it is heated above the T_g. Differences in modulus properties between material types can influence thermal reliability performance, but it should also be noted that for conventional materials for PCBs, the actual modulus values in a PCB will also be affected by the glass fabric type and copper foil, in addition to the resin system.

9.3.1.3 Degree of Cure. The resin systems used in base materials begin with subcomponents that contain reactive sites on their molecular structures. The application of heat to the resin system and curing agents causes the reactive sites to *cross-link* or bond together. This process of curing the resin system brings about physical changes in the material in proportion to the degree to which the cross-linking occurs, including increases in the T_g. When most of the reactive sites have cross-linked, the material is said to be fully cured and its ultimate physical properties will be established.

Besides TMA, two other thermal analysis techniques are also commonly used for measuring T_g: differential scanning calorimetry (DSC) and dynamic mechanical analysis (DMA), with DSC one of the most common methods used today.

- DSC measures heat flow versus temperature rather than the dimensional changes measured by TMA. The heat absorbed or given off will also change as the temperature increases through the T_g of the resin system. T_g measured by DSC is often somewhat higher than measurements by TMA.
- DMA measures the modulus of the material versus changes in temperature, and also will give somewhat higher values for T_g.

Materials that are not fully cured can cause problems in circuit manufacturing processes and with finished circuit reliability. For example, an undercured multilayer circuit can exhibit greater amounts of total *z*-axis thermal expansion. This adversely affects circuit board reliability due to the increased stress on the plated through holes as the circuit expands.

Because increased cross-linking will require greater amounts of energy (heat) to weaken the bonds in the molecular structure of the resin system, measurements of T_g can sometimes be used to determine the degree of cure of the resin system. For some resin system types, especially the "dicy-cured" FR-4 materials widely used before the advent of lead-free assembly, a measure of the degree of cure can be obtained by performing two thermal analyses on the same sample. After the first analysis, the sample is subjected to a thermal cycle designed to promote additional cross-linking within the resin system, and then a second thermal analysis is performed. The degree of cure is measured by comparing the difference in measured T_g between the two analyses (see Fig. 9.4). If the material is fully cured, the difference between T_{g2} and T_{g1} will be small. It should also be noted that internal stress and sample composition can affect the degree of cure

measurements, particularly on nondicy cured higher T_g materials.

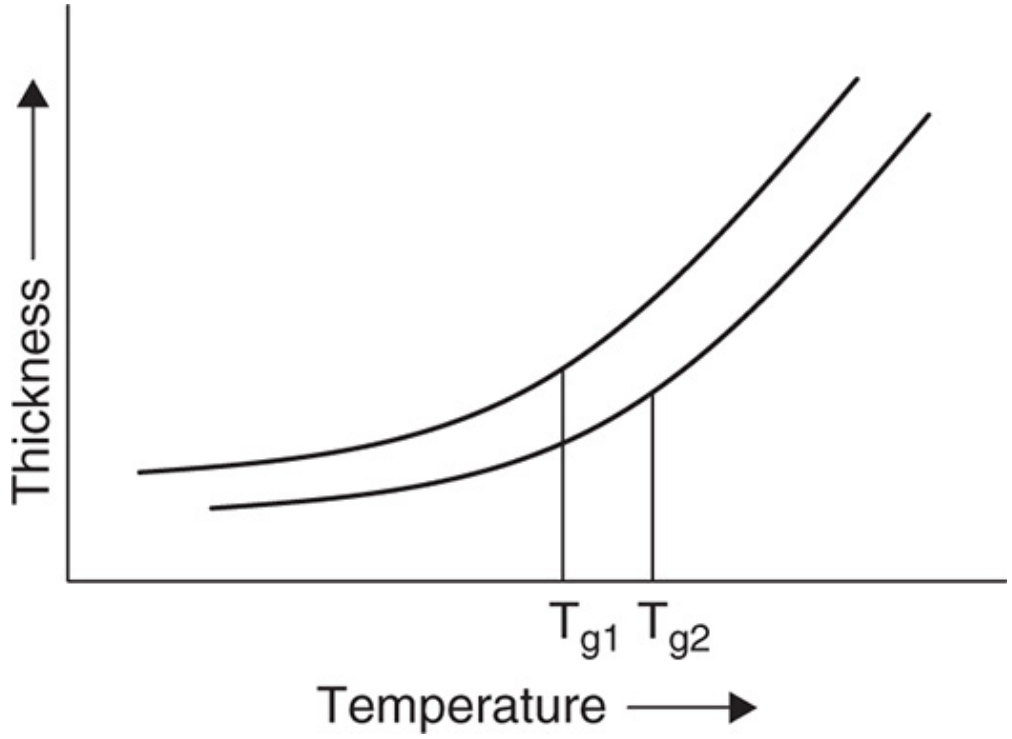

FIGURE 9.4 Measuring degree of cure.

However, great care must be exercised when using these methods to assess degree of cure. An understanding of the resin system is important because not all resins will behave the same way when performing sequential tests such as this. The "phenolic-cured" FR-4 resin systems that grew in volume with the advent of lead-free assembly will generally advance in cure somewhat with additional thermal cycles. With the dicy-cured FR-4s, it was common to use this difference in T_g as an assessment of cure, with a requirement of ± 5°C between measurements. With phenolic-cured FR-4 resins, as well as most new resin systems, this method is not always appropriate. It is recommended to discuss the feasibility of this assessment for a given material type with the supplier of that material.

The terminology used to discuss the degree of cure can also be important. Below are some common terms that can assist in

discussions related to the state of cure of a material.

- *Undercured*. Refers to material that will readily continue to cross-link when exposed to curing temperatures. The T_g and other properties can change significantly after exposure to curing temperature.
- *Poorly cured*. Refers to material that has a low T_g or low cross-link density compared to its potential cure level. In this case the material does not continue to cross-link or cure significantly when exposed to curing temperatures. T_g and other properties remain little changed with additional exposure to curing temperatures. This usually occurs due to the action of a contaminant or substance that interferes with curing. In many resin systems, moisture can cause this.
- *Well cured*. Refers to material cured to the point where it achieves its targeted T_g level and level of cross-linking. Note that a well cured material may or may not continue to form some additional cross-link bonds when exposed to curing temperatures, depending on the polymer and catalyst system.
- *Fully cured*. A fully cured material will not form significant new cross-link bonds when exposed to curing temperatures. Note that a poorly cured material as just defined is also fully cured in the sense that additional exposure to curing temperatures will not promote additional cross-linking.

9.3.1.4 Advantages and Disadvantages of High T_g Values. Implicit in many discussions of T_g is the assumption that higher values of T_g are always better. This is not always the case. While it is certainly true that higher values of T_g will delay the onset of high rates of thermal expansion for a given resin system, total expansion can differ from material to material. A material with a lower T_g could exhibit less total expansion than a material with a higher T_g, due to differing resin CTE values or by incorporating fillers into the resin

system that lower the CTE of the composite material. This is illustrated in Fig. 9.5. Material C exhibits a higher T_g than material A, but material C exhibits more total thermal expansion because its CTE value above T_g is much higher. On the other hand, with the same CTE values above and below the T_g, the higher-T_g material B exhibits less total thermal expansion than material A. Finally, although the T_g values are the same, material B exhibits less total expansion than material C due to a lower CTE value above T_g. This will be discussed further in Chap. 11 in the context of the impact of lead-free assembly temperatures on base materials.

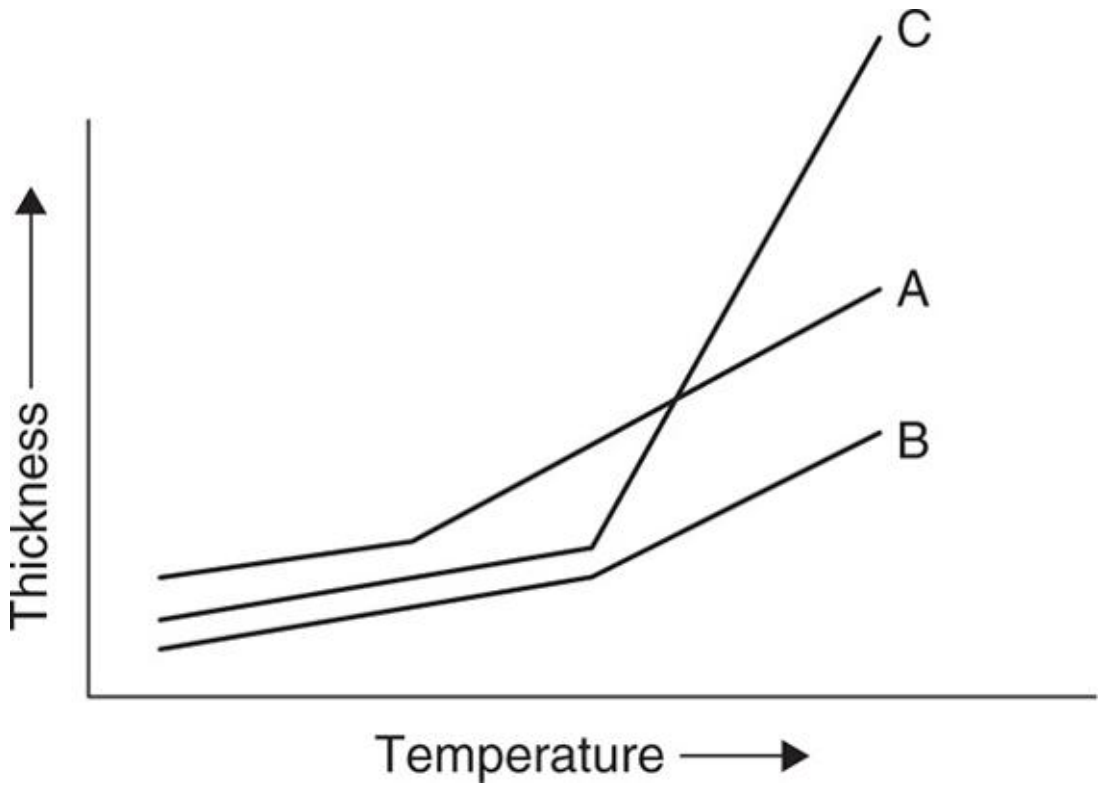

FIGURE 9.5 T_g versus thermal expansion.

Finally, there are other properties to consider when selecting a material. T_g is just one property and very often it is really the expansion properties that are most relevant rather than the actual value of T_g.

T_d is an important property for lead-free assembly, with higher values generally preferred, although once at a certain level, higher T_d's do not offer any further benefit. Advanced FR-4 resin systems can combine both high T_g and high T_d. This will be discussed in detail in Chap. 11.

In addition, higher T_g resin systems can be harder and more brittle than lower T_g systems. This can adversely affect productivity in the printed circuit manufacturing process. In particular, the drilling process can be affected as slower drilling, reduced drill bit life or reduced stack heights can be required for high-T_g materials.

Lower copper peel strength values and shorter times to delamination can also be correlated with higher T_g values, though other factors influence these properties as well. The time to delamination is a measure of the time it takes for the resin and copper, or resin and reinforcement, to separate or delaminate, and can be correlated to T_d. This will also be discussed in Chaps. 10 and 11. This time-to-delamination test utilizes TMA equipment to bring a sample to a specified temperature and then measures the time it takes for failure to occur. Failure is typically delamination between the resin and copper foil, or resin and glass within the laminate. Temperatures of 260°C (T260) and 288°C (T288) are commonly used for this testing.

9.3.2 Decomposition Temperature, T_d

As a material is heated to higher temperatures, a point is reached where the resin system will begin to decompose. The chemical bonds within the resin system will begin to break down and volatile components will be driven off, reducing the mass of the sample. The decomposition temperature, T_d, is a property which describes the point at which this process occurs. The traditional definition of T_d is the point where 5

percent of the original mass is lost to decomposition. However, 5 percent is a very large number when multilayer PCB reliability is considered, and temperatures where lower levels of decomposition occur are very important to understand, particularly with respect to lead-free assembly. To illustrate this, consider Fig. 9.9.

In Fig. 9.6, you can see curves for two FR-4 materials. The "traditional FR-4," a 140°C T_g material in this case, has a decomposition temperature of 320°C by the 5 percent weight loss definition. The "enhanced FR-4" has a decomposition temperature of 350°C by the 5 percent weight loss definition. Most of the dicy-cured high-T_g FR-4 materials used in the past actually have decomposition temperatures in the range of 290 to 310°C, while the 140°C T_{gd} FR-4 materials cured with dicy generally have slightly higher T_d values. The shaded regions indicate the peak temperature ranges for standard tin-lead assembly and lead-free assembly. A very common question is, if a PCB will be assembled at 260°C, and the material has a decomposition temperature of 310–320°C, then why wouldn't it be compatible with lead-free assembly?

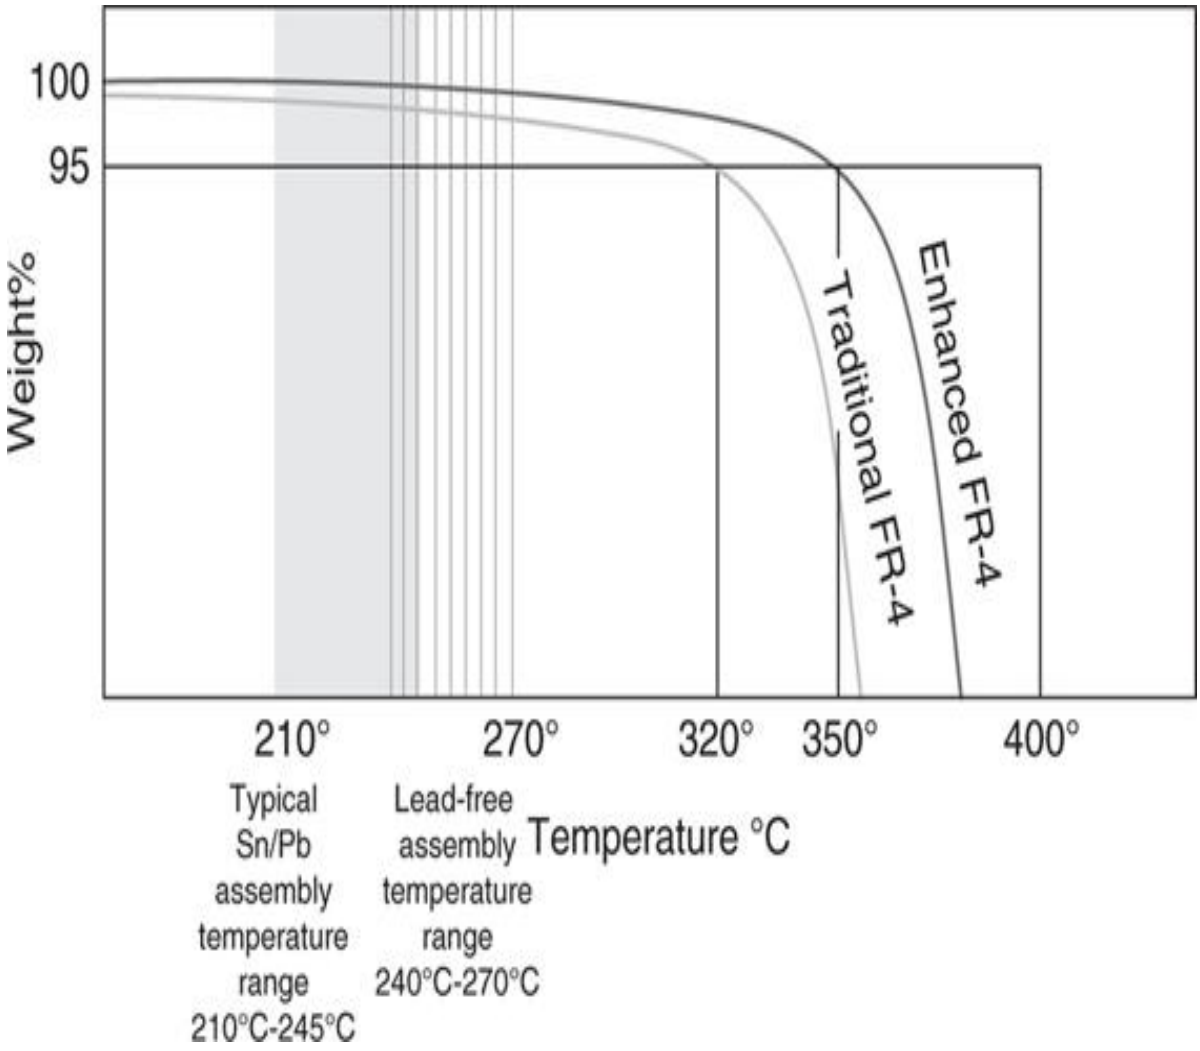

FIGURE 9.6 Illustration of decomposition curves.

The answer lies in the level of decomposition in the temperature ranges where assembly will take place. In the tin-lead temperature range, neither material exhibits a significant level of decomposition. However, in the lead-free assembly temperature range, the traditional FR-4 begins to exhibit 1.5 to 3 percent weight loss. This level of decomposition can compromise long-term reliability or result in defects such as delamination during assembly, particularly if multiple assembly cycles or rework cycles are performed. On the other hand, beyond a certain value, higher levels of T_d do not offer any further benefit. If the peak temperatures a PCB will be subjected to do not approach or exceed the critical range of

decomposition, then specifying a higher value does not provide any value, and may result in the exclusion of materials with good cost-performance value.

9.4 TYPES OF FR-4

As can be seen in Table 9.2, several materials listed are considered FR-4. This begs the question: What is FR-4? In Table 9.2, it can be seen that each material considered FR-4 is flame-resistant, uses a woven fiberglass reinforcement and is primarily an epoxy-based resin system.

9.4.1 Differences between FR-4s

So what can be different about these materials? The most obvious difference between the commercially available FR-4 materials is in T_g values. Specification sheet 21 refers to an FR-4 with a minimum T_g of 110°C. More common are FR-4 materials with T_g values between 130 to 140°C and 170 to 180°C. Therefore, it is obvious that FR-4 materials can consist of different types of epoxy resins. Indeed, there are many types of epoxy resins that will provide differing T_g values, as well as differences in other properties.

Specification sheets 92-95 list FR-4 materials with non-halogen-based flame retardants, as well as different T_g ranges. Sheets 92 and 94 indicate the use of a phosphorus-based flame retardant, whereas sheets 93 and 95 show the use of aluminum hydroxide. So FR-4 may include different types of flame retardants. In addition, several FR-4 materials, such as those shown in sheets 99, 101, and 126, show that these materials contain inorganic fillers. These fillers are often used to reduce the amount of *z*-axis expansion.

9.4.2 The Longevity of FR-4

FR-4 materials have been the most successful, most commonly used materials in printed circuit manufacturing for many years. Why? Well, as we just discussed above, FR-4 actually encompasses a range of material types, even though they share certain properties and are primarily epoxy based. The result is that there is often an FR-4 material readily available for the most common end-use applications. For relatively simple applications, the 130 to 140°C T_g FR-4s have become the material of choice. In higher layer count multilayer circuits, in very thick circuits, as well as those requiring improved thermal properties, the 170 to 180°C T_g FR-4s have become the material of choice, although properties beside the T_g must also be considered in these applications.

In addition, the components used in FR-4 materials, particularly woven fiberglass cloth and epoxy resins, provide a very good combination of performance, processability, and cost. The range of woven fiberglass cloth styles available makes it easy to control dielectric and overall circuit thicknesses. As noted earlier, the range of epoxy resin types also makes it relatively simple to tailor material properties to end-use applications. The combination of good electrical, thermal, and mechanical properties of epoxies also explains why they have become the primary type of resin used in printed circuits. Epoxy-based materials are also relatively easy to process through conventional printed circuit manufacturing processes, at least in comparison to some of the other types of materials available.

9.4.3 UL Reclassification of FR-4: FR-4.0 and FR-4.1

Originally, FR-4 materials were brominated epoxy resins with fiberglass cloth reinforcement. As just noted, as the range of applications with varying performance criteria increased, many

variants of these components were introduced in order to meet the needs of the different applications. The result was a range of materials with somewhat different compositions and differing levels of performance, even though all were called FR-4. As a result, Underwriters Laboratories (UL) initiated a reclassification of FR-4 into FR-4.0 and FR-4.1.

FR-4.0 is the category for the original brominated epoxy based materials while FR-4.1 consists of resin systems with a non-halogen-based flame retardant. For FR-4.1, there are limits on bromine, chlorine and total bromine plus chlorine contents. The limit is 900 parts per million (ppm) each for bromine and chlorine, with the total not to exceed 1500 ppm. For the resin system, both categories must contain at least 50 percent epoxy resin, and a maximum inorganic filler content of 45 percent. Inorganic fillers would include silica, talc, clay, aluminum hydroxide, ceramics and other types of inorganic particles. Woven fiberglass cloth is still the reinforcement type for both categories.

9.5 LAMINATE IDENTIFICATION SCHEME

As IPC specifications are regularly reviewed and updated, it is recommended that the latest IPC specification be used for actual applications. However, an example of a laminate designation in IPC-4101 is

L	25	1500	C1/C1	A	A
Material Designator	Specification Sheet Number	Nominal Laminate Thickness	Metal Cladding Type and Nominal	Thickness Tolerance Weight/Thickness	Surface Quality Class

Material designator. "L" refers to laminate.

Specification sheet number. This designation references the specification sheet number as in Table 9.2.

Nominal laminate thickness. Four digits identify this variable. It may be specified either over the cladding or over the dielectric. For metric specification, the first digit represents whole millimeters, the second represents tenths of millimeters, and so on. For orders requiring Imperial units, the four digits indicate the thickness in ten-thousandths of an inch (tenths of mils). In the example shown, 1500 is designated for a thickness of 1.5 mm, which would be specified as 0591 when using Imperial units.

Metal cladding type and nominal weight/thickness. Five designators are used to specify cladding type and thickness. The first and fourth indicate the type, the second and fifth indicate thickness, and the third is a slash to differentiate sides of the base material. Table 9.5 lists the types of metal cladding. Table 9.6 lists copper foil weights and thicknesses.

TABLE 9.5 Metal Cladding Types Summarized in IPC-4101 (see also IPC-4562, Metal Foil for Printed Wiring Applications)[2]

Designation	Metal Cladding Type
A	Copper, wrought, rolled (IPC-4562, grade 5)
B	Copper, rolled (treated)
C	Copper, electrodeposited (IPC-4562, grade 1)
D	Copper, electrodeposited, double treat (IPC-4562, grade 1)
G	Copper, electrodeposited, high ductility (IPC-4562, grade 2)
H	Copper, electrodeposited, high temperature elongation (IPC-4562, grade 3)
J	Copper, electrodeposited, annealed (IPC-4562, grade 4)
K	Copper, wrought, light cold rolled (IPC-4562, grade 6)
L	Copper, wrought, annealed (IPC-4562, grade 7)
M	Copper, wrought, rolled, low temperature annealable (IPC-4562, grade 8)
N	Nickel
O	Unclad
P	Copper, electrodeposited, high temperature elongation, double treat (IPC-4562, grade 3)
R	Copper, reverse treated electrodeposited (IPC-4562, grade 1)
S	Copper, reverse treated electrodeposited, high temperature elongation (IPC-4562, grade 3)
T	Copper, copper foil parameters as dictated by contract or purchase order
U	Aluminum
X	As agreed between user and supplier
Y	Copper Invar Copper
Z	Copper, electrodeposited, high temperature elongation, double-treat (IPC-4562, grade 3) for buried capacitance applications

TABLE 9.6 Foil Weights and Thicknesses from IPC-4101 (see also IPC-4562, Metal Foil for Printed Wiring Applications)[4]

		Metric		English		
Foil Designator	Common Industry Terminology	Area Weight (g/m^2)	Nominal Thickness (mm)	Area Weight (oz/ft^2)	Area Weight ($g/254\ in.^2$)	Nominal Thickness (10^{-3} in)
E	5 µm	45.1	5.1	0.148	7.4	0.20
Q	9 µm	75.9	8.5	0.249	12.5	0.34
T	12 µm	106.8	12.0	0.350	17.5	0.47
H	1/2 oz	152.5	17.1	0.500	25.0	0.68
M	3/4 oz	228.8	25.7	0.750	37.5	1.01
1	1 oz	305.0	34.3	1	50.0	1.35

14	14 oz	4270.0	480.1	14	700.0	18.90

Thickness tolerance class. This variable references the thickness tolerance as agreed between user and supplier (see Table 9.7). Classes A, B, and C refer to measurement by micrometer of the base material without cladding. Class D requires measurement by microsection (see Fig. 9.7). Classes K, L, and M refer to measurement by micrometer of the base material with the metal cladding.

TABLE 9.7 Base Laminate Thickness Tolerances from IPC-4101

Nominal Thickness of Laminate, mm [in.]	Class A/K mm [in.]	Class B/L mm [in.]	Class C/M mm [in.]	Class D mm [in.]
0.025 to 0.119 [0.0009 to 0.0047]	±0.025 [±0.000984]	±0.018 [±0.000709]	±0.013 [±0.000512]	−0.013 [−0.000512] +0.025 [+0.000984]

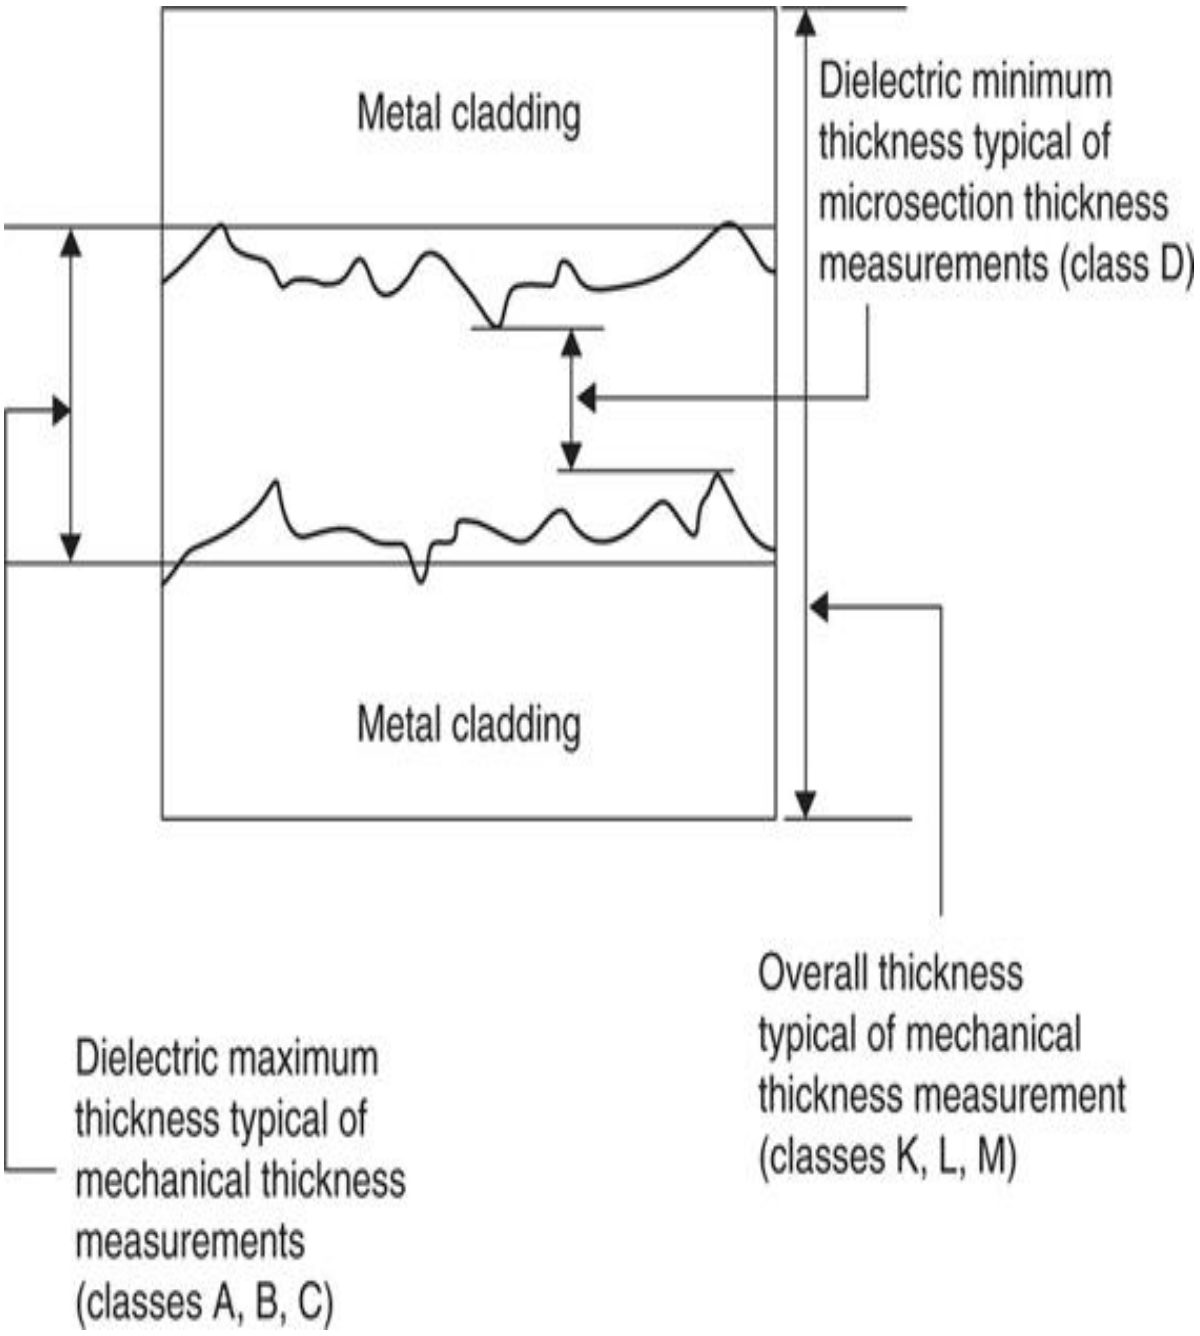

FIGURE 9.7 Dielectric minimum thickness measurements by microsection. (*From IPC-4101*.)

Surface quality class. This class is identified by either A, B, C, D, or X (as agreed upon between user and supplier). Specimens are examined with normal or corrected 20/20 vision. The worst 50 mm × 50 mm (1.97 in. × 1.97 in.) is examined at 10× magnification. Indentations are located

visually using normal or corrected 20/20 vision. The longest dimension of each foil indentation in a specimen is measured with a suitable reticule on a minimum 4× magnifier, with referee inspections at 10×. A point value is allocated according to the longest dimension, as shown in Table 9.8. Surface quality class is determined by the total point count of foil indentations within 300 mm × 300 mm (11.81 in. × 11.81 in.), as shown in Table 9.9.

TABLE 9.8 Pit and Dent Point Values from IPC-4101

Longest Dimension, mm (in)	Point Value
0.13–0.25 mm (0.005–0.009)	1
0.26–0.50 mm (0.009–0.019)	2
0.51–0.75 mm (0.019–0.029)	4
0.76–1.00 mm (0.029–0.039)	7
>1.00 mm (0.039)	30

TABLE 9.9 Surface Quality Grades from IPC-4101

Surface Quality Class	Maximum Point Count	Other Requirements
Class A	29	
Class B	17	
Class C	5	Longest dimensions </=380 µm (14.96 mil)
Class D	0	Longest dimensions <125 µm (4.92 mil) Resin spots = 0
Class X	As agreed between user and supplier (AABUS)	

9.6 PREPREG IDENTIFICATION SCHEME

An example of a prepreg identification in IPC-4101 is

P	25	E7628	TW	RE	VC
Material Designator	Specification Sheet	Reinforcement Style Number	Resin Content Method	Flow Parameter Method	Optional Prepreg Method

Material designator. P refers to prepreg.

Specification sheet number. This designation references the specification sheet number as in Table 9.2.

Reinforcement style. The reinforcement type and style of prepreg is indicated by five digits based on the chemical type and style. In the example, E refers to E-glass and 7628 is the glass fabric style.

Resin content method. This variable refers to the method used to specify resin content of a prepreg. The two methods are RC, which refers to percent resin content of the prepreg, and TW, which refers to the treated weight of the prepreg. A 00 designator would indicate that no method is specified.

Flow parameter method. This variable indicates how much the resin in the prepreg will flow under specified conditions—a critical property. The options are

MF: resin flow percent
SC: scaled flow thickness
NF: no flow
RE: rheological flow
DH: delta H
PC: percent cure
00: no method specified

Optional prepreg method. Other test methods may also be designated here. These include

VC: volatile content
DY: dicy inspection
GT: gel time
00: none specified

The choice of test methods and their required nominal values and tolerances are normally agreed upon between user and supplier.

In addition to properties on the specification sheets, IPC-4101 includes class specifications for other properties as well. These include length and width, bow and twist, and thermal conductivity, among others.

9.7 LAMINATE AND PREPREG MANUFACTURING PROCESSES

While there are a few different processes that can be used to integrate the components that make up printed circuit base materials, the overwhelming majority of materials are manufactured using a common process. In recent years, however, new techniques have been developed and continue to be developed. These new processes have been designed to either lower the cost of manufacturing or to improve material performance, or both. Common to all processes is the need to manufacture a copper clad laminate and the bonding sheets or *prepregs* used to manufacture multilayer circuits.

9.7.1 Conventional Manufacturing Processes

The overall conventional manufacturing process is illustrated in Fig. 9.8. This process can be subdivided into two processes: prepreg manufacturing and laminate manufacturing. Prepreg is also called *B-stage* or bonding sheets, while laminate is sometimes called *C-stage*. The terms B-stage and C-stage refer to the degree to which the resin system is polymerized or cured. B-stage refers to a state of partial cure. B-stage is designed to melt and continue polymerizing when it is exposed to sufficient temperatures. C-stage refers to a state of “full” cure (typically we never realize *full* cure, in the sense that not all reactive sites on the resin molecules have cross-linked; however, we use the term *full cure* to mean that the overwhelming majority of such sites have reacted and additional exposure to temperature will do little to advance the state of cure).

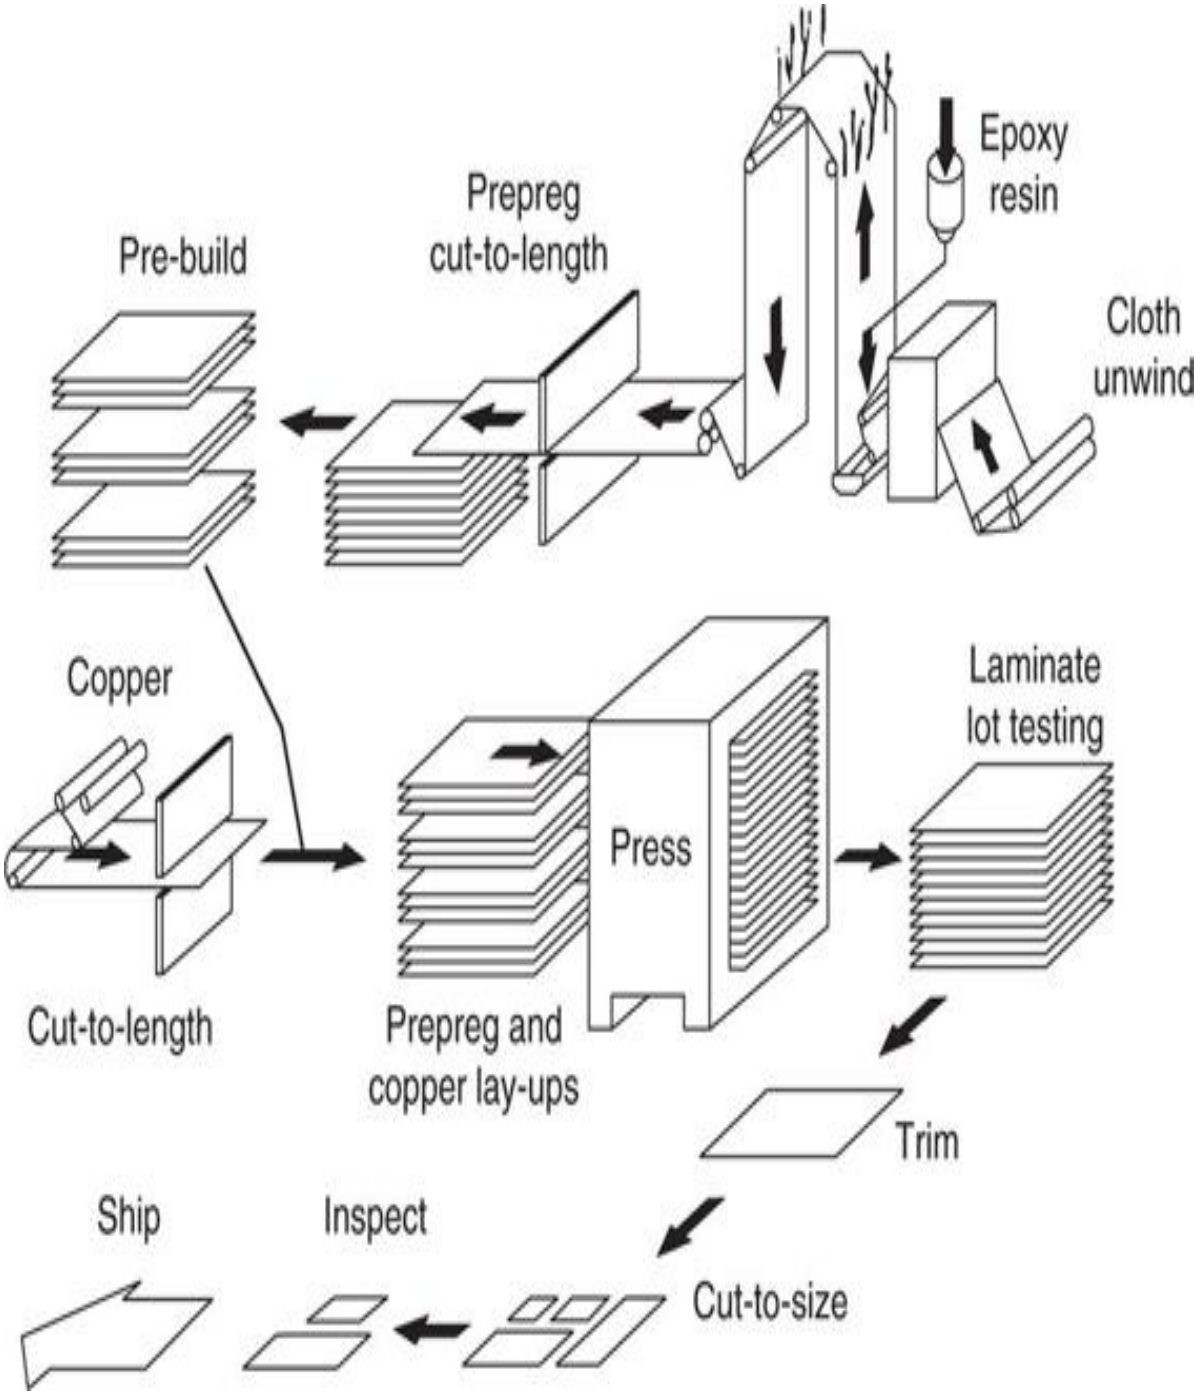

FIGURE 9.8 The conventional manufacturing process.

9.7.2 Prepreg Manufacturing

The first step in most of these processes involves coating a resin system onto the chosen reinforcement, most commonly a

woven fiberglass cloth. Rolls of fiberglass cloth or alternative reinforcement type are run through equipment called *treaters*. Figure 9.9 shows some of the resin system components that are mixed and aged prior to application to the fiberglass cloth. Figure 9.10 illustrates the overall treating process. The fiberglass cloth is drawn through a pan containing the resin system and then precise metering rolls help control thickness and also push resin into the yarns of the glass cloth (see Fig. 9.11).

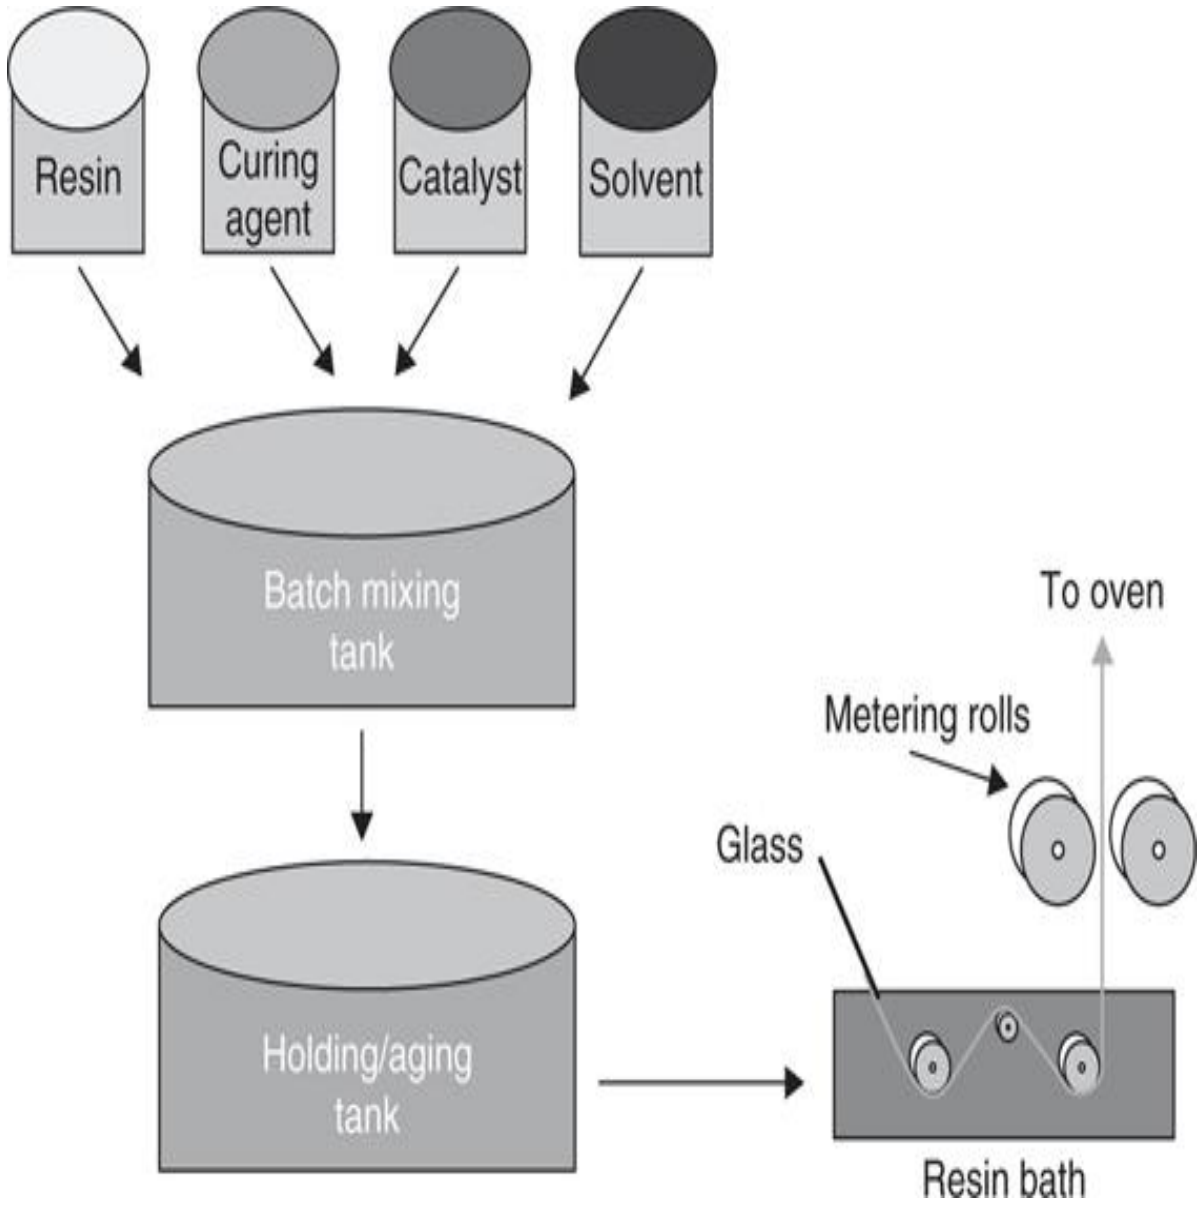

FIGURE 9.9 Resin mixing, aging, and treating.

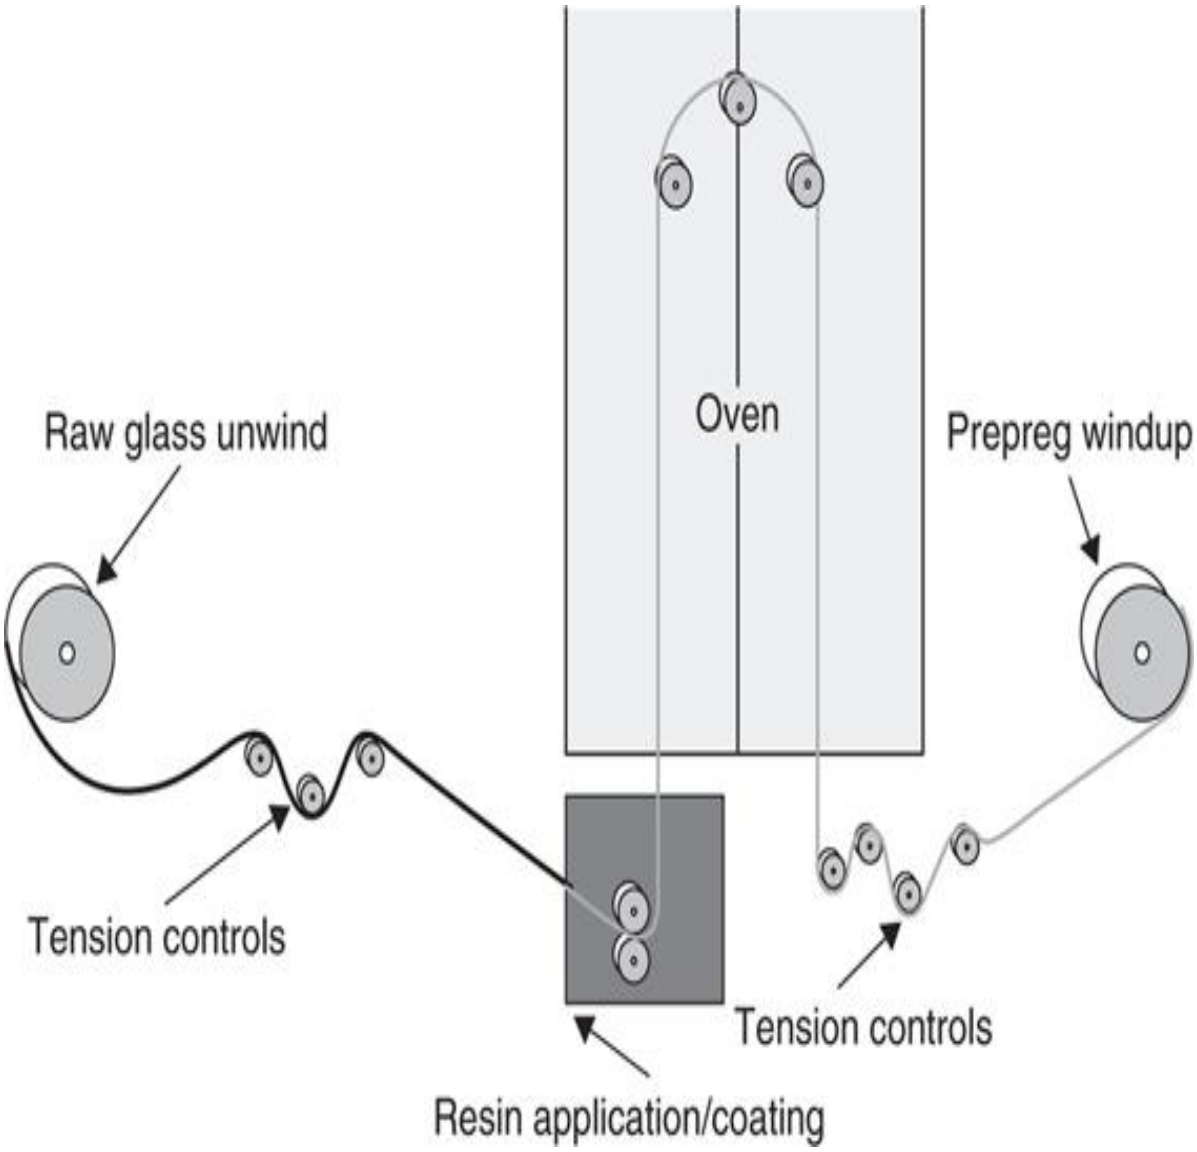

FIGURE 9.10 “Treating” fiberglass cloth with resin.

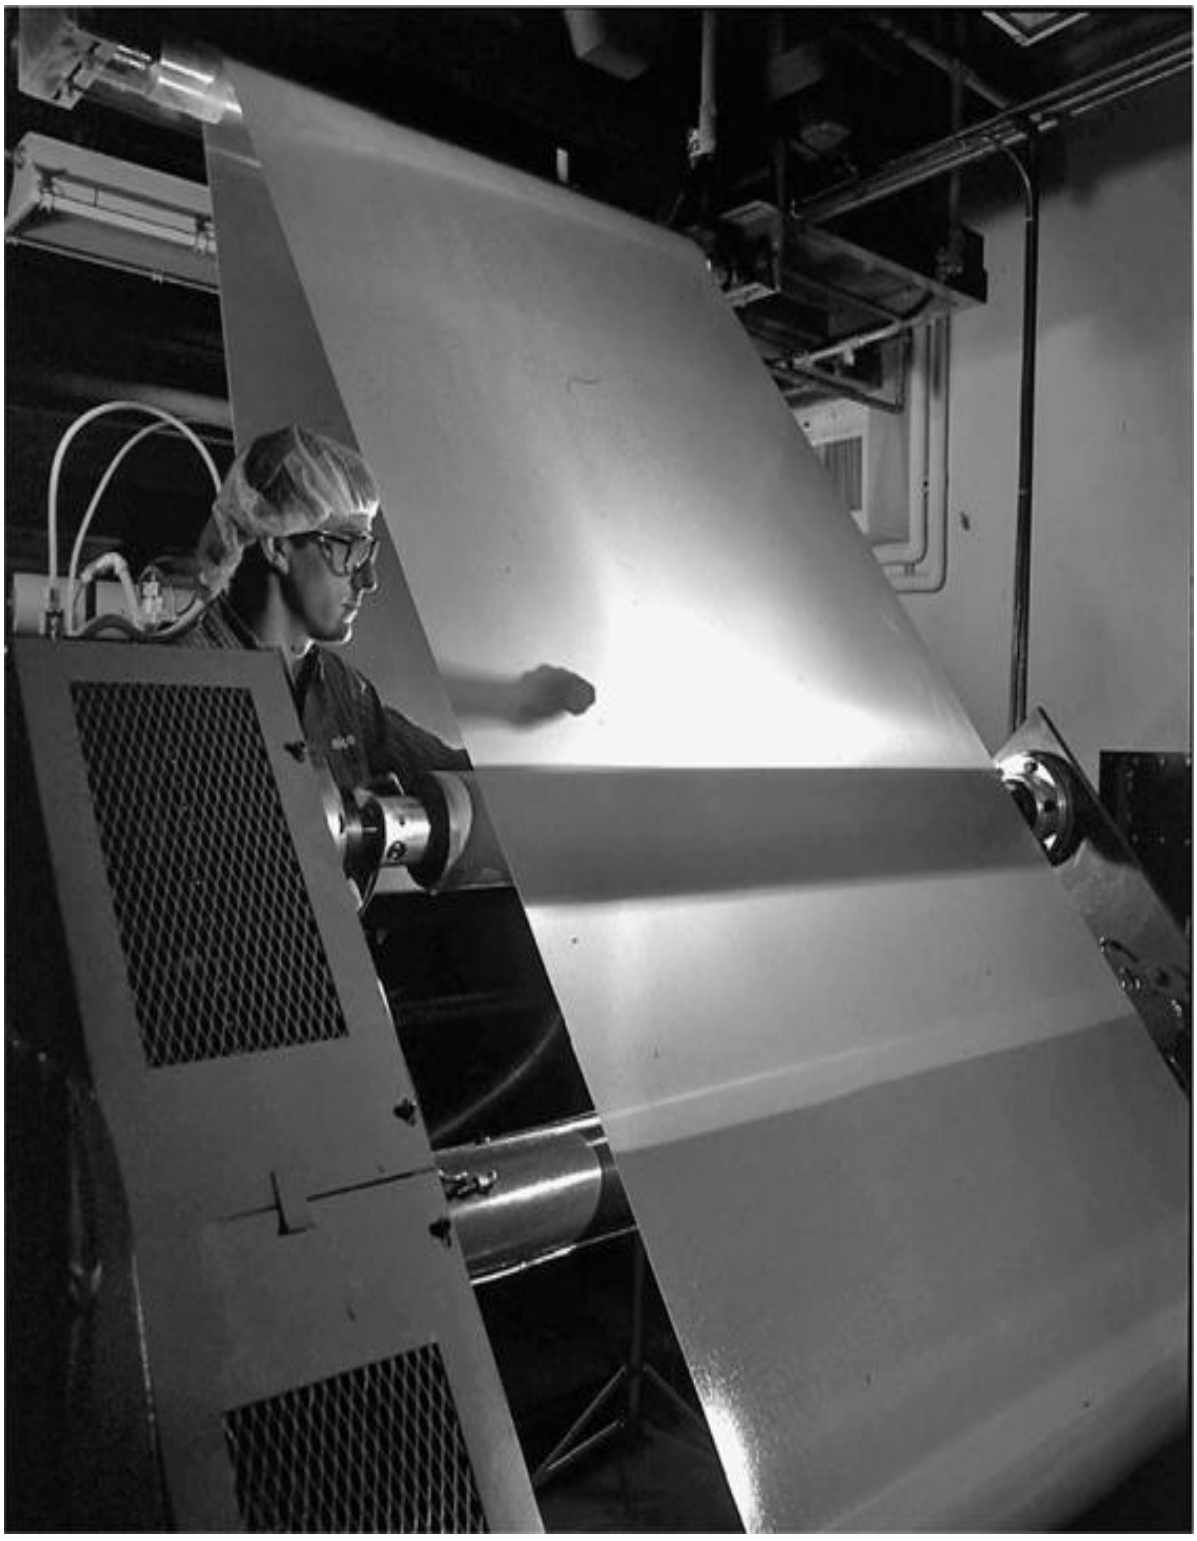

FIGURE 9.11 Prepreg after treating with resin.

Next the cloth is pulled through a series of heating zones. These heating zones commonly utilize forced air convection,

infrared heating, or a combination of the two. In the first set of zones, solvent used to carry the resin system components is evaporated off. Subsequent zones are dedicated to partially curing the resin system, or B-staging the resin. Finally, the prepreg is then rewound into rolls or cut into sheets.

A number of process controls are required in this operation. The concentrations of the resin system components must be controlled and the viscosity of the resin system maintained within acceptable limits. Tension on the cloth as it is pulled through the treater is also important, for among other reasons, it is vital not to distort the weave pattern of the cloth. Control of the resin-to-glass ratio or resin content, the degree of cure of the resin and cleanliness are also critical.

Because the resin system at this point is only partially cured, prepregs must typically be stored in temperature- and humidity-controlled environments. Temperature, for obvious reasons, could affect the degree of cure of the resin and therefore its performance in laminate or multilayer circuit pressing. Since moisture can affect the performance of many curing agents and accelerators, not to mention the performance of the resin system during lamination or press cycles, humidity is also important to control during prepreg storage. Absorbed moisture that becomes trapped during lamination cycles can also lead to blisters or delaminations within the laminate or multilayer circuit.

9.7.3 Laminate Manufacturing

The process of copper clad laminate manufacturing begins with the prepreg material. Prepregs of certain fiberglass cloth styles and specific resin contents are combined with the desired copper foils to make the finished laminate. First, the prepregs and copper foils are sheeted to the desired size. Figure 9.12 shows an automated copper-sheeting process.

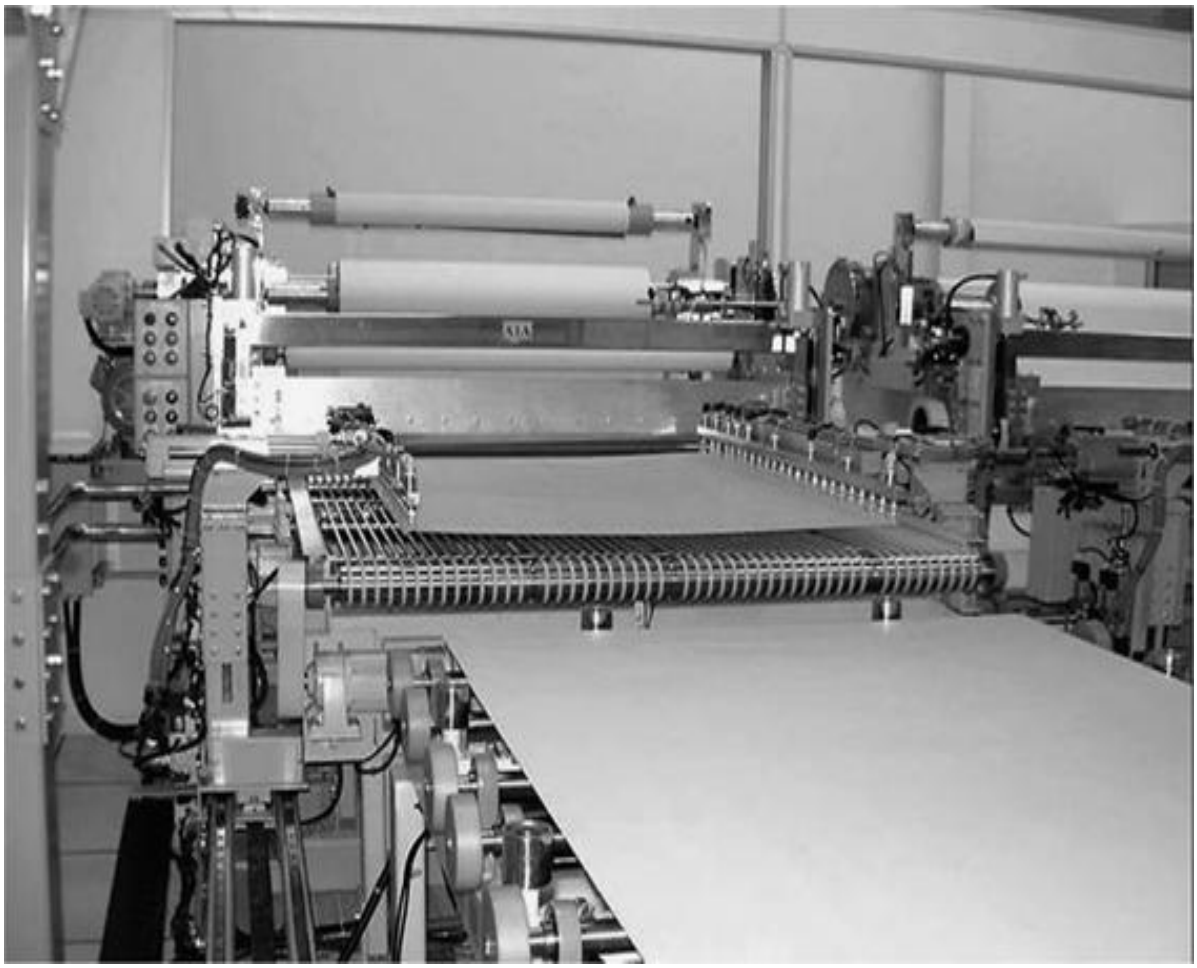

FIGURE 9.12 Sheeting of rolls of copper foil.

These materials are then laid up in the proper sequence to produce the desired copper clad laminate. Figures 9.13 and 9.14 are examples of an automated build-up process where the prepreg and copper foil materials are combined prior to being pressed together. Several of these individual sandwiches of prepreg and copper foil are stacked on top of each other, typically separated by stainless steel plates, although other separator materials, including aluminum, can also be used. These stacks are then loaded into multi-opening lamination presses (see Figs. 9.15 and 9.16), where pressure, temperature, and vacuum are applied. The specific press cycle used will vary depending upon the particular resin system, the degree of cure of the prepregs and other factors. The presses themselves have many platens that can be heated by steam or

hot oil that flows through the platens, or they can also be heated electrically.

FIGURE 9.13 Automated build-up of copper and prepreg.

FIGURE 9.14 Automated build-up of copper and prepreg.

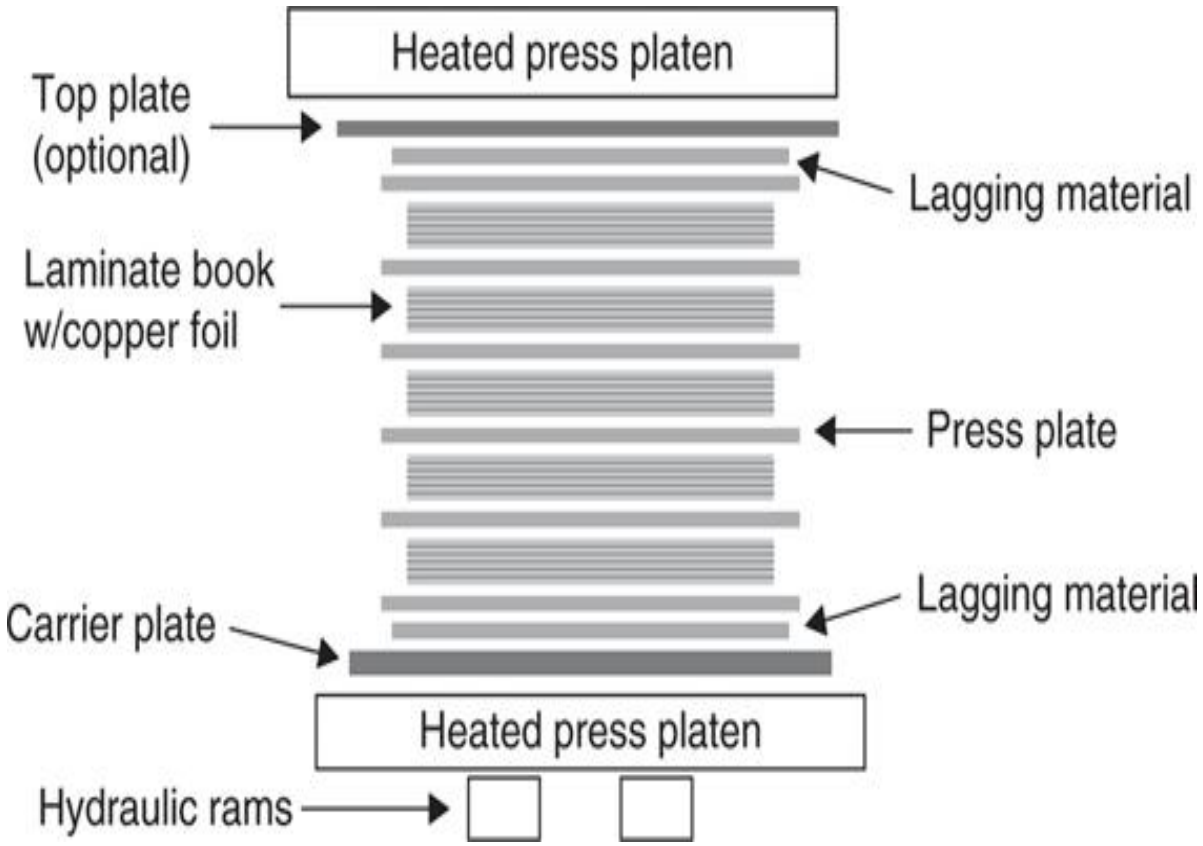

FIGURE 9.15 Laminate pressing.

FIGURE 9.16 Lamination press with multiple openings.

Process controls in the lamination/pressing process are also critical. Cleanliness in the manufacturing environment and cleanliness of the steel separator plates are critical in achieving

good surface quality and in avoiding embedded foreign material within the laminate. Control of the temperature rise during lamination will provide the desired amount of resin flow, while control of the cooldown rate can impact warp and twist. The length of time that the laminate is above the temperature required to initiate the curing reaction will determine the degree of cure, as will the degree to which the actual temperature exceeds this temperature.

While these descriptions of prepreg and laminate manufacturing give a simple description of the processes used, it is important to understand that there are many variables that influence the quality and performance of the finished products. In addition, many of these variables interact with each other, meaning that a change in one may influence others and may require adjustments to these other process variables. In summary, prepreg and laminate manufacturing is much more complex than it appears at first glance.

9.7.4 Direct Current or Continuous Foil Manufacturing

Continuous foil or direct current manufacturing is an alternative method used to manufacture copper clad laminates (see Fig. 9.17). Prepregs are still used in this process, however, the lay-up and pressing operations are somewhat different. In this process, the copper foils are not sheeted, but kept in rolls. To start, copper foil with the side to be bonded to the prepreg facing up, is laid down, while still part of a continuous roll. The prepregs are laid up in the proper sequence, and then the roll of copper foil is passed over the prepregs so that it is applied to the top of what will become the finished laminate. Typically, two rolls of foil are used to allow dissimilar copper weights or types to be bonded to either side of the laminate. A separator plate, typically anodized aluminum, is then placed on top of this sandwich, and the process is repeated so that several laminates are stacked up.

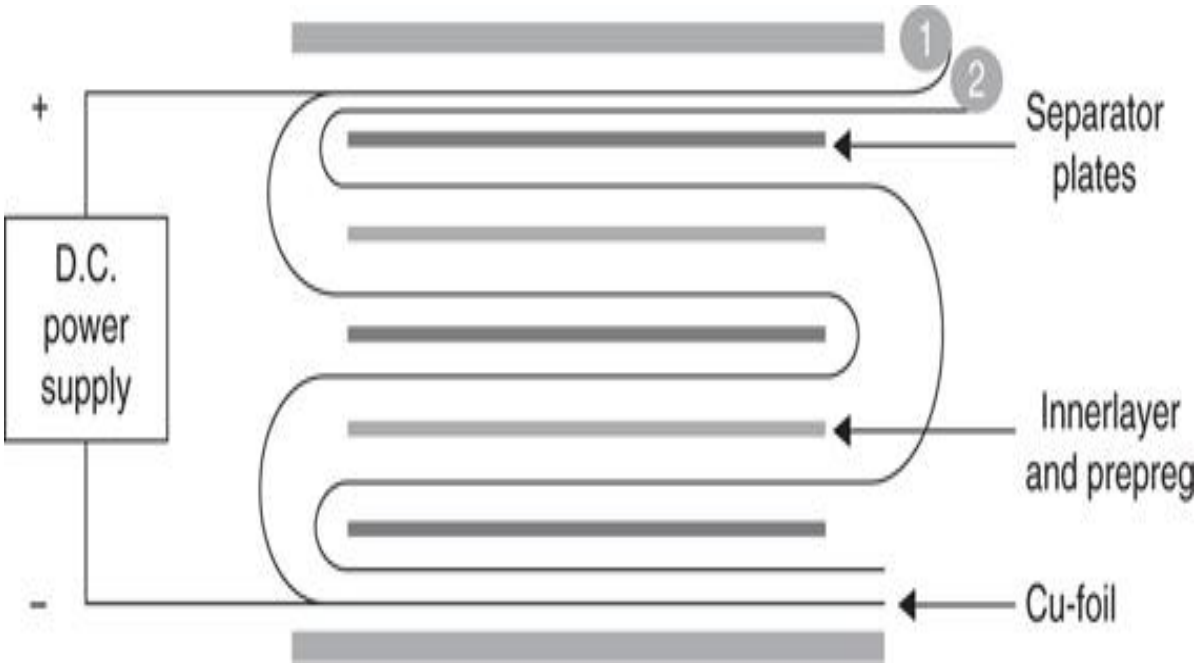

FIGURE 9.17 Laminate pressing with continuous copper foil and direct current heating.

At this point, the stack of laminates is loaded into a press and subjected to heat, pressure, and vacuum. However, as opposed to the conventional process, this technique involves applying direct current to the copper foil that runs throughout the stack. The current heats the foil and therefore the prepregs are adjacent to the foils. By controlling the amount of current, you control the temperature of the materials in the stack.

9.7.5 Continuous Manufacturing Processes

Over the years, continuous lamination processes have also been designed. Rather than cut the prepregs and foils into sheets, lay them up and press them as individual laminates, these processes use rolls of prepreg or bare fiberglass cloth and rolls of copper foil that are continuously unwound and fed together into a continuous horizontal press. One process starts with rolls of prepreg. Another starts with the bare, untreated fiberglass cloth, applies a resin to the cloth and is sandwiched

with the copper foil as it is fed continuously into a horizontal press. At the back end of the press, sections of the continuous laminate can be cut into sheets, or with thin laminates, rolls of copper clad laminate can be manufactured.

CHAPTER 10
BASE MATERIAL COMPONENTS

Edward Kelley
Douglas Trobough
Isola Group, Chandler, Arizona

10.1 INTRODUCTION

While there are many types of base materials, there are three basic components:

1. The resin system, including additives and fillers
2. The reinforcement(s)
3. The conductor

Each of these components is important in its own right, and in combination determines the properties of the base material as well as the relative cost of the material. Environmental legislation such as the European Union's Restriction of Hazardous Substances (RoHS) directive has had a profound impact on all levels of the electronics supply chain, including these components. RoHS restricts the use of lead, which is an element in the solder used for component

assembly onto printed circuits. The impact on the base materials and components is primarily the result of higher assembly temperatures that are associated with lead-free assembly. Table 10.1 summarizes the key issues for base material components. The impact of RoHS will be discussed further in Chap. 13.

TABLE 10.1 Lead-Free Assembly Impact on Base Material Components

Component	Lead-Free Assembly Impact	Potential Solutions	Related Considerations
Resin system	1. Peak assembly temperatures can reach point where resin decomposition begins. 2. Higher temperatures result in increased thermal expansion, delamination and stress on plated holes as a result. 3. Vapor pressure of absorbed moisture much higher at lead-free assembly temperatures; can lead to blistering/ delamination. 4. "Phenolic" lead-free compatible materials often not as good for electrical performance, especially Df.	1. Formulate resin system with higher decomposition temperatures. 2. Formulate for lower coefficients of thermal expansion. 3. Evaluate materials for moisture absorption/release characteristics; drying processes in PCB fabrication and/or assembly. 4. Evaluate nondicy/ nonphenolic laminate materials with lower Df.	1. Reformulation can adversely affect electrical properties and manufacturability. 2. Can also impact mechanical properties and manufacturability. 3. PCB storage conditions during manufacturing and prior to assembly are much more important, especially humidity conditions. 4. Cost/performance trade-off. New materials now in high volume use that offer more choices.
Fiberglass cloth	Thermal and mechanical stress on resin-to-glass bond. Volatilized components can also stress this bond.	Cleanliness, moisture resistance and choice of proper coupling agent for resin adhesion more important.	Loss of resin-to-glass adhesion through thermal cycling could impact CAF resistance. Use of spread glass cloth may be beneficial.
Copper foil	Thermal and mechanical stress on resin-to-copper bond.	Improved copper surface treatments for improved adhesion, i.e., coupling agents.	Roughness will impact signal attenuation, especially at high frequencies.

The RoHS directive also restricts specific halogen-containing flame retardants. However, most base materials for printed circuits do not contain the restricted flame retardants. Nevertheless, there is growing interest in halogen-free materials, and this will be discussed further in this chapter.

10.1.1 Epoxy Resin Systems

The most successful and widely used resin systems for printed circuit applications are epoxy resin systems. There are many types of epoxy resins, and this class of resin system continues to be the workhorse among printed circuit board materials. This is a result of the combination of good mechanical, electrical, and physical properties and the relatively low cost of epoxies in comparison to the higher-performance resins. In addition, epoxy systems are relatively easy to process, which aids in keeping manufacturing costs down.

10.1.2 Definition of Epoxy

One of the most common versions of epoxy resin for printed circuit applications is manufactured from reacting epichlorohydrin and bisphenol-A. This reaction is shown in Fig. 10.1. The bromination of the bisphenol-A provides flame retardancy to the finished resin system. Figure 10.2 shows the structure of tetrabromobisphenol-A, or TBBPA. Figure 10.3 shows a reaction used to manufacture brominated epoxy resins. Brominated epoxy resins such as this are the most common component used to incorporate flame retardancy to the finished product, although non-halogen-based flame retardants can also be used, and are discussed in Sec. 10.3.7. The triangular rings on either end of the difunctional epoxy are the epoxide functional groups. In

subsequent resin polymerization, these groups react and result in the curing of the resin system. The –OH groups present on the epoxy molecule also react with the epoxide groups, providing crosslinking among the epoxy molecules (Fig. 10.4).

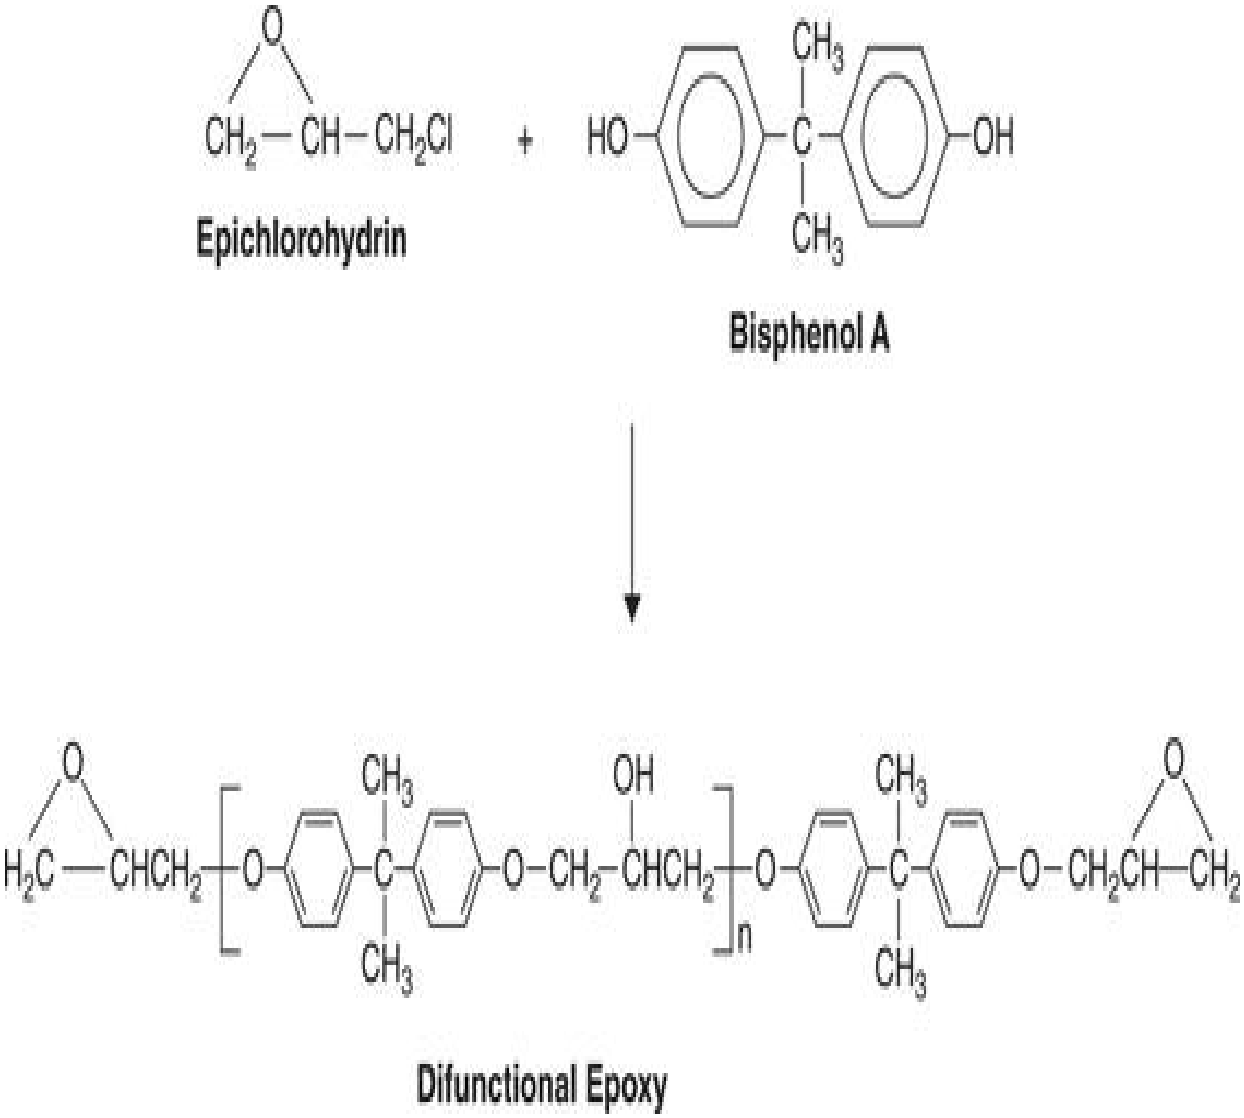

FIGURE 10.1 Reaction to form difunctional epoxy resin.

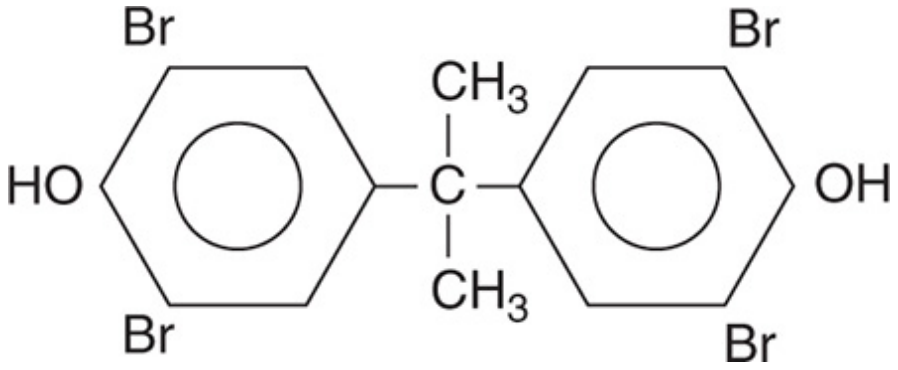

FIGURE 10.2 Tetrabromobisphenol-A (TBBPA).

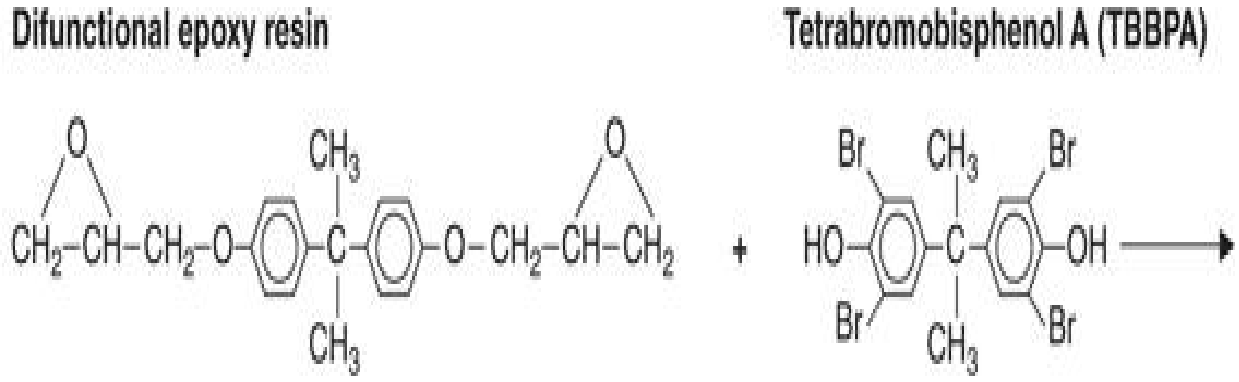

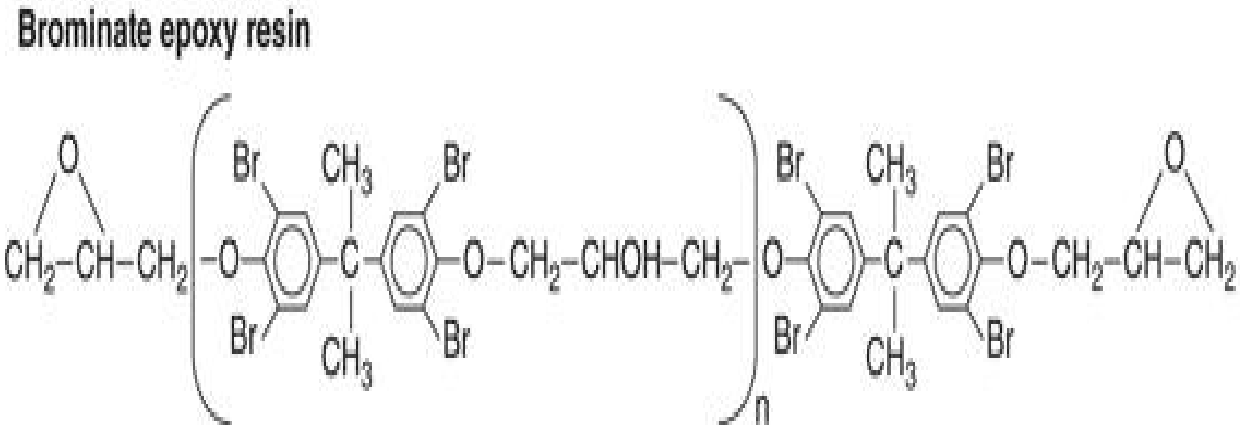

FIGURE 10.3 Brominated difunctional epoxy resin.

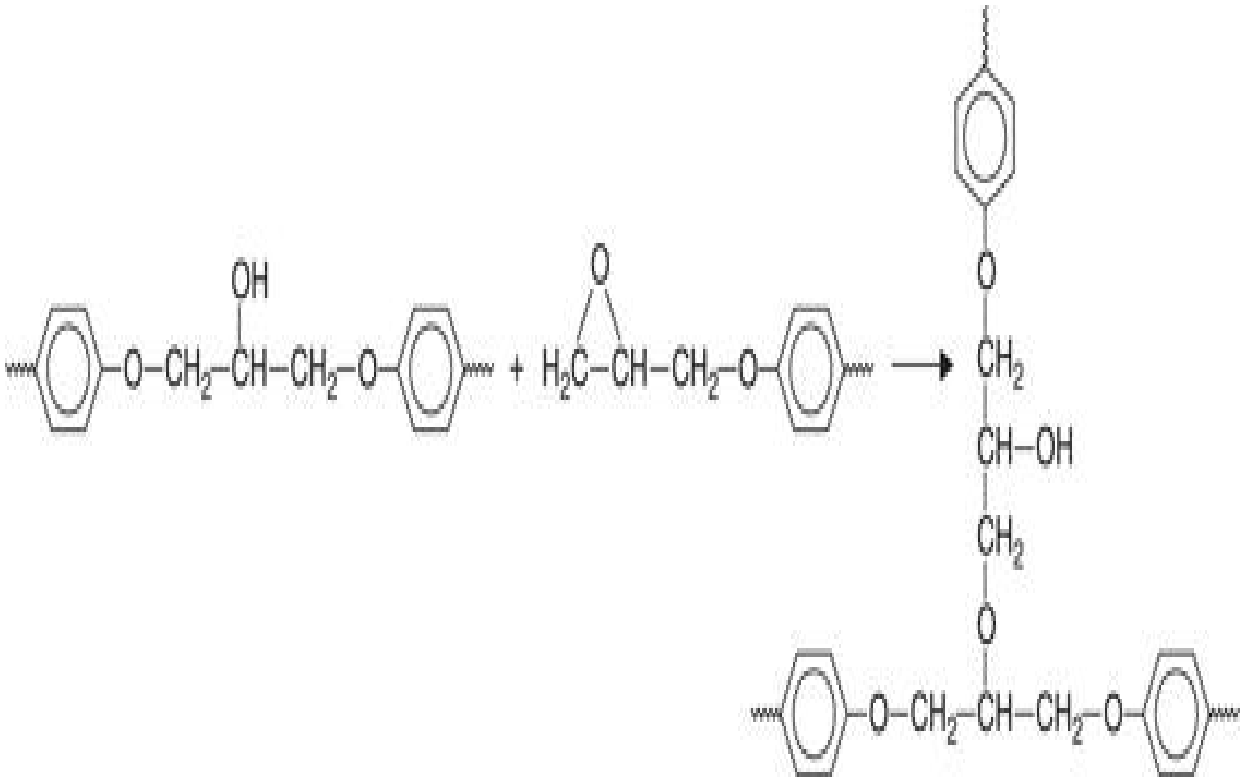

FIGURE 10.4 Crosslinking of –OH and epoxide functional groups.

10.1.3 Difunctional Epoxies

The epoxy resins in Figs. 10.1 and 10.3 are difunctional epoxies. The molecular weight of the epoxy can be varied based on the number of repeating groups shown in the center of the molecule. On either end of the molecule you see the epoxide functional groups. The name *difunctional epoxy* is derived from the fact that there are two epoxide groups, one on either end of the molecule. The molecular weight, the curing agents used to react the resin, and other factors will affect the finished properties of the resin system, including T_g and T_d. The T_g is the temperature at which the resin turns from a rigid or glassy state to a softer, more deformable state. The T_g is important because it affects the thermal and physical properties of the base material and finished circuit board, especially thermal expansion

properties. The T_d is the decomposition temperature and will influence thermal reliability of the printed circuit. These properties are discussed in more detail in Chaps. 11 and 12, and again in Chap. 13 as they relate to compatibility with lead-free assembly processes.

Difunctional epoxies can have a range of T_g's, but are typically below 120°C. These epoxies are sometimes used in relatively unsophisticated products such as simple double-sided printed circuits, but are more commonly blended with other epoxies in higher performance systems.

10.1.4 Tetrafunctional and Multifunctional Epoxies[1]

The use of epoxy compounds with more than two epoxide functional groups per molecule results in greater cross-linking when the resin is cured. Among other things, this results in higher T_g levels. Resin systems with these types of epoxies can exhibit improved thermal and physical properties. However, the curing chemistry will also have an impact on these properties, and often the higher-T_g materials can be harder and more brittle, requiring process adjustments in the printed circuit manufacturing process. Common commercially available laminate materials based on epoxy resin systems can be segmented into a few T_g ranges, 125 to 145°C, 150 to 165°C, and greater than 170°C. There are epoxy systems, or epoxies blended with other resins that have T_g's above 190°C as well. These resin systems may be blends of difunctional, tetrafunctional and multifunctional epoxy resins. Figures 10.5 and 10.6 are examples of tetrafunctional and multifunctional epoxies.

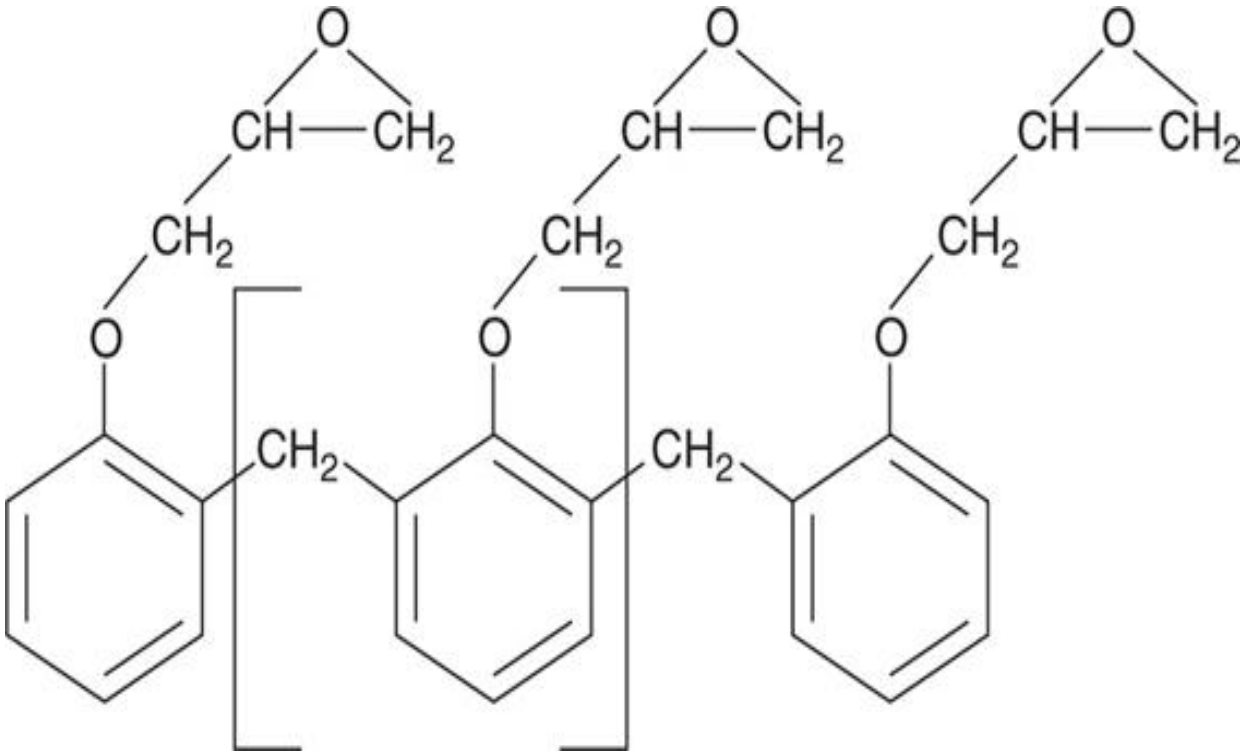

FIGURE 10.6 A multifunctional epoxy phenol novolac resin.

A cost-performance trade-off exists among the commonly used epoxy resin systems. In general, resin systems offering higher levels of T_g and T_d will cost more. In addition, the higher-T_g systems can incur increased circuit manufacturing costs, due primarily to increased multilayer lamination cycle times and decreases in drilling productivity. However, the improvement in performance is often required to meet design and reliability requirements.

10.2 OTHER RESIN SYSTEMS

Many other resin systems are also available. In choosing a resin system, the circuit board designer and fabricator will have to consider what level of performance is needed, as there is typically a strong cost-performance relationship. This cost-performance relationship is driven not only by the base

price of the material itself, but also by the impact the material has on processing costs, both during laminate and prepreg manufacturing, and during printed circuit manufacturing processes.

10.2.1 Epoxy Blends

Blends of epoxy resins with other types of resins have become common in order to tailor material properties, especially for improvements in electrical performance. These are used when performance demands exceed the capabilities of even the high-T_g/T_d epoxies, but where the costs of the highest performance materials cannot be justified. In many cases, the driving force behind these materials is the need for improved electrical properties versus the standard epoxy offerings. Specifically, improvements in the dielectric constant (permittivity) and dissipation factor (loss tangent) are the properties of interest. Materials with lower values for these properties are needed for circuits that operate at high frequencies. A variety of polymers have been used to make these materials; however, many of them are proprietary to a specific material supplier.

Historically, these blends included epoxy-polyphenylene oxide (PPO) (see Fig. 10.7) and epoxy-cyanate ester, as well as epoxy isocyanurate (see Fig. 10.8). However, these materials have become less widely used as new polymers have been adopted. Styrene maleic anhydride (SMA) (Fig. 10.9) is one of these polymers. Besides the improvement in electrical properties, SMA has high heat resistance and high dimensional stability.

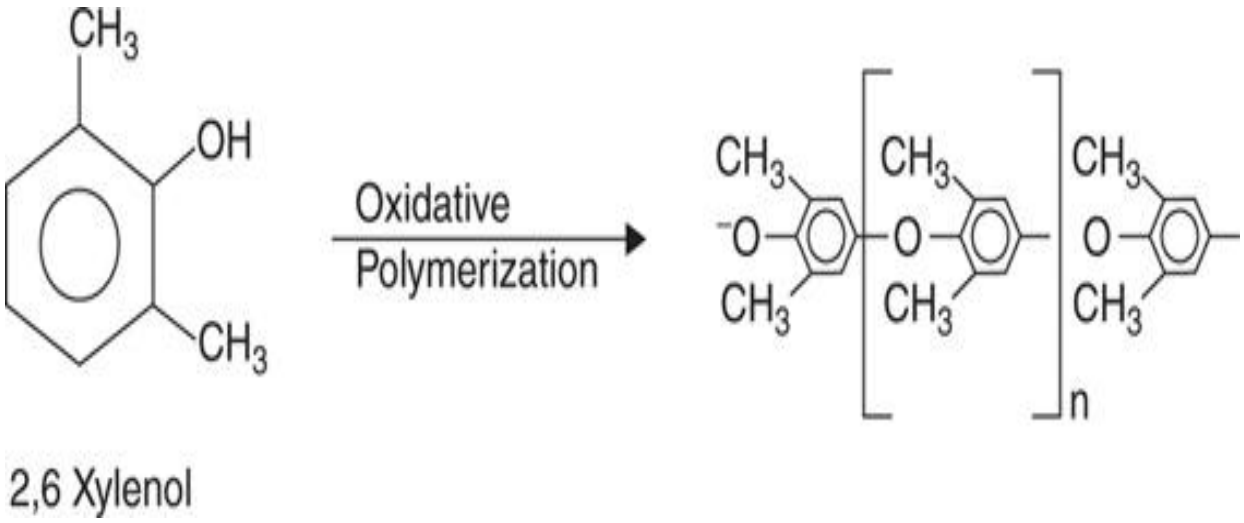

FIGURE 10.7 Polyphenylene oxide (PPO).

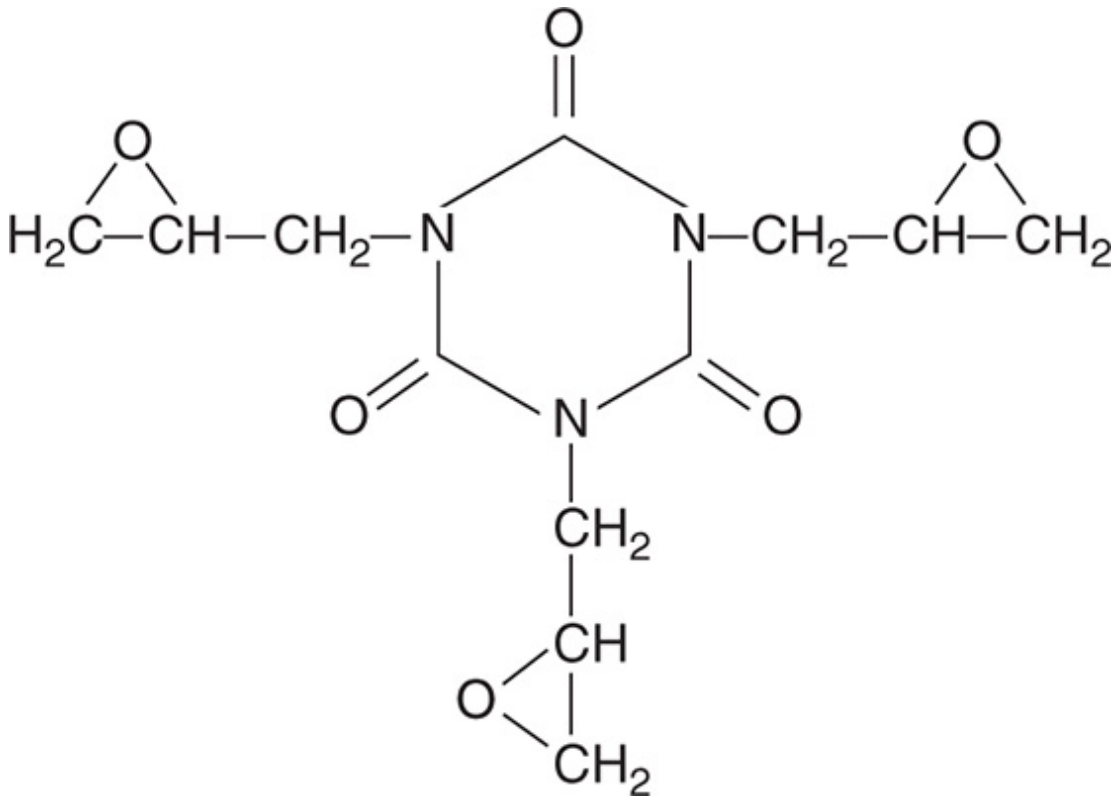

FIGURE 10.8 Epoxy isocyanurate.

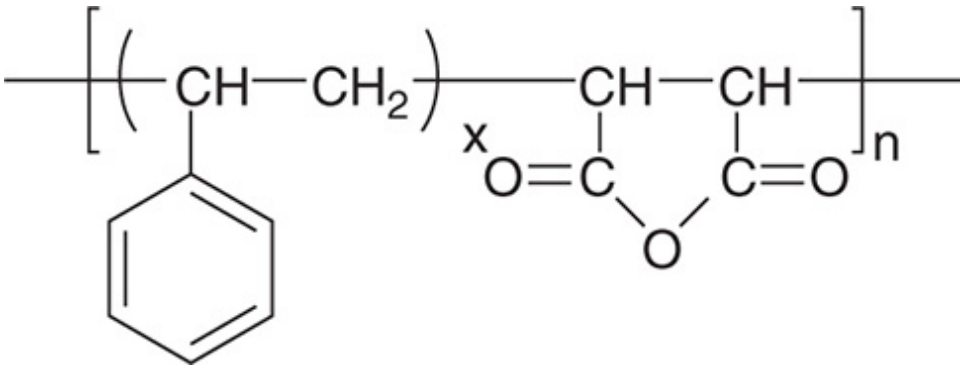

FIGURE 10.9 Styrene maleic anhydride.

While these various resin blends have been developed to minimize impacts to common printed circuit manufacturing processes, they can impact productivity in multilayer lamination and drilling and can require special desmear and hole wall conditioning processes, depending on the design of the printed circuit and fabrication process used. On the other hand, they may have less of an impact to these processes when compared to the even higher performance materials.

These epoxy blends are often used in high frequency applications including communications equipment, servers, storage devices and high speed computing applications.

10.2.2 Bismaleimide Triazine/Epoxy

Typically, epoxy is added to Bismaleimide Triazine (BT) resins in order to modify the properties of pure BT. Therefore these materials are also considered epoxy blends. BT/epoxies normally have T_g values in the range of 180 to 220°C and exhibit a good combination of electrical, thermal, and chemical resistance properties. BT/epoxy is commonly used in BGA substrates and chip scale packages since it can meet the requirements of specifications for use in semiconductor chip packaging. It can also be used in high-density multilayers requiring good thermal, electrical, and chemical performance.

The primary disadvantage of BT based materials is cost. The greater the amount of BT, the higher the cost. BT can also be more brittle than pure epoxy systems, and moisture absorption can also be higher.

10.2.3 Cyanate Ester

Cyanate ester systems possess very high T_g values, typically in the neighborhood of 250°C, and exhibit good electrical performance. Thermal stability is also good. However, cyanate esters are relatively expensive and require special processing which can add additional cost to the finished circuit. They can also be very sensitive to moisture. For these reasons, cyanate ester materials are used only in niche applications, and alternate resin systems have been introduced with more desirable properties. Blends with epoxies have also been used to modify processability, electrical performance, and cost.

10.2.4 Polyimide

When extreme heat resistance is required, polyimide resins offer outstanding performance. With a T_g of 260°C for the purest systems to 220°C for modified or toughened systems, and very high decomposition temperatures, circuits manufactured with polyimide materials exhibit very high levels of thermal reliability. The high T_g of these resin systems also helps to minimize thermal expansion, as most of the thermal expansion occurs pre-T_g, where expansion rates are relatively low. These materials have commonly been used in burn-in boards, aerospace and avionics, down-well oil drilling, and military applications where thermal performance is vital. Again, however, these resin systems

are relatively expensive and more difficult to process, generally limiting them to niche applications.

10.2.5 Polytetrafluoroethylene (Teflon®)

A variety of Polytetrafluoroethylene (PTFE) based products are also available for applications where extremely good electrical properties are required. These materials often require very specialized processing and are relatively expensive. Hybrids of PTFE-based materials and other material types are often used to gain the performance benefits of the PTFE-based materials where needed, while controlling the total circuit cost by using other less costly materials in other layers of the multilayer circuit. PTFE-based materials are commonly used in RF/microwave applications.

10.2.6 Polyphenylene Ether

Polyphenylene Ether (PPE) -based products offer superior electrical properties compared to the epoxy blends discussed above, and also offer excellent thermal performance. This resin system can be used in RF and wireless communications as well as high-speed computing applications. Early versions of these resin systems were difficult to process, but improvements have been made to enable the manufacture of PCBs using conventional PCB manufacturing methods.

10.2.7 Halogen-Free Resin Systems

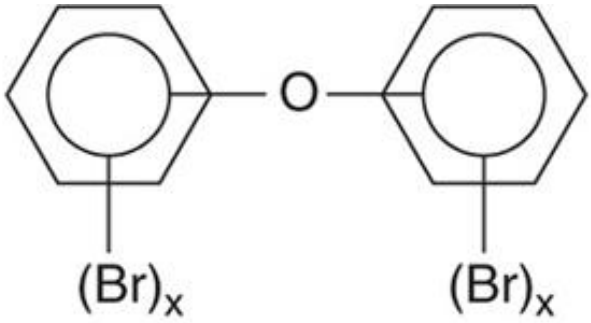
The use of halogen-free resin systems has been increasing. While there has been much discussion about the potential environmental impact of halogenated flame retardants, it

should be noted that the typical halogenated flame retardant used in printed circuits, TBBPA, which is commonly incorporated into a reactive polymer, has been the subject of many toxicology studies and is considered quite safe. In contrast, some other halogenated flame retardants have been restricted, and this will be discussed shortly. But as a result of concerns about halogenated flame retardants generally, some companies have promoted halogen-free alternatives as being better for the environment, so called “green” marketing. The issue to be aware of is that there is a long history of safety in products based on TBBPA chemistry, with less of a history with some of the alternatives. On the other hand, in some cases, using halogen-free chemistry can result in an improvement in electrical performance, specifically a lower dissipation factor. Research and development in this area has increased in recent years, so it is recommended to search the current literature when making decisions about what products to use.

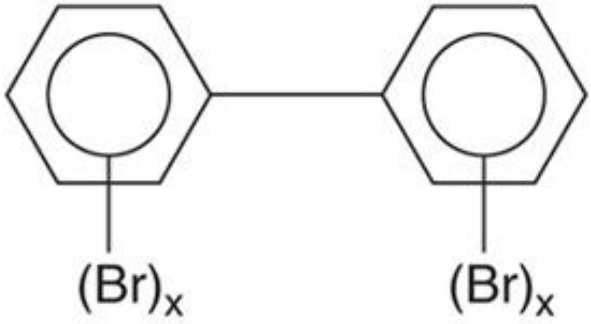
10.3 LEGISLATIVE ISSUES

The European Union’s RoHS and WEEE directives (the WEEE directive addresses waste electronic equipment and recycling requirements) affect not only the lead used in printed circuits, but the flame retardants used in the resin system as well. The RoHS directive restricts the use of specific types of brominated flame retardants. The restricted class of compounds are polybrominated biphenyls (PBBs) and polybrominated biphenyl oxides (PBBOs), also called polybrominated diphenyl ethers (PBDEs). The generic structure of these compounds are shown in Fig. 10.10. Specific compounds within these classes of flame retardants can vary in their toxicity, and given the dynamic nature of legislative initiatives, it is important to check the current

status of these compounds when making decisions on what materials to use.



Polybrominated Biphenyl Oxide (PBBO or PBDE)



Polybrominated Biphenyl (PBB)

FIGURE 10.10 Restricted brominated flame retardants.

In the case of standard epoxy materials used in printed circuits, flame retardancy has commonly been achieved by brominating the epoxy resin. This normally involves manufacturing the epoxy resins with tetrabromobisphenol A (TBBPA), which contains bromine within the chemical backbone (see Fig. 10.2). TBBPA is not restricted by the RoHS directive. Because TBBPA is reacted into the epoxy resin itself, it is not available for release into the environment. Under excessive exposure to heat, the bromine is released and retards burning. TBBPA has been used successfully for

many years as a flame retardant and is still used in the majority of materials. However, while the RoHS directive applies only to specific brominated flame retardants, the WEEE directive may require separation and special handling of materials containing any brominated flame retardant. The separation and special handling relate to concerns about the by-products of incineration, especially if incineration is done at too low a temperature. Furthermore, individual countries continue to look at introducing their own legislative initiatives in regards to these flame retardants, and as such, it is always important to check the status of these efforts.

10.3.1 Flame Retardant Chemistry

Polymer combustion occurs in a continuous cycle, as highlighted in Fig. 10.11. Heat generated in the flame is transferred back to the polymer surface, producing volatile polymer fragments that constitute fuel for further burning. These fragments diffuse into the flame zone where they react with oxygen by free-radical chain reactions. This in turn produces more heat and continues the cycle. Flame retardancy is achieved by interrupting this cycle.

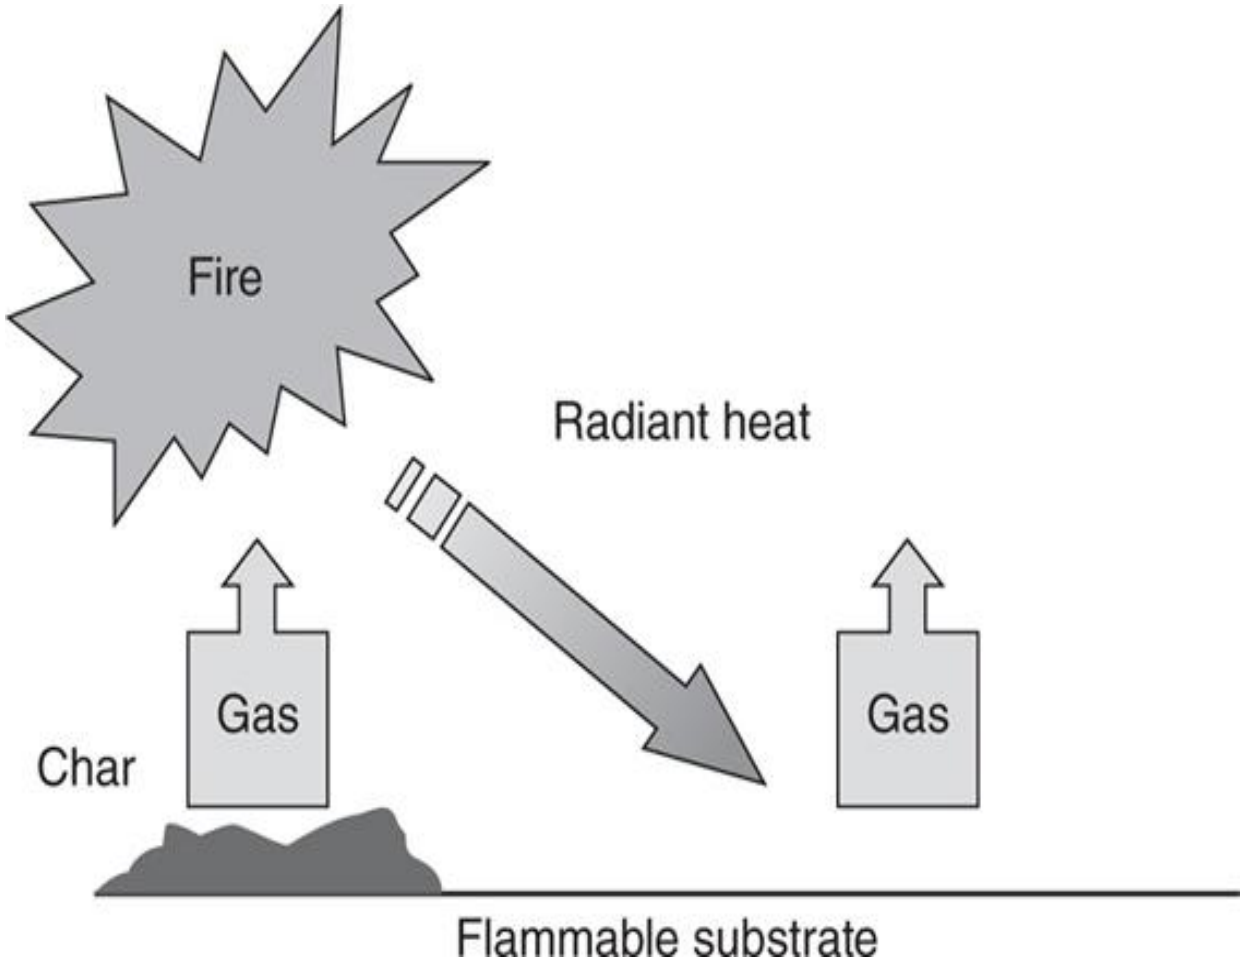


FIGURE 10.11 Polymer combustion.

There are two basic ways to interrupt this cycle. One method is called solid phase inhibition and involves changes in the polymer substrate. Systems that promote extensive polymer crosslinking at the surface form a carbonaceous char upon heating. The char then insulates the underlying polymer from the heat of the flame, preventing production of new fuel and further burning. Other systems evolve water during heating, cooling the surface and increasing the amount of energy needed to maintain the flame.

The second method is called vapor phase inhibition and involves changes in the flame chemistry. Reactive species are built into the polymers, which are transformed into volatile free-radical inhibitors during burning. These materials diffuse into the flame and inhibit the branching

radical reactions. As a result, increased energy is required to maintain the flame and the cycle is interrupted. For many materials, both solid and vapor phase inhibition occur.

Polymers, including the various types of epoxy resins, differ in their inherent flammability. The types of resins and curing agents selected can impact the fundamental flammability of the resin system, and determine how much additional flame retardant components are needed to achieve the desired flammability rating. For example, polymers with a high concentration of aromatic groups will generally have higher thermal stability as well as the ability to form char on burning. Additives such as TBBPA, or epoxy resins built from TBBPA contain bromine on the molecular backbone. Most organic halogenated compounds such as these retard burning by vapor phase inhibition. They typically decompose to yield HBr or HCl (HBr in the case of TBBPA-based materials) which quench chain-branching free radical reactions in the flame. Some halogen acids also catalyze char formation.

10.3.2 Halogen-Free Alternatives

Halogen-free alternatives include phosphorus-based compounds, nitrogen-based flame retardants, inorganic flame retardants and hydrated fillers. These can be subdivided into reactive components and additives. A reactive component is one that becomes directly incorporated into the resin system itself, like TBBPA. As with TBBPA, reacted components have the advantage of not being available for release to the environment through leaching or solvent extraction. An example of a reactive, nonhalogen flame retardant would be epoxidized phosphorus compounds. The epoxide groups of these compounds make them reactive and result in chemical bonding into the polymer backbone. In contrast, red phosphorus is an

inorganic solid that can be dispersed into an epoxy formulation. Hydrates, such as aluminum hydroxide or magnesium hydroxide, decompose and liberate water, which then suppresses the burning process. In some cases, organic flame retardants may be dispersed into the bulk resin system as an additive, in the way inorganic fillers can be dispersed within the resin system to alter other properties.

In choosing a flame retardant, consideration must be given to the impact on the performance of the resin system and the finished base material. These materials, at the levels required for flame retardancy, can affect the physical properties of the laminate, change rheological properties and alter cure kinetics of the resin system. Generally, the reactive compounds are preferred since they are bound to the polymer backbone, which prevents release into the environment, and they seem to facilitate obtaining the desired material properties in comparison to additives or fillers. But combinations of reactive compounds and additives to the resin system can work synergistically and still meet other performance requirements. Table 10.2 summarizes some of the available halogen-free flame retardants.

TABLE 10.2 Halogen-Free Flame Retardants

Type	Primary Mechanism	Examples	Considerations
Phosphorus	Char former	Red phosphorus, ammonium polyphosphate, organic phosphorus compounds	Red phosphorus difficult to process, toxic. Organic phosphorus compounds are a common alternative, but generally more costly and can lower T_g.
Inorganic/ hydrated fillers	Evolve water, endothermic, may promote char	Alumina trihydrate, magnesium hydroxide, zinc borate, antimony oxides	Inexpensive, but generally require high loadings and can degrade mechanical and other properties. Toxicity of antimony-based retardants a concern. Can be used with other flame retardants synergistically.
Nitrogen	Intumescent System, generates gas that foams char	Melamine, melamine Cyanurate	Impact on material properties, other environmental impact concerns.

Organic phosphorus-based flame retardants have become a common alternative flame retardant used in printed circuit base materials. However, others are also being used and combinations of two or more types of halogen-free flame retardants can also be used synergistically to achieve adequate flammability levels while minimizing adverse impacts on material properties. Some of the impacts that must be evaluated are moisture absorption, copper peel strength, T_g reduction, changes in resin flow, change in mechanical or electrical performance, and the impact on CAF resistance. Some of the currently used alternatives include the following:

- *Alumina trihydrate (ATH)*. ATH works by generating water vapor to reduce the flammable gas concentration and also

forms a char. It is relatively inexpensive and easy to drill, but lowers the decomposition temperature, T_d, and typically requires a fairly high loading to pass UL94 V-0 flammability rating.(see Fig. 10.12).

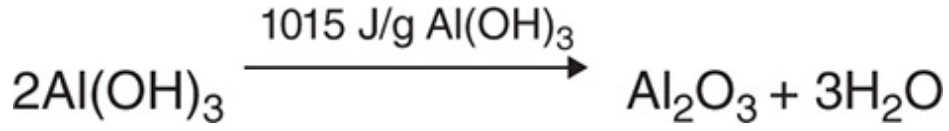

FIGURE 10.12 Decomposition of ATH.

- *Melamine derivatives*. Melamine polyphosphate (MPP) (Fig. 10.13) is one example of this category of flame retardant. Such nitrogen containing compounds decompose to generate an inflammable gas and the phosphorous compounds create a char. These flame retardants are widely available and inexpensive, but may result in higher moisture absorption and are nonreactive.

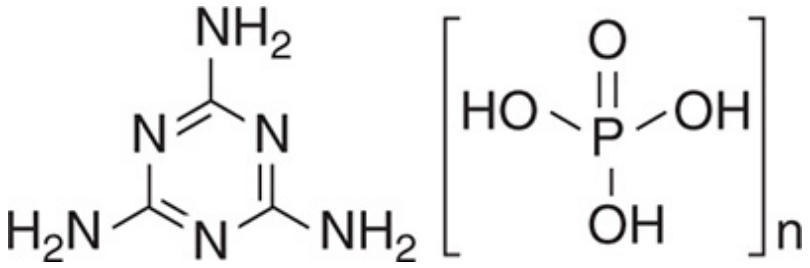

FIGURE 10.13 Melamine polyphosphate (MPP).

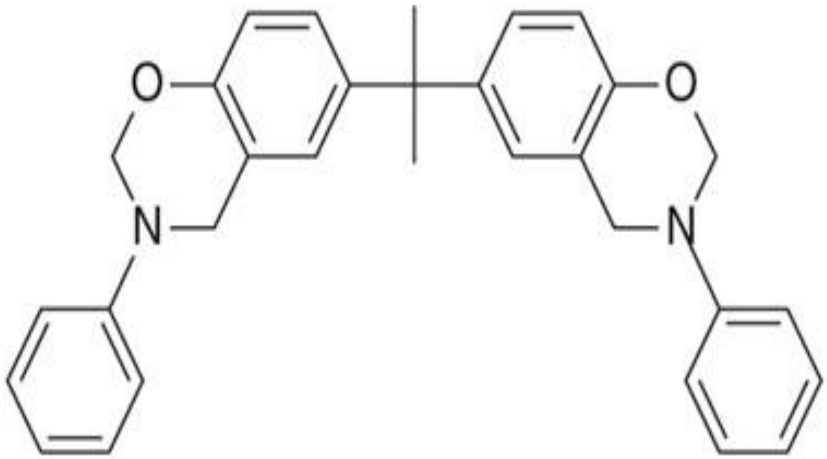
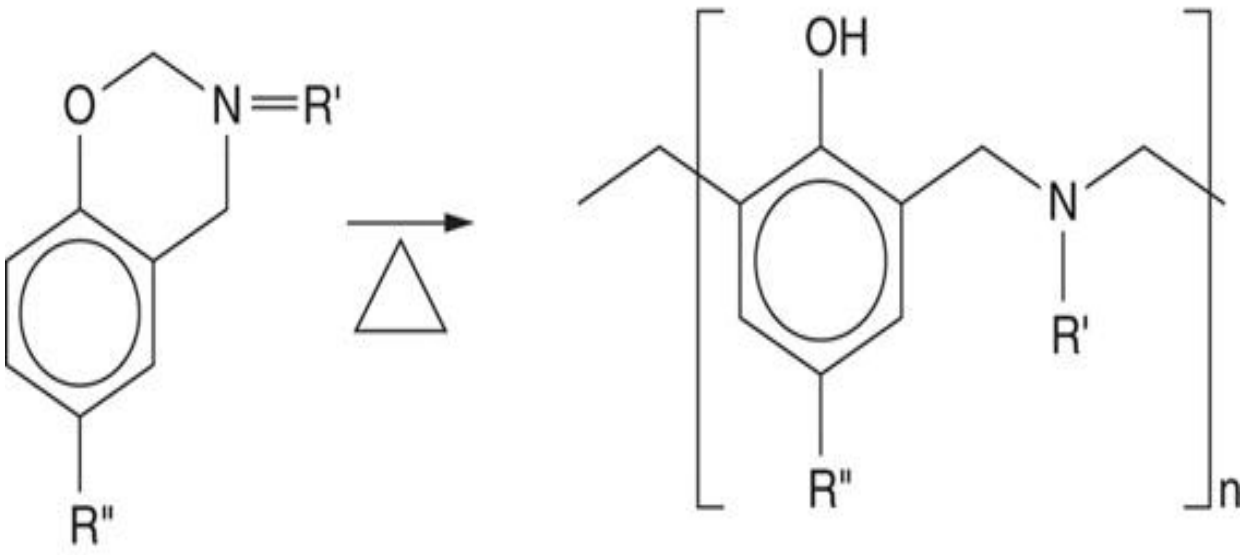
- *Nitrogen containing resins*. Examples include benzoxazine and melamine phenolic formaldehyde novolac as shown in Figs. 10.14 and 10.15. The advantage of these compounds is that they are reactive and support a high T_g. On the other hand, they are generally not as effective as reactive phosphorous compounds, can be difficult to fully cure, and are often not as thermally stable. They can also be relatively brittle.



Benzoxazine



Benzoxazine reaction schematic

FIGURE 10.14 Benzoxazine.

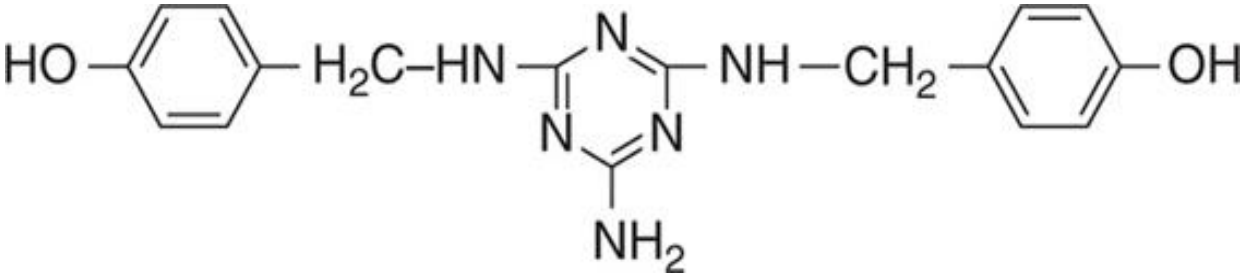


FIGURE 10.15 Melamine phenolic formaldehyde novolac.

- *Phosphorous containing resins and hardeners*. A commonly used compound used to make phosphorous containing resins and hardeners is DOPO (9,10-dihydro-9-oxa-10-phosphaphenanthrene-10-oxide), as shown in Figs. 10.16, 10.17 and 10.18. DOPO may be used to create epoxy resins which contain the DOPO chemistry for flame retardancy that are also reactive into the resin system. These resins are now commonly available, but many limit the range of T_g that can be achieved and are relatively more expensive. Hardeners based on DOPO can offer more flexibility in formulation of the resin system, and as a result can be used to develop higher-T_g resin systems that also have higher decomposition temperatures.

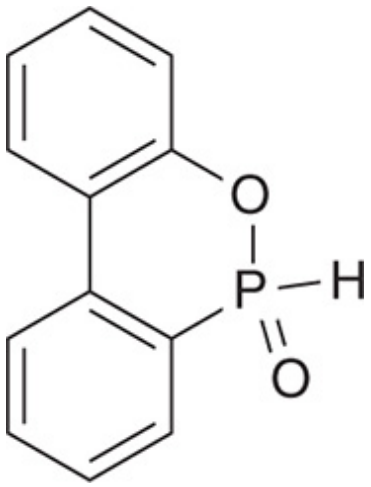

FIGURE 10.16 DOPO.

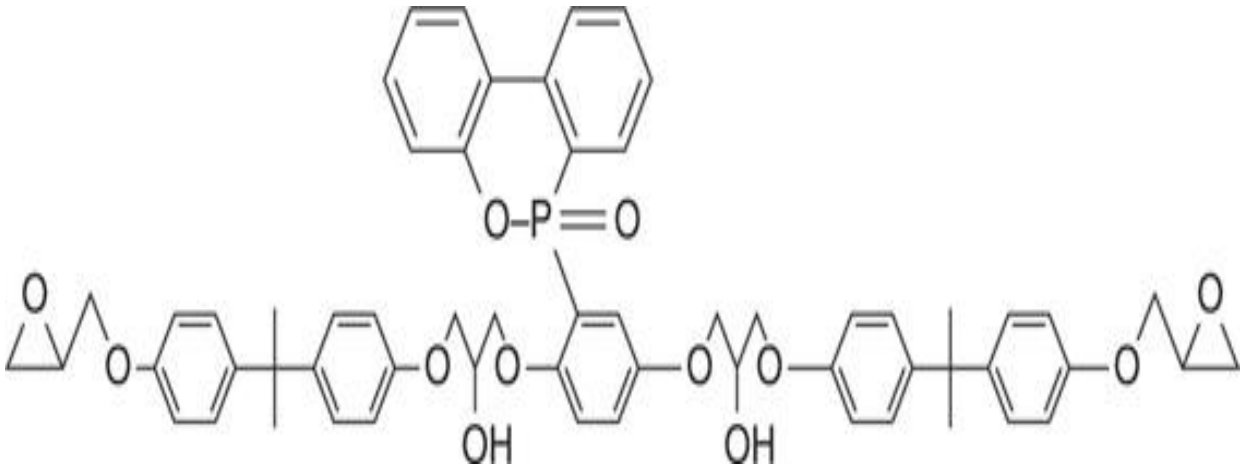

FIGURE 10.17 DOPO-HQ difunctional epoxy.

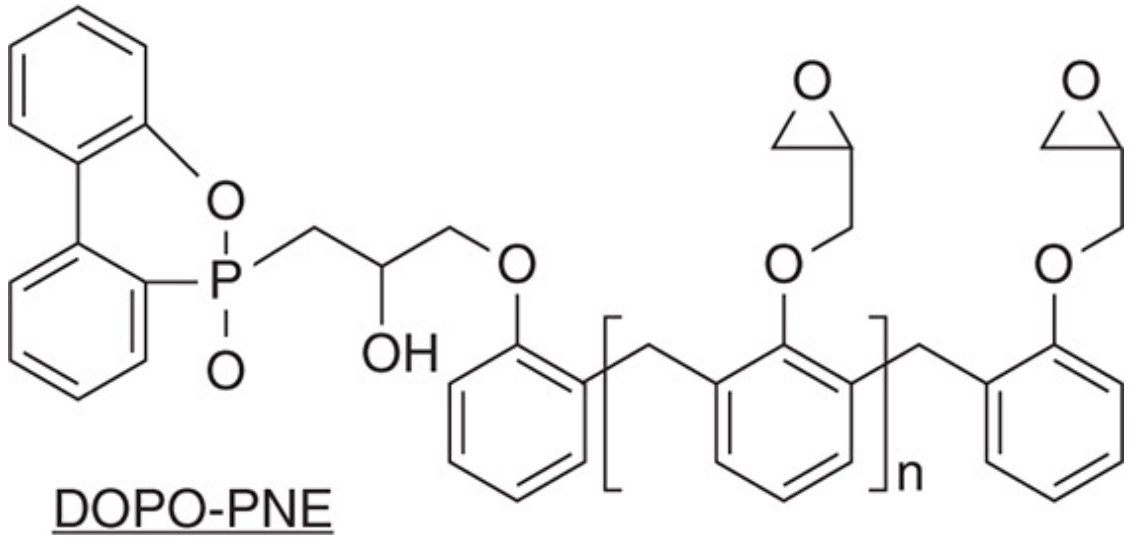

FIGURE 10.18 DOPO-based phenol novolac epoxy.

10.3.3 Other Resins and Formulations

For many of these resins, there are several different types of molecular structures that can be used to modify the ultimate properties of the base material. In addition, other types of resins are also in use or are being developed to meet the growing requirements for the various applications printed circuits are used in. Often, these resins are proprietary in

nature and therefore discussions of these products focus on their properties rather than the specific chemistry used to achieve the properties. In addition, fillers are increasingly being used to modify thermal expansion or electrical performance, or both. Fillers will be discussed shortly.

10.4 ADDITIVES

The resin systems discussed above will typically contain a variety of additives that either promote curing of the resin system or modify the properties in some way. Some important types of additives are given here:

10.4.1 Curing Agents and Accelerators

Each resin system contains organic components that must be reacted together in order to promote polymerization and cross-linking. Curing agents and accelerators are used to promote these reactions. Amine based curing agents have been commonly used to cure epoxy resins. Some of these, such as aliphatic diamines are used to cure epoxies at room temperature. Others, such as aromatic diamines require elevated temperatures. Figure 10.19 shows an example of curing epoxy with an aromatic amine. Note the –OH group formed on the new molecule. As shown in Fig. 10.4, the –OH can also crosslink with other epoxide groups.

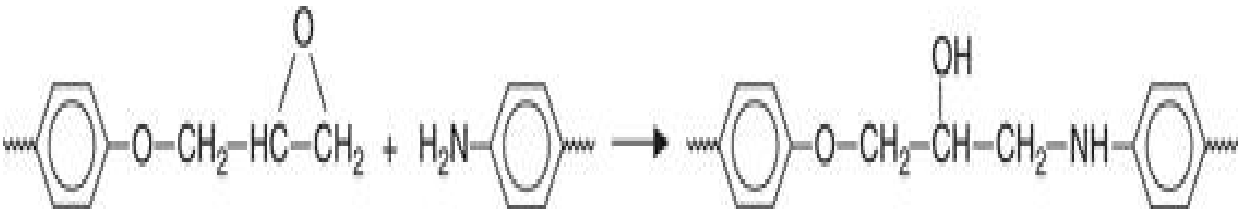

FIGURE 10.19 Curing epoxy with an aromatic amine.

Historically, the most common curing agent used in epoxy resin systems for printed circuit base materials has been dicyandiamide or “dicy.” However, nondicy systems have been developed to promote faster curing, reduce moisture sensitivity, and improve thermal stability. The choice of curing agent and accelerator is also driven by the resin type. Nondicy cured epoxy materials will be discussed further in Chap. 13. Figure 10.20 illustrates some of the curing reactions that occur as the resin system polymerizes, and Fig. 10.21 illustrates a phenol curing mechanism.

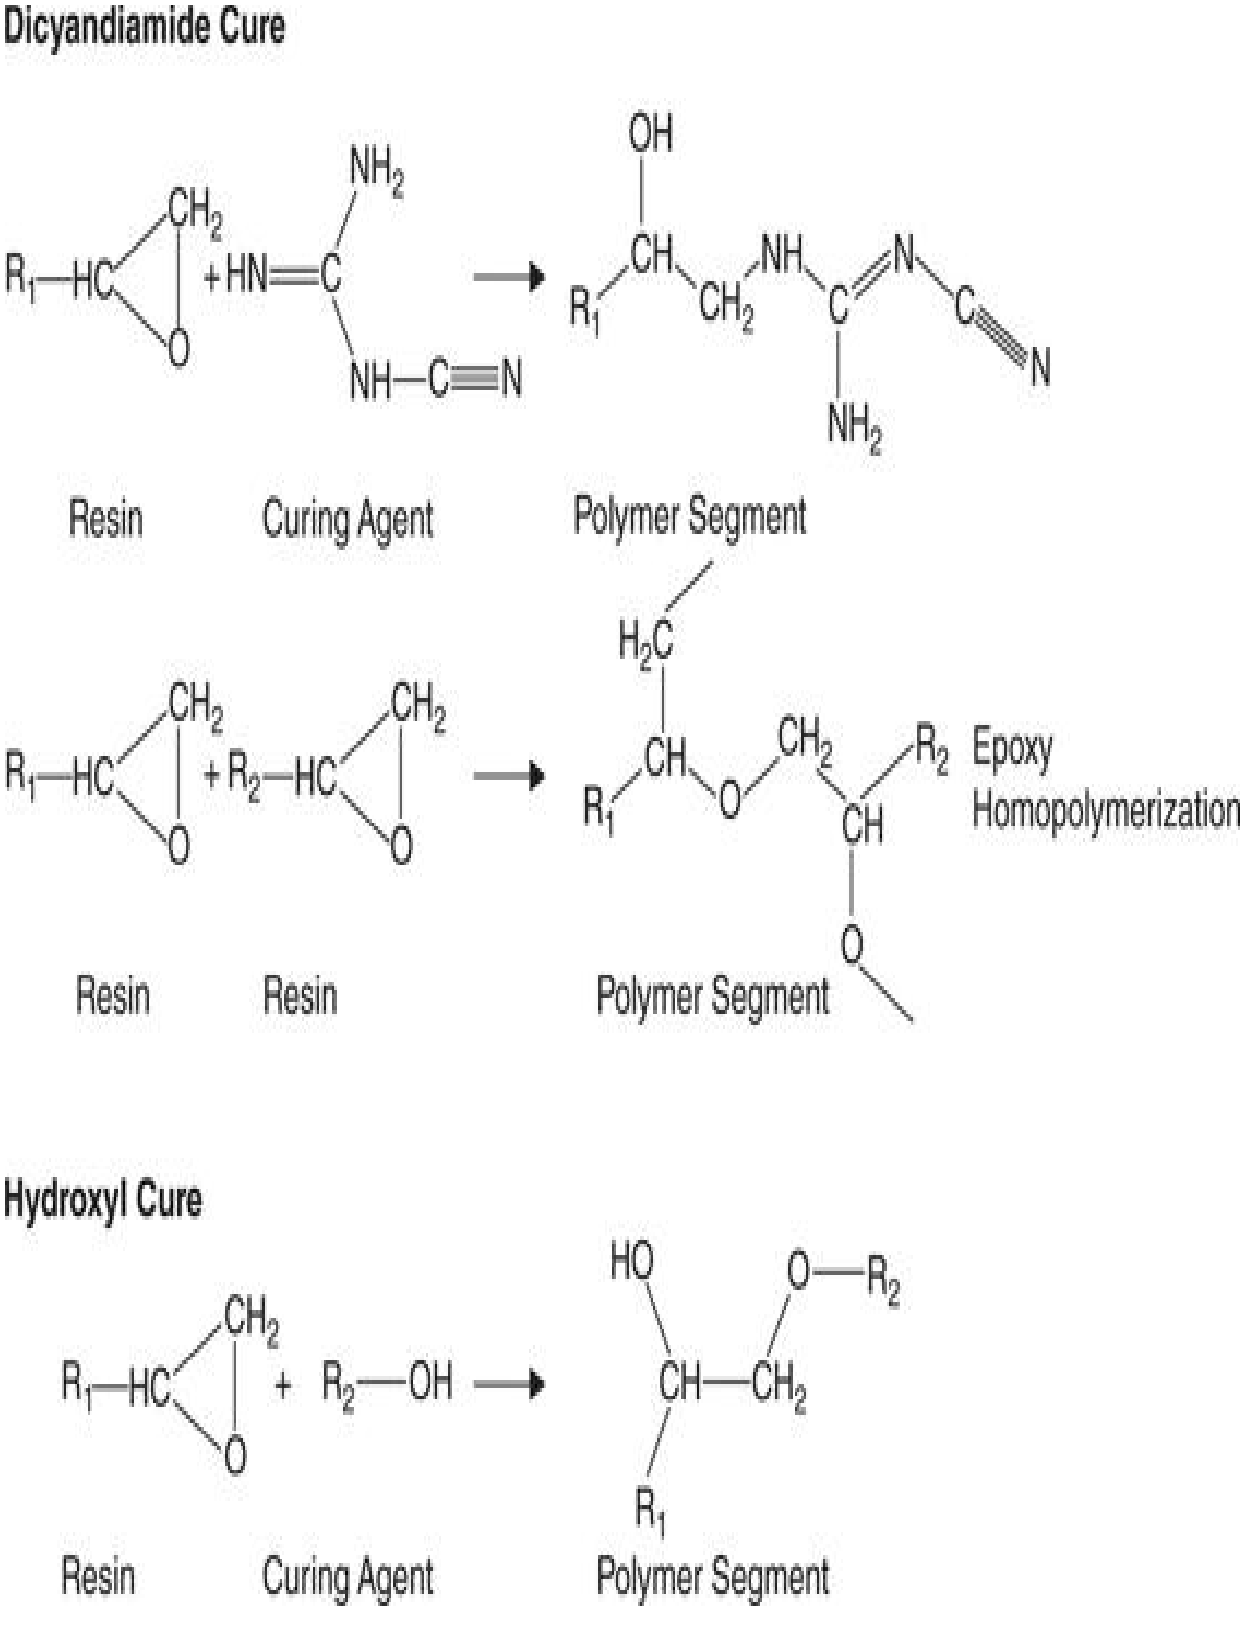

FIGURE 10.20 Epoxy curing mechanisms.

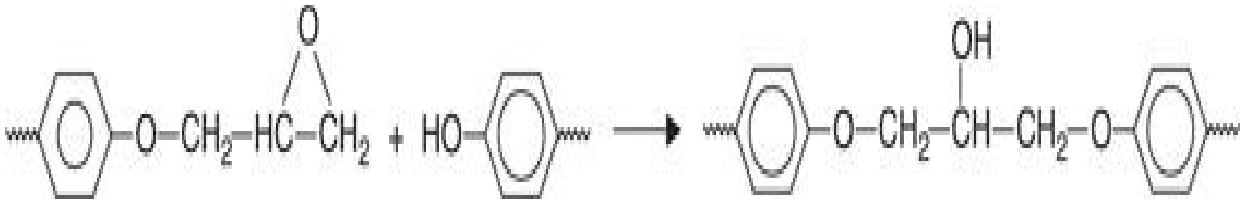

FIGURE 10.21 Phenol curing mechanism.

10.4.2 UV Blockers/Fluorescing Aids

Some resins naturally absorb ultraviolet light. Others absorb very little. There are two reasons why this property is important. First, some automatic optical inspection (AOI) equipment is laser based and relies on the resin system in the base material to fluoresce upon exposure, which allows the AOI device to detect the conductor pattern. The second reason involves photoimaging on very thin circuits, during the solder mask imaging process for example. In very thin circuits, if the base material does not absorb UV light sufficiently, the UV light from one side of the circuit board can pass through to the other side and cause unwanted exposure of the photoresist on the opposite side. Therefore, components that absorb UV light are sometimes added to resin systems that do not sufficiently absorb UV light.

10.4.3 Inorganic Fillers

Fillers are small particles that can be added to a resin system in order to modify the electrical or thermomechanical properties of the composite material. These materials range from talc, silica, kaolin clay powders, tiny hollow glass spheres, to a variety of other inorganic materials. These materials are typically used to tailor the properties of the base material for specific uses. For example, kaolin clay powders coated with a layer of palladium and dispersed within the base materials have been used as catalysts for

electroless copper plating. Hollow glass microspheres have been used to reduce the dielectric constant of materials. The most common use of fillers is to reduce thermal expansion and improve reliability. The reduced *z*-axis expansion helps offset the increased expansion and stress on plated through holes that results from the higher temperatures associated with lead-free assembly. They may also improve the machinability of materials in the drilling process and alter electrical properties such as Dk and Df. Talc and silica based fillers are commonly used for reduction in *z*-axis expansion.

The performance of fillers is a function of a number of factors, including the methods used to manufacture the fillers and the size and shape of the fillers. Materials incorporating a given filler composition (i.e., silica) may have different properties depending on the specific filler type and form. The amount of filler within the resin system will also change the overall properties, and the optimal amount requires consideration of a balance of properties. For example, some fillers may provide excellent thermomechanical properties, but may also increase drill bit wear.

10.5 REINFORCEMENTS

While there are also a variety of reinforcements used in base materials, woven fiberglass cloths are by far the most common. Other materials include paper, glass matte, nonwoven aramid fibers, nonwoven fiberglass and a variety of fillers. The advantages of woven glass cloths include a good combination of mechanical and electrical properties, a wide range of types for achieving various laminate thicknesses, and good economics.

10.5.1 Woven Fiberglass

The process of manufacturing woven fiberglass cloth begins with melting the various inorganic components required for a particular grade of glass. The molten components travel through a furnace and ultimately flow through specialized bushings to form the individual fiberglass filaments and yarns. These yarns are then used in a weaving process in order to manufacture the fiberglass cloth. The relative concentrations of the components used will affect the chemical, mechanical, and electrical properties of the fiberglass. The compositions of a few fiberglass types are provided in Table 10.3. Figure 10.22 illustrates the process used to manufacture the fiberglass yarns. The yarns are then woven into fiberglass cloths.

TABLE 10.3 Fiberglass Compositions

Component	E-Glass	NE-Glass	S-Glass	D-Glass	Quartz
Silicon dioxide	52–56%	52–56%	64–66%	72–75%	99.97%
Calcium oxide	16–25%	0–10%	0–0.3%	0–1%	
Aluminum oxide	12–16%	10–15%	24–26%	0–1%	
Boron oxide	5–10%	15–20%		21–24%	
Sodium oxide and potassium oxide	0–2%	0–1%	0–0.3%	0–4%	
Magnesium oxide	0–5%	0–5%	9–11%		
Iron oxide	0.05–0.4%	0–0.3%	0–0.3%	0.3%	
Titanium oxide	0–0.8%	0.5–5%			
Fluorides	0–1.0 %				

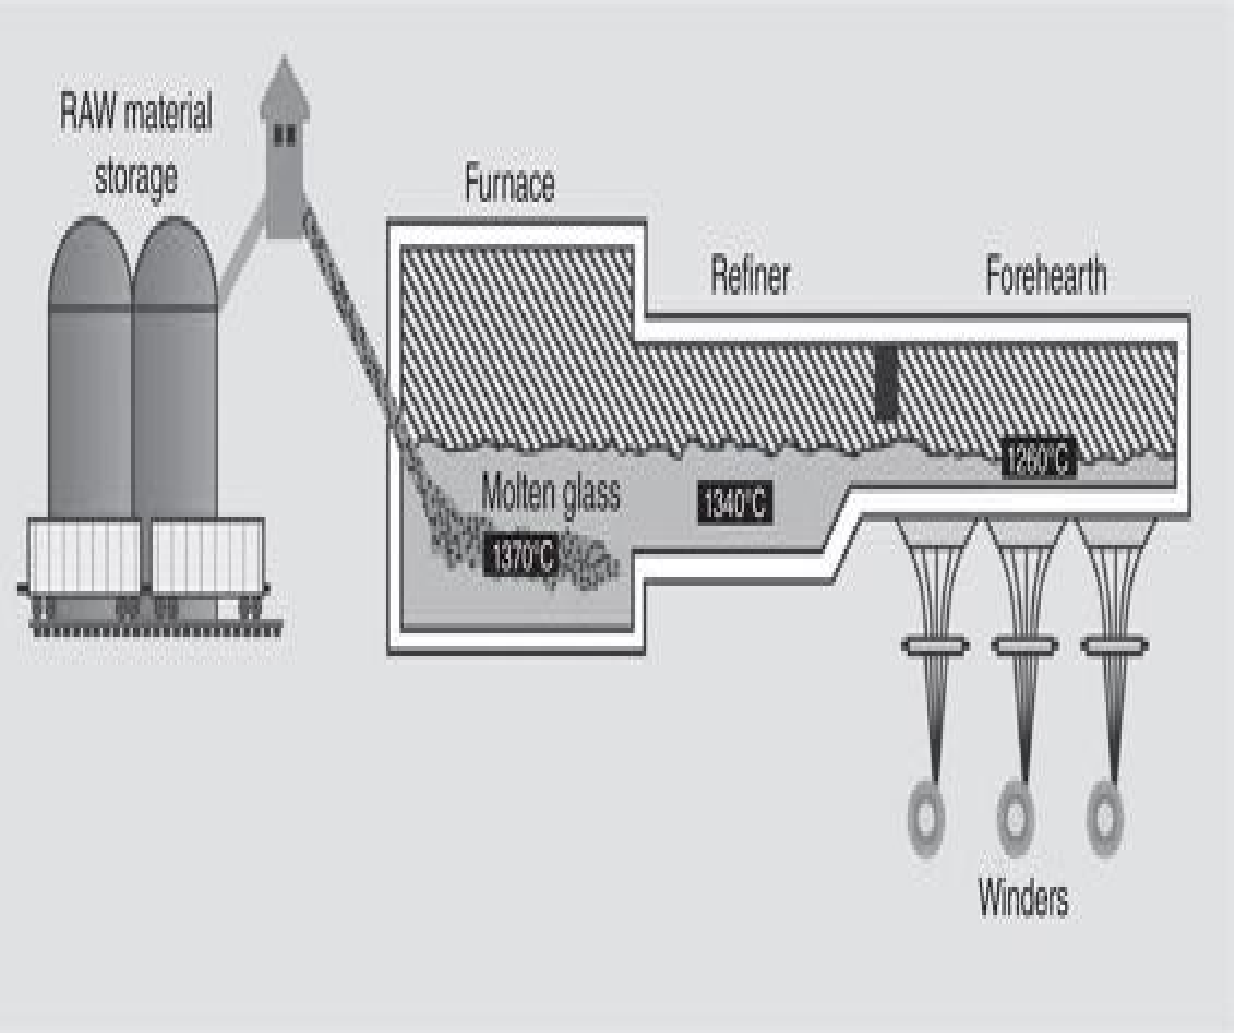

FIGURE 10.22 Illustration of fiberglass yarn manufacture.

E-glass is the most commonly used fiberglass for printed circuits. E-glass provides an excellent combination of electrical, mechanical, and chemical properties at a reasonable cost. NE-glass had been used in limited quantities, but usage has grown as the need for better electrical performance grows. NE-glass offers improved permittivity (Dk) and loss (Df) properties. Another glass type more recently introduced is L-glass. L-glass also offers improved Dk and Df properties in comparison to E-glass. However, NE and L glass are more expensive than E-glass. Note that the Dk and Df values in Table 10.4 are approximate and based on commercially available technical data sheets.

These measurements can vary based on measurement method and other factors, so are meant only to show that both NE and L glass offer improved Dk and Df values compared to E-glass, not to show the relative performance of NE and L glasses. S-glass provides greater strength but is more difficult to process through the mechanical drilling operation. Other glass types are less commonly used, though there are also low CTE glasses used in chip packaging substrates.

TABLE 10.4 Comparison of E-Glass and NE-Glass

Property	E-Glass	NE-Glass	L-Glass
CTE, ppm/°C	5.5	3.4	3.9
Dielectric constant @ 1 GHz	6.8	4.8	4.8
Dielectric constant @ 10 GHz	6.6	4.8	4.8
Dissipation factor @ 1 GHz	0.004	0.0015	0.001
Dissipation factor @ 10 GHz	0.0066	0.0035	0.003

There are several diameters of filaments available (Table 10.5), as well as many different yarn types. D, DE, E, and G filaments are the most commonly used. Combining the various yarn types in the weaving process leads to many different types of cloth styles. While there are also many different weave types, virtually all cloths for printed circuits use a plain weave (Fig. 10.23). The plain weave consists of yarns interlaced in an alternating fashion one over and one under every other yarn. This weave pattern provides good fabric stability. Some of the common plain weave cloth styles used for printed circuits are shown in Table 10.6. The fiberglass cloths are also coated with a finish or coupling

agent tailored for improving the bond between the glass filaments and the specific resin coated onto the glass. This coupling agent and the resin-to-glass bond that results, is an important consideration for CAF resistance, which will be discussed in Chap. 14.[2]

TABLE 10.5 Glass Filament Diameters

Filament Designation	Nominal Diameter (microns)	Nominal Diameter (10^{-5} inches)
BC	4	15.7
C	4.5	17.7
D	5	21.0
DE	6	25.6
E	7	28.0
G	9	37.0

10.5.2 Yarn Nomenclature

Because there can be so many types of yarn manufactured from the available grades of glass and filament diameters, special nomenclature systems have been developed. The two systems used are the U.S. system and the SI/Metric system.

10.5.2.1 The U.S. System. An example of a yarn name in the U.S. system is ECD 450-1/0. This yarn is used in making a 1080 style glass cloth. Each letter and number in the name describes something about the yarn:

- *First letter:* describes the glass composition. Electrical grade, or E-glass is the most common grade used for manufacturing materials for printed circuits.
- *Second letter:* C indicates that the yarn is composed of continuous filaments. S would indicate staple filaments.
- *Third letter:* indicates the individual filament diameter (Table 10.5).
- *First number:* represents 1/100th the normal bare glass yardage in 1 pound of the basic yarn strand. In the example above, multiply 450 by 100 which results in 45,000 yards in 1 pound.
- *Second number:* represents the number of basic strands in the yarn. The first digit represents the original number of twisted strands. The second digit separated by the diagonal represents the number of strands plied or twisted together. 1/0 means that the yarn is a singles yarn (no or "zero" plying required).

The name may also include a designation indicating the number of turns per inch in the twist of the final yarn, and the direction of the twist. An example would be 3.0S, or 3 turns per inch with an "S" direction twist. An "S" twist has

spirals that run up and to the left. A “Z” twist has spirals that run up and to the right.

10.5.2.2 The SI/Metric System. An example of a yarn name in the SI/Metric System is EC5 11 1X2.

- *First letter:* designates the glass composition.
- *Second letter:* C indicates that the yarn is composed of continuous filaments. S indicates staple filament.
- *First number:* indicates the individual filament diameter expressed in microns.
- *Second number:* represents the TEX number of linear density. TEX is the mass in grams per 1000 meters of yarn. So 11 in the above example refers to 11 g/km.
- *Third number:* indicates yarn construction or the basic number of strands in the yarn. The first digit represents the original number of twisted strands and the second digit, after the X, indicates the number of these strands twisted or plied together.

10.5.3 Fiberglass Cloths[3]

With the possible combinations of glass compositions, filament diameters, yarn types, and the number of different weave patterns available, the number of possible fiberglass cloths can almost be unlimited. The effects that these glass fabrics have on the base material are driven by these variables. In addition, the fabric count, or the number of warp yarns and fill yarns also helps determine the properties of the fabric and the base material. Warp yarns are those that lie in the length (machine direction) of the fabric while the fill yarns lie across the warp direction. The warp direction is also commonly called the grain direction. Fabrics with a balanced amount of glass in both directions is called “square

weave” glass. Examples include 1067 and 1086 in Table 10.6. The fabric count for 1067 is 70 × 70 and for 1086 it is 60 × 60. Contrast these with the 1080 glass cloth, which is 60 × 47. This can have an impact on signal integrity and will be discussed further in Chap. 14.

As pointed out earlier, E-glass is the most commonly used glass type, and virtually all use what is called a plain weave. A plain weave results in a fabric constructed so that one warp yarn passes over and under one filling yarn (and vice versa). This weave pattern offers good resistance to yarn slippage and fabric distortion. Common fiberglass cloths used in materials for printed circuits are shown in Table 10.6, using the U.S. nomenclature system. The IPC specification IPC-4412 documents additional cloth styles as well as the SI/Metric nomenclature. Some common styles are shown in Figs. 10.24 through 10.30. At a given resin content, each style will yield a different nominal dielectric thickness. Having the flexibility of many glass styles and thicknesses is important for meeting controlled impedance and overall thickness requirements.

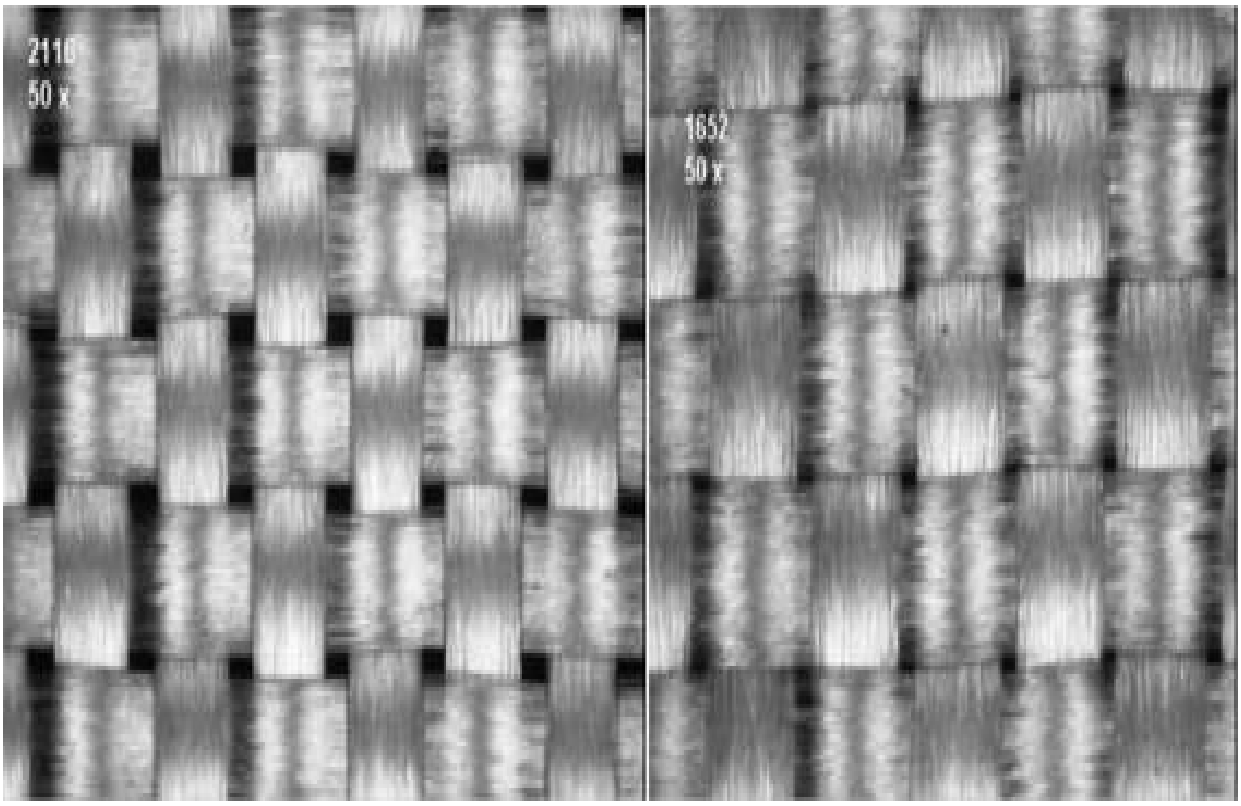

FIGURE 10.29 1080 and 1086 Glass fabrics.

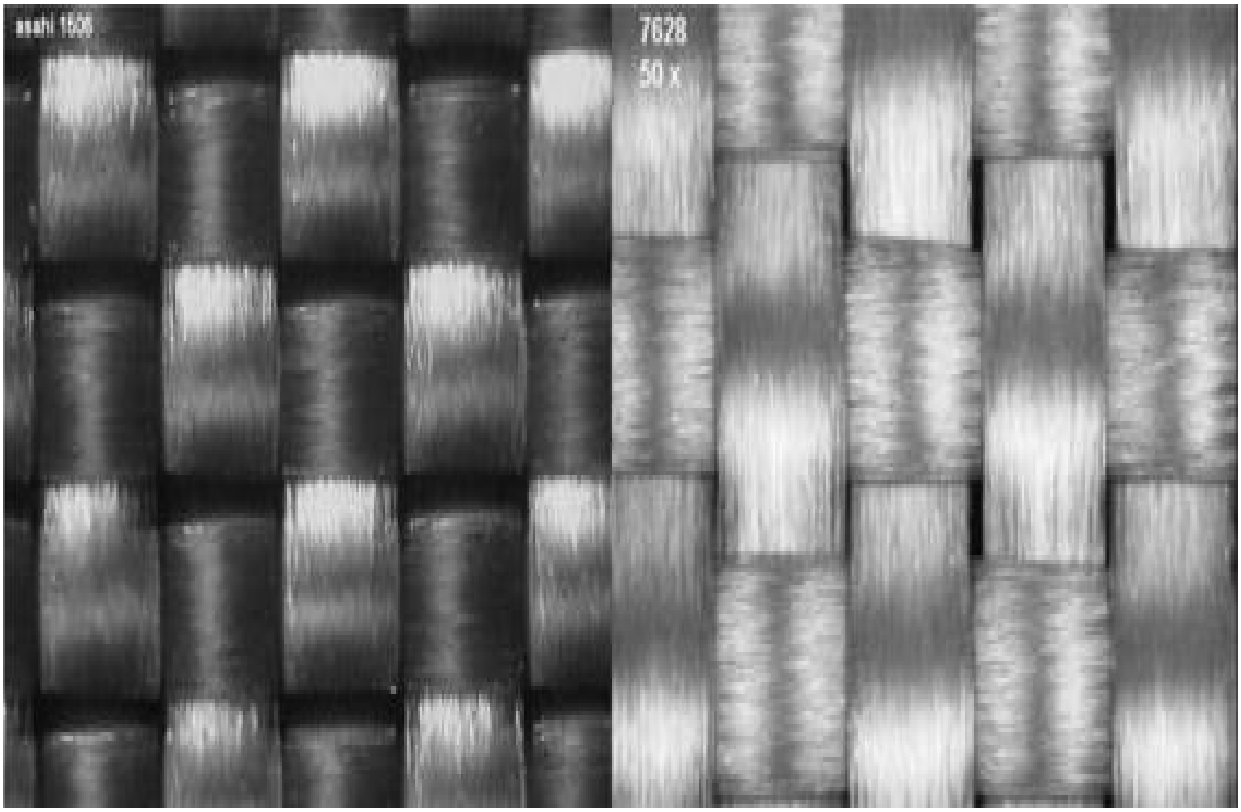

FIGURE 10.30 2113 and 2313 Glass fabrics.

In recent years, the use of many of the very thin, lightweight fabrics has dramatically increased. This has been driven largely by the need for very thin dielectrics in mobile devices such as smartphones and tablet computers. But use of these fabrics is also growing in thicker, higher layer count PCBs where the need to increase circuit density continues to necessitate thinner dielectrics, some of which require two plies of glass cloth in a thin dielectric. In smartphones and tablet devices, 1037 glass is common with the use of 1027 and 1017 growing. Figure 10.31 is an example of an HDI PCB using very thin glass cloth in a smartphone.

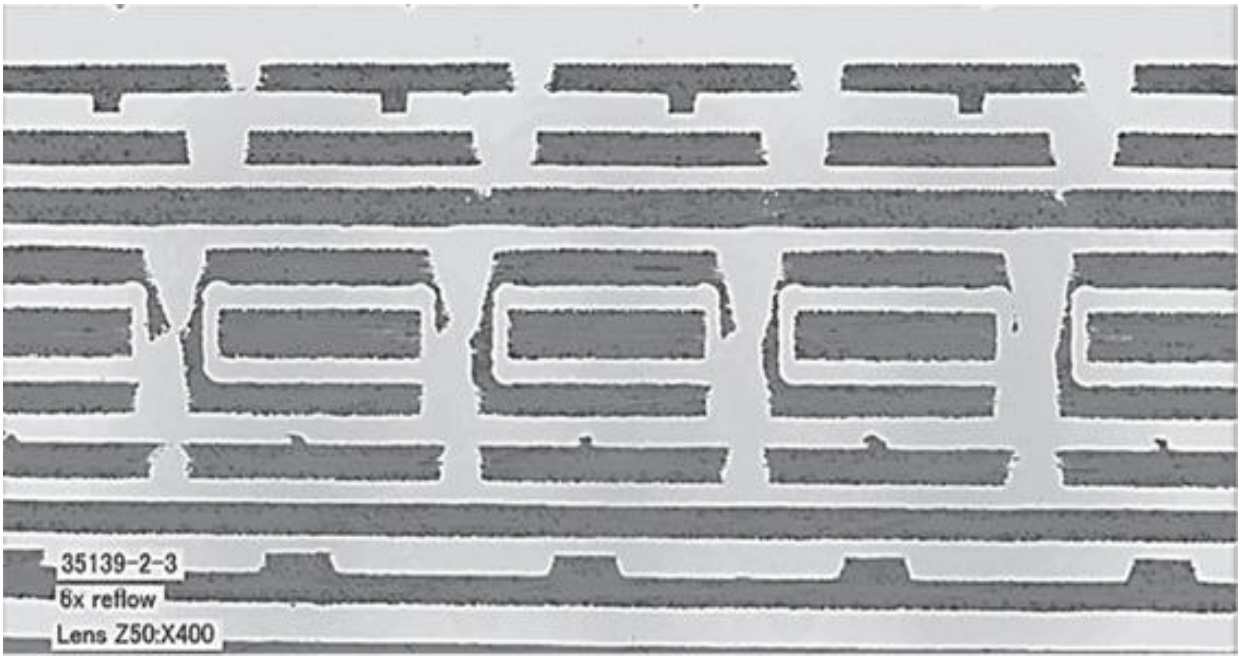

FIGURE 10.31 3070 and 3313 Glass fabrics.

In PCBs for devices such as servers, storage and telecommunications infrastructure equipment, 1080 and 106 glass cloth styles have been common for a long time, with styles such as 1086 and 1067 also now common and growing rapidly. Styles such as 1037, 1035, and even 1027 are beginning to be used in more applications as well. Some of these glass styles are commonly “expanded” or “spread,” where the filaments in a yarn are spread out after the weaving process. This results in a more uniform distribution of resin and glass in the laminate or prepreg material. Figure 10.32 illustrates expanding and spreading of the yarns and resulting glass fabrics. Initially such fabrics were used for laser drilling applications where microvias were part of the PCB design. Since resin will be laser ablated much faster than the glass, the more uniform distribution of resin and glass resulted in more uniform microvia quality. In fabrics with very glass-rich areas and large spaces between the yarns, the resulting dielectric would have very resin-rich areas and very glass-rich areas. In the glass rich areas, greater laser energy is required compared to the resin-rich

areas. At a given laser drilling setting, a glass-rich area might not be ablated sufficiently, while a resin-rich area may be over-ablated. The left photo in Fig. 10.33 shows a glass-rich area insufficiently ablated, as you can see part of a glass yarn still remaining over the innerlayer copper surface. The same laser setting was able to ablate to the inneralyer copper surface when a spread glass cloth was used, as shown in the picture on the right. This is also discussed in Chap. 25 on High Density Interconnection (HDI). In addition, expanding or spreading can also result in improved resin-to-glass wetting for CAF resistance, allow for better thickness control and dimensional stability, and also improve signal integrity. These topics will be discussed further in Chap. 14.

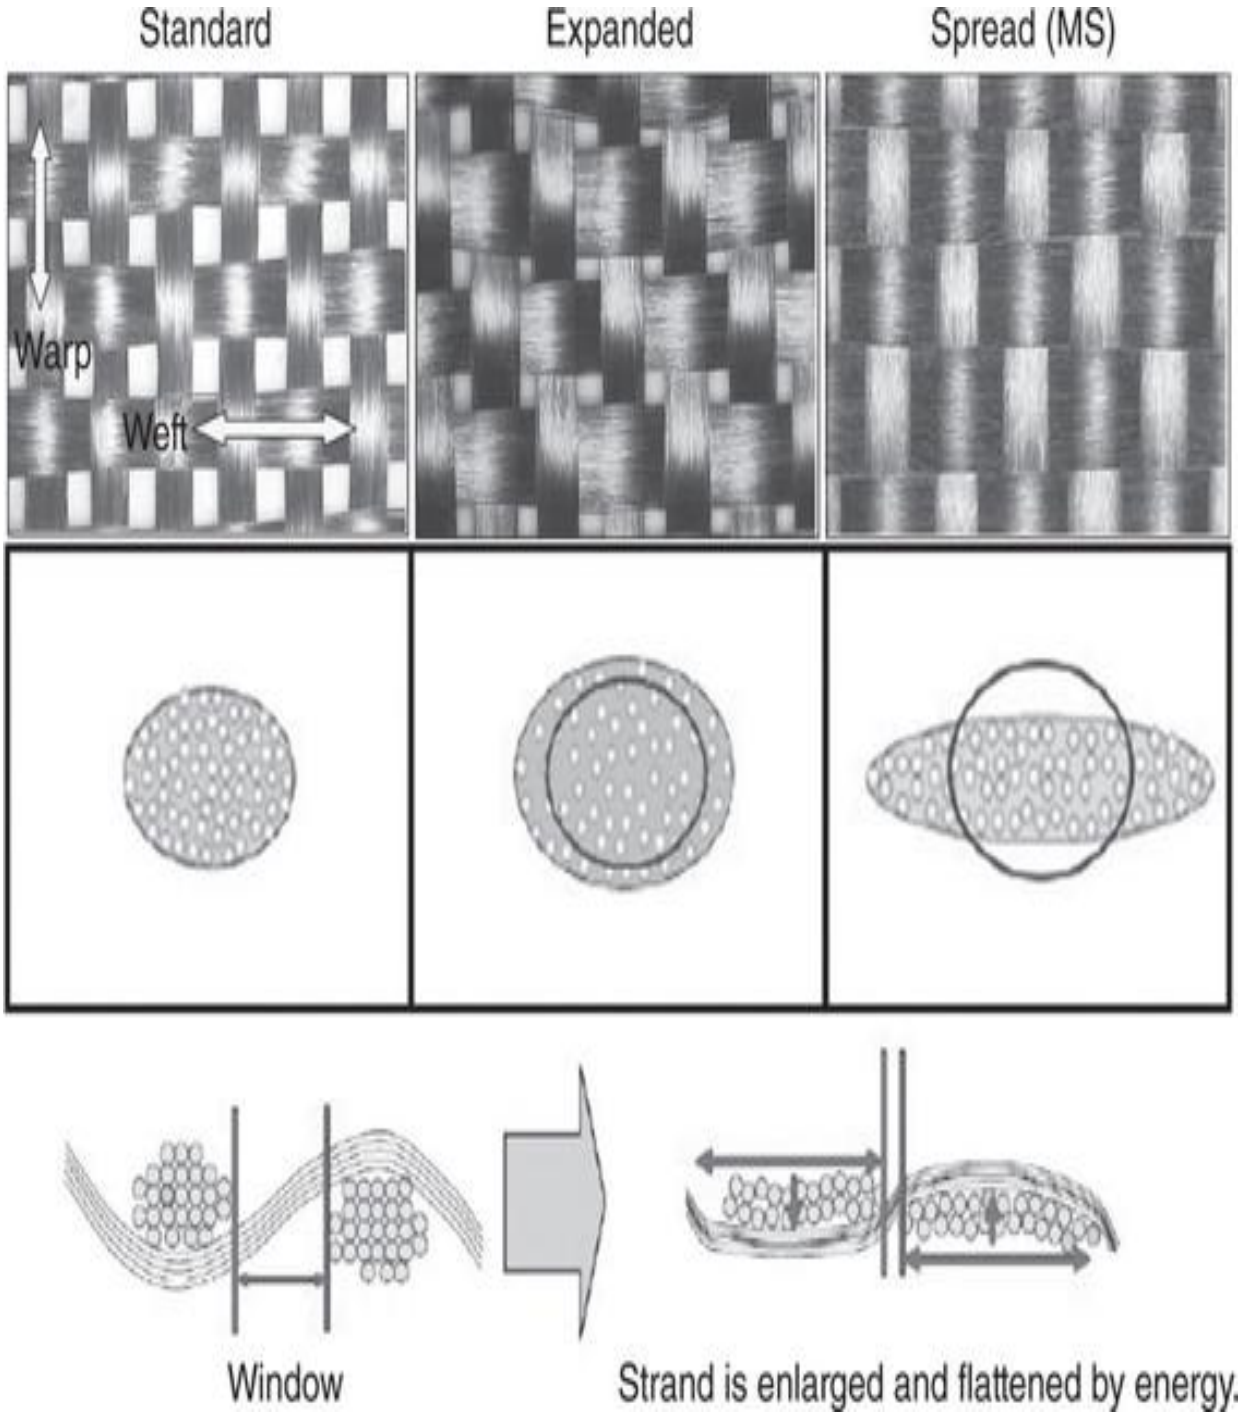

FIGURE 10.32 2116 and 1652 Glass fabrics.

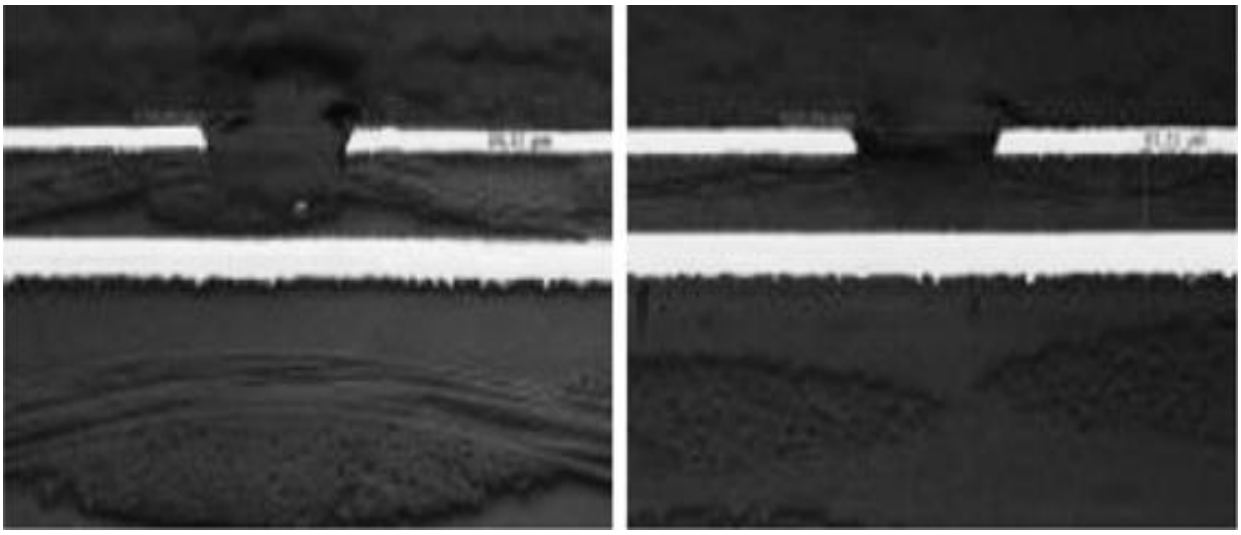

FIGURE 10.33 1506 and 7628 Glass fabrics.

During the manufacture of the filaments and woven fabrics, a variety of surface finishes may be applied to the glass in order to improve manufacturability and to help prevent abrasion, static, and to aid in holding the filaments together. The most important of these surface finishes to the laminate and printed circuit manufacturer is the coupling agent applied to the finished fabric. The coupling agent, typically an organosilane compound, aids in the wetting of and adhesion to the resin applied to the glass. It is important for the reliability of the finished circuit board that this coupling agent improves the resin to glass adhesion during both the circuit manufacturing process, for example, in mechanical drilling, as well as during the actual end use environment of the circuit. The coupling agent also plays a role in long term CAF resistance, which is discussed in Chap. 14. A variety of these compounds are commercially available, with the specific choice primarily driven by the type of resin to be applied to the fiberglass cloth. Figure 10.34 provides examples of silane coupling agents.

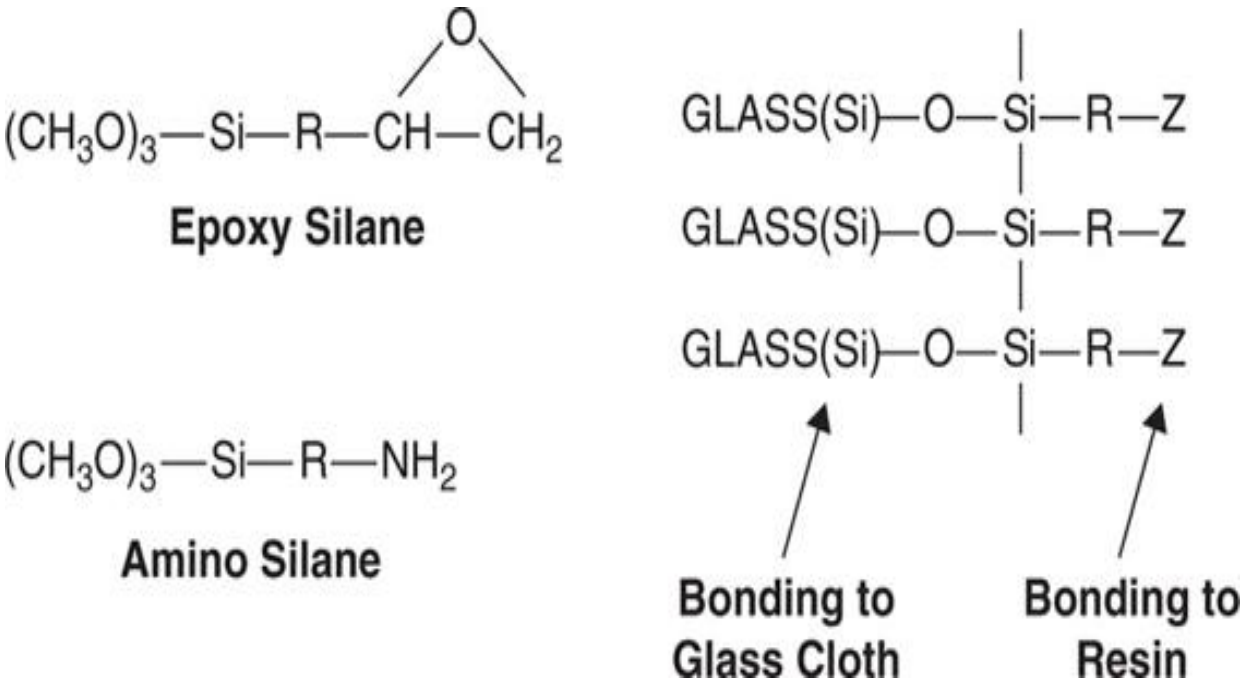

FIGURE 10.34 Examples of silane coupling agents.

10.5.4 Other Reinforcements

While woven fiberglass cloth makes up the overwhelming majority of the reinforcements used for printed circuit base materials, there are other types that can be used exclusively or in combination with woven glass fabric. These other reinforcements include the following.

10.5.4.1 Glass Matte. As opposed to woven cloths, glass matte reinforcement exhibits a more random orientation. Chopped strand matte consists of fiberglass strands that have been chopped into 1- to 2-in lengths and distributed evenly. Continuous strand matte, as the name implies, consists of continuous strands of fiberglass in a random, spiral orientation. Glass matte is used in the core of CEM-3, which is used in relatively unsophisticated products.

10.5.4.2 Aramid Fiber. As opposed to the inorganic chemistry of fiberglass reinforcements, aramid fibers consist

of aromatic polyamide organic compounds, and therefore exhibit different properties. The unique properties of aramid fibers can offer advantages in specific high-performance printed circuits and laminate based multichip modules (MCM-L). For example, aramid fiber reinforced materials are sometimes used in microvia applications since they are easily ablated by plasma or laser. Other interesting properties of aramid fibers are their low weight, high strength, and negative coefficient of thermal expansion (CTE) in the axial direction. When combined with the resin system, the resulting composite can offer reduced overall CTEs in the X-Y plane compared to conventional materials.

10.5.4.3 Paper. Cellulose-based papers can also be used as a reinforcement for base materials. Paper-based reinforcements are also used in conjunction with other reinforcements such as woven glass, and these materials can also allow punching of through holes rather than drilling. This makes them economical in some high-volume, low-technology applications including consumer electronics such as radios, toys, calculators and television games. Paper is used in FR-2, FR-3, and the core of CEM-1.

10.6 CONDUCTIVE MATERIALS

The primary conductive material used in printed circuits is copper foil. However, the trend toward circuit densification and higher operating frequencies has brought about recent developments in copper foil technology as well. In addition, copper foils subsequently plated with other metal alloys are employed to manufacture printed circuits with resistive components buried within a multilayer structure. Copper foil grades are shown in Table 10.7.

TABLE 10.7 Foil Grades from IPC-4562[4]

Grade	Foil Description
1	Standard electrodeposited (STD-Type E)
2	High ductility electrodeposited (HD-Type E)
3	High-temperature elongation electrodeposited (HTE-Type E)
5	As rolled-wrought (AR-Type W)
7	Annealed-wrought (ANN-Type W)
8	As rolled-wrought low-temperature annealable (LTA-Type W)
9	Nickel, standard electrodeposited
10	Electrodeposited low-temperature annealable (LTA-Type E)
11	Electrodeposited annealable (A-Type E)

10.6.1 Electrodeposited Copper Foil

The most common foil used in manufacturing printed circuits is electrodeposited copper foil (ED foil). ED foil is produced through the use of an electrochemical process where copper feed stock or scrap copper wire is first dissolved in a sulfuric acid solution. The purified copper sulfate/sulfuric acid solution is then used to electroplate copper onto a cylindrical drum typically made from stainless steel or titanium. Figure 10.35 illustrates the overall process used to make electrodeposited copper foil. This process results in a copper foil with a relatively smooth, shiny side, and a coarser matte side, as illustrated in Fig. 10.36. The shiny side mirrors the surface of the plating drum while the microscopically rough matte side is formed by the copper grain structure. By controlling the plating solution chemistry, the surface

condition of the plating drum, and the electroplating parameters, the properties of the copper foil can be modified for various usage environments. For example, mechanical properties such as tensile strength and elongation, as well as the surface profile of the matte side, can all be adjusted through control of these process variables. The foil produced in this process is then run through a treatment process. This treatment process typically plates copper nodules that further roughen the surface for adhesion, and also applies other metal barrier layers and antitarnish coatings, as shown in Fig. 10.37. Standard copper foil area weights and thicknesses were shown in Chap. 10, Table 10.6.

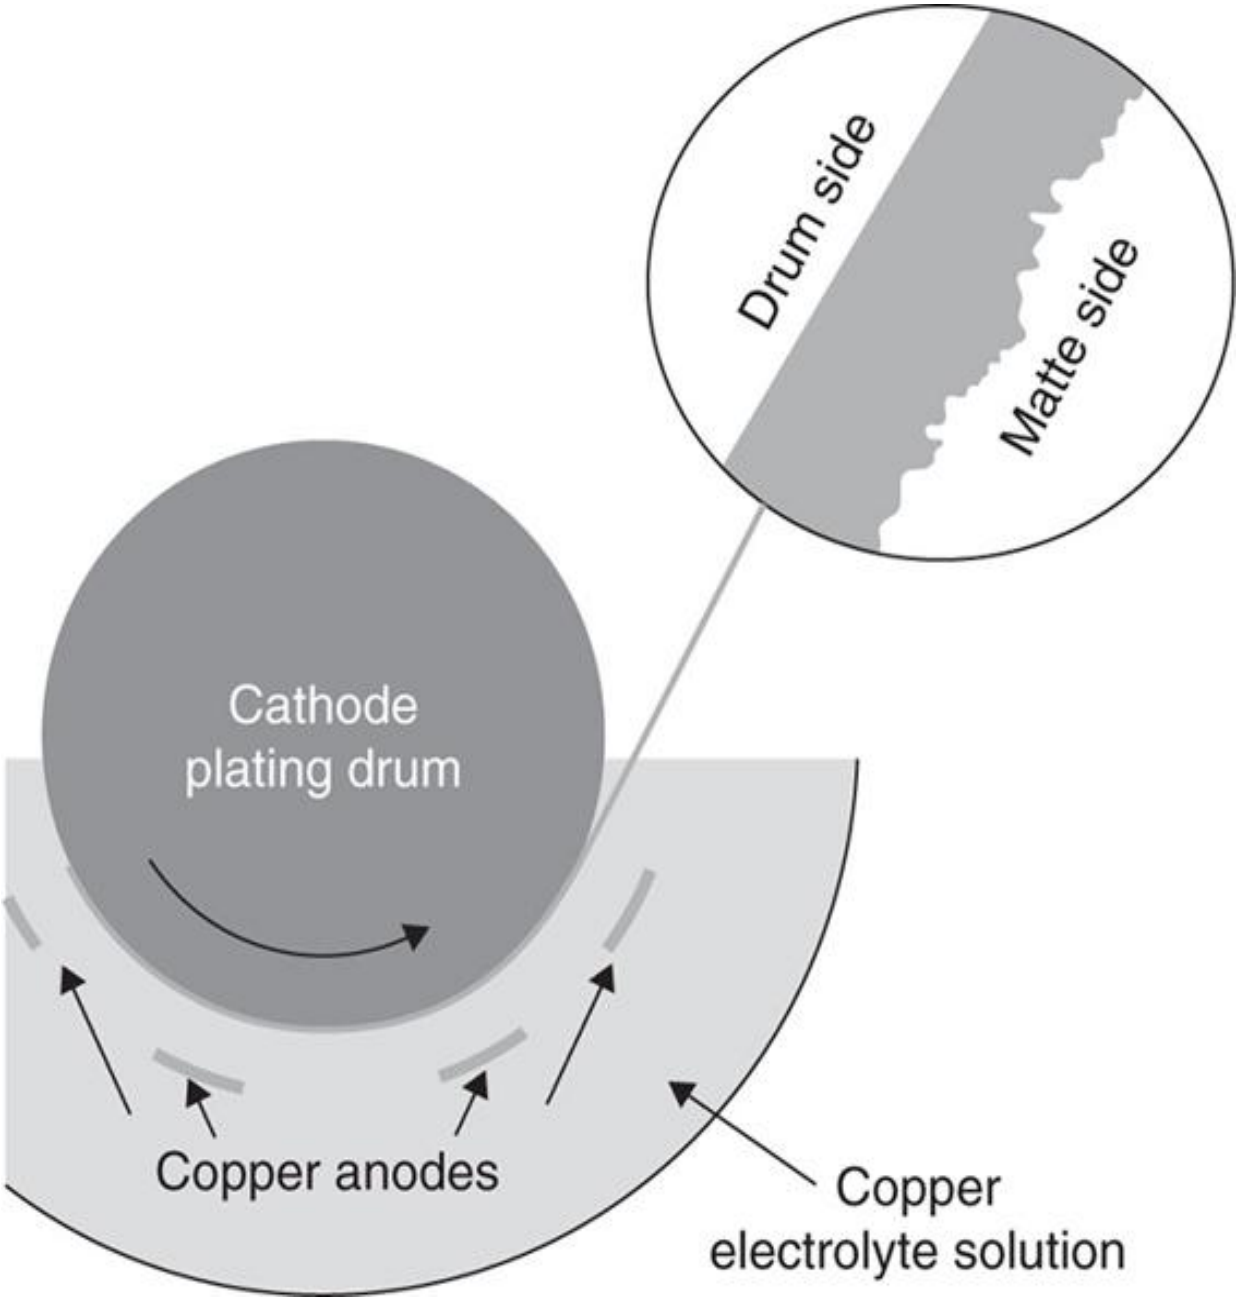

FIGURE 10.36 Electroplating copper foil.

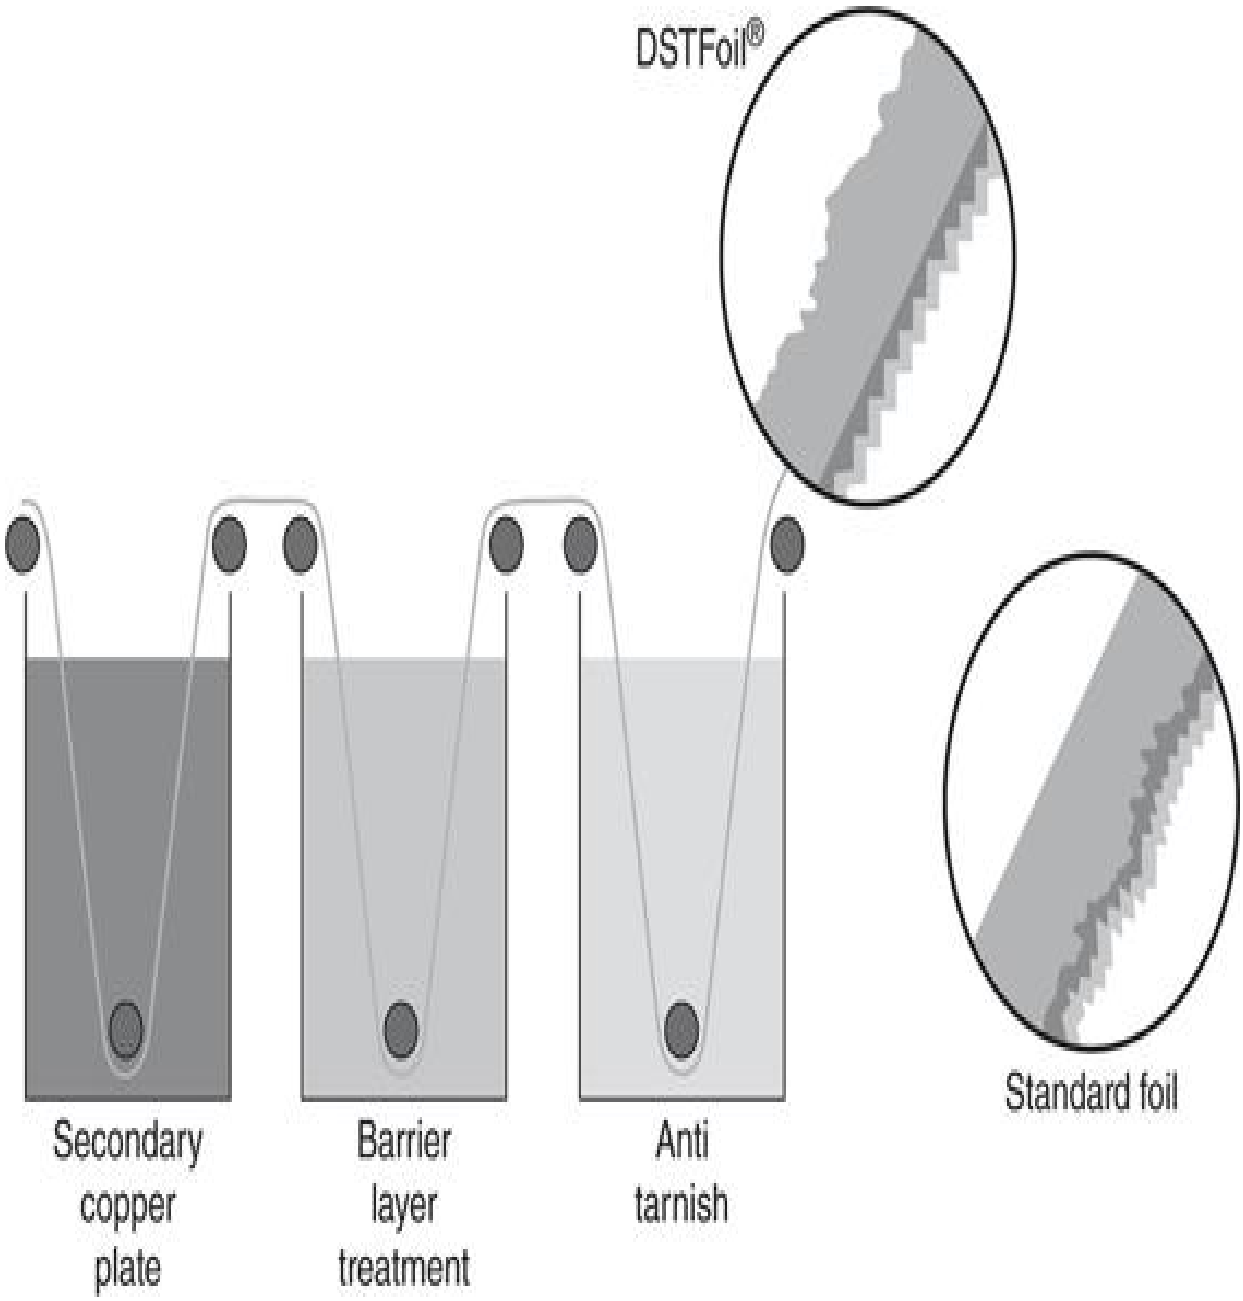

FIGURE 10.37 Treating of copper foil.

The foils most commonly used in printed circuit manufacturing are grade 1 and grade 3 foils. Unlike grade 1 foil, grade 3 foil must meet specific elongation requirements at elevated temperatures (180°C). Grade 3 foil, also commonly referred to as high-temperature elongation, or simply “HTE” foil, is widely used in base laminates used to

manufacture multilayer printed circuit boards. The increased ductility at elevated temperatures provides resistance to copper foil cracks when the multilayer circuit is thermally stressed and expands in the *z* axis. Changes to the plating bath are made to alter the grain structure of HTE foil. This results in different mechanical properties. Tables 10.8 and 10.9 show the tensile strength and ductility requirements for standard grade 1 copper foil and high-temperature elongation grade 3 copper foil. These requirements come from IPC-4562 “Metal Foil for Printed Board Applications,” which lists requirements for the other grades as well. It is recommended to check the latest revision of these specifications to confirm the current requirements.

kpsi	15	20	20
MPa	103	138	138
Elongation % @ 180°C	2	2	3

The surface profile of the copper foil is also important in printed circuit manufacturing. On one hand, a relatively rough surface profile aids in the bond strength of the foil to the resin system. On the other hand, a rough profile may require longer etching times, which impact productivity and the geometry of the etched features. With longer etching times, there is an increased propensity to form trapezoidal circuit traces since there is more time for lateral etching of the conductor. This has obvious implications for manufacturing fine line circuits in high yield and controlling impedance properties. In addition, as circuit operating frequencies increase, roughness of the copper foil will impact signal attenuation. At higher frequencies, more of the electrical signal is conducted near the surface of the conductor. A rougher profile results in a longer path for the signal to travel, which also results in greater attenuation, or loss. As a result, high-performance materials for high-speed circuits require foils with low profiles that have adequate adhesion to the high-performance resin systems. This is the subject of much research and development and will be discussed further in Chap. 14.

Low profile and very low profile characteristics are included in the IPC-4562 specification and are summarized in Table 10.10. Figures 10.38 and 10.39 give an example of profile differences between these foils, as defined in this specification. However, there have been a number of new copper foils developed and now in volume use that have even lower profiles. New ranges for these lower profiles have not yet been established in this specification, though the committee responsible for this specification is working on this. As such, it is recommended to check the latest revision of this specification for any updates. In the meantime, some suppliers will call out the foil as VLP along with the average roughness, that is, a foil with an average of 2 µm roughness would be called VLP-2. This is becoming more and more important as the roughness has a significant effect on signal loss at high frequencies.

TABLE 10.10 Foil Profile Criteria

Foil Profile Type	Max. Foil Profile (µm)	Max. Foil Profile (µin)
S – Standard	N/A	N/A
L – Low profile	10.2	400
V – Very low profile	5.1	200
X – No treatment or roughness	N/A	N/A

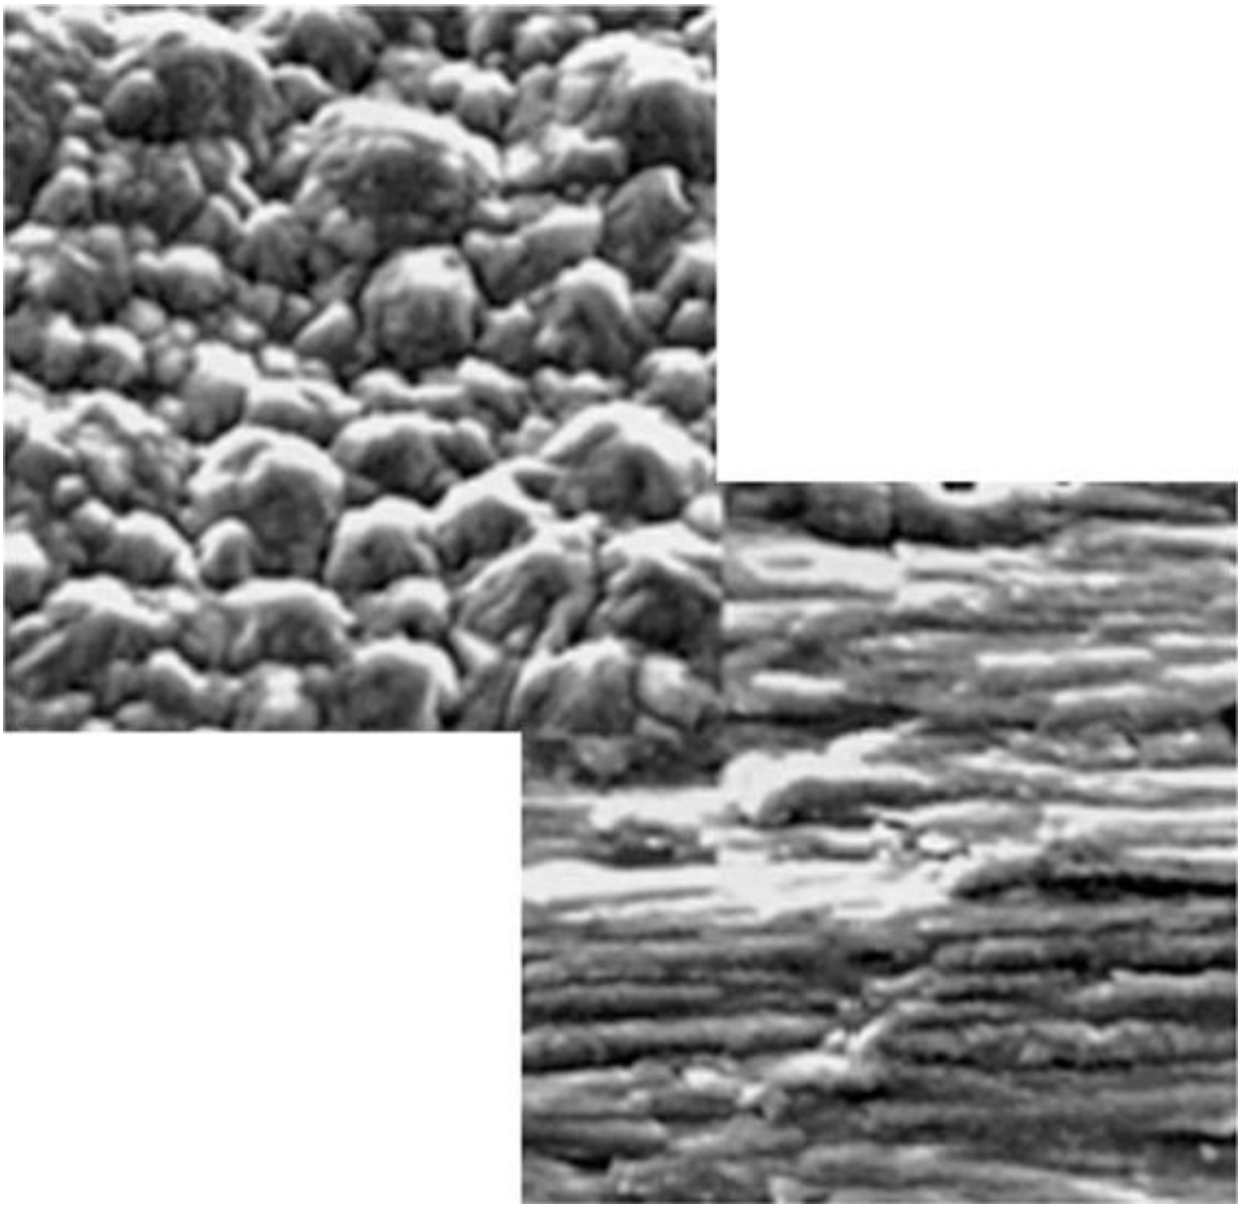

FIGURE 10.38 Cross section and matte side of standard grade 1 foil.

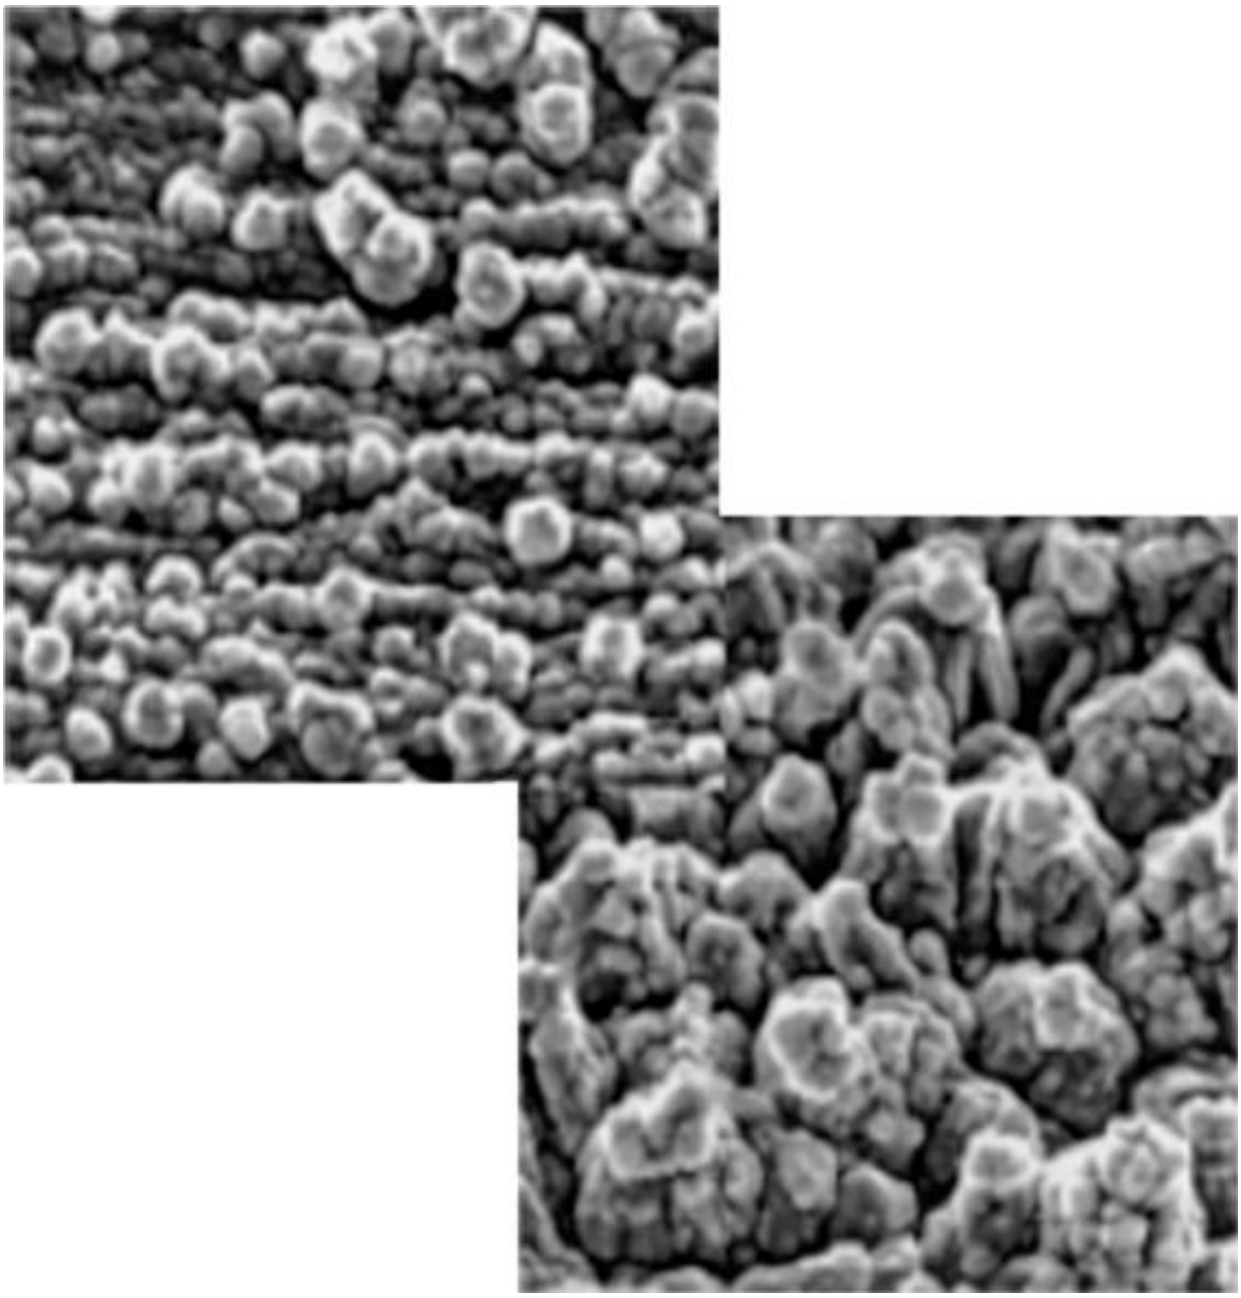

FIGURE 10.39 Cross section and matte side of low profile grade 1 foil.

Subsequent to the manufacturing of the base copper foil, a variety of surface treatments are typically applied, and these too will vary depending on the usage environments. These treatments fall into four categories.

10.6.1.1 Bonding Treatments or Nodularization. This treatment increases the surface area of the foil by plating

copper or copper-oxide nodules to the surface of the foil. The increased surface area results in increased foil to resin bond strengths. The thickness of this treatment is relatively small, but can be tailored for adhesion to high performance resin systems. The matte side images in Figs. 10.40 and 10.41 include these nodules.

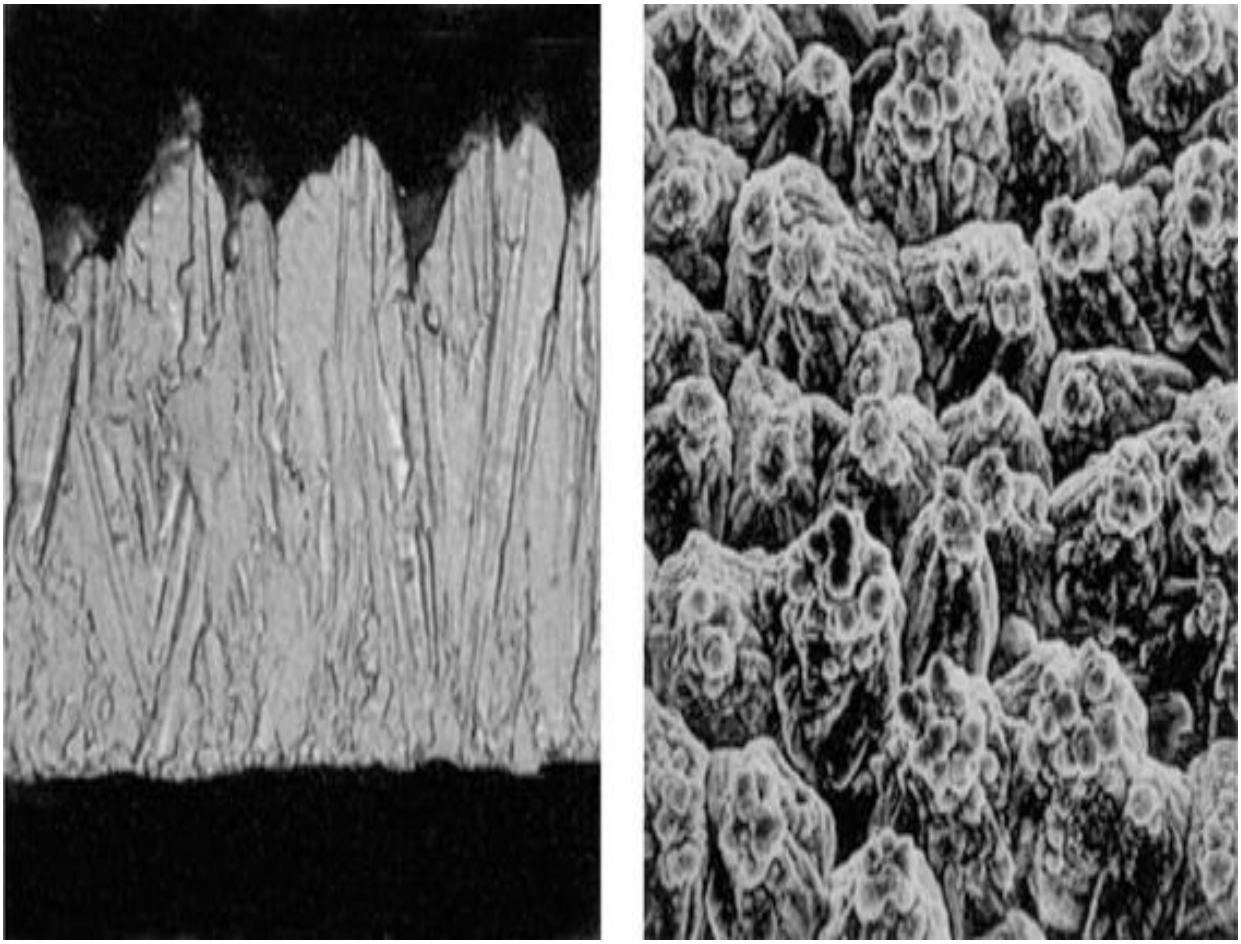

FIGURE 10.40 External sides for RTF (upper photo) and standard (lower photo) foils.

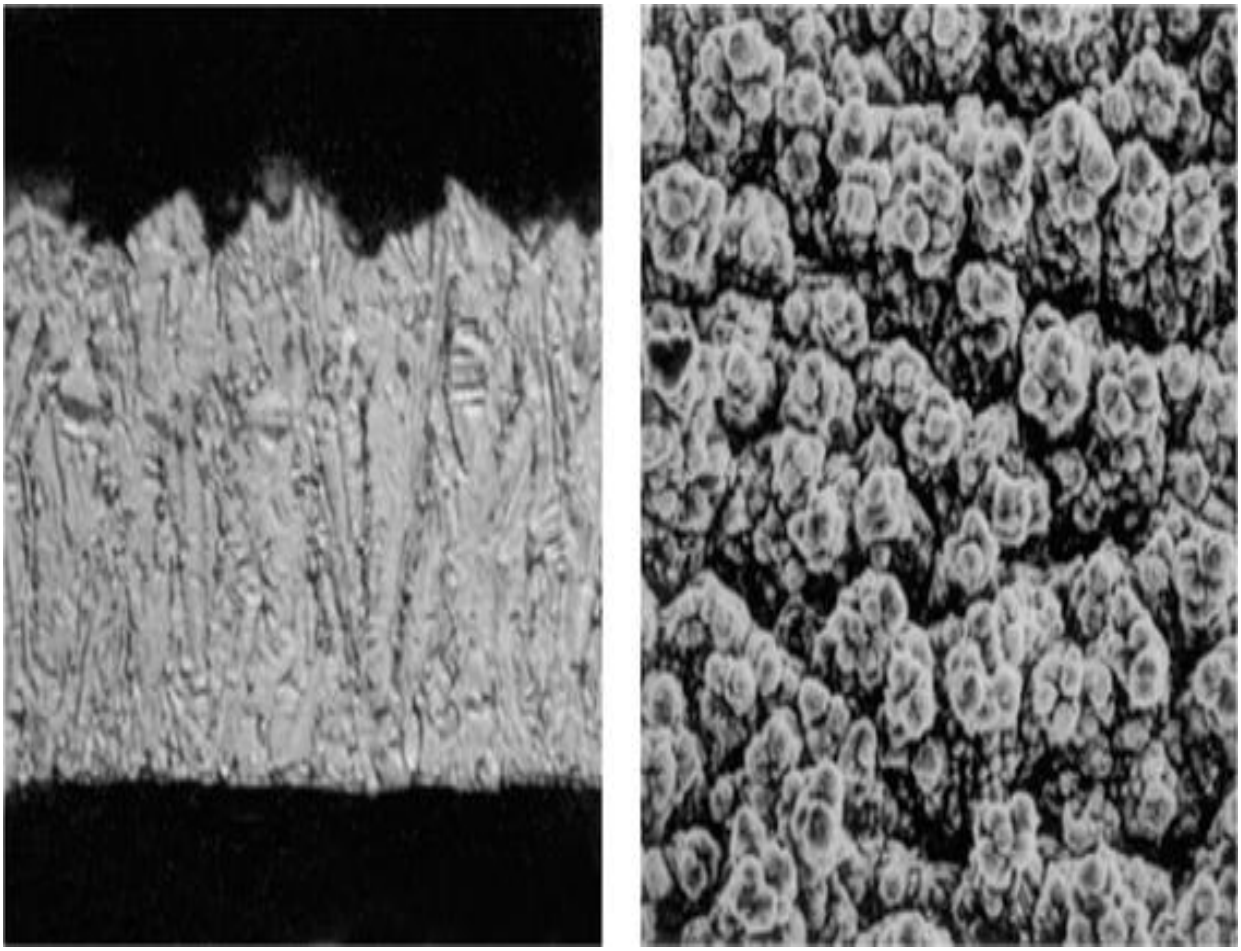

FIGURE 10.41 Sides bonded to laminate for RTF (upper photo) and standard foils (lower photo).

10.6.1.2 Thermal Barriers. A coating of zinc, nickel, or brass is usually applied over the nodules. This coating can prevent thermal or chemical degradation of the foil to resin bond during manufacture of the laminate, the printed circuit, and the circuit assembly. These coatings typically measure several hundred angstroms in thickness and vary in color due to the specific metal-alloy used, although most treatments are brown, gray, or a yellow mustard color. Low levels of arsenic have been used in foil treatments for a long time, though in recent times the use of arsenic-free foils is growing.

10.6.1.3 Passivation and Antioxidant Coatings. In contrast to the other coatings, these treatments are virtually always applied to both sides of the foil. Although many of these treatments have been chromium based, organic coatings can also be utilized. The primary purpose of these treatments is to prevent oxidation of the copper foil during storage and lamination. These coatings are usually less than 100 angstroms thick and are typically removed by the cleaning, etching or scrubbing processes normally used at the start of printed circuit manufacturing processes.

10.6.1.4 Coupling Agents. The use of coupling agents, primarily silanes like those used to promote fiberglass to resin adhesion, can also be used on copper foils. These coupling agents can improve the chemical bond between the foil and the resin system and can also be used to help prevent oxidation or contamination.

10.6.2 Drum Side Treated Foils or Reverse Treated Foils

Drum side treated (DSTFoil®) or reverse treated foil (RTF) is also an electrodeposited copper foil, but the treatments are coated onto the smooth drum side of the foil rather than the matte side, as with conventional electrodeposited foil (see Figs. 10.36 and 10.37). This results in a very low profile surface bonded to the laminate, with the rough matte side facing out. The low surface profile against the laminate aids in the production of fine circuit features on the innerlayer, while the matte surface can aid in photoresist adhesion. The low profile against the laminate can also improve electrical performance at high frequencies. In addition, in very thin laminates the low surface profile can aid in achieving consistent dielectric thickness with a reduced concern of inadequate dielectric separation between the corresponding

points on the tooth profile. These benefits come at the price of a slight reduction in peel strength.

10.6.3 Wrought Annealed Copper Foils

Wrought annealed foil is typically used in flexible circuit manufacturing because of its superior ductility. In contrast to an electrodeposition process, wrought annealed foil begins with a slab or ingot of copper that is worked through a series of rollers in conjunction with heat cycles to obtain the desired thickness and mechanical properties. The resulting grain structure of wrought annealed copper foil, which is very random compared to the columnar or fine-grain structure of electrodeposited foil, is a significant contributor to the differences in mechanical properties. In addition, wrought annealed foil consists of two very low profile sides, so the treatment steps account for any surface roughness. The tensile and elongation requirements for grade 7 wrought annealed copper are provided in Table 10.11. The requirements for other wrought foils are included in IPC-4562, and as always, the latest revision of these specifications should be checked to validate current requirements.

TABLE 10.11 Tensile and Elongation Properties of Wrought Annealed Foil

Property	½ Oz	1 Oz	2 Oz
Tensile strength @ 23°C:			
kpsi	15	20	25
MPa	103	138	172
Fatigue ductility % @ 23°C	20	35	65
Elongation % @ 23°C	5	10	20
Tensile strength @ 180°C:			
kpsi	10	13	18
MPa	69	90	124
Elongation % @ 180°C	3	5	10

10.6.4 Copper Foil Purity and Resistivity

IPC-4562 Metal Foil for Printed Wiring Applications also specifies the purity and resistivity of electrodeposited and wrought copper foils. Electrodeposited copper foils without treatment shall have a minimum purity of 99.8 percent, with any silver counted as copper. The value for wrought foils is 99.9 percent. Table 10.12 provides the resistivity requirements for electrodeposited foil. The maximum resistivity requirements for wrought copper range from 0.155 to 0.160 Ωg/m^2, depending on the weight.

TABLE 10.12 Maximum Resistivity of Deposited Foil

Weight Designator	Common Industry Terminology	Maximum Resistivity
E	5 µm	0.181 Ωg/m^2
Q	9 µm	0.171 Ωg/m^2
T	12 µm	0.170 Ωg/m^2
H	½ oz	0.166 Ωg/m^2
M	¾ oz	0.164 Ωg/m^2
1 oz and over (305 g/m^2)	1 oz...	0.162 Ωg/m^2

10.6.5 Other Foil Types

10.6.5.1 Double Treated Copper Foil. As discussed in the preceding text, the foil surface that is bonded to the base laminate is treated with coatings designed to improve foil to resin bond strength and reliability. In double treated foils, these coatings are also applied to the foil surface that forms the outside laminate surface. It is also possible to have a “reverse treated” double treat foil, meaning that the smooth surface is bonded to the laminate with the matte surface facing out, while both sides have been treated.

The advantage of double treat foil is that it eliminates the oxide or other surface preparation process typically used to prepare the innerlayer circuitry for multilayer lamination. However, no abrasion of this double treat coating can be tolerated, and removal of any surface contamination becomes difficult. This also makes double treated foil more sensitive to handling practices in the circuit manufacturing process.

10.6.5.2 Resistive Foils. Other treatments can also be applied to the base foil for use in manufacturing innerlayer circuits with *buried resistors*. This technology can enable the creation of resistors on internal layers of a multilayer circuit, with removal of many of the resistors commonly assembled on the outside of the multilayer circuit. This can improve board reliability and free up space on the outside of the board for active components. These foils typically use a resistive metal alloy coated onto the base foil. The laminate made with this foil can then be sequentially imaged and etched to produce the desired circuit pattern along with resistive components.

CHAPTER 11

PROPERTIES OF BASE MATERIALS

Edward Kelley
Douglas Trobough
Isola Group, Chandler, Arizona

11.1 INTRODUCTION

A variety of base material properties are of interest to the printed circuit manufacturer, assembler, and original equipment manufacturer (OEM). These include thermal, physical, mechanical, and electrical properties. This chapter introduces a few of the more important properties and also provides some comparisons between material types. Most of the test methods used to evaluate these properties can be found in the IPC Test Methods Manual, IPC-TM-650, which includes test methods for many other properties as well.[1]

11.2 THERMAL, PHYSICAL, AND MECHANICAL PROPERTIES

Historically, the properties that received the greatest amount of attention were the glass transition temperature, T_g, and the coefficients of thermal expansion (CTEs), particularly in the *z* axis. With the advent of lead-free assembly processes, other properties have increased in importance as well. The most notable is the decomposition temperature, T_d. These properties were described in more detail in Chap. 10, and will be discussed again in Chap. 13, which focuses on the impact of lead-free assembly on base materials. However, some additional information and examples of the test data are included here, as well as comparisons of some common material types.

11.2.1 Thermomechanical Analysis T_g and CTEs

Materials undergo changes in physical dimensions in response to changes in temperature. The rates of expansion of fiberglass cloth reinforced materials differ in the respective axes of the material due to the directionality of the reinforcement. The length and width of the laminate, or printed circuit, are termed the *x*/*y* plane, whereas the axis perpendicular to this plane is the *z* axis.

Thermal expansion can be measured by thermomechanical analysis (TMA). TMA uses a device that measures a dimension of a sample versus temperature. Depending upon the orientation of the sample in the device, either the *x*/*y* CTE or the *z* axis CTE can be measured.

Figure 11.1 provides an example of a TMA scan on a high-T_g, filled FR-4 material designed to be compatible with most lead-free assembly applications. The T_g is determined by extrapolating the linear portions of the expansion curve to

the point where they intersect. In this case, a T_g of 154.45°C is measured. The z-axis CTE values are typically calculated both pre-T_g, also called “alpha 1” (α1), and post-T_g, also called “alpha 2” (α2). In this example, the pre-T_g CTE is measured at just over 45 ppm/°C, and the post-T_g CTE is measured at just over 219 ppm/°C. The total expansion from 50 to 250°C is also shown as a percent expansion value at 2.58 percent.

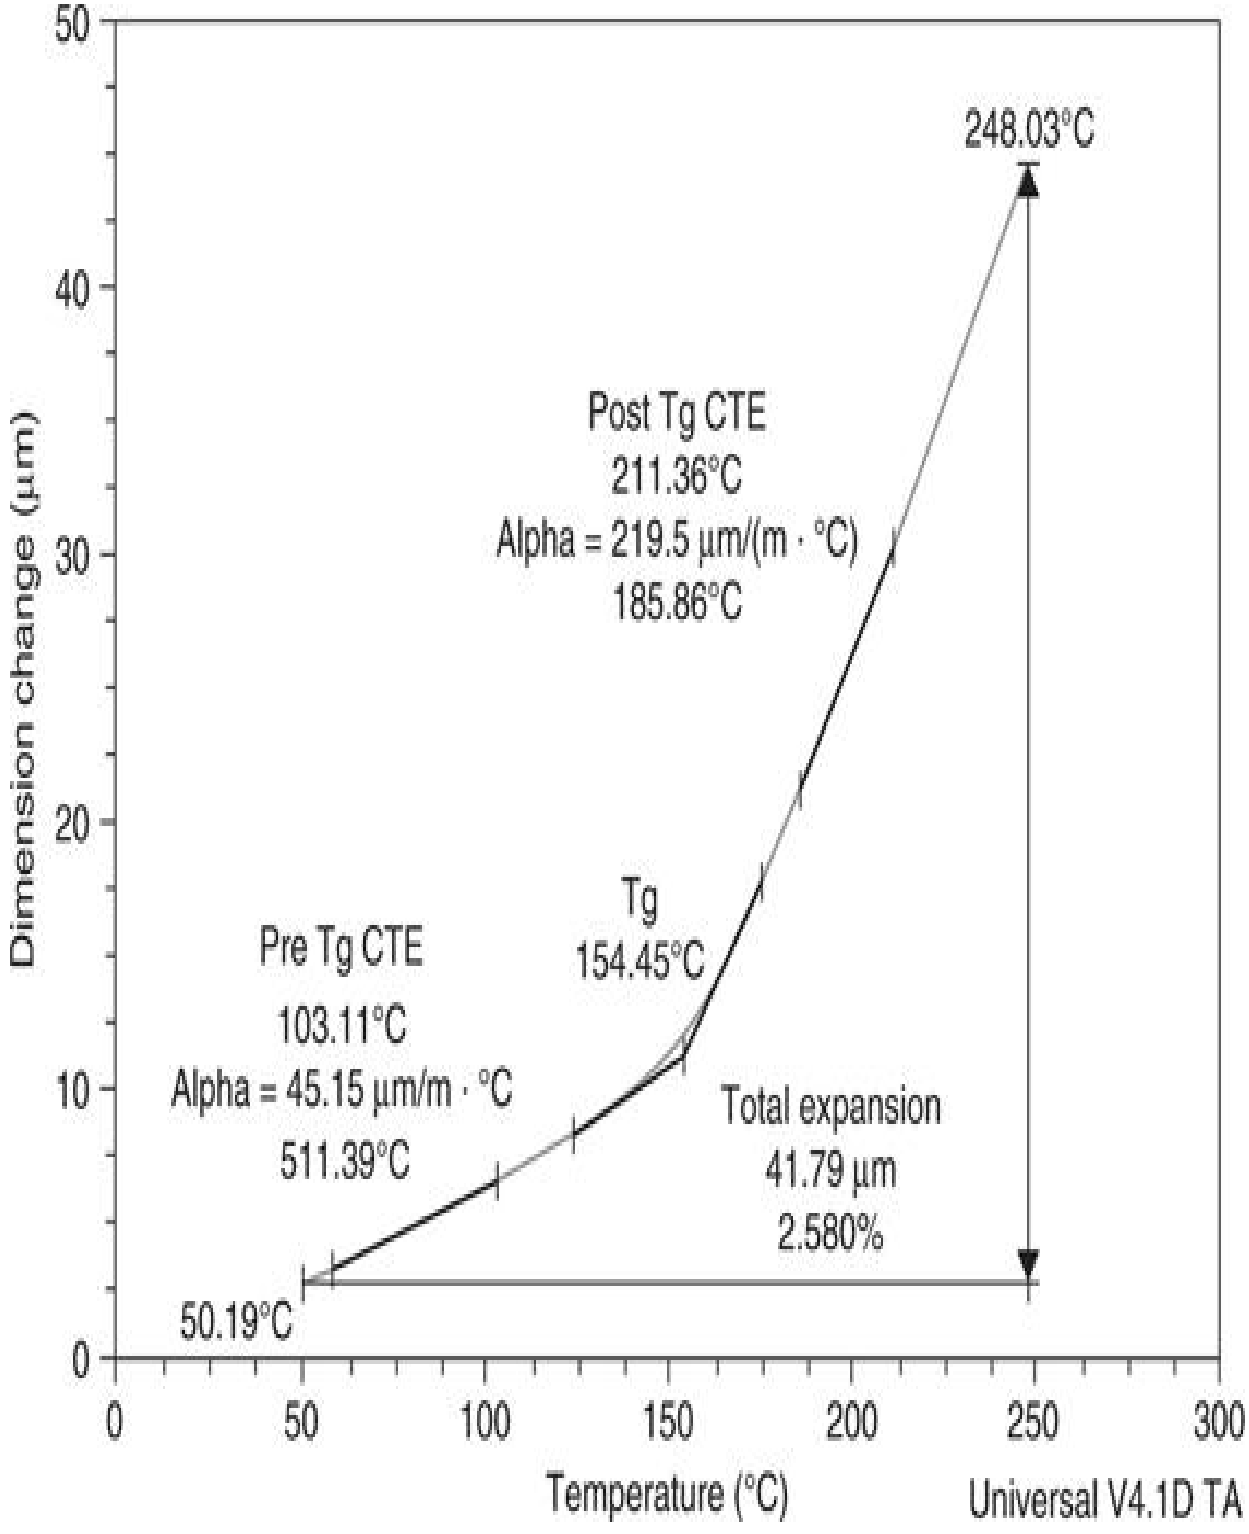

FIGURE 11.1 TMA scan illustrating T_g and CTE determination.

Thermal expansion in the *z* axis can significantly affect the reliability of printed circuits. Since plated through holes run

through the *z* axis of the printed circuit, thermal expansion and contraction in the base materials causes strain and can result in plastic deformation of the copper plated in the hole, and can also deform the copper pads on the surface of the printed circuit. Repeated thermal cycling can ultimately cause cracks in the plated copper, and several test methods have been developed to assess the reliability of printed circuits by exposing them to accelerated thermal cycling. Other things being equal, lower levels of thermal expansion in the base material will improve reliability of the plated through holes.

Thermal expansion in the *x*/*y* axes is of more importance when discussing the attachment of components to the printed circuit. This is of particular importance when chip scale packages (CSPs) and direct chip attach components are used because the difference in thermal expansion between the printed circuit board and the component can compromise the reliability of the bond between them as they undergo thermal cycles. While not generally a problem, the higher temperatures of lead free assembly have raised a concern about constructing a multilayer PCB with layers of dielectrics that have significantly different *x*/*y* CTE properties. The concern is that the dissimilar *x*/*y* CTE properties, if large enough, will result in enough stress to cause a separation or delamination between these layers. This may depend somewhat on the specific type of resin and glass cloth used. Furthermore, hybrid constructions, meaning PCBs that utilize different base material types in the same PCB, should be analyzed very carefully, as different base material types can have different CTE values even with a given fiberglass cloth style and resin content.

11.2.2 CTE Values

CTE values of some common materials at approximately 42 percent resin content are shown in Table 11.1.

TABLE 11.1 T_d and CTE Values at 42 Percent Resin Content of Some Common Base Materials

Material	T_g (°C)	Decomposition Temp., T_d (5% Wt. Loss), °C	Z-Axis Expansion (% from 50–260°C)	X/Y CTE (ppm/°C)
Standard T_g FR-4	140	320	4.2	15–17
Filled mid-T_g FR-4	150	330	3.3	13–14
Halogen free, filled mid-T_g FR-4	155	390	3.1	13–14
High-T_g FR-4	170	300	3.5	13–14
High-T_g/T_d FR-4	175	340	3.5	13–14
Filled high-T_g/T_d FR-4	180	340	2.8	13–14
Halogen-free high-T_g/T_d FR-4	180	395	2.9	13–14
Mid-loss epoxy	200	370	3.0	13–14
BT/Epoxy blend	200	350	3.4	13–14
BT/Epoxy blend-low Dk glass	200	350	3.4	11–13
Low loss epoxy blend	180	360	2.8	15–17
Low loss epoxy blend-low Dk glass	180	360	2.8	14–16
Very low loss	200	360	2.8	12–13
Halogen free very low loss	200	390	2.9	15–17
Ultra low loss	200	390	2.8	12–13
Polyimide	260	416	1.8	12–14

11.2.2.1 Controlling Thermal Expansion. The rate of thermal expansion is a function of the components used in the base material and their relative concentrations. The resin system will have a relatively high coefficient of thermal expansion compared to fiberglass cloth or other types of inorganic reinforcements.

In controlling *z*-axis expansion, the key factors to consider are the choice of resin system, the resin system T_g, and the resin content of the base materials. Fillers in the resin system, in addition to the fiberglass cloth, can also be used to lower the CTE of the material. Table 11.1 compares the thermal expansion of several commercially available base materials. These values can vary significantly based on the exact resin content of the material or PCB tested. In multilayer PCBs, the amount of copper in the sample will also have a significant impact as the *z*-axis expansion of copper is very low compared to the resin system.

Note the general difference in CTE values as T_g increases. A higher T_g delays the onset of the more rapid post-T_g rate of expansion. Also note that the filled materials have lower levels of *z*-axis expansion in comparison to equivalent unfilled materials.

11.2.3 T_g Determination by Other Methods

Besides TMA, two other methods are commonly used to measure T_g. These are differential scanning calorimetry (DSC) and dynamic mechanical analysis (DMA). DSC measures heat flow versus temperature rather than dimensional changes as measured by TMA. The heat absorbed or given off will change as the temperature increases through the T_g of the resin system. T_g measured by DSC is typically higher than measurements by TMA. DMA

measures the modulus of the material versus temperature and also typically results in higher measured values of T_g.

As more complex resin systems are developed, and as more blends of resins are used, it becomes more difficult to measure T_g by TMA. For example, if two resins are used that have somewhat different TMA T_g's, the combination of the two resins can make it difficult to get a clear transition in expansion rates. For these materials, DSC is the preferred technique for measuring T_g. Figures 11.2 and 11.3 provide examples of DSC and DMA scans, respectively, and the resulting measurement of T_g.

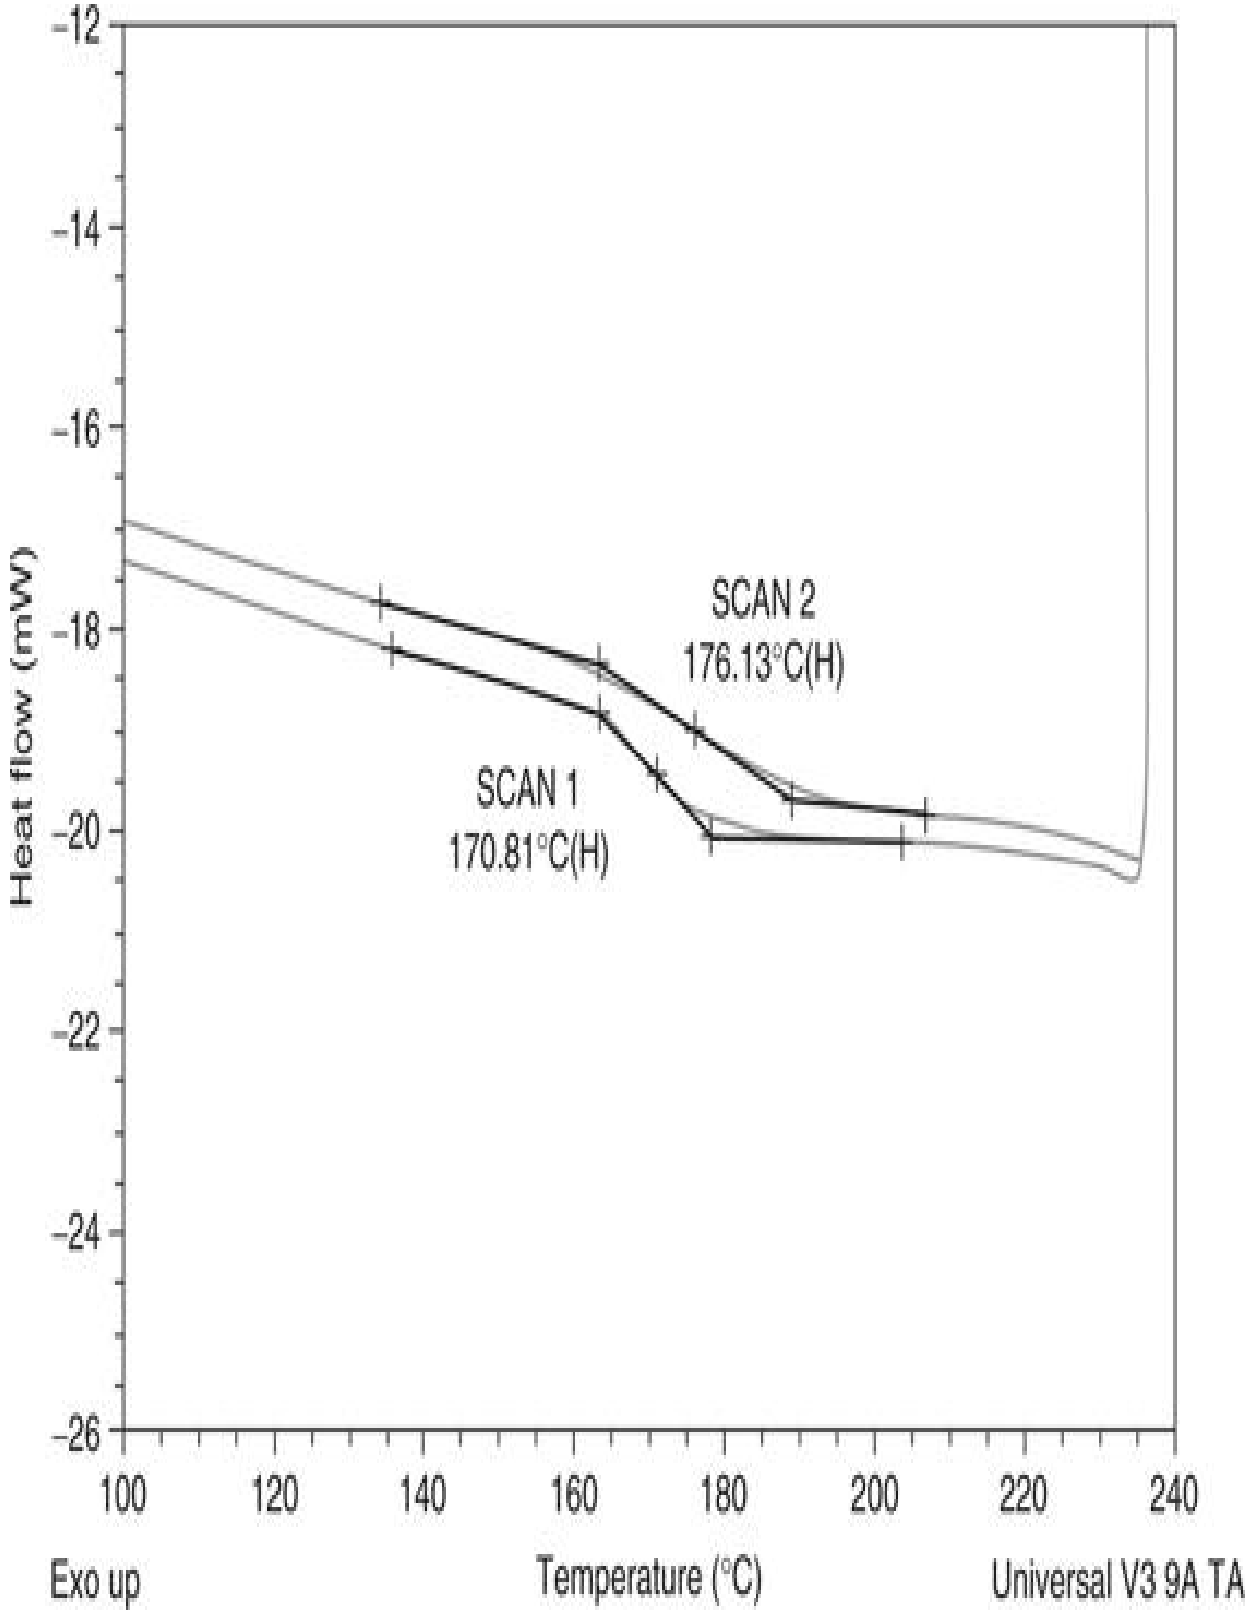

FIGURE 11.2 Measurements of T_g by DSC.

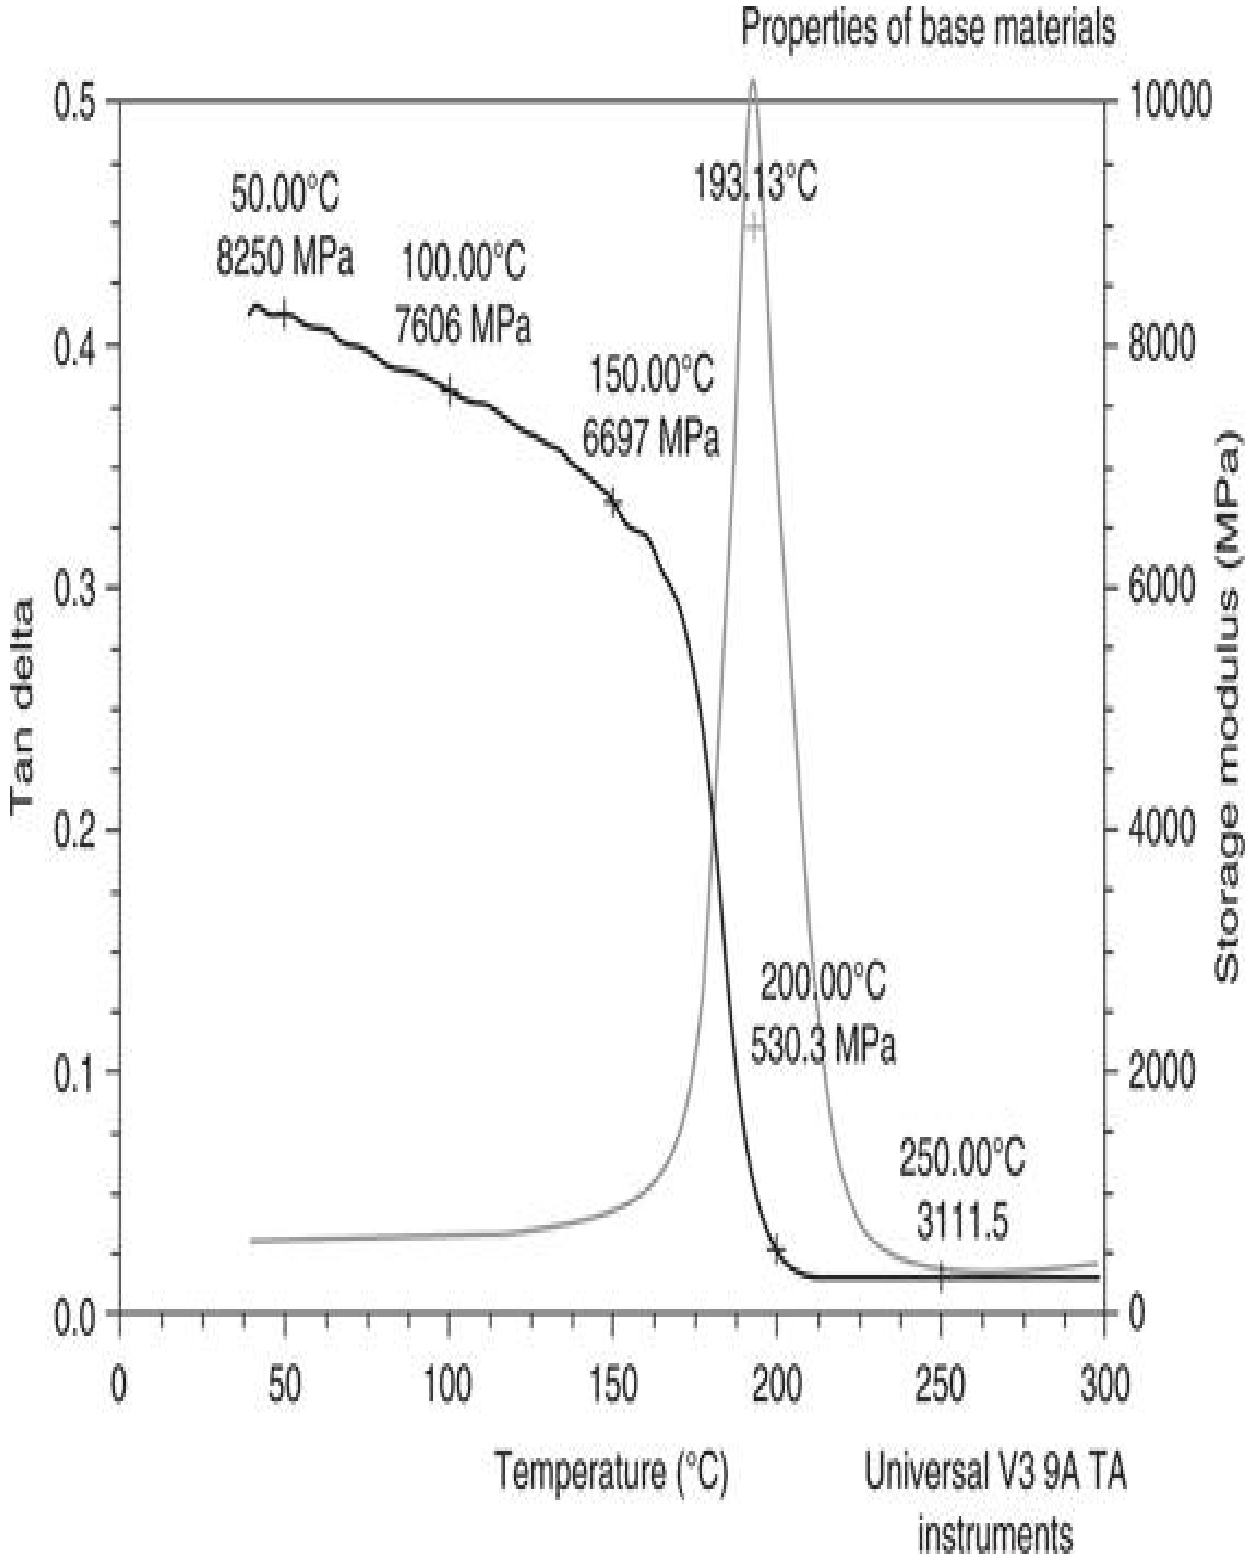

FIGURE 11.3 Measurement of T_g by DMA.

11.2.4 Decomposition Temperature

As a material is heated to higher temperatures, a point is reached where the resin system will begin to decompose. The chemical bonds within the resin system begin to break down and volatile components are driven off, reducing the mass of the sample. The decomposition temperature, T_d, is a property that describes the point at which this process occurs. The traditional definition of T_d is the point where 5 percent of the original mass is lost to decomposition. Table 11.1 shows 5 percent decomposition temperatures for several common materials. However, 5 percent is a very large number when multilayer PCB reliability is considered, and temperatures where lower levels of decomposition occur are very important to understand, particularly with respect to lead-free assembly. To illustrate this, consider Fig. 11.4.

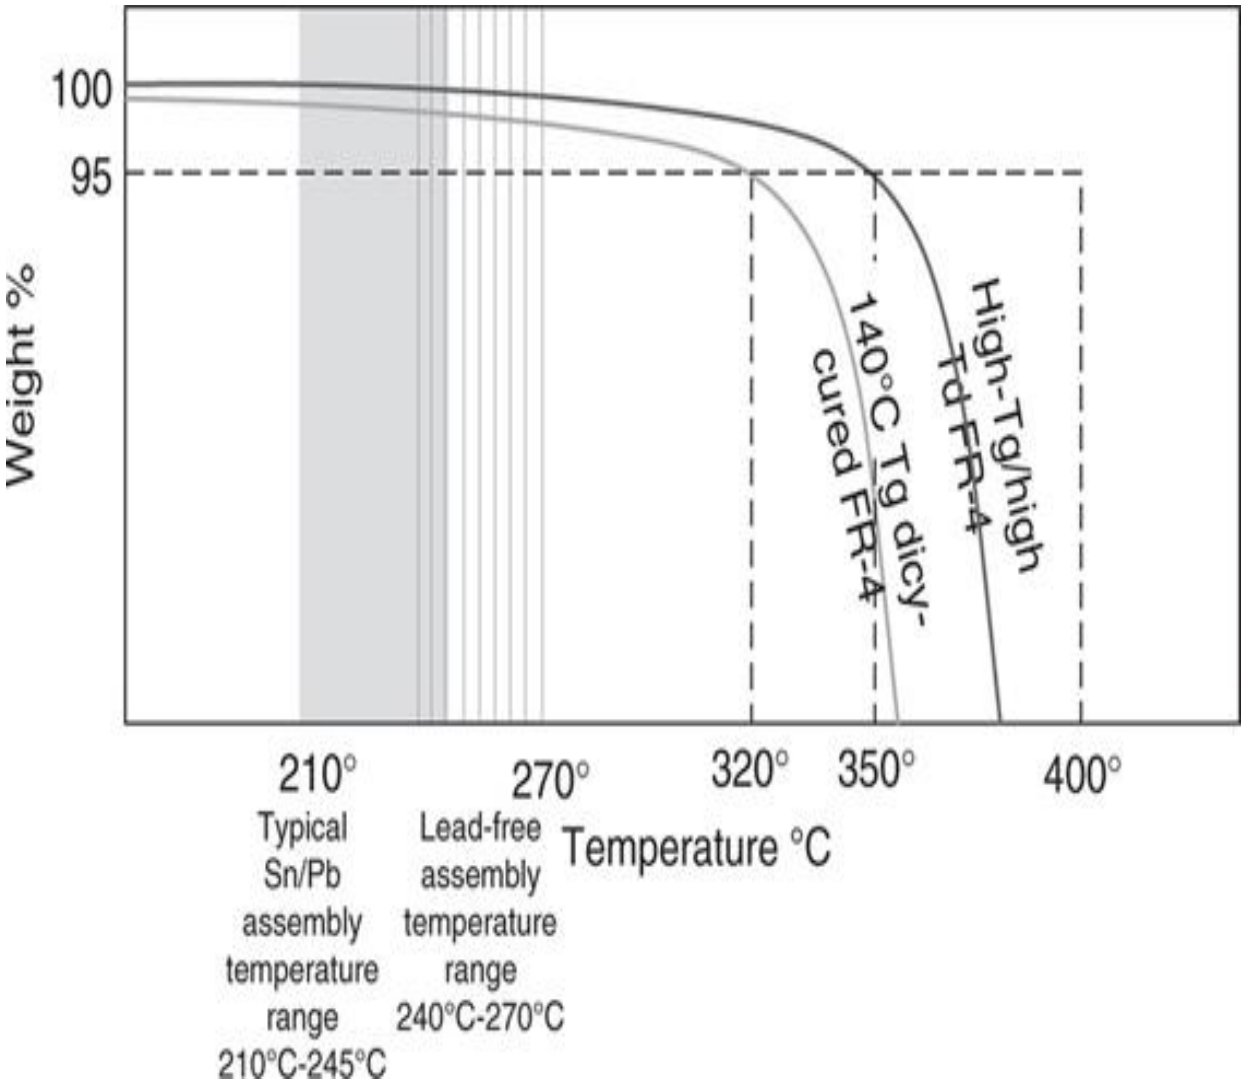

FIGURE 11.4 Illustration of decomposition temperature measurement.

In Fig. 11.4, you can see curves for two FR-4 materials. The 140°C T_g dicy-cured FR-4 has a decomposition temperature of 320°C by the 5 percent weight loss definition. The high-T_g/high-T_d FR-4 has a decomposition temperature of 350°C by the 5 percent weight loss definition. Many dicy-cured high-T_g FR-4 materials actually have decomposition temperatures in the range of 290 to 310°C, whereas the dicy-cured 140°C T_g FR-4 materials generally have slightly higher T_d values. The shaded regions indicate the peak temperature ranges for standard tin-lead assembly and lead-

free assembly. A very common question is, if a PCB will be assembled at 260°C, and the material has a decomposition temperature of 310 to 320°C, then why wouldn’t it be compatible with lead-free assembly?

The answer lies in the level of decomposition in the temperature ranges where assembly will take place. In the tin-lead temperature range, neither material exhibits a significant level of decomposition. However, in the lead-free assembly temperature range, the traditional dicy-cured FR-4 begins to exhibit 1.5 to 3 percent weight loss. This level of decomposition can compromise long-term reliability or result in defects such as delamination during assembly, particularly if multiple assembly cycles or rework cycles are performed. Figures 11.5 through 11.7 show thermogravimetric analysis (TGA) curves assessing decomposition temperatures for three types of base material.

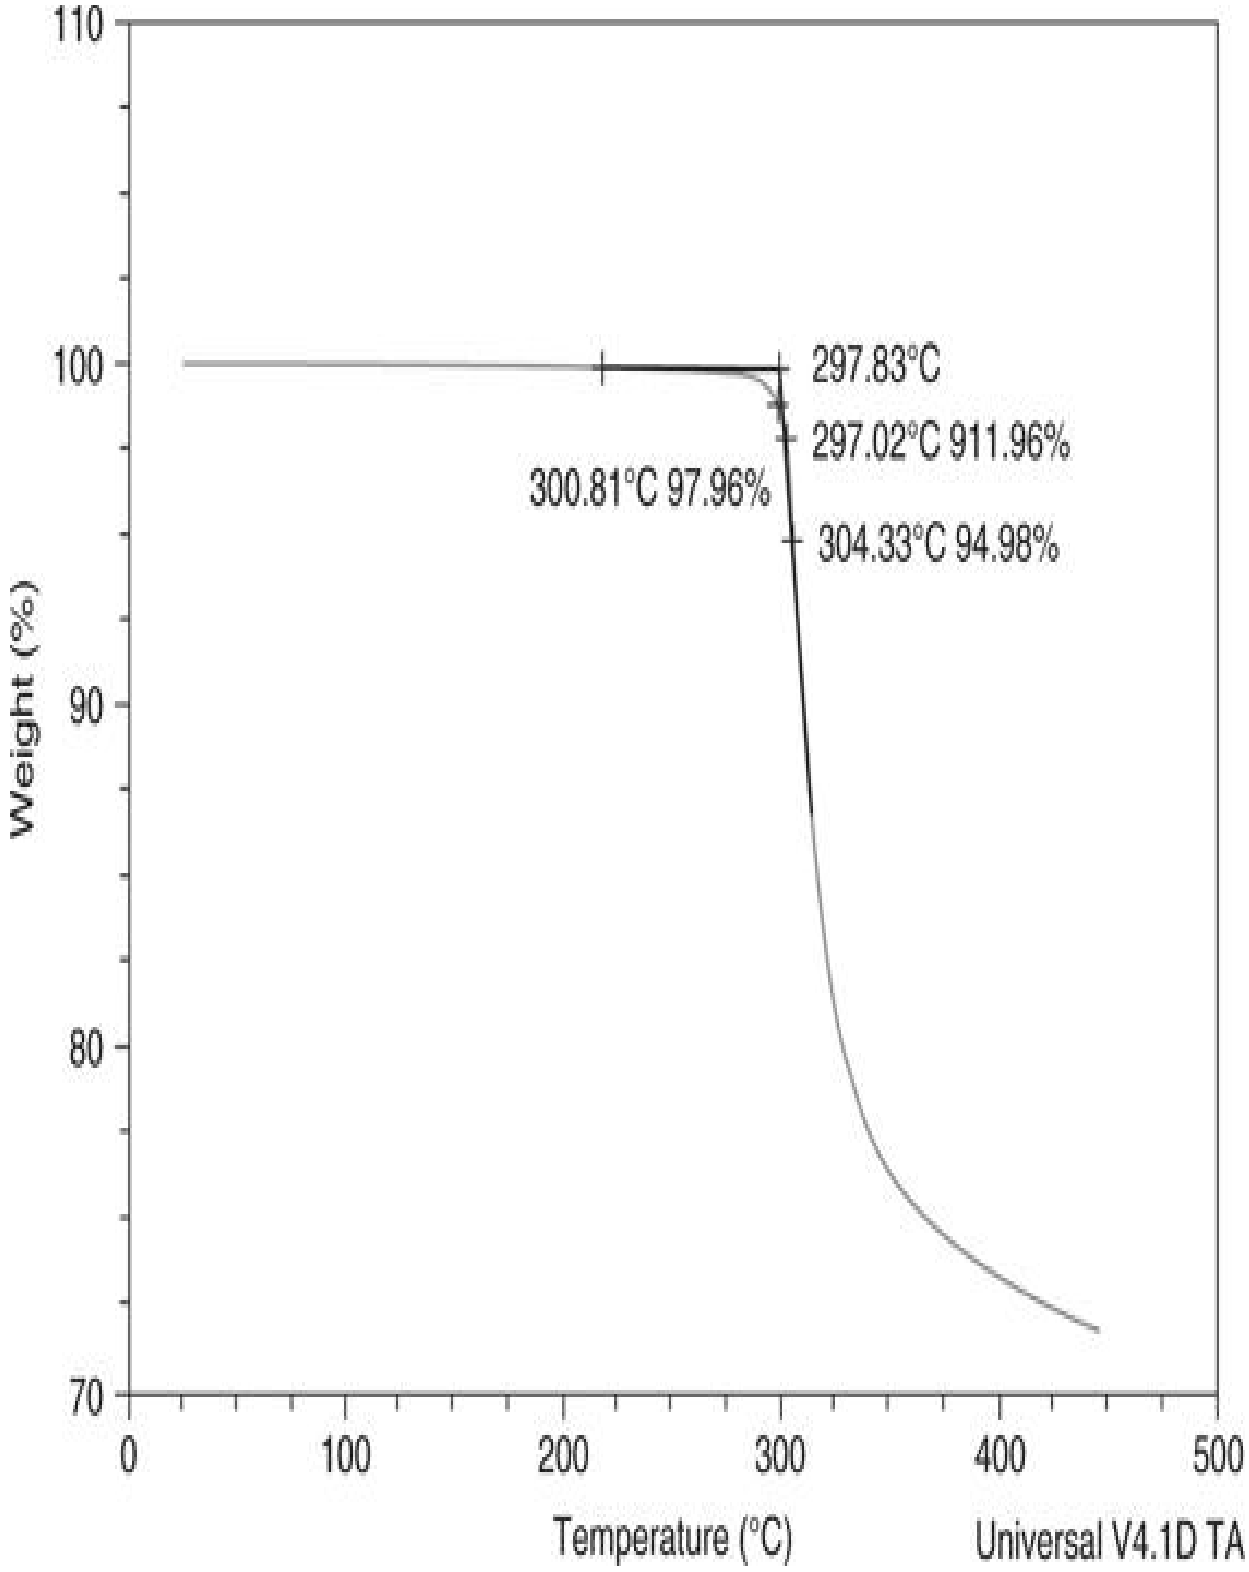

FIGURE 11.5 Decomposition curve for dicy-cured high-T_g FR-4.

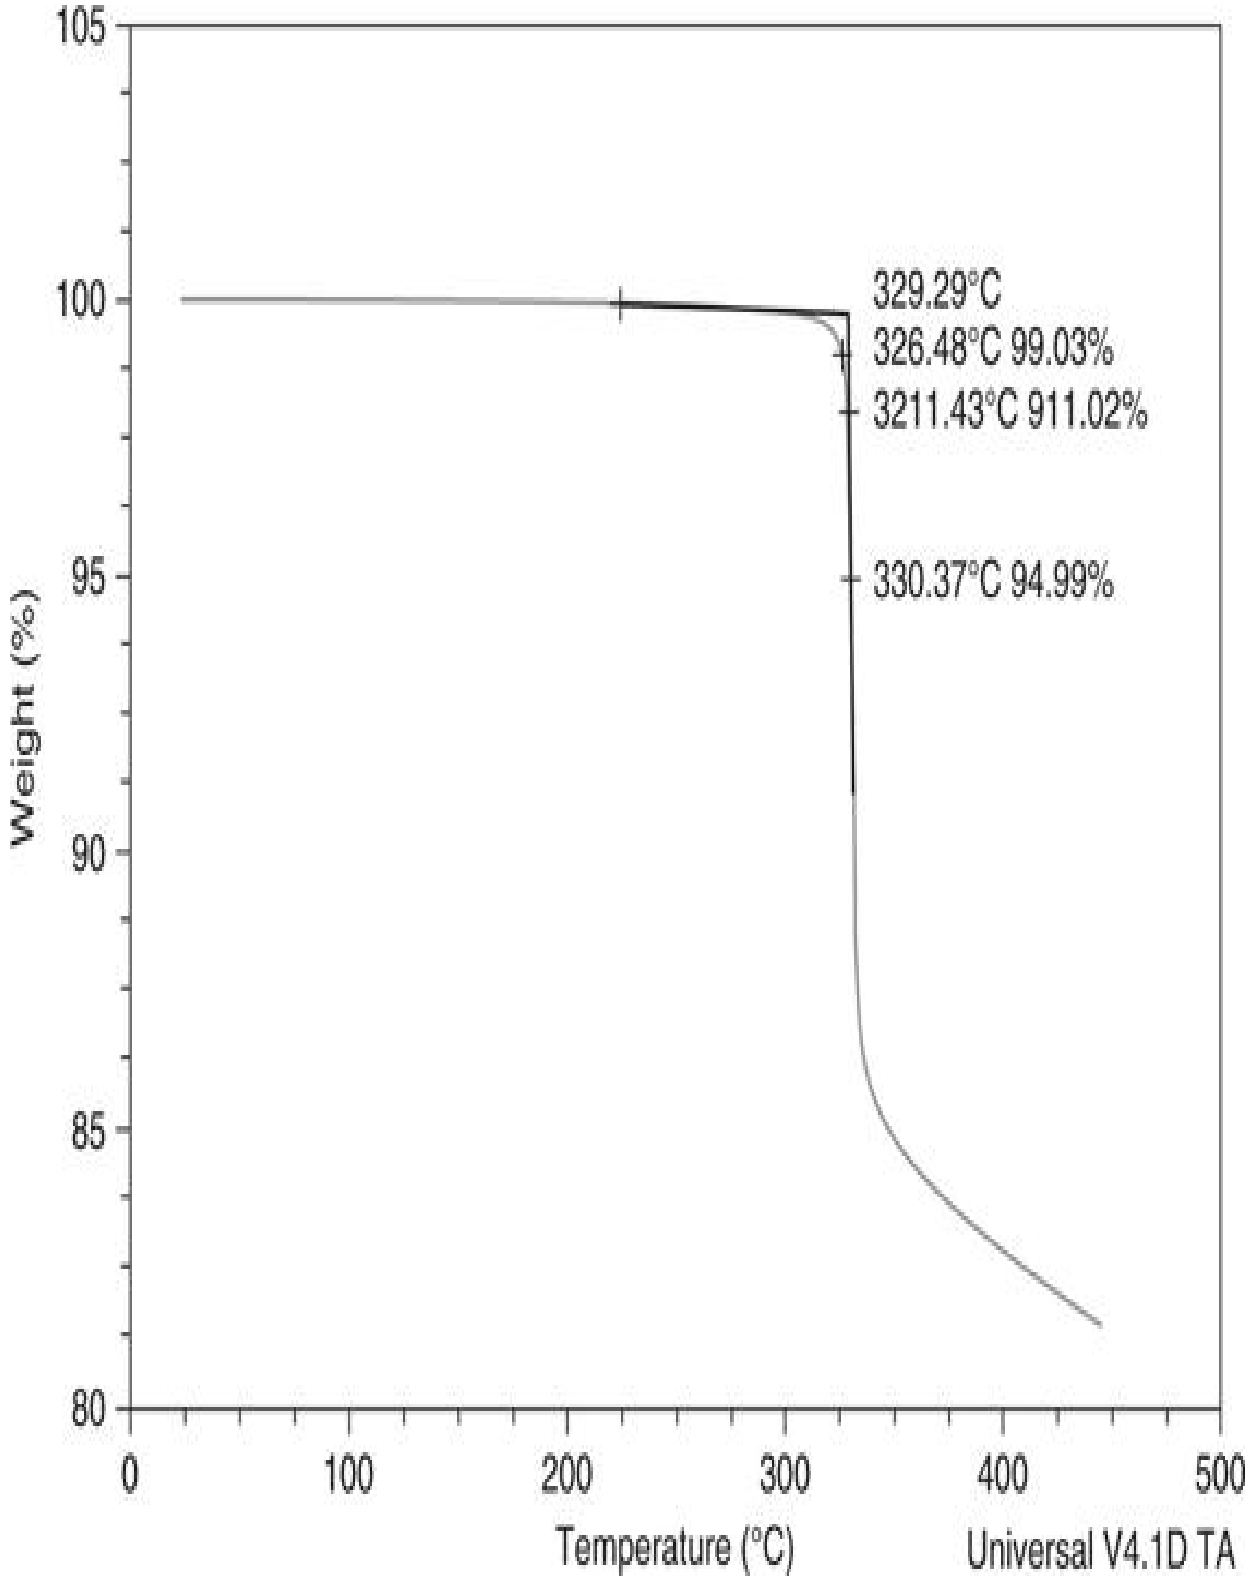

FIGURE 11.6 Decomposition curve for an enhanced high-T_g FR-4.

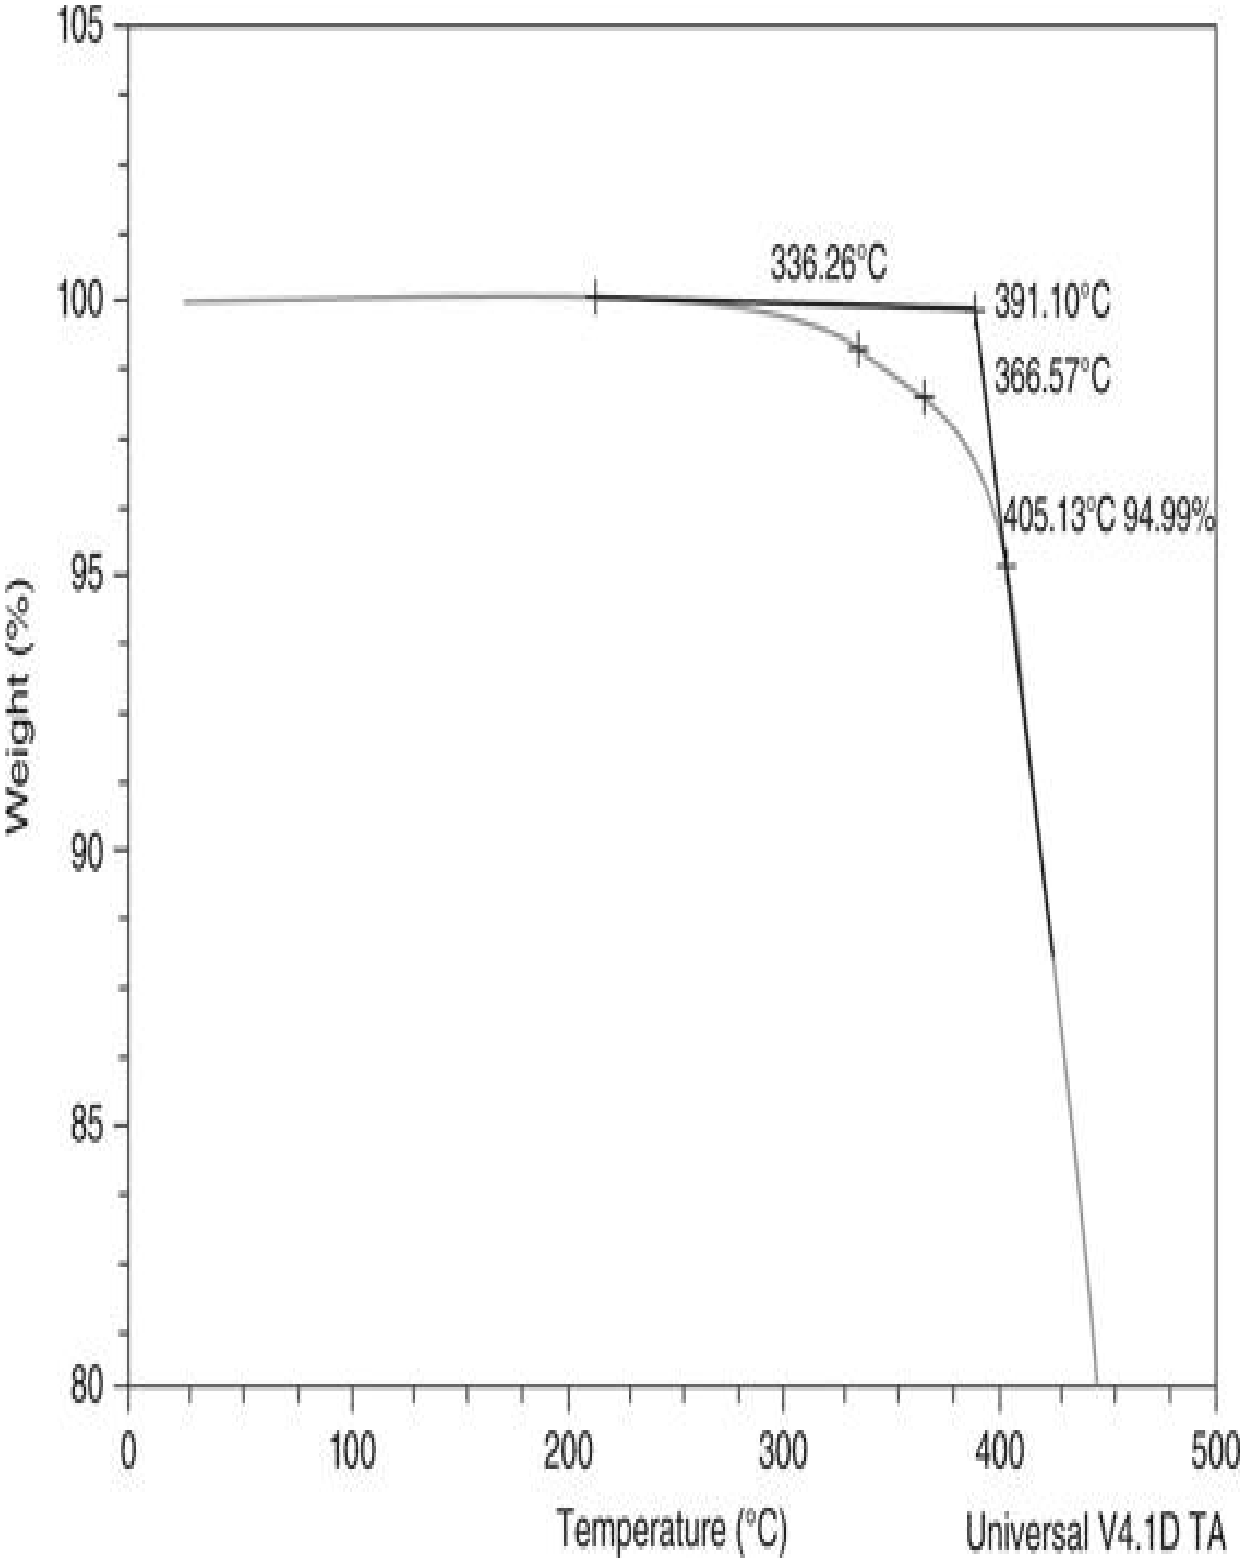

FIGURE 11.7 Decomposition curve for a low Dk/Df material.

These curves show different measurements for decomposition temperature. The value traditionally reported is the level at which 5 percent weight loss occurs, or where the mass is 95 percent of the starting sample mass. But as already discussed, this is a very high level of decomposition when considering PCB reliability. These curves also show 1 percent and 2 percent decomposition temperatures, as well as the “onset” decomposition temperature. The onset temperature extrapolates the linear portions of the curve. The point at which they intersect is reported as the onset temperature.

Note that in Figs. 11.5 and 11.6 decomposition occurs very rapidly, while in Fig. 11.7 decomposition is more gradual, highlighted by the much bigger range between 1, 2, and 5 percent decomposition temperatures. With the material in Fig. 11.7, the 5 percent decomposition temperature would be reported as 405°C, even though some decomposition is beginning around 336°C. This highlights the need to understand not just the 5 percent decomposition temperature, but lower levels as well.

Note that certain IPC-4101 specification sheets include values for the decomposition temperature. These values are based on the 5 percent decomposition value, and as just noted, this is a very high level of decomposition when assessing reliability.[2] So caution should be used when determining which specification sheet to use, or in establishing a specification for decomposition temperature. There are many materials that perform very well in lead-free assembly applications that have T_d values below 340°C by the 5 percent definition, which is a common value used. Alternatively, there are also materials that have T_d values well above 340°C that do not perform well in lead-free applications. The decomposition temperature is just one property to consider when selecting a material, and other properties are also important for reliability. Achieving the

right balance of properties for a given application is important.

11.2.5 Time to Delamination

Time to delamination refers to a specific test procedure used to measure how long a material will resist blistering or delamination at a specific temperature. The procedure utilizes a thermomechanical analyzer (TMA) in which a sample is heated to the specified temperature. The most common temperature used is 260°C. This test is commonly called a T260 test. Other temperatures are also used, such as 288°C or 300°C. Table 11.2 compares the performance of various material types. When reviewing this table, it is important to note that there can be large variation between similar materials across the manufacturers of these materials. T260 values can be affected by a number of factors: the specific resins and curing agents used in a given material, differences in CTE values between the components in the sample, the quality of copper bonding treatment, curing of the material during lamination, and in some cases volatile content. For example, note the lower T260 values reported for the 175°C epoxy versus the 140°C epoxy. Although the T260 value is shorter, thermal cycling tests typically show improved reliability with the 175°C T_g material because of the lower levels of thermal expansion that result with the higher-T_g material. The enhanced FR-4 materials, which use a different curing chemistry, generally exhibit better performance in both time-to-delamination tests as well as thermal cycling tests. Figure 11.8 is an example of a TMA scan on a multilayer PCB that evaluates T260 performance. The top curve plots the temperature while the other curve measures sample thickness. Delamination results in a rapid increase in sample thickness and indicates the endpoint for the test. Figure 11.9 is a T288 scan for the

same material. Note that times to delamination on PCBs are generally much shorter than times on either copper clad laminate or unclad laminate.

TABLE 11.2 Time to Delamination and Arc Resistance Data for Common Materials

Material	T_g (°C)	T260	T288	Arc Resistance (seconds)
Standard T_g FR-4	140	30	5	120
Filled mid-T_g FR-4	150	60	10	120
Halogen free, filled mid-T_g FR-4	155	60	10	115
High-T_g FR-4	170	10	2	90
High-T_g/T_d FR-4	175	45	10	125
Filled high-T_g/T_d FR-4	180	60	30	115
Halogen-free high-T_g/T_d FR-4	180	60	60	115
Mid-loss epoxy	200	60	20	120
BT/Epoxy blend	200	30	10	123
BT/Epoxy blend-low Dk glass	200	30	10	123
Low loss epoxy blend	180	60	60	137
Low loss epoxy blend-low Dk glass	180	60	60	137
Very low loss	200	60	60	139
Halogen-free very low loss	200	60	60	139
Ultra low loss	200	60	60	125
Polyimide	260	60	60	130

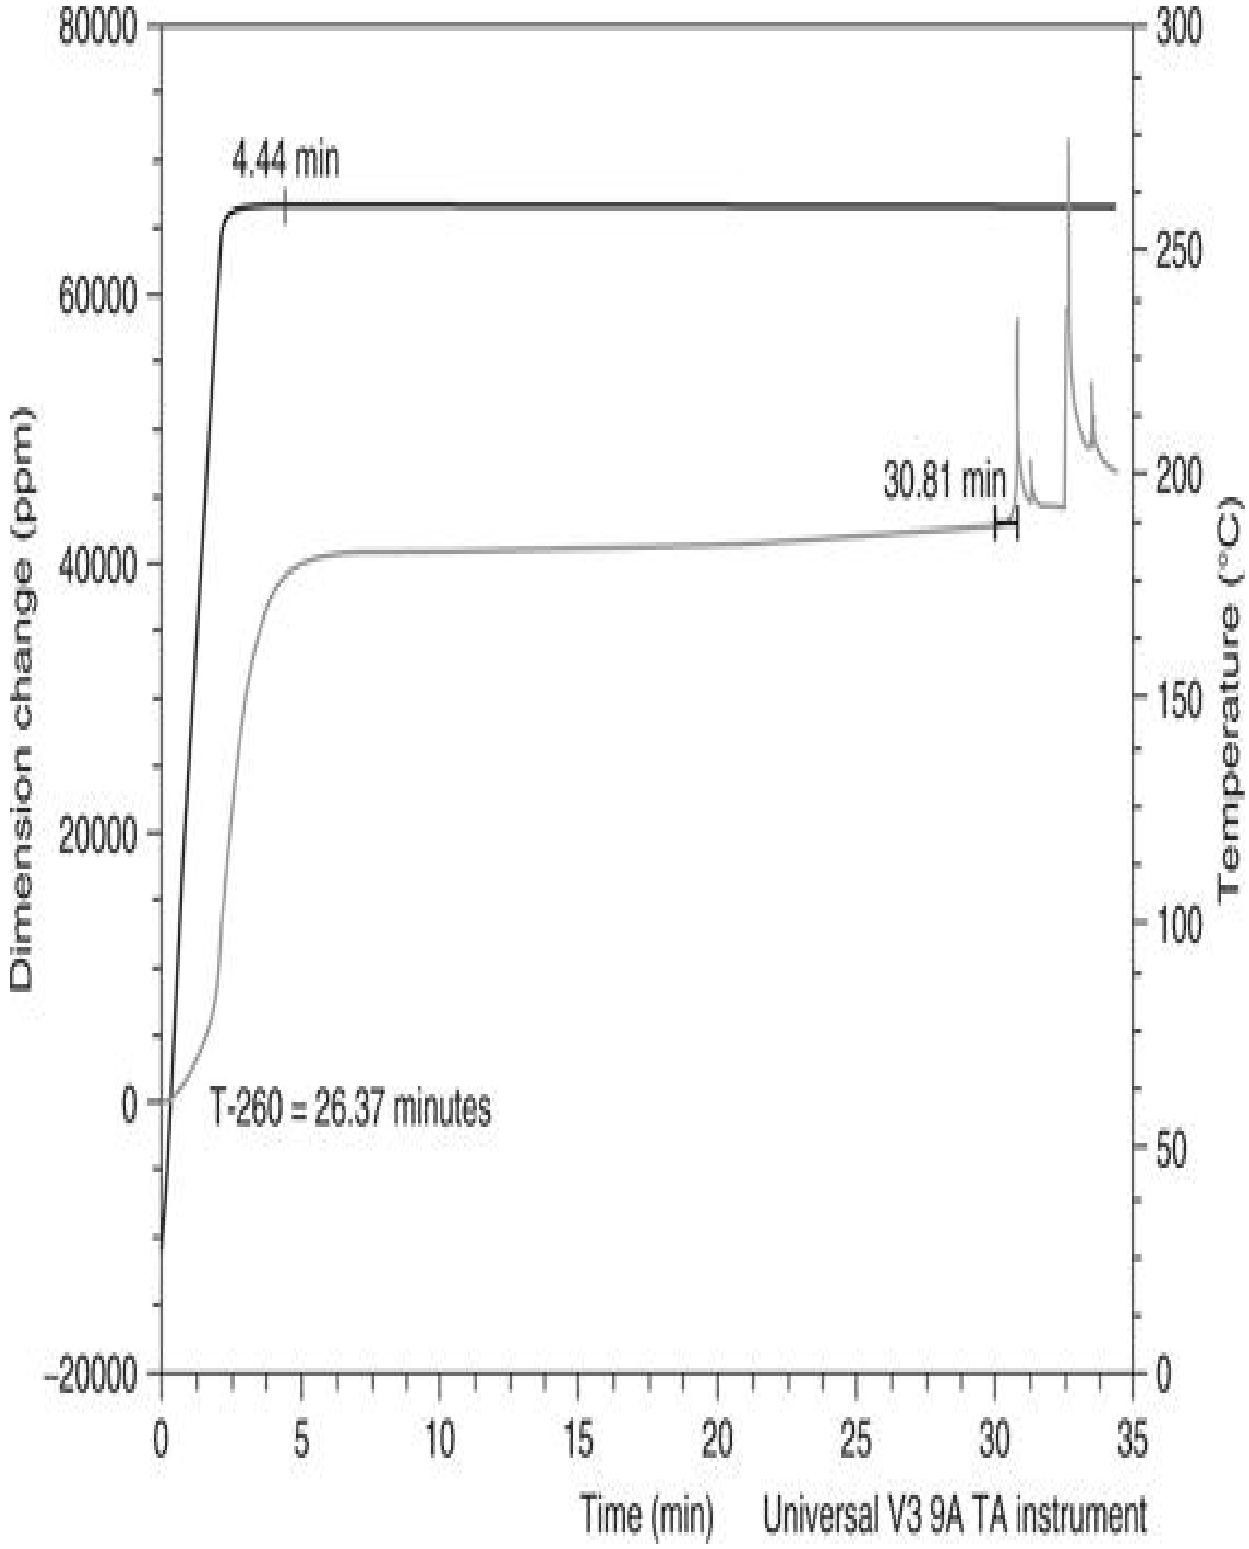

FIGURE 11.8 T260 example for an enhanced high-T_g FR-4.

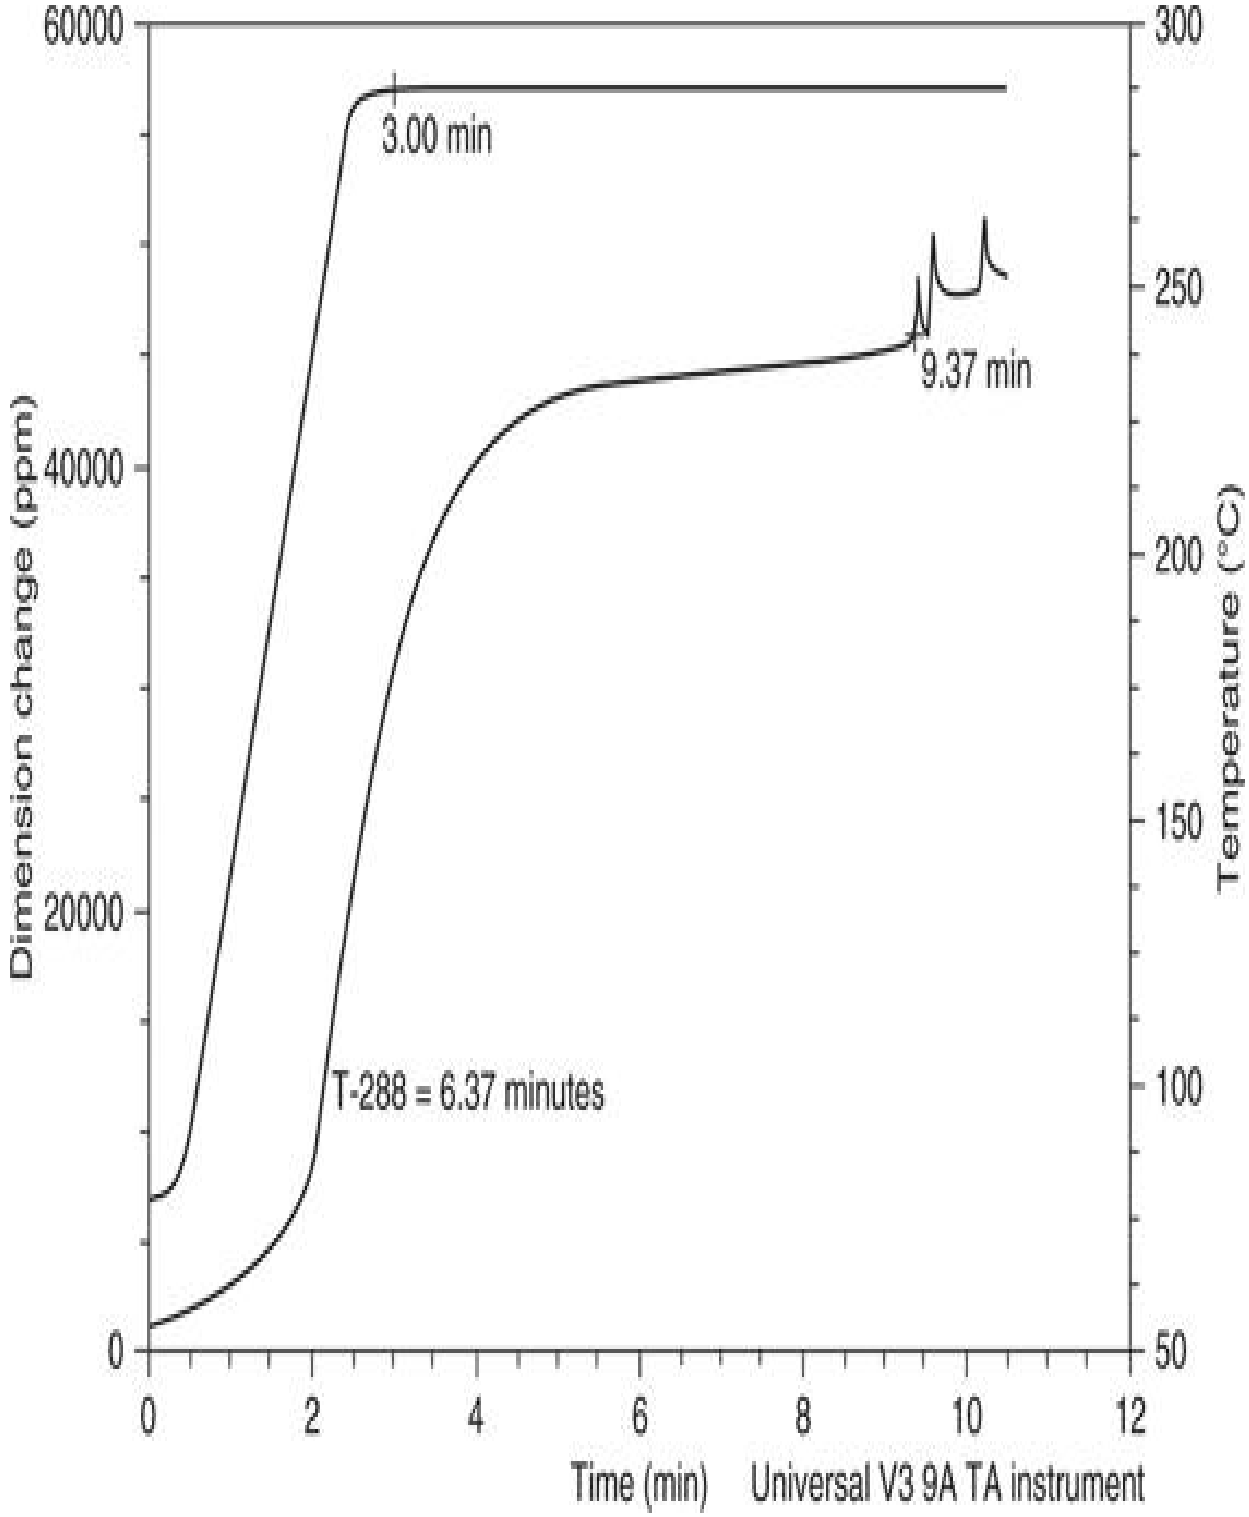

FIGURE 11.9 T288 example for an enhanced high-T_g FR-4.

Although time-to-delamination tests have received much attention as lead-free assembly processes have become common, it is important not to focus exclusively on one property or type of measurement when specifying laminate materials for lead-free applications. First, the correlation between time-to-delamination performance and lead-free assembly compatibility is not always clear. Long T260 or T288 times by themselves do not ensure good reliability in lead-free applications. Conversely, some materials with good but not necessarily great T260 or T288 times have exhibited excellent performance in lead-free applications. So although it is important to consider time-to-delamination performance when specifying materials for lead-free assembly applications, these values should not be looked at exclusively. A balance of several properties is necessary in these applications.

11.2.6 Arc Resistance

In this test technique, a low current arc is placed above the surface of a material. Arc resistance describes the time the material resists tracking, or forming a conductive path, under this condition. Arc resistance values are also shown in Table 11.2. Figure 11.10 illustrates the test technique.

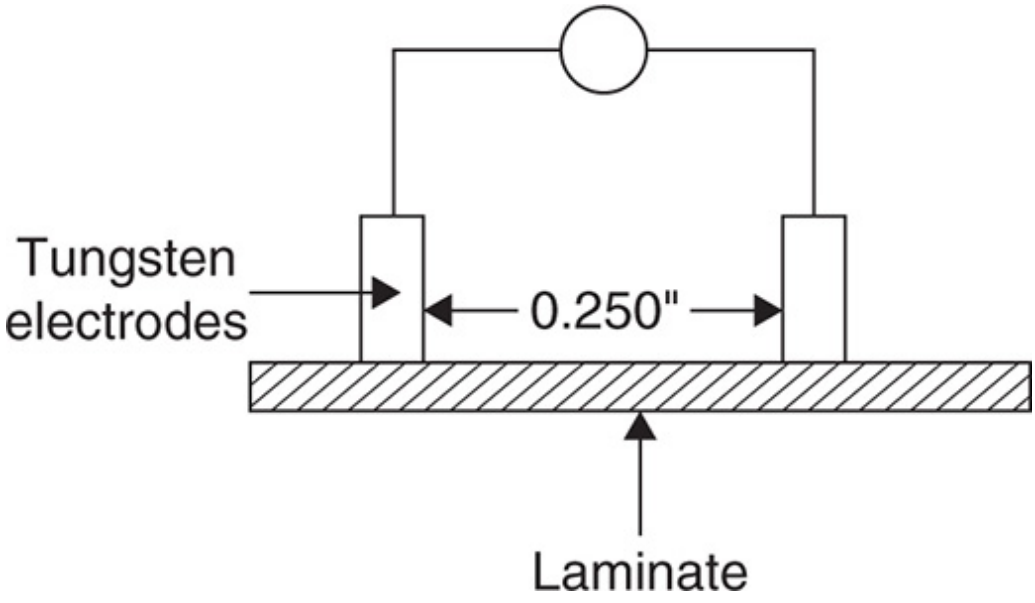

FIGURE 11.10 Arc resistance test technique.

11.2.7 Copper Peel Strength

Peel strength testing is the most popular method used to measure the bond between the conductor and the substrate. Peel strengths can be measured in the “as received” condition, after thermal stress, at elevated temperature, and after exposure to processing chemicals. The standard procedure requires that the sample consist of traces or strips of copper foil, or other metal to be tested, and that they be imaged onto the sample using standard printed circuit manufacturing processes. The strips should be at least 0.79 mm (0.032 in) in width for testing after exposure to processing chemistries and 3.18 mm (0.125 in) in width for the other tests. Metal cladding thickness can influence the measured peel strength and therefore it is accepted practice to use 1 oz cladding, and if a thinner cladding is used, it may be plated up to 1 oz thickness.

One end of the strip is peeled back and attached to a load tester such as a tensile strength tester equipped with a load cell. The peel strength is calculated per the formula:

$$\text{lb/in} = L_m/W_s$$

where L_m is the minimum load, and W_s is the measured width of the peel strip.

For testing after thermal stress, the sample is first floated on solder at 288°C for 10 seconds. For testing after exposure to processing chemistries, the sample is exposed to a series of conditions. First the sample is exposed to an organic stripper at 23°C for 75 seconds. Historically, methylene chloride has been used, but due to environmental concerns, equivalents are now allowed. After drying, the sample is then immersed in a solution of 10 g/L sodium hydroxide at 90°C for 5 minutes. The sample is rinsed and then exposed to 10 g/L sulfuric acid and 30 g/L boric acid at 60°C for 30 minutes. The sample is again rinsed and dried and then immersed in a hot oil bath maintained at 220°C for 40 seconds. Finally, the sample is immersed in a degreaser at 23°C for 75 seconds to remove the oil and then dried. Testing at an elevated temperature may be performed by placing the sample in a hot fluid or in hot air while performing the peel strength measurements. For FR-4 materials, 125°C is commonly used.

Table 11.3 shows 1 oz copper peel strength values in N/mm at various conditions for several common materials. It should be noted that the type of copper treatment and profile bonded to the laminate can have a big influence on copper peel strength values, and therefore the values in this table should only be used as a reference as they are taken from data sheets without reference to copper profile or treatment type.

TABLE 11.3 Peel Strength Values for Common Base Material Types with Standard Copper (N/mm)

Material	T_g (°C)	Low and Very Low Profile Copper	After Thermal Stress	At Elevated Temp.	After Exposure to Chemistry
Standard T_g FR-4	140	1.10	1.45	1.25	1.45
Filled mid-T_g FR-4	150	1.00	1.45	1.25	1.45
Halogen-free, filled mid-T_g FR-4	155	1.00	1.25	1.15	1.20
High-T_g FR-4	170	1.10	1.6	1.19	1.60
High-T_g/T_d FR-4	175	1.20	1.58	1.23	1.58
Filled high-T_g/T_d FR-4	180	1.10	1.25	1.15	1.25
Halogen-free high-T_g/T_d FR-4	180	1.00	1.25	1.05	1.25
Mid-loss epoxy	200	1.14	1.23	1.14	1.20
BT/Epoxy blend	200	1.1	1.31	1.39	1.31
BT/Epoxy blend-low Dk glass	200	1.1	1.31	1.39	1.31
Low loss epoxy blend	180	0.96	1.00		0.96
Low loss epoxy blend-low Dk glass	180	0.96	1.00		0.96

Note that peel testing is measuring force required to pull foil off of a material surface. Depending on the elasticity of the material tested, the effective surface area that the copper is being pulled from changes, as elastic materials will deform during the peel testing. An example is polyimide, long used for its thermal reliability characteristics. Polyimide exhibits low peel strength values as it is very hard and not very elastic, so it has a small area of contact to distribute the force. This illustrates that the absolute value of peel strength is not always the best indicator of quality or reliability.

Measuring and monitoring of peel strengths for a given material type for comparison to its normal values can be used as a process control tool, an inspection criteria, or for failure analysis purposes, but in choosing a material, a higher peel strength does not necessarily imply higher reliability in the end-use environment. Many of the advanced materials being developed and introduced into commercial use will exhibit lower peel strengths. Last, if drum-side treated foil, also called reverse-treated foil, is used, the peel strength values will be lower because of the lower surface profile. In fact, copper foils with lower and lower profiles are being developed for use in high frequency/high speed applications since the copper foil roughness will impact signal loss properties. These lower profile foils will generally result in lower peel strength values.

11.2.8 Water and Moisture Absorption

The ability of a material to resist water absorption, either from the air or when immersed in water, is important for printed circuit reliability. Besides the obvious concerns of moisture causing defects when a material is subjected to thermal excursions, absorbed moisture also affects the ability of a material to resist conductive anodic filament (CAF) formation when a bias is applied to the circuit, and can affect dielectric and loss properties as well.

The test method for measuring water absorption for metal-clad base laminates involves immersing a sample in distilled water at 23°C for 24 hours after etching off the metal cladding and drying the sample for 1 hour at 105 to 110°C and cooling in a desiccator. The sample is weighed after drying, immersed in water under the specified conditions, and weighed again. The water absorption is calculated as follows:

Increase in weight, percent = (wet weight − conditioned weight)/conditioned weight × 100

An additional moisture absorption test measures weight gain after 60 minutes at 15 psi.

11.2.9 Flammability

Underwriters Laboratories (UL) classifies flammability properties as 94V-0, 94V-1, or 94V-2. Definitions of these classifications are as follows:

11.2.9.1 94V-0. Specimens must extinguish within 10 seconds after each flame application (see Fig. 11.11) and a total combustion of less than 50 seconds after 10 flame applications. No samples are to drip flaming particles or have glowing combustion lasting beyond 30 seconds after the second flame test.

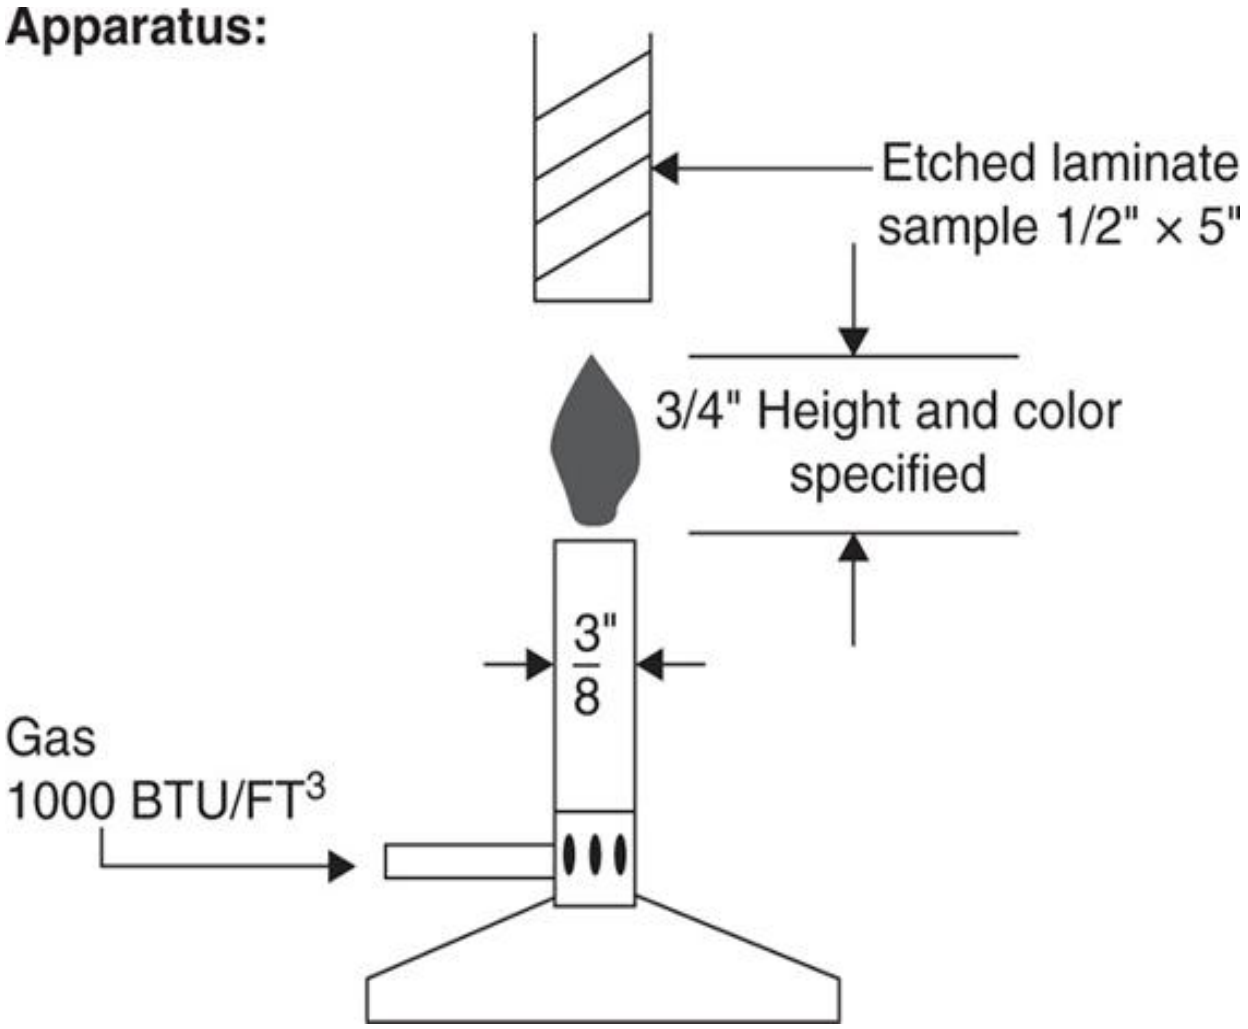

FIGURE 11.11 Flammability testing.

11.2.9.2 94V-1. Specimens must extinguish within 30 seconds after each flame application and a total combustion of less than 250 seconds after 10 flame applications. No samples are to drip flaming particles or have glowing combustion lasting beyond 60 seconds after the second flame test.

11.2.9.3 94V-2. Specimens must extinguish within 30 seconds after each flame application and a total combustion of less than 250 seconds after 10 flame applications. Samples may drip flaming particles, burning briefly, and no

specimen will have glowing combustion beyond 60 seconds after the second flame test.

11.3 ELECTRICAL PROPERTIES

A variety of base material electrical properties are important to understand when designing and manufacturing printed circuits. Some of the most important properties are discussed in this section. As noted earlier in the chapter, the demand for circuits operating at high frequencies requires materials with good permittivity and loss characteristics. These properties will be discussed further in Chap. 14.

11.3.1 Dielectric Constant or Permittivity

The dielectric constant can be defined as the ratio of the capacitance of a capacitor with a given dielectric material to the capacitance of the same capacitor with vacuum as a dielectric, as illustrated in Fig. 11.12. In other words, the dielectric constant is a measure of the ability of a material to store an electric charge. There are actually several test methods used to measure dielectric constant or permittivity and a complete discussion of these methods is beyond the scope of this chapter. However, it should be noted that measuring permittivity at high frequencies can be very difficult and that reported values can vary with the specific test method used. Therefore, when comparing the reported values for different materials, the best comparisons will be those that used the same test method. This will be discussed further in Chap. 14.

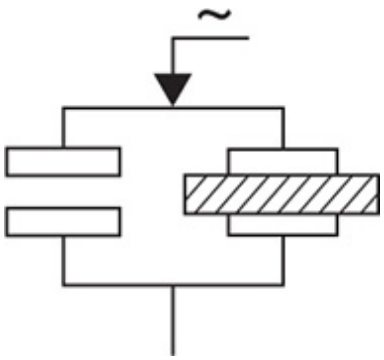

FIGURE 11.12 Dielectric constant.

Furthermore, the dielectric constant is not really a constant. As just implied, the dielectric constant will often vary with frequency and with temperature and humidity exposure. Last, even with the same material type, variations in resin content (resin-to-reinforcement ratio) normally affect the dielectric constant and the variation in glass content of woven materials leads to micro Dk variation. These variations will be further discussed in Chap. 14. Table 11.4 shows dielectric constants for some common fiberglass (E-glass) reinforced materials at 50 percent resin content.

TABLE 11.4 Dielectric Constants and Dissipation Factors of Common Materials

Material	Dielectric Constant					Dissipation Factor				
	1 MHz	1 GHz	2 GHz	5 GHz	10 GHz	1 MHz	1 GHz	2 GHz	5 GHz	10 GHz
Standard T_g FR-4	4.60	4.40	4.35			0.015	0.016	0.017		
Filled mid-T_g FR-4	4.25	3.95	3.90			0.020	0.022	0.023		
Halogen-free, filled mid-T_g FR-4	4.10	4.01	4.00	3.97	3.97	0.013	0.016	0.0167	0.0172	0.0172
High-T_g FR-4	4.10	3.95	3.93	3.92	3.92	0.013	0.0161	0.0167	0.0172	0.0172

Filled high-T_g/T_d FR-4	4.24	4.17	4.04	3.92	3.92	0.0180	0.0195	0.021	0.0225	0.0235
Halogen-free high-T_g/T_d FR-4	4.23	4.18	4.16	4.14	4.14	0.0120	0.0148	0.0154	0.0160	0.0165
Mid-loss epoxy	3.75	3.71	3.70	3.70	3.70	0.0107	0.0120	0.0125	0.0127	0.0130
BT/Epoxy blend		3.7	3.7	3.6	3.6		0.0090	0.0095	0.0100	0.0105
BT/Epoxy blend-low Dk glass		3.4	3.3	3.2	3.2		0.0080	0.0085	0.0090	0.0095
Low loss epoxy blend	3.70	3.65	3.64	3.63	3.63	0.0050	0.0058	0.0060	0.0067	0.0071
Low loss epoxy blend-low Dk glass			3.30	3.28	3.27			0.0064	0.0066	0.0064
Very low loss			3.45	3.45	3.45			0.0031	0.0031	0.0031
Halogen-free very low loss			3.44	3.44	3.44			0.0039	0.0039	0.0039
Ultra low loss			3.04	3.02	3.02			0.0021	0.0021	0.0021
Polyimide	4.3	4.0	3.76	3.74	3.74	0.0180	0.0180	0.0170	0.0190	0.0210

11.3.2 Dissipation Factor or Loss Tangent (Tan δ)

The dissipation factor in an insulating material is the ratio of the total power loss in the material to the product of the voltage and current in a capacitor in which the material is a dielectric (see Fig. 11.13). Many of the test methods used for measuring dielectric constant also measure the dissipation factor. Dissipation factor also varies with frequency, resin content, temperature, and humidity. Dissipation factor is discussed in more detail in Chap. 14. Table 11.4 also lists the dissipation factors of some common fiberglass (E-glass) reinforced materials. However, great care should be used when comparing values from material data sheets. Not all suppliers use the same measurement methods or sample resin contents. This can result in significant variation in reported values.

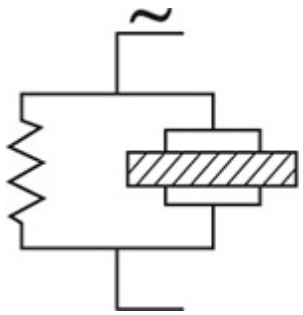

FIGURE 11.13 Dissipation factor.

11.3.3 Insulation Resistance

The insulation resistance between two conductors or plated holes is the ratio of the voltage to the total current between the conductors. Two measures of electrical resistance are volume and surface resistivities. Since these properties can vary with temperature and humidity, testing is normally performed at two standardized environmental conditions,

one involving humidity conditioning, the other involving elevated temperature. Humidity conditioning subjects the sample to 90 percent relative humidity and 35°C for 96 hours (96/35/90). The elevated temperature conditioning normally subjects the sample to 125°C for 24 hours (24/125).

11.3.4 Volume Resistivity

Volume resistivity is the ratio of the DC potential applied to electrodes embedded in a material to the current applied between the electrodes, typically expressed in megohm-centimeters. The measured current flows between electrodes 1 and 3, while stray current applied between the electrodes flows between electrodes 2 and 3, as shown in Fig. 11.14. Table 11.5 shows the volume resistivity values of some common fiberglass-reinforced material types.

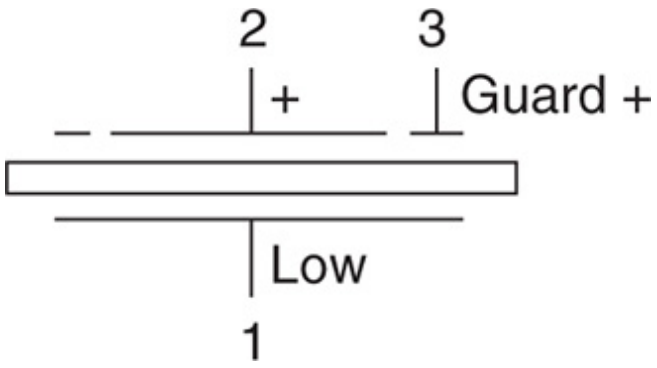

FIGURE 11.14 Circuit for volume resistance.

TABLE 11.5 Additional Electrical Properties of Common Base Materials

Material	Volume Resistivity (96/35/90)	Volume Resistivity (24/125)	Surface Resistivity (96/35/90)	Surface Resistivity (24/125)	Electric Str. (V/mil)
FR-4 Epoxy	10^8	10^7	10^7	10^7	1250
Filled FR-4 Epoxy	10^{10}	10^{11}	10^8	10^9	1250
High-T_g FR-4 Epoxy	10^8	10^7	10^7	10^7	1300
BT/Epoxy Blend	10^7	10^7	10^6	10^7	1200
Low Dk Epoxy Blend	10^8	10^7	10^7	10^7	1200
Cyanate Ester	10^7	10^7	10^7	10^7	1650
Polyimide	10^7	10^7	10^7	10^7	1350

11.3.5 Surface Resistivity

The surface insulation resistance between two points on the surface on any insulating material is the ratio of the DC potential applied between the two points to the total current between them. For surface resistivity, the measured current flows between electrodes 1 and 2, while stray current flows between electrodes 1 and 3, as shown in Fig. 11.15. Table 11.5 shows the surface resistivity values of some common fiberglass-reinforced materials.

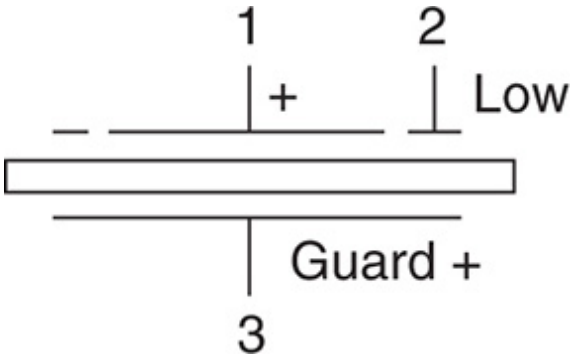

FIGURE 11.15 Circuit for surface resistance.

11.3.6 Electric Strength

Electric strength is a measure of the ability of an insulating material to resist electrical breakdown perpendicular to the plane of the material when subjected to short-term, high voltages at standard AC power frequencies of 50 to 60 Hz and is reported in volts per mil (see Fig. 11.16). Results can be affected by moisture content in the sample, so measurements may vary with different preconditioning environments. Unless otherwise noted, measurements are taken at 23°C, after preconditioning for 48 hours in distilled water at 50°C and immersion in ambient temperature distilled water for 30 minutes minimum, 4 hours maximum. Measurements are performed under an oil medium to prevent flashover on a small specimen. The values may decrease with increasing specimen thickness for an otherwise identical material.

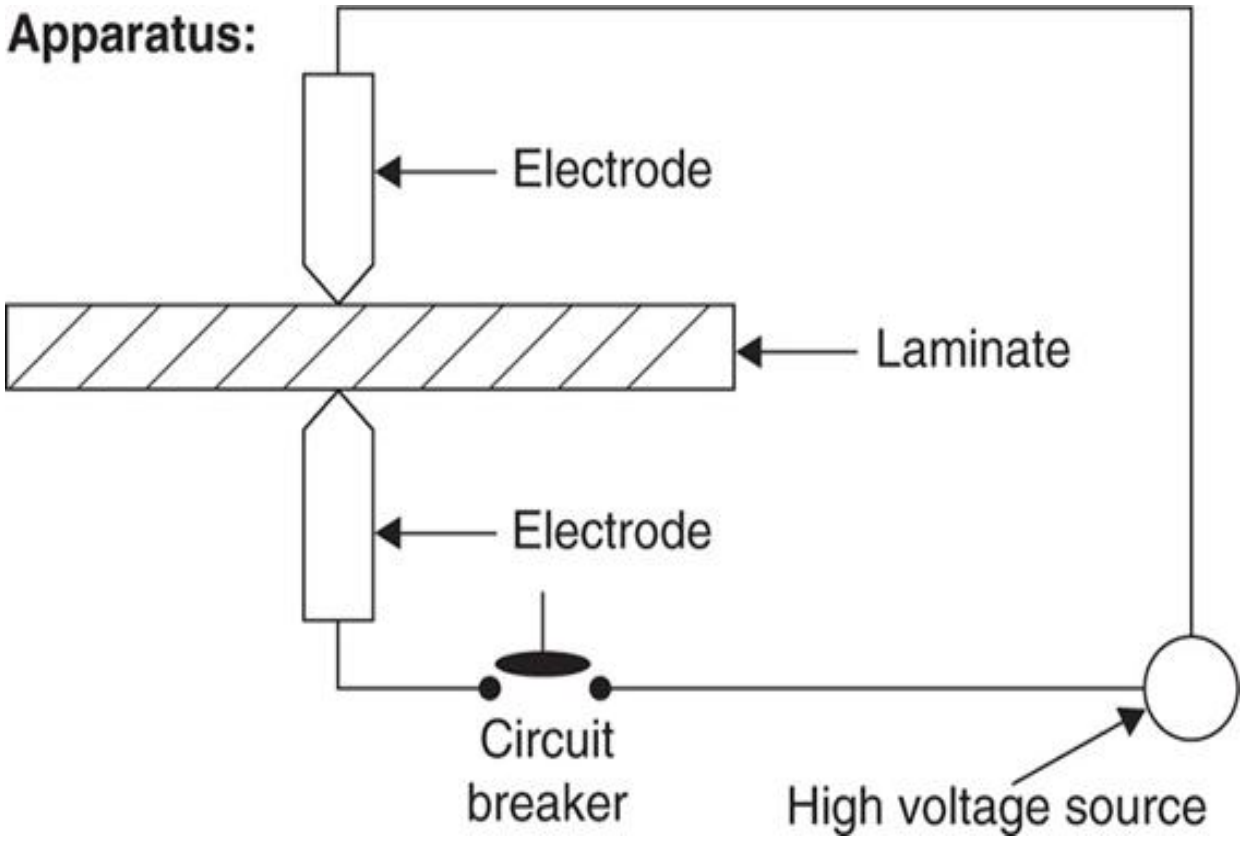

FIGURE 11.16 Dielectric strength.

11.3.7 Dielectric Breakdown

Dielectric breakdown measures the ability of rigid insulating materials to resist breakdown parallel to the laminations (or in the plane of the material) when subjected to extremely high voltages at standard AC power frequencies of 50 to 60 Hz (see Fig. 11.17). As with electric strength, values obtained on most materials are highly dependent on the moisture content and preconditioning method. Unless otherwise noted, measurements are performed at 23°C after preconditioning for 48 hours in distilled water at 50°C followed by immersion in ambient temperature distilled water for 30 minutes minimum, 4 hours maximum. Dielectric breakdown is also performed in an oil medium. Dielectric

breakdown for the materials shown in Table 11.5 is normally above 50 kV.

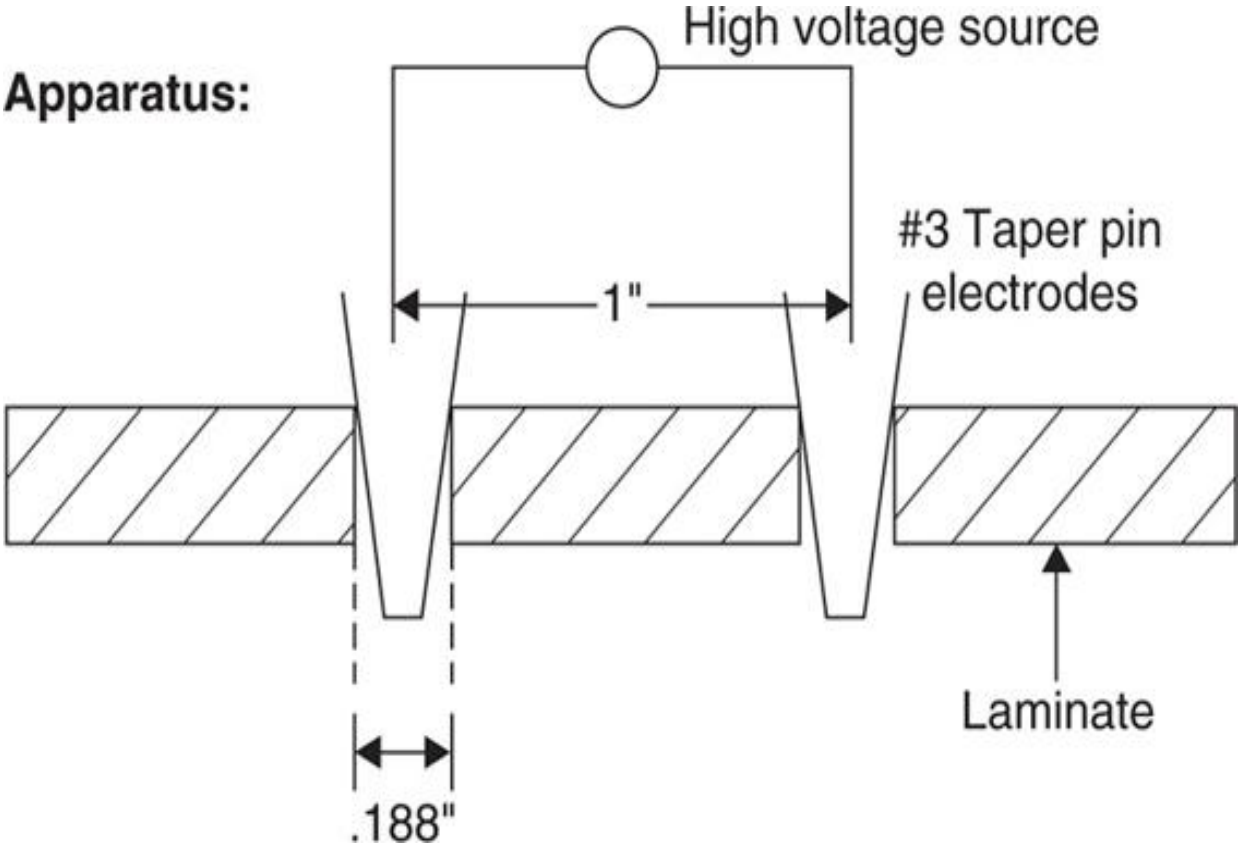

FIGURE 11.17 Dielectric breakdown strength parallel to laminations.

Last, it should be noted that electric strength and dielectric breakdown are measures of instantaneous failure of the dielectric material. These values do not imply long-term resistance to high-voltage values in most uses.

11.4 OTHER TEST METHODS

The test methods described in this chapter are just some of the relevant test methods contained in the IPC Test Methods Manual, IPC TM-650.[3] TM-650 also covers test methods applicable to the components of base materials, such as

copper foil and glass fabrics, as well as printed circuits. IPC TM-650 is available on-line at www.ipc.org.

CHAPTER 12

BASE MATERIAL PERFORMANCE IN PCBs

Edward Kelley
Douglas Troboug h
Isola Group, Chandler, Arizona

12.1 INTRODUCTION

As the fundamental building block for printed circuits, base materials must meet the needs of the printed circuit board (PCB) manufacturer, the circuit assembler, and the original equipment manufacturer (OEM). A balance of properties must be achieved that satisfies each member of the supply chain. In some cases, the desires of one member of the supply chain conflict with another. For example, the need for improved electrical performance by the OEM, or improved thermal performance by the assembler, may necessitate the use of resin systems that require longer multilayer press cycles, less productive drilling processes, and the use of plasma desmear processes.

Lead-free assembly processes have driven the need for greater thermal reliability. Other trends are also driving the need for greater performance. These include

- Circuit densification
- Higher circuit operating frequencies

The density of IC packaging technologies, such as ball grid array (BGA) and chip scale packages, continues to increase. In turn, this requires greater interconnection density in the printed circuits onto which they are assembled. The need for increased density in the PCB impacts each of the components of the base material as well as the way in which they are manufactured. To achieve high levels of interconnection, component pitch densities result in smaller and more closely spaced plated through holes and circuit features. As the space between these holes and features decreases, the potential for conductive anodic filament (CAF) failures increases substantially.

Higher operating frequencies can also impact each of the three main components of base materials. Circuits operating at high frequencies are driving the use of materials with low dielectric constants, low dissipation factors, and tighter thickness tolerances. These performance issues and the impact to the printed circuit manufacturing process are discussed in this chapter.

12.2 METHODS OF INCREASING CIRCUIT DENSITY

There are basically three ways to increase printed circuit density:

1. Decrease conductor line widths and the spacing between them.
2. Increase the number of circuit layers in the PCB.
3. Reduce via and pad sizes, and via-to-via pitch.

Decreasing conductor line widths requires very-low-profile copper foils for high yields in circuit etching processes. However, other things being equal, lower profiles result in decreased foil adhesion to the dielectric. Balancing the copper surface profile for both adhesion to the dielectric and the ability to etch fine circuit features, not to mention the impact of surface roughness on electrical performance at high frequencies, is an important consideration. Copper foil manufacturers continue to research methods to improve the chemical adhesion between the foil and the various dielectric materials in use, relying less on a rough surface profile for mechanical adhesion, and allowing for very low profiles for circuit etching and lower conductor losses at high frequencies.

Increasing layer counts have resulted in both greater overall multilayer thicknesses and thinner individual dielectrics, making thickness control and thermal reliability more important than ever. Adding layers to a PCB also demands improved registration capabilities. One of the critical variables in controlling registration is the dimensional stability of the laminate material, which can become more challenging with the thinner laminates used as layer counts increase. Reducing via and pad sizes also requires improved laminate dimensional stability for registration of high layer count circuits, and smaller via-to-via distances require much more thermally robust materials.

12.3 COPPER FOIL[1]

One obvious method to increase printed circuit functionality is to put more circuitry per unit area of the circuit. Printed circuit densification has driven several improvements in copper foil technology. One of the first developments was high temperature elongation (HTE) foils. Other advances include low- and very-low-profile foils, thin foils, and foils for high-performance resin systems.

12.3.1 HTE Foil

HTE or class 3 copper foil exhibits improved elongation properties at elevated temperatures as compared to standard electrodeposited or class 1 copper foil. Typical elongation values for HTE copper foil range from 4 to 10 percent at 180°C.

The growth in multilayer printed circuits has resulted in HTE becoming the most commonly used foil, since its excellent ductility at elevated temperatures helps prevent innerlayer copper foil cracking. As a printed circuit experiences a thermal cycle, the base materials will expand. The *z*-axis expansion applies stress to the connection of the innerlayer foil and the plated hole. With HTE foil, the reliability of this connection is improved. This property is particularly important in thicker circuits and high resin content constructions where increased *z*-axis expansion occurs. Virtually all copper used in multilayer PCBs today are HTE.

However, there are many variants of HTE and the terminology can become confusing. For example, virtually all reverse-treated copper foil (RTF) used in multilayer PCBs also meets the requirements for high temperature elongation (HTE). But some people will use the term “HTE” copper to refer to foil on laminate with the drum side of the foil facing out, and “RTF” to refer to the drum side against the

laminate, even though technically both foils meet the HTE requirement.

12.3.2 Low-Profile and Reverse-Treated Copper Foils

Three classifications in IPC specifications describe the profile of the copper foil surface (Table 12.1).

TABLE 12.1 Copper Foil Profiles

Foil Profile Type	Max. Foil Profile (microns)	Max. Foil Profile (μ inches)
S—standard	N/A	N/A
L—low profile	10.2	400
V—very low profile	5.1	200
X—no treatment or roughness	N/A	N/A

Copper foil profile is important for etching of fine-line circuits. Figures 10.38 through 10.41 illustrate the difference between standard- and low-profile foils. As can be seen in those photos, the tooth profile of the standard profile foil is much more pronounced. The etching of the lower profile foil results in more control of the geometry of the circuit trace. In addition, in very thin laminates, the large tooth structure of the standard profile foil can result in inconsistent dielectric thickness, making impedance control more difficult, and can even result in electrical failures if the tooth structures from the opposing sides of the laminate protrude sufficiently.

Reverse-treated foils (RTFs) take this concept a step further. When copper foil is manufactured, there is a very

smooth, shiny side and a rougher matte side. Conventional technology involved treating the matte side and laminating this side to the base material. Reverse-treated foil, as its name implies, involves putting the treatments on the smooth, shiny side of the foil and laminating this side to the base material. This has two important effects. First, the side bonded to the base material has a very low profile that aids in etching very fine circuit traces. Second, the rougher matte side, which is now on the surface of the laminate, can improve photoresist adhesion. This enables the removal of surface roughening processes during PCB manufacturing and can also improve innerlayer imaging and etching yields. Figure 12.1 compares laminates made with conventional and RTF foils.

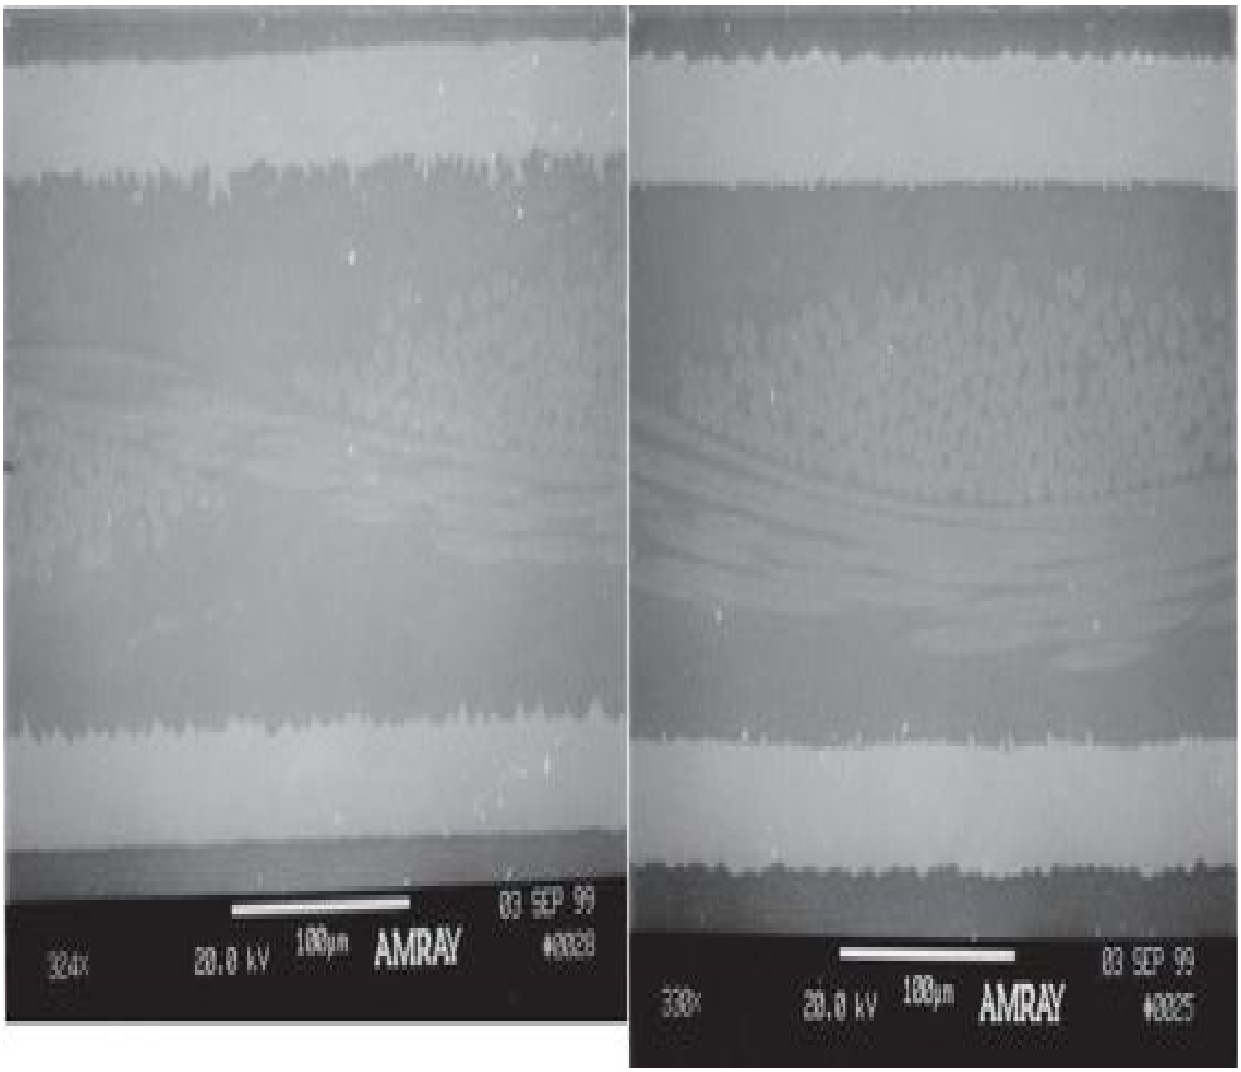

FIGURE 12.1 Comparison of laminates with standard (left) versus RTF (right) copper foils.

12.3.3 Thin Copper Foils

The capability to etch fine-line circuits is also improved through the use of thinner copper foils. Although limited current carrying capacity and higher resistance than thicker foils can limit the use of very thin foils on innerlayer circuits. These thin foils can be used on external layers since the outerlayer process involves plating on top of the foil to the desired overall thickness. HDI products primarily use this type of foil to allow for fine-line circuitry and controlled layer

thickness. 5.0 micron, 9.0 micron and 13.0 micron copper foils are mostly used. Processes to use 3.0 micron copper foil have also been developed.

12.3.4 Foils for High-Performance Resin Systems

Many of the high-performance resin systems such as BT, polyimide, cyanate ester, and even some high-T_g epoxies, especially those with high levels of inorganic filler, exhibit lower peel strengths and resistance to undermining of the copper foil when exposed to aggressive chemistries. For these applications, foils with increased nodularization and coupling agents tailored to the resin system are often used. The increased nodularization results in more surface area for mechanical adhesion whereas the specific coupling agent aids in chemically bonding the foil to the resin system.

12.3.5 Copper Roughness and Attenuation

As circuit operating frequencies increase, more of the signal travels in the outermost part of the conductor. The “skin depth”—that is, the region where much of the signal travels—is shown in Fig. 12.2 as a function of frequency. As shown in this graph, the skin depth approaches the average roughness of 0.5 oz copper foil above 1 GHz. Signal attenuation due to conductor losses related to the roughness of the foil becomes an important factor at these frequencies, and should be considered by the design engineer.

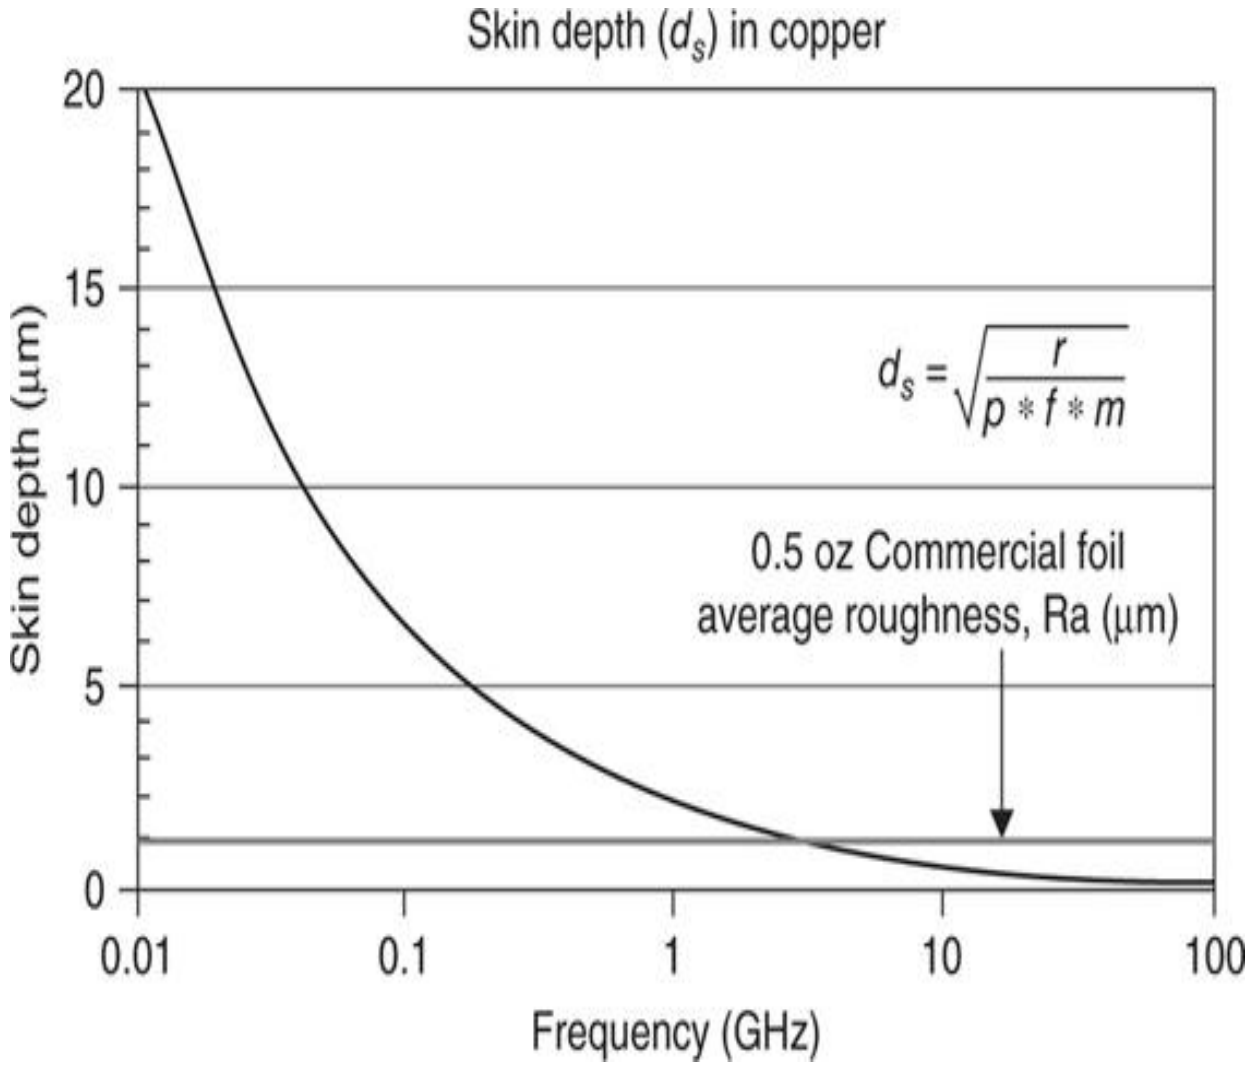

FIGURE 12.2 Skin depth versus frequency.

A study of several different copper foil types correlated roughness and attenuation values.[2] Figures 12.3 and 12.4 show pictures of the foils to highlight their relative roughness differences. Figure 12.5 shows the roughness distributions of these foils. Finally, in Fig. 12.6, the loss values associated with each of these foil types are graphed versus frequency. Up to about 1 GHz, there is very little difference in the observed loss across the several foil types. However, at higher frequencies, the difference becomes much greater, correlating to the roughness of the individual foil types; the

greater the roughness, the greater the measured attenuation.

FIGURE 12.3 Cross-sectional view of several copper foils.

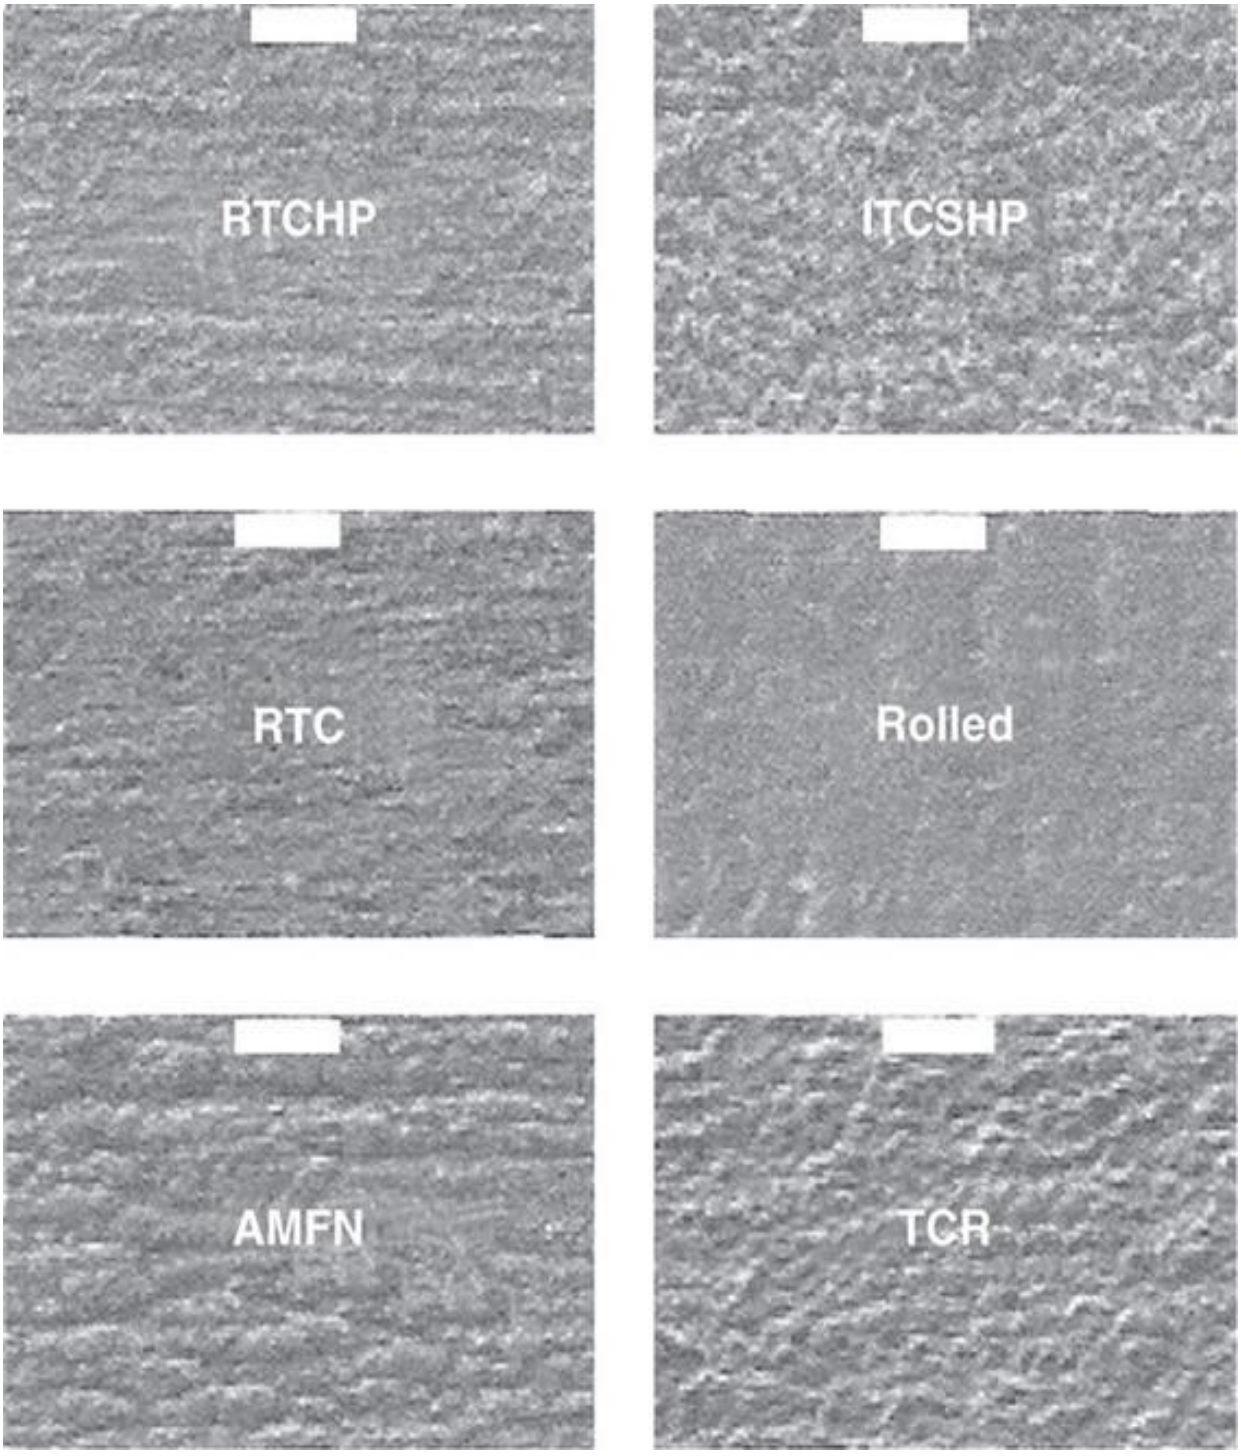

FIGURE 12.4 SEM views of several copper foils.

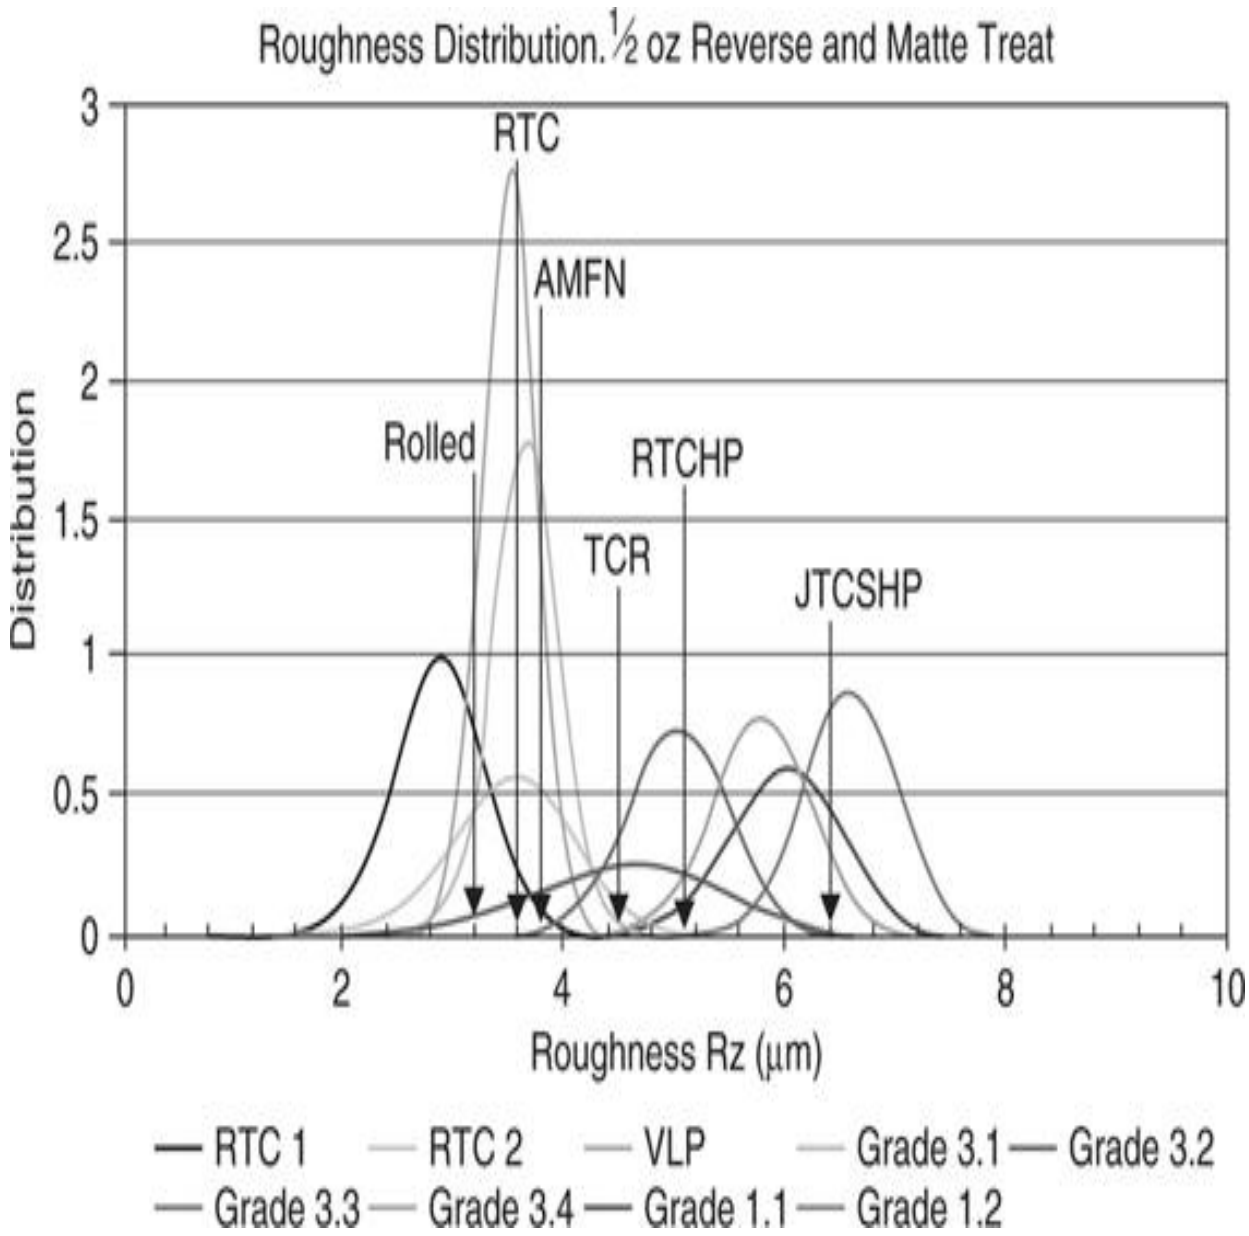

FIGURE 12.5 Roughness distributions for several foil types.

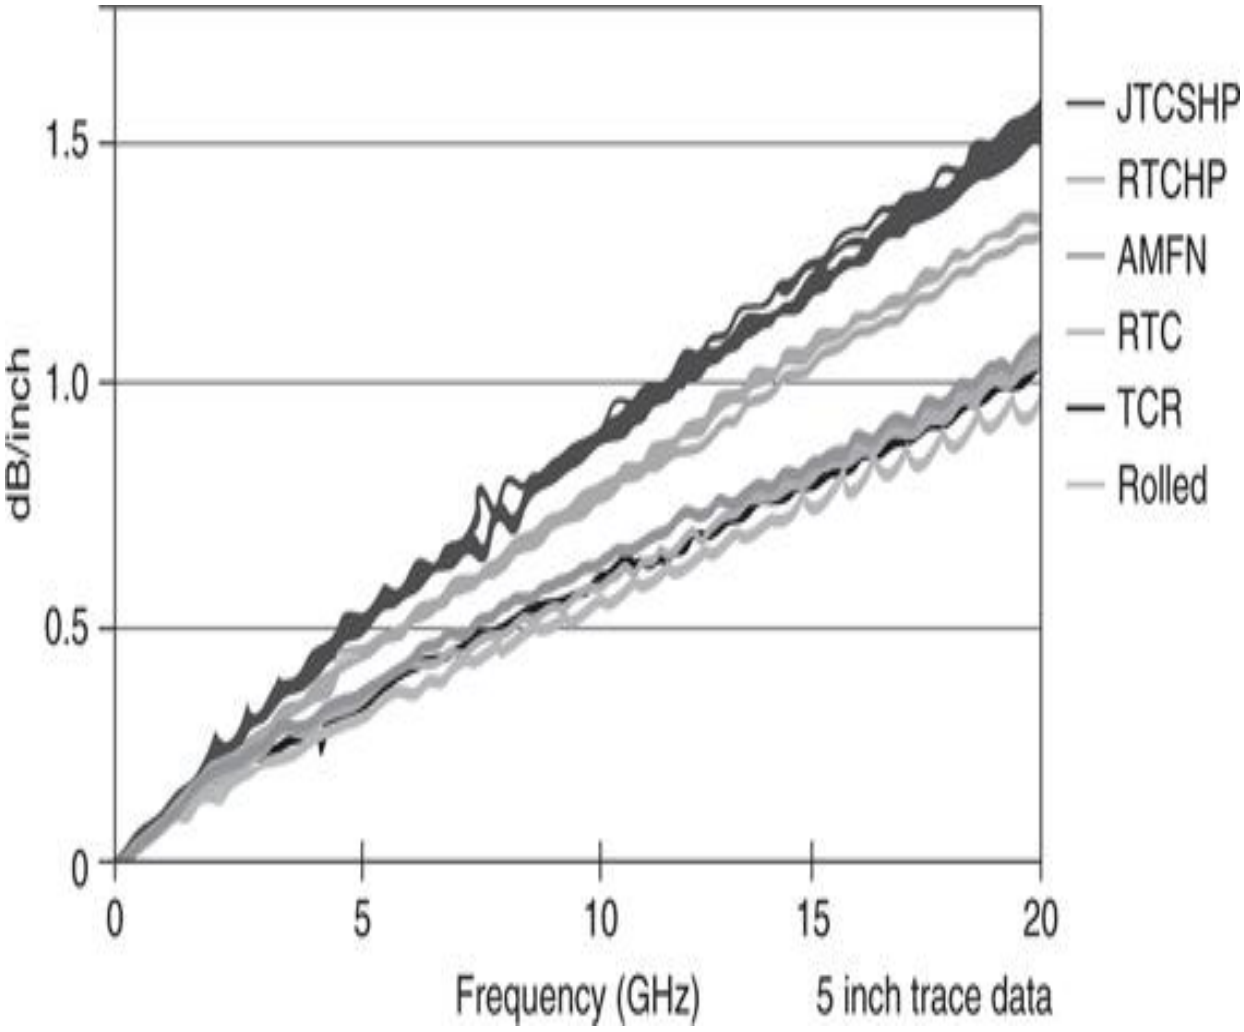

FIGURE 12.6 Loss versus frequency for several foil types.

Due to the marked improvement in performance with smoother copper surfaces, there have been significant enhancements made to copper roughness in recent years. There are no industry-standard roughness specifications for this class of copper foils currently, so they are generally marketed under trade names. However, the relevant IPC committee is working on this and the latest foil specification should be consulted. These foils are more expensive than the conventional RTF or VLP foils, so performance data for the foil should be investigated prior to use. The use of these foils becomes very beneficial at frequencies above 10 GHz.

The roughness that results from the oxide/oxide alternative surface preparation process during printed circuit manufacturing is also very important. Figures 12.7 and 12.8 compare the roughness obtained from two of these processes. The base copper foil and FR-4 resin system used were held constant. The test vehicles from which these cross sections were taken were also measured for attenuation. This measurement technique was used to calculate an effective dissipation factor, D_f, for these material sets. The measured D_f for the sample in Fig. 12.7, with the relatively smooth profile, was 0.021 at 1 GHz. The measured D_f for the sample in Fig. 12.8, with the rougher profile, was 0.026. Obviously, the rougher profile created by the oxide alternative process in Fig. 12.8 resulted in a significantly higher loss value.

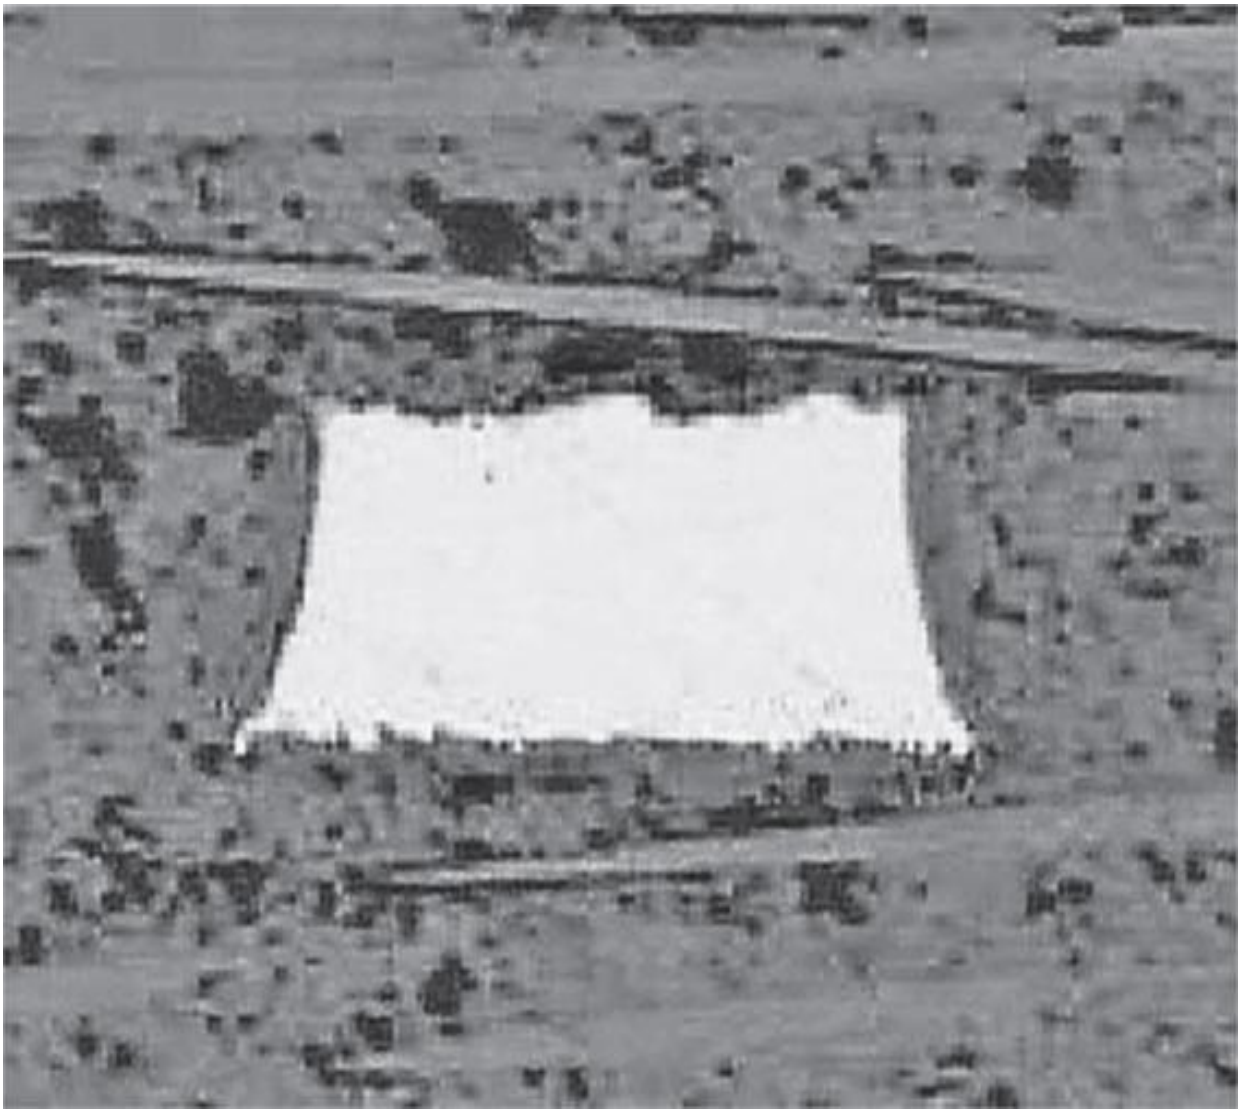

FIGURE 12.7 Copper profile obtained from process A.

12.4 LAMINATE CONSTRUCTIONS[3]

To satisfy requirements for impedance, layer count, and overall PCB thickness, a broad range of laminate dielectric thicknesses are needed. Table 12.2 shows many common laminate dielectric thicknesses, along with typical constructions and resin contents, though there are many more possibilities. Individual laminate suppliers may have preferred constructions, so not every construction shown in

this section will be available from every laminate supplier. In addition, some of the high-performance resin systems will have slightly different constructions or resin contents in order to target certain performance characteristics, such as dielectric constant.

TABLE 12.2 Common Laminate Constructions[4]

Laminate Thickness (in.)	Fiberglass Cloth(s)	Approx. Resin, %
0.0020	1-106	71–72
0.0025	1-1080	53–54
0.0025	1-1067	69–70
0.0030	1-2113	46–47
0.0035	1-1086	64–65
0.0035	1-2113	52–53
0.0040	1-2113	53–54
0.0040	1-3313	54–55
0.0040	1-106/1-1080	59–60
0.0040	2-106	68–69
0.0045	1-2116	50–51
0.0045	2-1080	55–56
0.0050	1-2116	52–53
0.0050	1-1652	42–43
0.0050	2-1080	56–57
0.0050	2-1067	69–70
0.0060	2-2113	46–47
0.0062	1-1080/1-2313	53–54
0.0080	1-7628	44–45
0.0080	1-2116/1-2313	49–50
0.0080	2-2116	45–46
0.0090	2-2116	50–51
0.0100	2-1652	42–43
0.0100	2-2116	52–53
0.0120	2-1080/1-7628	47–48
0.0140	2-7628	40–41
0.0210	3-7628	40–41

Also note that resin contents are based on weight. So care should be exercised when comparing different resin systems since the density can vary. A resin with a relatively high density will need a higher resin content by weight in order to achieve the same dielectric thickness.

12.4.1 Single-Ply versus Multiple-Ply Constructions

For many years multiple-ply constructions were the industry standard. Long ago, multiply constructions were found to be more reliable than single ply, mostly due to manufacturing quality of the time. Over the past 20 years, as quality levels greatly increased, single-ply constructions have replaced multiple-ply constructions as the standard on thicknesses up to 0.0050 in, though OEMs may still want two-ply constructions for some applications when possible. For thicknesses of 0.0050 to 0.0080 in, the use of single-ply versus multiple-ply varies with application. Above 0.0080 in, multiple-ply constructions are always used.

Within each range, there are often multiple cloth and resin content combinations that can achieve the desired dielectric thickness. The choice of laminate construction can significantly impact both cost and performance.

A single-ply construction will typically represent a cost savings compared to a multiple-ply construction, as well as generally having improved dielectric thickness control. Few applications actually require multi-ply constructions. These are mostly demanded by military/aerospace designers, and for dielectric layers between high voltage differential plane layers, or high power plane layers.

12.4.2 Resin Contents

As Table 12.2 illustrates, the same dielectric thickness can be achieved with multiple fiberglass cloth and resin content combinations. Constructions with relatively lower resin contents are often preferred since they result in less *z*-axis expansion and can therefore improve reliability in many applications. In addition, lower resin contents can also improve dimensional stability, resistance to warpage, and dielectric thickness control. On the other hand, constructions with higher resin contents result in lower dielectric constant values, which are sometimes preferred for electrical performance, which is discussed further in Sec. 12.8. In addition, a certain minimum resin content is required to ensure adequate resin-to-glass wet-out and to prevent voids from occurring within the laminate. The ability to wet out the glass filaments fully with resin is also important for CAF resistance. In summary, for each glass style, there is an optimal resin content range that balances the various performance requirements.

12.4.3 Laminate Flatness and Flexural Strength

When manufacturing the innerlayer circuit patterns, the flatness and flexural strength of the base material is important for successfully transporting these circuit layers through conveyorized equipment during PCB manufacture. This is particularly important for very thin laminates. If the laminate is curled, it can become caught or damaged inside this equipment. If the thin laminate with the circuit image sags on the conveyors, similar damage can occur.

For these reasons, it is sometimes preferred to use constructions with relatively high glass contents and use the thickest cloths possible, as this will result in greater flexural strengths, bearing in mind the performance requirements just discussed in Sec. 12.4.2. In addition, *balanced*

constructions, or those that use a symmetrical construction, are normally preferred to avoid curling. Asymmetrical constructions are more prone to curling and causing problems in conveyorized equipment in the PCB manufacturing process. Consider a 0.0080-in laminate as an example. Table 12.2 shows three constructions for this thickness, 1-7628, 1-2313/1-2116, and 2-2116. The asymmetrical 1-2313/1-2116 construction will be more prone to curling than the other constructions. A word of caution is warranted, however. Curling is but one property that must be considered. Dimensional stability, thickness control, electrical, thermal and possibly CAF properties must also be considered when choosing a construction.

12.5 PREPREG OPTIONS AND YIELD-PER-PLY VALUES

Just as there are a variety of base laminate constructions, there are a variety of prepreg options. Each fiberglass cloth style can be treated to multiple resin contents and flow values. While the same properties must be considered for prepreg materials as for base laminates, prepregs must also contain sufficient resin to flow and fill in the innerlayer circuitry of a multilayer circuit board. Since the innerlayer circuits can vary in terms of copper thickness and circuit density, a variety of resin content and flow value options are typically required when specifying prepreg styles. Higher resin contents may be needed when filling heavy copper weights and signal layers, while lower resin contents can be used against lighter copper weights and power or ground circuit patterns. And as noted above, some resin systems are more dense than others, so when choosing a prepreg resin content based on weight, the user should be aware that a higher resin content may be needed to ensure enough resin

volume for filling circuitry and thickness in the dielectric. Table 12.3 shows some common prepreg styles with various resin contents and thickness yields per ply.

TABLE 12.3 Common Prepreg Styles with Examples of Thickness for One Product[4]

Glass Style	Approximate Resin Content, %	Thickness, in*
106	66	0.00175
106	71	0.0020
106	75	0.00225
1067	70	0.0024
1067	74	0.0027
1080	57	0.0025
1080	64	0.0030
1080	66	0.00325
1086	64	0.0033
1086	68	0.0036
2113	50	0.0035
2113	55	0.0040
3313	55	0.0040
3313	59	0.0045
2116	50	0.0045
2116	52	0.00475
2116	55	0.00525
7628	40	0.0070
7628	42	0.00725
7628	44	0.0075
7628	45	0.00775

12.6 DIMENSIONAL STABILITY

As circuit layer counts grow and via-to-pad size ratios get tighter, the alignment or registration of the layers of circuitry become extremely important. Although several material and process variables contribute to the capability to achieve layer-to-layer and via-to-innerlayer feature registration, laminate dimensional stability is one of the most important. This is especially true in high-layer-count circuits that use thin laminates, since thinner laminates are generally not as dimensionally stable as thicker laminates.

12.6.1 Dimensional Stability Test Methods[5]

A common test method used to evaluate dimensional stability starts with a sample of a copper-clad laminate with scribed targets or holes in the four corners of the sample. Baseline measurements of the distances between these holes are taken prior to conditioning of the sample. One conditioning procedure involves etching the copper cladding off and remeasuring and determining the dimensional movement compared to the baseline. A second method subjects the sample to a thermal cycle, commonly a bake at 150°C for 2 hours. Again, measurements are taken after conditioning and compared to the baseline dimensions. A third method involves first etching the cladding off, measuring, subjecting the sample to the bake cycle, and measuring again. Each of these methods can be used as a process control tool in the laminate manufacturing process.

However, these test methods are of limited value to the printed circuit manufacturer, who etches circuit images on these laminates, combines them with prepreg materials and other laminates, and presses them together under

temperature and pressure to form a multilayer circuit. It is the predictability and consistency of laminate movement through the printed circuit manufacturing process, across a variety of circuit patterns and especially through the multilayer lamination cycle, that is of concern for the circuit manufacturer and ultimately for the designer who wants to increase circuit density. Multilayer lamination cycles commonly reach 185°C or higher, and normally exceed the T_g of the base material. Above the T_g, the resin softens and allows tension in the laminate to be released and is also subject to stresses from the surrounding materials and lamination pressure. Most of the movement of the laminate in the circuit manufacturing process occurs during this lamination cycle.

12.6.2 Improving Dimensional Stability

Although many variables in laminate and circuit manufacturing processes can influence dimensional stability, some common techniques involve laminate press cycle optimization, control of laminate resin contents, and the use of higher T_g materials. New materials and process techniques have also been developed to improve dimensional stability.

12.6.2.1 Laminate Manufacturing Process Considerations. Many laminate manufacturers reduce the lamination pressure at a specified point in their lamination cycle to minimize the stress that becomes stored in the finished product, which improves subsequent dimensional stability.

Other process controls in the laminate manufacturing process are also important for dimensional stability. Control of the raw materials, especially the glass cloth, can

contribute to dimensional stability. The tension applied to the cloth during the treating process, the heat rise, temperature, and pressure profiles during lamination, as well as laminate stack-up techniques during lamination can all affect dimensional stability. Consistency in these parameters will generally improve the consistency observed during the printed circuit manufacturing process.

12.6.2.2 Impact of RTFs. RTF copper foils typically allow the elimination of surface-roughening processes in the innerlayer circuit imaging process. These surface-roughening processes can be mechanical scrubbing processes that can stretch or distort thin laminates. In addition, variation in the mechanical scrubbing process over time can introduce lot-to-lot variation, which adversely impacts registration capabilities. RTF foil, which facilitates the removal of these scrubbing processes because of the improved photoresist adhesion to the matte side of the foil, can therefore result in improvements in registration capability.

12.6.2.3 Fiberglass Cloths and Resin-to-Glass Ratios. Each fiberglass cloth style used in laminates and prepregs has a resin content range that results in sufficient wet-out of the glass cloth, is relatively easy to control, and therefore results in more uniform thickness and more consistent dimensional stability. The specification of laminates and prepregs with resin contents in the desired ranges can result in improvements in dimensional stability and therefore registration capabilities. As a result, having a range of fiberglass cloth styles available is important to be able to achieve a wide range of dielectric thicknesses.

12.6.2.4 Nonwoven Reinforcements. Because of the woven, serpentine geometry of the yarns in fiberglass cloths, they can behave like springs when used as the reinforcement of base materials. During the resin treating process and the

laminate pressing operation, the fiberglass cloth is subjected to stresses that can be stored in the laminate as the resin is cured. These stresses can then be released during the circuit manufacturing process, causing dimensional changes.

Nonwoven materials can avoid these stresses. In one nonwoven material type, short, randomly oriented fibers are treated with the resin system. In a second type, linear strands of fiberglass are laid down in a balanced, cross-plied orientation, which resists subsequent stresses.

12.6.2.5 Multilayer Press Cycle Optimization. Most of the dimensional changes in the laminate occur during the multilayer press cycle when the temperature exceeds the T_g of the resin in the laminate. Above the T_g, the resin system in the laminate softens and allows any stored stress in the reinforcement to be released and allows the laminate to be affected by the adjacent materials and the pressure of the lamination cycle.

Understanding the rheology of the resin in the prepreg is important when designing the multilayer lamination cycle. The point at which the resin begins to melt, the point at which it begins to cure, and the relationship between the heat rise and the viscosity profile of the resin are all important. With respect to viscosity, not only is the minimum viscosity achieved important, but the length of time that the resin is below a certain viscosity, allowing the resin to flow and fill the internal circuit features, is also important. With an understanding of these parameters, it is possible to design “kiss” cycles, or “soak” cycles, where pressure and temperature profiles, respectively, are designed to improve performance, including dimensional stability.

In addition, although seldom done in practice, using a resin system in the prepreg materials that can be cured below the T_g of the resin system in the laminate can avoid the softening of the laminate resin system and therefore prevent

much of the movement that takes place. The resistance to the use of this technique is usually driven by a desire to keep the resin system same throughout the multilayer PCB.

12.7 HIGH-DENSITY INTERCONNECT/MICROVIA MATERIALS

One method used to increase circuit density is to use blind and buried vias. Rather than placing a via hole completely through the PCB, blind and buried vias go only partly through the multilayer circuit, joining only the layers that require connection. By not extending these vias through the entire multilayer, real estate on the other layers becomes available for additional circuit routing. Buried vias are those that are not visible from the outside of the finished circuit board, and are formed in a subcomposite or copper-clad laminate. Blind vias are those that are visible from the outside of the multilayer circuit but do not go completely through it. By limiting the size of these vias, you can significantly increase interconnection density. Microvia or high-density interconnection (HDI) printed circuit designs utilize these technologies to increase circuit density.

While the materials already discussed are used in blind and buried via applications using conventional processes, additional materials can be used to increase density using more specialized materials and process techniques. The specialized processes used to form microvias include laser ablation, plasma etching, and photoimaging, with laser formation by far the most common today.

The resin system will generally ablate much faster in laser drilling processes. Also, plasmas are not effective in etching through fiberglass. As a result, materials that use an alternative reinforcement or do not contain an inorganic

reinforcement have been developed for some types of applications.

For blind via applications, resin-coated copper foil can be used to form the external circuit layer and dielectrics between layers 1 to 2 and n to $n - 1$, using laser or plasma processes to form the vias. Buried vias could be formed in sequential processes. Two basic types of resin-coated copper foil have been used. The first type uses one layer of partially cured resin (see Fig. 12.9).

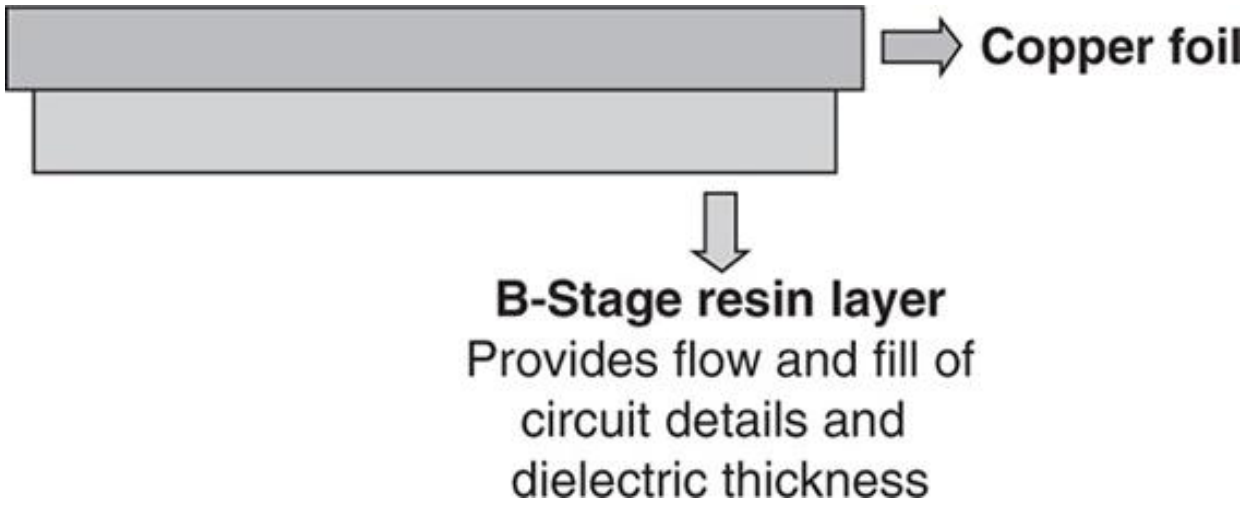

FIGURE 12.9 Resin-coated copper foil with a single layer of B-staged resin.

This resin-coated foil is then laminated to the rest of the multilayer circuit. A second type of resin-coated copper foil uses two layers of resin (see Figs. 12.10 and 12.11). The first layer is fully cured whereas the second is partially cured. This technique guarantees a minimum dielectric separation between the external foil and the circuitry on the next layer in, since the cured resin layer limits how close the internal circuit layer can get to the external foil.

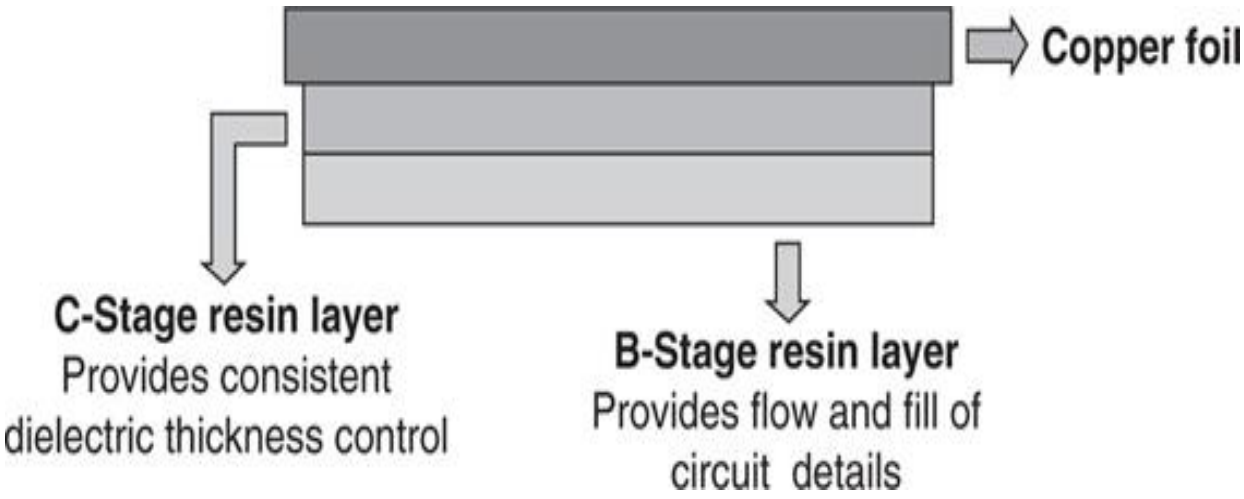

FIGURE 12.10 Resin-coated copper foil with a C-stage and B-stage layer.

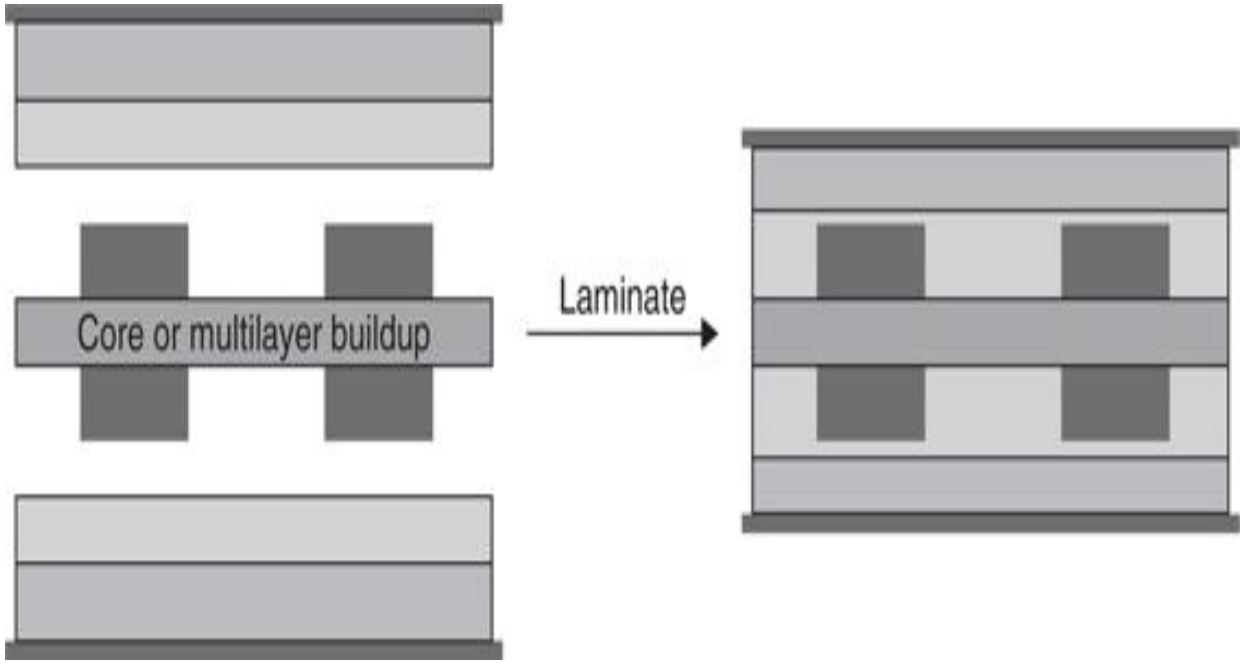

FIGURE 12.11 C-stage plus B-stage resin-coated copper foil laminated to PCB.

Other materials used in HDI designs utilize an organic reinforcement that can be laser ablated or plasma etched. These systems use proprietary polymer systems and can have a variety of properties.

Another process technique used in these applications involves photoimaging a permanent dielectric material in order to form the microvias. These photoimageable

dielectrics resemble plating resists but must be able to be catalyzed for subsequent plating operations that will form the external circuit image, and must adhere sufficiently to the rest of the multilayer circuit to provide long-term reliability.

12.8 CONDUCTIVE ANODIC FILAMENT GROWTH

Conductive anodic filament (CAF) formation is a term used to describe an electrochemical reaction in which conductive paths are formed within a dielectric material due to transport of metal or metal salts through the dielectric. These paths may form between two circuit traces, between two vias, or between a trace and a via, as illustrated in Fig. 12.12. CAF formation between a hole and a plane inside the PCB is also possible, and is similar in concept to hole-to-trace CAF formation. By definition, as circuit density increases, the space between these features decreases. With shorter paths between features, CAF growth becomes a more critical reliability consideration.

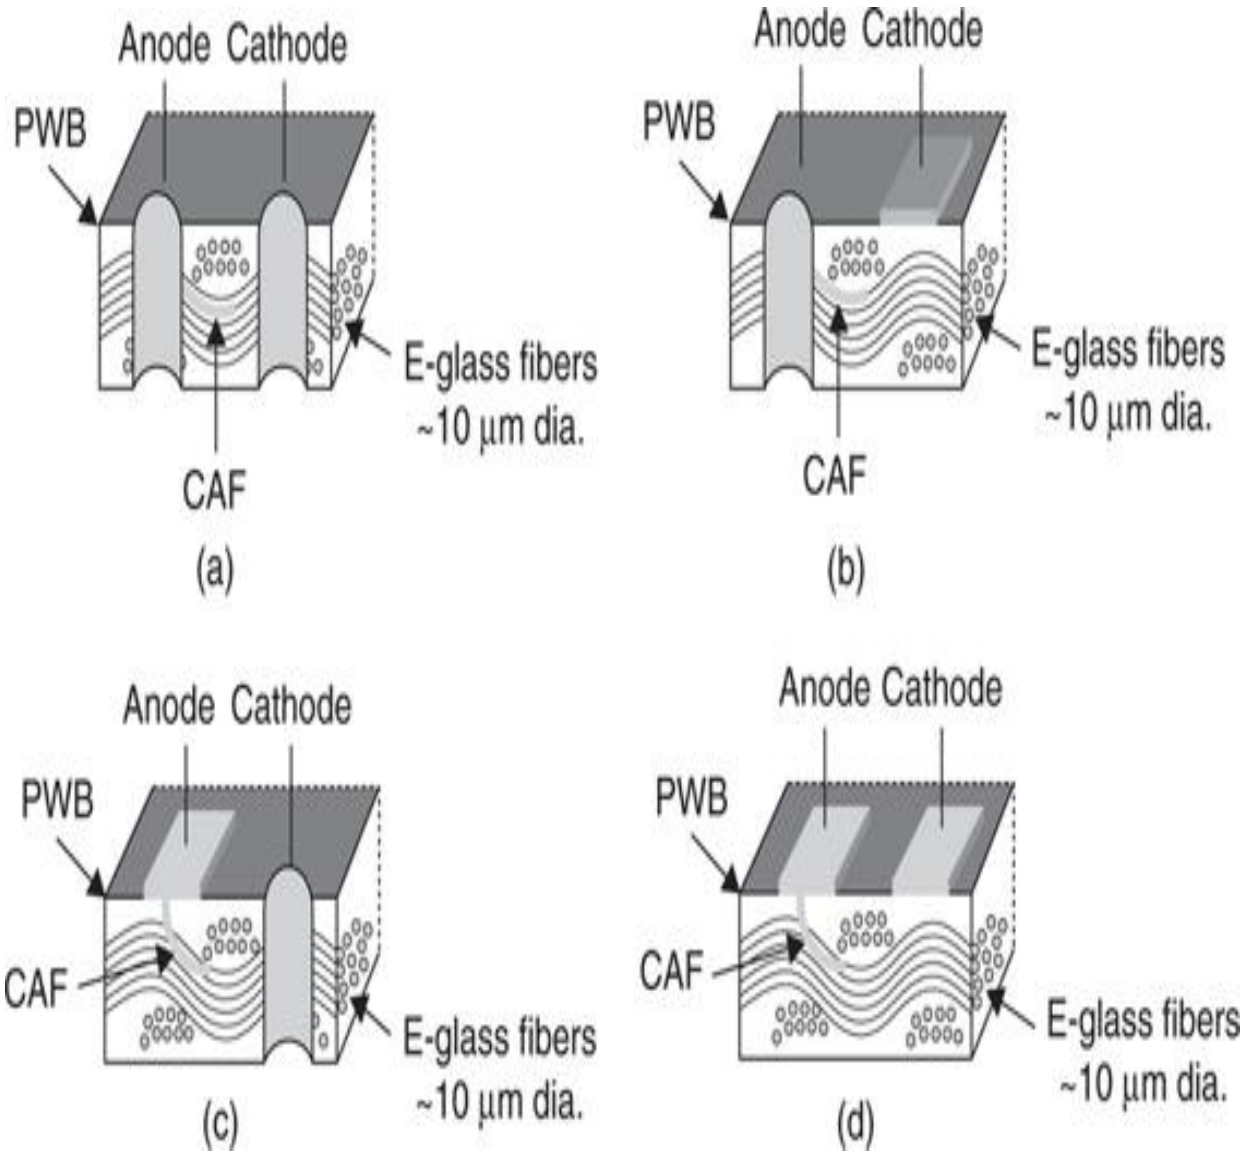

FIGURE 12.12 Pathways for CAF formation: (*a*) hole to hole, (*b*) hole to track, (*c*) track to hole, and (*d*) track to track.

For CAF growth to occur, a bias and a path for this filament growth must be present. In fiberglass-reinforced materials, a gap between the resin and the fiberglass filaments is the most common pathway. If the glass is not completely wet-out with resin, or if the bond between the resin system and the fiberglass filaments is insufficient or is compromised, the resulting gap can become such a path. Hollow fiberglass filaments can also provide a path. In addition, there must be a medium in which this electromigration can occur, such as

absorbed moisture that allows dissolved ionic species to migrate and promote the electrochemical reaction that leads to CAF. Figure 12.13 is an actual example of CAF formation.

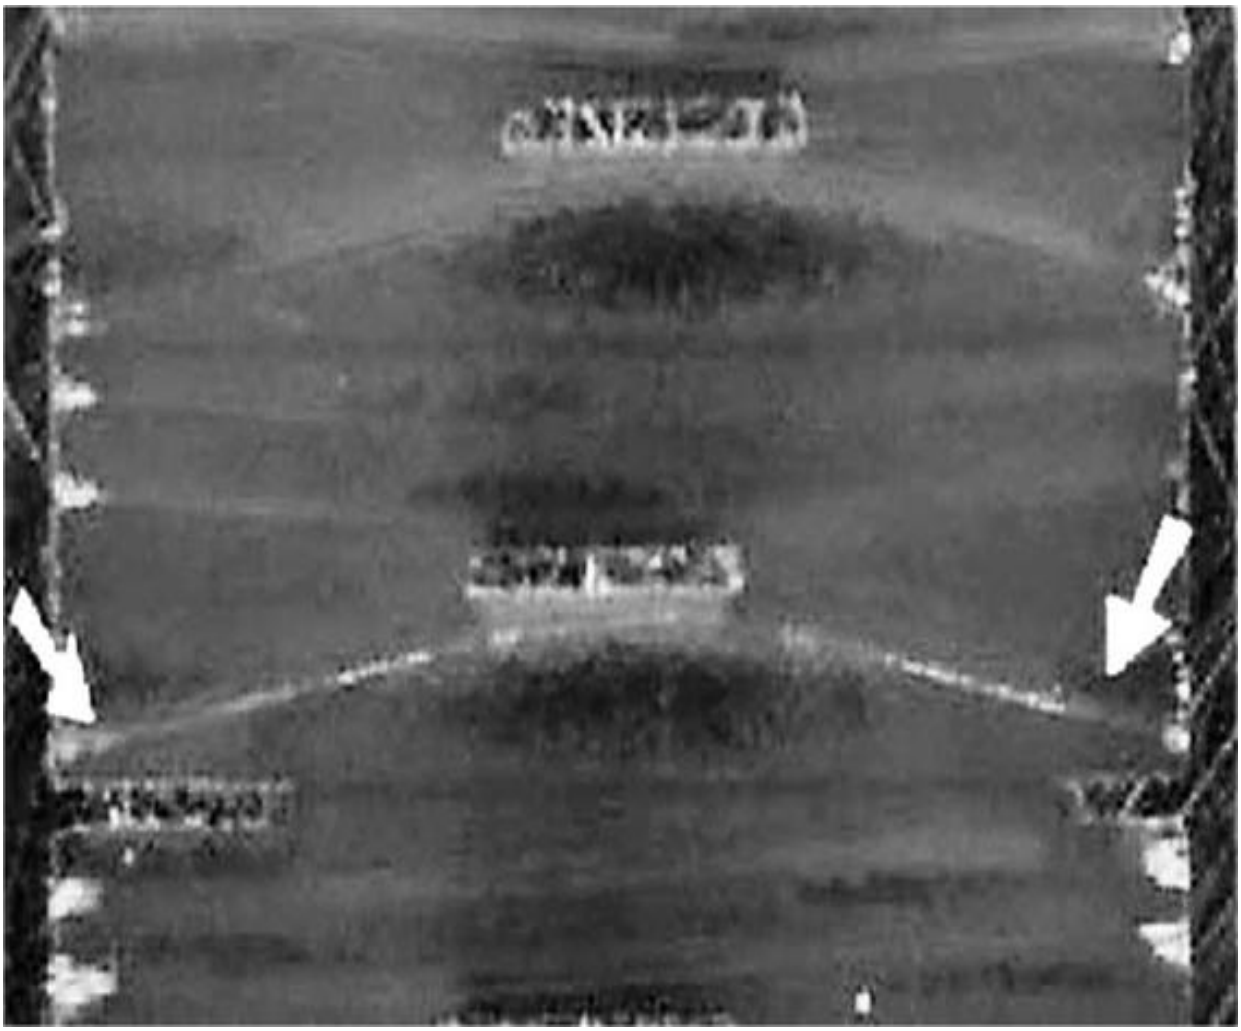

FIGURE 12.13 An example of CAF between two plated through holes.

End product use also influences the overall risk. In general, low voltage and office equipment environments where humidity is low, are lower risk. Outdoor uses, such as automobiles, military, airplanes, and outside electronics are much higher risk, as temperature and humidity levels in the operating environment can be higher.

Product design has a large role in determining CAF risk. If you are concerned about CAF formation in a product under

design, there are sources of good information on reducing CAF risk with design. This is the easiest and least expensive way to manage CAF risk.

A later chapter in this book is devoted specifically to CAF, and further discussion is provided in the next chapter on selecting materials, but the following items present some key findings of CAF research:

- CAF is a two-step process consisting of path formation and the electrochemical reaction.
- The filament is usually in the form of a copper salt.
- Moisture absorption can influence the rate of CAF formation, and there is a minimum threshold for moisture absorption below which CAF is unlikely to occur.
- Temperature can influence the rate of the electrochemical reaction.
- The level of voltage bias can also influence the rate of CAF formation.
- Resin-to-glass wet-out is critical in that it eliminates a potential pathway.
- Beyond glass wet-out, the bond between the resin and the glass is important to ensure that adhesion is not lost due to moisture or thermal stress. Selection of the coupling agent used to improve adhesion between the resin and the glass is critical in this regard, and different resin systems may require different coupling agent types. Figure 12.14 shows examples of silane coupling agents, where “R” represents various chemical species that can be modified for different applications.

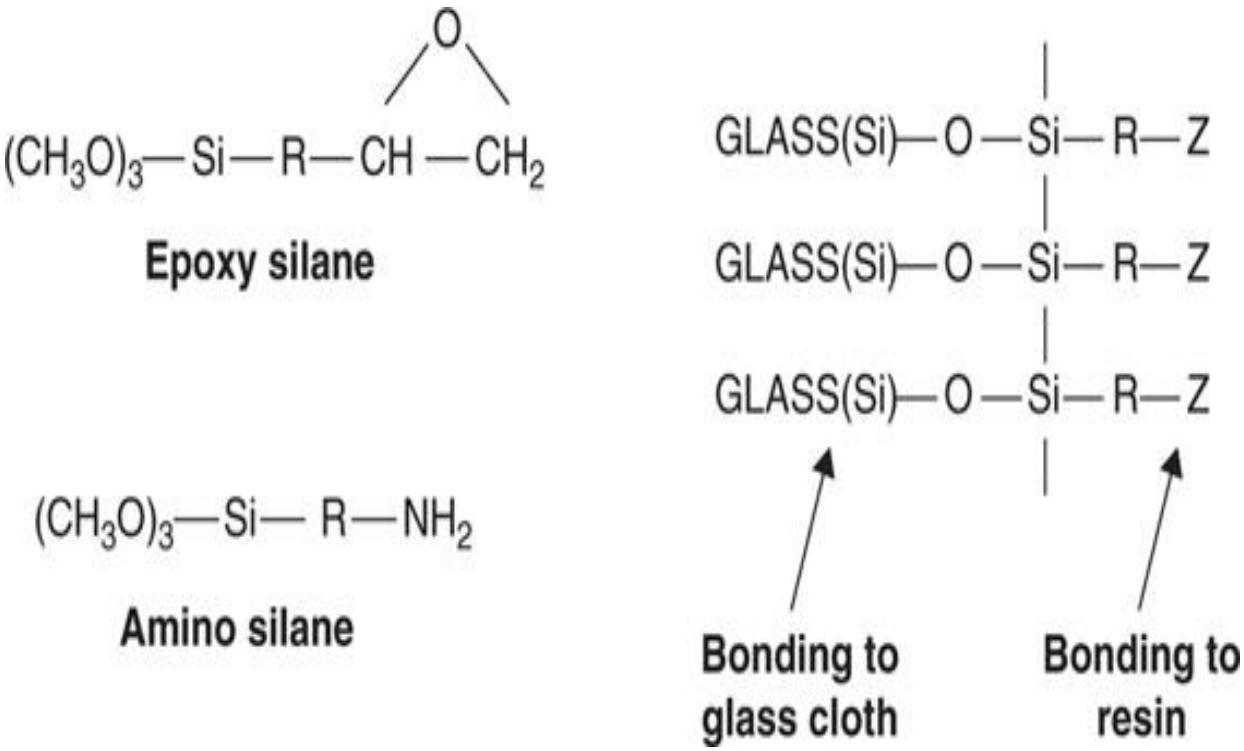

FIGURE 12.14 Examples of silane coupling agents.

- The cleanliness of the glass, both before coating with silane as well as prior to coating with the resin system, is important to ensure proper wetting and bonding of resin to glass.
- The curing agent used in the resin system can influence CAF formation. This may be due to the tendency of some curing agents to absorb moisture, or to the electrochemical nature of the specific curing agent, or both.
- Contaminants on the glass cloth or within the resin system can also accelerate CAF formation. For example, residual hydrolyzable chlorides present in some epoxy resins are known to catalyze electrochemical reactions that can lead to CAF.
- Resin system thermal stability and thermal expansion may influence performance as well, especially as lead-free assembly processes cause PCBs to be subjected to more severe thermal excursions. This is due to the possibility of

thermal decomposition of the resin causing reduced resin-to-glass adhesion or even voids within the laminate that can provide path- ways for CAF formation. With respect to thermal expansion, the higher temperatures of lead-free assembly result in a greater total stress at the resin-to-glass interface due to the CTE mismatch between them. If this stress is high enough, or the bond strength low enough, separation of the resin from the glass can occur and provide a pathway for CAF as well.

The processing used in printed circuit fabrication can also influence CAF resistance. Some of the factors to consider in PCB fabrication include the following:

- The innerlayer surface must be clean. Adequate rinsing of the innerlayers after chemical processes is important to minimize residual ionic contamination.
- Storage conditions and shelf life of prepreg materials are important to control to ensure adequate flow properties during multilayer lamination.
- Multilayer lamination processing is important to ensure good resin flow and full wetting of resin to glass in the prepreg layers. Vacuum, temperature, and pressure profiles are all important.
- Drilled hole quality is also important. With respect to CAF performance, minimizing resin- to-glass fracturing that can result in excessive wicking of plating chemistries is critical.
- Control of desmear and electroless copper-plating chemistries is also important. Minimizing any further attack of the resin-to-glass interface and plating into the dielectric are the key considerations. Good rinsing to minimize residual ionic contamination from these processes is also important.

12.8.1 CAF TESTING

Many different types of test vehicles are used to assess CAF performance, but most include the design features described in Fig. 12.12. Differences between common test vehicles include the distances between features, the thickness and layer counts of the PCBs, and the glass styles and resin contents used to build the PCB. All of these factors influence CAF, if not directly, as a result of the processes used to build the specific test vehicle. In addition, testing parameters such as bias, temperature, and humidity also influence results. Various OEMs will also have different requirements for the time of testing, with typical time requirements ranging from 500 to 1000 hours.

Figure 12.15 shows an example of CAF found in one test vehicle. In this case, the pathway formed between individual filaments of the glass cloth, either because they had not been sufficiently coated with resin or because resin decomposition, moisture, or other volatile compounds created a void.

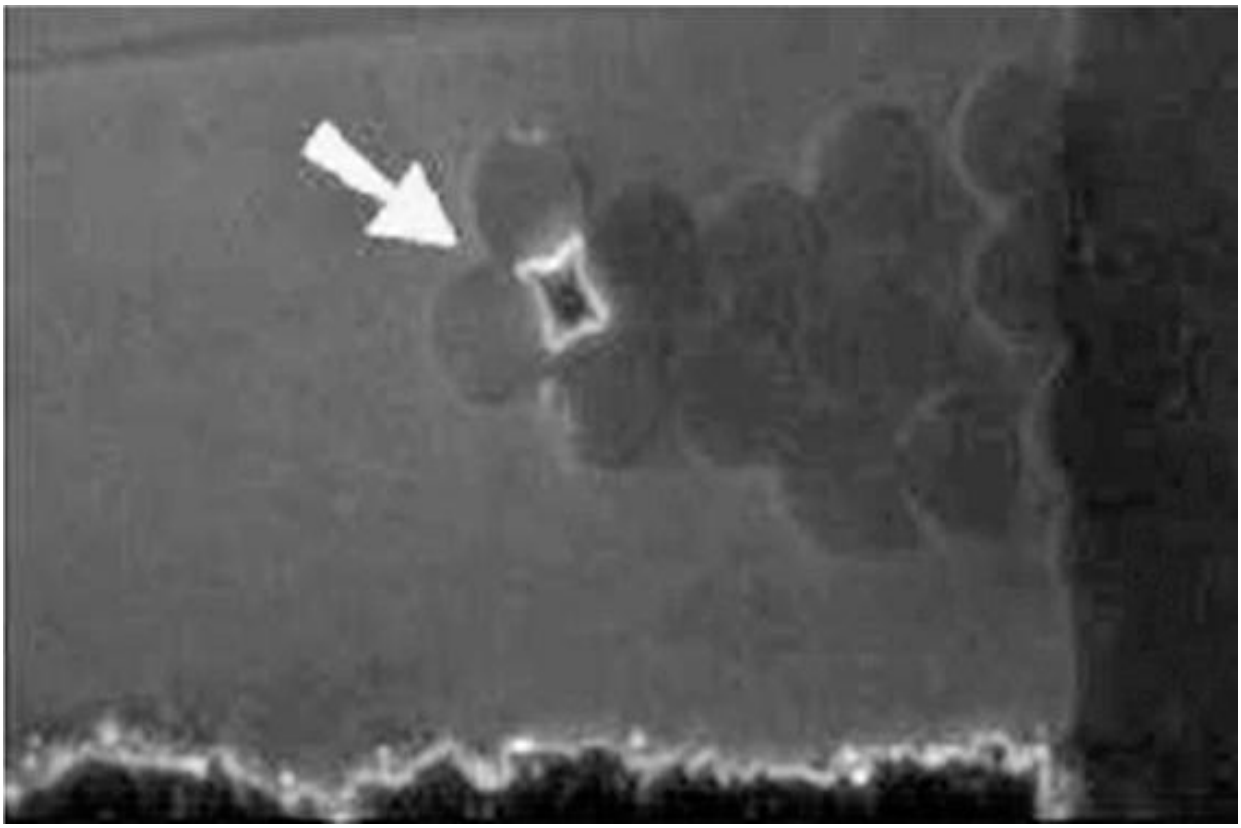

FIGURE 12.15 CAF formation between glass filaments in a PCB test vehicle.

A general suggestion for CAF testing is to perform failure analysis on at least some of the failed nets. The failures could be unrelated to material, as many fabrication issues cause the same results. Also, the failure may not be internal to the PCB, but along the surface, which is not a CAF type failure. The key is to make the correct decision about the material to use, and this will be discussed further in the next chapter.

Using material that has been functionally tested for CAF resistance is a recommended practice if you have concerns about products failing for CAF. Either set up your own testing or ask to see testing data run at an independent testing lab.

12.8.1.1 CAF Test Example #1. A common test vehicle used to assess CAF performance consists of a 10-layer PCB, often made of single-ply 2116 style dielectrics in each of the

core and prepreg layers, though other glass styles can and should be evaluated. Common test conditions are either 65°C/85 percent relative humidity (RH) or 85°C/85 percent RH, with 10 or 100 V bias. This test vehicle includes design features such as those shown in Fig. 12.12, but the hole-to-hole features are typically the most critically examined. In addition, placement of the holes relative to the glass cloth weave can influence results. When the holes are placed in line with the glass weave, the filaments can bridge the holes, providing a potential CAF pathway. If the holes are placed diagonal to the weave orientation such that no individual filament bridges two holes under test, this potential pathway is eliminated. In practice, holes placed in line with the glass weave are the most relevant for assessing CAF resistance. Hole spacing is a critical parameter, and this particular test vehicle examines holes placed approximately 10, 15, 20, and 25 mil apart. Although the definition of failure can vary slightly from OEM to OEM, the criteria usually consist of some minimum insulation resistance value, and often a maximum decrease in resistance of one order of magnitude, or “a decade drop in resistance.” Figure 12.16 provides results for one laminate material processed by one PCB fabricator.

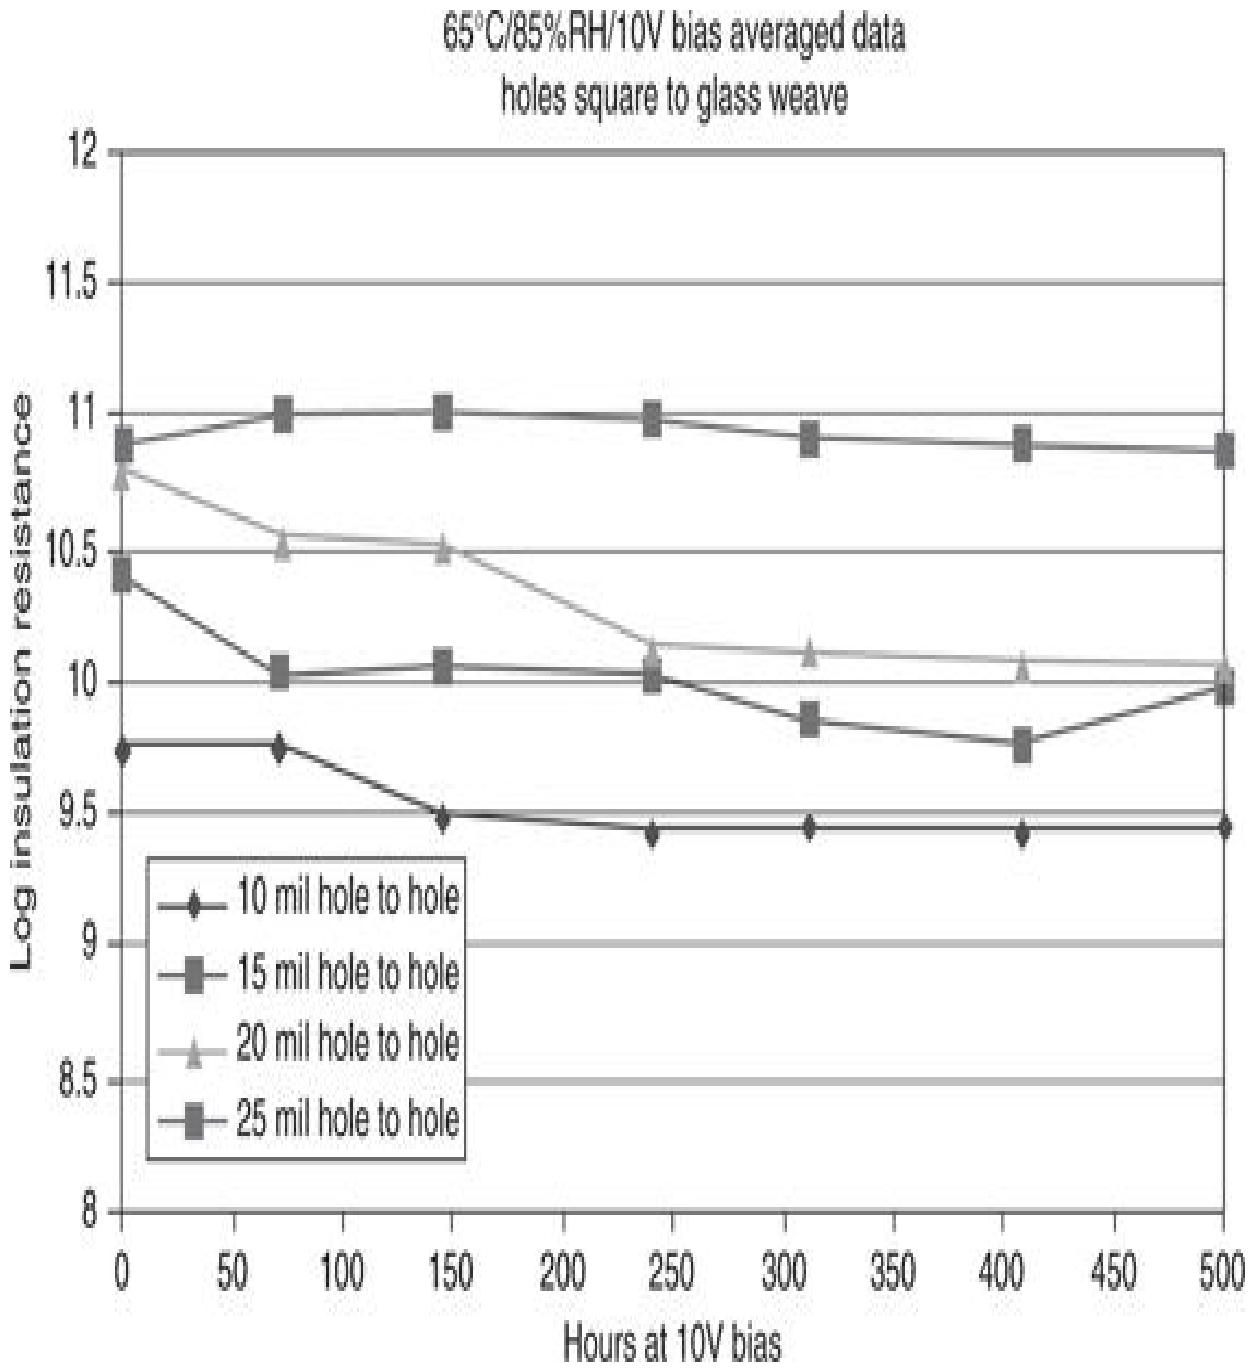

FIGURE 12.16 Insulation resistance CAF test results for example #1.

This chart plots average insulation resistance for 25 test coupons (on a log scale in this example) versus time in hours at a 10 V bias with 65°C/85 percent RH environmental conditions. It also shows the data separately for the 10, 15, 20, and 25 mil hole-to-hole spacings. Other things being

equal, average insulation resistance will be higher for holes spaced further apart, as this means there will be more dielectric between features. For this particular test, the average insulation resistance for each spacing did not decrease by an order of magnitude, indicating good results. However, it is also important to examine the individual coupons tested, and a common way to assess performance in this regard is to calculate the percentage of individual test coupons that pass or fail. Figure 12.17 provides this data for this same test, and shows results for the test material highlighted in Fig. 12.16 versus a control group that utilized a different laminate material.

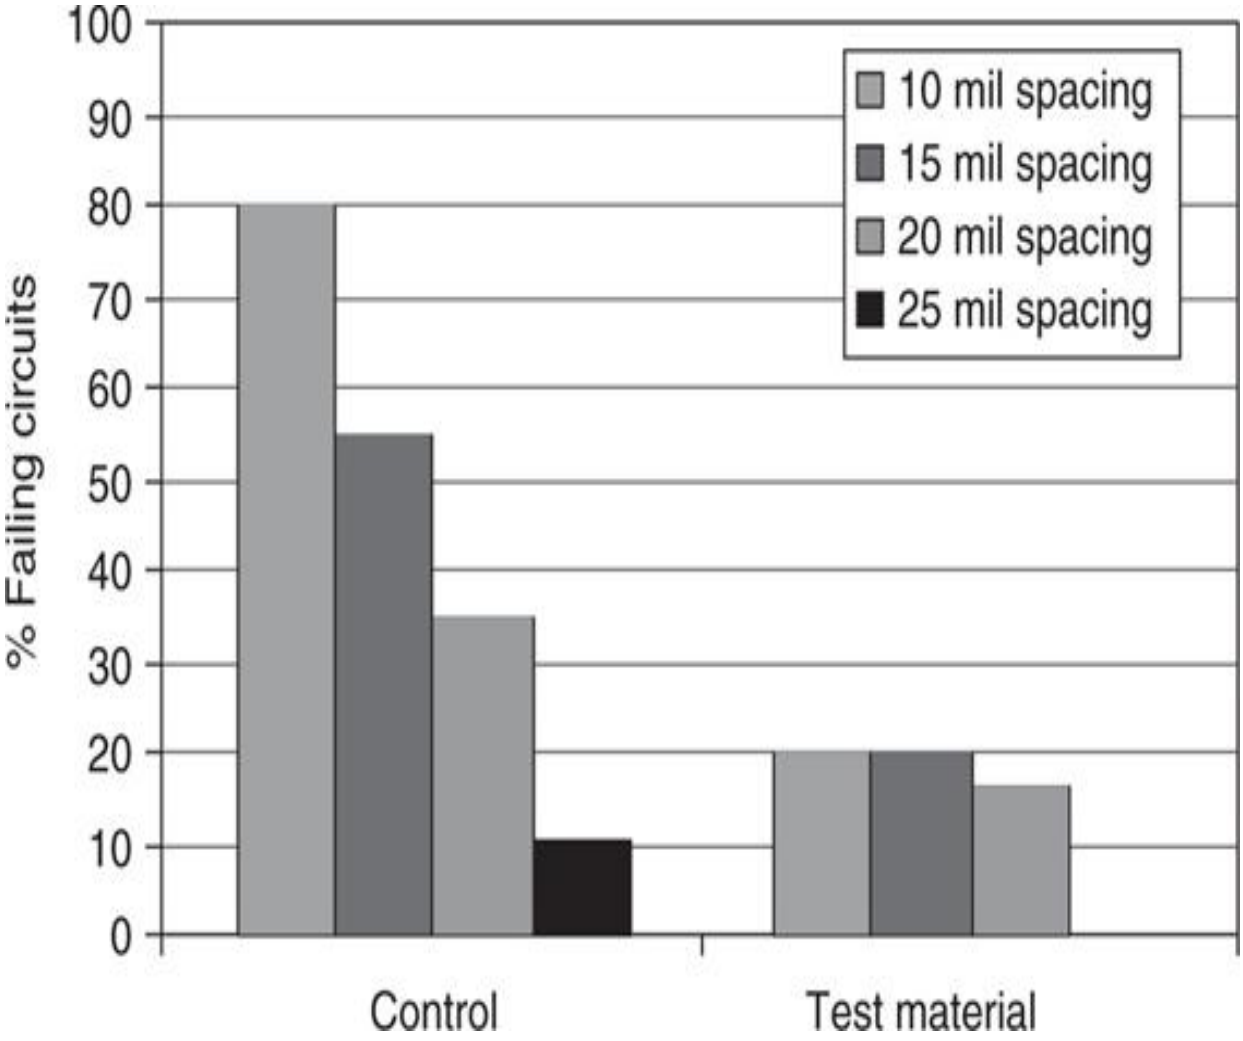

FIGURE 12.17 Percent failing coupons in CAF test example #1.

As is common, the control group shows fewer individual failures as the spacing between holes increase. The test material shows a much lower percentage of individual failures for each spacing. As stated earlier; however, it is important to perform failure analysis in order to determine if the failures in terms of insulation resistance were really caused by CAF, or by some other defect such as contamination.

12.8.1.2 CAF Test Example #2. In a second example, four commonly available FR-4 materials were compared by building the same CAF test vehicle as described in example #1. These materials are all promoted as being "CAF-resistant." The coupons were manufactured by the same PCB fabricator during the same time period. In this evaluation, the test conditions were 100 volts bias, 85°C and 85 percent RH. The same hole-to-hole spacings were evaluated, but for simplicity, Figs. 12.18 and 12.19 show only the data for the 15 and 25 mil spacings, respectively. It is common to use a 1 MΩ resistor in series with the test point in these tests, so where the average insulation resistance drops to 10^6 Ω (6 on the *y* axis of the chart), this indicates that the resistance has dropped excessively and it is the resistor that is now being measured. In this evaluation, materials A, C, and D all drop to this level at 500 hours of testing with 15 mil hole-to-hole spacings. At 25-mil spacings A and C both drop to this level. B and C do not, but C drops in resistance by more than one order of magnitude. Only material B drops by less than one order of magnitude at both spacings. By these criteria, materials A, C, and D would have failed this test. Only material B passed.

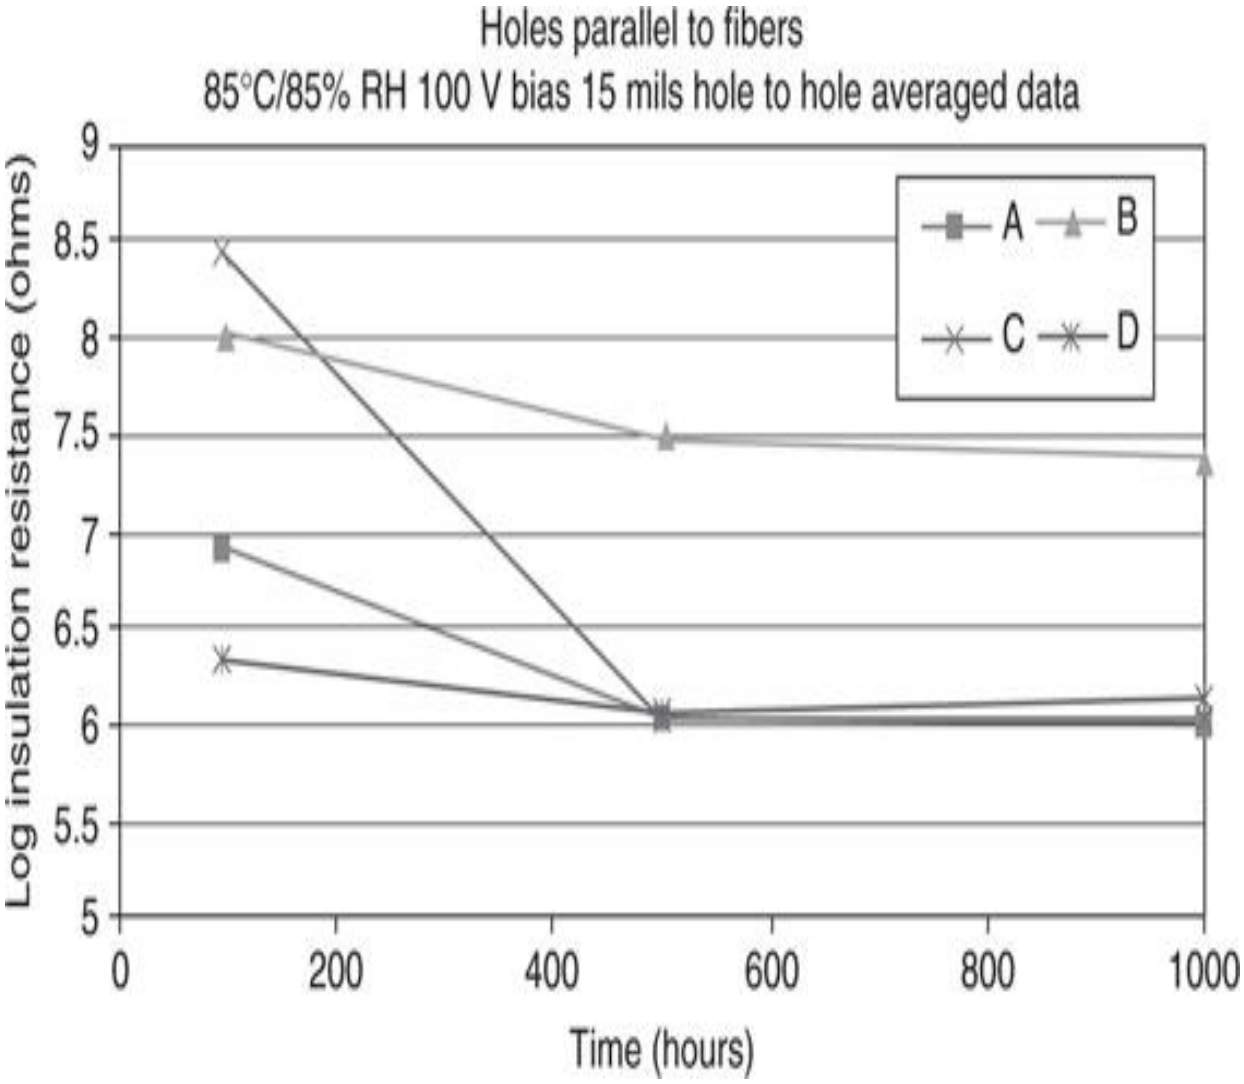

FIGURE 12.18 CAF results for 15-mil hole spacings in example #2.

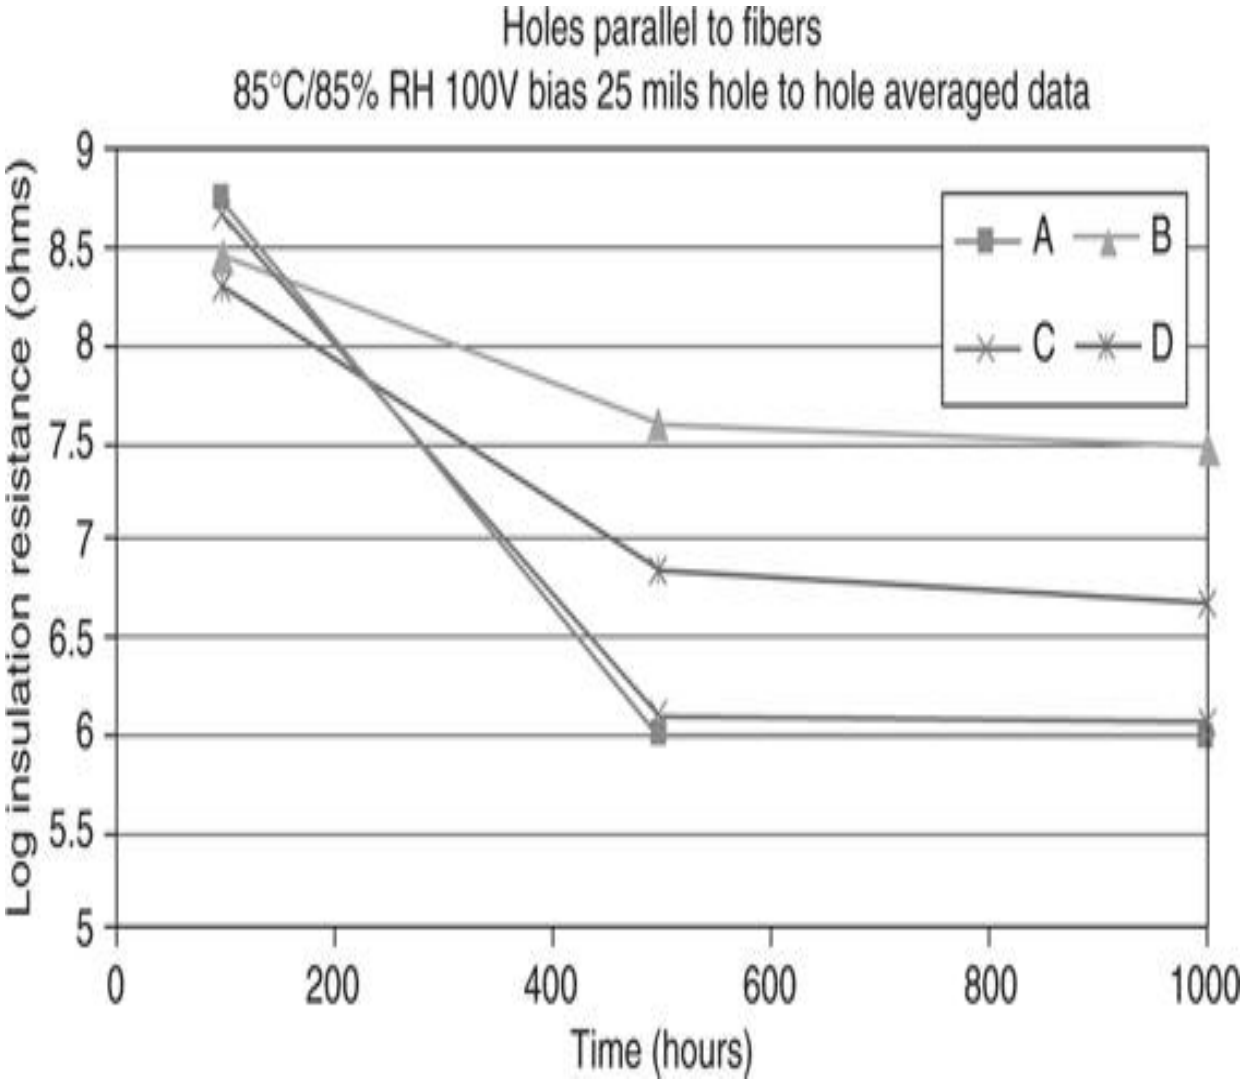

FIGURE 12.19 CAF results for 25-mil hole spacings in example #2.

12.8.1.3 CAF Test Example #3. In this third example of CAF testing, a different test vehicle design was used, and different temperature, humidity, and bias levels were also used. However, all the test coupons were manufactured at the same time by the same PCB fabricator, and in addition, the same resin system was used in groups 1 through 4. The differences between groups 1 through 4 involve different types of fiberglass cloth and differences in process controls used when treating the glass cloth with the resin system. This is the key point of this third example.

Figure 12.20 shows that while each group used exactly the same laminate material type, differences in glass cloth and treating process controls resulted in different CAF performance levels.

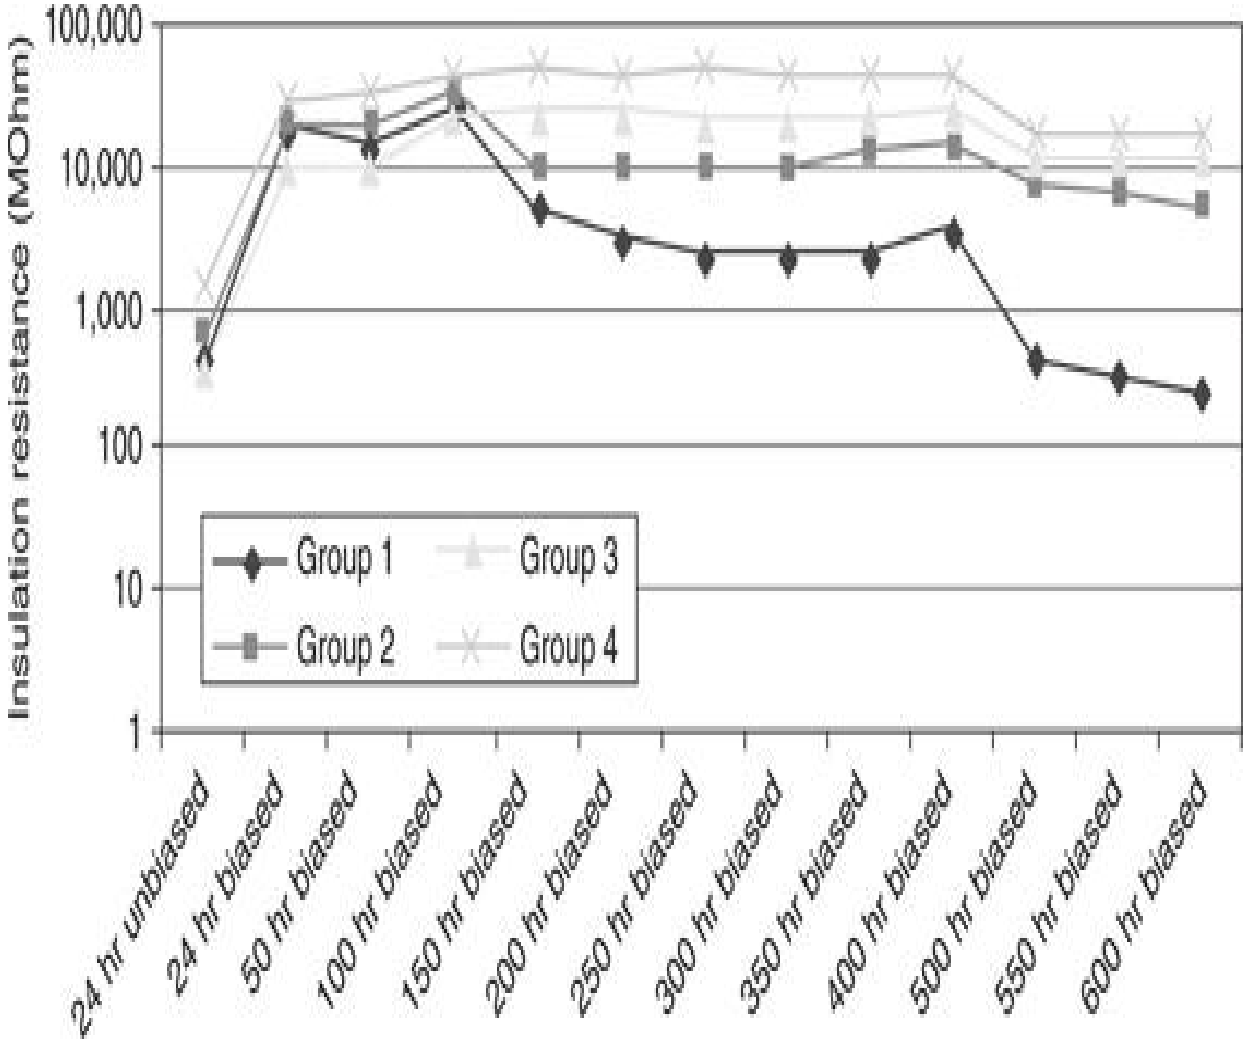

FIGURE 12.20 Results for CAF test example #3.

For each group, the chart shows average insulation resistance for a set of coupons over time. Clearly, the average insulation resistance varied by group, with group 1 showing the most significant decline in resistance. In addition, evaluating the individual coupons in each group provides additional insight into performance differences. In group 1, 40 percent of the coupons failed by 600 hours, with

the first failure occurring at 400 hours. In group 2, 20 percent of the coupons failed at 600 hours. Groups 3 through 5 did not have any failures in this test. So even though the resin system was the same for each group, differences in glass cloth and laminate manufacturing processes clearly can have a significant impact on CAF performance.

Chapter 14, covering material selection, will discuss this further and provide some recommendations for selecting materials when concerned about CAF.

12.9 ELECTRICAL PERFORMANCE

Base material electrical properties are an important consideration in sophisticated printed circuits operating at high frequencies. High data rates, measured in gigabits per second (Gbps), and high clock speeds make the dielectric constant (D_k) and dissipation factor (D_f) of base materials very important in high-speed digital circuits. Wireless and RF applications operating at very high frequencies also demand very low D_k and D_f values. Moreover, the consistency of these properties over a large frequency range is also important. These properties were defined generally in Chap. 12 as follows:

- *Dielectric constant/permittivity*. This is the ratio of the capacitance of a capacitor with a given dielectric material to the capacitance of the same capacitor with air as a dielectric. It refers to the ability of a material to store an electric charge.
- *Dissipation factor/loss tangent*. The property is the ratio of the total power loss in a material to the product of the voltage and current in a capacitor in which the material is a dielectric.

12.9.1 Importance of D_k and D_f

These properties are important because they affect signal transmission in the printed circuit. At low frequencies, a signal path in a printed circuit can typically be represented electrically as a capacitance in parallel with a resistance. However, as frequencies increase, at some point signal paths must be considered transmission lines where the electrical and dielectric properties of the base materials have a greater effect on signal transmission. A full discussion of capacitive versus transmission line environments is beyond the scope of this chapter, but the premise is to determine, for the transmission of a signal pulse of a given rise time, the acceptable length of a conductor before a significant voltage difference is realized along its length. Conductors longer than this critical value are then regarded as transmission lines. Because the velocity of signal propagation is inversely proportional to the square root of the permittivity of the dielectric, a lower permittivity value results in faster signal speeds and a longer rise distance. With a larger rise distance, larger conductor lengths are acceptable before a significant voltage drop is experienced. However, if the ratio of conductor length to rise distance is large enough, signal reflections from a mismatched load impedance may be received back at the source after the pulse has reached its maximum plateau value, and pulse additions that occur under these circumstances may lead to false triggering of a device.

On the other hand, signal attenuation can result in missed signals. One of the causes of signal attenuation is dielectric loss. As the circuit operates, the dielectric medium absorbs energy from the signal. Attenuation of the signal by the dielectric is directly proportional to the square root of permittivity and directly proportional to the loss tangent. In addition, dielectric losses increase as frequencies increase. When a high bandwidth is desired, this effect has a greater

impact on the higher-frequency components, and the bandwidth of the propagating pulse decreases and degrades the rise time.

Because the permittivity and loss tangent vary with frequency, and other factors to be discussed later in this chapter, the degree to which these properties vary is also an important circuit design consideration. If these properties vary significantly with frequency, designing a circuit with devices that operate at various frequencies becomes that much more complex. In addition, operating within a given bandwidth becomes that much more difficult as different frequency components experience different dielectric properties, which in turn lead to differences in signal propagation and loss.

Therefore, base materials with low permittivity values and low loss factors are desired for high-speed, high-frequency printed circuits. In addition, consistency of these properties across frequencies is also required. Besides frequency dependence, since operating environments can also vary, the consistency of these properties across environmental conditions is also important and is discussed in the following sections.

12.9.2 High-Speed Digital Basics

Figure 12.21 is a representation of high-speed digital communication that involves sending bits of information coded in waveforms.

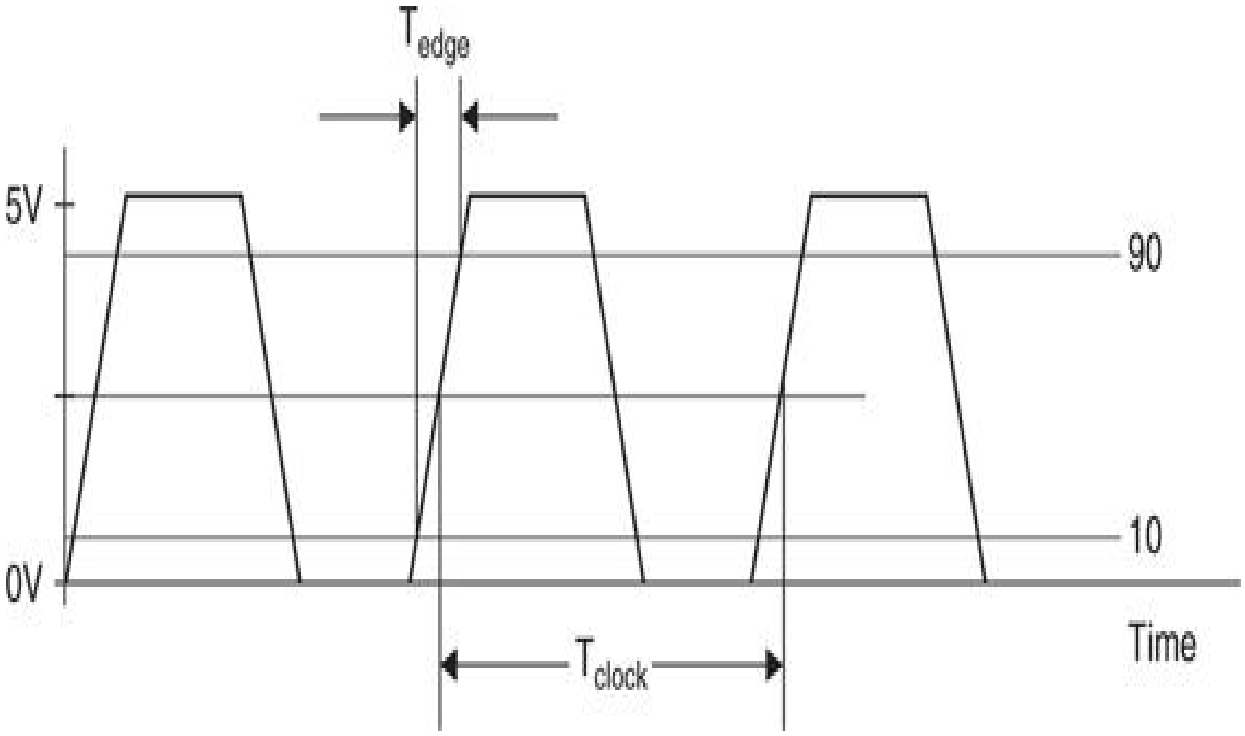

FIGURE 12.21 Digital communication.

The zeros and ones of binary information are coded on the rise time or on both the rise time and fall time. The high voltage represents 1 and the low voltage represents 0. The faster the rise time, the faster the signal. To achieve faster rise times, sinusoidal wave forms are superimposed on one another. The range of frequencies used is called the bandwidth, with the bandwidth given as 0.35/rise time. In short, a faster rise time allows for a greater range of frequencies, or greater bandwidth.

Figure 12.22 provides an example of eye pattern analysis. The eye opening size is related to these attributes: signal attenuation, rise time degradation, signal noise, and jitter. In this analysis, the height of the central eye opening is a function of amplitude degradation in the received signal. The width of the signal band at the corner of the eye measures the jitter. Signal attenuation and rise time degradation are a function of dissipation factor and frequency; lower dissipation factor (D_f) decreases the magnitude of change to

these factors. Jitter is caused by several factors, but small areas of varying dielectric constant (D_k) is an important material related cause. Transitions between the top and bottom of the eye show the rise and fall times of the signal.

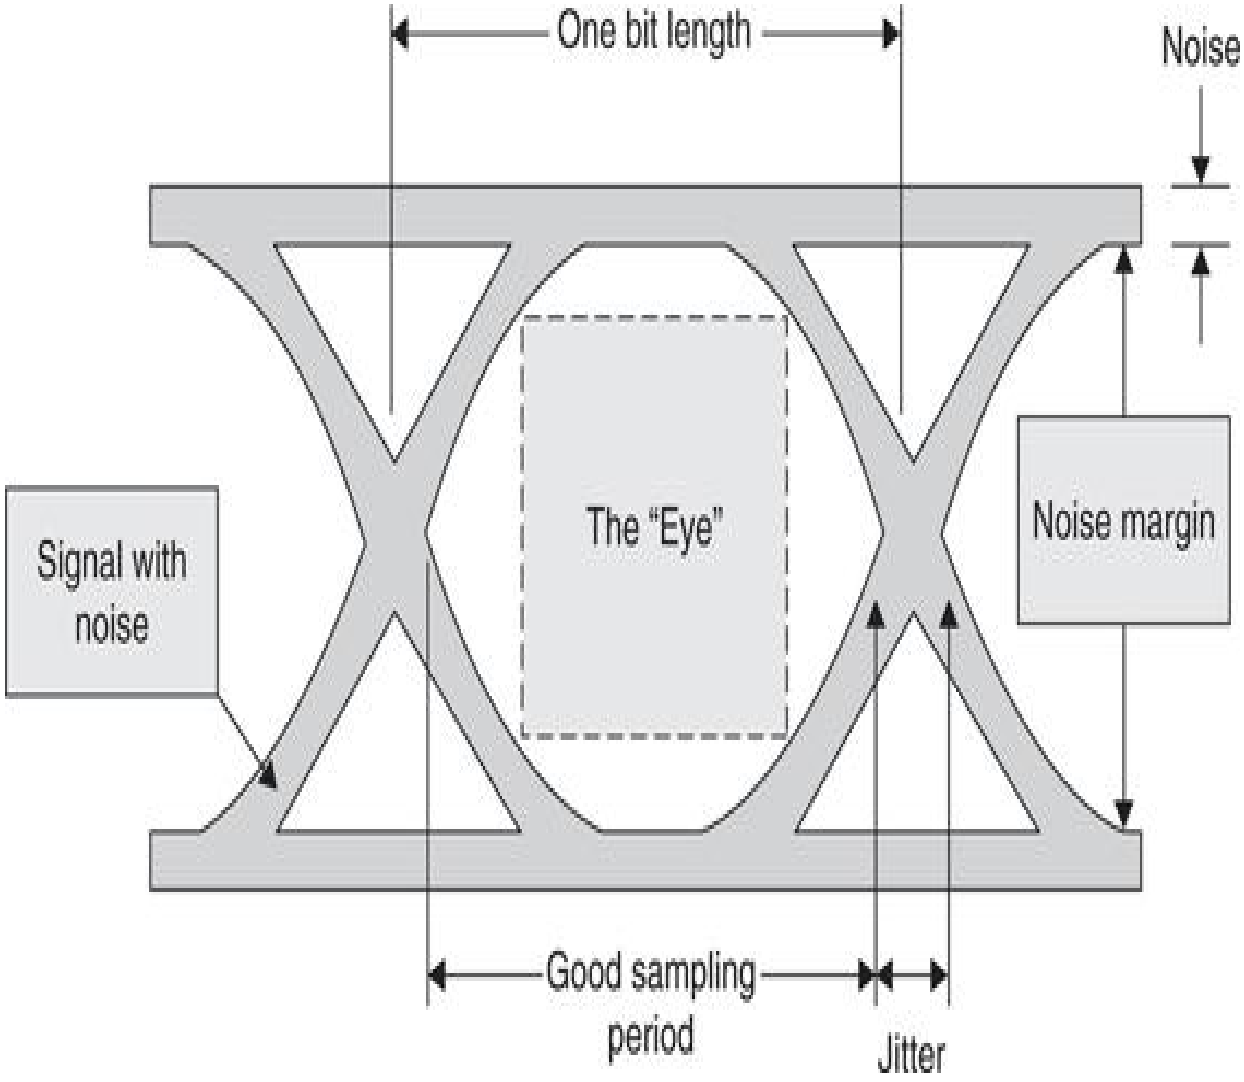

FIGURE 12.22 Eye pattern analysis.

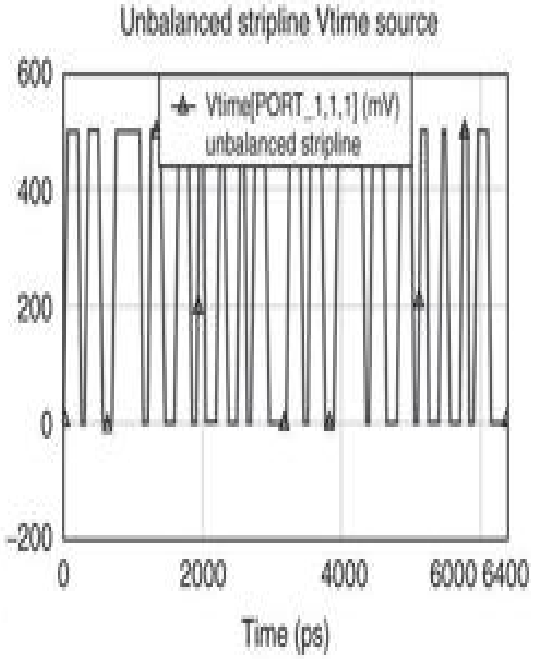
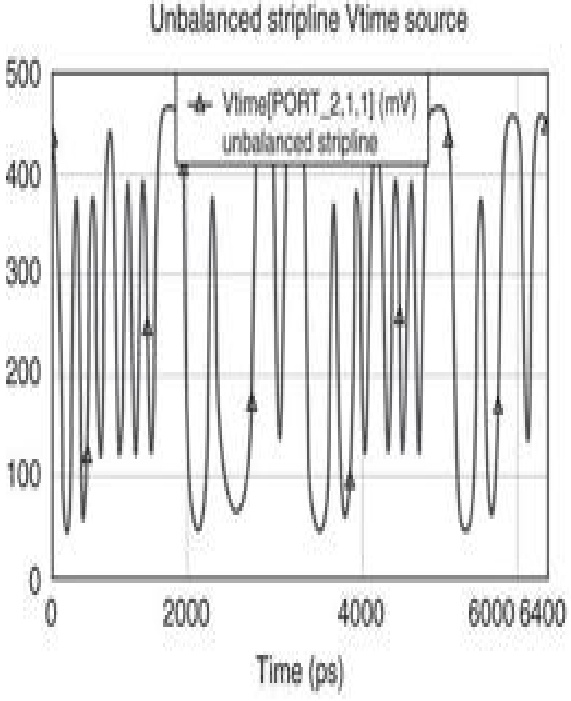
Figure 12.23 illustrates potential signal integrity differences when different base materials are used. The top chart shows an example of a 10-Gbps signal at the source. Note the pattern in this chart. It changes from 0 in the *x* axis (0) to its peak value (1). Now look at the chart in the lower-left corner of Fig. 12.23, representing the use of a standard

FR-4 material. Note the change in the pattern, particularly the decreased amplitude. When the signal degrades as illustrated here, the function of the circuit can be significantly impacted. Now examine the chart in the lower-right corner. This is for a low D_k/D_f material. Note the improved amplitude compared to the standard FR-4 material and a pattern much closer to the signal at the source. Figure 12.24 takes this analysis further. The chart in the upper-left corner is the signal at the source. This is as good as it gets. The remaining charts illustrate how the signal is affected with materials of increasing D_f. Note the diagram for the standard FR-4 under these conditions. This would represent an unacceptable condition, as the eye is almost completely closed. As the D_f is decreased from the FR-4 level, the pattern improves.

A 10 Gbps signal at source



After 40 inches through standard FR-4



After 40 inches through a low Dk/Df material

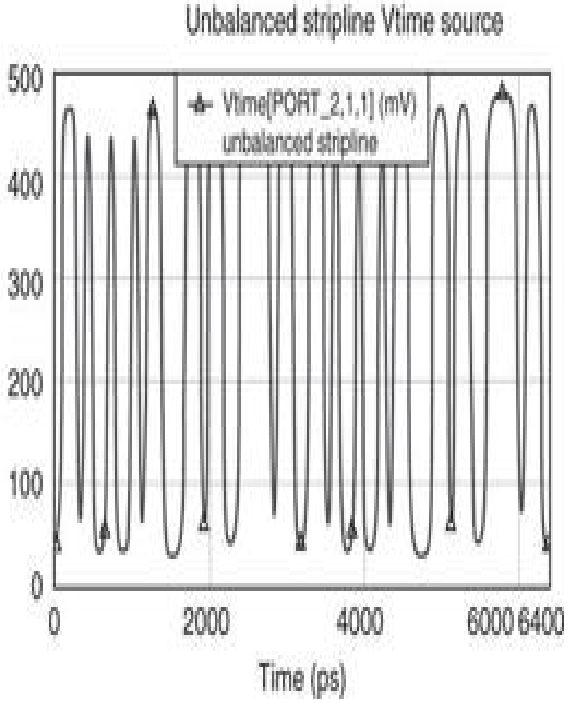


FIGURE 12.23 Substrate influence on signal integrity.

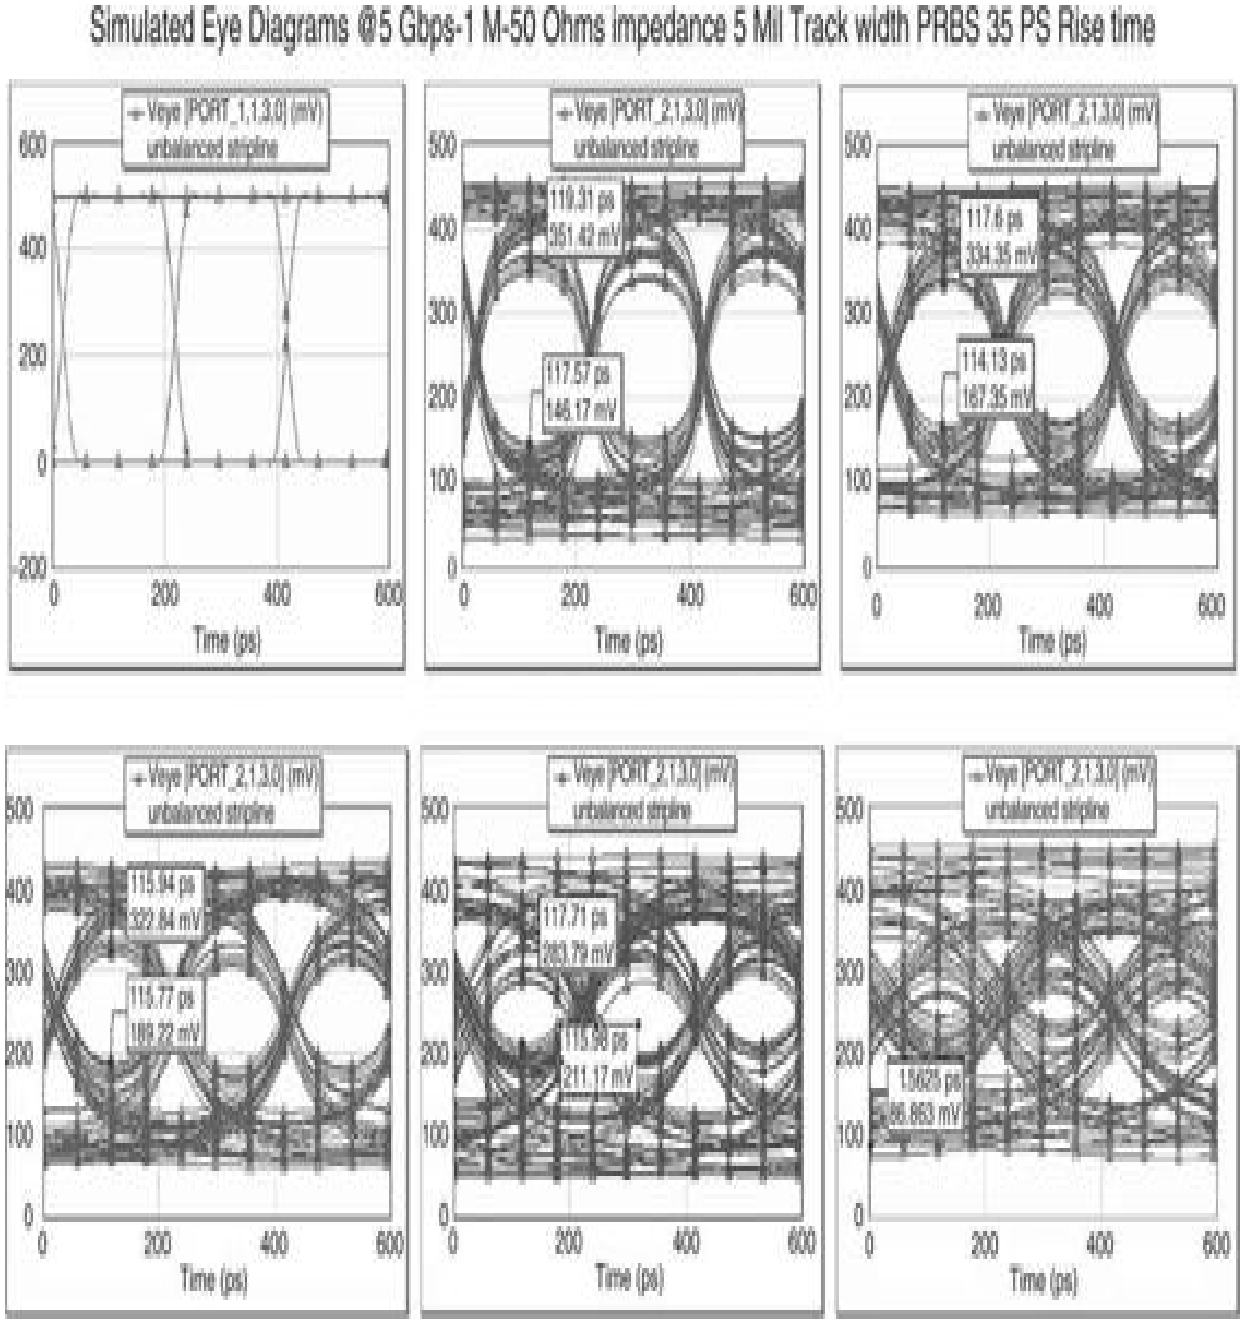

FIGURE 12.24 Simulated eye diagrams at 5 Gbps, 1 M, 50 Ω impedance, 5-mil track width.

Another way to illustrate the impact of D_f is to graph loss in decibels (dB) per unit length versus the D_f. Figure 12.25 provides a simulation of this relationship for a 5-mil line.

Because wider line widths are less “lossy” because of reduced skin effect, some of this can be compensated for by using a wider line. However, this negatively impacts circuit density. Figure 12.26 shows the impact of line width on loss for two different low D_k/D_f materials. In this case, material B would allow the designer to use a thinner line to increase circuit density while maintaining a given level of loss. For example, to keep the loss in this example below 15 dB/m, material A would require a line width of approximately 8 mils. However, with the same loss requirement, material B enables the line to be reduced to approximately 5 mils. This is a significant benefit in increasing circuit density.

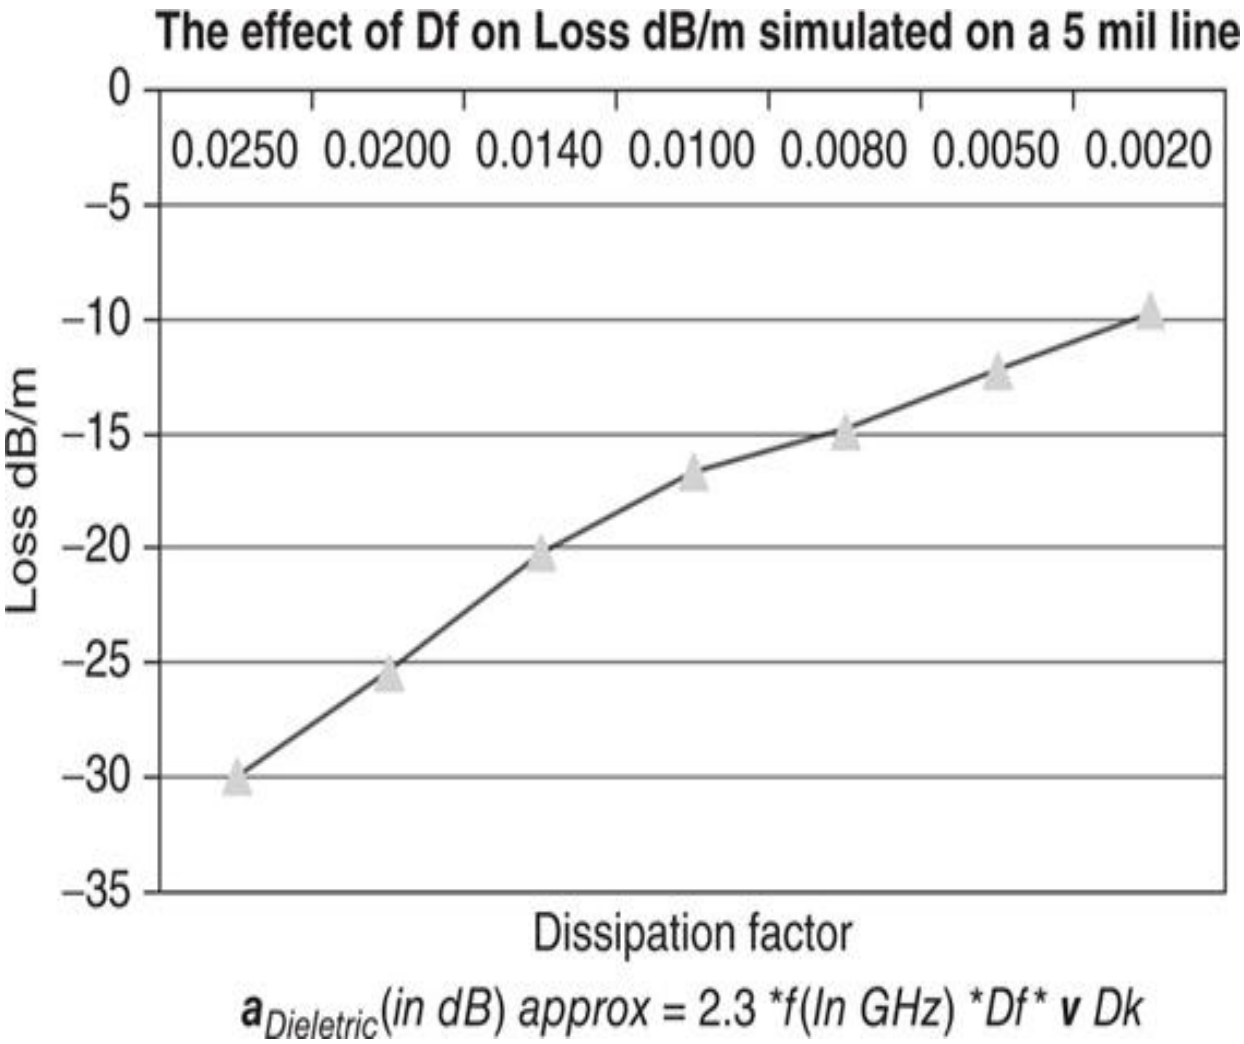

FIGURE 12.25 The effect of D_f on dielectric loss in dB/m simulated on a 5-mil line.

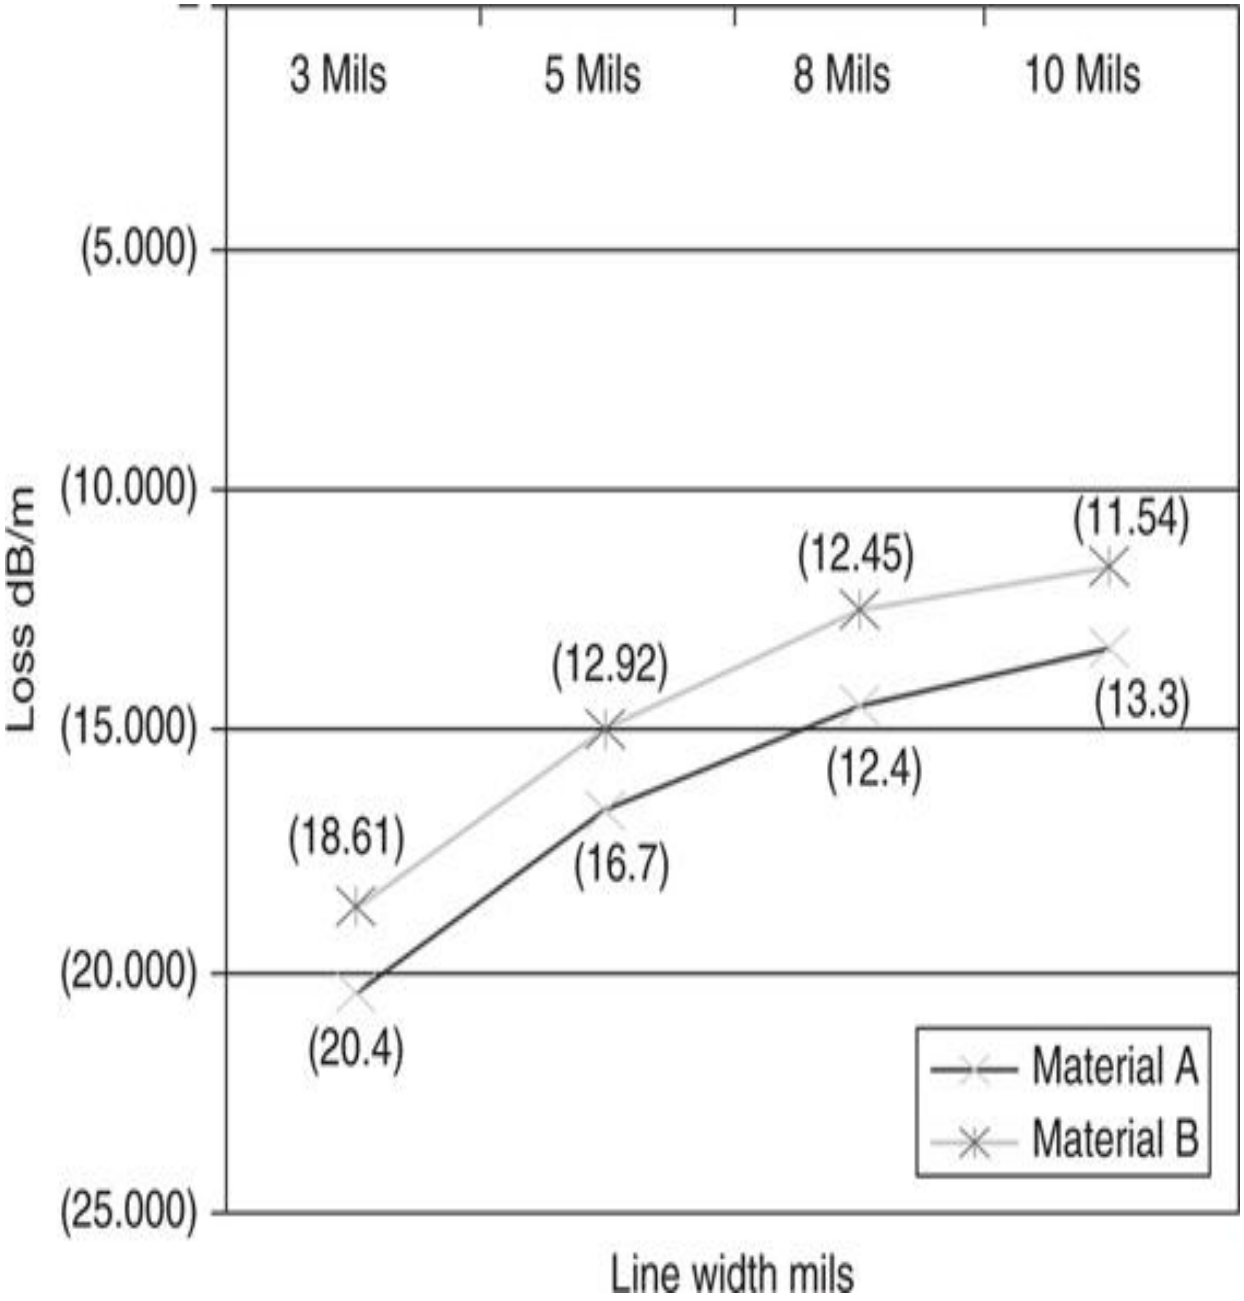

FIGURE 12.26 Effect of line width on loss for two material types.

12.9.3 Choosing a Base Material for Electrical Performance

The dielectric constant and dissipation factor of the dielectric material are determined by both the resin system and the reinforcement type. Therefore, each of these should be considered when choosing a material.

There are a large number of different low-dielectric, low-loss resin systems, most of which are proprietary resins only available from a single supplier. Likewise, a few different reinforcements and fillers are available that can be used to modify the electrical properties of the base material. Although E-glass is still the most commonly used fiberglass reinforcement, others are available and the use of low-D_k glass fabrics is growing rapidly. In addition, inorganic fillers are sometimes used to modify electrical properties as well. Table 12.4 provides electrical property data on some of the available fiberglass materials. Table 12.5 provides data on some of the base material composites available.

TABLE 12.4 Dielectric Constants and Dissipation Factors of Common Glass Types

Property	E-Glass	NE-Glass	L-Glass
Dielectric constant @ 1 GHz	6.8	4.8	4.8
Dielectric constant @ 10 GHz	6.6	4.8	4.8
Dissipation factor @ 1 GHz	0.004	0.0015	0.001
Dissipation factor @ 10 GHz	0.0066	0.0035	0.003

PTFE	E-Glass	2.3	2.3	0.0013	0.0009
Hydrocarbon	E-Glass/Ceramic	3.4	3.3	0.0025	0.0024

Table 12.5 lists values for approximately 50 percent resin content. These values change as the resin content varies, with the magnitude of the change depending on the specific resin system. Also, comparable resin system types from various suppliers could differ. For example, since there are many types of epoxies, with a wide range of electrical properties, specific epoxy formulations from different material suppliers can exhibit somewhat different dielectric and loss properties. In addition, the test method used to

measure D_k and D_f, especially at higher frequencies, will have a significant impact on the reported value. When comparing materials, it is critical to compare values derived from the same test method, or at least to understand the differences in the test methods. The differences in test methods are beyond the scope of this chapter, but their importance should not be underestimated. The purpose of this table is to highlight the relative differences between various resin systems and reinforcement types. Chapter 15 will discuss this further.

A significant change since 2010 is the increase in functional testing being performed to assess electrical properties of different dielectric materials. These tests are standardized and are widely used in the industry. For higher frequencies, >10 GHz for example, or loss sensitive applications, these tests have been very useful for good decision making in selecting materials.

These values also vary with resin content and frequency. Figure 12.27 illustrates the dependence of the dielectric constant versus resin content for a few materials. Figure 12.28 shows the impact of resin content on the dissipation factor of an epoxy blend, and Fig. 12.29 shows the impact of frequency on D_k for a few of these materials. Beyond frequency and resin content effects, the dielectric constant and dissipation factor can also vary with temperature and moisture absorption.

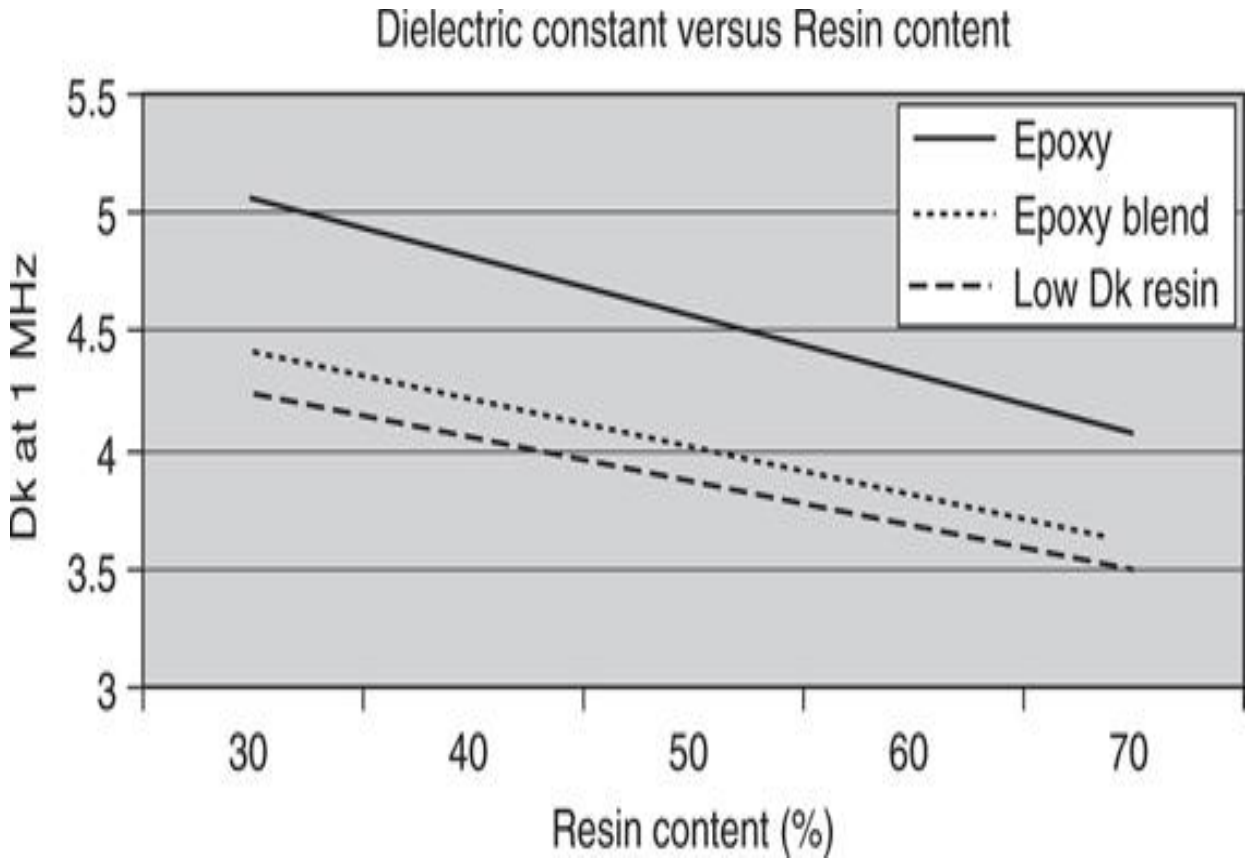

FIGURE 12.27 Dielectric constant versus resin content.

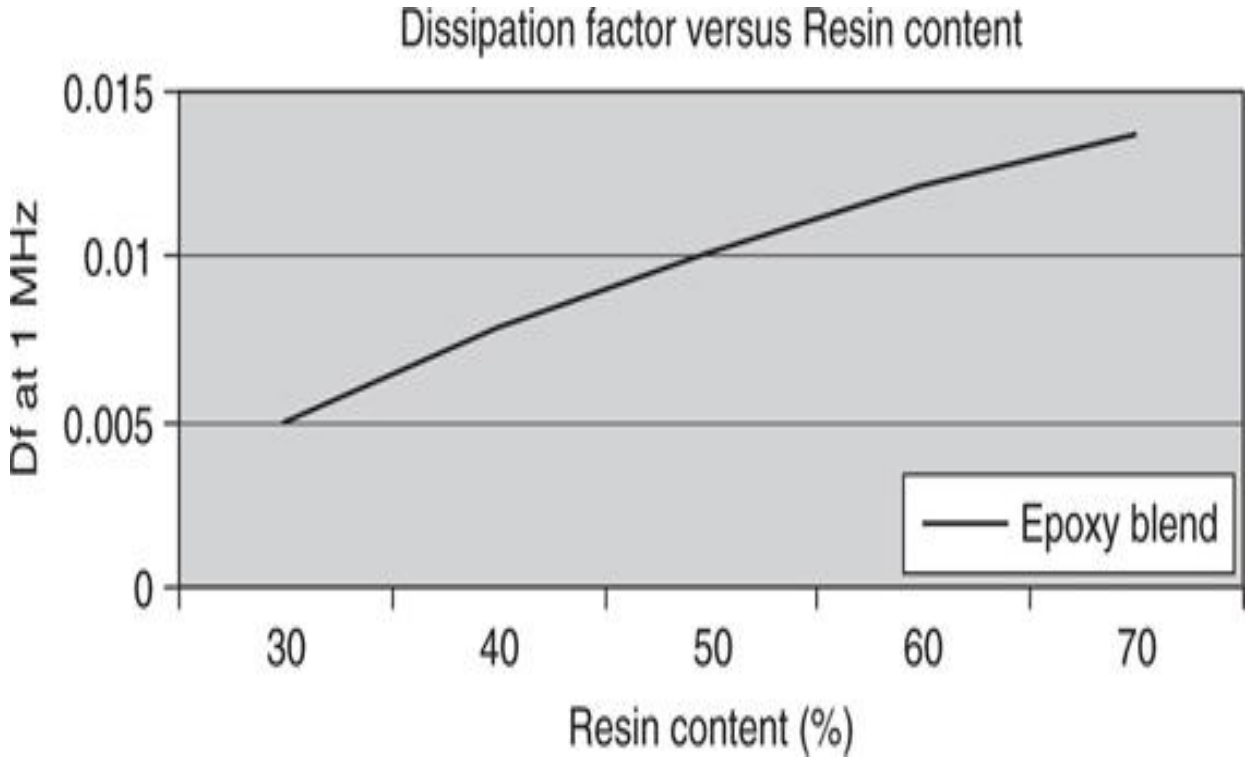

FIGURE 12.28 Dissipation factor versus resin content for a low D_k epoxy blend.

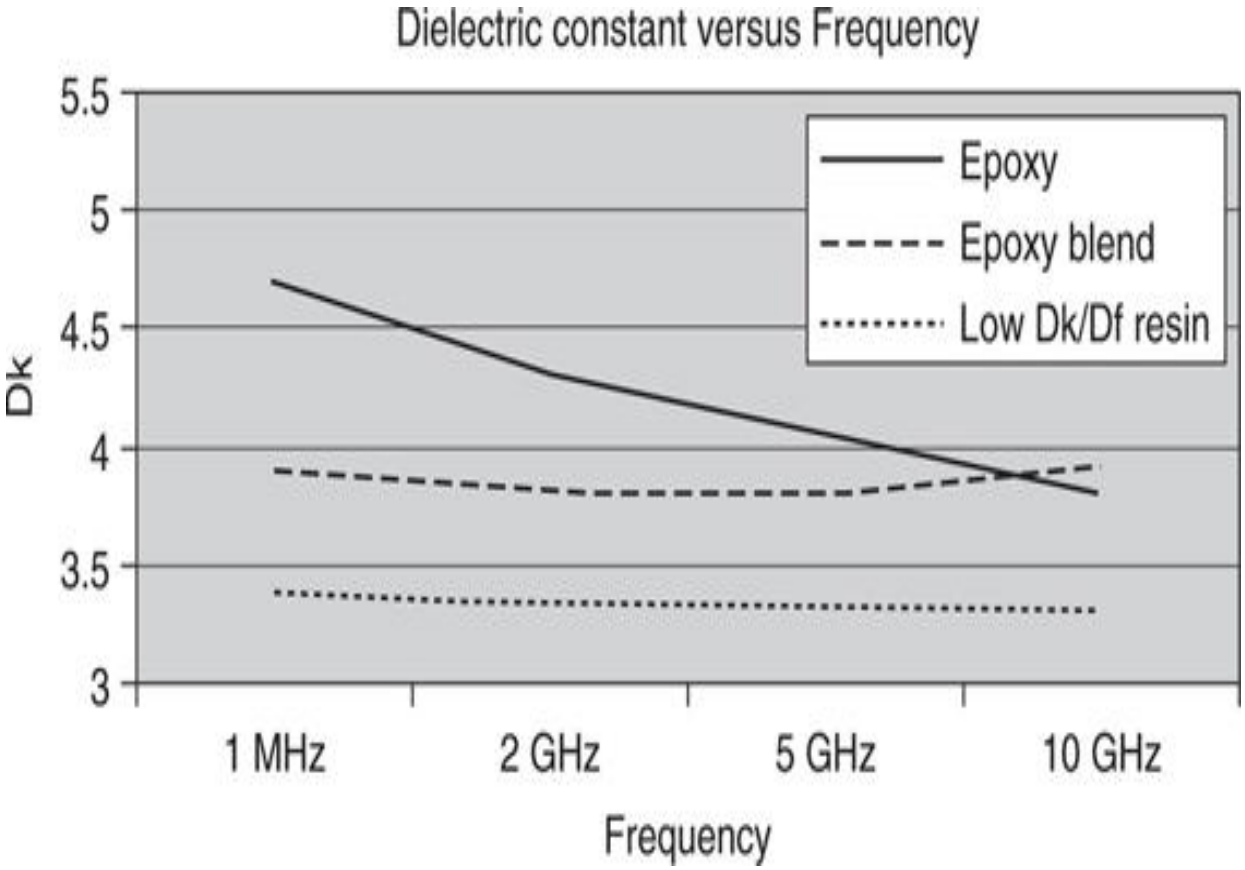

FIGURE 12.29 Dielectric constant versus frequency.

When choosing a material for a specific application, it is important to understand the operating conditions and environment in which the circuit will be used. Some resin systems exhibit less sensitivity to these conditions than others. For example, base material suppliers are continually developing resin systems to meet the demanding electrical properties requirements of high-speed and wireless applications, which include consistent properties over frequency ranges and environmental conditions. In short, different material types can have different responses to changes in frequency, resin content, temperature, and humidity conditions. These responses become more important to understand in high-speed, RF, and wireless applications.

In addition, when selecting a material, it is important not simply to select the material with the lowest dielectric constant or dissipation factor, since there are typically cost-performance trade-offs to be made. In general, the lower the dielectric constant and dissipation factor, the more costly the material, and very often the more difficult it is to process.

In summary, some general relationships include the following:

- The dielectric constant generally decreases with increasing resin content.
- The dissipation factor often increases with increasing resin content.
- The dielectric constant typically drops as frequency increases.
- The dielectric constant and dissipation factor typically increase as water absorption rises.
- The dielectric constant of E-glass is only mildly frequency-dependent and therefore lower resin contents result in less variation across frequencies.
- The dissipation factor generally rises with frequency, but may exhibit maxima at certain frequencies.

12.9.4 Electrical Performance of Lead-Free Compatible FR-4 Materials

Most of the FR-4 laminate materials developed for lead-free assembly applications use an alternative resin chemistry in comparison to the dicyandiamide (“dicy”) cured FR-4s used in the past. “Phenolic” or “novolac” cured epoxies are the most common of these materials. Although there is some variation between these materials, as a group they tend to exhibit somewhat different electrical performance compared to dicy-cured FR-4s. For most applications operating in lower

frequency ranges, the differences are not significant. However, as operating frequencies increase toward the higher end of “FR-4 applications,” and impedance control becomes more critical, these differences can become significant. Table 12.6 includes two common dicy-cured FR-4 materials (A and C) and two phenolic FR-4 materials compatible with many lead-free assembly applications (B and D). It also includes a lead-free compatible material (E) designed to improve D_k and D_f performance in comparison to the “phenolic” lead-free compatible materials. Note that different types of measurement systems can result in different measured values for D_k and D_f. Laminate resin contents and other factors also influence these properties. Thus, in Table 12.6 the comparisons between these materials are more important than the absolute values reported for each material. For these comparisons, the same measurement system and resin contents were used.

TABLE 12.6 Properties of Several Base Material Types

Product	Description	Glass Transition Temp., °C	Decomp. Temp., °C	% Expansion, 50–260°C (40% RC)	D_k @ 2 GHz	D_k @ 5 GHz	D_f @ 2 GHz	D_f @ 5 GHz
A	Dicy-cured, 140°C T_g FR-4	140	320	4.2	3.9	3.8	0.021	0.022
B	Phenolic, mid-T_g FR-4	150	335	3.4	4.0	3.9	0.026	0.027
C	Dicy-cured, high-T_g FR-4	175	310	3.5	3.8	3.7	0.020	0.021
D	Phenolic, high-T_g FR-4	175	335	2.8	3.9	3.8	0.026	0.026
E	Nondicy, nonphenolic	200	370	2.8	3.7	3.7	0.013	0.014

In Table 12.6, the improved phenolic FR-4 materials are clearly not as good in terms of electrical performance at

higher frequencies as the dicy-cured materials used in the past, particularly with respect to D_f. However, material E exhibits thermal properties comparable to the phenolic materials. In addition, the electrical performance of material E is even better than the dicy-cured materials, especially in terms of D_f performance. Figures 12.30 and 12.31 provide higher frequency D_f and D_k data for several lead-free compatible FR-4 materials in comparison to a dicy-cured, high-T_g FR-4, using a split-post resonant cavity test method. It also includes data for the nondicy/nonphenolic material. Note that there is a wide range of D_f values for the phenolic materials, and to a lesser extent some variation in D_k values as well. In comparison, the nondicy/nonphenolic material offers lower and more stable D_f properties and a slightly lower D_k.

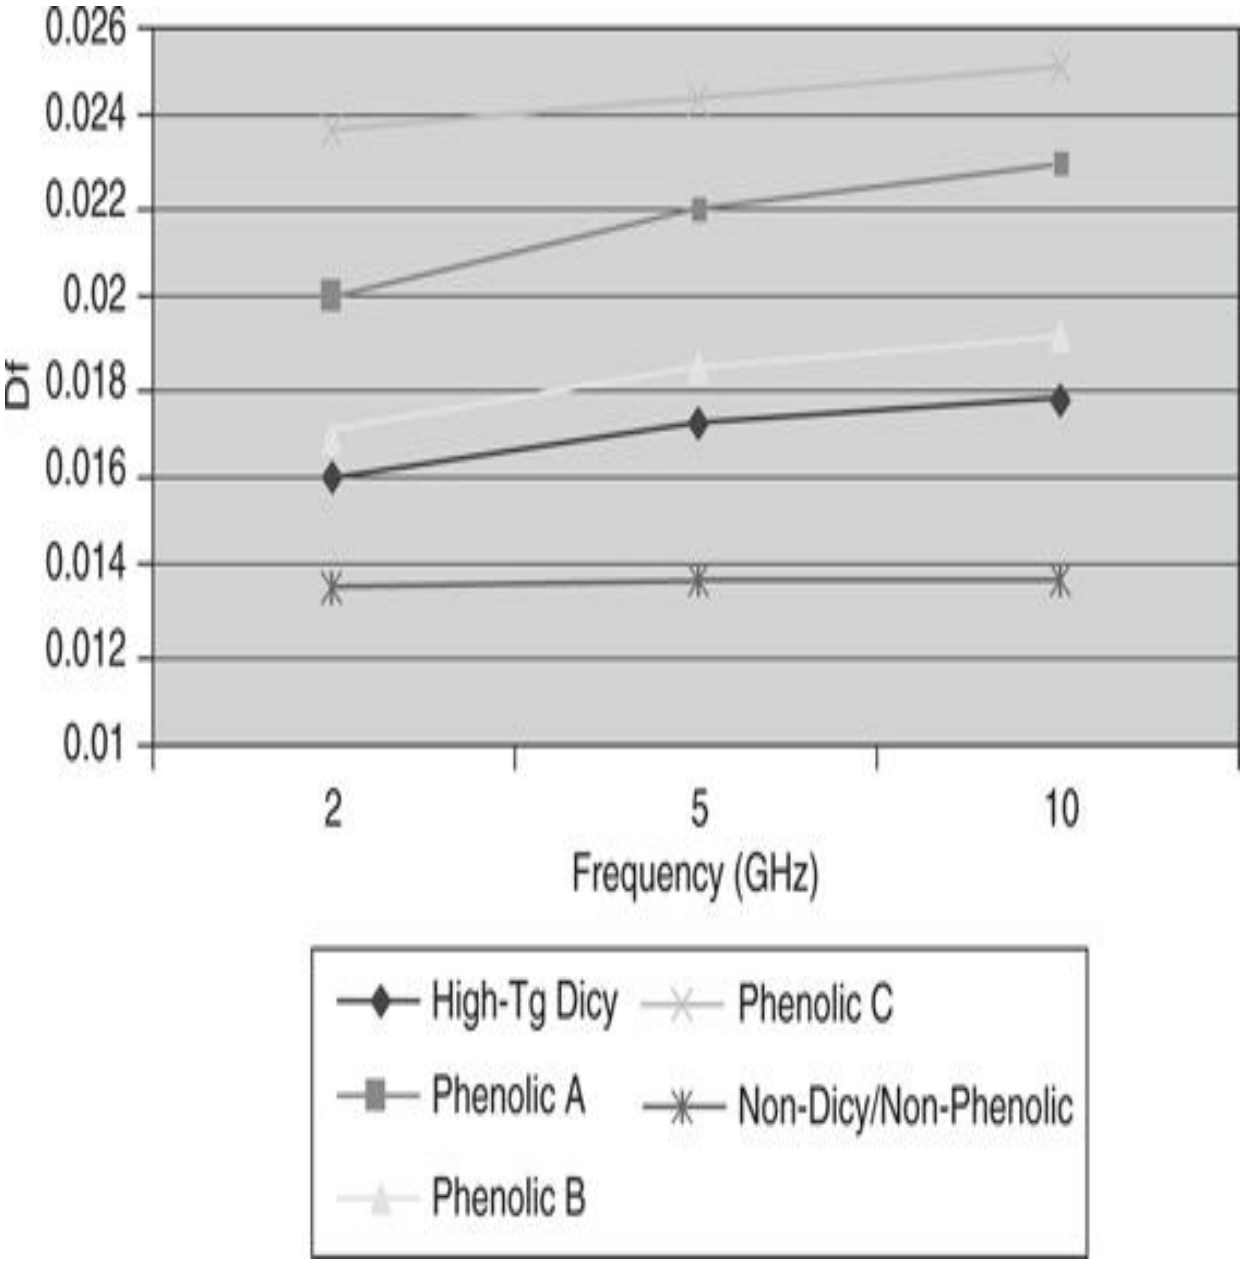

FIGURE 12.30 D_f versus frequency for lead-free compatible FR-4 materials.

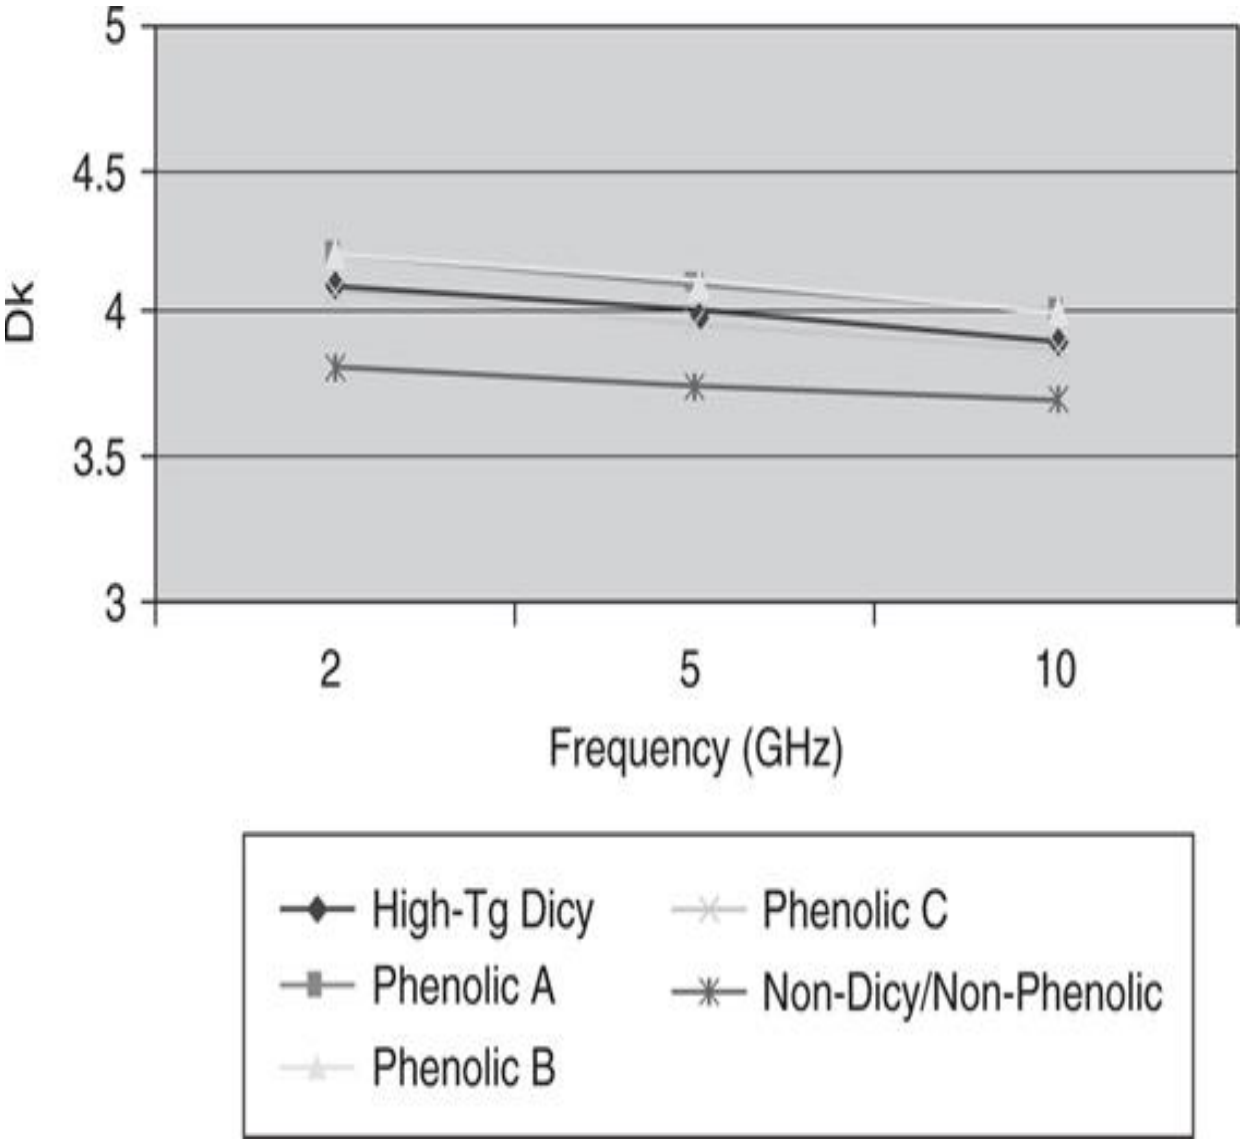

FIGURE 12.31 D_K versus frequency for lead-free compatible FR-4 materials.

Furthermore, Table 12.7 provides several laminate constructions for a common phenolic material, along with resin content and D_k data at 2 and 5 GHz. Note how different constructions and resin contents can vary in D_k. Table 12.8 provides the same construction data with D_f data at 2 and 5 GHz. Tables 12.9 and 12.10 provide this same data for the nondicy/nonphenolic material with additional data at 10 GHz.

12.10 ELECTRICAL PERFORMANCE OF LOWER D_K/D_F LEAD-FREE

COMPATIBLE MATERIALS

However, for performance at very high frequencies, lower D_k/D_f materials are preferred. While low D_k/D_f materials have been available for many years, the advent of lead-free assembly has complicated material selection, and in these applications not only are the laminate D_k and D_f properties critical, but their thermal properties are just as important. Many new lead-free compatible materials are available with differing electrical performance. Figures 12.32 and 12.33 provide D_f and D_k data for three different low D_k/D_f materials that are also compatible with lead-free assembly.

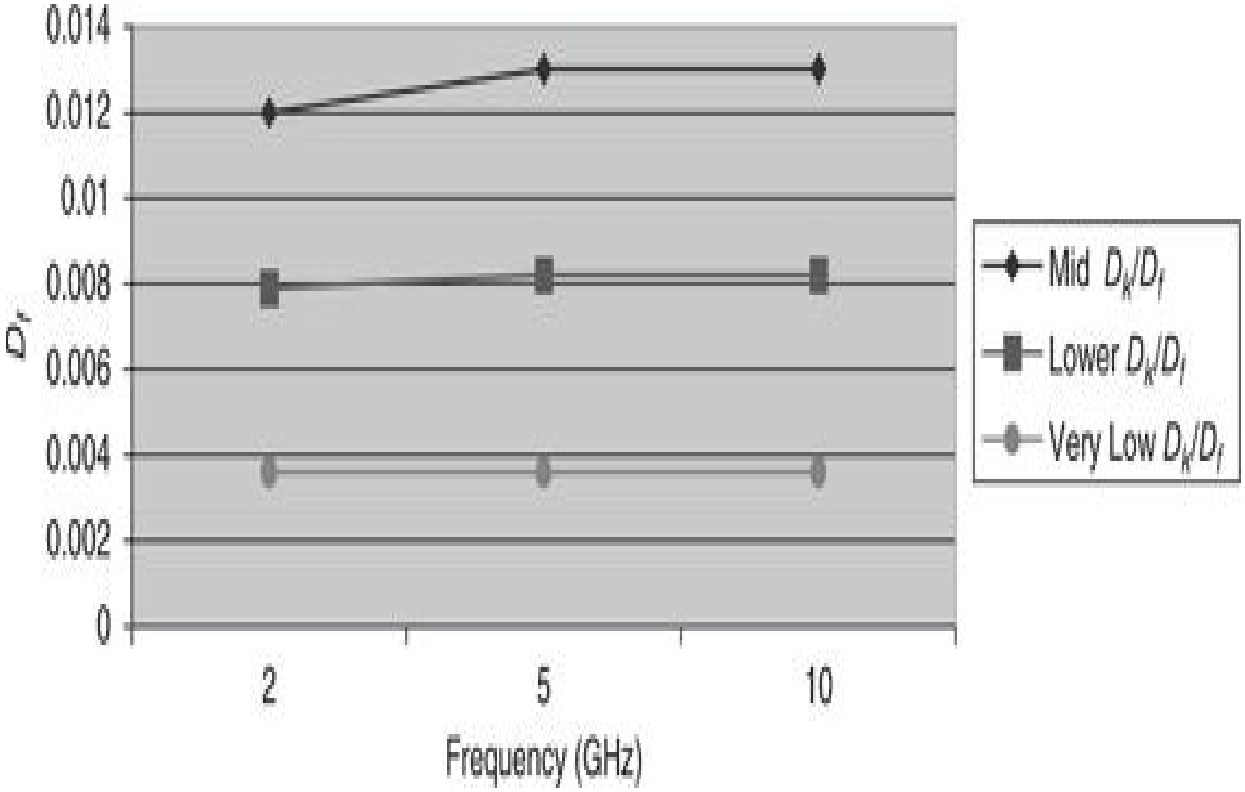

FIGURE 12.32 D_f versus frequency for low D_k/D_f, lead-free compatible materials.

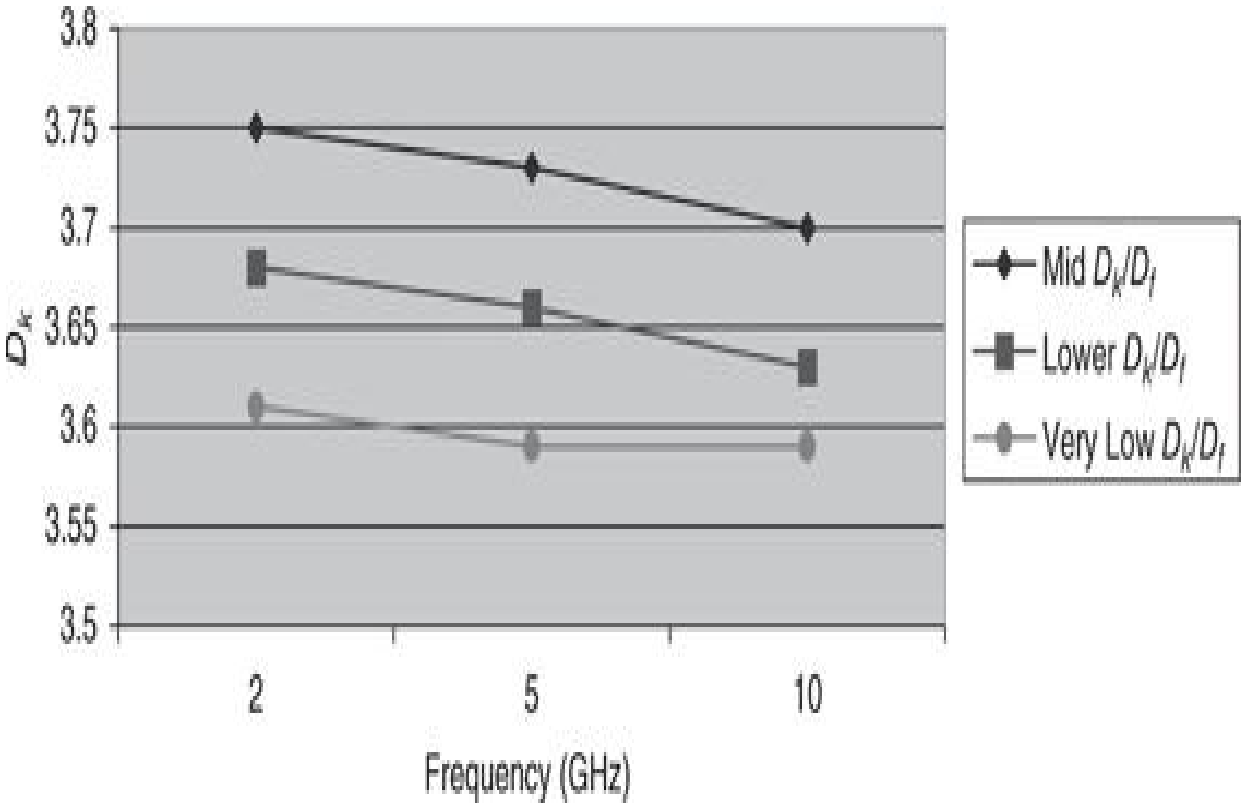

FIGURE 12.33 D_k versus frequency for low D_k/D_f, lead-free compatible materials.

Table 12.11 provides D_k and D_f data for the very low D_k/D_f material by construction and resin content. This sample of constructions illustrates how these properties vary with resin content in addition to frequency. For a full list of constructions available for any product, it is recommended that the manufacturer's data sheets be consulted.

12.11 RESIN AND GLASS MICRO-D_k EFFECTS

Another issue in high-speed circuits using differential pairs of conductors is skew, which we will describe shortly. Skew can arise from the differences in resin D_k versus glass cloth D_k when pairs of conductors are patterned in glass-rich areas of the dielectric versus resin-rich areas. The potential for skew arises from materials with large differences between the resin D_k and glass D_k, in dielectrics that contain glass cloth styles with large open areas between the yarns that make up the cloth.

Figure 12.27 provided an example of how D_k can vary with resin content, and Tables 12.7, 12.9, and 12.11 gave examples of laminate constructions with different resin contents, and the subsequent differences in D_k. This illustrates the potential D_k differences, although the D_k of E-glass and the D_k of most resins will have even larger differences. Now examine Figs. 12.34 and 12.35, which provide photographs of 106 and 1067, and 1080 and 1086, respectively.

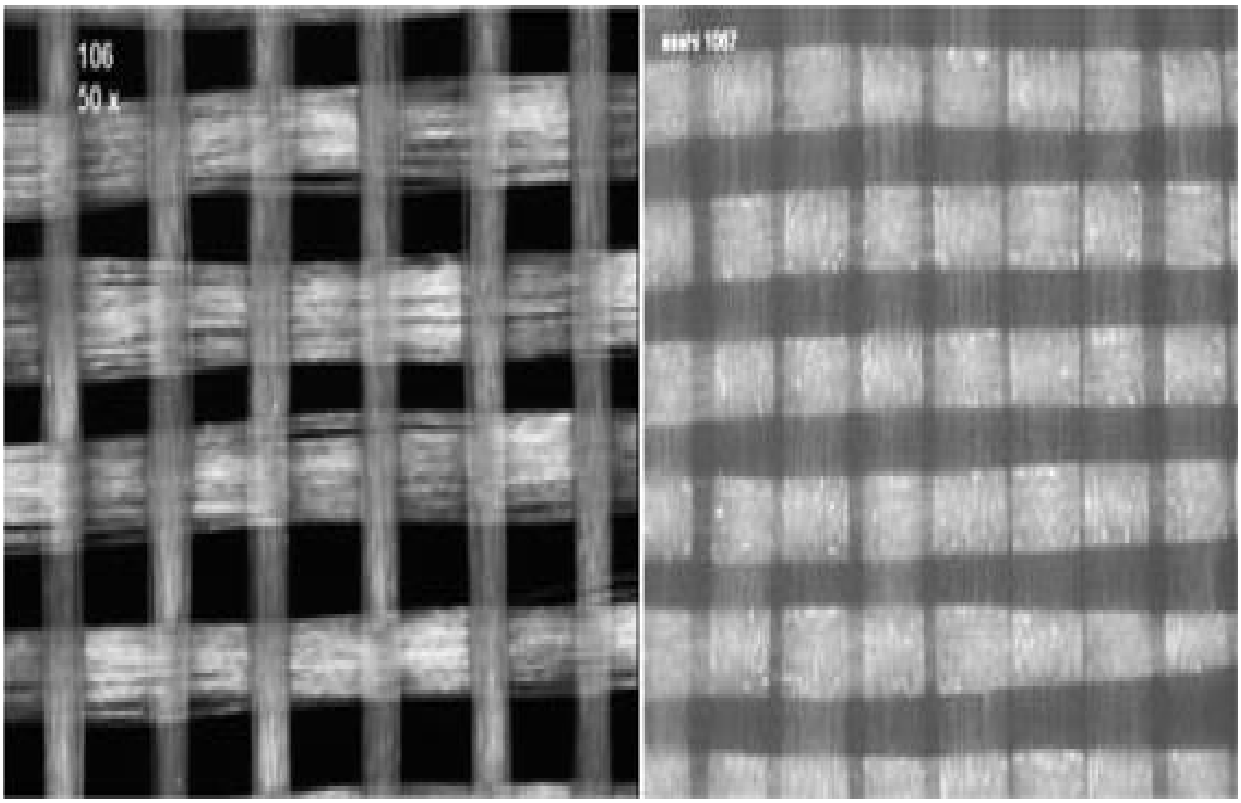

FIGURE 12.34 106 and 1067 Glass fabrics.

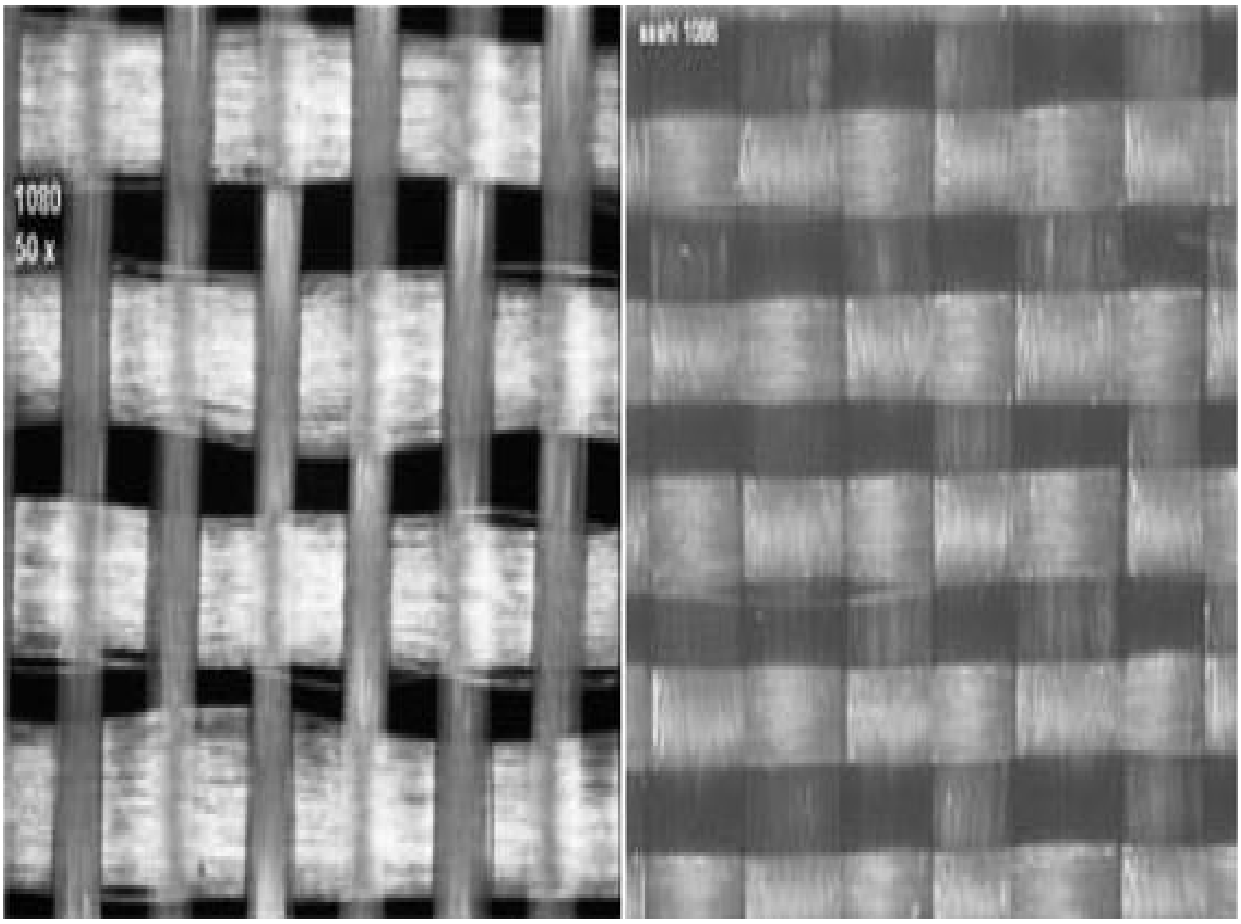

FIGURE 12.35 1080 and 1086 Glass fabrics.

In these figures you can see that 106 and 1080 glass cloth contain much open space between yarns. In Chap. 11, we discussed both spread and expanded glass cloths, and the 1067 and 1086 in these figures are examples. With spread and expanded glass cloths the filaments in the yarns are more homogeneously distributed. Now particularly in dielectrics that use glass fabrics with large open areas, conductors may be placed along glass yarns, in areas with much open space between yarns, or overlapping these areas. In PCB designs using differential pairs of conductors, it is critical that signals in the two conductors travel at the same speed, which is impacted by the D_k of the dielectric material. Skew refers to the difference in time that signals in the differential pair of conductors reach the receiver. If this

difference in time is large enough, then this leads to data errors. Figure 12.36 illustrates the potential for conductors to be imaged in glass-rich versus resin-rich areas. In Fig. 12.37 is an eye pattern without skew for a 2.5 Gb/S differential pair. Note the equal magnitude and opposite value at any time. In contrast, Figs. 12.38 and 12.39 are eye patterns with 40 picoseconds (ps) and 80 ps skew. Note how the eye closes as skew increases.

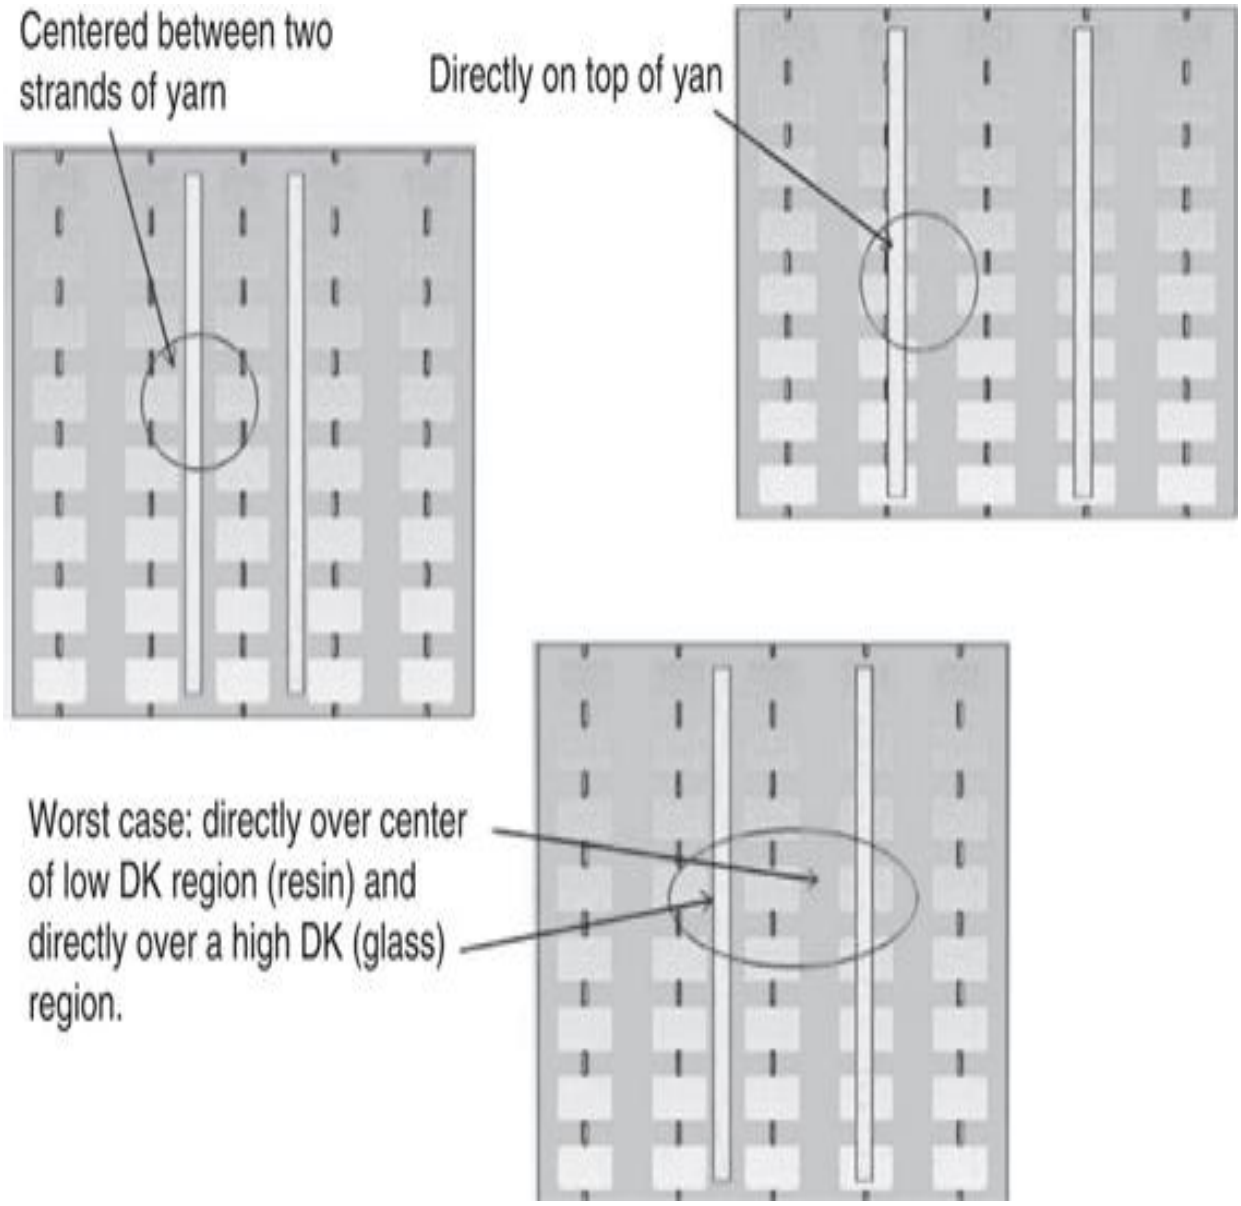

FIGURE 12.36 Illustration of conductors in glass-rich versus resin-rich areas.

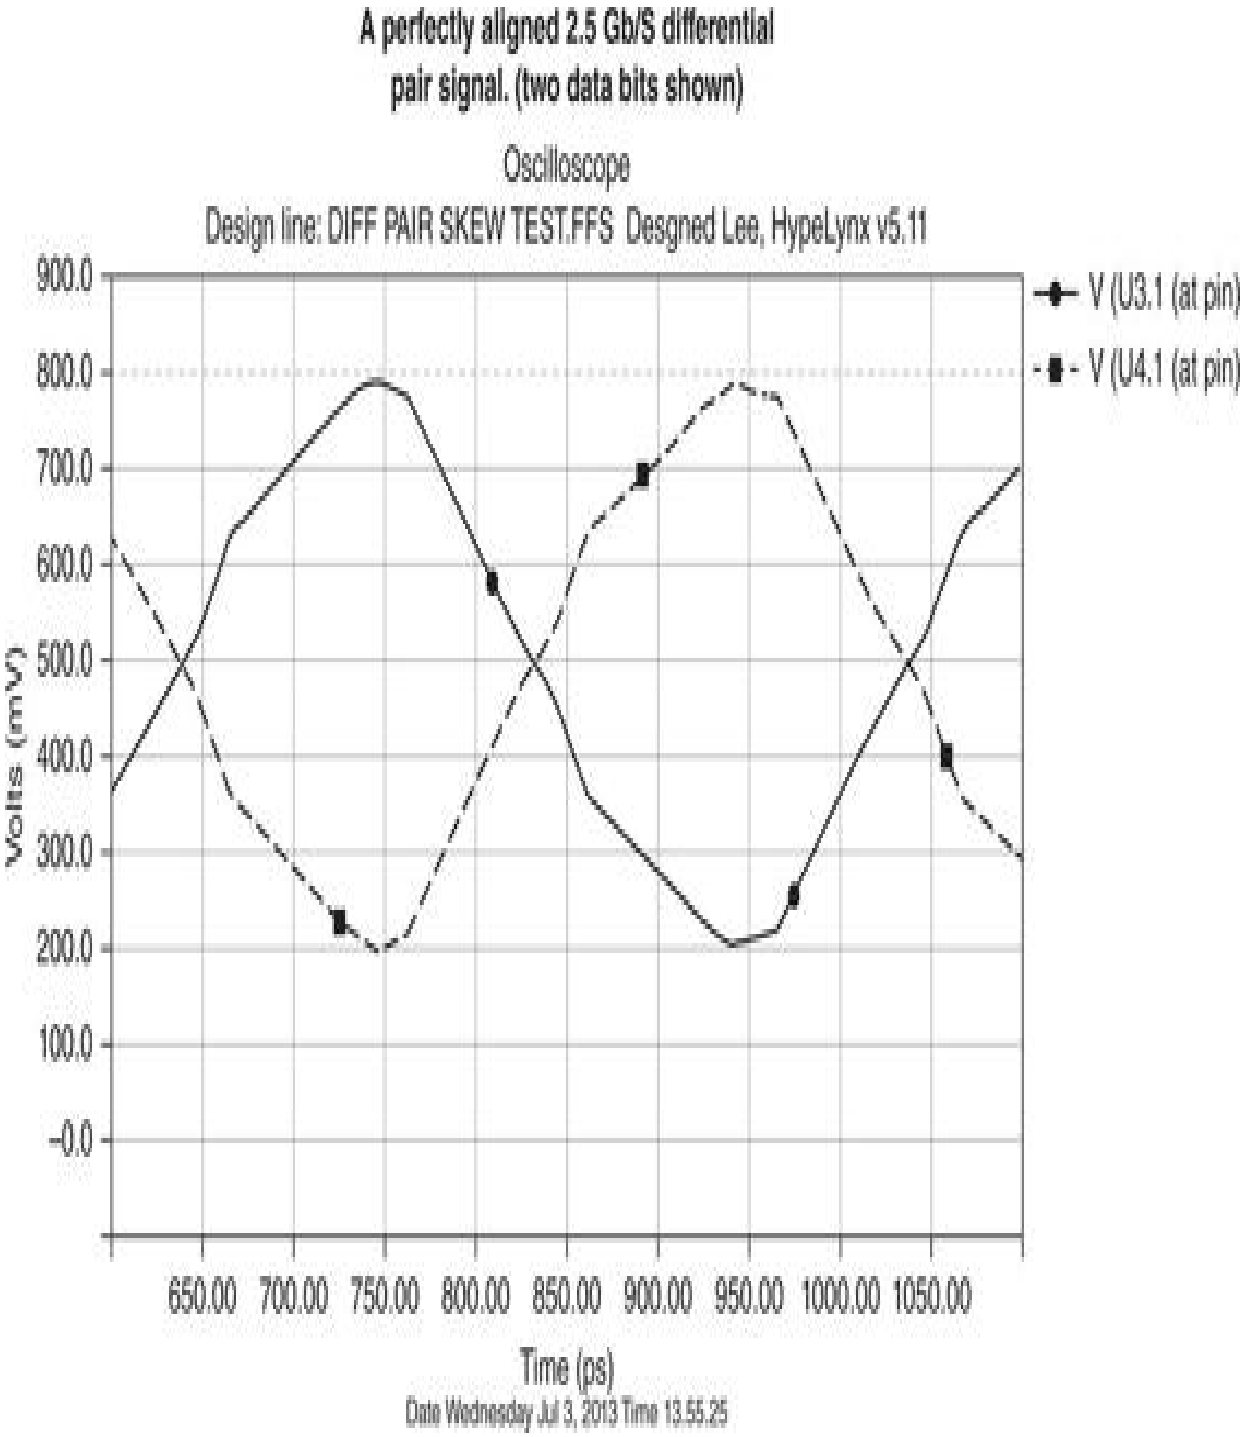

FIGURE 12.37 Eye pattern without skew.

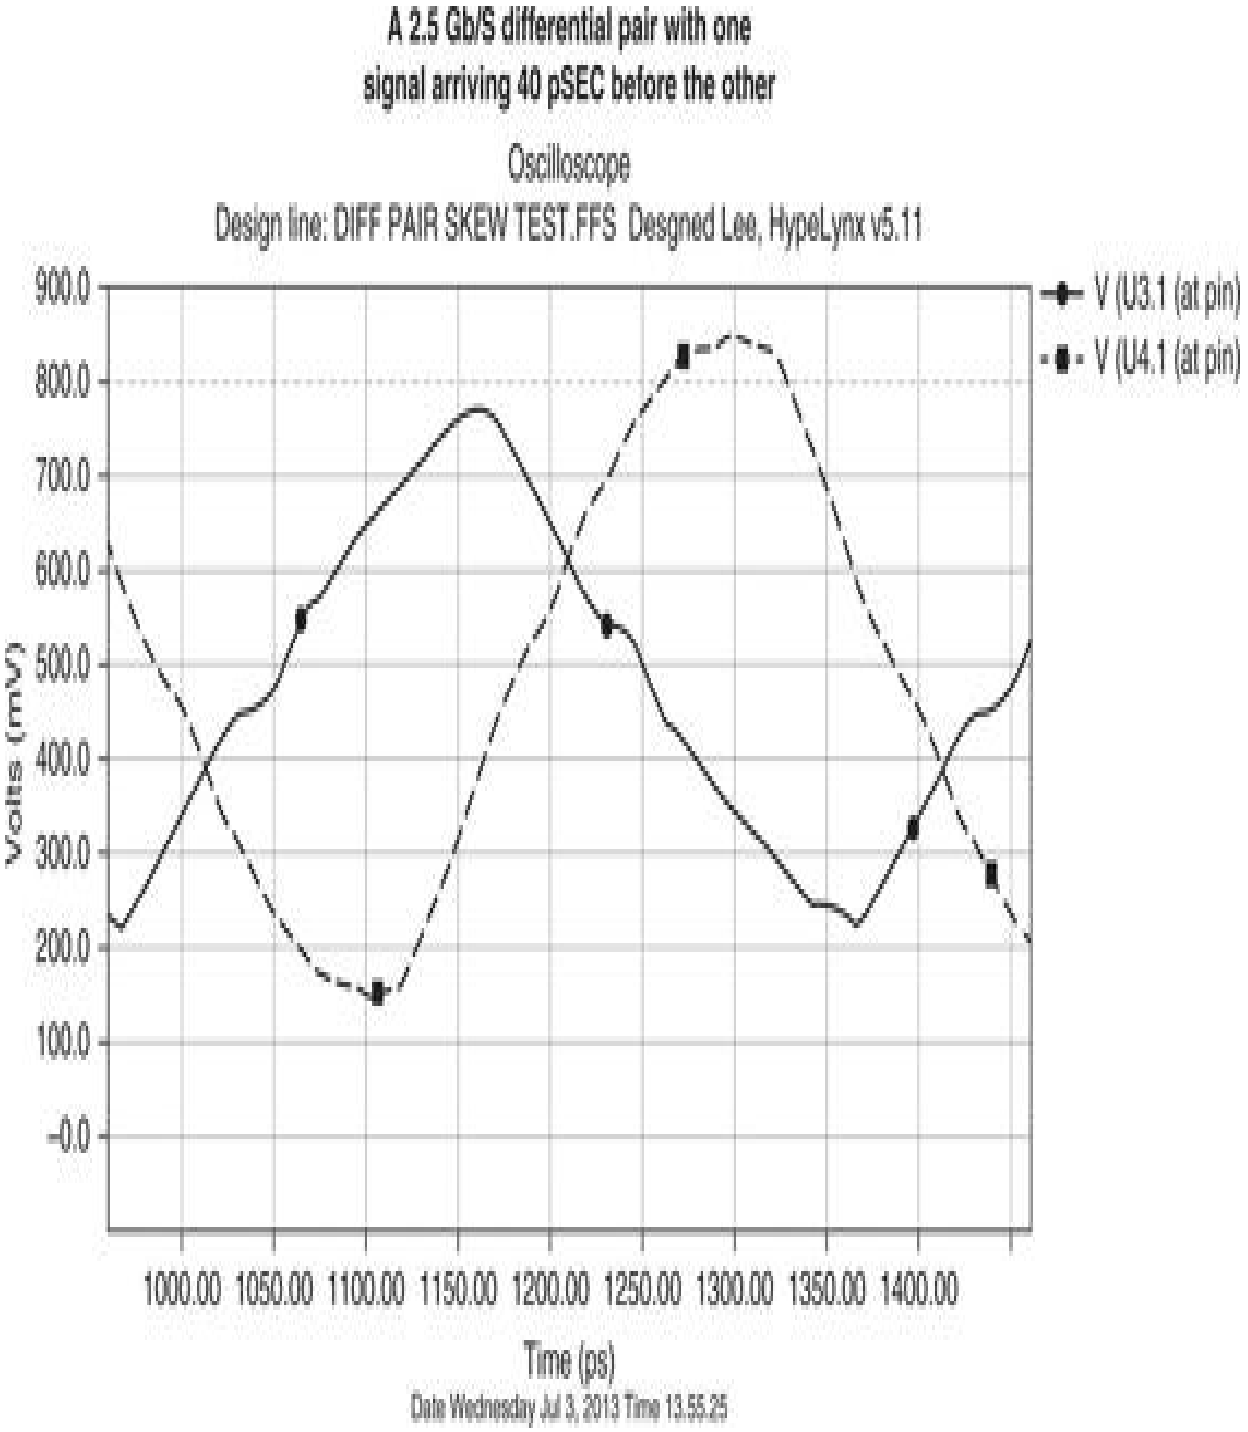

FIGURE 12.38 Eye pattern with 40 ps skew.

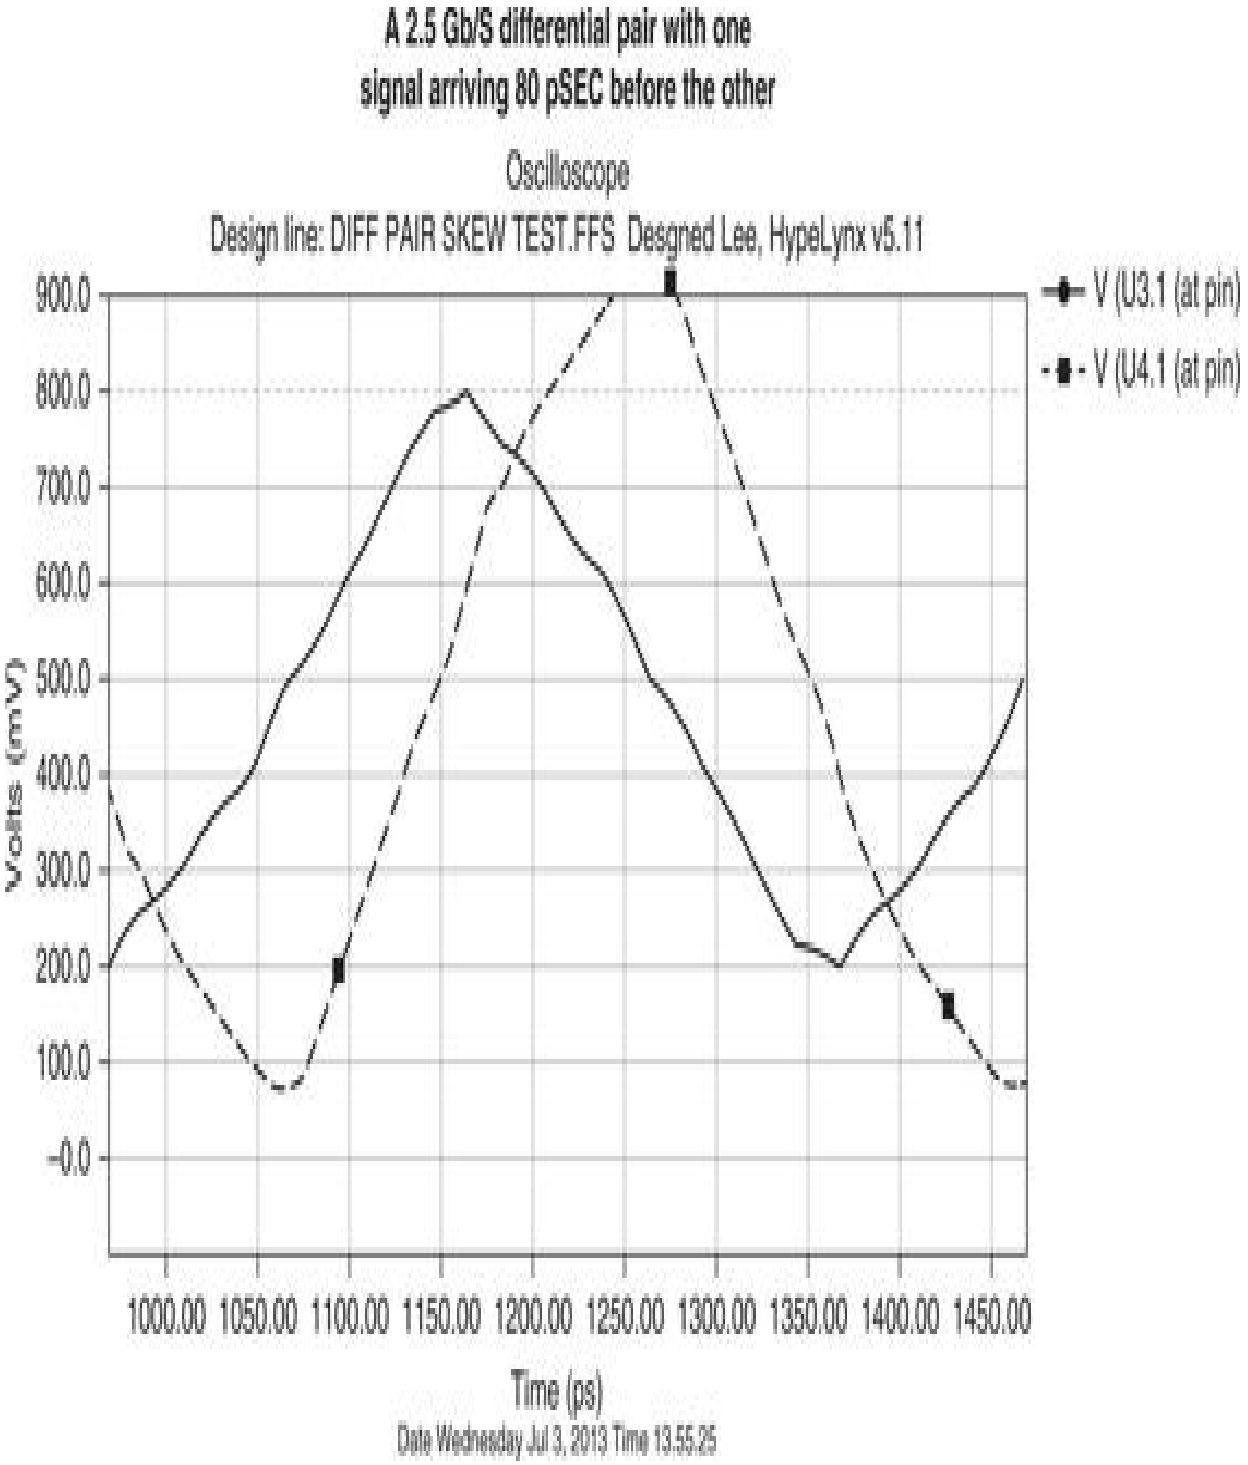

FIGURE 12.39 Eye pattern with 80 ps skew.

Skew has become a significant issue for very high speed PCB design, and there are a few ways that this has been addressed. Examples are

- The use of the expanded and spread glass cloth styles helps to mitigate some of the issue since this helps provide a more uniform distribution of resin and glass. These cloth styles generally cost more than the nonspread/nonexpanded glass cloths, so the benefit needs to be assessed versus the cost.
- The use of low-D_k glass cloth can help reduce the difference in D_k between resin and glass. Low-D_k glass cloth is more expensive than E-glass, and again presents a cost-benefit trade-off.
- Circuits can be rotated relative to the glass fabric so that conductors do not travel in-line with the yarns in the glass fabric. Normally this is achieved by imaging circuits at an angle relative to the length and width of the copper clad laminate. The cost of this approach depends on the size of the circuit relative to the size of the copper clad laminate, but the added cost can be very high if the circuit rotation reduces the number of circuits that can be imaged on the laminate, or if rotating requires a circuit to be built using a larger laminate size.
- Materials have been developed where there is very little difference in D_k between resin and glass and therefore across resin contents. In addition to the low skew that these products enable, this simplifies design of the laminate and prepreg styles used throughout the multilayer stack-up since they are uniform in D_k. Table 12.12 provides a few examples of core constructions with different resin contents, along with the D_k.

CHAPTER 13

THE IMPACT OF LEAD-FREE ASSEMBLY ON BASE MATERIALS

Edward Kelley
Douglas Trobough
Isola Group, Chandler, Arizona

13.1 INTRODUCTION

The European Union's Restriction of Hazardous Substances (RoHS) directive has had a profound impact on all levels of the electronics industry supply chain, including the base materials used in printed circuit boards (PCBs). While debate over the net environmental benefits of this initiative continues, it is clear that all levels of the supply chain must continue to deal with the implications. Product groups with exemptions are approaching deadlines, and indeed, many of these product groups were, or are being forced to transition ahead of schedule due to component availability and constraints within the assembly services industry. The product groups granted initial exemptions are generally those with the most stringent reliability requirements, and

many involve complex PCB designs that even further complicate the issues with respect to base materials. This chapter will introduce the key issues related to base materials, the important properties with respect to lead-free assembly compatibility, and examples of material evaluation.

13.2 RoHS BASICS

RoHS restricts the use of

- Lead (Pb)
- Cadmium (Cd)
- Mercury (Hg)
- Hexavalent chromium (Cr^{VI})
- Polybrominated biphenyl (PBB)
- Polybrominated diphenyl ethers (PBDE)

The first four substances are metals used for a variety of applications, whereas the last two are generally used as flame retardants in plastic materials. It is important to note that these halogenated flame retardants are not generally used in laminate materials for printed circuits.

Chapter 11 discussed flame retardants in more detail. The key point to be made here is that the most common flame retardant used in base materials, tetrabromobisphenol-A (TBBPA), is not restricted. Furthermore, in FR-4 materials, TBBPA is generally reacted into one of the epoxy resins, and thus does not exist as a free-standing molecule, but is incorporated into the molecular backbone of the resin system.

The metals that are restricted are not used in base materials either. So from the standpoint of compliance, most laminate materials are acceptable. The key issue is the

restriction on the use of lead, and the implications that this has for assembly of components onto PCBs. Eutectic tin/lead (Sn/Pb) has been the primary solder alloy used in assembly of printed circuits, and has a melting point of 183°C. Peak assembly temperatures using eutectic tin/lead commonly reach 230 to 235°C. With the elimination of lead from electronics assembly, alternative solder alloys have been developed. These lead-free alloys have higher melting points. Tin/silver/copper (Sn/Ag/Cu) alloys, also called “SAC” alloys, are the most common lead-free solder alternatives, with the most common of these alloys having melting points around 217°C and peak assembly temperatures of up to 260°C. Assembly rework temperatures can be even higher. It is the increase in temperature to which PCBs are exposed to that is the primary issue with respect to base materials. In other words, the issue for base materials is not compliance with the restriction on the banned substances, but compatibility with the manufacturing processes and temperatures used.

13.3 BASE MATERIAL COMPATIBILITY ISSUES

The question of base material compatibility is very complex. This is the result of several factors. First, PCB design and construction have a significant impact on the base material properties required. Thin, low-layer-count PCBs may have different requirements than very thick, high-layer-count PCBs. Copper weights, aspect ratios, PTH-to-PTH pitch and other design features also have an impact. End-use application and the associated requirement for long-term reliability and electrical performance also impacts the decision-making process. The requirements for a cell phone, video game, or even a computer motherboard are very

different than those for high-end servers, telecommunications gear, avionics, and critical medical and automotive electronics. Finally, not all lead-free assembly processes are the same. Some designs experience peak temperatures of around 245°C, whereas others experience peak temperatures of up to 260°C, or even higher in some cases. Some PCBs may experience two to three thermal cycles, others up to five, six, or even more depending on how many reworks are allowed. All of this makes it impossible to recommend one base material type for all applications without either underspecifying the laminate material and risking defects during assembly or later on in the field, or over-specifying the material and paying too much for the material or limiting availability.

Beyond the complexity introduced by the PCB design and construction, there are fundamentally two issues:

1. Surviving lead-free assembly processes without defects
2. Maintaining the required level of long-term reliability for the given application

The critical base material properties required for each are summarized here, and discussed in more detail later in this chapter.

13.3.1 Surviving Lead-Free Assembly without Defects

The primary defects related to base materials that can occur during lead-free assembly include measling, blistering, or delamination. These defects are related to the thermomechanical properties of the base material, the decomposition properties of the material, as well as the interaction of these properties with any absorbed moisture that may be contained within the PCB during assembly,

which can be volatilized as the PCB is heated. Fundamentally, these defects represent either the creation of voids within the PCB due to the volatilization of moisture, retained solvents, other organic components including the by-products of resin decomposition, or the loss of adhesion between the fundamental base material components: glass cloth, resin system, and copper. The adhesion loss and subsequent blistering or delamination may be the result of pressure from volatilized components, mismatches between component thermal expansion rates, degradation of the components at the interfaces, or combinations of these factors. Figure 13.1 is an example of delaminations within a PCB after lead-free assembly processing. This PCB used a dicyandiamide (dicy) cured, high-T_g FR-4 base material. The left and right-side images in this figure are from the same area of the PCB, but photographed with different lighting to highlight the specific interfaces where delamination occurred.

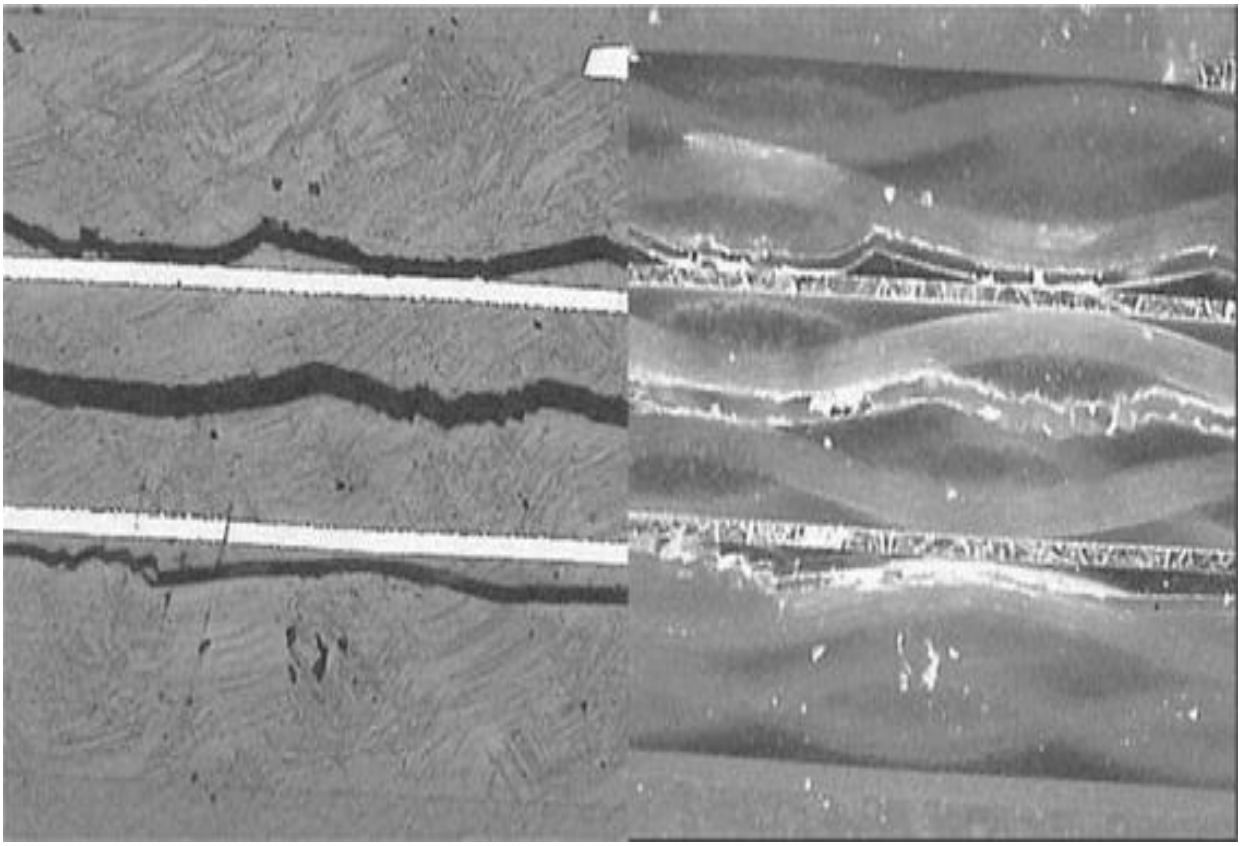

FIGURE 13.1 PCB delamination after lead-free assembly.

Among the key base material properties that relate to survivability in lead-free assembly processes are

- Decomposition temperature (T_d)
- Coefficients of thermal expansion (CTE_s)
- Moisture absorption
- Time to delamination
- Modulus

Time to delamination, or T260 time, which is the time it takes for a sample to delaminate when held at an isotherm temperature of 260°C, is not a fundamental base material property, but is a functional test related to the other material properties. In multilayer PCBs, this property can be affected

by the quality of the innerlayer copper surface preparation and multilayer lamination, among other things.

13.3.2 Lead-Free Assembly and Long-Term Reliability Issues

The second fundamental issue for base materials and PCBs is the impact to long-term reliability assuming a PCB has survived assembly. Other things being equal, the long-term reliability of a PCB assembled in a lead-free process with higher temperatures is not as good as a PCB assembled in a tin-lead assembly process with lower temperatures, unless the properties of a material are so robust that lead-free temperatures do not have an impact on the material. The magnitude of the difference is dependent on many factors. Some of the key properties of the base material with respect to long-term reliability include

- CTEs
- Glass transition temperature (T_g)
- Decomposition temperature (T_d)
- Moisture absorption

Additionally, the specific construction of the PCB in terms of resin content, the types of fiberglass cloth used, and the adhesion and long-term thermochemical compatibility between the resin system and copper which is plated within vias can have a significant impact on long-term reliability. Some of these factors relate to the impact they have on CTEs, both in the *z* axis as well as in the *x* and *y* axes. For example, using a very high resin content prepreg layer adjacent to a very low resin content layer increases the stress at the interface of these layers due to the differences in thermal expansion that result from the differences in resin-

to-glass concentrations. The higher temperatures of lead-free assembly result in a greater absolute level of expansion or stress at these interfaces. The distribution of the glass filaments within the resin system can have a similar effect. Within a given layer or prepreg, if there are “resin-rich” versus “glass-rich” areas, the differences in thermal expansion between these areas cause stresses that can lead to micro-delamination, or at the interface with a plated-through hole (PTH) will result in points of stress-strain discontinuity resulting from differences in the *z*-axis expansion values. It is not uncommon to see cracks in the PTH copper begin at these points.

Section 13.5 discusses the material properties relevant to both surviving lead-free assembly as well as ensuring long-term reliability. Although the test methods used to assess long-term reliability are beyond the scope of this chapter, where relevant, a brief description will be provided to help explain performance differences. However, before discussing these properties in more detail, Sec. 13.4 with Table 13.1 presents some of the concerns related to the components used to make base materials.

TABLE 13.1 Primary Lead-Free Issues for Base Material Components

Component	Lead-Free Assembly Impact	Potential Solutions	Related Considerations
Resin system	1. Peak assembly temperatures can reach point where resin decomposition begins. 2. Higher temperatures result in increased thermal expansion, delamination and stress on plated holes as a result. 3. Vapor pressure of absorbed moisture much higher at lead-free assembly temperatures; can lead to blistering/delamination. 4. "Phenolic" lead-free compatible materials often not as good for electrical performance, especially Df.	1. Formulate resin system with higher decomposition temperatures. 2. Formulate for lower coefficients of thermal expansion. 3. Evaluate materials for moisture absorption/release characteristics; drying processes in PCB fabrication and/or assembly. 4. Evaluate nondicy/ nonphenolic laminate materials with lower Df.	1. Reformulation can adversely affect electrical properties and manufacturability. 2. Can also impact mechanical properties and manufacturability. 3. PCB storage conditions during manufacturing and prior to assembly are much more important, especially humidity conditions. 4. Cost/performance trade-off. New materials now in high volume use that offer more choices.
Fiberglass cloth	Thermal and mechanical stress on resin-to-glass bond. Volatilized components can also stress this bond.	Cleanliness, moisture resistance and choice of proper coupling agent for resin adhesion more important.	Loss of resin-to-glass adhesion through thermal cycling could impact CAF resistance. Use of spread glass cloth may be beneficial.
Copper foil	Thermal and mechanical stress on resin-to-copper bond.	Improved copper surface treatments for improved adhesion, i.e., coupling agents.	Roughness impacts signal attenuation, especially at high frequencies.

13.4 THE IMPACT OF LEAD-FREE ASSEMBLY ON BASE MATERIAL COMPONENTS

The higher temperatures of lead-free assembly have an impact on each of the three main components of laminate materials: the resin system, the glass cloth, and the copper foil. Table 13.1 summarizes the key issues for each of these main components.

13.5 CRITICAL BASE MATERIAL PROPERTIES

Substantial work describing the impact of lead-free assembly temperatures on base materials and finished PWBs has been gathered. These works have identified the critical base material properties that must be considered when selecting a material for lead-free assembly applications, though work on this subject continues. Table 13.2 provides a summary of some key properties.

TABLE 13.2 Critical Base Material Properties for Lead-Free Assembly Applications

Property	Definition	Issue
Decomposition temperature, T_d	Measurement of weight loss from resin system degradation as a function of temperature. T_d is typically defined as the point at which 5% of the original mass is lost to decomposition, but other levels can also be reported, e.g., 1%, 2%, or "onset."	Resin decomposition can result in adhesion loss and delamination. A 5% level of decomposition is severe, and intermediate levels are important for assessing reliability since peak temperatures in lead-free assembly can reach onset points of decomposition. A high T_d by the 5% definition does not guarantee performance. Conversely, a low T_d by the 5% definition is not necessarily bad if the onset temperature of decomposition is high enough.
Glass transition temperature, T_g	Thermodynamic change in polymer from a relatively rigid, glassy state, to a softened, more deformable state.	Several properties change as the T_g is exceeded, including the rate at which a material expands versus temperature. Modulus also decreases significantly as T_g is exceeded.
Coefficients of thermal expansion, CTEs	Rate of change in physical dimension (in *x*, *y*, or *z* axis) as a function of temperature, expressed as a coefficient of thermal expansion. Can also be expressed as a percentage expansion over a given temperature range.	Resin system CTE values above T_g are much higher than below T_g. *Z*-axis expansion induces stress on plated vias. The higher temperatures of lead-free assembly result in more total expansion for a given material. Several mature lead-free-compatible materials incorporate inorganic fillers that reduce CTE values. *X*- and *y*-axis CTEs are also important for reliability at component and layer interfaces.
Moisture absorption	Tendency of a material to absorb moisture from the surrounding environment. Can be assessed by more than one method, including water soak or in an increased pressure and humidity environment.	Vapor pressure of water is much higher at lead- free assembly temperatures. Absorbed moisture can volatilize during thermal cycling and cause voiding or delamination. PWBs that initially pass lead-free assembly testing may exhibit defects after storage in an uncontrolled environment as a result of moisture absorption. This should be considered when evaluating materials and PWB designs.
Time to delamination	Not a fundamental property; measurement of the time for delamination to occur at a specific temperature, e.g., 260°C (T260) or 288°C (T288).	This property is related to decomposition temperature and adhesion between material components. Thermal expansion and moisture absorption can also influence results. In multilayer PWBs, the treatment of the internal copper surfaces is also critical, among other factors.

A very critical point that must be emphasized with respect to these issues is that although laminate manufacturers can easily make improvements in one property, doing so can often adversely affect other important properties. For example, it is relatively easy to formulate a resin system with a very high time to delaminate in conventional T260 or T288 tests, or to engineer a resin system with a very high decomposition temperature. However, this is often achieved at the expense of mechanical properties and can make the material more difficult to use successfully in conventional PWB manufacturing processes, or without sacrificing design flexibility. Interactions between these and other material properties such as hardness, modulus, and fracture toughness with the processes used in PCB fabrication can greatly influence the reliability of a PCB during and after assembly. For example, an increase in decomposition temperature with a simultaneous decrease in fracture toughness does little good if the PCB exhibits cracking or fracturing during scoring processes or similar defects during the mechanical drilling of tight pitch holes for PTHs. Therefore, achieving the best balance of properties to meet the needs of the OEM, Electronic Manufacturing Services (EMS) company, and PWB manufacturer is critical.

13.5.1 The Historical Focus on T_g

Chapter 10 explained how and why T_g has historically been one of the properties used to classify base materials, while Chap. 12 provided additional information on the measurement of T_g. In short, the historical focus on T_g as an indicator of reliability is probably the result of its effect on total *z*-axis expansion. However, because of differences in CTE values, even the relationship between T_g and thermal expansion requires further analysis. Figure 13.2 illustrates

the relation-ship between T_g and thermal expansion for the products in Table 13.3.

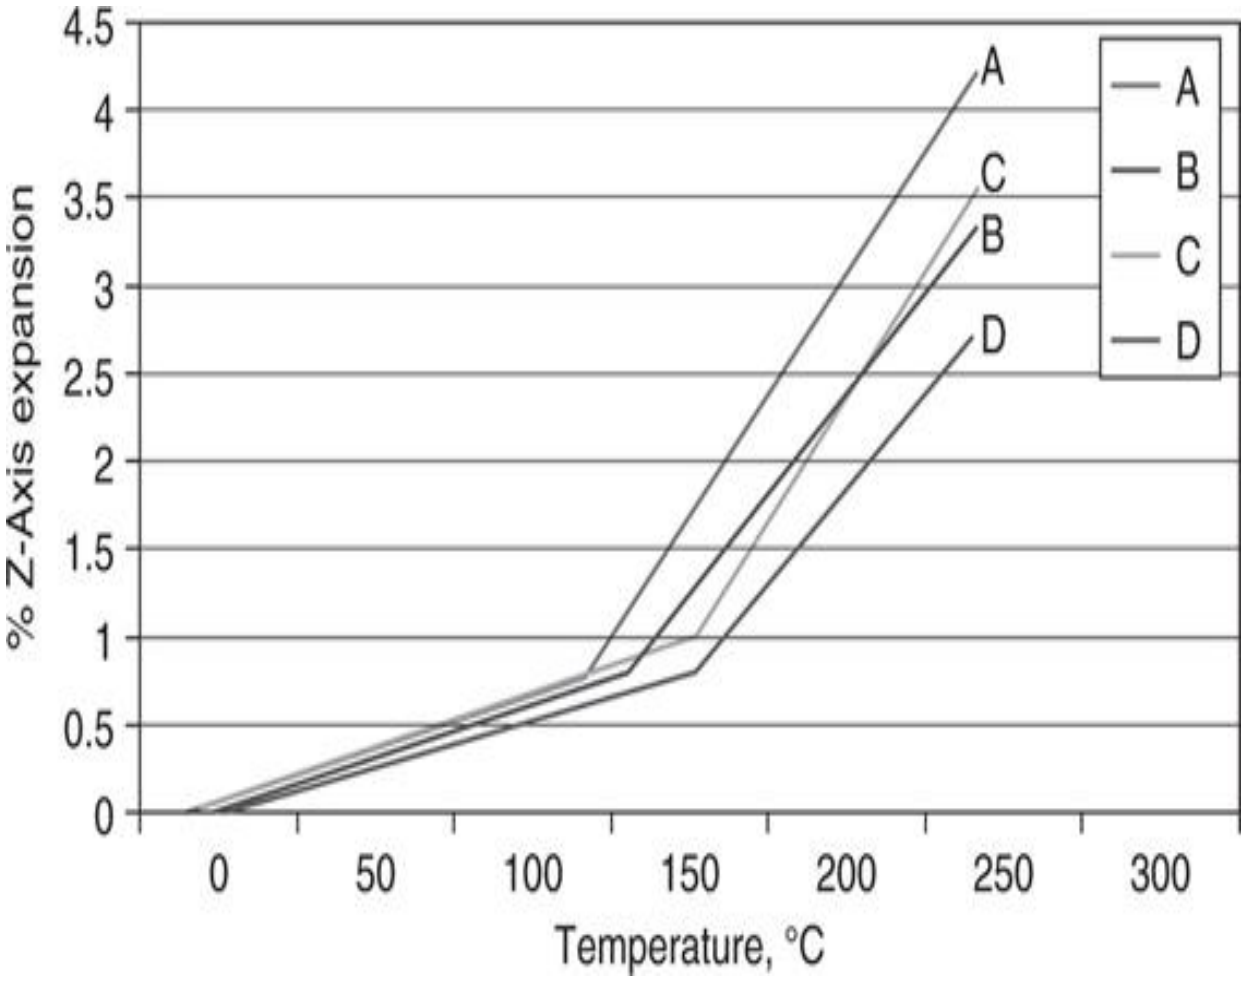

FIGURE 13.2 The impact of T_g and CTE values on total expansion.

TABLE 13.3 Properties of Some Common FR-4 Base Materials

Product	Description	Glass Transition Temp., °C	Decomposition Temp., °C	% Expansion, 50–260°C (40% Resin Content)
A	Traditional dicy-cured 140°C T_g FR-4	140	320	4.2
B	Phenolic" mid-T_g FR-4	150	335	3.4
C	Traditional dicy-cured High-T_g FR-4	175	310	3.5
D	Improved high-T_g FR-4	175	335	2.8

From Fig. 13.2, products with the same pre- and post-T_g CTE values (A and C, for example; note that above T_g the lines are parallel) differ in total expansion based on their T_g values. For example, the 175°C T_g material C exhibits less total expansion than the 140°C T_g material A because the onset of the higher post-T_g rate of expansion is delayed by 35°C. However, the 175°C T_g material D, with a lower CTE value, exhibits much less total expansion than the 175°C T_g material C even though the T_g values are the same. Furthermore, the 150°C T_g material B with reduced CTE values exhibits approximately the same total expansion (3.4 percent) as the 175°C T_g material C (3.5 percent). However, with a decomposition temperature that is significantly higher, this mid-T_g FR-4 material is much more compatible with lead-free assembly than the 175°C T_g material in this case, as it is a dicy-cured material.

13.5.2 The Importance of Decomposition Temperature

Although glass transition temperature (T_g) and *z*-axis expansion have been a primary focus of attention over the years, only with the introduction of lead-free assembly has the decomposition temperature (T_d) gained significant attention. The decomposition temperature has always been important in terms of reliability, yet most people have used T_g as a proxy for material reliability. One reason for this is that other things being equal, a higher-T_g results in less total thermal expansion, and therefore less stress on plated vias. What wasn't discussed is that it is common for dicy-cured, high-T_g FR-4 materials to exhibit somewhat lower decomposition temperatures than dicy-cured, 140°C T_g FR-4 materials. This is highlighted by the fact that most dicy-cured 140°C T_g FR-4 materials exhibit longer T260 times than dicy-cured high-T_g FR-4 materials. To highlight the importance of T_d, examine Fig. 13.3.

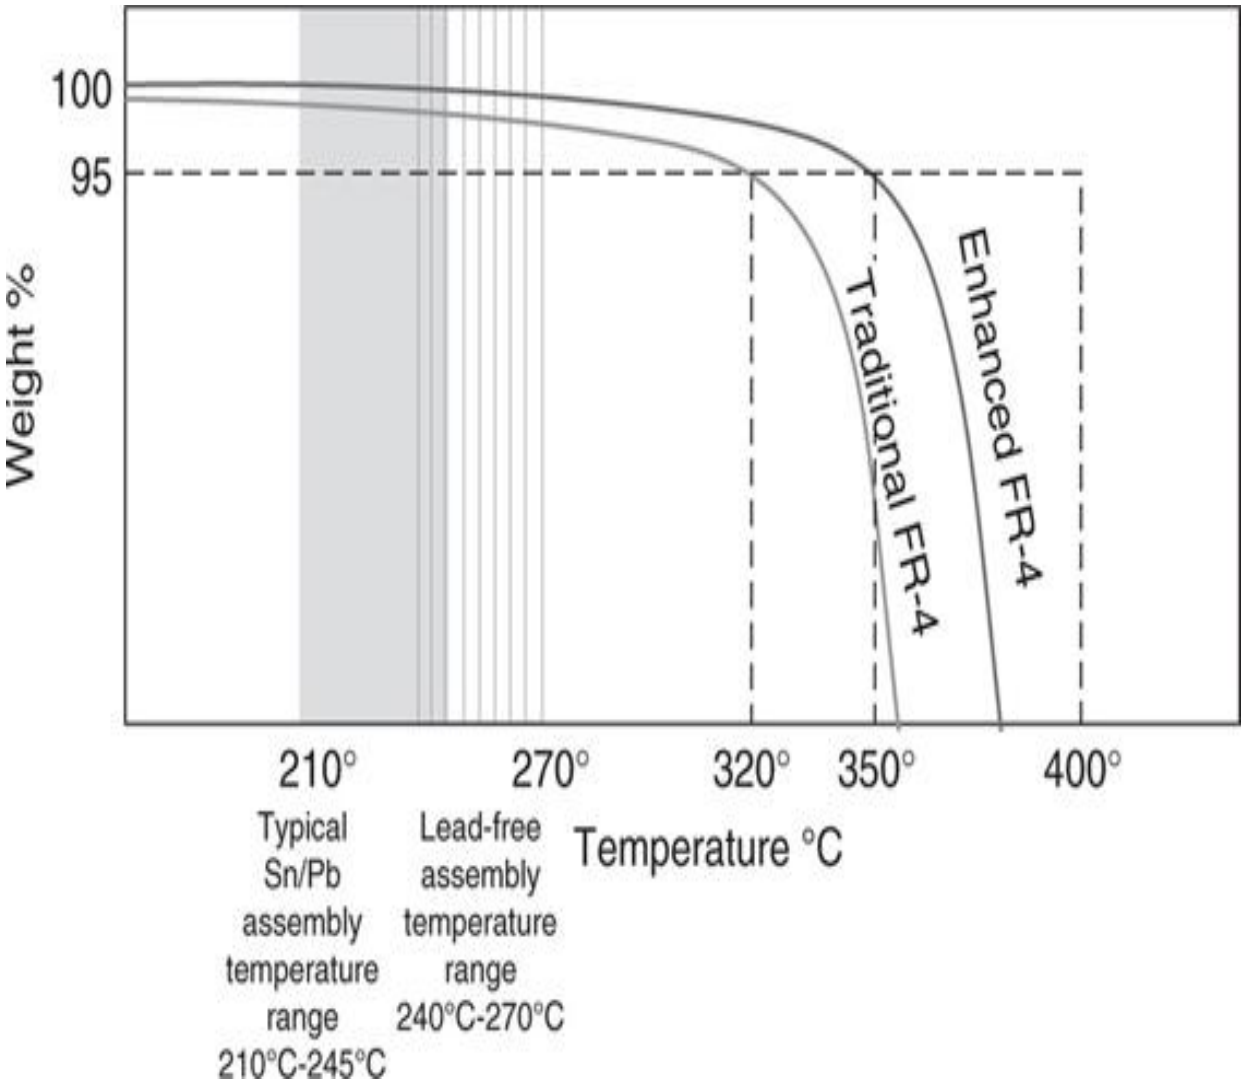

FIGURE 13.3 Decomposition curves for a traditional and improved FR-4 material.

The traditional dicy-cured, high-T_g FR-4 materials have T_d values in the range of 290 to 310°C. Traditional 140°C T_g dicy-cured materials are generally somewhat higher, with a typical example of a material with a T_d of 320°C shown in Fig. 13.3. In the typical tin-lead assembly environment, peak temperatures do not reach the point where decomposition is significant for either the traditional or enhanced products. However, in the lead-free assembly environment, peak temperatures can reach the point where a small but significant level of decomposition can occur for the

traditional dicy-cured materials, but not for the enhanced products.

This seemingly small level of decomposition in the conventional products can have extremely significant effects on reliability, especially if multiple thermal cycles are experienced.

On the other hand, as long as the temperatures experienced during assembly and rework do not exceed the temperature at which decomposition begins, there may not be further benefit to higher decomposition temperatures. In addition, the resin system modifications often made to increase T_d can sometimes lead to other problems, such as brittleness or hardness of the resin system that negatively impacts PCB manufacturability (as in drilling, scoring, and routing) or fracture toughness in tight pitch PTH areas. As not all lead-free-compatible materials use the same resin systems, great care should be used in selecting a material that balances the requirements of the OEM, assembler, and PCB fabricator. A simple review of a material data sheet or IPC slash sheet is not sufficient to guarantee success. Involvement with the base material supplier to fully understand the capabilities of a material and the processing required for success is vital. To expand on this, examine Figs. 13.4 through 13.6, which were also presented in Chap. 12.

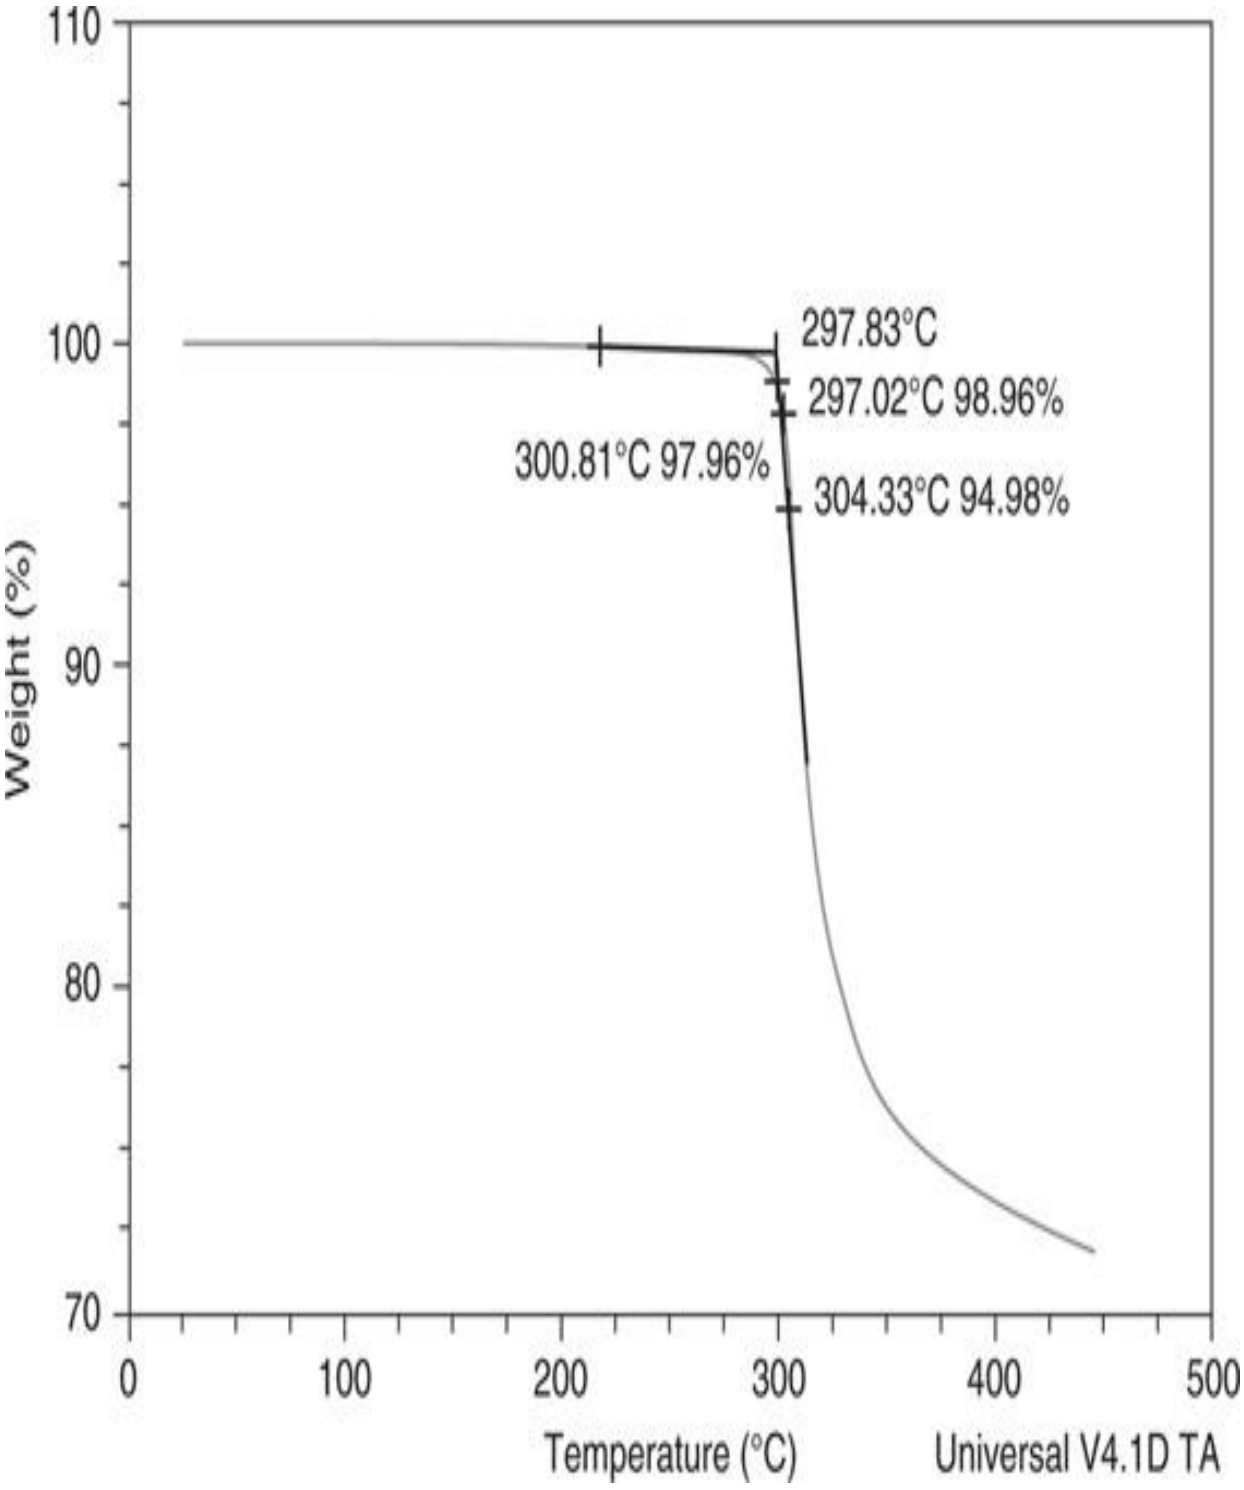

FIGURE 13.4 Decomposition curve for a standard dicy-cured high-T_g FR-4.

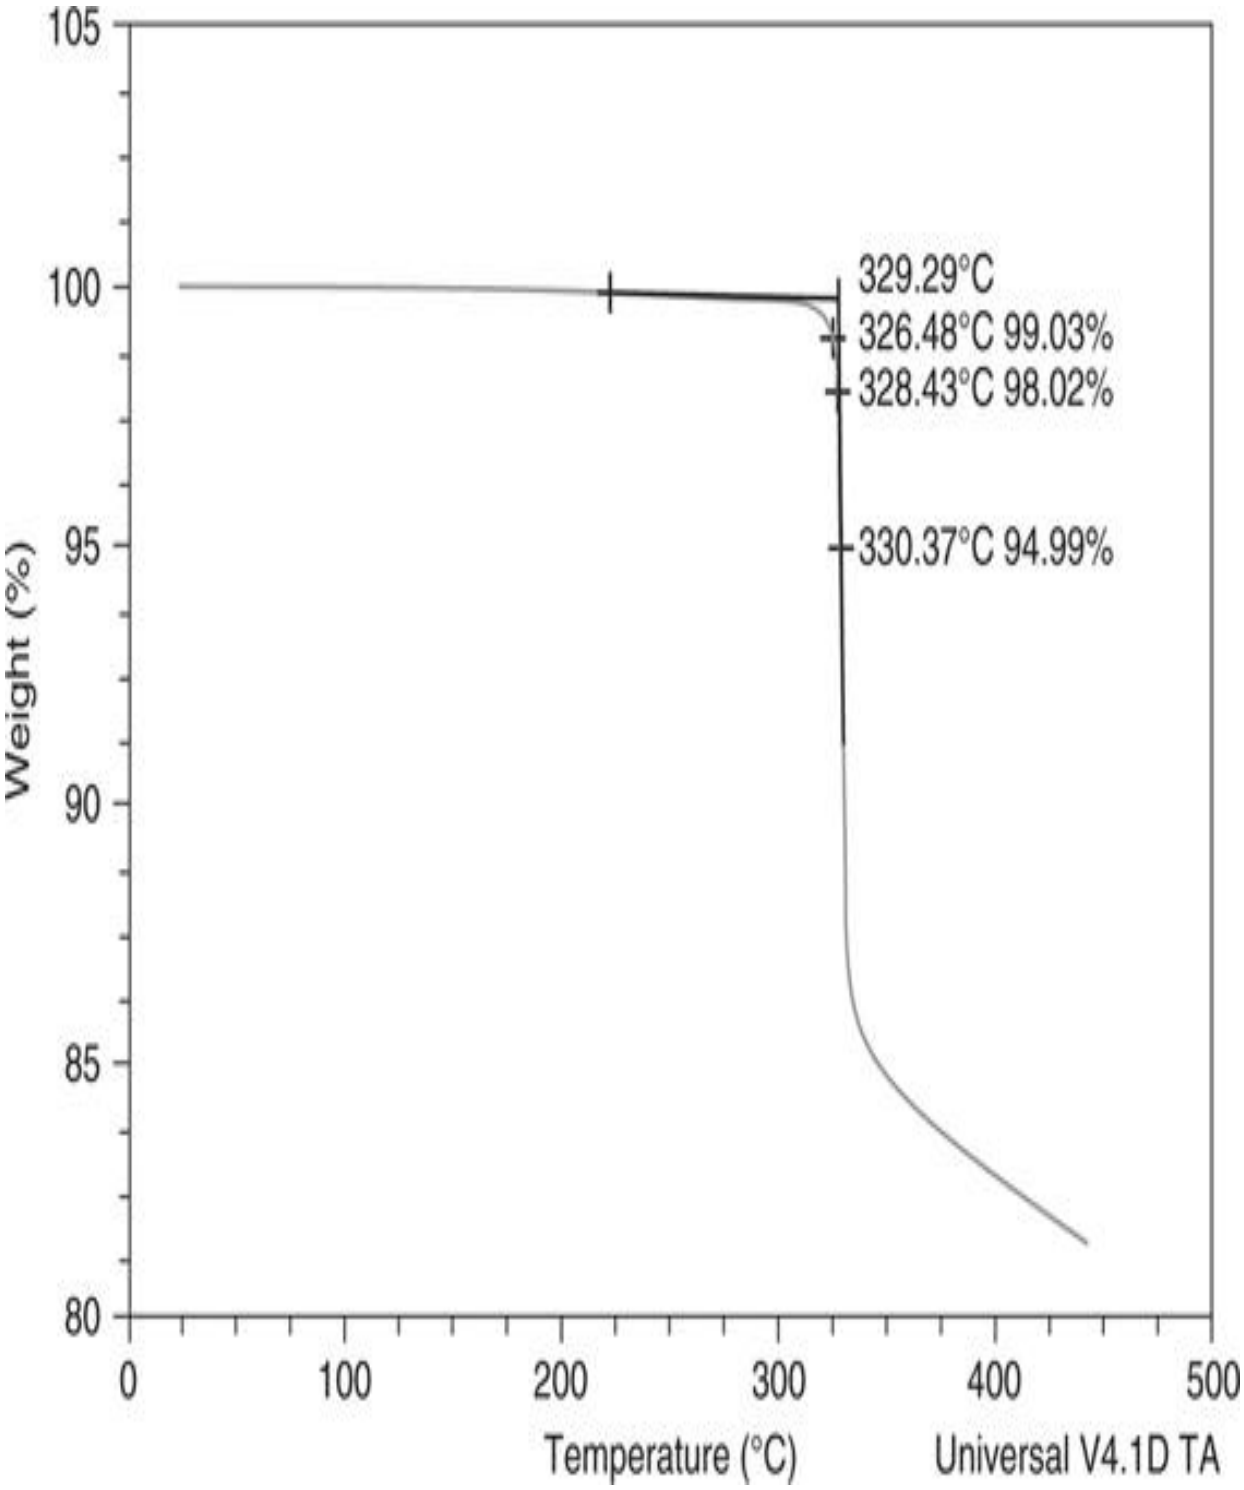

FIGURE 13.5 Decomposition curve for a phenolic high-T_g FR-4.

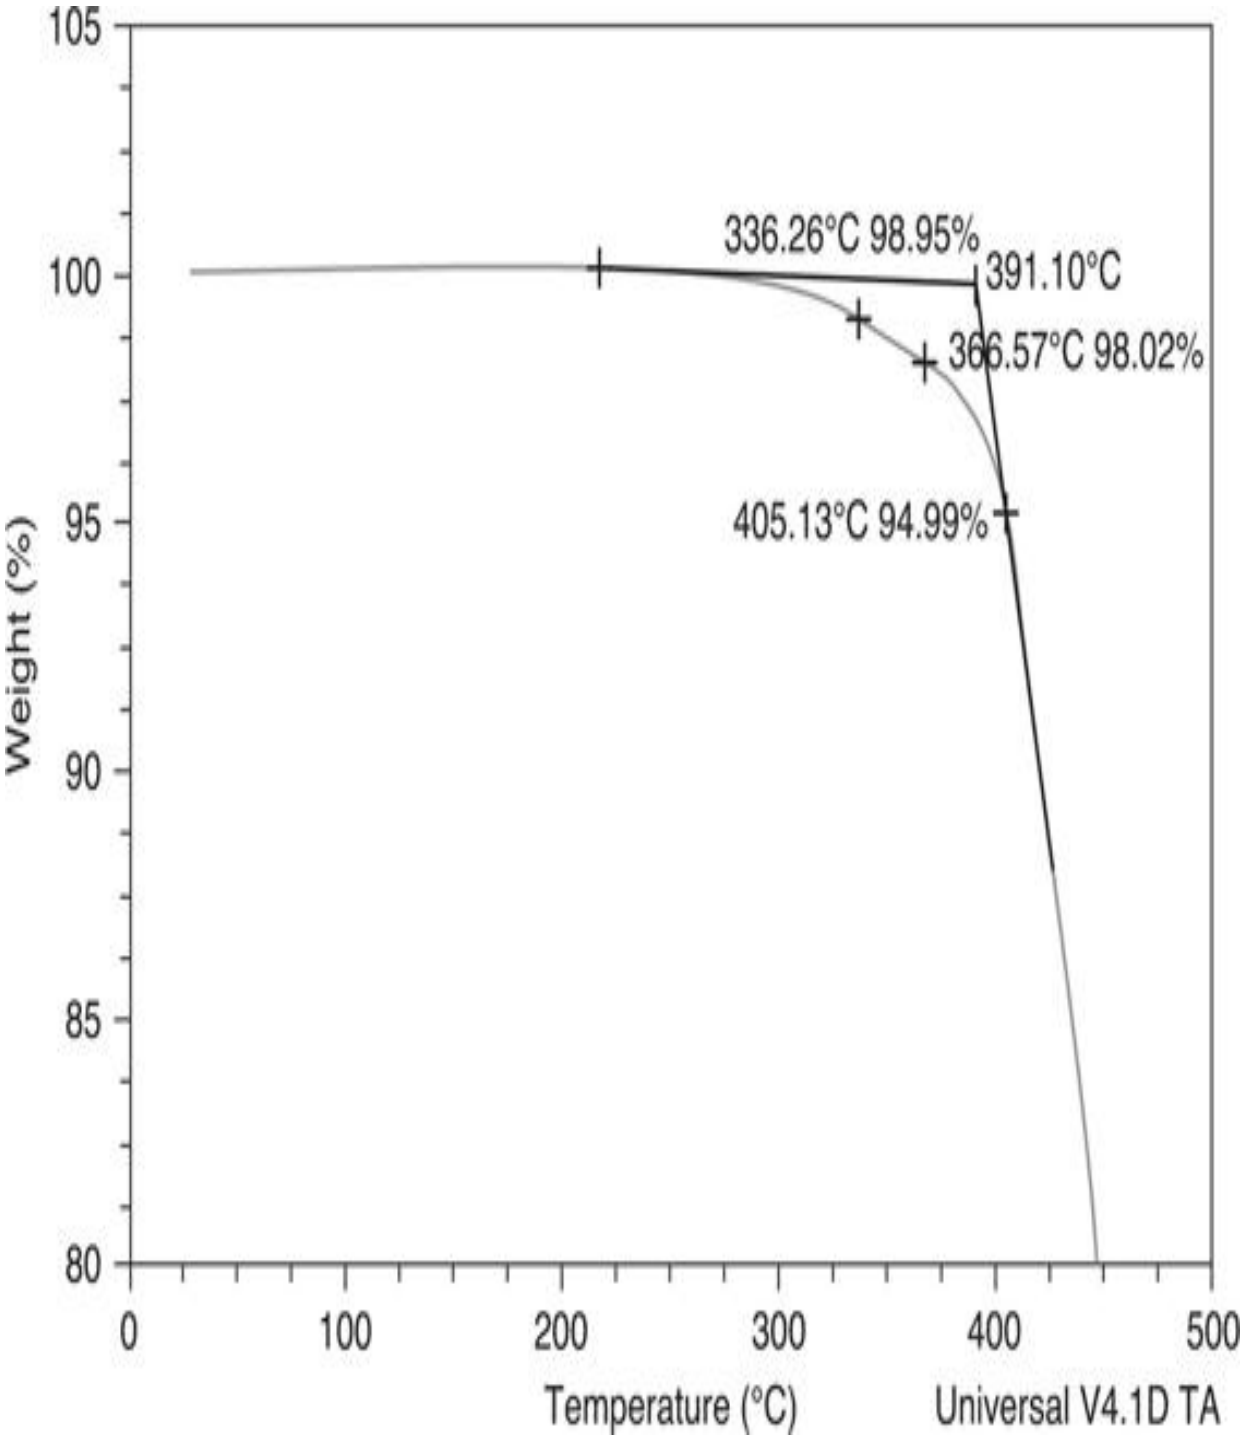

FIGURE 13.6 Decomposition curve for an alternative high-T_g/high-T_d material.

First, note the slope of the decomposition curve in Fig. 13.6. By the 5 percent decomposition definition, this material has a T_d of 405°C. However, looking at 1 percent and 2

percent values, the temperatures are 336°C and 367°C, which are significantly lower than a reported 5 percent value of 405°C. This is not to say that a 1 percent T_d of 336°C is bad. In fact, this material has exhibited exceptional reliability in lead-free applications. However, it does point to the need to understand decomposition levels other than the 5 percent level. In contrast, the material in Fig. 13.5 has a 5 percent T_d of 330°C with 1 percent and 2 percent T_d's of 326°C and 328°C, respectively. In this case, there is a very small difference between the 1 percent, 2 percent, and 5 percent values, and this material has also proven to have excellent performance in a broad range of lead-free assembly applications. Last, the dicy-cured high-T_g material in Fig. 13.4 exhibits a 5 percent T_d of 305°C with 1 percent and 2 percent values of 297°C and 301°C. This is also a small range of values, but in this case the absolute values are lower and begin to approach the range of temperatures that can be experienced, at least locally, in a printed circuit board that undergoes lead-free assembly and rework. Materials such as this have not performed with adequate reliability to be considered for anything but the simplest lead-free applications. In addition, if PCBs made with these materials are stored in uncontrolled environments and are allowed to absorb even a modest level of moisture, the combination of lower T_d's with the higher vapor pressure of water at lead-free temperatures can lead to catastrophic defects in assembly or severely degraded long-term reliability.

To take this a step further, examine the materials listed in Table 13.3. These are four FR-4 materials, with material C being the same material as shown in Fig. 13.4, and material D being the same as the material in Fig. 13.5. The impact of decomposition temperature when these materials are exposed to multiple thermal cycles to different peak temperatures is highlighted in Figs. 13.7 and 13.8. Figure 13.7 graphs cumulative weight loss (decomposition) for

these materials when cycled repeatedly to a peak temperature of 235°C. Clearly, there is little impact on resin decomposition when the peak temperature reaches 235°C. Figure 13.8 presents the same results when the peak temperature is increased to 260°C. The increase in temperature to 260°C has a severe impact on resin decomposition for the traditional dicy-cured FR-4 materials as they experience multiple thermal cycles, especially the high-T_g material (product C). The rapid degradation in material C after only a few thermal cycles highlights why this material is not recommended for lead-free assembly applications.

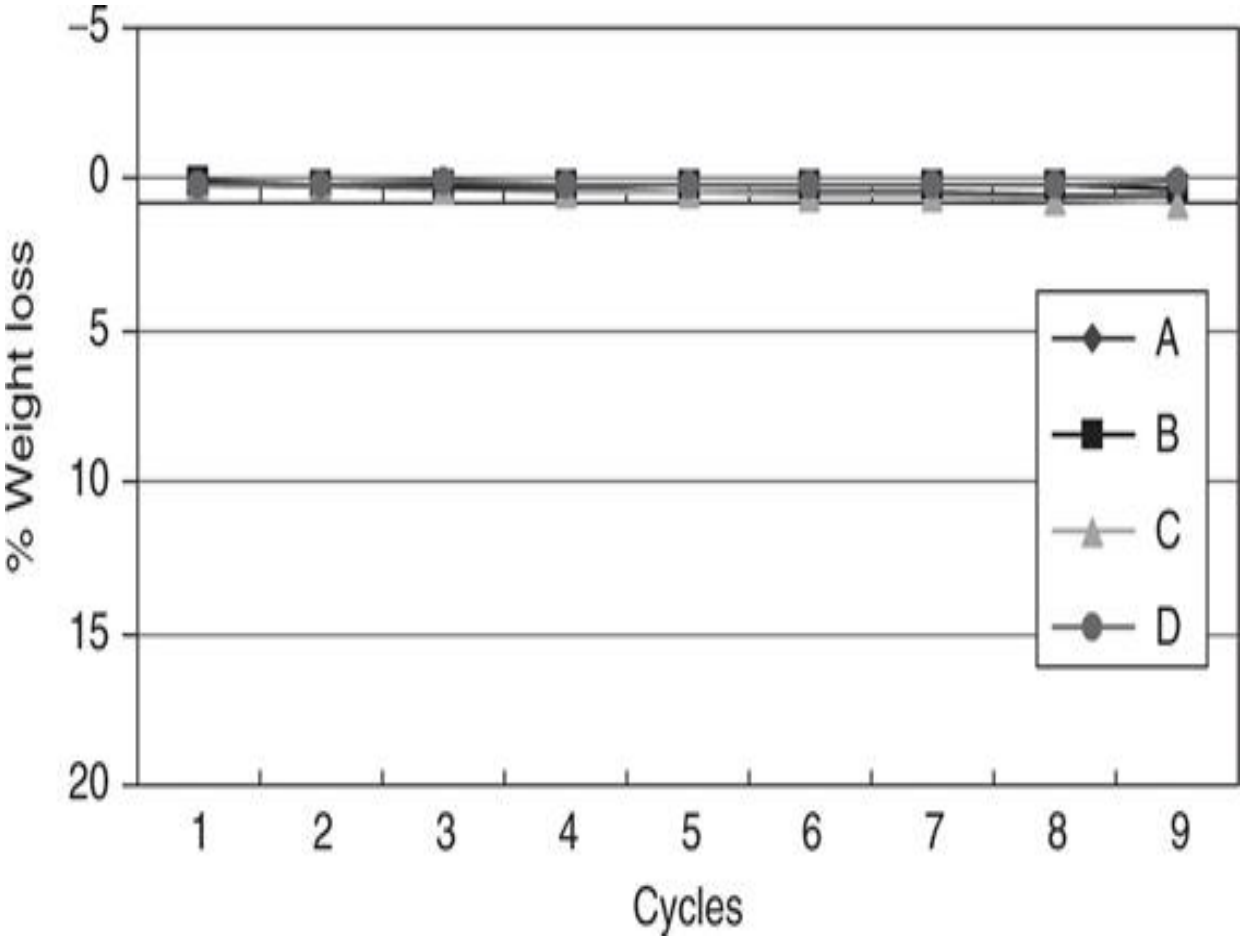

FIGURE 13.7 Decomposition through multiple cycles to 235°C.

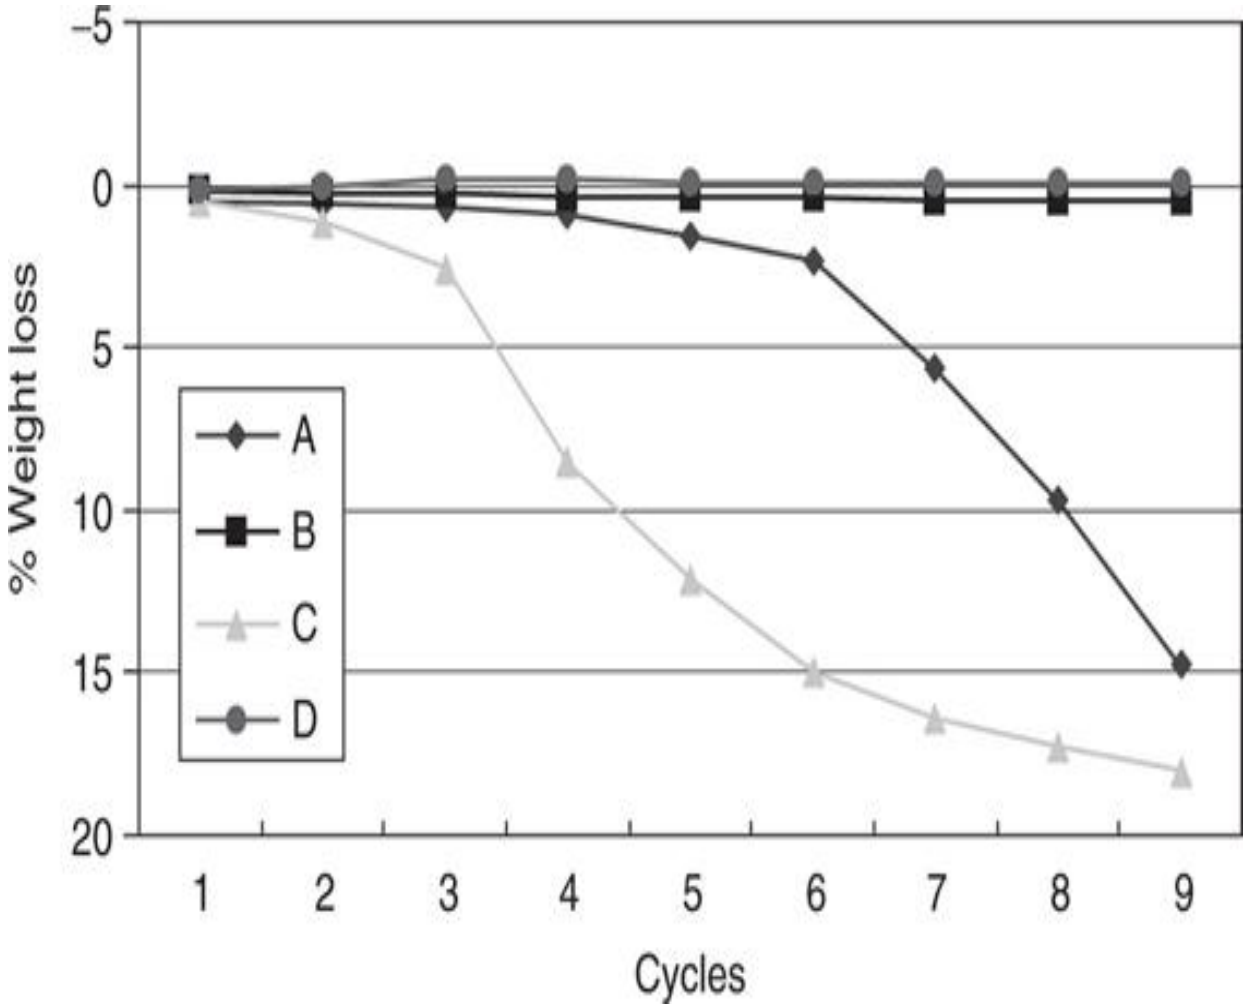

FIGURE 13.8 Decomposition through multiple cycles to 260°C.

13.5.3 Moisture Absorption

As pointed out in Table 13.2, the vapor pressure of water at lead-free assembly temperatures—260°C for example—is much higher than at eutectic tin-lead assembly temperatures such as 230°C. Figure 13.9 plots the vapor pressure of water, in both mm Hg and psi, versus temperature. At 230°C the vapor pressure of water is near 400 psi. At 260°C, it is close to 700 psi. Therefore, any absorbed moisture within a PCB during assembly can have a much greater impact in lead-free assembly, as the greater pressure stresses the adhesion between the base material

components and can also create small voids within the resin system.

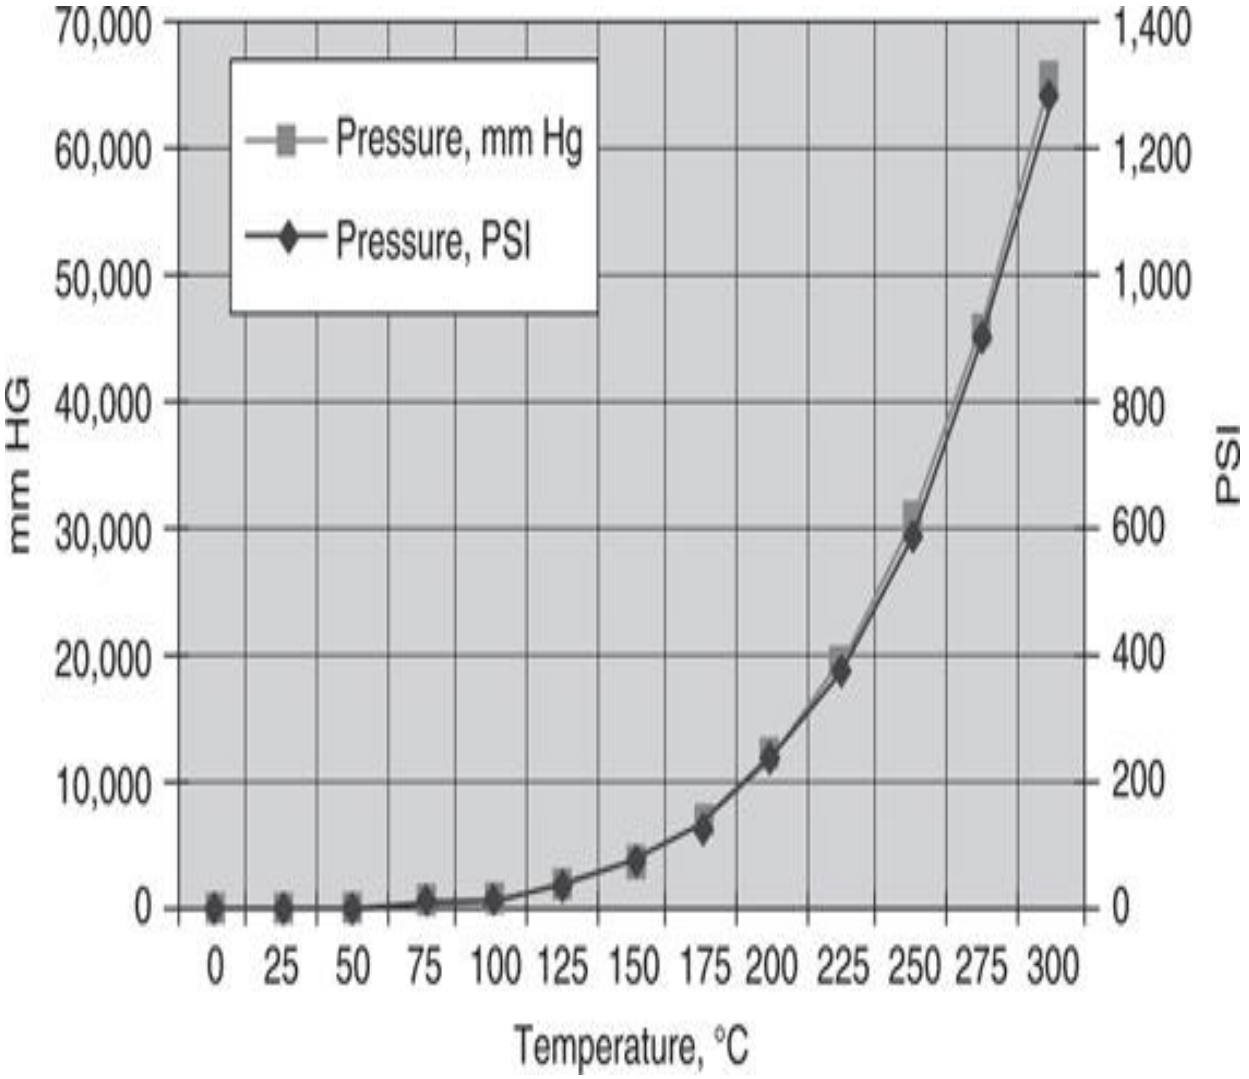

FIGURE 13.9 Vapor pressure of water versus temperature.

This means that much more care must be used in selecting materials for their moisture absorption properties. However, all common base materials absorb some level of moisture.

So the storage of these materials, both during manufacturing of the PCB as well as prior to assembly, must also be assessed. Additional drying or baking steps may be needed in some applications to drive off any absorbed moisture prior to exposure to high temperatures.

Additionally, it can be difficult to correlate actual performance with the moisture absorption data commonly found on material data sheets. One reason for this is that it may not be just the moisture absorption that is important, but the rate at which moisture can be driven from the material as well. As an illustration, consider the data in Fig. 13.10.

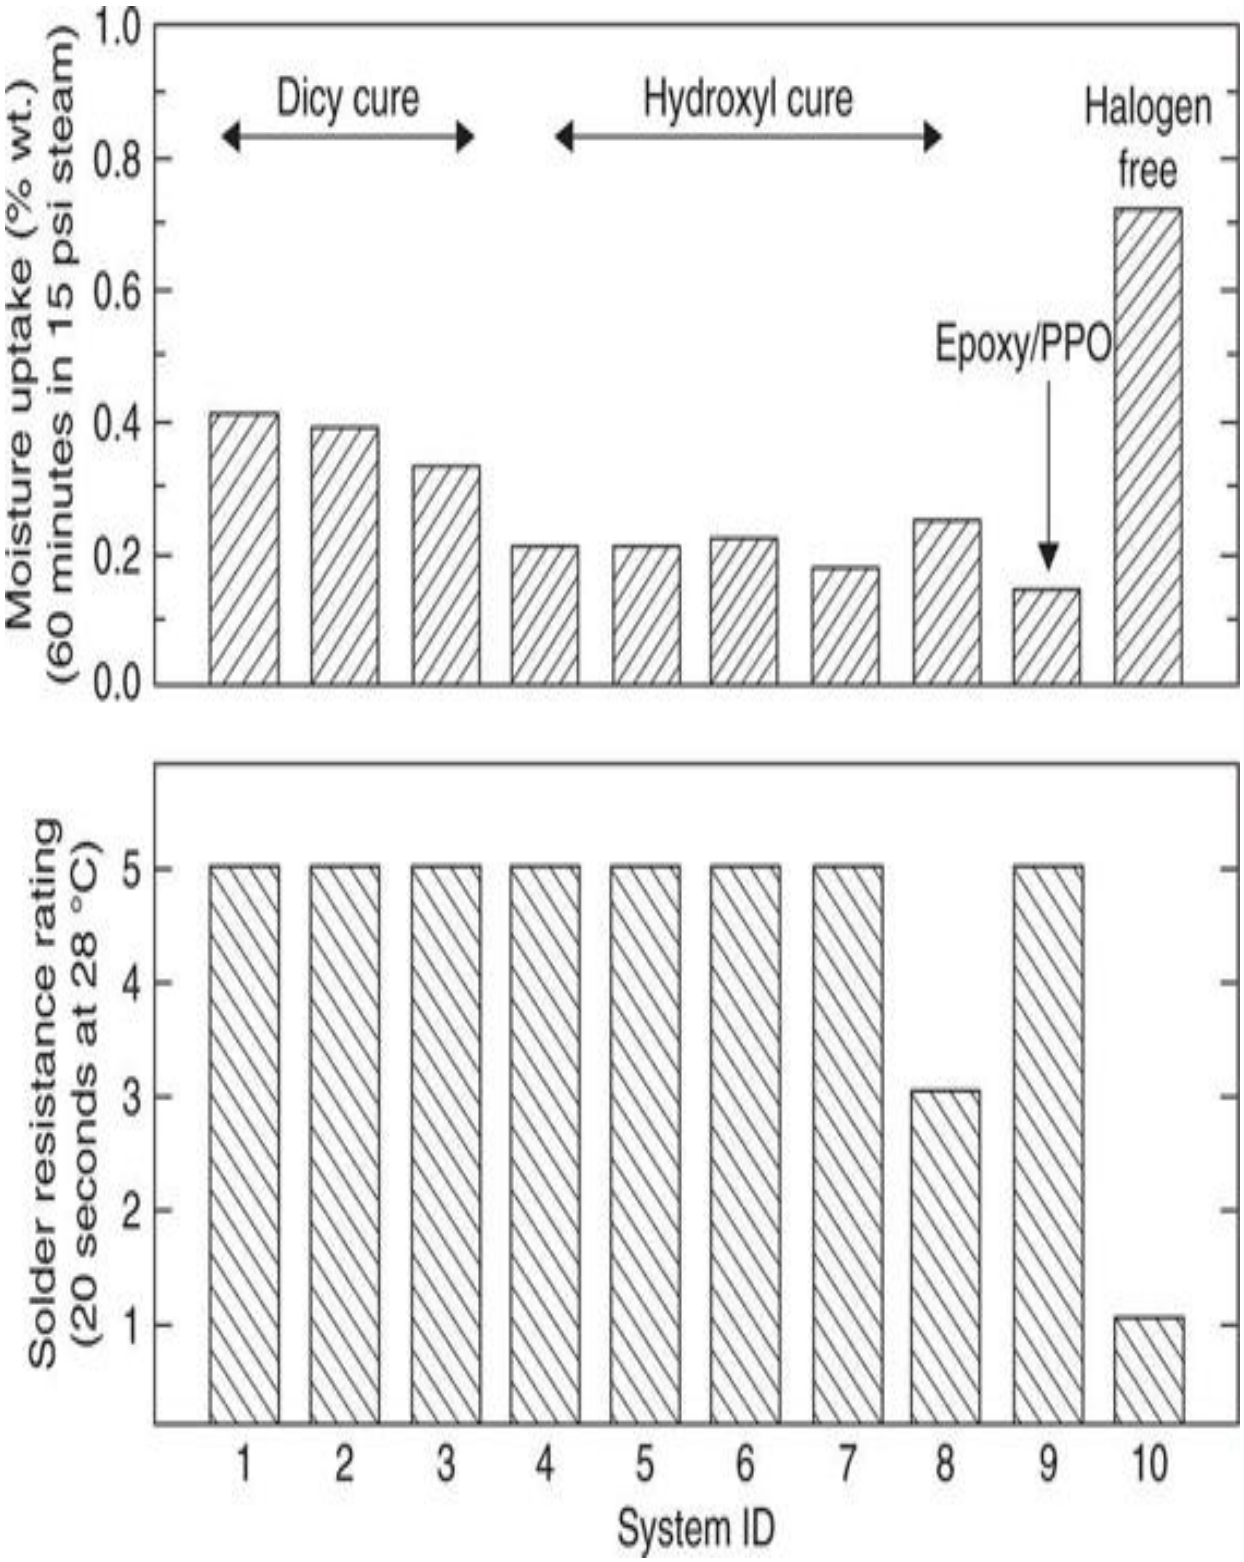

FIGURE 13.10 Moisture absorption versus solder shock resistance for several materials.

These materials were conditioned for 60 minutes in 15 psi steam and then solder shocked for 20 seconds at 288°C. Their moisture absorption was measured and compared to their performance in the solder shock testing. The particular halogen-free material shown in this graph exhibits a very high level of moisture absorption and does indeed exhibit poor solder shock resistance. However, with the exception of only one material, all the other materials exhibited good solder shock resistance in this test, even though their moisture absorption levels ranged from less than 0.2 percent to just over 0.4 percent. The one other material that exhibited some level of defects had an intermediate level of moisture absorption, around 0.3 percent. The point is that it is very difficult to draw conclusions about material performance based on reported levels of moisture absorption. Actual resistance to blistering or delamination may be affected by the interaction of the absorbed moisture with other properties of the material, such as modulus, yield and ultimate strengths. Additional reliability testing relevant to the application being considered is needed to make good decisions about material compatibility.

With respect to moisture absorption and the subsequent drying or baking of PCBs, consider the tests summarized by Figs. 13.11 and 13.12. In each test, several different types of base material were evaluated, including dicy-cured and phenolic-cured FR-4 materials, as well as low D_k/D_f and halogen-free materials. Figure 13.11 shows moisture absorption data for samples that were dried, then soaked in water at room temperature for five days, measured, and then baked at 125°C for 24, 96, and 120 hours. Samples from this test were then submitted to 35°C and 85 percent RH for seven days, measured, and then baked at 125°C for 24 and 48 hours. The results of this second test are shown in Fig. 13.12. Although these graphs show that the different types of materials may absorb somewhat different amounts of moisture, in each case the moisture was able to be driven

off by baking. Beyond this, little correlation could be found between the relative levels of moisture absorption and performance in lead-free assembly applications. Although the materials tested here that showed relatively low levels of moisture absorption have performed well in lead-free assembly applications, some that showed relatively high levels of moisture absorption in these tests have also performed well. The materials in this group that have not done well in lead-free applications fell somewhere in the middle in terms of relative moisture absorption. Thus, although moisture absorption is a critical property, it must also be evaluated within the context of other properties as noted above.

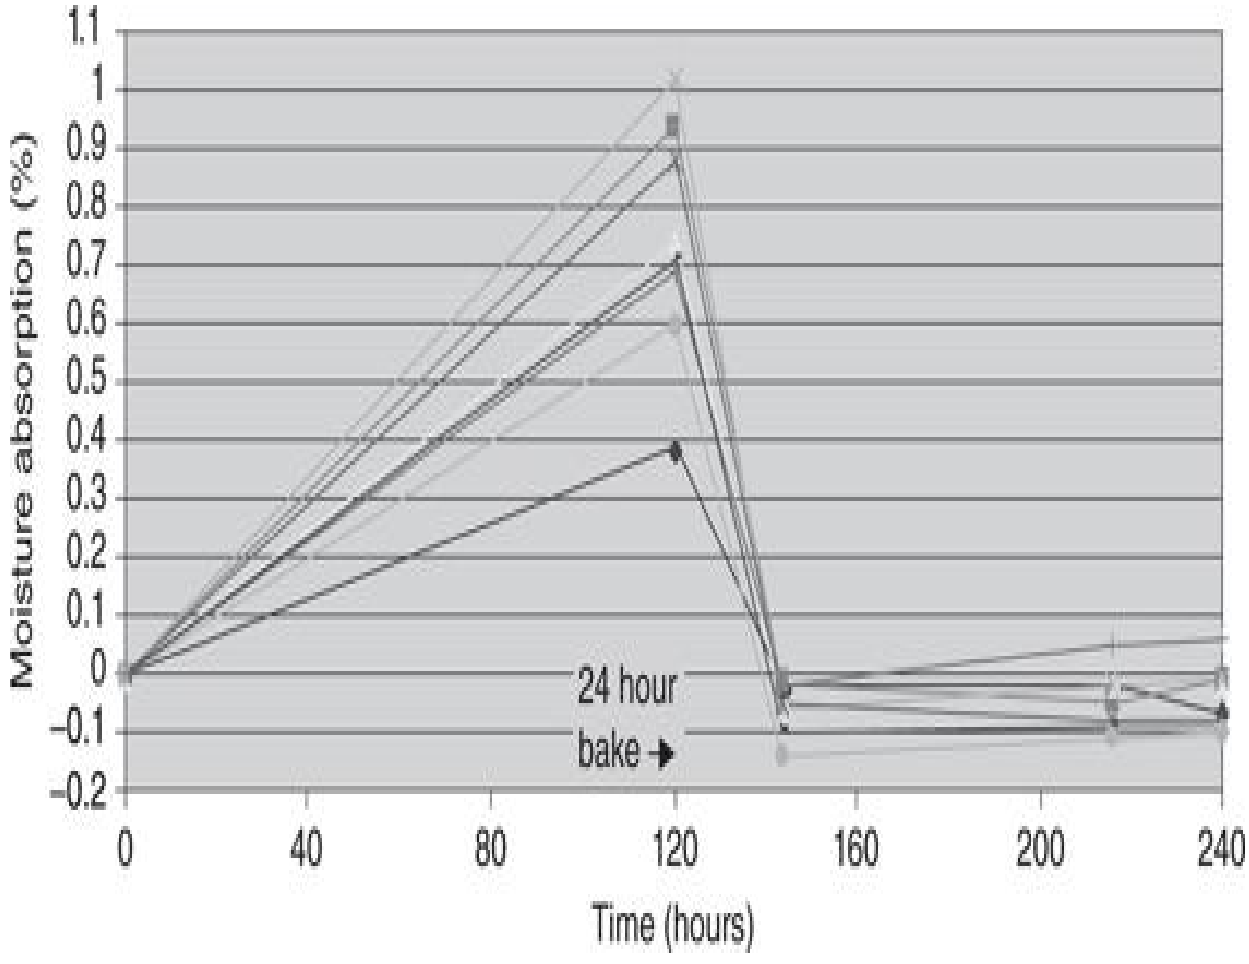

FIGURE 13.11 Percent weight change after a 5-day ambient moisture test and 125°C bake.

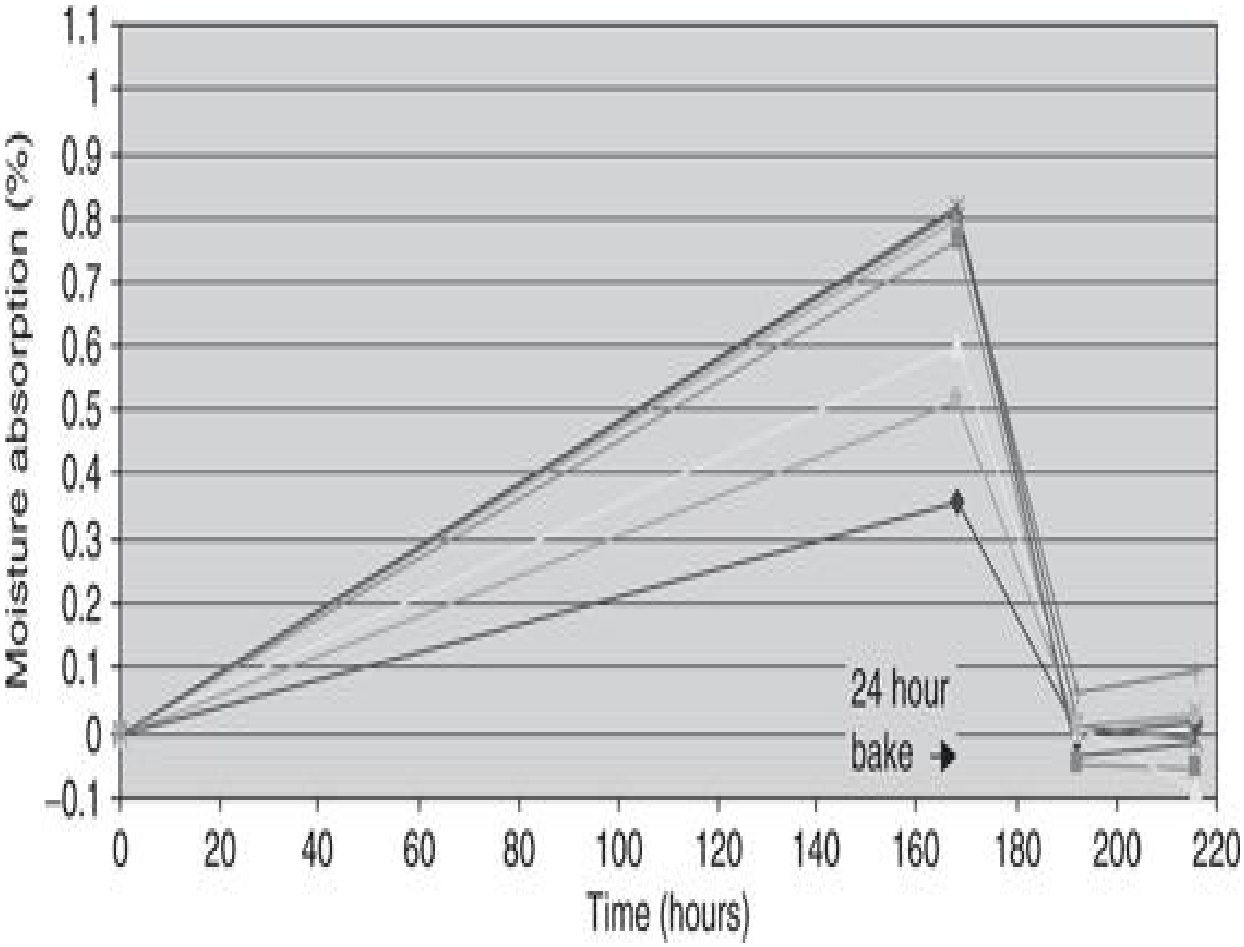

FIGURE 13.12 Percent weight change after seven days at 35°C/85 percent RH moisture test and 125°C bake.

13.5.4 Time to Delamination

The time to delamination, and how it is measured, was discussed in further detail in Chap. 12. This test method involves placing a sample of laminate or PCB in a thermomechanical analyzer (TMA) and heating the sample to a specific isothermal temperature, most commonly 260°C (T260) or 288°C (T288). The time it takes for the sample to delaminate is then measured and reported. Figure 13.13 is an example of a complex backplane PCB that was subjected to T260 testing. This PCB used a conventional dicy-cured high-T_g FR-4 material and delaminated before reaching 2

minutes. Note the charring and degradation of the resin system. Alternate resin systems, including alternate types of FR-4 materials, can offer significantly improved performance. Figure 13.14 compares time-to-delamination performance at different temperatures for four different resin systems: two dicy-cured FR-4s and two that use an alternate type of curing mechanism. Note that the materials using an alternative curing mechanism offer much longer times to delamination at each temperature, although all systems exhibit much shorter times as the temperature is increased.

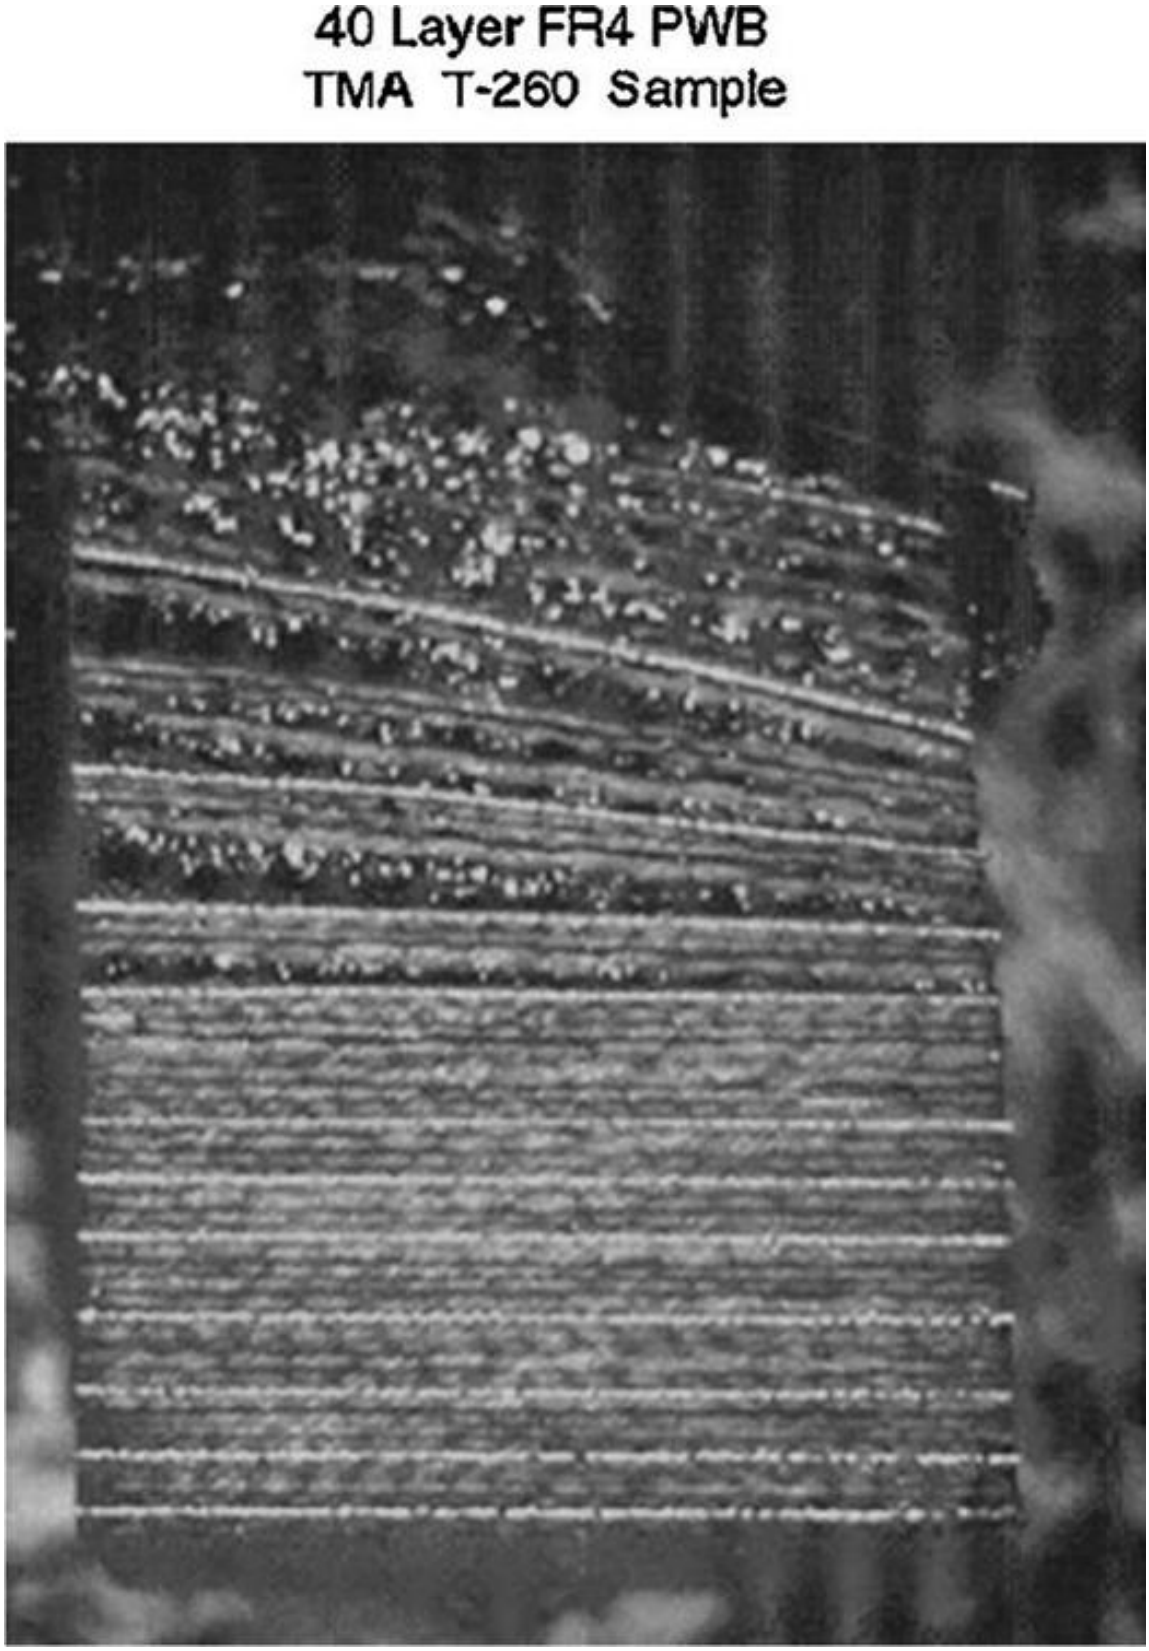

FIGURE 13.13 Delamination and resin decomposition after T260 testing.

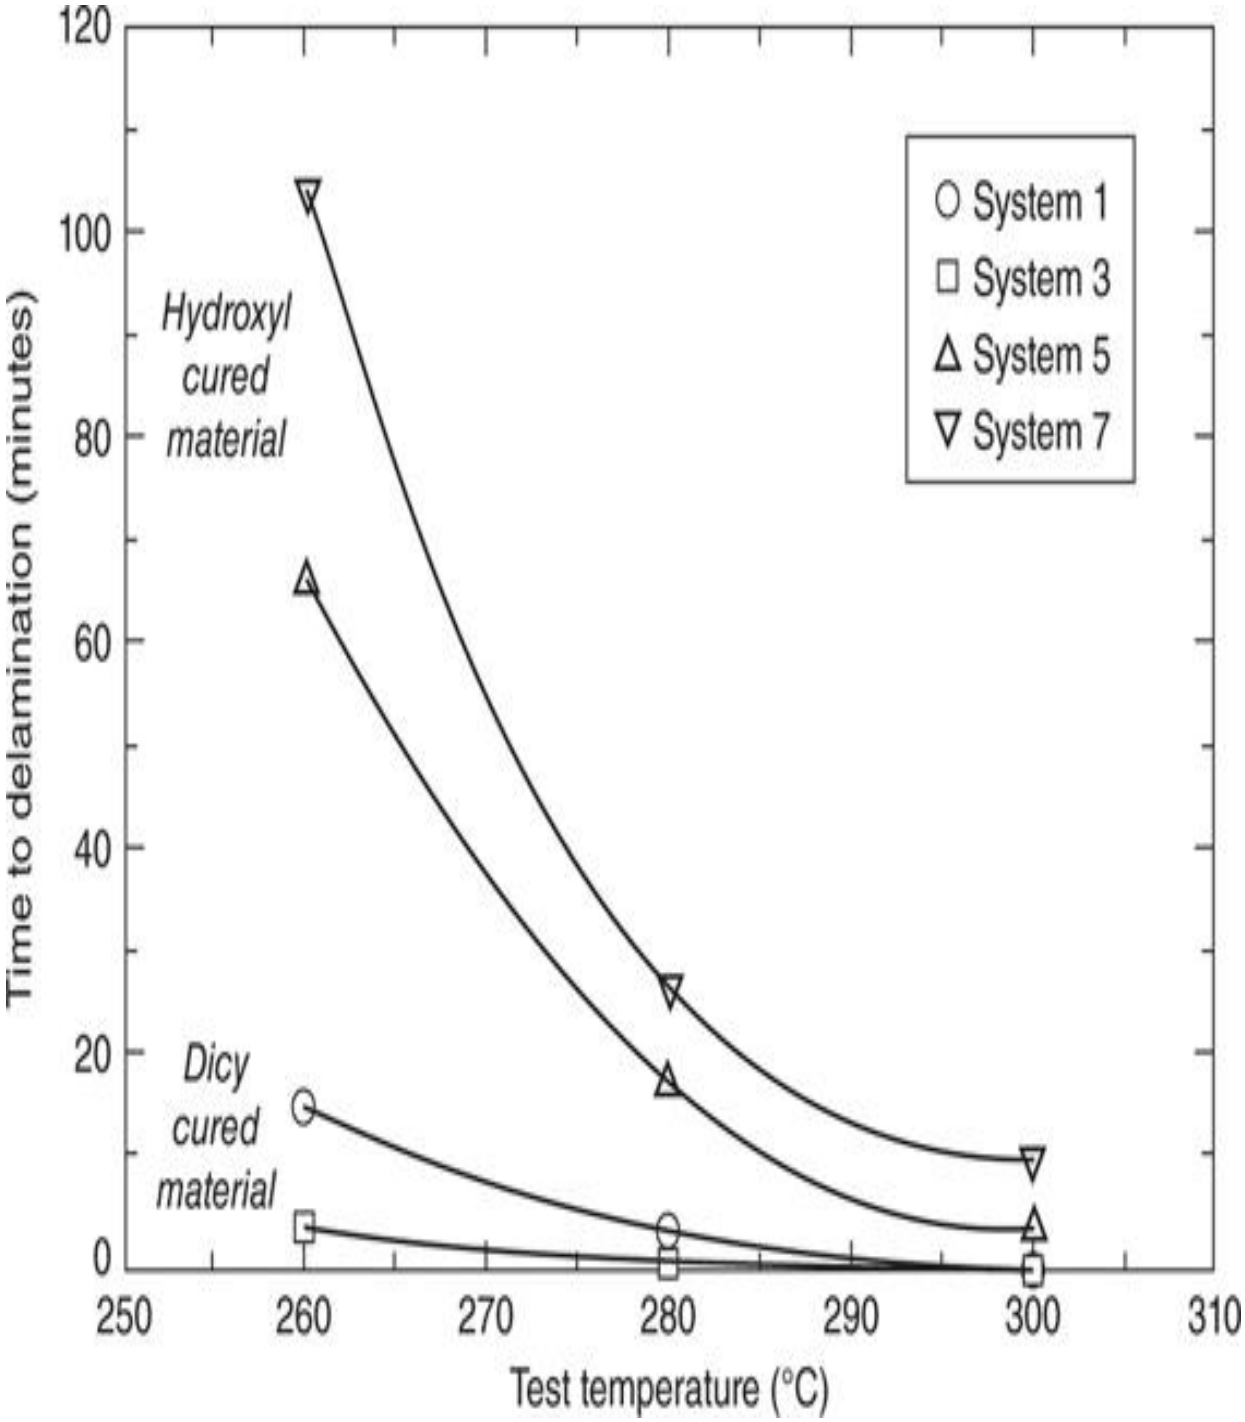

FIGURE 13.14 Time to delamination versus temperature for different resin systems.

Times to delamination also vary based on the type of sample measured. Laminates with the copper foil removed generally exhibit longer times than laminates with copper

foil. Clad laminates in turn exhibit longer times than multilayer PCBs. Figure 13.15 provides data on clad versus unclad samples for several material types in T260 and T288 testing. In multilayer PCBs, usually the interface between the resin and the internal copper surfaces will fail first. Time to delamination in multilayer PCBs is affected by the quality of the surface treatment of the internal copper layers, the quality of the multilayer lamination processing, as well as the type and condition of the bonding prepreg.

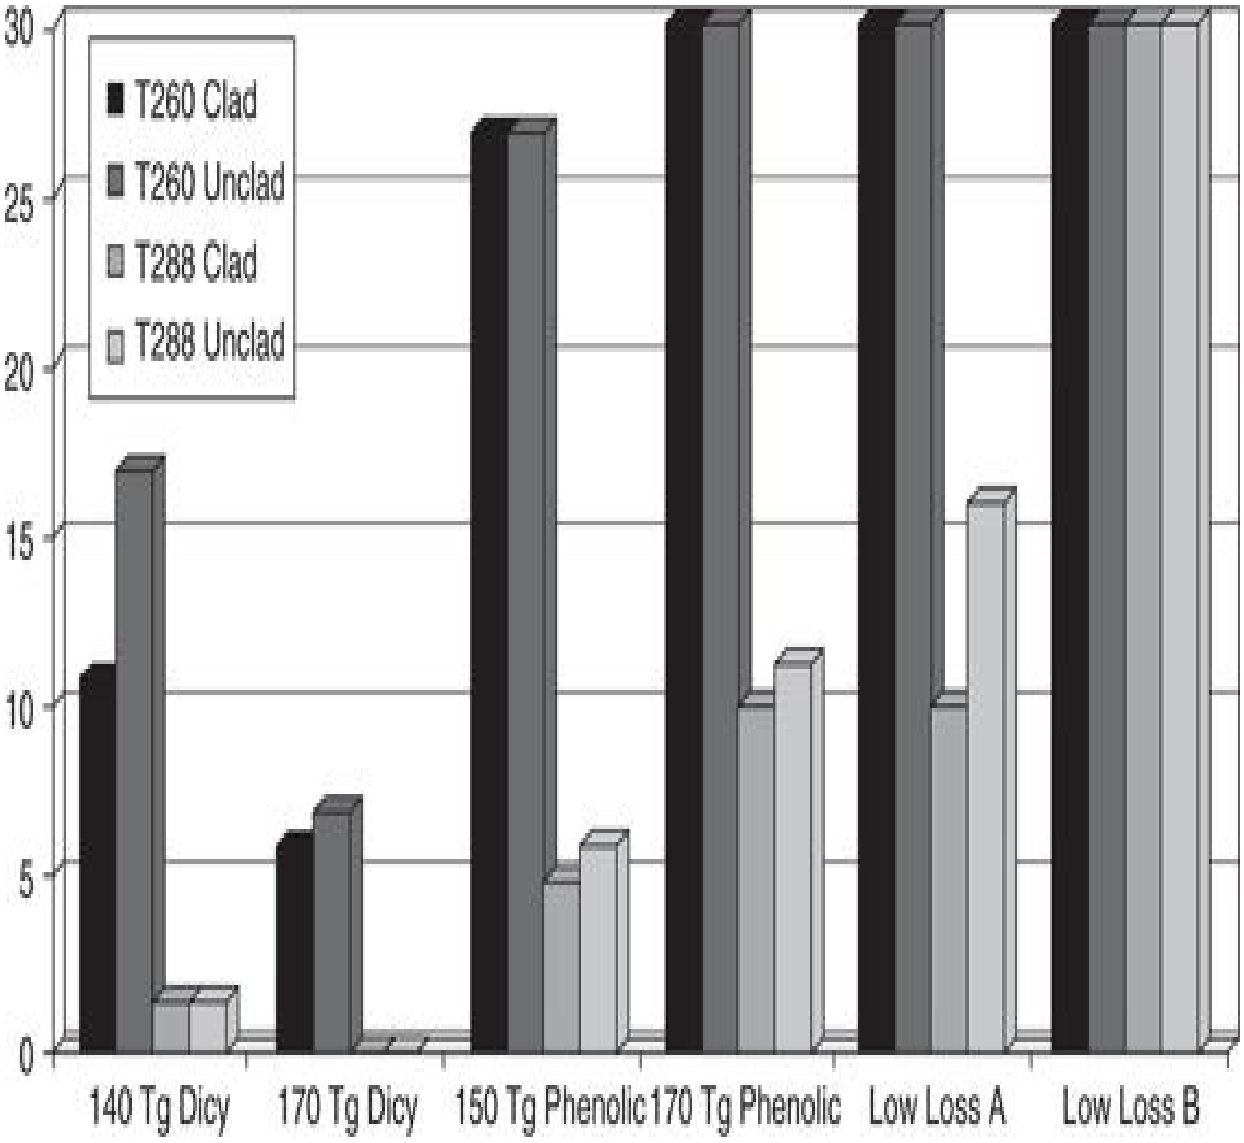

FIGURE 13.15 T260 and T288 testing on clad and unclad samples of several material types.

Time to delamination testing of multilayer PCBs has become a common test for lead-free assembly compatibility. However, several factors beyond the base material type can have an influence on performance. So care needs to be taken in assessing why a particular PCB might exhibit a low time to delamination. On the other hand, if a particular type of base material exhibits low times to delamination, little can be done in PCB manufacturing to improve performance. In short, a given material offers a certain performance entitlement. Whether this performance level is realized in the finished PCB is dependent on several factors, primarily related to PCB manufacturing processing. It should also be noted that, as with decomposition temperature, values beyond a certain level may not indicate that a material is more reliable.

13.5.5 The Impact of Lead-Free Assembly on Other Properties

Exposure to assembly temperatures can have a significant effect on the properties of base materials, including the T_g and modulus properties of the material. This is particularly true if the material is exposed to multiple thermal cycles. In addition, the magnitude of the effect is dependent on the specific peak temperature experienced. Figures 13.16 and 13.17 compare the effect of multiple thermal cycles on dynamic mechanical analysis (DMA) T_g for various material types when cycled to 235°C (Fig. 13.16) and 260°C (Fig. 13.17). When cycled repeatedly to 235°C, none of these materials exhibits a significant change in DMA T_g. However, when cycled repeatedly to 260°C, the dicy-cured materials show significant degradation in the measured DMA T_g, especially the high-T_g dicy-cured material.

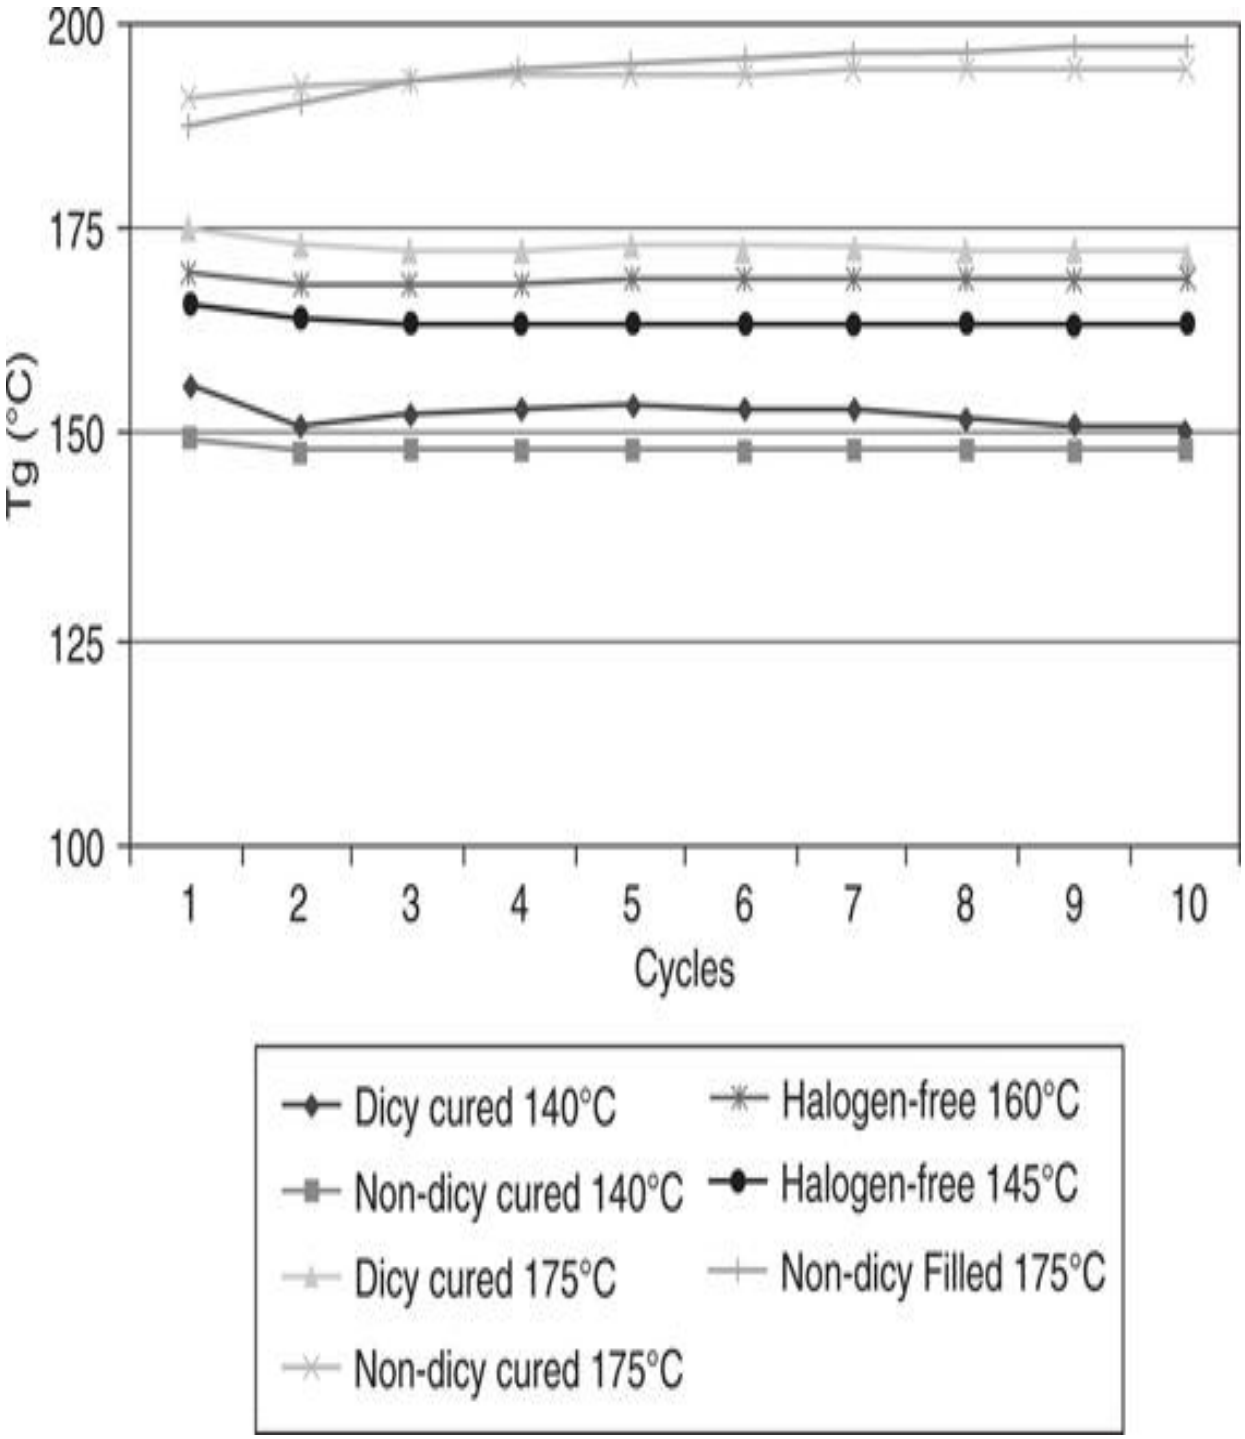

FIGURE 13.16 DMA T_g versus multiple thermal cycles to 235°C.

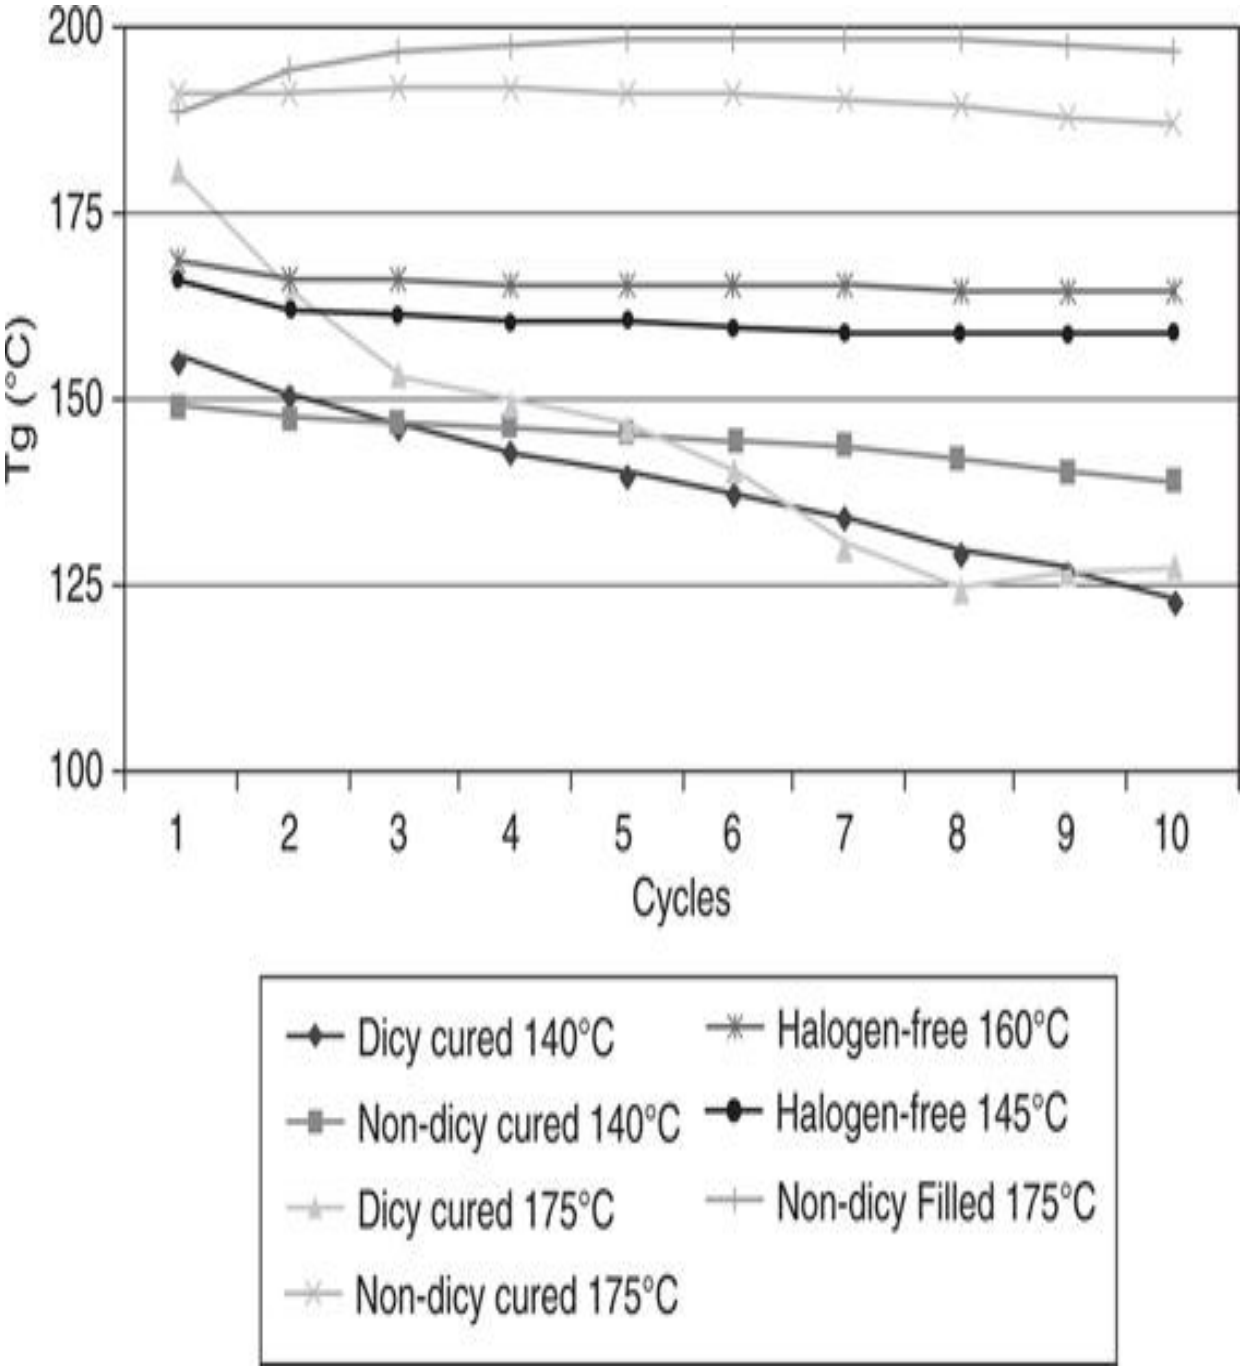

FIGURE 13.17 DMA T_g versus multiple thermal cycles to 260°C.

Figures 13.18 and 13.19 present similar data for measurements of the percent change in DMA modulus through multiple thermal cycles. Note that even when cycled to a peak temperature of 235°C, the high-T_g dicy-cured FR-4

material exhibits a consistent decline in DMA modulus. The 140°C T_g dicy-cured material exhibits a decrease only after several cycles.

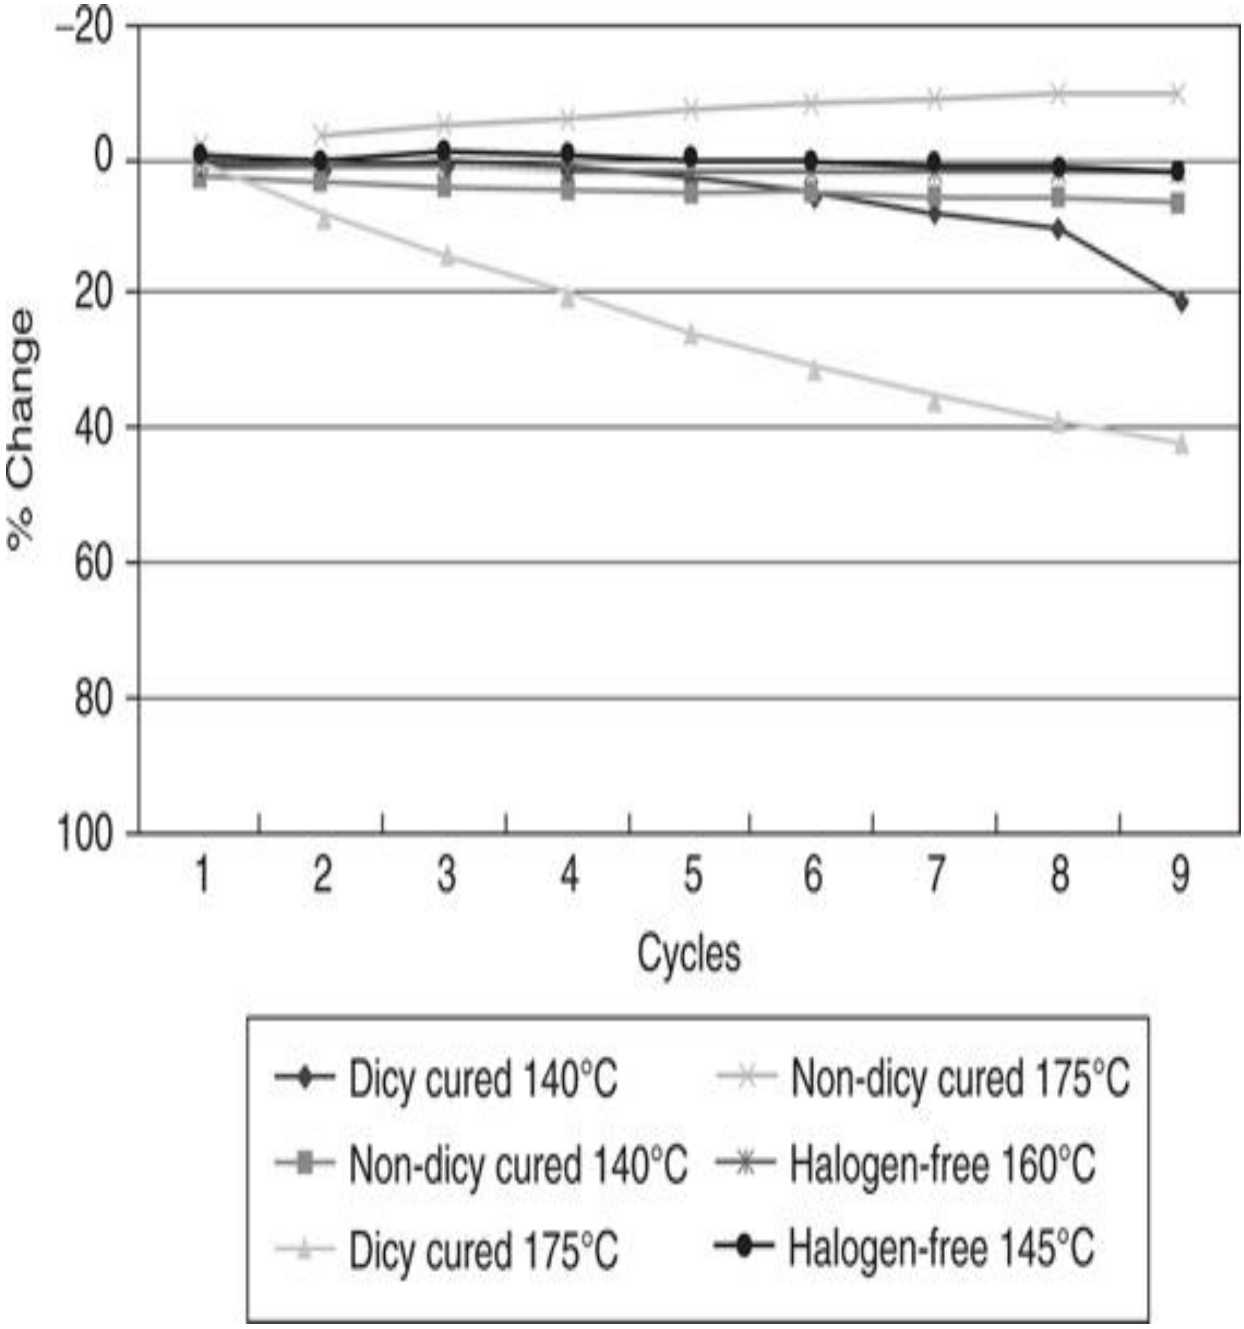

FIGURE 13.18 Percent change in DMA modulus versus multiple thermal cycles to 235°C.

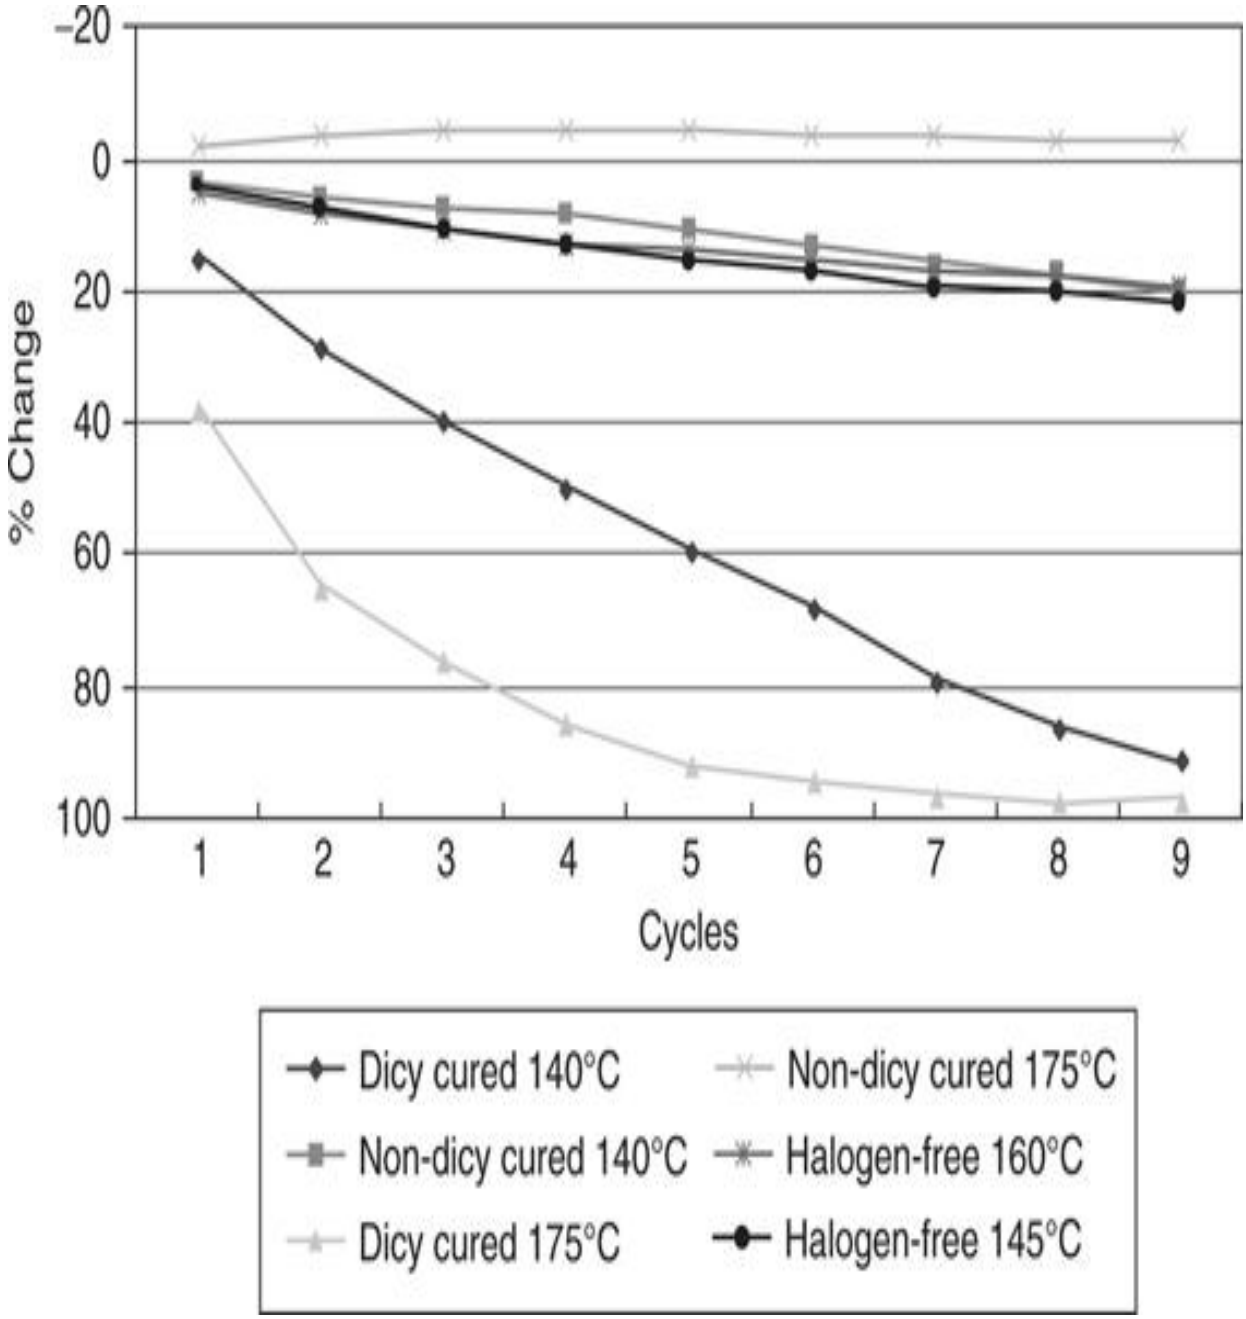

FIGURE 13.19 Percent change in DMA modulus versus multiple thermal cycles to 260°C.

When cycled to a peak temperature of 260°C, both of the dicy-cured FR-4 materials exhibit rapid declines in DMA modulus. In all of these cases, the nondicy (phenolic) FR-4 materials show little impact whether cycled to 235°C or

260°C. If anything, they exhibit very slight increases in T_g and modulus.

13.6 IMPACT ON PRINTED CIRCUIT RELIABILITY AND MATERIAL SELECTION

In addition to the works already cited, there have been excellent studies on the impact of lead-free assembly, specifically on PWB reliability. These works present statistical analyses showing the impact of lead-free assembly on PWB reliability and reach important conclusions regarding the base materials. Although there is not perfect agreement among all published works, the differences typically are the result of a different focus—for example, whether the focus is on complex, thick PWBs with stringent reliability requirements versus relatively less complex PWBs with shorter intended field lifetimes or less stringent reliability requirements. Conclusions include

- A minimum decomposition temperature is critical for lead-free assembly compatibility, but higher T_d's are not *always* better. Trade-offs with other properties, such as manufacturability, fracture toughness, and so on, make achieving the right balance of properties critical. Beyond a certain value, increases in T_d do not result in greater lead-free assembly reliability.
- T_g and CTE values are important because of the effects on thermal expansion, especially in thicker PWBs.
- Most dicy-cured high-T_g FR-4 materials are generally not compatible with lead-free assembly, or can be used successfully only in a very limited range of applications.

- Dicy-cured 140°C T_g materials may still be suitable for PWB designs with limited thickness and reliability requirements, particularly when intermediate peak temperatures are used in assembly. This is largely the result of these materials having slightly higher decomposition temperatures than the higher-T_g equivalents.
- Mid-T_g FR-4 materials with high decomposition temperatures are viable products for many lead-free assembly applications involving intermediate-complexity PWB designs.
- Materials with a sufficiently high-decomposition temperature, high-T_g, and reduced CTE values are suitable for the broadest range of applications, including complex PWBs assembled at 260°C peak temperatures.
- For reliability through assembly, total thermal expansion is important, which is affected by both pre-T_g and post-T_g thermal expansion values.
- For long-term field reliability, pre-T_g thermal expansion properties are more important as the temperature in the operating environment does not generally exceed the material T_g.
- Balancing material properties with PWB manufacturability is critical. Materials that exhibit excellent properties have failed because of difficulties experienced when fabricating the PWB, such as fracturing in drilling, routing or scoring, difficulty in texturing drilled holes for copper plating, resin recession, or hole wall pull-away during thermal stress.

13.6.1 Example of Material Types and Properties versus Assembly Reliability

To highlight a couple of these conclusions, consider the following test. First, multilayer PWBs made from the materials in Table 13.3 were processed through infrared (IR) reflow cycles at different peak temperatures. The PWB was a 10-layer, 0.093-in (2.6 mm) thick board “designed to fail,” meaning the copper weights and patterns, construction, and resin contents were chosen so that the board would be more sensitive to thermal cycles. In addition, the dwell time at the peak temperature was 1.5 minutes. This allowed differences in material performance to be detected more clearly. Figure 13.20 graphs the percentage of boards surviving six reflow cycles without any evidence of blisters, measles, or delamination.

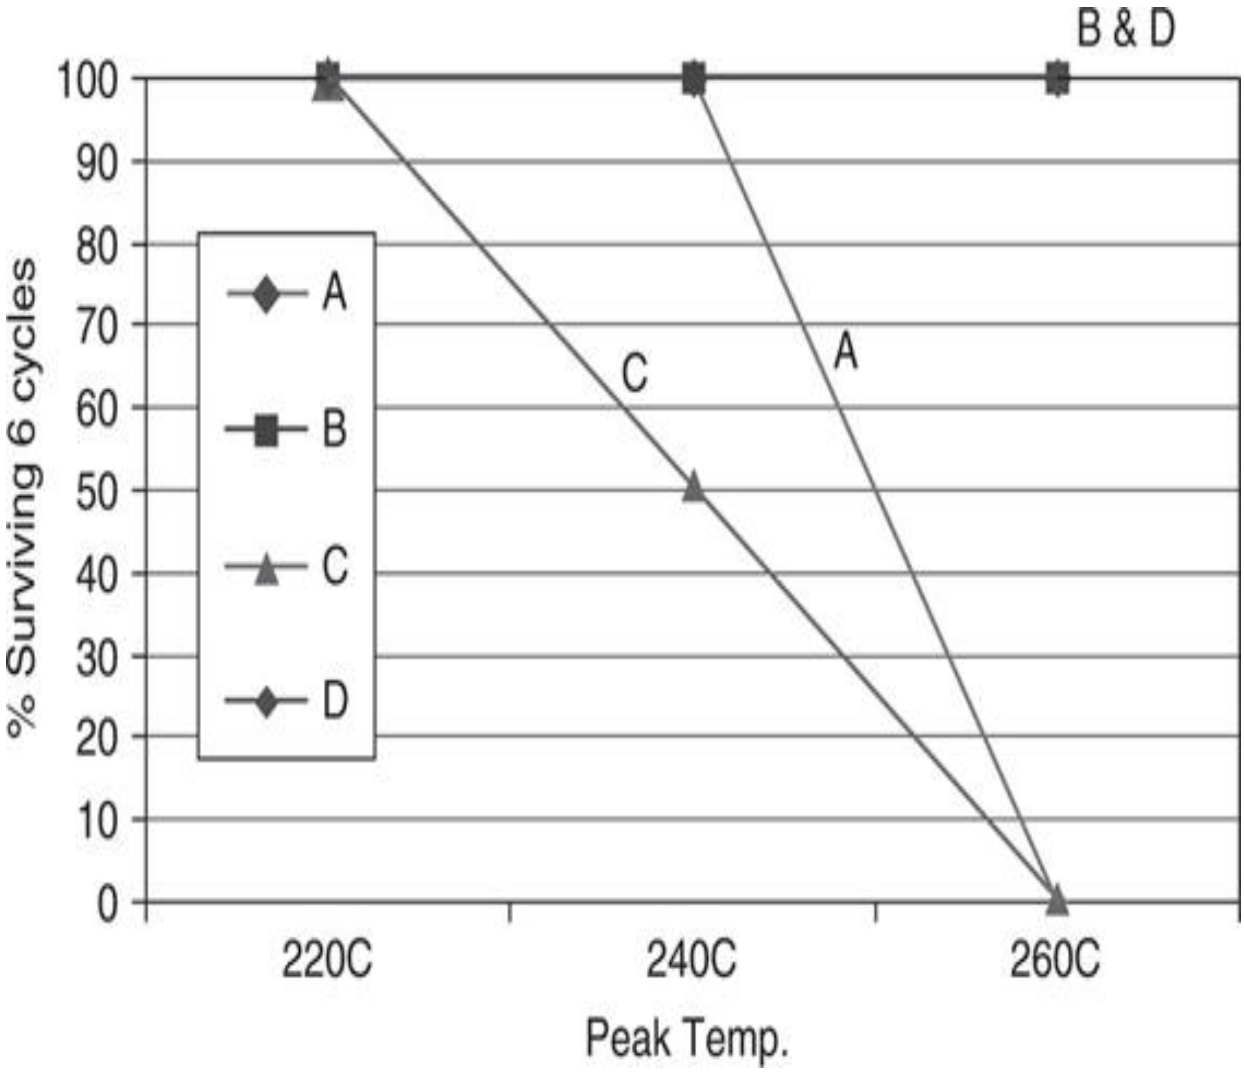

FIGURE 13.20 Survival after six reflow cycles at different peak temperatures.

Notably, the first material to exhibit defects is the conventional dicy-cured, high-T_g FR-4 material. This material began to exhibit defects when the peak temperature reached 240°C. At a peak temperature of 260°C, the conventional dicy-cured FR-4 materials, both the 175°C T_g and the 140°C T_g products, all exhibited evidence of defects. On the other hand, the materials with higher decomposition temperatures, both the 150°C T_g and the 175°C T_g products, all survived six cycles to 260°C.

13.6.2 Example of Material Types and Properties versus Long-Term Reliability

In another test, three high-T_g materials were evaluated through Interconnect Stress Test (IST) testing.[11] This particular test provided insight into the effect of thermal expansion and decomposition temperature on long-term reliability, as assessed by the IST method. The IST test method uses an electric current to heat test coupons that contain a network of plated through holes. The test samples are generally preconditioned several times to simulate exposure to assembly processes, and then cycled back and forth between an elevated temperature, most commonly 150°C, and room temperature. The samples are cycled in this manner until failure occurs, with failure generally being defined as a change in measured resistance of 10 percent. The materials evaluated in this example are described in Table 13.4.

TABLE 13.4 Materials Evaluated through IST Testing

Product	Description	Glass Transition Temp., °C	Decomposition Temp., °C	% Expansion, 50–260°C (40% Resin Content)
C	Conventional high-T_g	175	310	3.5
D*	High-T_g/high-T_d	175	335	3.4
D	High-T_g/high-T_d/ Reduced CTE	175	335	2.7

Note that the T_g values of these materials are the same, but differences exist in decomposition temperatures and

thermal expansion values. Product D* is similar to product D except that it has a higher level of thermal expansion. Product D* exhibits approximately the same thermal expansion as Product C, but Product D* has a higher decomposition temperature. Product D has both a high decomposition temperature and a very low level of thermal expansion. The PWB tested was a 14-layer, 0.120-in (3.1 mm) thick multilayer with 0.012-in (0.30 mm) diameter plated through holes. The average copper plating in the via was 0.8 mil (20.3 micron), although 1.0 mil (25.4 micron) had been requested. Figure 13.21 charts the average number of cycles to failure (10 percent resistance change in the plated via net) for each material type at each preconditioning level: as is (no preconditioning), three cycles to 230°C, six cycles to 230°C, three cycles to 255°C, and six cycles to 255°C.

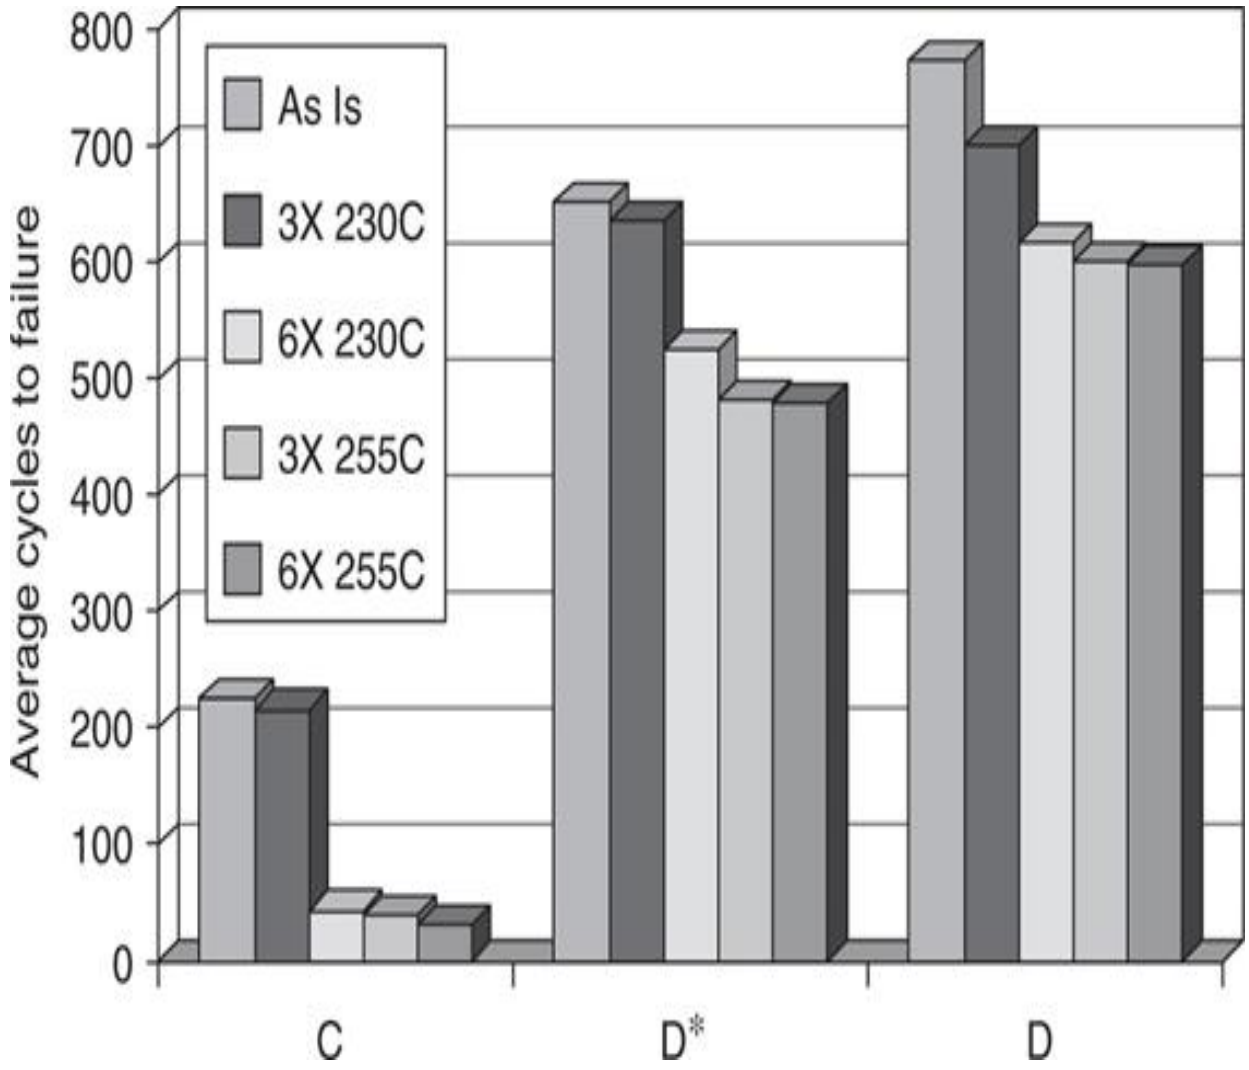

FIGURE 13.21 IST results for three 175°C T_g materials.

Clearly, the two materials with improved decomposition temperatures exhibit much better performance than the conventional high-T_g product. Also, in comparing product D to product D*, it appears that the lower thermal expansion of product D does offer improvement in the number of cycles to failure, but this improvement is smaller in comparison to the improvement due to the higher decomposition temperature, at least for this PWB design. The benefit of reduced thermal expansion becomes more important as the thickness of the PWB increases and as hole-to-hole pitch decreases.

As noted above, pre-T_g thermal expansion properties are especially important for long-term reliability, and other things being equal, materials with low pre-T_g CTEs will perform better than materials with higher pre-T_g CTEs in accelerated tests like IST. The High Density Packaging User Group (HDPUG) has also done extensive work in evaluating materials using more complex test vehicles, that among other things, compares multilayer PCB stack-ups with different levels of resin content, and therefore different levels of thermal expansion.

13.6.3 Understanding the Potential Impact on Electrical Performance

Most of the FR-4 laminate materials developed for lead-free assembly applications use an alternative resin chemistry in comparison to the dicyandiamide (dicy) cured FR-4s which were prevalent in the past. The most common FR-4 epoxy materials used today are commonly referred to as phenolic or novolac cured materials. Although there is some variation between these materials, as a group they tend to exhibit somewhat different electrical performance, particularly with respect to dielectric loss, or D_f (dissipation factor). For many applications the differences are not critical. However, as operating frequencies increase these differences can become very significant. Table 13.5 includes the same materials as Table 13.3, but also shows the differences in dielectric constant (D_k) and dissipation factor (D_f). It also includes a lead-free-compatible material designed to improve D_k and D_f performance in comparison to the phenolic lead-free-compatible materials. Note that different types of measurement systems can result in different measured values for D_k and D_f. Laminate resin contents and other factors also influence these properties. So when

examining Table 13.5, the comparisons between these materials are more important than the absolute values reported for each material. For these comparisons, the same measurement system and resin contents were used.

TABLE 13.5 Properties of Several Base Material Types

Product	Description	Glass Transition Temp., °C	Decomp. Temp., °C	% Expansion, 50–260°C (40% RC)	D_k@ 2 GHz	D_k@ 5 GHz	D_f@ 2 GHz	D_f@ 5 GHz
A	Dicy-cured 140°C T_g FR-4	140	320	4.2	3.9	3.8	0.021	0.022
B	Phenolic mid-T_g FR-4	150	335	3.4	4.0	3.9	0.026	0.027
C	Dicy-cured high-T_g FR-4	175	310	3.5	3.8	3.7	0.020	0.021
D	Phenolic high-T_g FR-4	175	335	2.8	3.9	3.8	0.026	0.026
E	Nondicy, nonphenolic	200	370	2.8	3.7	3.7	0.013	0.014

From this table it is clear that the thermally improved phenolic FR-4 materials are not quite as good in terms of electrical performance in the range of 2 to 5 GHz as the dicy-cured materials, particularly with respect to D_f. However, material E exhibits excellent thermal properties as well as good electrical performance.

13.7 SUMMARY

While most base materials comply with the RoHS directive, the question of compatibility with lead-free assembly processes is a more complex issue. The material properties that are important for lead-free assembly compatibility include

- Decomposition temperature (T_d)
- Coefficients of thermal expansion (CTEs)
- Glass transition temperature (T_g) (especially because of the impact on thermal expansion)
- Moisture absorption
- Time-to-delamination performance, which is not a fundamental material property, but is a simple method used to assess thermal stability of a composite material at different temperatures

While laminate manufacturers can easily make improvements in one of these properties, it is not as easy to make improvements without affecting other properties, including properties important for ease of manufacturing in the PCB fabrication process. Achieving the optimal balance of properties that consider the requirements of each level of the supply chain—from OEM to EMS to PCB fabricator—is crucial for success in lead-free assembly applications.

Dicy-cured FR-4 materials, especially the high-T_g dicy-cured materials, are significantly impacted by lead-free assembly temperatures, and are generally not recommended for lead-free applications. Phenolic-cured FR-4 materials, and particularly those containing inorganic fillers to reduce thermal expansion, have gained widespread acceptance in these applications. Nondicy, nonphenolic materials that offer good thermal and good electrical performance have also

been developed for lead-free applications where improved electrical performance at high operating frequencies are required.

CHAPTER 14
SELECTING BASE MATERIALS

Edward Kelley
Douglas Trobough
Isola Group, Chandler, Arizona

14.1 INTRODUCTION

The selection of the best base material for a given application can be very complex, particularly as circuit design complexity increases. To best approach this decision, it is important to understand the design parameters, the usage requirements, and the electrical performance requirements. Once these performance factors are understood, choosing the best material(s) can proceed in an orderly manner.

In performing this assessment, it is good to determine what performance factors are changing compared to designs currently in production. If the performance factors are essentially unchanged, continue with materials successfully used on prior designs. If the performance factors are being changed, focus on the changes to determine the required material type(s).

Material Qualification testing has become quite common at both large OEMs and PCB fabricators. The purpose of these qualifications is to create a “performance window” for a qualified material. Material qualification performance windows can be compared with the PCB design and performance requirements. If the performance requirement falls within currently qualified material performance window, then it can be selected. Qualification testing has been very successful at simplifying the material selection process.

A reference table of some performance factors is provided in Table 14.1:

TABLE 14.1 Performance Factor Examples in Selecting Materials

	Factor	Measurement	Effect
Design Parameters	Circuit Density	Hole Grid Pitch mm	Pitch ↓ Thermal Requirements ↑ CAF ↑
	Number of nets	Layer Count	Thickness + Resin content ↑ Thermal Requirements ↑ Hole Life ↑
	Thickness	mm	Thickness ↓ Thermal Requirements ↓ Hole Life ↓
	Size	Length x width	Size ↑ Thermal Requirement ↑
	Component Type	Thermal Mass	High Thermal Mass ↑ Thermal Requirements ↑
Usage Requirement	Office Environment		Standard Requirements IPC
	Outdoor usage	Temperature range	CAF Hole Life
	Use Temperature	Max Temperature	Thermal Reliability Hole Life
Elertrical Performance	Maximum Data Rate	Gb/sec	Frequency ↑ Loss ↑
	Frequency	GHz	Data rate ↑ Loss ↑
	Loss Budget	Db/in(mm)	Db/in(mm) ↓ Loss ↑
	Skew Budget	psec	Skew budget ↓ Micro Dk uniformity ↑

↓ factor reducing, requirements becoming easier
↑ factor increasing requirements increasing

Often, changes in performance requirements relate to thermal reliability, electrical performance, and CAF performance. With thermal reliability, there are two general considerations. First, the PCB must survive assembly processes, and the conversion to lead-free assembly makes this a much more challenging consideration as discussed in previous chapters. Second, the PCB must meet the requirements for reliability in the operating environment. In terms of electrical performance, the focus is on signal integrity as operating frequencies and data rates increase.

Finally, as circuit feature distances decrease, in particular hole wall-to-hole wall distances, CAF resistance becomes a more critical consideration. Each of these topics was discussed in previous chapters, so the emphasis in this chapter is to discuss how to approach base material selection with these performance requirements in mind.

14.2 SELECTING MATERIALS FOR THERMAL RELIABILITY

Chapter 13 discussed the impact of lead-free assembly on printed circuit boards (PCBs) and base materials, and also discussed many of the critical base material properties relevant to performance in lead-free applications. Refer to Table 12.2 for a summary of some of the key material properties:

- Decomposition temperature (T_d)
- Glass transition temperature (T_g)
- Coefficients of thermal expansion (CTEs)
- Moisture absorption
- Time to delamination, such as T260 and T288 tests

Also, the need to achieve the right balance of properties with ease of use in the PCB fabrication process, in addition to the requirements of assemblers and original equipment managers (OEMs), was highlighted.

This is the result of the impact that PCB fabrication can have on the performance of the material and finished PCB during assembly and in end-use application. A given material type offers a certain level of performance in the finished PCB. However, this level of performance may or may not be realized, depending on how the materials were processed

during fabrication. This makes it extremely complicated to make general recommendations on what material should be used in a given application. However, this section describes an approach in addressing this question. But first, some of the PCB fabrication and assembly issues that can affect performance are outlined.

14.2.1 PCB Fabrication and Assembly Considerations

The reliability of the assembled PCB in the end-use application is a function not only of the base materials selected, but how the materials were processed during PCB fabrication and component assembly. Different base material types may require different processing conditions in order to achieve the best results in the finished product. In reviewing these items, understand that these are general considerations that should be evaluated within the context of the specific fabrication and assembly processes and with regard to the specific materials being considered. The specific requirements for long-term reliability must also be considered. So while it is not possible to give exact, optimal processing conditions for all applications, the items that follow represent parameters that should be considered as products are converted to lead-free assembly.

14.2.1.1 Moisture Absorption. As discussed in Chap. 12, a given level of moisture absorption can be much more serious in lead-free assembly applications than it is for conventional tin-lead assembly applications. This is due to the increase in water vapor pressure at the higher temperatures of lead-free assembly. Figure 14.1 is a graph showing the vapor pressure of water versus temperature. At lead-free assembly temperatures, the pressure is much higher, which causes substantially more stress within the

laminate and on the interfaces within the PCB, including resin-glass, resin-oxide, resin-copper, and resin-resin interfaces. As a result, additional drying or baking processes may be needed to drive off moisture prior to processes involving thermal cycles.

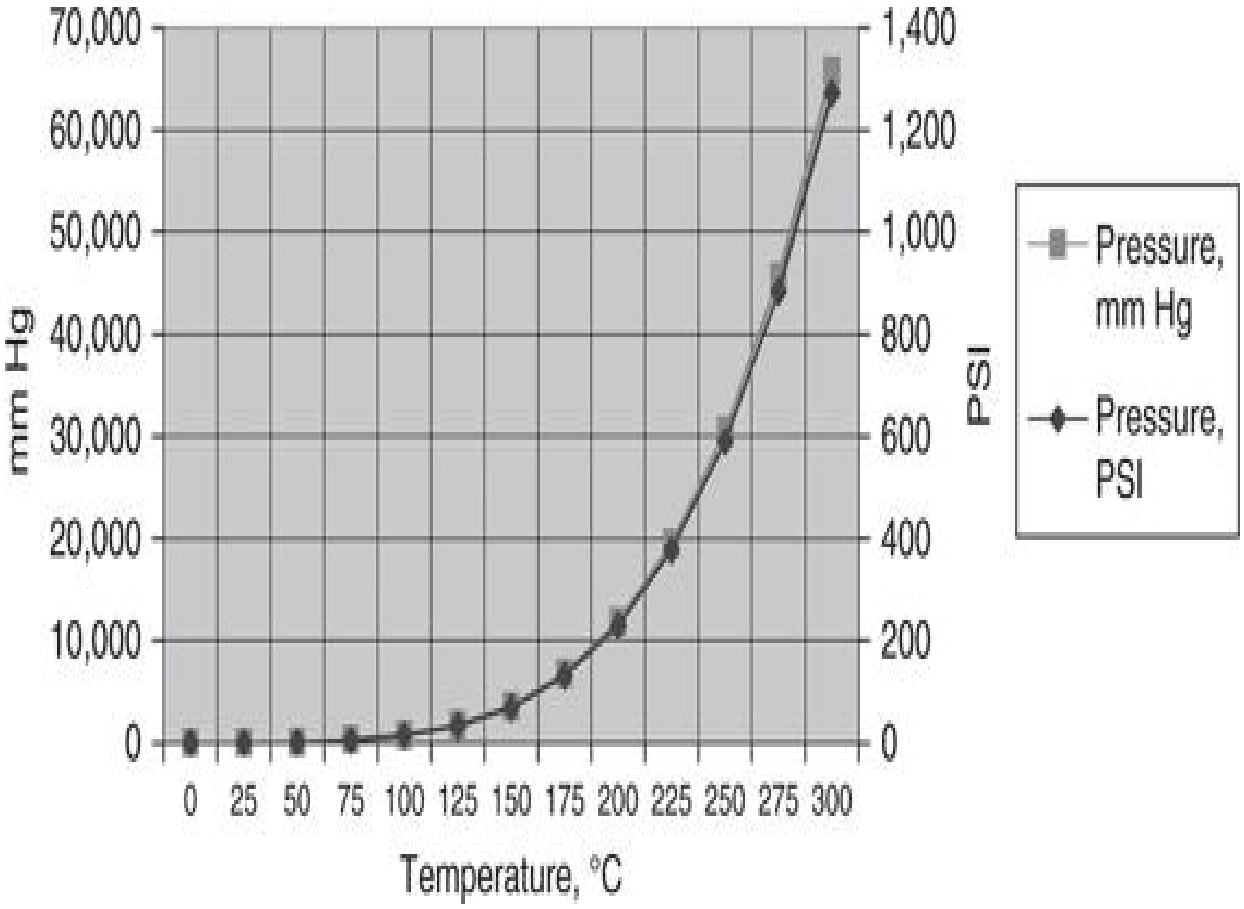

FIGURE 14.1 Vapor pressure of water versus temperature.

14.2.1.2 PCB Stack-Up. In terms of thermal reliability, one of the main considerations in selecting the stack-up of a multilayer PCB is to make sure that laminate and prepreg constructions use glass styles and resin contents suitable for the assembly environment. A particularly important consideration is to insure that prepreg resin contents are sufficient to fill innerlayer circuitry completely, and without resulting in what is called “glass stop,” where the fiberglass

cloth is pressed against the innerlayer circuit pattern, as discussed below.

A key factor in choosing the material BOM is the PCB stack-up. This factor crosses all material types, and requires some comments. There are two types of PCB materials: laminate and prepreg. Laminate is cured material with copper on both sides of the dielectic material. Prepreg is partially cured material that is the glue of the PCB.

Some important laminate choice factors:

- Laminate material is more consistent in thickness control than prepreg, particularly laminates made with a single ply of glass. This leads to improved control for electrical properties, particularly impedance. Making the laminate thinner than the prepreg layer takes full advantage of the increased thickness uniformity.
- Laminate material is made in a variety of thicknesses and glass constructions, which have differing electrical properties, in most materials. If the design has demanding electrical performance requirements, the electrical properties of different laminate types needs to be considered in making the selection.
- On thin laminate materials (<100 microns thick) used between planes at differing voltages, it is common to use laminate made with two plies of glass. This is more expensive than laminate built with one ply of glass.

Some important prepreg choice factors.

- The main purpose for prepreg is to fill the areas between copper features with resin and glue the laminate circuit layers together. It is very important that there be enough resin available to fill all the areas between copper features and provide a little extra to create a buffer between the glass and copper layers. While the reliability impact of this phenomenon can vary across material types, it is a best

practice to design the stack-up so that there is at least some resin buffer between the innerlayer copper pattern and the fiberglass cloth. Figure 14.2 shows two different PCB designs exhibiting glass stop. The cross section on the left of Fig. 14.2 shows a more minor case of glass stop while the cross section on the right, which is a design with very heavy copper weight on the innerlayer, is severe glass stop. Glass stop represents a reliability concern for both thermal reliability as well as CAF resistance. Lack of resin is one of the more significant causes of design failures during assembly and in field usage.

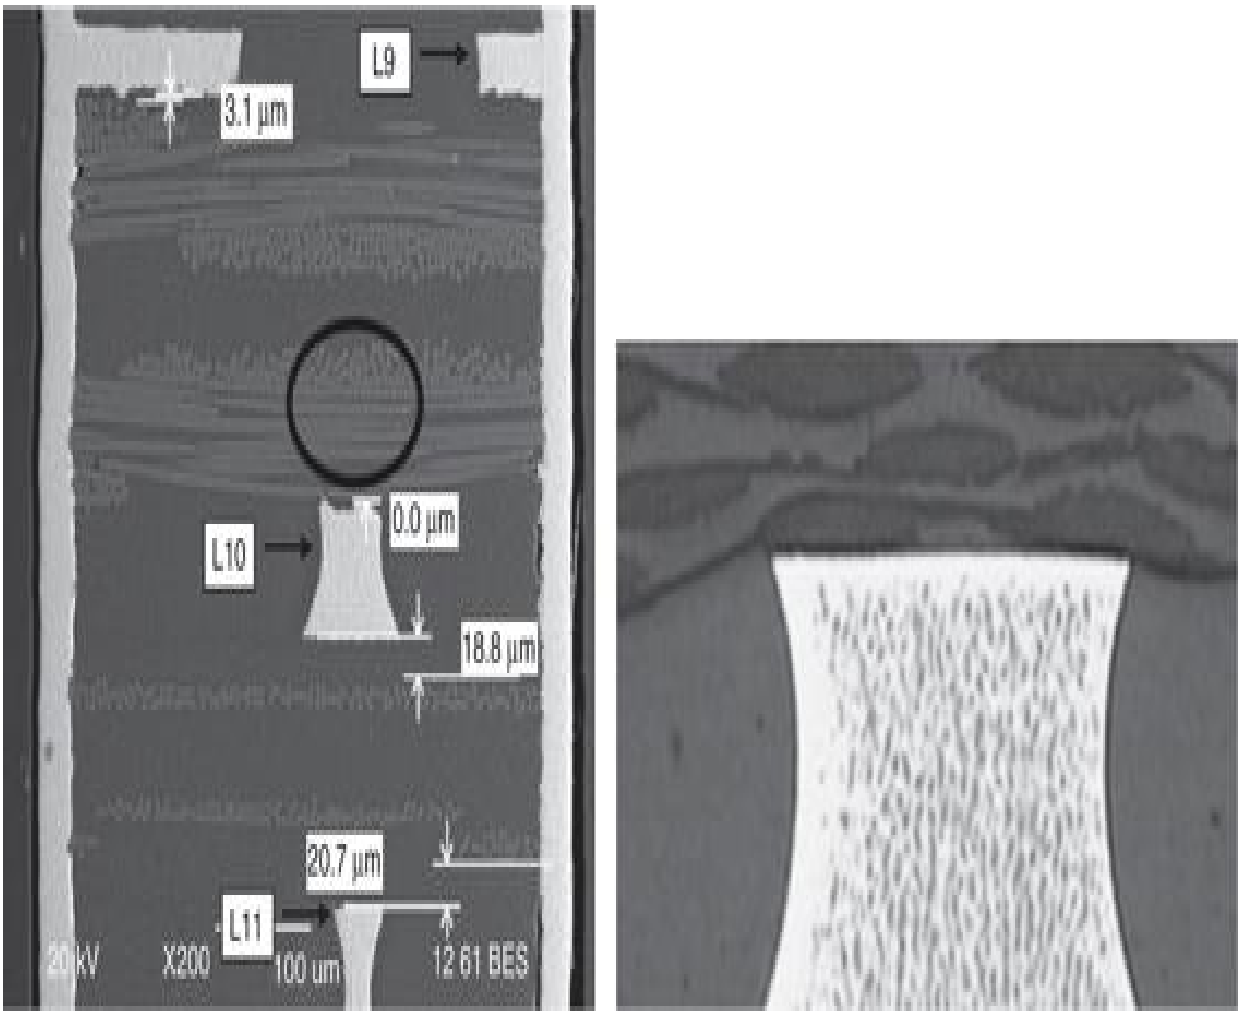

FIGURE 14.2 Cross sections exhibiting “glass stop.”

- For cost and control purposes the use of a single ply of prepreg is preferred, in most cases. It is important to make sure that this single layer has adequate resin, per previous point. Thin single ply is higher risk between plane layers with different voltages.
- Large areas without copper, or with significantly reduced copper content on plane layers can be a serious problem on higher layer count or boards with thick copper. These areas require a lot of resin to fill and often lead to glass-stop and even resin voids. In some cases these areas of the PCB will be much thinner than average leading to PCB processing problems or assembly issues. Add copper fill in these larger open areas when allowed to the design. If not allowed, choose prepreg types with additional resin volume.
- Most suppliers sell prepreg by resin content. This value is based on weight and not on volume, so different types of materials will have different resin volume for the same resin content. Prepregs should be selected by glass style and thickness. The available resin for fill is prepreg thickness—glass thickness.

CTE mismatches between layers can also be a concern if adjacent dielectrics have very different resin contents or if dissimilar resin systems with very different CTE and modulus values are used. While not usually a dominant consideration, this should be considered when designing the multilayer stack-up in particularly demanding applications. Table 14.2 contains examples of X-Y CTE values for some common glass styles.

TABLE 14.2 *X*- and *Y*-Axis CTE Values for Some Common Glass Styles

Glass Style	X-Axis CTE	Y-Axis CTE
106	22.2	22.2
1080	16.9	19.4
2113	14.3	14.9
2116	14.7	14.9
1652	14.1	14.1
7628	12.1	14.9

14.2.1.3 Oxide and Oxide Alternative Processes.

During PCB fabrication, the internal copper surfaces are generally chemically treated to improve the adhesion between the resin system and the copper layer. Two primary types of processes are used. The first involves an oxidation of the copper surface to micro-roughen the surface, usually followed by a reduction step to improve chemical resistance of this layer in subsequent processes. The second type of process is referred to as an oxide alternative, or oxide replacement process. These processes generally use etching chemistries, which also roughen the copper surface to provide greater surface area for resin bonding, and often use proprietary chemistries designed to further enhance adhesion and chemical resistance. In short, compatibility of the resin system with the oxide or oxide alternative is critical for any application, but becomes even more important in lead-free assembly applications due to the increased stress on the resin to innerlayer copper bond. The reduced oxides can also be degraded at higher temperatures, and this degradation can be influenced by the type of resin system and temperature at which the resin system must be laminated at. Functional testing of the

compatibility of the resin-to-oxide/oxide alternative surface is recommended.

14.2.1.4 Multilayer Lay-Up Prior to Lamination. In addition to the oxide and oxide alternative processing discussed in the previous section, the hold time between this process and multilayer lay-up and lamination is also important. This is due not only to the possibility of oxidation of the innerlayer surfaces, but to the potential for moisture absorption by the exposed resin surfaces on the innerlayer, for the reasons already discussed. For some high performance resin systems, moisture may also interfere with resin curing reactions, making it even more important to dry the cores prior to lamination.

So the hold time between surface preparation and lamination should be minimized, and the storage of the innerlayers prior to lay-up should be in a temperature- and humidity-controlled environment to reduce the likelihood of absorbing moisture. Typical environmental conditions for this storage are 68°F or 20°C, and a maximum of 50 percent relative humidity (RH), although lower humidity levels are recommended.

Similarly, the prepreg materials used in constructing the multilayer PCB must be stored in a temperature- and humidity-controlled environment. This is due not only to the potential for moisture absorption, but also because the shelf life and performance of the prepreg can be significantly impacted by temperature and humidity conditions prior to use. This can often be a subtle point, but it is a critical one, especially as lead-free applications demand greater performance from the base materials. Again, storage conditions generally should be no worse than 68°F or 20°C and 50 percent RH for typical FR-4 materials, although some high-performance materials can be even more sensitive and perform better if stored in even cooler or drier environments. Some of the high-performance materials may even require

vacuum desiccation prior to use. This is a fairly common practice for polyimide materials, for example. Finally, storage of the multilayer books prior to lamination should ideally be done in a controlled environment, with the hold time between lay-up and lamination also minimized.

14.2.1.5 Multilayer Lamination Processing. Multilayer lamination cycles must be designed around the specific material being used. However, there are some general recommendations that can be applied to most materials:

- *Prelamination vacuum*. Expanding on the discussion of moisture absorption, it is important to apply a vacuum to the lamination books prior to ramping up the temperature and curing the resin in the prepreg. This removes moisture that could volatilize during the lamination cycle. Drawing a vacuum can also remove other volatile components such as residual solvents in the prepreg materials. This is an often overlooked factor that can be vitally important. Recommended vacuum times can depend on the actual moisture levels of the materials used, but generally range from 15 to 30 min. It is important during this time that the materials are not heated too much. In addition, as mentioned in the previous section, some materials, such as polyimides, are often vacuum-desiccated prior to lay-up.
- *Heat rise and pressure application*. For a given type of resin system, it is important to understand the rheology of the resin in the prepreg as a function of the rate of temperature rise. This, along with the proper application of pressure, ensures adequate filling of the internal circuitry and good wet-out of the resin into the fiberglass filaments. Complete wet-out of the internal circuitry and good resin flow on the oxide or oxide alternative surface are important for reliability in subsequent thermal cycles. This is also discussed in Sec. 14.2.2.2.

- *Stress relief pressure profiles*. It is important to have sufficient pressure on the lamination book, as the resin in the prepregs are heated and begin to flow into the innerlayer circuit patterns. The actual pressure needed can vary with the type of material being used and the level of vacuum achieved during the process. However, after the resin cures to a certain point and stops flowing, a reduction in pressure can help reduce the levels of stress in the multilayer PCB. This can improve reliability in subsequent thermal cycling. The reduction in pressure is typically to the range of 50 to 75 psi.
- *Cool down rate*. After the product has been held at the proper temperature for the proper period of time, which will depend on the type of material used, the rate at which the product is cooled is also important. In general, slower cooldown rates will minimize warpage and residual stress in the finished product. However, slower cooldown rates can adversely impact productivity, so a reasonable balance must be identified. In many cases, a slow cooldown through the T_g of the resin system, followed by a somewhat faster cooling rate after the product cools below T_g, represents a good balance of performance and productivity.

14.2.1.6 Drilling. Many of the materials designed for compatibility with lead-free assembly, as well as those developed for high-speed/high-frequency applications, require optimization of drilling parameters. These resin systems can have higher modulus values and be harder, impacting not only the optimal drill parameters but accelerating drill wear and leading to lower acceptable hit counts.

14.2.1.7 Desmear Processing. Many of the resin systems in volume use today are more chemically resistant than the materials used in the past. Adjustments may be

needed in the times and/or temperatures used for solvent swelling and permanganate desmear processes, and the supplier of these chemistries should be consulted when transitioning to new materials. The processing guidelines provided by the laminate material supplier will also typically provide recommendations for desmear processing. For many advanced products, plasma desmear may be required. This is true for most high-speed materials.

14.2.1.8 Surface Finishes. If a lead-free hot air solder leveling (HASL) process is used, the higher temperatures required by the lead-free alloys should be considered when selecting the base material. The common alternatives to HASL typically do not involve a bake process or significant thermal cycle. Although this is good in terms of the reduced thermal cycling exposure to the base material, it also results in one less opportunity for moisture to be removed from the PCB prior to assembly. This should be considered when deciding whether a drying step is needed prior to assembly.

14.2.1.9 Assembly Temperatures. Given that there is a range of temperatures used in assembly processes, including lead-free assembly processes, it is critical that the base material be selected knowing what the peak assembly temperatures will be. In the lead-free assembly temperature range, seemingly small differences in temperature can have significant impacts on both reliability in assembly as well as long-term reliability. For example, many materials that are perfectly acceptable for assembly at 245°C will not be suitable at 260°C, depending on the PCB design features such as hole-to-hole pitch, copper weights used, etc.

14.3 SELECTING A BASE MATERIAL FOR THERMAL RELIABILITY

14.3.1 Overview of Test Vehicles and Test Methods

A very common request from PCB fabricators, electronic manufacturing services (EMS) companies, and OEMs is whether a given material is compatible with lead-free assembly. Although everyone is looking for a simple answer, the solution becomes complex because of the range of PCB designs (board thicknesses, layer counts, copper weights, via pitch, and so on) as well as the differences in lead-free assembly processes, such as the specific peak temperature and number of thermal cycles a PCB will experience. In addition, people usually want to use the least expensive material that is suitable for a given application. So although it is easy to specify an advanced product for lead-free compatibility, the approach taken here is to balance cost and performance.

There are a variety of test vehicles and test methods used to assess thermal reliability of base materials at the PCB level. The variants exist because of the wide range of designs used as well as the wide range of requirements for long-term reliability. The reliability requirement for a PCB used in a cell phone or other consumer electronics device that is used for a relatively short time frame will be different than for a network infrastructure device that will be in service for decades, or for an automobile, or in aerospace and avionics applications. As such, a full discussion of these test methods is beyond the scope of this chapter. However, we can outline approaches to material evaluation, qualification and selection based on some common industry practices, which include

- Using test vehicles or actual PCB designs that represent certain levels of PCB technology and using these to evaluate new materials through multiple assembly processes at the temperatures of interest. The test

vehicles are inspected after different numbers of assembly simulations for blisters, delamination, or other defects. Testing is typically performed in the as-manufactured condition, and sometimes after temperature and humidity conditioning as well.

- These same test vehicles, or specially designed test vehicles are used to assess long-term reliability. Typically, specially designed coupons are used in the test vehicle or built along with the actual PCB design. These coupons are typically put through accelerated testing to assess long-term reliability, and typically focus on plated-through hole reliability. These coupons are often tested in the as-manufactured state as well as after different numbers of assembly simulations at different temperatures.
- There are multiple test methods used to assess long-term plated through hole reliability, including air-to-air thermal cycling and oil-to-oil thermal cycling. A very common test method in use today uses an electric current to repeatedly heat a sample to the desired temperature. The resistance of a series of plated holes is monitored as the test vehicle is thermally cycled, with failure usually defined as an increase in resistance of over 10 percent. “IST” testing, which was briefly described in Chap. 13, is one such test.[1] Figure 14.3 is an example of IST coupons. In this figure there are two coupons, one with a 1.0-mm hole-to-hole pitch, and a second with a 0.8-mm hole-to-hole pitch. In short, while the science behind the requirements for the temperature range and number of cycles to failure is beyond the scope of this chapter, the OEM will typically define the requirement based on the type of electronic device the PCB will be used in and how long it is designed to be in service. The coupon designs can also be used to evaluate performance of different hole sizes, aspect ratios and hole-to-hole pitch.

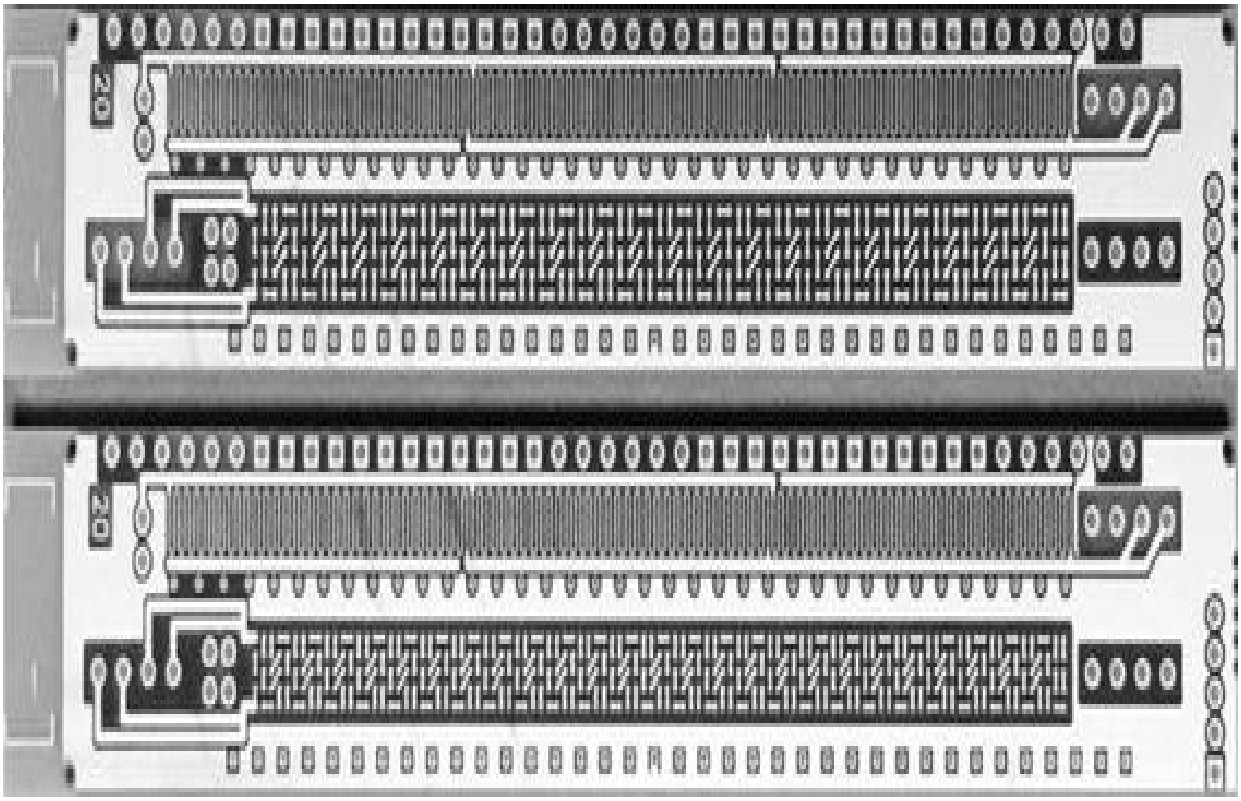

FIGURE 14.3 IST coupon used for thermal cycling testing.

- In the automotive industry for example, there are multiple levels of thermal reliability testing depending on the specific application of the PCB and the operating environment. Test vehicles are designed with layer counts, overall thickness, hole size and hole-to-hole pitch levels based on the design criteria to be used in the actual printed circuits. While some other industries have used only one or two test vehicle designs to qualify all materials, if the test vehicle is much more difficult than actual PCB designs, then the risk is over specifying the material, which can have significant cost impacts or reduce availability. As such, more and more OEMs are dividing qualification criteria into levels that represent certain ranges of PCB technology.

14.3.1.1 "Standard FR-4" Material Selection. As explained in Chap. 13, with the introduction of lead-free

assembly, substitutes for the dicy-cured FR-4 epoxy materials had to be developed and introduced. While some very simple lead-free applications still use these materials, in general they are not suitable for lead-free assembly applications. Phenolic or novolac-cured epoxies were developed to provide improved thermal performance in lead-free applications, and tested through the methods outlined above. Table 14.3 summarizes the performance of these materials.

TABLE 14.3 General Recommendations by Lead-Free Peak Temperature Range

Category	240–245°C Peak Temperatures	250–260°C Peak Temperatures
Dicy-cured 140°C T_g FR-4s	May be suitable for PCBs of limited thickness and complexity where a limited number of thermal cycles will be experienced.	Generally not recommended, but may be suitable for low-technology applications where a limited number of thermal cycles will be experienced.
Dicy-cured high-T_g FR-4s	Generally not recommended; even though initial results may be positive, extended storage in an uncontrolled environment prior to assembly could lead to problems.	Not recommended.
Phenolic mid-T_g FR-4s	Suitable for a broad range of applications because of the higher decomposition temperature and overall thermal expansion being similar to standard high-T_g materials.	Suitable for a broad range of applications because of the higher decomposition temperature and overall thermal expansion being similar to standard high-T_g materials. Consider higher T_g versions for thicker, more complex PCBs.
Phenolic high-T_g FR-4s	Compatible in the broadest range of designs and applications. Recommended when long-term reliability is critical.	Compatible in the broadest range of designs and applications. Recommended when long-term reliability is critical.

14.3.1.2 General Approach to Material Selection. With the many studies and reliability tests that have been performed on the conventional FR-4 epoxy materials, selection of these materials is relatively straightforward. However, as the demands for better electrical performance accelerate, and interest in halogen-

free materials grows, new materials are almost constantly being introduced. As such, there is often less industry experience with these materials to draw from, and furthermore, these materials can be more sensitive to variations in the PCB manufacturing process, in addition to variations in the PCB design. So while the approach to evaluating materials as described above is still valid, it is extremely difficult to give general recommendations. Industry groups such as the High Density Packaging User Group[2] (HDPUG) and the International Electronics Manufacturing Initiative (iNEMI) have sponsored many valuable testing programs to help build the knowledge base required.

In addition, most PCB manufacturers have their own testing programs that take into account the requirements of their end markets, the PCB designs they build, and the manufacturing equipment and processes they use, among other factors. So while there is no single method used in selecting materials, the example below provides a very general format used for determining which materials are suitable for different applications.

Since most PCB fabricators will manufacture a range of PCB designs, and often for various end markets, they need to develop a system for categorizing the acceptability of different materials in different applications. Some of the key variables include

- The peak reflow temperatures the PCB is exposed to in assembly and rework processes. As discussed in Chap. 13, there is a range of temperatures used for lead-free assembly processing, and seemingly small differences in temperature can have very significant impacts on reliability. It is common to categorize material compatibility at 245°C and 260°C, for example. While only a 15°C difference, this can be the difference between good results and bad.

- The number of reflow and rework cycles that a given PCB can be exposed to. As you would expect, the more exposures to reflow temperatures, the more thermally reliable a material needs to be. Common test requirements are 3 times (3×), 5×, 6×, 8× and up to 10×. As mentioned earlier, testing is sometimes performed after temperature and humidity conditioning as well.
- PCB layer count and thickness. With higher layer count, it is common for the individual dielectrics to be thinner and have higher resin contents. With higher resin content, more thermal expansion is experienced at reflow temperatures, as well as in thermal cycling tests designed to assess long-term reliability. In the thermal cycling tests for long-term reliability, the peak temperature is normally below the material T_g. As such, the pre-T_g CTE is a critical factor in these tests. As board thickness increases, the total thermal expansion will be greater.
- Plated through hole size, aspect ratio and hole-to-hole pitch. In general, as hole-to-hole pitch decreases, the demand for greater thermal reliability increases. As PCB thickness increases, this becomes more critical. Testing of PCBs at 2.5 mm thickness and above, with 0.8 mm hole-to-hole pitch and below, is a very active area for testing of new materials.
- Innerlayer copper thickness. In designs where innerlayer copper thickness can be 2 oz or greater, resin content selection and resin flow and fill properties become more important. The issue of glass stop was described in Chap. 13, and the potential for this condition increases as copper thickness increases. In addition, many of the resins used in new materials for high-speed/high-frequency applications have higher minimum viscosities when the resin is melted during the multilayer lamination cycle. As a result, it is more challenging to get good resin flow and fill into thick copper patterns. In addition, where multiple prepreg layers

are used to insure adequate resin volume for filling thick copper layers, a high resin viscosity can make it difficult for resin to flow through the fiberglass cloth and assist in filling the innerlayer circuit pattern, especially if there is little space between the yarns in the cloth. While the spread and expanded glass cloths have benefits for laser drilled via quality, signal integrity performance and resin-to-glass wetting for CAF performance, these glass styles are not preferred when there is a need to allow resin from adjacent prepreg layers to flow through a glass cloth to assist in filling the innerlayer circuit pattern. This also makes an understanding of resin melt viscosity important when designing a PCB stack-up and in setting up lamination cycles. Figure 14.4 is an example of a dynamic viscosity plot for a phenolic FR-4 epoxy. A sample of 106 prepreg is used in this example, with resin viscosity on the *x* axis and temperature on the *y* axis. Note how faster heat rise rates (1 to 3.5°C/min heat rise rates are shown) lead to lower minimum viscosities. Minimum viscosity decreases from 732 pascal-seconds (Pa-s) to 163 Pa-s in this range of heat rise rates. Figure 14.5 shows viscosity curves for two different material types at a 2°C/min rate of rise, and Fig. 14.6 shows the same materials with a rate of rise of 3°C/min. These used 2116 prepreg. Note the large difference in minimum viscosity between the two material types, as well as the decrease in minimum viscosity for both products as the rate of rise increases from 2 to 3°C/min.

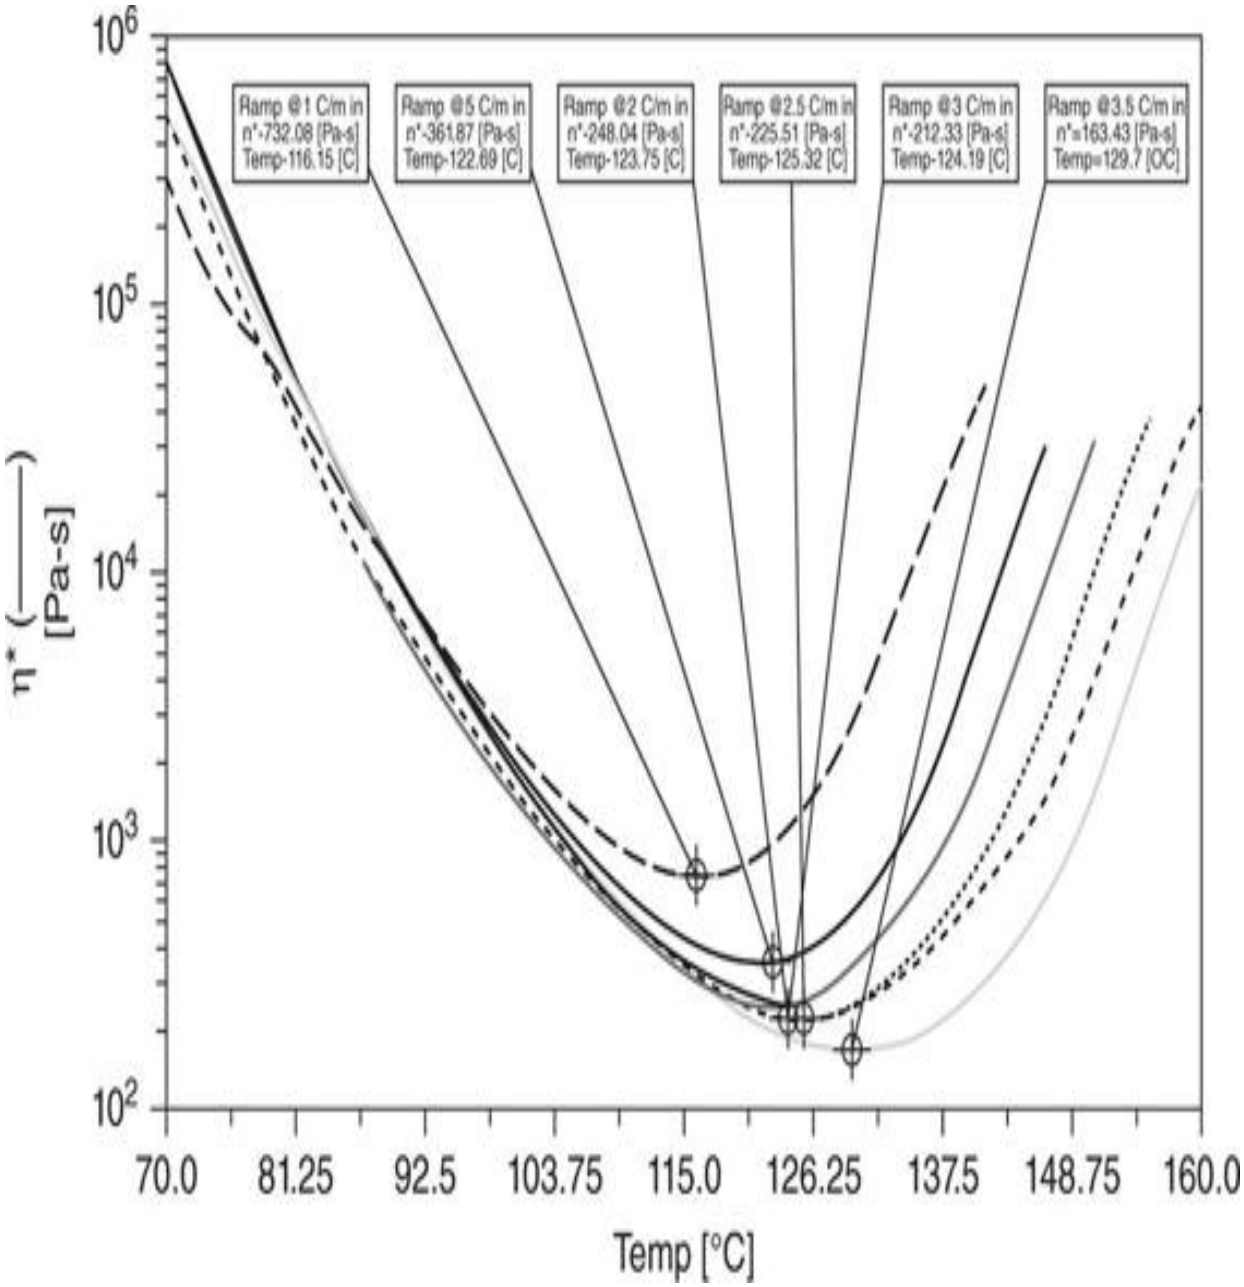

FIGURE 14.4 Dynamic viscosity curves for one material at different heat rise rates.

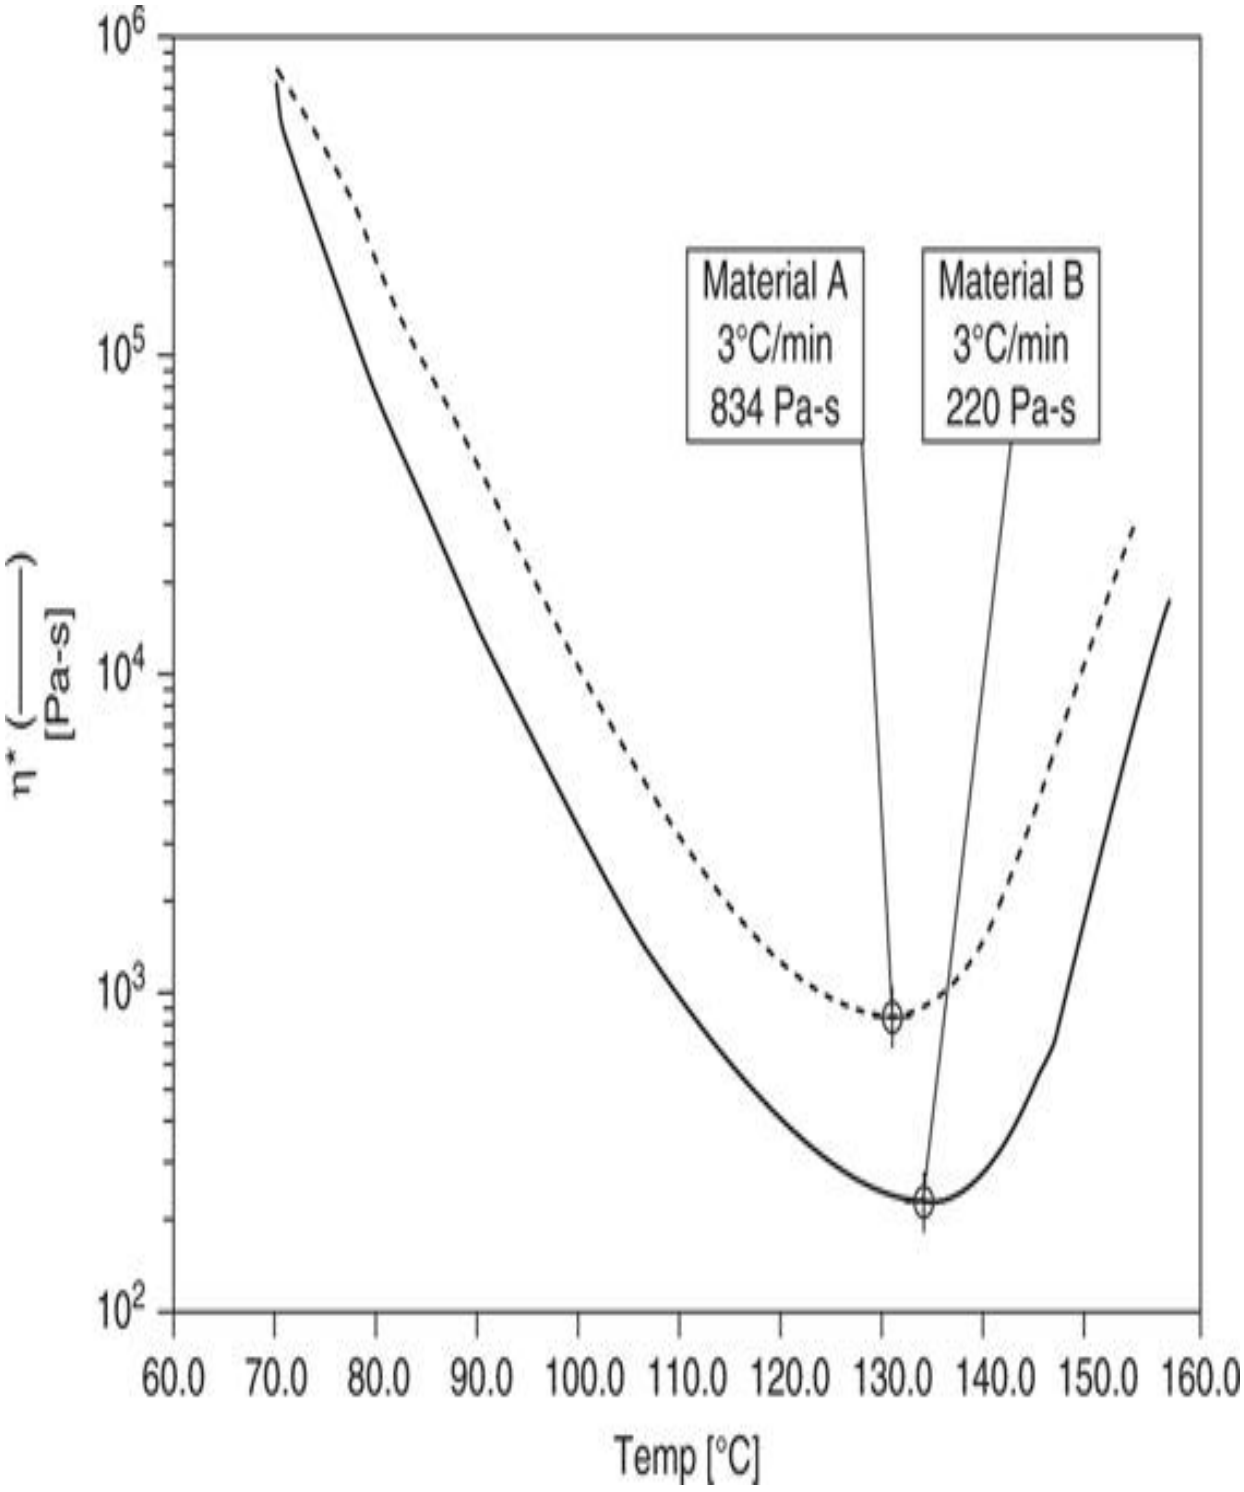

FIGURE 14.5 Dynamic viscosity curves for two different materials at 2°C/min heat rise rate.

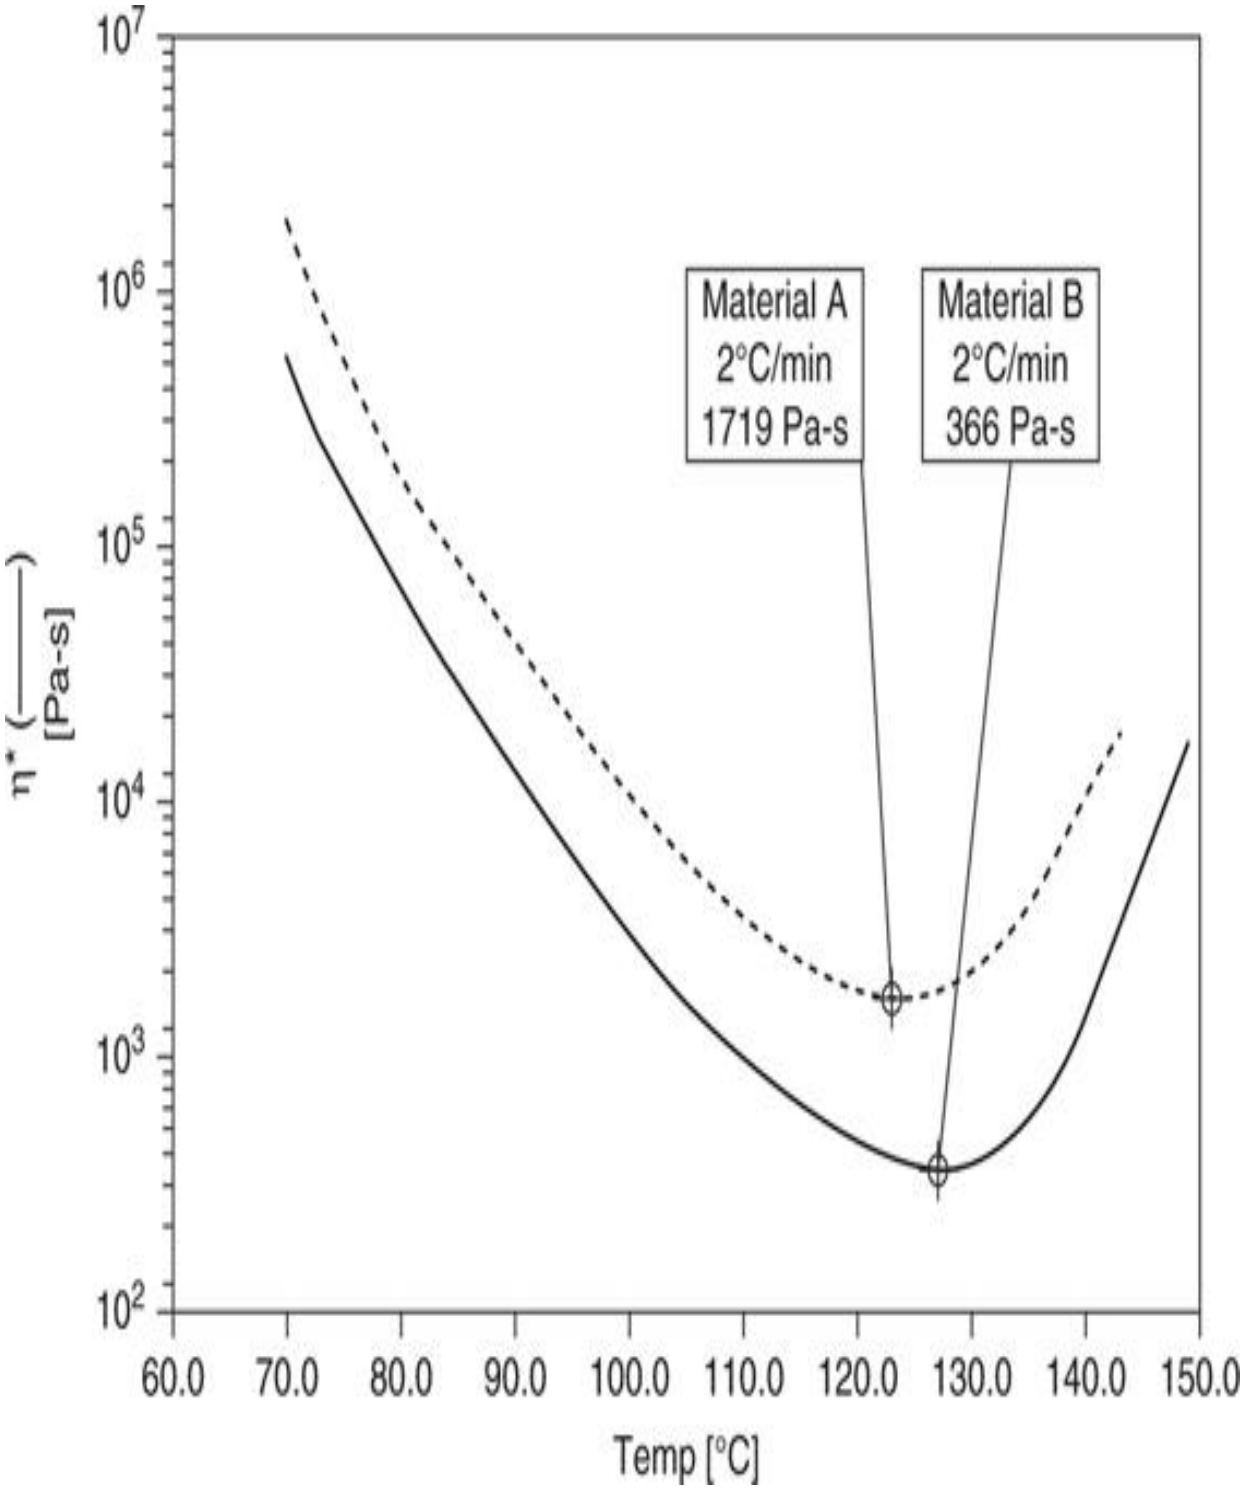

FIGURE 14.6 Dynamic viscosity curves for two different materials at 3°C/min heat rise rate.

With these variables in mind, and through the testing methods described earlier, one way to categorize material thermal performance is shown in Fig 14.7. Bear in mind that this is just one way to categorize performance across material types, and each manufacturer may devise their own system. Also, Fig. 14.7 is an arbitrary example. However, it is not unusual for some products to perform well at 245°C, but not perform as well at 260°C. Or some may be reliable at 1.0 mm pitch but be less reliable at 0.8 mm pitch, which may also depend on innerlayer copper weights or overall resin content.

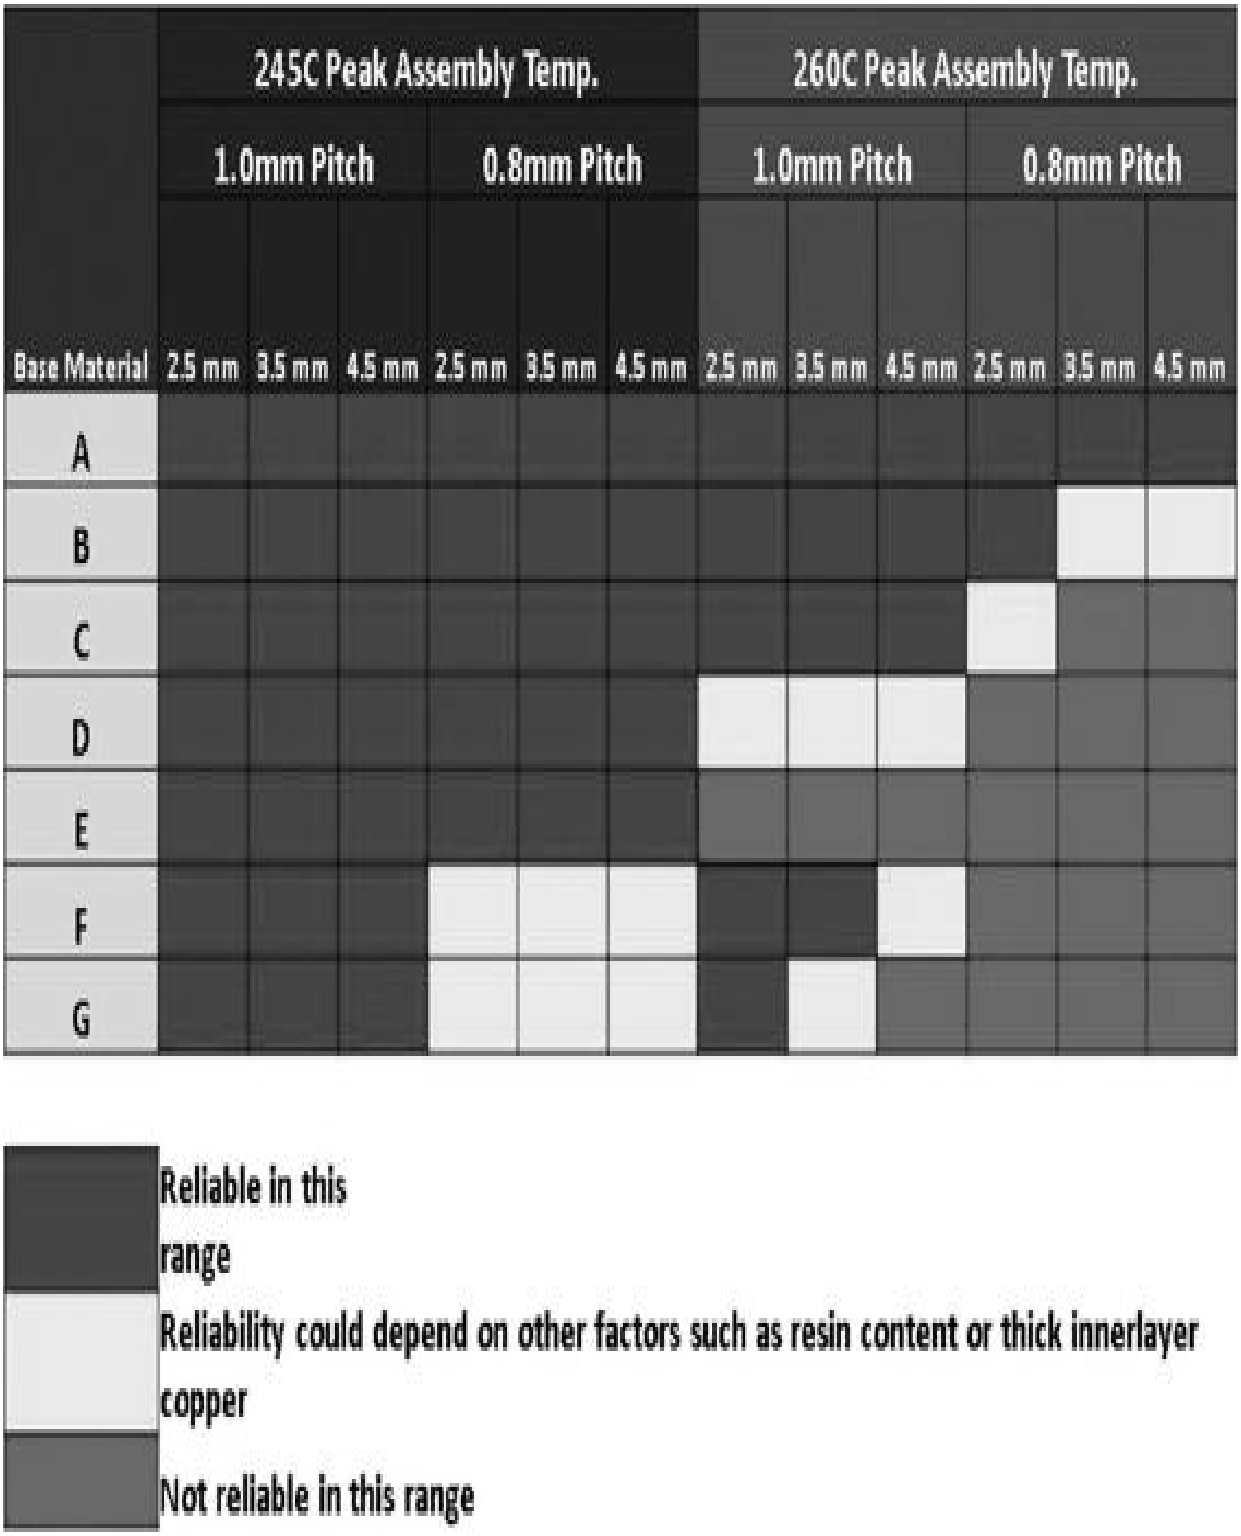

FIGURE 14.7 Example of material thermal reliability rating.

14.3.2 IPC Specification Sheets

IPC specifications and specification sheets for different material types were introduced in Chap. 10. This included IPC-4101, Specification for Base Materials for Rigid and Multilayer Printed Boards, and IPC-4103, Specification for Base Materials for High-Speed/High-Frequency Applications. IPC-4101 in particular contains a number of specification sheets for different types of base materials. Many of the more recently added specification sheets were developed with the demands of lead-free assembly in mind, and include properties such as decomposition temperature, thermal expansion, T260 and T288 values.

However, there are some important limitations to these specification sheets that should be well understood. First, the specifications refer to the laminate materials, and not to the PCBs made with the material. For example, a specification sheet with a requirement for the T_g to be a minimum of 170°C refers to the laminate, and not to a multilayer PCB made with that same material. There are a few reasons why the measured T_g on a PCB could be different than the laminate material. Second, just because a material meets the requirements of a specific specification sheet, even one that has requirements for decomposition temperature, thermal expansion and time to delamination, doesn't mean that the material will be reliable in a given lead-free application. Conversely, just because a material does not meet all the requirements stated in a given specification sheet, does not mean the material is unsuited for a given application. The material performance should be validated through testing such as that described above.

It is also critical to understand that no one property will guarantee success in lead-free applications. All of the variables outlined in this chapter must also be considered when specifying a material. When faced with uncertainty, the

natural tendency is to overspecify each property. Not only could this cause the user to pay too much for a material, but overspecifying specific properties can also lead to functional problems. These problems can be the result of the interaction between advanced materials and the PCB fabrication processes required to manufacture reliable PCBs.

Take decomposition temperature, T_d, as an example. Although the 5 percent level of decomposition is the standard reported value, this is a very high level of decomposition from the standpoint of PCB reliability. It is important to understand when decomposition begins and how close this temperature is to actual assembly and rework process temperatures. A material with a reported T_d, based on the 5 percent level, of 325°C may perform just as reliably, or even more reliably, than a material with a 5 percent T_d value of 340°C, depending on what the decomposition characteristics are in the lead-free assembly and rework temperature ranges. Specifying materials with significantly higher T_d values may not improve reliability, and may potentially add cost and difficulty to the manufacturing process if the higher T_d material is more difficult to process—for example, if the lamination times are longer, or if it is harder to drill. Although future specification sheets may include T_d values based on lower levels of decomposition, it is very important to understand these properties in some detail and specify the appropriate material for a given application.

Last, a potentially valuable use of the specification sheets is to use them as a baseline. A given specification sheet that meets most of the requirements desired by the user can be selected. The user can then call out exceptions to the values on the sheet, or add or delete other requirements. One example could be peel strength when very low profile copper foils are used to improve signal integrity. Existing peel strength values may be too high for some materials with

extremely low profile copper foils. In this case, if thermal reliability of the material with the desired copper foil has been validated by the user, then they can reference a certain specification sheet and make an exception to the peel strength requirement.

14.3.3 Summary

The question of whether a given laminate material is compatible with lead-free assembly can be very complex due to the many variables in PCB design and manufacturing. In addition, there are variations in lead-free assembly processes. Specifically, peak temperatures, dwell times at peak temperatures, heatup rates, cooldown rates, and rework processes can all vary and complicate this decision. As stated earlier, the temperature range from 240 to 260°C is critical for laminate materials; some materials may be successful at the low end of this range but fail at the higher end.

Critical base material properties with respect to lead-free assembly applications include

- *The decomposition temperature*. Some minimum value is needed, but above that minimum level, higher values are not always better.
- *Thermal expansion properties*. Improved materials have reduced levels of thermal expansion.
- *Glass transition temperature*. A higher glass transition temperature delays the onset of rapid thermal expansion and therefore reduces total expansion within a temperature range.
- *Moisture absorption*. In particular, if PWBs are stored in an uncontrolled or humid environment prior to assembly, drying of boards prior to assembly or selection of a

material less prone to moisture-related problems should be considered.

- *Time to delamination*. T260 and T288 values are a simple way to screen materials for compatibility with lead-free assembly. However, testing at higher temperatures or requiring excessive times may not be necessary.

Balancing these properties with the level of reliability required along with PWB manufacturability and assembly concerns is vital.

14.4 SELECTING MATERIALS FOR ELECTRICAL PERFORMANCE

As with thermal reliability, there are many factors that affect the performance of a PCB in terms of electrical performance. The components that make up the base material as well as the processes used to make the PCB can all affect performance. Many of these factors were discussed in previous chapters. So in the following sections we will summarize some of the key considerations related to the base material components and PCB processes, and then discuss how base materials are categorized and measured. For an overview of skew issues in differential signaling, refer to Sec. 12.11 in Chap. 12

14.4.1 The Influence of Base Material Components on Electrical Performance

Each of the three basic components that comprise a laminate material has an impact on the electrical

performance of the composite structure. The key factors were discussed in Chap. 10, and summarized here:

- *Resin system*. Clearly the resin system, which includes any inorganic or organic fillers, has an enormous impact on the electrical performance. The Dk and Df of the resin system are the primary factors to consider when selecting a resin system. Recall that for most common materials the resin content selected in in the laminate and prepregs will result in different values of Dk and Df. Usually as resin content increases the Dk will decrease and Df will increase. An exception to this was discussed in Sec. 12.11 in Chap. 12 when discussing skew in differential pairs of signals. In this section a material that had very uniform Dk properties regardless of resin content was described. In general, lower Dk/Df resin systems will incur added costs.
- Glass cloth. Historically E-glass has been by far the most common type of fiberglass cloth used in PCBs. In recent years the use of lower Dk glass fabrics has been growing significantly. In addition, the use of spread/expanded glass cloths has also been increasing. While these fabrics have other benefits, some of the increased usage is due to the improved uniformity of Dk across the dielectric. This was also discussed in Sec. 12.11 of Chap. 12. There is some cost premium associated with spread/expanded glass fabrics, and the low Dk glass cloths are also more expensive than standard E-glass.
- *Copper foil*. The primary consideration with copper foil is surface roughness, as discussed in Chap. 12. As operating frequencies increase, the impact of copper surface roughness becomes increasingly important, and can be a dominant factor at very high frequencies. Copper foil manufacturers continue to develop extremely low profile copper foils that still have suitable bond strength to advanced resin systems. These foils are also sold at a premium to more standard foils. Table 14.4 provides

simulation data for loss in dB/in using a 20-mil long, 4-mil stripline with ½ ounce copper and four different types of copper foil with decreasing levels of surface roughness from “standard” profile to “EVLP,” which has an extremely low surface roughness. In addition, the table provides simulation data for three material types at three different frequencies. From this table you can get an idea of the impact of copper foil roughness and operating frequency on the performance of three types of resin system. As conductor width will also affect loss, Table 14.5 presents data for a 6-mil stripline so that a comparison can be made with the 4-mil stripline.

TABLE 14.4 Single-Ended 4 mil ½ oz Stripline—20 Inches Long

	dB/Inch @ 4 gigahertz			dB/Inch @ 8 gigahertz			dB/Inch @ 12 gigahertz		
Foil	A	B	C	A	B	C	A	B	C
Standard	0.588	0.533	0.484	0.913	0.811	0.712	1.223	1.069	0.908
RTF	0.532	0.477	0.426	0.839	0.732	0.630	1.126	0.972	0.807
VLP	0.491	0.436	0.384	0.781	0.675	0.570	1.055	0.901	0.734
EVLP	0.459	0.404	0.351	0.737	0.631	0.524	1.001	0.846	0.678

TABLE 14.5 Single-Ended 6 mil ½ oz Stripline—20 Inches Long

	dB/Inch @ 4 gigahertz			dB/Inch @ 8 gigahertz			dB/Inch @ 12 gigahertz		
Foil	A	B	C	A	B	C	A	B	C
Standard	0.479	0.424	0.359	0.765	0.658	0.536	1.035	0.880	0.691
RTF	0.437	0.382	0.318	0.707	0.601	0.477	0.964	0.809	0.603
VLP	0.407	0.352	0.288	0.665	0.559	0.435	0.912	0.757	0.568
EVLP	0.384	0.329	0.265	0.632	0.526	0.403	0.872	0.718	0.528

In addition to the individual components, the laminate manufacturing process can also have some impact. In short, control of resin contents, dielectric thickness uniformity and degree of cure of the resin system can all influence the electrical performance of the finished laminate.

14.4.2 PCB Manufacturing Influences on the Base Material

There are a few key processes within the overall PCB manufacturing process that can influence the material performance. These include

- *Innerlayer circuit etching*. Control of line widths and geometries will influence impedance control and attenuation. Wider circuit traces will result in less loss, but the width is typically specified by the circuit designer.
- *Innerlayer surface preparation*. The oxide or oxide alternative processes can have a significant impact on loss as a result of any increase in surface roughness they create. Figure 14.8 showed an example of differences that can be observed through these processes.

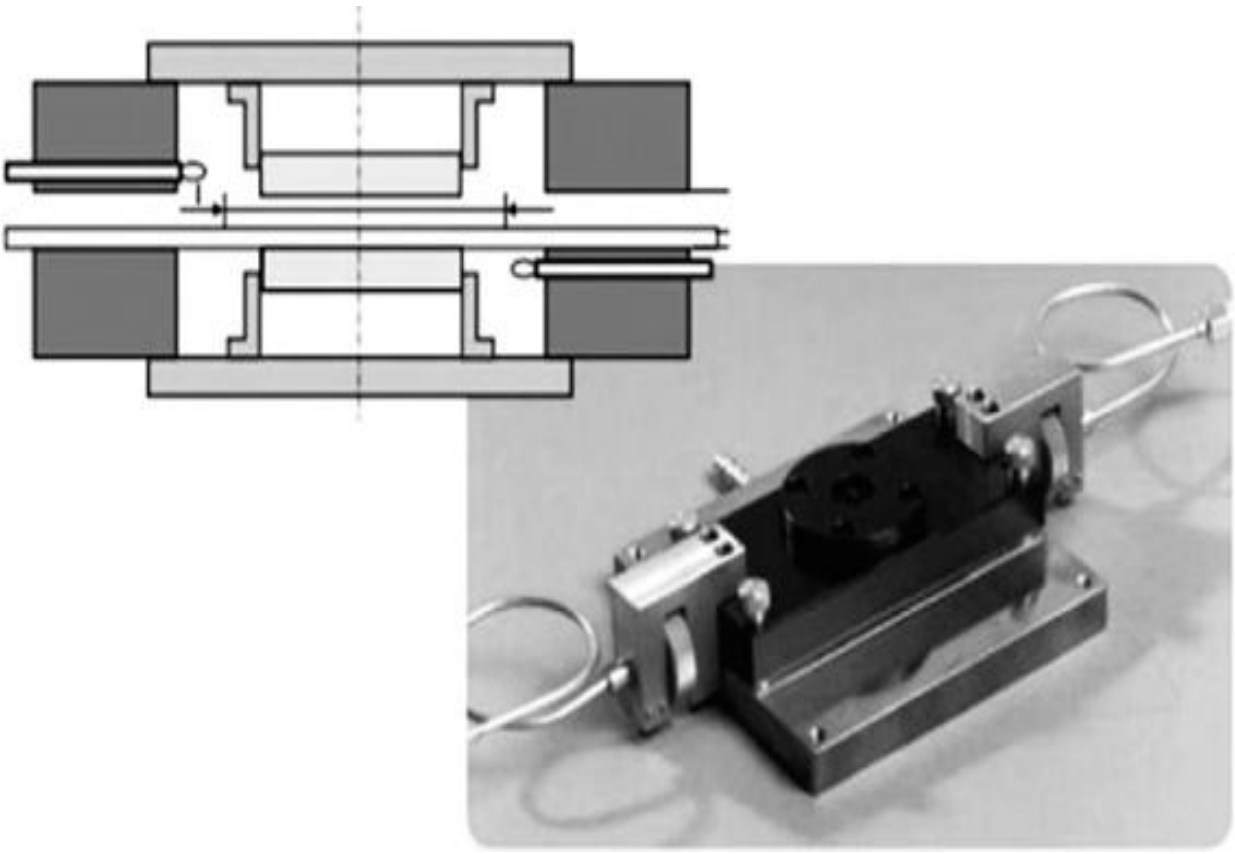

FIGURE 14.8 Example of resonator used in SPDR method.

- *Multilayer lamination*. Achieving good cure of the resin in the prepregs is important as it can affect the dielectric Dk and Df properties. Moisture can interfere with the curing of some high performance resin systems, and therefore it can be important to fully dry the innerlayer laminates prior to lay-up of the multilayer. Proper storage of the prepregs prior to use is also important.

14.4.3 Classification of Base Materials for Electrical Performance

Historically the most common way to classify materials was simply by reporting Dk and Df values. However, both Dk and Df vary with resin content, frequency, and test method. This also made it very difficult to compare materials based on

supplier data sheets, as different suppliers use different test methods or resin contents. Furthermore, measurements on the base laminate materials, with some methods using unclad laminates and therefore not taking into account the impact of copper, often did not correlate well to actual performance in the PCB. So in more recent years, test methods that characterize material performance in the finished system have been developed. Some of these will be described shortly.

While many OEMs have their own system of classification for electrical performance, it is common to specify ranges of dissipation factor, Df, or loss. A common classification is shown in Table 14.6.

TABLE 14.6 Examples of Classification of Materials by Df

OEM	Test Method	Df Categories				
A	Uses impedance optimization coupons and TDR/TDT hardware	Standard Loss 0.020–0.023	Mid Loss 0.014–0.020	Low Loss 0.008–0.015	Very Low Loss 0.004–0.008	Ultra Low Loss <0.004
B	S-parameter measurements	High Loss >0.020	Standard Loss 0.014–0.020	Mid Loss 0.010–0.015	Low Loss 0.005–0.010	Ultra Low Loss <0.005

Table 14.4 highlights that different OEMs may have different preferred test methods, as well as different terminology and categories for loss levels. Most of the preferred methods used by OEMs require multilayer PCB structures and use insertion loss measurements to extract effective Dk and Df values. Some are also able to de-embed the effect of copper surface roughness. In others, PCB structures with different types of copper foils and/or oxide processes can be compared to understand these influences.

Unsurprisingly, as material Df decreases there is typically an increase in cost. In terms of industry usage and using the categories defined by OEM “B” in Table 14.4, high loss materials represent the highest volumes in PCB manufacturing, however for some OEMs their use of materials in this category has peaked. Standard loss materials as defined by OEM B have grown in usage in recent years. While volumes of mid-loss and low-loss materials are relatively smaller, they are experiencing faster growth rates. Ultra-low loss materials are the focus of much current development work, and are expected to grow in coming years. These ultra-low loss materials are expected to use very low loss resin systems along with ultra-low profile foils and low-Dk/Df glass cloths.

As noted above, there are many test methods used to assess base material electrical performance. While a full discussion is beyond the scope of this chapter, there are some increasingly common methods used by OEMs and fabricators to assess material performance at high frequencies, and a recent technical paper published by the High Density Packaging User Group (HDPUG) discussed and compared several of these methods.[3] One example given in this study was to select one material and measure Df by multiple test methods. The range of Df values measured by four different methods was 0.002 to 0.008, highlighting the need to understand what test method is used to assess a material.

IPC test method 2.5.5.12 describes five methods for determining the amount of signal propagation loss caused by material characteristics of conductors in PCBs, and is a good reference for those looking for more technical details, along with the HDPUG technical paper already cited. Table 14.7 is an overview found in the IPC test method. There are other methods also briefly described below.

TABLE 14.7 Overview of Test Methods from IPC-TM-650 2.5.5.12

	EBW	RIE	SPP	SET2DIL	FD
Instrument	TDR	TDR/VNA	TDT	TDR/TDT	VNA/TDT
Stimulus	Selected for appropriate spectral content	250 ps or specified	11-35 ps	11-35 ps	300 KHz to 10 GHz or as specified
Coupon	>5 cm	1.25 cm and 20.32 cm or as specified	3.0 cm and 10.0 cm	4" (8" effective length)	20.32 cm or as specified
SW	Scope Algorithm	Algorithm and IPC website pointer	Algorithm and IPC website for software	Algorithm	Algorithm
Probe	Matched impedance probe	Matched impedance probe	Matched impedance probe, RF connector	High Frequency hand-held probe	Matched impedance probe, RF connector
Test Quantity	Maximum slope in MV/sec	Averaged loss (dB)	Tan δ ε_r, α, β, and Z_o vs. frequency	SDD21 vs. frequency	Loss fit and slope
Applicability	Printed board fabrication testing	Printed board fabrication testing	Printed board material qualification, printed board model generation	Printed board fabrication qualification and testing	Printed board fabrication testing, printed board design guide specification

A few of the more common test methods used widely today include

- *Split post dielectric resonator (SPDR)*. Historically a very commonly used method. This method utilizes unclad

dielectrics and therefore does not include the influence of the conductor. Many laminate material data sheets report values based on this method as well as the parallel plate method (IPC 2.5.5.9). However, the values reported by these methods often do not reflect the effective Dk and Df on actual PCBs. Figure 14.8 is an example of the resonator.

- *Stripline resonators*. Stripline resonators use either a metal clad substrate or a conductor placed in very close contact to the dielectrics under test. IPC 2.5.5.5 is an example, though there are other methods as well, such as the Bereskin stripline method. Figure 14.9 shows examples of the equipment set up used.

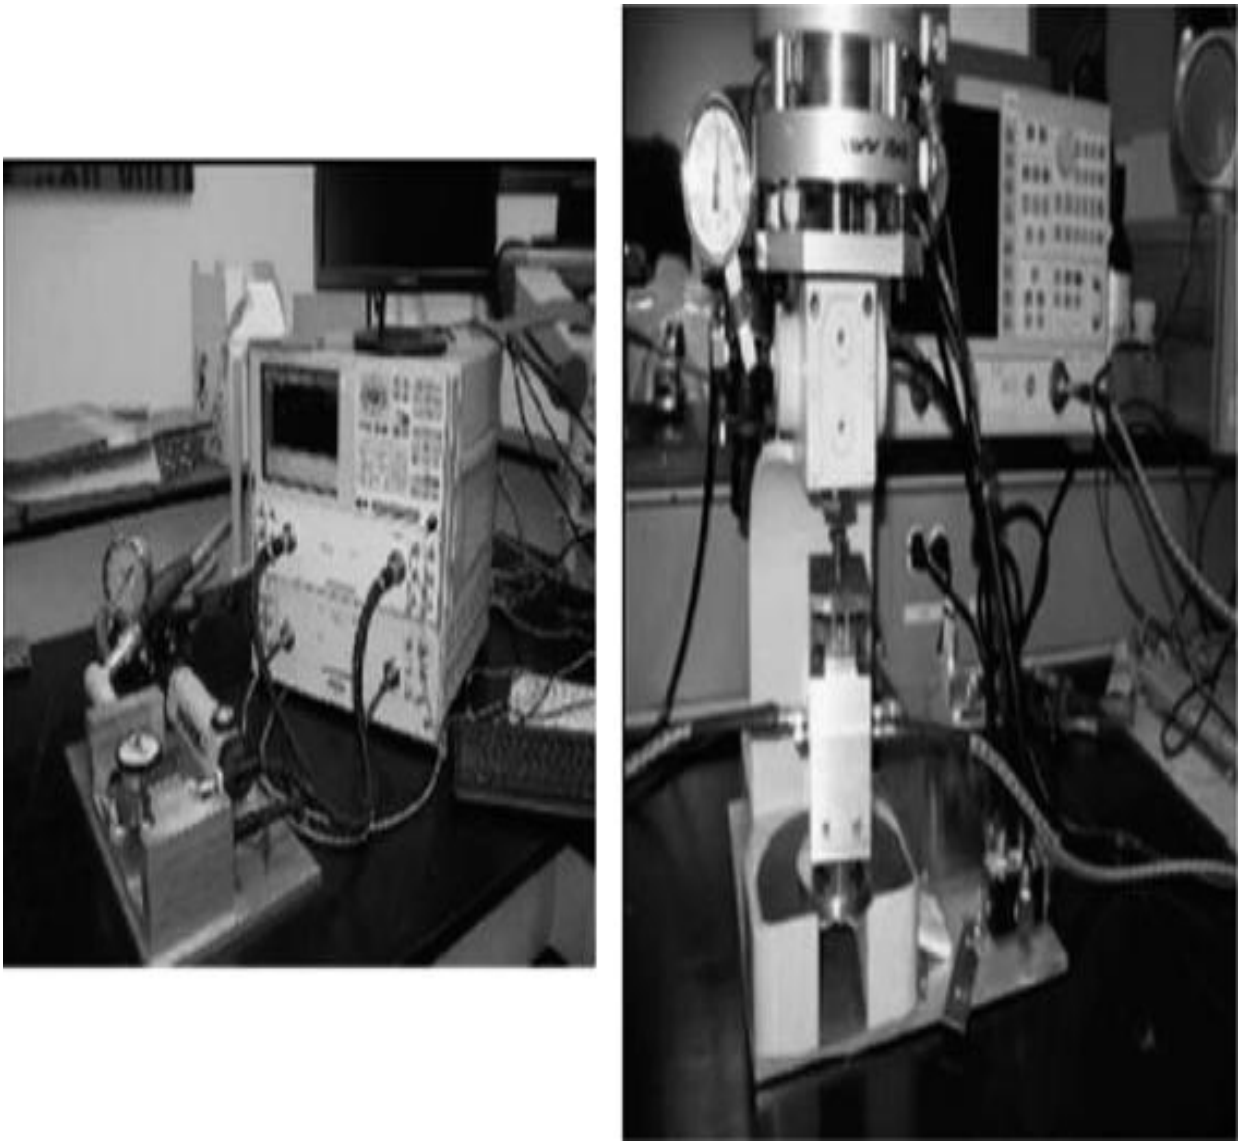

FIGURE 14.9 Fixture used in IPC and Bereskin methods.

- *Short pulse propagation (SPP)*. Described in IPC 2.5.5.12, uses time domain reflectometry/time domain transmission (TDR/TDT) equipment and characterizes insertion loss and effective Dk/Df. Typically multilayer test vehicles using both a high resin and low resin stack-up are assessed in order to assess Dk/Df variation with resin content. Figure 14.10 illustrates SPP testing.

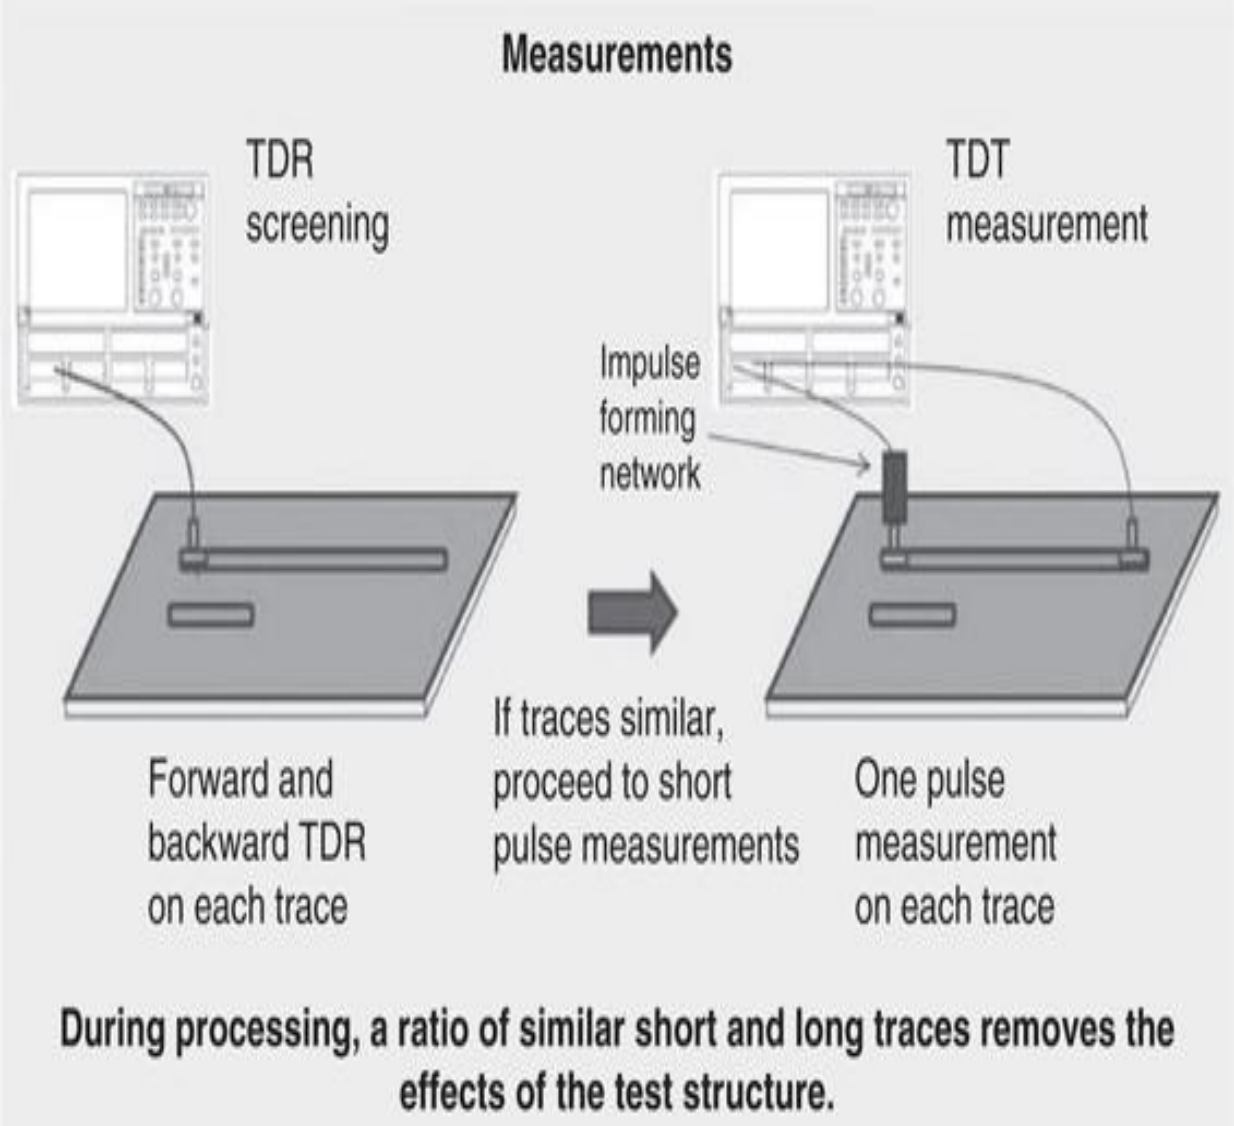

FIGURE 14.10 Illustration of SPP methods. (*From Introbotics Corp.*)

- *Single ended time domain to differential insertion loss (SET2DIL)*. Also described in IPC 2.5.5.12, SET2DIL is a relatively inexpensive and easy way to measure PCB insertion loss in volume manufacturing environments. SET2DIL also uses TDR/TDT hardware and is used to measure both stripline and microstrip interconnects (Fig. 14.11). Commonly used to report insertion loss at 4 and 8 GHz.

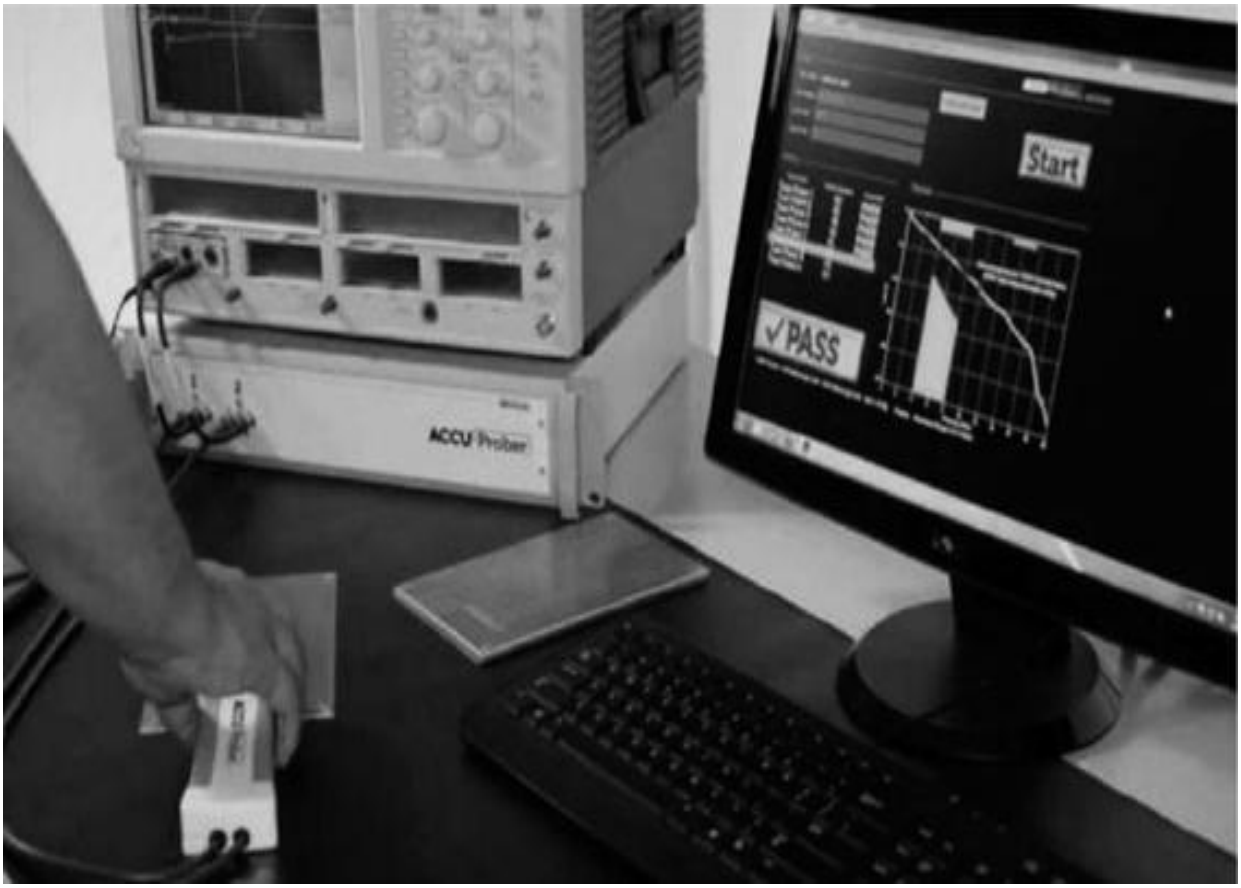

FIGURE 14.11 Example of SET2DIL measurement. (*From Introbotics Corp*.)

14.4.4 Summary

As with thermal reliability, OEMs and fabricators are using various test vehicles and methods to assess base material electrical performance and to classify materials into various performance categories. In fact, many users will first assess the electrical performance of a material in order to understand what level of performance it offers, and will then proceed to test thermal reliability and possibly CAF performance as we will discuss shortly. The end result might be a list of materials as in Fig. 14.7 for each level of electrical performance, as in Table 14.6. Such a material database would allow for easy selection of materials for new applications.

14.5 CAF RESISTANCE

Many aspects of CAF were discussed in Sec. 12.8 of Chap. 12. In addition, there is a chapter dedicated to CAF later in the book. So we refer the user to these sections of the handbook for more information, and here will outline some general conclusions that are useful when selecting materials. Also, an additional example of a CAF test vehicle will be described along with examples of CAF test results. As this discussion will make clear, performing failure analyses when failing insulation resistance measurements are observed is critical in understanding performance. There are reasons why a failed insulation resistance may have nothing to do with the base material performance.

14.5.1 General Considerations When Selecting Materials

From the years of research on CAF, there are several general conclusions that can assist the user when selecting materials. These include

- All base materials have some level of CAF resistance, but even materials promoted as “CAF-resistant” can vary widely in actual performance.
- The test vehicle design has a significant impact on results. The closer the circuit features, the more likely that CAF failures will occur. In addition, the other attributes of the test vehicle design can impact the fabrication variables that influence CAF—for example, the thickness of the PCB and drilled hole sizes can lead to high aspect ratios that can be more challenging to manufacture. As a result of these factors, there is not universal agreement on what

constitutes a “CAF-resistant” material. This can vary by OEM and application.

- One type of resin system can vary in performance based on other factors, such as the glass cloth quality and the controls used during laminate and prepreg manufacturing.
- The specific glass styles can also impact performance. Although 7628 glass was the focus of much attention in CAF testing historically, 106 and 1080 styles can be challenging as well, in that getting full resin-to-glass wetting can be challenging with these styles. The spread/expanded styles such as 1067 and 1086 are easier in completely wet-out with resin for improved performance. In short, getting complete wet-out of the resin to the glass filaments is critical.
- It is critical to define appropriately the performance level required and to design a test vehicle and test protocol that reflects the requirements of the application. Failure to do so can result in either underspecifying the material attributes and risking PCB failures or overspecifying the material and paying too much for it.
- For resistance to CAF growth, the resin system and the bonding of the resin system to the fiberglass cloth are key considerations. Coupling agents, typically silanes, are used to promote adhesion between the fiberglass filaments and the resin system. The molecular structure of the coupling agent includes a portion that bonds well to the fiberglass surface and other portions that bond well to the resin system. Specific coupling agents have been developed for specific resin types. Achieving a good bond between the fiberglass filaments and the resin system with an appropriate coupling agent helps prevent this interface from becoming a path for CAF growth.
- Low rates of moisture absorption and low levels of ionic contamination within the resin system also aid in resisting CAF growth. Epichlorohydrin is a precursor material used

to make epoxy resins. The use of this compound can result in residual hydrolyzable chlorides in the epoxy resin. In the presence of moisture, these hydrolyzable chlorides form ionic species that can promote electromigration. When CAF resistance is a critical consideration, the use of high-purity resins may be required.

- Lead-free assembly can stress the resin-to-glass bond, and even cause some level of resin decomposition, which can create microvoids within a PCB and cause failures in materials that are not robust enough for the lead-free assembly process used.
- On the other hand, many lead free compatible materials will actually improve in CAF performance after exposure to lead-free assembly. It is recommended that lead-free preconditioning on CAF coupons be performed prior to testing. Many OEMs will want to test in both the “as received” condition as well as after multiple reflow simulations to understand any change in performance.

14.5.2 Example of CAF Test Vehicle, Test Results and Findings in Failure Analyses

Figure 14.12 is an external photo of a multilayer CAF coupon that has been used to assess many different materials. This coupon is being used in a larger test vehicle that contains many other types of coupons that test, among other things, thermal reliability. From the surface you can see that there are two orientations for the rows of holes, and perhaps not as obvious, two hole-to-hole distances. While the other discussions of CAF noted that there are different types of CAF formation, including hole wall to hole wall, hole to plane or hole to trace, trace to trace, and layer to layer, generally the most challenging feature is hole-to-hole. The coupons in

Fig. 14.12 have two orientations so that both dimensions of the glass fabric are tested. In some cases, the warp (or grain) direction has filament bundles that are more densely packed and therefore can be more difficult to completely wet-out with resin. This is one reason to test both dimensions.

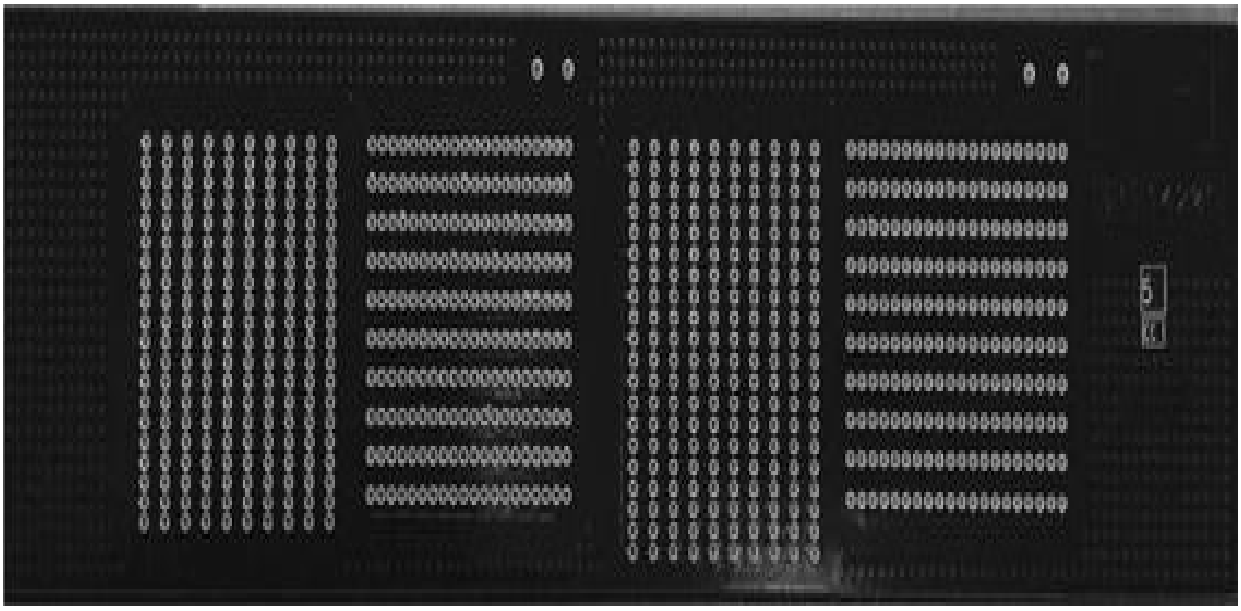

FIGURE 14.12 Example of a common CAF coupon. (*Courtesy of Alcatel-Lucent*.)

Another test vehicle design which is used to test the various types of CAF referenced above is shown in Fig. 14.13. Figure 14.14 shows the design of the hole wall-to-hole wall coupons in this test vehicle. Note the wall-to-wall distances, the number of opportunities for failure, and the two different drilled hole sizes, which allows an assessment of the impact of drilled hole quality. These coupons are generally tested in both the as manufactured condition as well as after multiple lead-free reflow cycles.

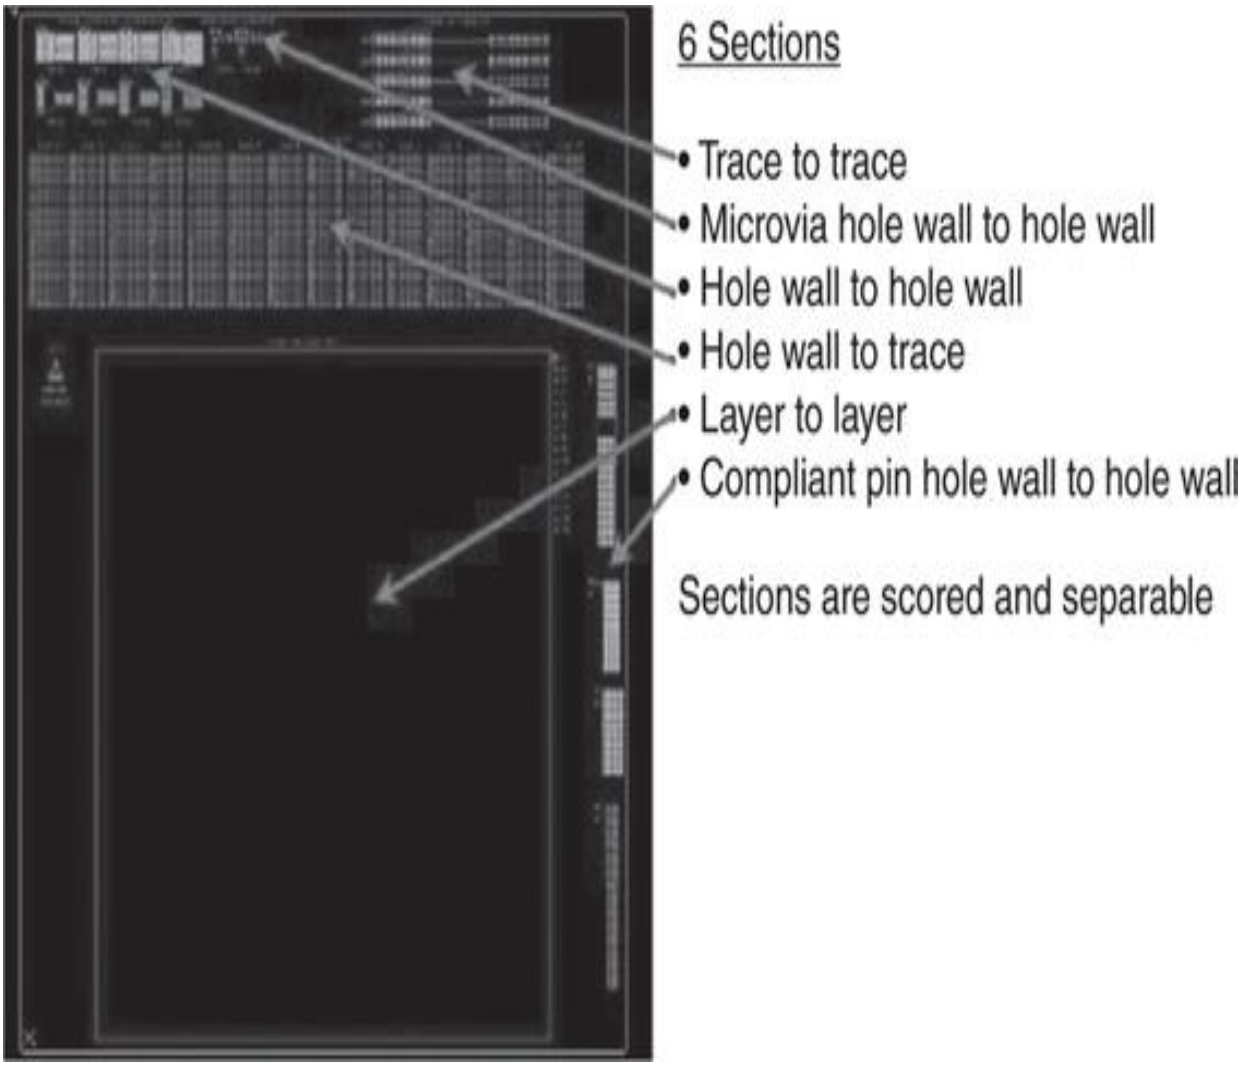

FIGURE 14.13 Example of A CAF coupon with multiple design features. (*Courtesy of Alcatel-Lucent*.)

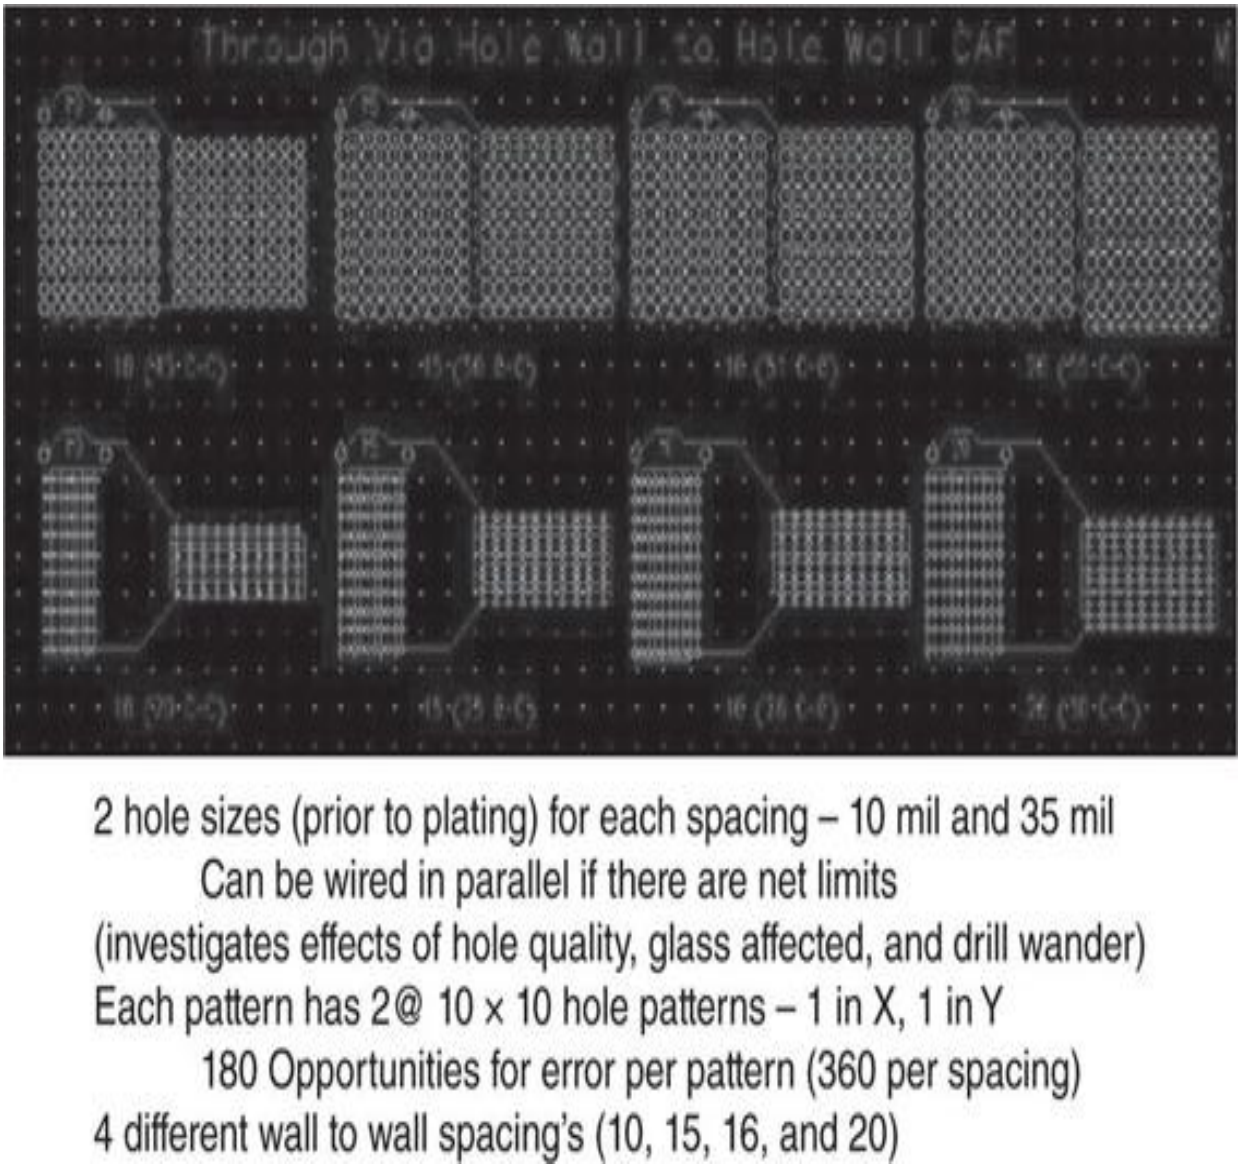

FIGURE 14.14 Example of CAF coupon design with multiple hole wall to hole wall spacings. (*Courtesy of Alcatel-Lucent*.)

Figure 14.15 graphs the insulation resistance for eight coupons with 10-mil drilled holes at a 16-mil hole wall-to-hole wall distance after 3× lead free reflow cycles. The coupons are conditioned at the test temperature and humidity for 96 hours prior to the application of steady state bias. This explains the apparent dip in resistance at time “0” in the chart. It is normal to have a high initial resistance reading and then a drop in resistance after temperature and

humidity conditioning and the application of the test voltage. Test conditions normally used for this test vehicle are 65°C, 85 percent relative humidity and 100 V. The minimum duration required is 500 hours, but it is preferred to go to 1000 hours. Failure is typically defined as an order of magnitude drop in resistance from time 0, or a drop in the absolute resistance below 10^8 Ω. The results in Fig. 14.15 are very good. Insulation resistance is very stable throughout the 1000 hours.

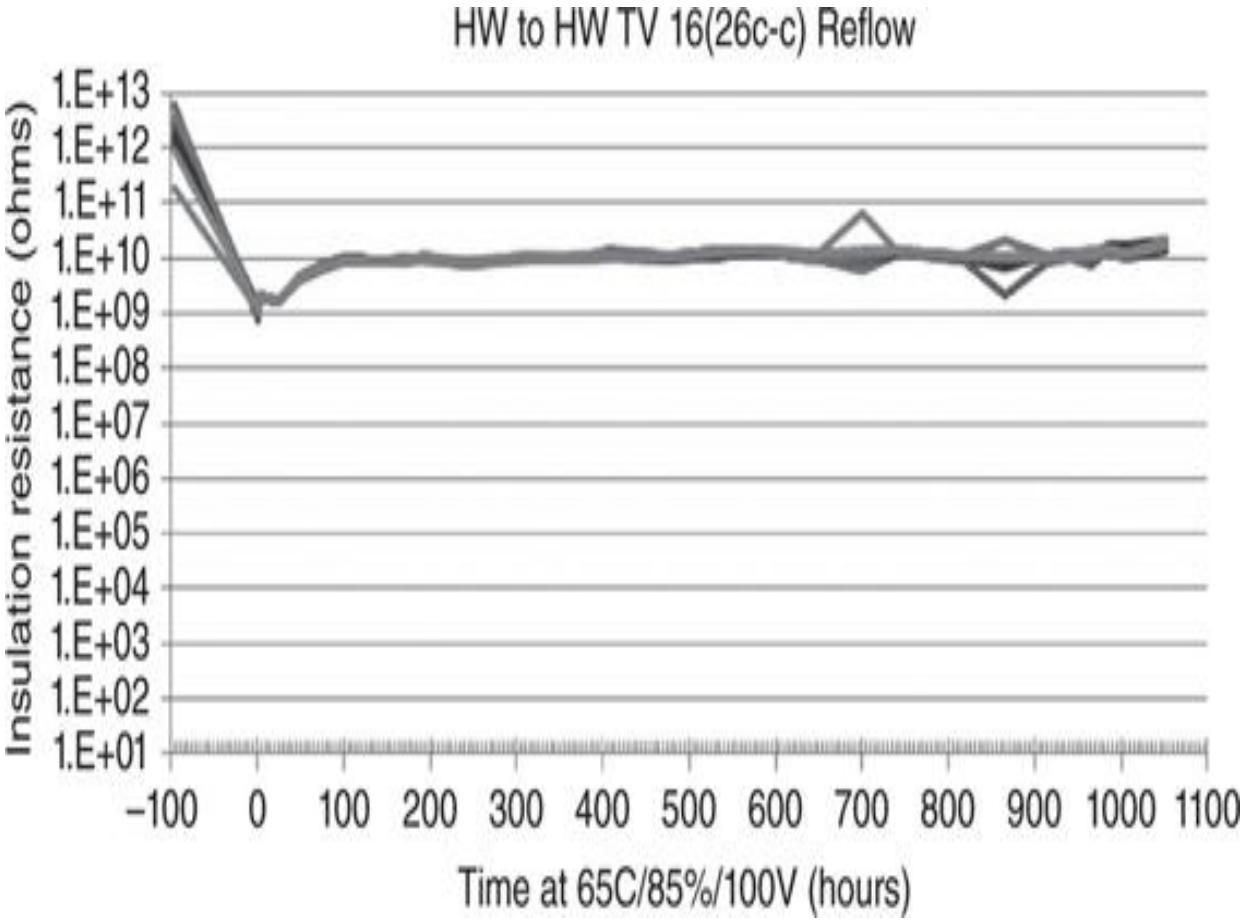

FIGURE 14.15 Example of CAF test results after lead free reflow 10-mil drilled hole size at a 16-mil wall-to-wall distance. (*Tested at i3 Labs*.)

Figure 14.16 shows test results for the exact same resin system and test conditions, but with a different glass cloth supplier and silane finish used in the laminate and prepreg

materials. In this case the result are extremely poor, with some coupons failing almost immediately. Figure 14.17 is an example of failure analysis results for failed coupons in this test.

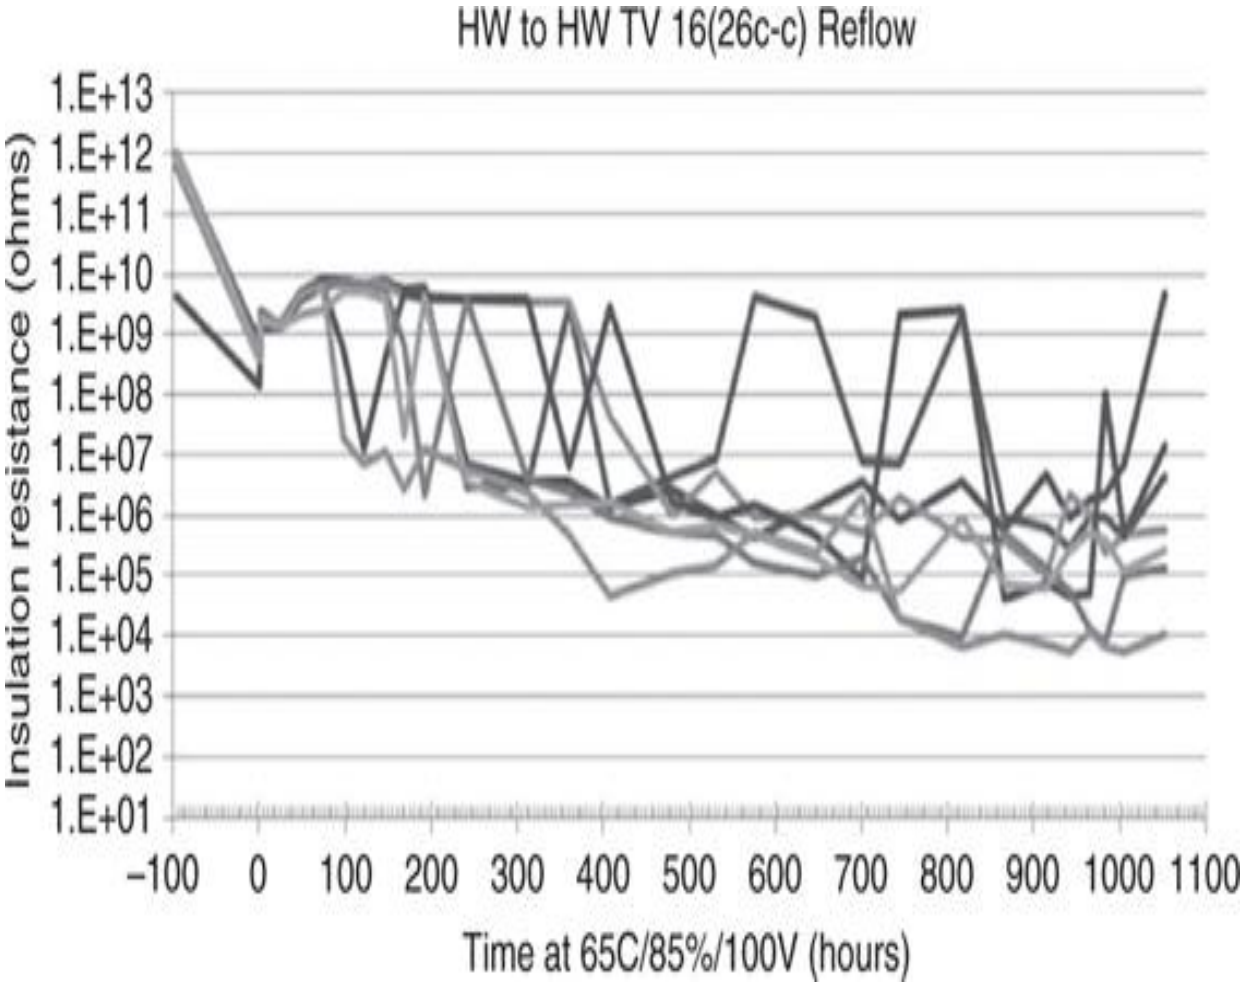

FIGURE 14.16 Example of CAF test results after lead free reflow 10-mil drilled hole size at a 16-mil wall-to-wall distance with alternate glass supplier and silane finish. (*Tested at i3 Labs*.)

FIGURE 14.17 Failure analysis for a coupon from Fig. 14.16. (*Analysis by i3 Labs*.)

The failure analysis in in this case showed copper migration along the resin-to-glass interface. EDX results exhibited not just copper metal, but other elements indicating that the conductive filament contained a copper salt, which is indicative of a true CAF failure. In this case, the glass cloth and silane source could not be qualified for use.

Figures 14.18 and 14.19 show CAF test results for another test sample. In this case, while there were failures in the insulation resistance testing, the failure analysis showed that the failure was not due to CAF, but to silver surface finish residues on the surface of the coupon. Figure 14.20 shows an insulation resistance failure due to embedded contamination. The contamination was a fiber that, through FTIR analysis and matching, was determined to be a rayon fiber. In Fig. 14.21 is a failure analysis where a hollow glass filament provided a pathway for copper migration to occur.

14.5.3 Final Comments on CAF

- The examples above are intended to highlight the importance of performing failure analysis subsequent to any insulation resistance failures in order to determine if the failure is truly the result of CAF or some other cause.
- The test vehicle described in this section can also utilize different stack-ups in order to test specific glass styles and resin contents.
- It is important to match the CAF test vehicle design and test protocol to the design features of the PCB in question. Using a test vehicle that is much more stringent than the actual PCB design risks ruling out acceptable, lower cost materials. On the other hand, not testing down to the minimum feature distances of the PCB risks selection of materials that may not offer adequate CAF resistance.

CHAPTER 15

LAMINATE QUALIFICATION AND TESTING

Michael Roesch

15.1 INTRODUCTION

Copper-clad laminate materials (single- or double-sided) are the base material for almost all printed circuit boards (PCBs). The properties of these materials have a large influence on the quality of the final product and therefore need to be understood and tested prior to release/manufacturing.

15.1.1 Impact of RoHS and Lead-Free Requirements

With a change toward RoHS-compliant “lead-free” assembly processes, laminate materials and complete printed circuit boards are facing a set of increased challenges:

- *Laminates* Materials have to survive the increased thermal stress of repeated lead-free assembly cycles. Due to the higher melting temperature of lead-free solders, a peak temperature during reflow of 260°C must realistically be expected (30°C to 40°C higher than eutectic soldering profiles). Most printed circuit boards will be required to withstand at least five such assembly cycles, but that number may increase to six and higher for more complex assemblies. A rule of thumb states that a 10°C increase of temperature doubles the reaction energy starting degradation or decomposition of the resin compound. The increased peak temperature therefore requires new or improved laminate materials with a higher decomposition temperature and enhanced thermal stability. New laminate test methodologies are also needed to assess the impact of the higher assembly temperatures.
- *PCB reliability* There should not be any degradation in the reliability of the printed circuit boards after assembly compared to boards assembled using traditional soldering profiles. When the same laminate material is used, plated through holes will see an increase in thermal expansion stresses after an equal number of assembly cycles with higher peak temperatures. This means that if the same laminate is used, the reliability margin of the PCB has decreased. To achieve comparable reliability of boards after both eutectic or lead-free soldering, a change in the base material is most likely. Additional PCB reliability concerns include innerlayer bonding, conductive anodic filament (CAF) growth, and dielectric strength, particularly with reduced dielectric thicknesses.
- *PCB performance* In addition to the preceding reliability challenges posed by lead-free assembly processes, it also

has to be guaranteed that all other performance characteristics of the printed circuit board stay the same. This includes dielectrical properties such as dielectric constant D_c (which influences impedance), dissipation factor D_f, and thermomechanical properties such as copper peel strength, glass transition temperature, or coefficient of thermal expansion (CTE). These properties should not be affected by the assembly processes applying higher temperatures.

15.1.2 Material Evaluation Process

In almost all cases, the laminate manufacturer will provide a set of data for its specific materials. This datasheet is a good starting point and can certainly be used to evaluate laminates at an early state of a project. Often, though, it will be necessary to perform additional tests in the PCB facility to verify or complement the manufacturer’s data to ensure that the laminate materials meet the requirements of manufacturing and assembly processes.

This chapter introduces the most important laminate properties and their characterization methods and has been revised to reflect RoHS-compliant manufacturing process and temperature requirements. It will serve as a quick reference guide for the printed circuit board specialist as well as an introduction to laminate testing for those who are new to the field. Laminate properties according to industry standards such as the National Electrical Manufacturers Association (NEMA) and IPC will be introduced. Then the actual test methods will be discussed in the form of a best-practice guide. This guide will help the PCB specialist make quick decisions during the testing process. Methods to test mechanical, thermomechanical, and electrical properties of printed circuit board materials will be described. The focus will be on how the tests are performed, what the results

actually mean in today's manufacturing environment, and how relevant the obtained test data are. In addition to the raw base material testing, the chapter will introduce a best-practice qualification guide to assess interactions between manufacturing processes and laminate properties.

15.2 INDUSTRY STANDARDS

A number of different industry standards can be used to evaluate copper-clad laminate properties. Many of the test methods for similar properties are very comparable, though, and in the end the materials engineer must decide which standard to use as a basis for his or her characterization. In some cases, it may even be necessary to define a new characterization method to qualify a laminate material for a specific customer application or a particular requirement.

15.2.1 IPC-TM-650

This document is the most comprehensive and most widely used compilation of copper-clad laminate test methods. It is administered by IPC (Association Connecting Electronic Industries) and available in print or online.[a]

Most of the test methods described in this chapter are based on the test manual IPC-TM-650. It contains industry-approved test techniques and procedures for chemical, mechanical, electrical, and environmental tests on all forms of printed wiring and connectors. An IPC test method is a procedure by which the properties or constituents of a material, an assembly of materials, or a product can be examined. These test procedures do not contain acceptability levels for specific properties.

15.2.2 IPC Specification Sheets

IPC publishes a wide variety of technical specification sheets for PCB and printed circuits assembly (PCA) products. A few are important in this context:

- *IPC 4101, "Specifications for Base Materials for Rigid and Multilayer Printed Boards," Rev. B 06/06* This document contains specification sheets for laminate materials used to manufacture PCBs for commercial and military applications. The minimum requirements for key material properties can be found in these specification sheets.
- *IPC 4103, "Specification for Plastic Substrates, Clad or Unclad, for High Speed/High Frequency Interconnections," 01/02* This document contains specification sheets for Teflon (polytetrafluoroethylene, or PTFE) and other laminate materials used to manufacture PCBs for high-speed or high-frequency applications.
- *IPC 4104, "Specification for High-Density Interconnect (HDI) and Microvia Materials," 05/99* This document contains specification sheets for materials used in HDI and microvia applications.

15.2.3 ASTM

The American Society for Testing and Materials (ASTM) develops standard test methods and specifications that are in some cases related to laminate materials. They will be referenced as appropriate. More information can be found online.[b]

15.2.4 NEMA

NEMA publishes standards on laminated thermosetting materials. The last published version is the LI 1-1998 Standard for Industrial Laminated Thermosetting Products, which includes the latest information concerning the manufacture, testing, and performance of laminated thermosetting products. Most copper-clad laminate materials are named according to NEMA grades, but it is important to understand that NEMA grades represent only material categories and not one individual material. One of the most commonly known material grades is FR-4, which is often thought of as a specific laminate material. This is not the case, however, as each NEMA grade represents a material class defined by properties that fall into a certain class. Thus, properties of different laminate materials from different suppliers that fall into the same class (FR-4, for example) may not be identical. More information can be found online.[c] (For a more detailed discussion of FR-4, see Sec. 6.4.)

15.2.5 NEMA Grades

Table 15.1 shows technical and industrial laminate grades as they apply to the most important printed circuit board materials.

TABLE 15.1 NEMA Grade Material Designations and Properties

NEMA grade	Resin system	Reinforcement	Description
XXXPC	Phenolic	Paper	Phenolic paper, punchable
FR-2	Phenolic	Paper	Phenolic paper, punchable, flame-resistant
FR-3	Epoxy	Paper	Epoxy paper, cold punchable, high insulation resistance, flame-resistant
CEM-1	Epoxy	Paper-glass	Epoxy paper core and glass on laminate surface, flame-resistant
CEM-2	Epoxy	Paper-glass	Epoxy paper core and glass on laminate surface
CEM-3	Epoxy	Glass matte	Epoxy non-woven glass core and woven-glass surface, flame-resistant
CEM-4	Epoxy	Glass matte	Epoxy non-woven glass core and woven-glass surface
FR-6	Polyester	Glass matte	Polyester non-woven glass, flame-resistant
G-10	Epoxy	Glass (woven)	Epoxy woven glass, not flame-resistant
FR-4	Epoxy	Glass (woven)	Epoxy woven glass, flame-resistant
G-11	Epoxy	Glass (woven)	High-temp epoxy, woven glass, not flame-resistant
FR-5	Epoxy	Glass (woven)	High-temp epoxy, woven glass, flame-resistant

15.3 LAMINATE TEST STRATEGY

Laminates contain different reinforcement materials (woven/non-woven glass/organic fibers, expanded PTFE, etc.), resin types (phenolic, epoxy, cyanate ester, polyimide, BT, etc.), resin formulations (blended, functionality, etc.),

hardeners (dicyanodiamide [dicy], phenol-novolak, cresol-novolak, p-aminophenol, isocyanurate, etc.), and sometimes filler particles (ceramic or organic). The ratio of all of these individual components can vary widely. To define a test strategy for laminates, it is important to understand the different main components of the materials as well as the conditions during manufacturing, as these will have a large influence on their properties and quality.

The evaluation and qualification of a laminate material can be a quite complex task and the new requirements for lead-free processing have specifically increased the focus on the thermal characteristics of laminate materials. A number of different qualification test methods are available to the materials engineer. However, very often not all of them are relevant or necessary for the final product. At the same time, the materials engineer faces pressure to produce quick results driven by shorter development cycles and increasing product and process requirements. The organization of the test methods described in this chapter follows a proposed best-practice guide aimed to help perform full material evaluations efficiently and at the same time address the new requirements of lead-free processing. The sections allow quick decisions, especially when a number of materials are being evaluated at the same time.

15.3.1 Data Comparison

The first step in every material evaluation is data comparison and assessment. This step may already allow the elimination of some material candidates without performing actual tests.

The first and most important thing to understand is the state of the material that is being considered. Is it an established material formulation that has a solid history at other manufacturing locations, or is it a newly developed

material that has not seen mass production yet? New developments often do not come with complete data sheets that allow an early assessment, whereas the laminator can often provide one for established materials.

Cost is another important factor. The laminator can provide guidance about volume pricing for the new material.

Other considerations are the history of the supplier, in terms of having met previous commitments and whether the material is already in high-volume production. If it is a new material that has not yet been ramped to high volume, if no more than one PWB manufacturer is using it, and if no second source can be identified, then these facts may be a red flag when considering the material for use.

15.3.2 Two-Tier Test Strategy

The qualification procedure proposed in this chapter follows a two-tier test strategy that enables quick decisions during a material qualification program. The first set of tests is easy to perform and focuses on key properties that should be evaluated when testing a new laminate material. Failure to pass any of them will likely result in rejection of a material for manufacturing. If multiple materials are being evaluated, the first tests will allow the easy elimination of the least probable candidates.

The second set of tests is an expanded set of qualification tests that focuses on all key properties that are commonly evaluated for laminates. However, the final decision about a qualification test plan for a new laminate should always be driven by product-level requirements, which means that additional laminate tests as well as board-level tests may need to be added to the set of tests described in the following section.

15.4 INITIAL TESTS

This first set of tests is most commonly performed when starting a material evaluation and qualification project. The tests can be performed easily and give some early indications of whether the material exhibits any major problems.

15.4.1 Surface and Appearance

This test is one of the very first tests to happen as the new material arrives in the shop. The laminate is inspected for its appearance and visual quality. Often the materials engineer will be able to assess the quality of the product without applying specification guidelines. Even packaging and shipping materials should be used to assess the laminator's overall quality control.

IPC-TM-650 method 2.1.2 and method 2.1.5 define procedures for how to inspect the surface and appearance of copper-clad laminates. These standards should be applied only to surface areas that are pertinent to the finished board. More than 90 percent of the copper will usually be removed during manufacturing, and a new material should not be discarded solely for cosmetic reasons. On the other hand, for areas that will contain edge card connector pads or very fine-line traces, these surface standards must be applied.

The specifications categorize the longest permissible dimensions of any copper pits and dents and define a point value-based rating system (as shown in Table 15.2).

TABLE 15.2 Longest Permissible Dimensions

Longest dimension (mm)	Point value
0.13–0.25	1
0.26–0.50	2
0.51–0.75	4
0.76–1.00	7
Over 1.00	30

The total point value for an area of 300 mm × 300 mm of laminate determines the material class (as shown in Table 15.3).

TABLE 12.3 Material Class

Class	A	B	C	D	X
Total point count	<30	<5	<17	0	Requirements agreed upon
		All dents <0.38 mm			

In addition to copper pits and dents, the specifications contain procedures on how to inspect for scratches, wrinkles, and inclusions.

15.4.2 Copper Peel Strength

The copper peel strength of copper-clad laminates is an indicator for a variety of their performance characteristics. It indicates the bond strength of the copper circuitry of a double-sided printed circuit construction after manufacturing and any successive assembly or repair cycles. To assess the copper bond strength of the outerlayer circuitry of a multilayer construction accurately, it is necessary to take a close look at the exact build-up and copper foil used in the construction and to build specific test vehicles that are similar to the original stack-up. Copper peel strength measurements have grown increasingly important as circuit traces and pads are becoming smaller. In addition, this test allows an assessment of any potential weaknesses in multilayer constructions and identifies the interface that might delaminate first after thermal stress. The higher the initial bond strength of a material, the better. For all characterizations after thermal stress in the temperature range of lead-free assembly, it is also important to look at the decrease of bond strength. This is especially important for applications that require multiple reflow operations and one or more repair cycles.

The test method is specified in IPC-TM-650, method 2.4.8, and the applicable test patterns are specified in IPC TM-650, method 5.8.3. Figure 15.1 shows an actual test pattern using a sample 100 mm × 100 mm coupon with 4-mm-wide copper strips.

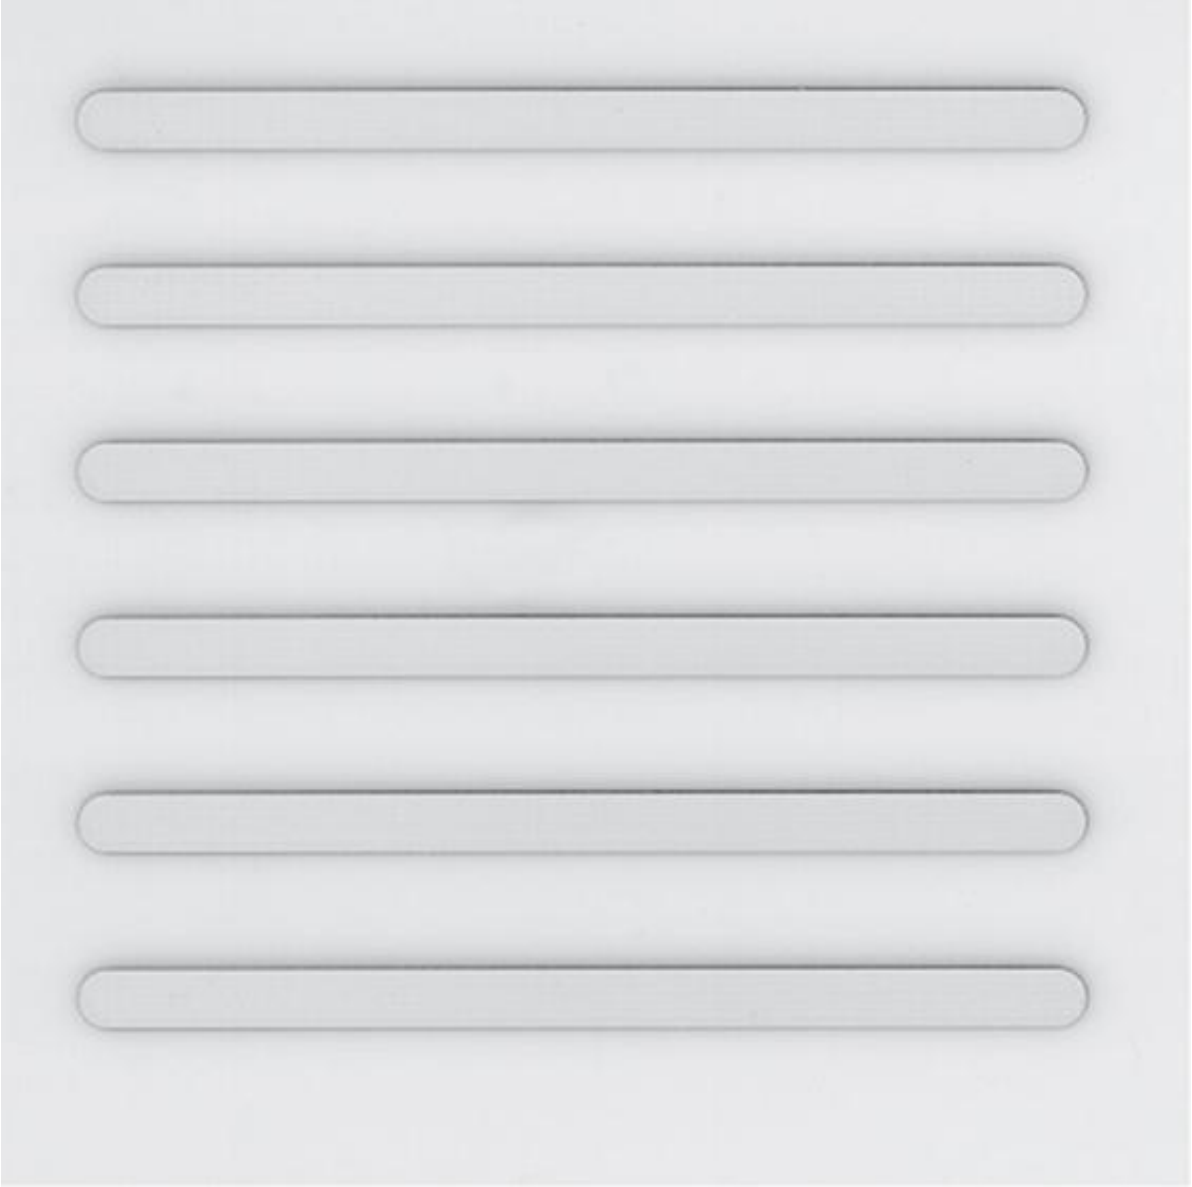

FIGURE 15.1 Test pattern used for a copper peel strength test.

The material being tested should be processed using the same fabrication steps that will be applied for the actual product. IPC-TM-650, method 2.4.8, recommends a specimen size of 50.8 mm × 50.8 mm (2.0 in. × 2.0 in.) and a minimum sample size of two for both the warp and fill (X and Y) direction of the laminate. The end of the test strip is peeled off so that a tensile tester can clamp it. The load cell should be calibrated to account for the weight of the clamp. The copper foil strip is then peeled from the material at a

rate of 2 in. per min. The measured value is dependent on the copper thickness. The thicker the copper foil, the more force is required to deform it plastically. The value is also dependent on the angle at which it is being pulled. Therefore, it is always important to specify the thickness of the copper foil tested and to maintain a peeling force radius of 90° during the test. The minimum load is determined as specified and the peel strength is calculated using Eq. 15.1:

$$\text{lb/in} = L_M/W_S \qquad (15.1)$$

where L_M = Minimum load
W_S = Measured width of peel strip

Copper bond retention after exposure to soldering or touch-up temperatures is measured as outlined in IPC-TM 650, method 2.4.8, condition B. The test samples are covered with silicone grease before floating them on the solder pot at 288°C for 5 to 20 sec. to avoid solder contamination on the test strip. After allowing the samples to cool down to room temperature and removing the grease, the test is performed in the same way as previously described. It is important to inspect the specimen for any blistering or delaminations prior to testing (see also the discussion of solder shock testing in Sec. 15.5.2) as this may interfere with the test procedure and may indicate that the laminate material has problems with solder shock resistance.

Another factor that can influence the adhesion strength of the copper foil is exposure to processing chemicals during manufacturing. Details about this test method can be found in IPC-TM 650, method 2.4.8, condition C. This test is usually performed only if specific requirements at the end-product level call for it or if the material during manufacturing exhibits low copper bond retention properties.

Minimum copper peel strength values for unstressed material should be 1 N/mm or higher. The acceptable values after thermal stress are 0.8 N/mm and 0.55 N/mm after process solutions. Measurements taken at elevated temperature (125°C) should yield a minimum value of 0.7 N/mm. The authors recommends using the preceding values as guidelines and validating acceptable minimum values with actual product requirements.

15.4.3 Solder Shock

The solder shock test is one of several methods to assess the thermal resistance of copper-clad laminates. It is easy to perform and represents another key test during the early assessment of a material. There are a number of different methods to choose from, which will be described in detail in Sec. 15.5.2. During the initial assessment of the material, it is important to choose at least one of the described test methods to make certain that the material meets the minimum requirements, especially if the material is used in higher-temperature lead-free assembly processes. Aside from solder shock testing of bare laminate material, it is also recommended that the PCB engineer consider PCB-level temperature shock as well as repeated reflow testing with a particular focus on resin-reinforcement delaminations. This will ensure that not only the raw material but also the completed PCB will be able to withstand the required temperature regime.

15.4.4 Glass Transition Temperature (T_g)

A further important data point within the initial assessment is the determination of the glass transition temperature (T_g).

Different test methods are described in more detail in Sec. 15.5.2. For the first assessment, one method should be selected. When choosing the method, it is important to make sure that the test procedure is compatible with the material in test (for some materials, the glass transition can be determined only using dynamic mechanical analysis [DMA]). A minimum of two samples should be tested. If a data sheet of the material is available, the measured value should correspond with the manufacturer's data (within the measurement accuracy of the equipment). The values of T_g1 and T_g2 (measured on the same sample) should not be more than 7°C apart. If T_g2 is significantly below the T_g1 measurement, this may be a strong first indication that resin system degradation has started during the measurement procedure. It is recommended to confirm this finding using the T_d measurement procedure.

15.4.5 Thermal Decomposition Temperature (T_d)

The determination of the thermal decomposition temperature (T_d) completes the initial assessment. This is a new test methodology, and both ASTM and IPC test procedures are available. IPC-TM-650, method 2.3.40, is called "Procedure to Determine the Thermal Decomposition Temperature T_d Using Thermo Gravimetric Analysis (TGA)," and the ASTM methodology is called "Standard Test Method for Rapid Thermal Degradation of Solid Electrical Insulating Materials by Thermo Gravimetric Analysis." In both cases, the test methodology is based on thermogravimetric analysis (TGA) of a laminate specimen that is heated with a set ramp rate assessing the onset and process of decomposition. At first, the thermoset laminate resin passes the glass transition point where the polymer changes from a rigid, brittle, and

“glasslike” state to a softer and more rubberlike material. As the material is heated further, the three-dimensional cross-linked structure begins to break down and individual bonds in the polymer structure open. As decomposition continues, gaseous decomposition products are set free, which can be detected as a loss of mass of the sample in test. This usually goes hand in hand with visible damage to the sample (delamination and/or strong discoloration) and significant changes in the mechanical properties of the laminate.

A dry test specimen of 2–20 mg is heated at 5°C/min to 150°C and then held at that temperature for 15 min. This ensures that the sample is completely dry and establishes the base weight used to characterize the weight loss. Then the sample is heated at 5°C/min up to a temperature of 800°C and the weight loss is continually recorded. The temperature at which a 5 percent weight loss of the sample is detected is defined as the T_d.

Although this test methodology is a good gauge of the thermal stability of laminate materials, the method and results must be evaluated carefully to ensure that correct conclusions are drawn from the results. For example, the results of this test are dependent on the surface/volume ratio of the specimen in test-specimens of the same weight, but different surface areas will show different results. The sample with the large surface area loses weight at a faster rate and therefore shows a lower T_d. Samples with a large percentage of nondecomposing filler or reinforcement material will also behave differently as the measured weight change is based only on the resin content of the sample. This again will lead to a seemingly higher measured T_d, which may lead to erroneous conclusions. Finally, the process of decomposition is as important as the determined value of T_d and a comparison of the onset of weight loss may also be a valuable parameter to assess when comparing laminate materials using this methodology.

In general, a higher T_d value is desirable for materials that are being selected for lead-free assembly processes as this indicates that the laminate withstands the higher assembly temperatures with an increased margin.

Figure 15.2 shows an example of different T_d measurements for three different laminate materials. It shows the typical decomposition rates for some sample materials and also highlights how the assessment of a material can change if different criteria are chosen. If the IPC value of 5 percent weight loss is chosen, then M3 is superior to M1 and M2. But if the materials engineer decides that the onset of weight loss (decomposition) is critical for the application, then M3 is the worst performing material. The authors recommend using materials with a high onset temperature as well as a high 5 percent decomposition temperature.

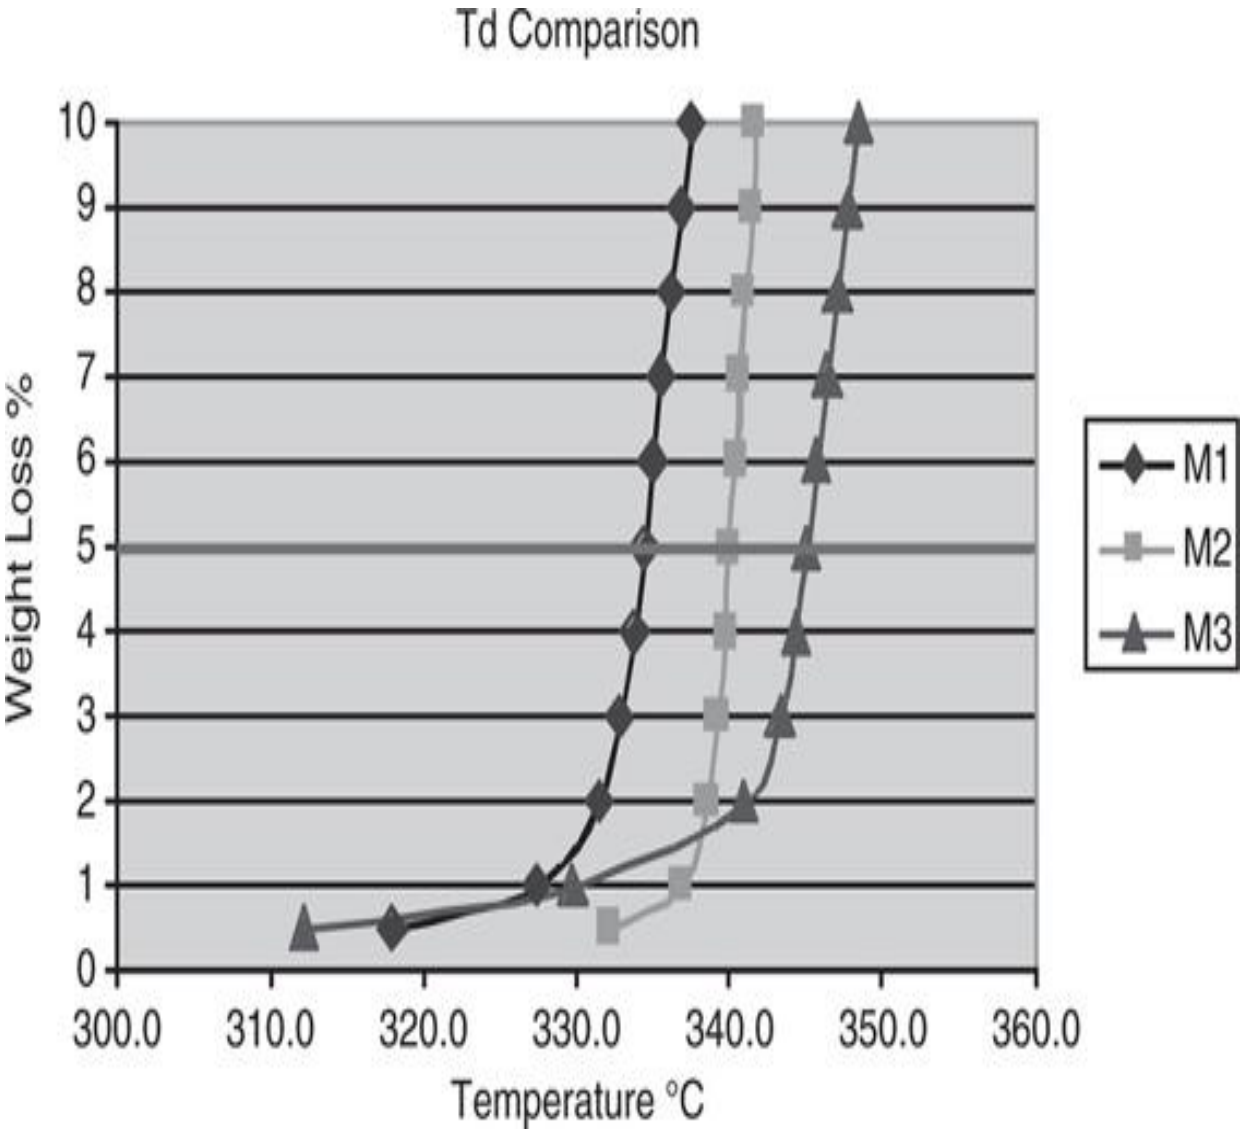

FIGURE 15.2 Example of different T_d measurements for three different laminate materials. (*T_d GraphCourtesy of Helmut Kroener, Multek*.)

15.5 FULL MATERIAL CHARACTERIZATION

The following set of characterization methods summarizes the most commonly used test methods to qualify copper-clad laminates for manufacturing. It is intended to guide the materials engineer through the laminate qualification

process. Yet it can only serve as a best-practices guide, as the final set of qualification methods will vary for each material and should always be driven by its specific application.

15.5.1 Mechanical Tests

Commonly used mechanical tests include tensile tests, flexural strength tests, and copper peel strength tests.

15.5.1.1 Modulus and Tensile Strength (Tensile Test). The test method to determine modulus and yield stress for copper-clad laminates described in this section is based on ASTM D 882, “Standard Test Methods for Tensile Properties of Thin Plastic Sheeting.” Other relevant industry standards are IPC-TM-650, method 2.4.19 (for flexible laminate materials), and IPC-TM-650, method 2.4.18.3 (for deposited organic free films). Elastic modulus and yield stress are always determined by the same method.

The elastic modulus is the indicator value for the stiffness and strength of a composite material under load, whereas the yield stress indicates the maximum load the material can take in x/y direction before it brakes. The modulus is the more important of the two values. It is used to differentiate materials and their actual strength during qualification testing. The elastic modulus is also one of the key properties of a material that need to be understood when performing computational modeling of packages and printed circuit board assemblies. In many applications, materials with different properties are combined, which leads to thermomechanical stresses that cause fatigue or interfacial failures. Computational modeling is often used when there is not sufficient time or resources available to perform actual product test, but fast reliability assessments are needed.

The standard test specimen for this test consists of a strip of laminate material 152.4 mm (6 in.) long and 15.7 mm (0.5 in.) wide. A minimum of 10 samples should be prepared and all copper must be removed before testing. It is important that only samples with identical thickness and glass stack-up be tested, as this will allow a meaningful comparison of the materials in the test. The test engineer also must ensure that both the warp and fill direction of the laminate composite are measured and documented separately.

After the samples are cut, they need to be inspected for any fractures, delamination, or roughness along the edges and if necessary they need to be sanded. The cross-sectional area of each specimen is calculated from the width and thickness in the measurement area. Then the individual samples need to be conditioned at 23°C (73.4°F) and 50 percent relative humidity (RH) for 24 hours. Although most specifications recommend conditioning of the material prior to cutting and preparation of the samples, the authors recommend first cutting the specimens to size and then conditioning them. This ensures more uniform properties of the individual samples.

The tests are performed using a standard tension and compression apparatus, which can be operated at a controlled rate of crosshead movement. The load-extension curve should be recorded and the specimen tested until it breaks. If extensometers are used, it is necessary to minimize the stress on the sample at the contact points of specimen and indicator.

The tensile strength is calculated by dividing the maximum load at break by the original minimum cross-sectional area. The unit is megapascals (MPa). Dividing the elongation at break by the initial gauge length and multiplying it by 100 will calculate percent elongation. When extensometers are employed, only the length of the section between them is used; otherwise, the distance between the grips represents the initial gauge length. Young’s modulus is calculated by

drawing a tangent to the linear portion of the stress-strain curve, selecting any point on this tangent, and dividing the tensile stress at that point by the corresponding strain. The unit is gigapascals (GPa). For all calculations, the values for 10 samples should be recorded and the average calculated.

In addition to the absolute values for the different mechanical properties, the stress-strain curve gives the materials engineer information about the elastic and plastic portion of the deformation in the laminate samples. The elastic (linear) part of the deformation is restorable, whereas plastic changes in the materials are not. Figure 15.3 shows a typical stress-strain curve.

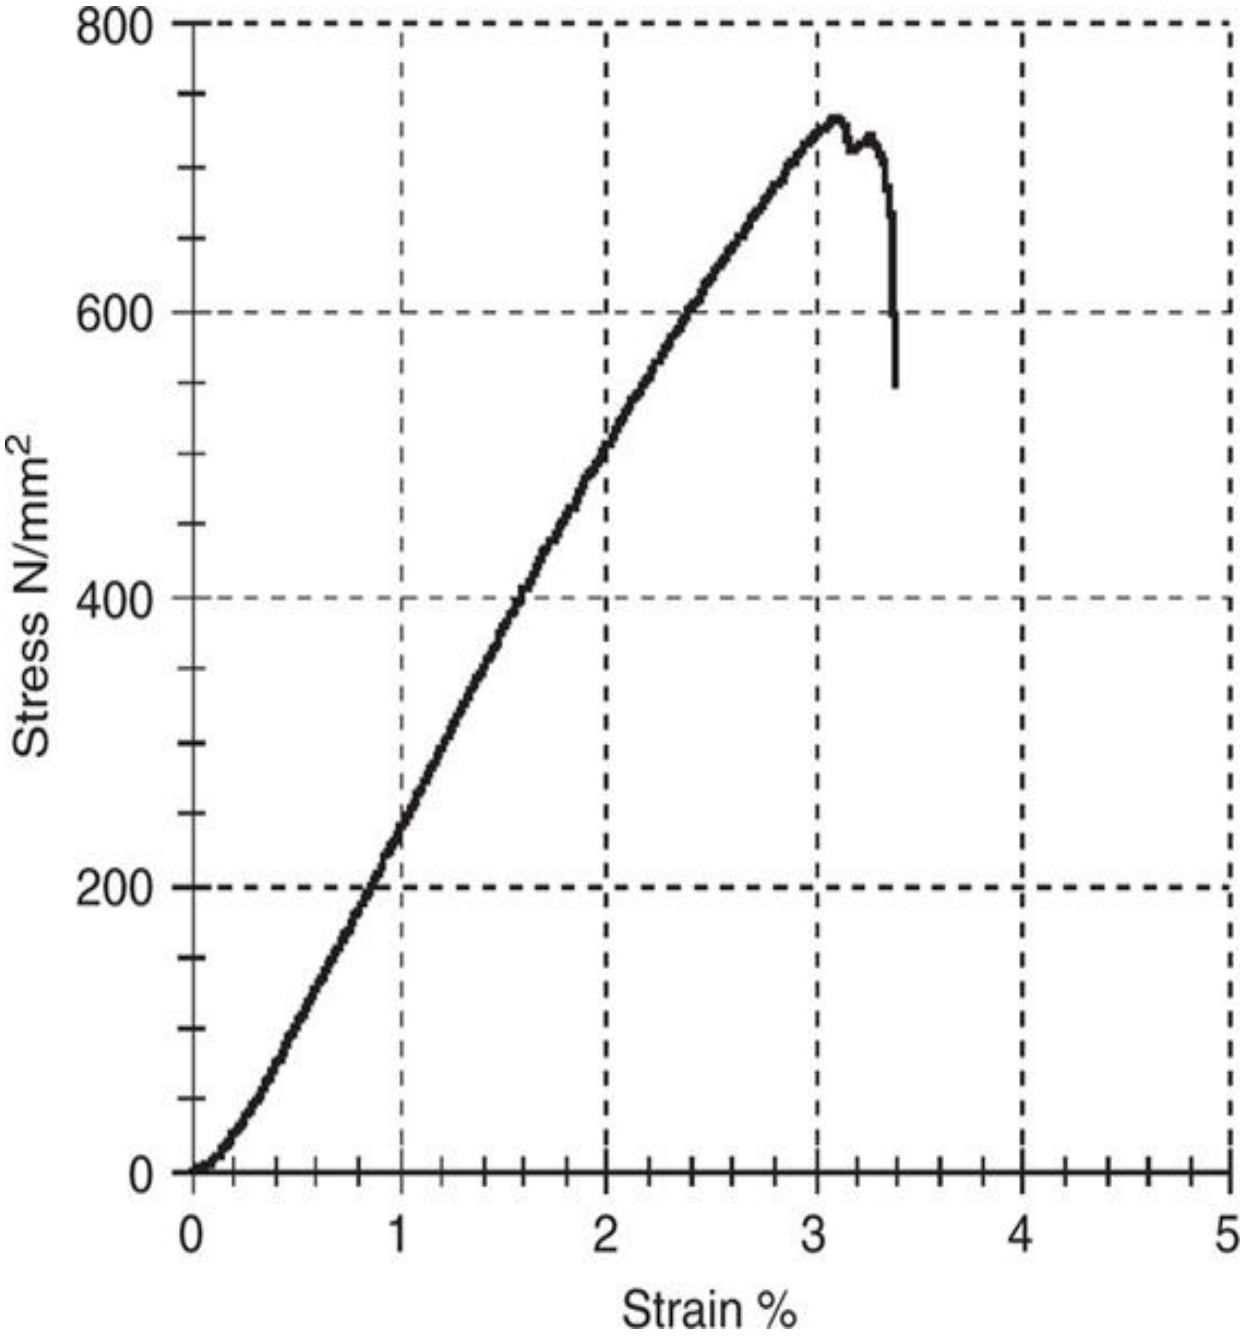

FIGURE 15.3 Typical stress-strain curve.

15.5.1.2 Flexural Strength. The test method to determine the flexural strength of copper-clad laminates is based on ASTM D 790 (“Flexural Properties for Un-Reinforced and Reinforced Plastics and Insulating Material”) and IPC-TM-650, method 2.4.4B (“Flexural Strength of Laminates at Ambient Temperatures”). The test method described in the

preceding section to determine the modulus in tensile mode does have the inherent problem that the glass reinforcement and its properties have a large influence on the results. This may be avoided when testing copper-clad laminates in flexural mode. Here the attributes of the resin system have a greater influence on the outcome of the test. When comparing the test results of different laminate materials, it is important to compare only data that were generated using the same test method.

This test also requires that the copper be completely removed from the laminate material by means of standard etching processes. The specific size (length and width) of the samples and test parameters (test span and speed) are dependent on the thickness of the laminate and can be found in IPC-TM-650, method 2.4.4. See Fig. 15.4 for a typical flexural strength measurement curve.

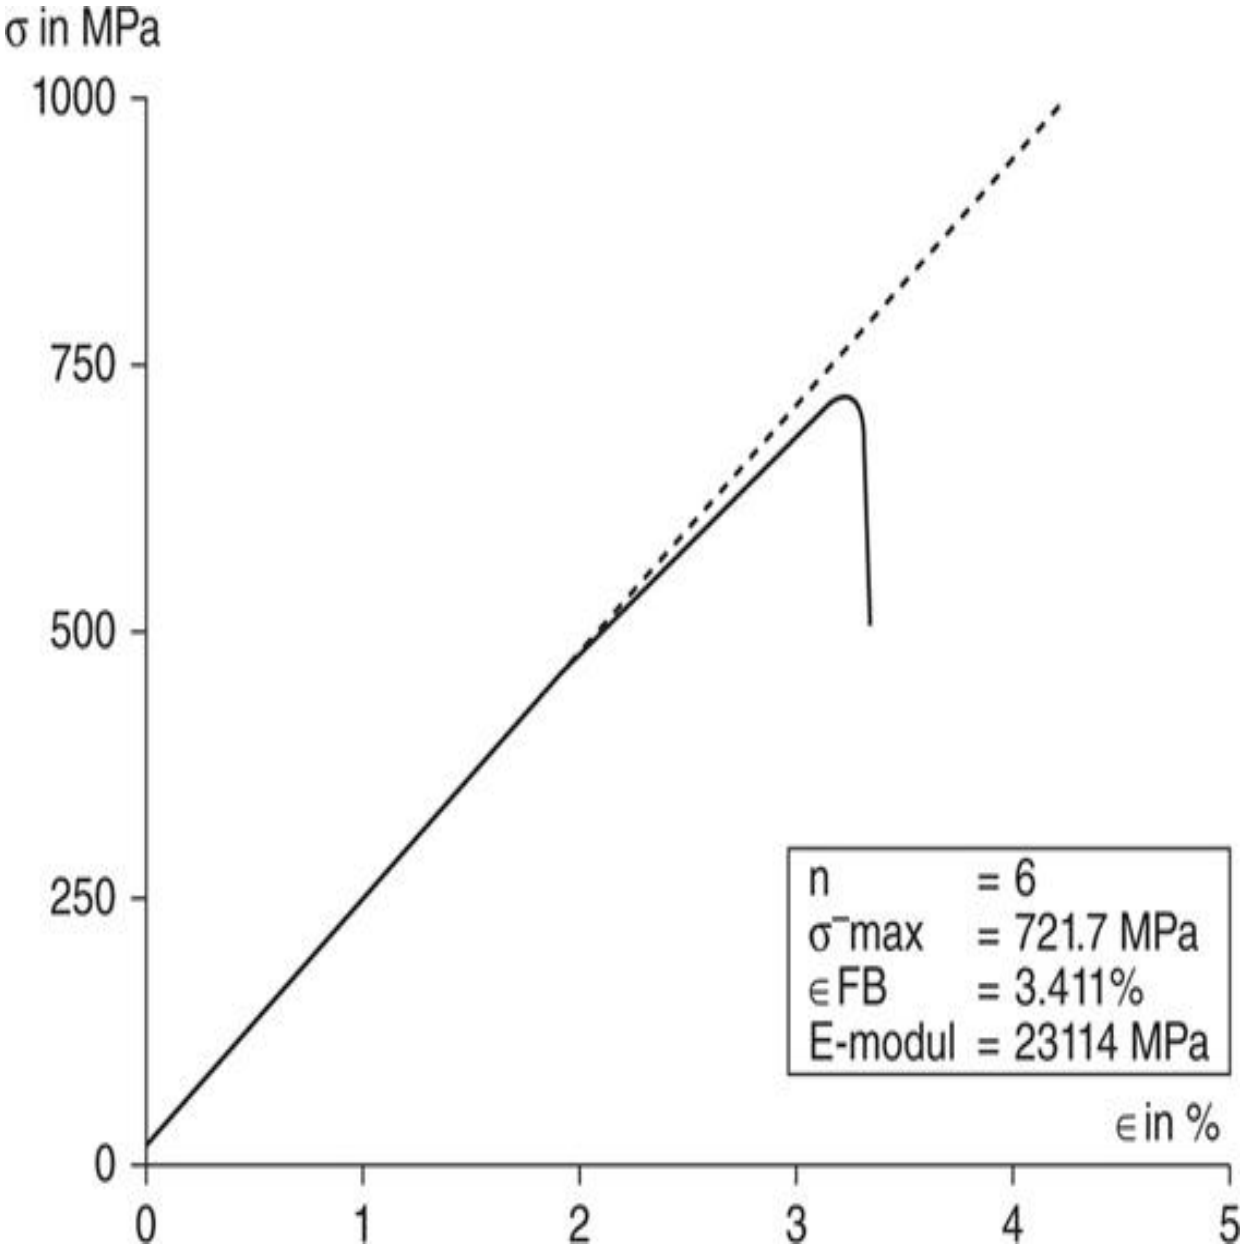

FIGURE 15.4 Typical flexural strength measurement curve.

The samples are conditioned to room temperature. They are then centered on the supports of the standard tension and compression test apparatus with the long axis of the specimen perpendicular to the loading nose and support. The samples are loaded at the defined speed and tested until they break. The load at breakage should be recorded. Use Eq. 1.2 to calculate the flexural strength.

$$S = 3PL/2bd^2 \qquad (15.2)$$

where S = Flexural strength (psi)
P = Load at breakage (lb.)
L = Span (in.)
B = Width of specimen (in.)
D = thickness (in.)

15.5.1.3 Copper Peel Strength (Before and After Thermal Stress). Test methods are described in Sec. 15.4.2 and results can be transferred to this point in the evaluation. To complete the data, perform additional tests if necessary after specific thermal stress (solder dip, reflow with different peak temperatures, and/or different dwell times) or after exposure to plating solutions.

15.5.2 Thermomechanical Tests

Properties that are tested thermomechanically include T_g, CTE, thermal resistance, solder dip resistance, and solder float resistance.

15.5.2.1 Glass Transition Temperature T_g (DSC, TMA, and DMA). The resin systems used in today's copper-clad laminates are almost all three-dimensionally cross-linked thermoset polymers. This means that the materials are manufactured (in a curing reaction) into a hard final product and cannot be remelted many times the way thermoplastic polymers can. In many cases, different resin systems are blended to create a material with specific properties. The functionality of the individual resins and their ratio in the blend define the properties of the thermoset. The degree of cure of the hardened thermoset resin system can be

described by characteristics such as percent of uncured monomer and heat of final cure or by mechanical properties such as hardness, modulus, and yield stress. But one of the most commonly used characteristics to describe the degree of cure and cross-link density of a thermoset polymer is the glass transition temperature (T_g).

The simplest definition of the T_g of a laminate is to call it the temperature at which the mechanical properties of a laminate change (deteriorate) rapidly. It is at this temperature that the polymer changes from a rigid, brittle, and “glasslike” state to a softer and more rubberlike material. However, this should not be confused with the melting point of a crystalline substance or the extreme softening of a thermoplastic polymer. In a thermoset material at T_g, the relative mobility of the cross-linked polymer molecules changes. Below T_g, they are immobile and the material is rigid; above T_g, the relative mobility of the molecules increases and slight movements are possible, which leads to a loss of mechanical strength in the material. Although all of the methods described in this section enable us to determine a specific glass transition temperature for laminate materials, it also needs to be emphasized that the glass transition in thermoset resins is not a single defined temperature. It usually occurs within a temperature range (for some resin systems, the range can span as much as 100°C), and the T_g is determined within this range.

In addition, the difference between T_g and T_d must be pointed out here. T_g is the temperature at which mechanical properties of the material change, whereas T_d is the temperature where the material starts to irreversibly degrade. If one wants to assess a laminate’s capability to withstand high-temperature lead-free processing temperatures, T_d is the more relevant measure. T_g is relevant when assessing loss of mechanical strength which

can lead to PCB warpage, bowing, and increased z-axis expansion, which in turn can have a significant impact on PCB reliability.

There are a number of different measurement techniques to determine the T_g. The most commonly used methodologies are thermal analysis techniques. Other techniques are available (such as spectral analysis and electrical characterization), but their use is limited and therefore they will not be discussed here. The three thermal analysis methods that will be discussed in this section are as follows:

- Differential scanning calorimetry (DSC)
- Thermomechanical analysis (TMA)
- Dynamic mechanical analysis (DMA)

All of these techniques measure slightly different property changes in the laminate material and therefore the values that are obtained will be different. They usually will follow this simple rule of thumb:

$$T_g \text{ (DMA)} > T_g \text{ (DSC)} > T_g \text{ (TMA)}$$

15.5.2.1.1 T_g by Thermomechanical Analysis (TMA). Thermomechanical analysis measures dimensional changes in a material as it is heated from room temperature to a preset final temperature. The change in length (width or height) of the specimen with the change in temperature determines the CTE of the material. At T_g, the expansion coefficient of the material changes and it is this property change that is used to determine the T_g by TMA.

The test procedure is specified in IPC-TM-650, method 2.4.24C. The specimen should have a minimum thickness of 0.51 mm and at least two samples taken from random locations in the material need to be tested. Any copper

cladding needs to be removed by etching. The treatment of the copper foil leaves a negative imprint on the laminate surface, which can lead to problems during the measurement right below the actual glass transition temperature. Therefore, the surface of the specimen should be sanded lightly prior to testing. The edges of the sample should also be smooth and burr-free. Use care to minimize stress or heat on the specimen.

The samples need to be preconditioned for 2 hours at 105°C (221°F), then cooled to room temperature in a desiccator. The actual measurement should be started at a temperature no higher than 35°C (95°F); an initial temperature of 23°C is recommended. Unless otherwise specified, a scan rate of 10°C (18°F) per min. is commonly used. The temperature ramp needs to be continued at least 30°C (54°F) above the anticipated transition region. The T_g is defined as the temperature at which the two tangent lines for the thermal expansion coefficient intersect. Figure 15.5 shows an example of a typical TMA scan. The material has a T_g of 136.7°C.

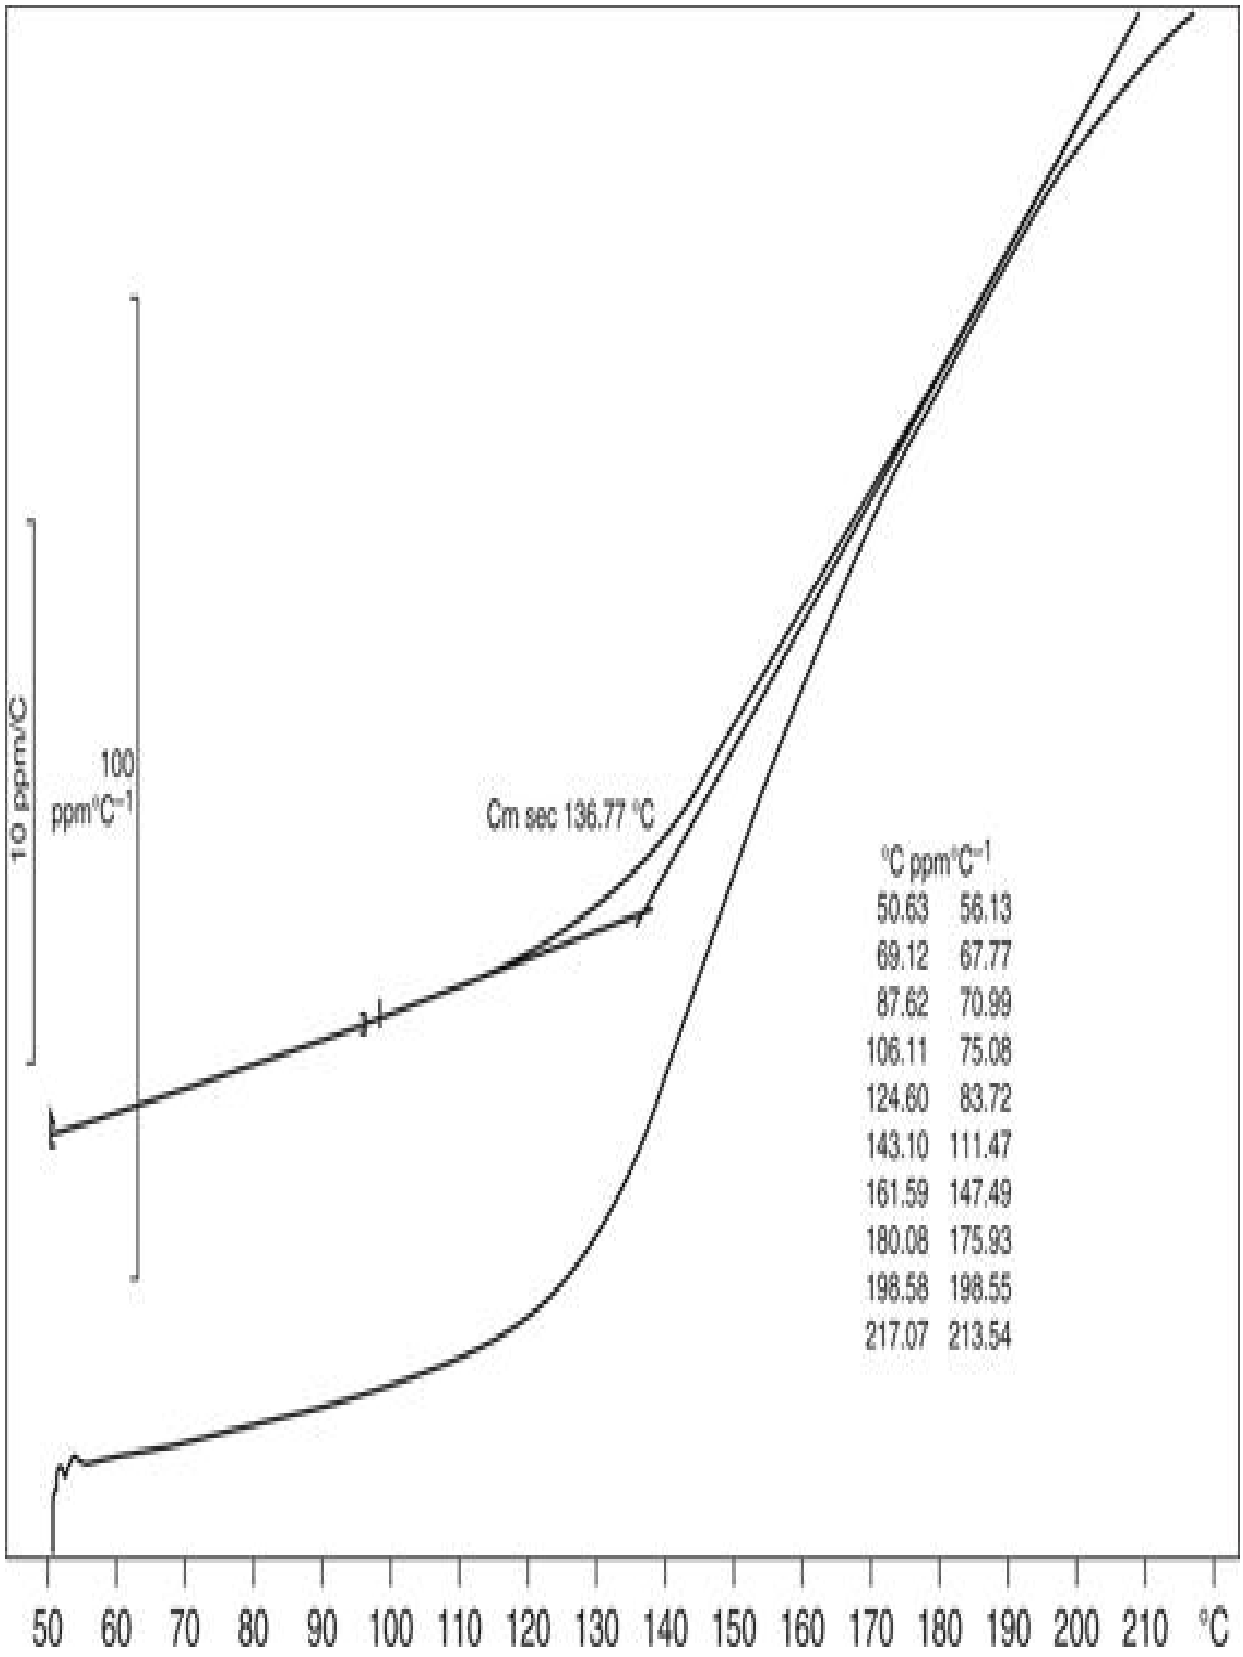

FIGURE 15.5 Typical TMA scan.

It is recommended to retest the same sample after allowing it to cool down to room temperature to determine whether the measured value for T_g2 is comparable to the measured value of T_g1. If T_g1 is significantly lower than T_g2, then this could be an indication that the sample material was not fully cured when it was tested the first time. If T_g1 is significantly higher than T_g2, that could indicate that the sample material has already started to decompose and was approaching T_d. The authors recommend further testing if these measurements differ by more than 5°C.

15.5.2.1.2 T_g by Differential Scanning Calorimetry (DSC). Differential scanning calorimetry measures the difference in heat absorption or emission from a test specimen in comparison to a reference sample (usually nitrogen gas). This makes the technique applicable to determine a variety of property changes in polymer materials. It can detect the exothermic cure reaction, crystallization energy, and residual reactivity in polymers, as well as endothermic melting points. For epoxy-based resin systems, DSC is a well-suited technique as these materials go through a crystalline transition at T_g and this property change can be used to determine the glass transition. For other resin systems that are more amorphous and have a T_g that occurs over a wider range (such as polyimides), the detection may be more difficult by DSC than TMA.

The test procedure is specified in IPC-TM-650, method 2.4.25C. The specimen should be a solid piece weighing between 15 mg and 25 mg. In the case of very thin materials, multiple pieces may be used. The specimen should be of the size and configuration that fits within the sample pan of the DSC equipment. All of the specimen preparation needs to take place before preconditioning to avoid any moisture influence prior to testing. Sample edges should be smoothed and burrs removed by light sanding or

an equivalent method to achieve proper thermal conduction. Use care to minimize stress or heating of the specimen. Even though the IPC test method allows samples to be tested with copper cladding, the authors recommend testing only without copper cladding. This increases the relative mass of polymer in the DSC sample pan and leads to a better signal and detection of T_g.

The samples need to be preconditioned for 2 hours at 105°C (221°F), then cooled to room temperature in a desiccator for at least a half-hour prior to testing. Place the specimen in a standard aluminum sample pan with an aluminum lid. For reference purposes, a cover lid crimped onto the sample pan should be used. Start the scan at a temperature at least 30° lower than the anticipated onset of T_g. Unless otherwise specified, a scan at a rate of 20°C/min (36°F/min) is recommended and the temperature ramp needs to be continued at least 30°C (54°F) above the anticipated transition region. The glass transition temperature is determined using the heat flow curve. In many cases, the DSC equipment will have applicable software installed to determine T_g. A tangent line is fit onto the curve above the transition region, and a second tangent line is fit below the transition region. The temperature on the curve halfway between the two tangent lines, or 1/2 *d* Cp, is the glass transition point T_g. Figure 15.6 shows an example of a DSC scan where the material has been scanned twice. The T_g of the first scan was 192.9°C. The second scan yielded a slightly higher value of 195.3°C (likely caused by additional curing of the material).

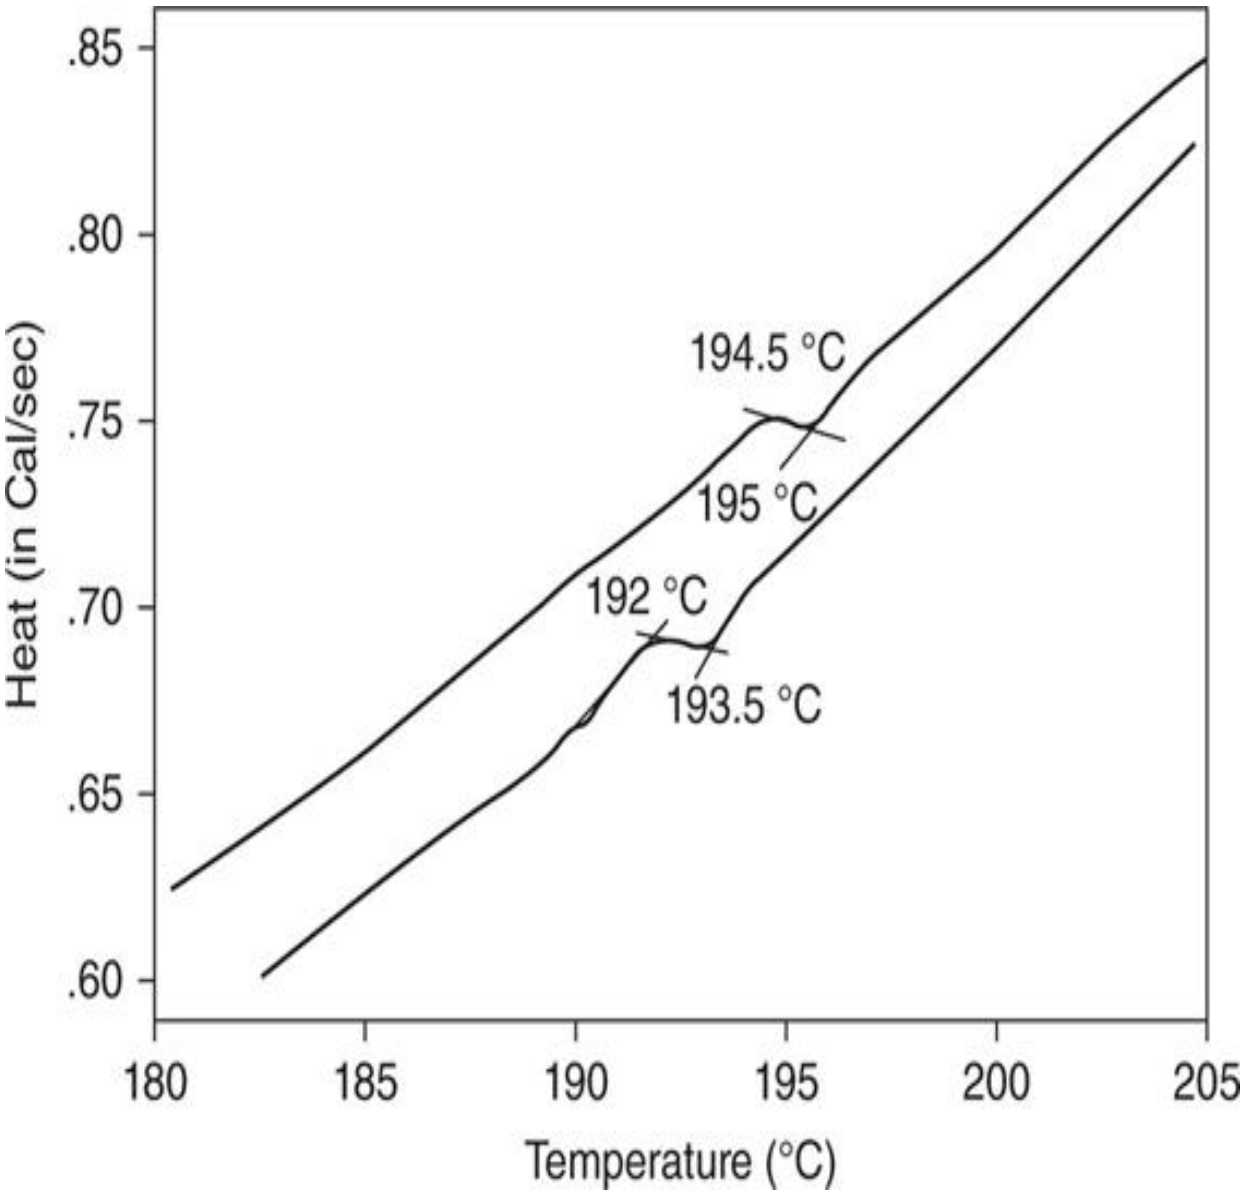

FIGURE 15.6 Example of a DSC result.

15.5.2.1.3 T_g by Dynamic Mechanical Analysis. Dynamic mechanical analysis (DMA) applies an oscillatory stress or strain on the sample while the temperature is increased during the experiment. The ability of the material to elastically store the mechanical strain energy changes during the heat cycle as it changes its viscoelastic behavior from glassy to rubbery. This property change determines the glass transition temperature by DMA.

The test procedure is specified in IPC-TM-650, method 2.4.24.2. The test specimen should consist of a strip of laminate material compatible to the measuring equipment. For all samples with woven reinforcement, it is necessary to make sure that the specimens are cut parallel or perpendicular to the woven structure. The analysis is based on an assumption of constant specimen geometry; therefore, the test specimens must be stiff enough not to deform plastically during the experiment. All copper needs to be etched off.

While the IPC-method recommends preconditioning of the samples at 23°C and 50 percent RH for at least 24 hours prior to testing, the authors recommend preconditioning similar to that employed for TMA or DSC measurements. Samples are baked for 2 hours at 105°C (221°F), then cooled to room temperature in a desiccator for at least a half-hour prior to testing. The sample is mounted in the fixture making sure that it is perpendicular to the clamps. Both clamps are tightened using torque screwdrivers to ensure that the sample does not slip during the measurement and that no stresses have built up around the sample that could negatively influence the results. The sample is loaded with a frequency of 1 Hz (6.28 radian/sec) while it is heated in dry nitrogen or dry air at a rate of no faster than 2°C per min. The temperature ramp needs to be continued at least 50°C above the transition region. The glass transition temperature is defined as the temperature corresponding to the maximum in the tan δ versus temperature curves at a frequency of 1 Hz. Tan δ is calculated from Eq. 15.3.

$$\tan \delta = E''/E' \qquad (15.3)$$

where $E'' =$ loss modulus

$E' =$ storage modulus

Figure 15.7 shows an example of a typical DMA scan. The material has a T_g of 193.17°C.

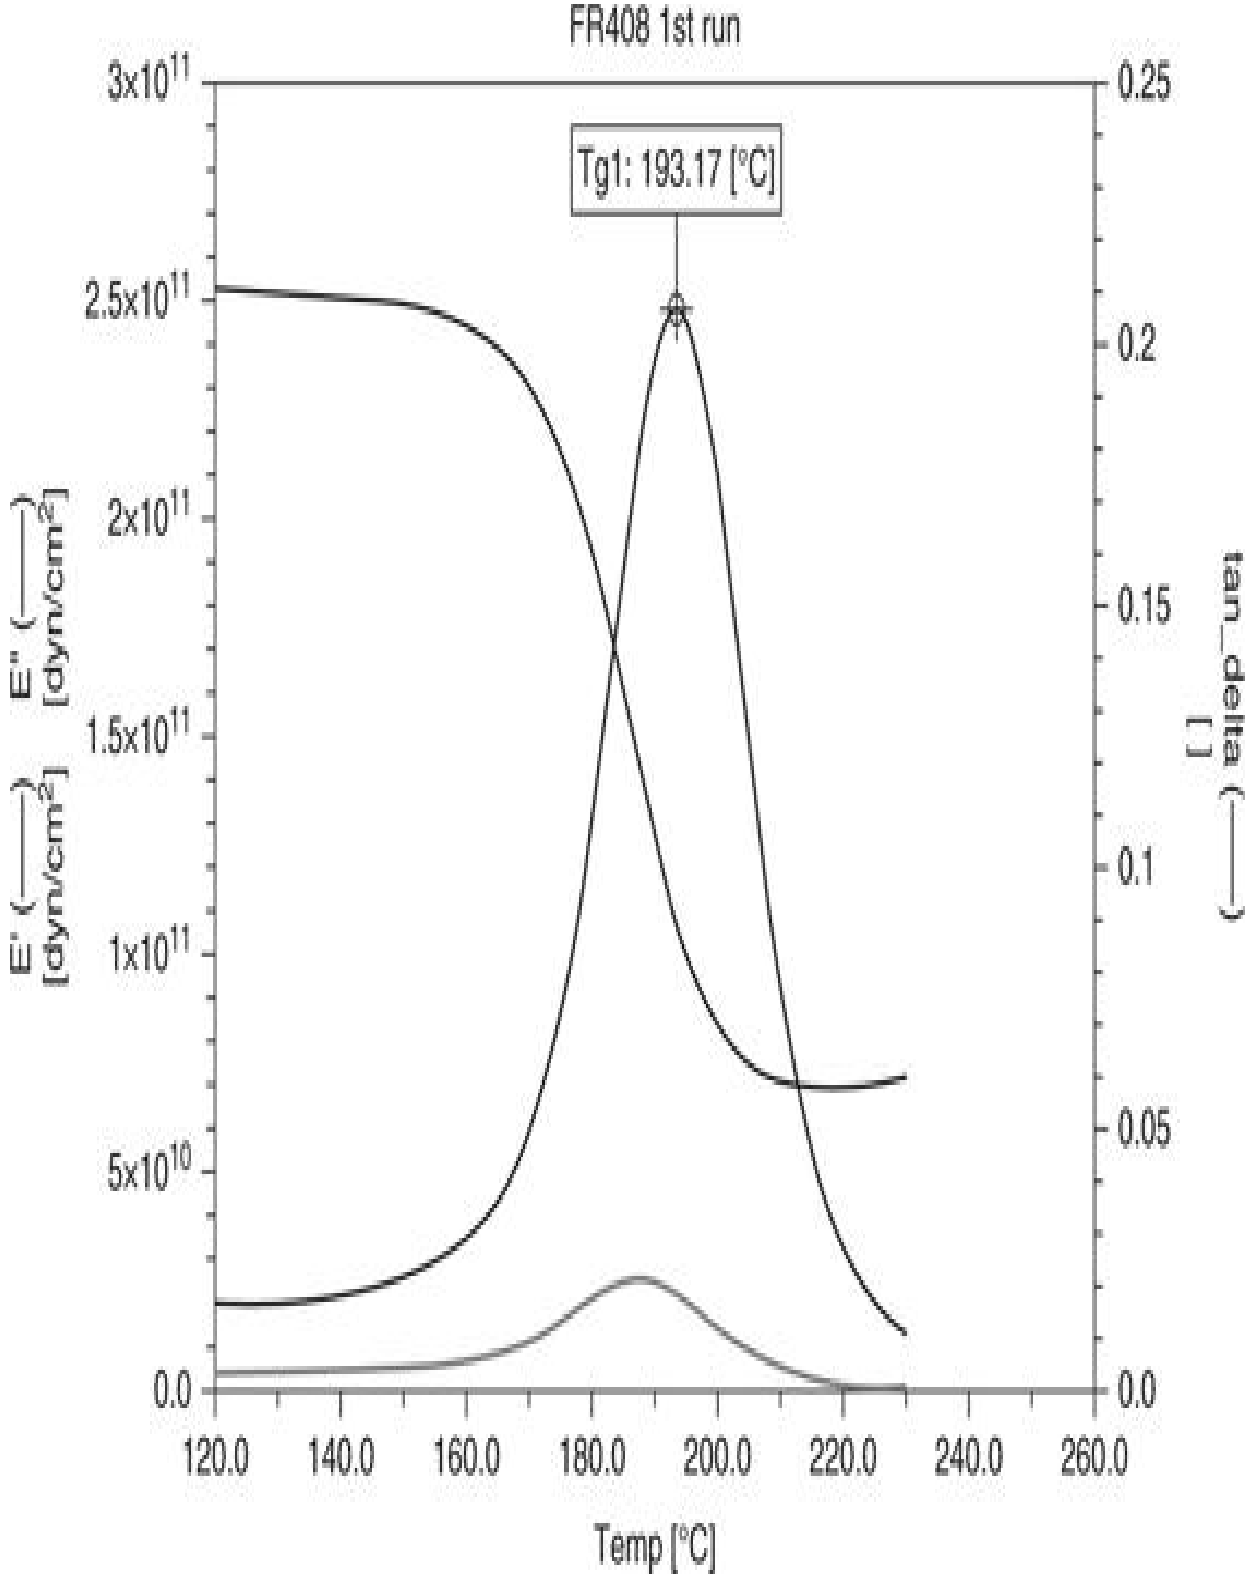

FIGURE 15.7 Typical DMA scan.

15.5.2.2 Coefficient of Thermal Expansion. The coefficient of thermal expansion (CTE) describes the property of materials to expand as they are being heated. Because of the reinforced composite construction of most laminates, the CTE in x and y direction is usually different from the CTE in z direction. By convention, the x direction corresponds to the warp direction of the reinforcement, whereas the y direction corresponds to the fill direction of the fabric. The z direction is the direction perpendicular to the plane of the laminate. The difference between the values is caused by the reinforcement, which severely restrains the expansion in x and y, whereas the resin can expand unrestrained in the z direction.

For copper-clad laminate materials used in printed circuit boards, the CTE in x, y, and z direction is of great importance. The x and y direction is critical because of all the components that will be mounted on the final printed circuit board. The greater the mismatch between the laminate material and the soldered components, the higher the risk that temperature changes will lead to solder fatigue and eventually to a reduction in the reliability of the board. The z direction is of equal importance because the expansion of the laminate during thermal cycles will lead to stresses in the copper plating (CTE of 17 ppm/K) of the plated through or buried holes in the board. A low z-axis CTE and high T_g are therefore generally desirable for increased through hole reliability.

A number of different measurement techniques are available to determine the CTE of copper-clad laminates. The most commonly used is TMA following IPC-TM-650, method 2.4.24C, as described in Sec. 15.2.1. When determining the CTE of a laminate, the temperature scan must start at a temperature sufficiently lower than the specified temperature range for which the CTE is being determined to allow the heat rate to stabilize. The typical scan rate is also 10°C (18°F) per min. and the scan should be continued to at

least 250°C (482°F). Because the expansion properties of the material change at T_g, there are usually two CTE values that are being reported: the CTE below T_g is commonly referred to as $a_{1,}$ and the CTE above T_g as a_2 (see Eq. 15.4).

$$\text{CTE:}\alpha = \Delta L/\Delta T \text{ ppm/K} \qquad (15.4)$$

where ΔL = change in length
ΔT = change in temperature
K = degrees Kelvin

In the TMA scan example (Fig. 15.5), the material has a z-axis CTE(a_1) of ~ 65ppm/K and a z-axis CTE(a_2) of ~150ppm/K.

The CTE in x and y direction can also be measured by TMA, although care must be taken during the preparation of the sample to avoid any influence of reinforcement material on the TMA probe. The results are strongly dependent on the properties of the reinforcement fabric.

Another method to determine the x- and y-axis CTE of laminate materials employs strain gauges. This method is described in IPC-TM-650, method 2.4.41.2. Many details need to be taken into consideration when making use of this method. The strain gauges need to be calibrated for the specific temperature range and the adhesive used to attach them needs to be stable over the whole range. Special care needs to be taken during specimen preparation and gauge attachment. It is recommended to run one heat cycle prior to the actual measurement to remove any residual stresses. More details can be found in IPC-TM-650.

15.5.2.3 Thermal Resistance. The thermal resistance of laminate materials is one of the key properties, especially in light of the lead-free processing conditions. It is the most

important indicator of the performance of printed circuit boards during assembly operations. As already mentioned in the Sec. 15.1, most printed circuit boards will be required to withstand at least five reflow cycles with a peak temperature in the range of 260°C, but that number may increase to six and above for more complex assemblies. During exposure to these process temperatures, the laminate cannot delaminate or begin decomposition. Another important factor that can be assessed with thermal resistance tests is the performance of the laminate in printed circuit board applications that expose the board to high-operating temperatures. Several different test methods should be considered when qualifying laminates.

15.5.2.3.1 Solder Dip Resistance. The test method is described in IPC-TM-650, method 2.4.23. The original purpose of this test technique was to assess the solderability of the laminate surface, but today it is often used to assess the ability of laminate materials to withstand the temperatures in a molten solder bath. It is important to note that the original IPC methodology has not been revised in a long time and the current version may not reflect the actual temperature requirements of lead-free processing. The authors still feel that this method is a very good assessment and differentiation technique for laminate materials and recommend that either solder pot temperatures or exposure times are increased if the laminates are intended for use in lead-free assembly processes. Performance factors that are being considered are resistance to softening, loss of surface resin, scorching, delamination, blistering, and measling.

The material will be tested in three different surface configurations: (1) a surface upon which no metal cladding was ever applied (if possible), (2) a surface with the metal cladding removed by standard etching processes, and (3) a surface with metal cladding as received. The sample size for all specimen is 1¼ in. × 1¼ in. thickness and three samples

are required for each surface configuration. All samples are tested using the same procedure.

Preclean the samples by immersing them for 15 sec. in 10 percent hydrochloric acid (HCl) (by volume) and then rinse in water. The HCl should be at a temperature of 60°C (140°F). Dry the specimen quickly to avoid excess oxidation of the sample. Dip the sample into a flux agent and allow draining for 60 sec. before proceeding with the solder dip. Stir and then skim the surface of the molten solder with a clean stainless steel paddle to ensure that the solder is of uniform composition and at a temperature of 245°C (473°F). Immerse the specimen edgewise into the molten solder. The insertion and withdrawal should be at a rate of 1 in. per sec. and the dwell time in the solder should be 4 sec. Upon withdrawal, allow the solder to solidify by air-cooling while the specimen is in a vertical position. Thoroughly remove the flux.

The samples are examined for any evidence of discoloration or surface contaminants, loss of surface resin, softness, delamination, interlaminar blistering, or measles. The specimens having metal cladding also need to be examined for blistering or delamination of the metal foil from the laminate material.

15.5.2.3.2 Solder Float Resistance. This test addresses the thermal resistance of the laminate material floating on the solder bath. Because this method subjects the sample to a thermal gradient across the z-axis of the material similar to an actual wave solder operation, the results of this test are particularly important and—as mentioned previously—either solder pot temperatures or exposure times should be increased if the laminates are intended for use in lead-free assembly processes.

The test method follows IPC-TM-650, method 2.4.13. At least two samples need to be tested for each material and they should be taken from random locations. For double-clad laminate, the copper foil needs to be removed from the

backside of each specimen by using standard etching processes. The test samples need to be preconditioned in an air circulating oven at 135°C for one hour to remove any excess moisture that could lead to premature failures. After preconditioning, the specimens can be held in a desiccator at room temperature. After attaching the sample to the solder float test fixture, float it for 10 sec., foil side down, on the surface of the molten solder at a temperature of 260°C (for method A) or 288°C (for method B). Then remove the sample and tap the edges to remove any excess solder. Thoroughly clean and visually examine the sample for blistering, delamination, or wrinkling.

In case more than one material is being qualified and no failures are being observed after testing for 10 sec. or if the goal is to determine the weakest point in the laminate and test to failure, then the authors recommend increasing the solder float time incrementally or repeating the test with the same sample until failures are observed.

15.5.2.3.3 T260 (TMA). Aside from testing materials in solder baths, there is one other technique to verify the thermal resistance of laminates. This test method is described in IPC-TM-650, method 2.4.24.1, and is used to determine the time to delamination of laminates and printed boards using a TMA system (see also sec. 15.5.2.1.1).

The sample requirements are identical to the ones for determination of the T_g by TMA. A minimum of two specimens should be tested, which can be taken from random locations of the material. Materials are tested as received; the metal cladding is not removed. The samples are preconditioned for 2 hours at 105°C (221°F), and then cooled down to room temperature in a desiccator. The TMA temperature ramp should start from an initial temperature no higher than 35°C (95°F) at a scan rate of 10°C/min. After the scan reaches the specified isothermal temperature, hold at that temperature (onset) for 60 min. or until failure. The

time to delamination is determined as the time from the onset of the isotherm to failure. Failure is defined as any event or deviation of the data plot where the thickness is shown to have irreversibly changed. On occasion, some materials will delaminate before the isotherm is reached. In this case, the temperature at the time of failure is recorded. For epoxy laminates and similar materials, the recommended isothermal temperature is 260°C (500°F). For materials intended for lead-free processing and for polyimides and other high-temperature materials, increasing the isothermal temperature to 288°C (550°F) is recommended.

15.5.3 Electrical Characterization

Electrical properties include D_c and D_f, surface and volume resistivity, and dielectric strength breakdown.

15.5.3.1 Dielectric Constant (D_c) and Dissipation Factor (D_f). The dielectric constant (also known as permittivity, D_c, and ε_r) is defined as the ratio of the capacitance of a capacitor with a given dielectric (laminate) to the capacitance of the same capacitor with air as the dielectric. It is a measure of the ability of a material to store electrostatic energy and determines the relative speed that an electrical signal will travel within that material. The higher the D_c, the slower the resulting signal propagation speed will be. The signal speed is inversely proportionate to the square root of the dielectric constant. It is not an easy property to measure or to specify, because it depends not only on the material properties and the resin-to-glass ratio, but also on the test method, test signal frequency, and the conditioning of the samples before and during the test. It also tends to shift with temperature. Still, D_c values are important for computer simulations that are used to predict the

performance of impedance-controlled high-end multilayer constructions, especially when new laminate materials are considered. See Fig. 15.8 for a schematic representation of the test.

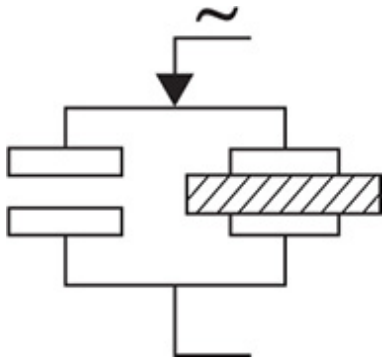

FIGURE 15.8 Dielectric constant test.

Related to the dielectric constant is the dissipation factor (D_f) or loss tangent. This is a measure of the percentage of the total transmitted power that will be lost as electrons dissipate into the laminate material. See Fig. 15.9 for a schematic representation of the test.

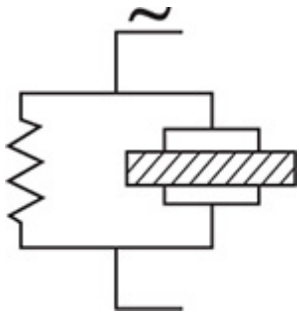

FIGURE 15.9 Dissipation factor test.

Several test methods are specified in IPC-TM-650 to determine the dielectric constant and the dissipation factor (methods 2.5.5, 2.5.5.1, and 2.5.5.2). Both methods 2.5.5 and 2.5.5.2 test laminate material with fully removed copper. At least three samples need to be tested because of the large influence of the dielectric thickness on the determined

value. Method 2.5.5.1 employs samples with an etched pattern. All of these measurements are based on the capacitance of the corresponding sample. With this capacitance and the area and thickness of the sample capacitor it is possible to calculate the dielectric constant.

The dissipation factor is determined with methods 2.5.5.1 and 2.5.5.2. In one case, the value can be read from the equipment display (Agilent Technologies Mdl 4271A); in the other, it can be calculated from the measured sample conductance and capacitance and the measuring frequency.

15.5.3.2 Surface and Volume Resistivity. Electrical resistivity of laminate materials is differentiated between specific surface resistance and volume resistance. The surface resistance s characterizes the electrical resistance between two conductors along the surface of the laminate material. The volume resistance ρ describes the electrical resistance between two layers of conducting copper along the z-axis of the laminate material. The higher the values for both of these electrical properties, the better, as this ensures proper isolation of individual copper conductors in the printed circuit board.

Both resistance values are determined according to IPC-TM-650, method 2.5.17. All resistance measurements are done with equipment capable of measuring up to 10^{12} meg-ohm while applying 500 volts direct current to the test specimen (Agilent Technologies 16008A). The sample's size is 101.6mm × 101.6mm for laminates thicker than 0.51 mm and 50.8 mm × 50.8 mm for laminates below 0.51 mm thickness. The test pattern according to method 2.5.17 should be applied to the samples using standard photo and etch processes.

All measurements are performed by applying 500 volts direct current. The voltage needs to be applied to the samples for 60 sec. before taking the resistance reading to allow the test structures to stabilize. The surface resistance

is determined between the outer ring electrode and the inner solid electrode. The volume resistance is determined between the solid front and back electrodes after changing the connecting cables appropriately. The values for volume and surface resistivity can be calculated from the measured resistance values as shown in Eqs. 15.5 and 15.6.

Volume resistivity ρ (meg-ohm-cm)

$$\rho = (R*A)/T \qquad (15.5)$$

where R = Measured resistance in meg-ohms
A = Effective area in square cm
T = Average thickness of specimen in cm

Surface resistivity σ (meg-ohms)

$$\sigma = (R*P)/D \qquad (15.6)$$

where R = Measured resistance in meg-ohms
P = Effective perimeter of electrode in cm
D = Width of test gap in cm

15.5.3.3 Dielectric Strength Breakdown. The dielectric strength of a laminate material is its ability to resist electrical breakdown. The dielectric strength defines a specific voltage that the laminate resists for a specified time whereas the dielectric breakdown voltage defines the maximum voltage at which the laminate fails. These properties can be measured perpendicular to the reinforcement (z-axis) or parallel to the reinforcement (x-y axis). The more important value is the z-axis strength because more and more thin prepreg and laminate cores are being used in high-end multilayer applications. The minimum

thickness in the laminate is defined as the shortest distance between the copper treatment peaks that needs to resist the desired test voltage. The values for dielectric strength vary with test setup, temperature, humidity, frequency, and wave shape, but are, if tested under controlled conditions, comparable between materials.

The test method following IPC-TM-650, method 2.5.6.2, describes the determination of the perpendicular electric strength of laminates. Four specimens should be tested. The sample size is recommended to be 4 in. × 4 in. with any copper cladding removed. Unless otherwise specified, the samples need to be conditioned for 48 hours in distilled water at 50°C. After that, the samples are immersed in ambient temperature distilled water for a minimum of 30 min. to allow the samples to achieve temperature equilibrium without a substantial change in moisture content. The test is performed at ambient temperature (23°C). Relative humidity is not significant as the tests are performed under oil. Samples are inserted into the high-voltage test equipment and tested to failure at a 500volts/sec. increase. The results are reported in volts/mil.

The test method (see Fig. 15.10) following IPC-TM-650, method 2.5.6, describes the determination of the parallel electric strength of laminates. Four specimens should be tested: two in machine direction, and two in the transverse direction for reinforced materials. The samples size is recommended to be 3 in. long by 2 in. wide with any copper cladding removed. Two holes 0.188 in. in diameter are to be drilled along the centerline of the 3 in. dimension and midway between the edges in the 2 in. dimension, with a spacing of 1 in. center to center. Conditioning and test setup in oil is identical. Electrodes are inserted in the holes and the samples are tested to failure at a 500 volts/sec. increase. The results are reported in kilovolts (KV).

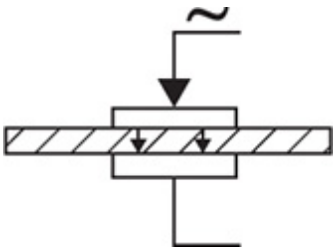

FIGURE 15.10 Dielectric strength breakdown

15.5.4 Other Laminate Properties

Other laminate properties to consider include flammability and water absorption.

15.5.4.1 Flammability. The flammability of laminate materials is classified according to Underwriters Laboratories (UL) specifications. All of the tests are performed using a standard test setup under an exhaust hood using a Bunsen burner as a source for the flame. The categories are as follows:

- *UL-94-V-0* Specimens must extinguish within 10 sec. after each flame application and within a total of less than 50 sec. after a total of 10 flame applications. No samples are to drip flaming particles or exhibit glowing combustion that lasts for more than 30 sec. after the second flame test.
- *UL-94-V-1* Specimens must extinguish within 30 sec. after each flame application and within a total of less than 250 sec. after a total of 10 flame applications. No samples are to drip flaming particles or exhibit glowing combustion that lasts for more than 60 sec. after the second flame test.
- *UL-94-V-2* Specimens must extinguish within 30 sec. after each flame application and within a total of less than 250 sec. after a total of 10 flame applications. Samples may drip flaming particles or burn briefly, but no specimen may exhibit glowing combustion that lasts for more than 60 sec. after the second flame test.

In most cases, the laminator will provide results for these tests routinely. In the case of new materials for which the laminator has not supplied any flammability data, it may be a good idea to check this property. This does not require an elaborate test setup, and you can get a first indication by igniting a sample specimen under an exhaust hood using a lighter.

15.5.4.2 Water Absorption. Depending on their specific molecular composition, every laminate material will absorb a certain amount of water. This will happen not only during the many wet processing steps in printed circuit board manufacturing but also as a result of exposure to normal environmental conditions. The absorbed moisture may change the properties of the laminate and increase the risk of blistering and delaminations during high-temperature processes such as reflow soldering.

The test method, according to IPC-TM-650, method 2.6.2.1, determines the amount of water that is absorbed by a laminate material sample when immersed in water for 24 hours. The test is easy to perform and the results for different laminates are readily comparable.

The test samples for this test need to be 2 in. long by 2 in. wide. The thickness is not specified but should not vary widely when more than one material is characterized. The edges of the samples need to be sanded smooth and copper cladding is to be removed using standard etching processes. The samples are preconditioned in a drying oven for 1 hour at 105°C (221°F), cooled down to room temperature in a desiccator, and weighed immediately after removal. Then the samples are placed in distilled water at 23°C. It is important to place the samples on their edge to maximize the laminate area exposed to water. After 24 hours, the samples are removed, dried with a dry cloth, and immediately weighed. The moisture absorption is reported in percent weight increase.

15.5.5 Additional Tests

In addition to the previously described test methods, many more can be found in IPC-4101 and in the test methods manual IPC-TM-650. All of these tests address laminate properties that may have a significant impact on the performance of the final product. The final decision as to which qualification tests to include or exclude always needs to be made on a case-by-case basis depending on the performance requirements for the printed circuit board.

At the same time, there are a number of laminate qualification tests that rarely will be performed in the printed circuit manufacturing facility. In many cases, the laminate supplier will perform a number of qualification tests itself and share the results with its customers. This may in many cases be sufficient, especially after a close relationship between the supplier and the PCB manufacturer has been established.

15.5.6 Prepreg Testing

During the qualification of a new laminate material, it may also become necessary to perform prepreg-specific tests to verify its quality. The most commonly tested properties of prepregs are resin content, flow during mutilayer processing, and gel time. Details about additional properties and all corresponding test methods can be found in IPC-4101.

15.6 CHARACTERIZATION TEST PLAN

Table 15.4 summarizes all of the test procedures.

TABLE 12.4 Laminate Characterization Test Plan

1. Step	Data comparison	Unit	Test result
	Material available in production volume	yes/no	
	Material cost	$/m^2	
	Material data sheet available	yes/no	

2. Step	First test runs in small volume	Unit	Test method	Conditioning	Data sheet	Test result
	Surface and appearance		IPC-TM-650, method 2.1.2 & 2.1.5	As received		
	Copper peel strength laminate Condition A	N/mm	IPC-TM-650, method 2.4.8	As received		
	Copper peel strength laminate Condition B	N/mm	IPC-TM-650, method 2.4.8	Solder pot 288°C/10s

15.7 MANUFACTURABILITY IN THE SHOP

During the qualification of a new material, it is also crucial to run the laminate through the production processes to check whether they are compatible. Table 15.5 summarizes all the steps that are necessary to control.

TABLE 15.5 Summary of Production Steps

Compatibility with innerlayer (IL) process steps
Preclean
Resist lamination
Exposure
Develop, Etch, Strip

Brush/Pumice/Deburr
Desmear/Plasma Desmear/Other
E’less copper or similar process

Compatibility with soldermask process step

Compatibility with different finish metallization processes

Electroless Ni/Au
Immersion Sn
Immersion Ag

Compatibility with routing process

The first process step is innerlayer processing. Here, a change in stiffness of the new laminate material can have a significant impact on the processability in horizontal manufacturing lines. This is especially important for thin cores. A change in the copper quality of the new laminate may impact the adhesion of the innerlayer photoresist and can also affect the copper etch rates. During automatic optical inspection (AOI), it is necessary to verify the contrast between copper circuitry and laminate and adjust the AOI settings if necessary. In case of necessary innerlayer repairs, the settings for the welding process may need adjustment to avoid thermal damage of the laminate and ensure reliable interconnects. The last step during innnerlayer processing is copper blackoxide. Here, it is necessary to verify the compatibility of the employed blackoxide (reduced/nonreduced or alternative) to the base material to obtain a sufficient innerlayer bond strength of the multilayer product. The dimensional stability of the innerlayers must be measured after the multilayer cycle to adjust the innerlayer scaling factors of the new material.

The next step after multilayer lamination and edge routing is drilling. A change in the thermomechanical properties of the laminate may impact the quality of the drilled holes, and adjustments to drill speeds or desmear settings may be necessary. After metallization and plating, the adhesion of the copper in the plated through hole as well as reliable contacts to all innerlayers must be verified.

The adhesion of soldermask may also change as well when a new material is introduced. This is especially critical in combination with any metal finish process steps (such as electroless Ni/immersion Au, immersion Sn, and immersion Ag). In addition to having a negative impact on soldermask adhesion, these processes in combination with new laminates can also lead to nonselective metal plating or skip plating. One of the last manufacturing steps that should be evaluated during the introduction of a new laminate material is board routing and scoring. Here the use of a new base material with changed stiffness or different reinforcement may lead to necessary process adjustments.

PART 4

ENGINEERING AND DESIGN

CHAPTER 16

PLANNING FOR DESIGN, FABRICATION, AND ASSEMBLY

Happy T. Holden
Co-Editor-in-Chief, Printed Circuits Handbook, *and PCB Technologist, Zeeland, Michigan*

16.1 INTRODUCTION

Advances in interconnection technologies have occurred in response to the evolution of component packages, electronic technology, and increasingly complex functions. Therefore, it comes as no surprise that various forms of printed wiring remain the most popular and cost-effective method of interconnections.

Manufacturing, assembly, and test technologies have responded by improvements in their technologies. These increased capabilities have made selection of technologies, design rules, and features so complex that a new function has developed to allow for the prediction and selection of design parameters and performance versus manufacturing costs. This is the planning for design, fabrication, and assembly. This activity has also been called *design for*

manufacturing and assembly or sometimes-*predictive engineering*. It is essentially the selection of design features and options that promote cost-competitive manufacturing, assembly, and test practices. Later in this chapter, we will offer a process to define producibility unique to each design or manufacturing process. Section 16.3.4 describes a process to define producibility unique to each design.

The purpose of this chapter is to provide information, concepts, and processes that lead to a thoughtfully and competitively designed printed circuit, ensuring that all pertinent design and layout variables have been considered.

16.1.1 Design Planning and Predicting Cost

Reducing costs to remain competitive is a principle responsibility of product planning. On the average, 75 percent of the recurring manufacturing costs are determined by the design drawing and specifications.[1] This was one of the conclusions found by an extensive study that General Electric conducted on how competitive products were developed. Manufacturing typically determines production setup, material management, and process management costs (see Fig. 16.1), which are a minor part of the overall product cost.

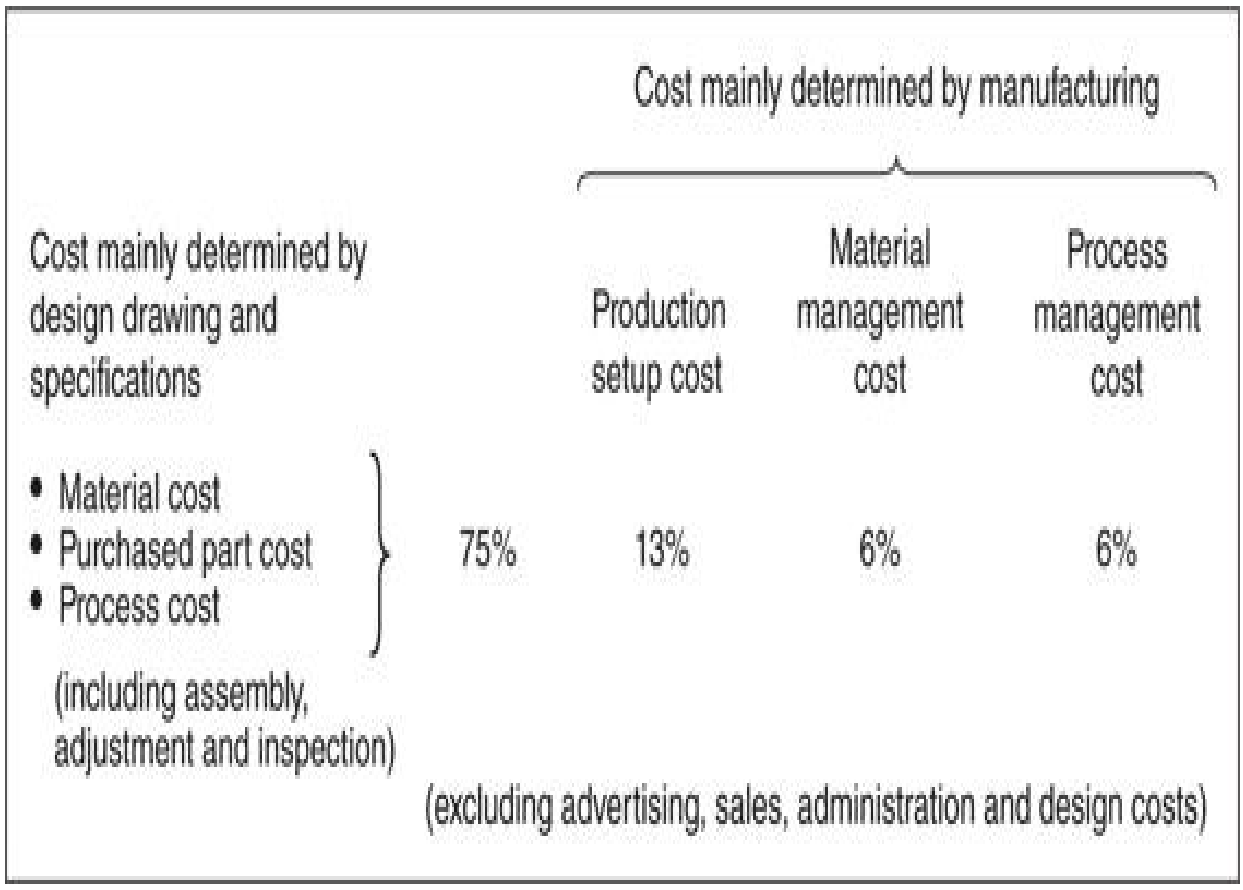

FIGURE 16.1 Design determines the majority of the cost of a product.

Time to market along with competitive prices can determine a product's ultimate success. Having the first of a new electronic product on the market has many advantages. By planning the printed wiring board (PWB) layout and taking into consideration aspects and costs of PWB fabrication and assembly, the entire process of design and prototyping can be done with minimum redesign (or respins).

16.1.2 Design Planning and Manufacturing Planning

Electronics is one of the biggest enterprises globally. It is common for design to be done in one hemisphere and manufacturing in another. It is also common for

manufacturing to be done in a number of different places simultaneously. An integrated approach must be adopted when the intention is to rationalize fabrication and assembly as part of the entire production system and not as individual entities, as shown in Fig. 16.2. This dispersed manufacturing must be taken into consideration during the design planning and layout process. No finished product is ever better than the original design or the materials from which it is made.

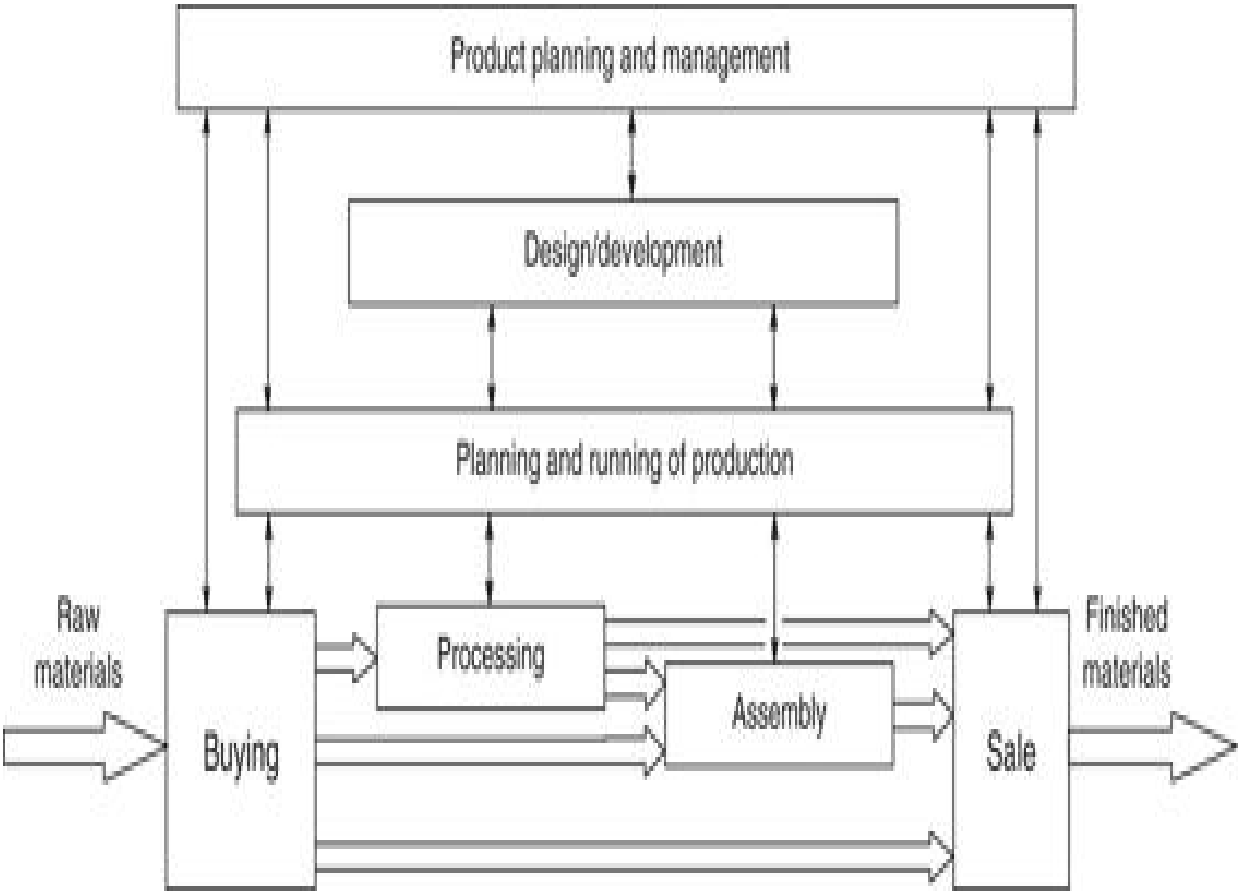

FIGURE 16.2 Fabrication and assembly rationalized by planning and design.

16.2 GENERAL CONSIDERATIONS

The planning process central focus will be the trade-offs between the loss and gain in performance for layout,

fabrication, assembly, and test versus the costs in these domains. Therefore, some major considerations will be discussed in the following sections:

- New product design process (Secs. 16.3.1 and 16.3.2)
- The role of metrics (Secs. 16.3.3 and 16.3.4)
- Layout trade-off planning (Sec. 16.5)
- PWB fabrication trade-off planning (Sec. 16.6)
- Assembly trade-off planning (Sec. 16.7)

16.2.1 Planning Concepts

Planning for design, fabrication, and assembly (PDFA) is a methodology that addresses all the factors that can impact production and customer satisfaction. Early in the design process, the central idea of PDFA is to make design decisions to optimize particular domains, such as producibility, assemblability, and testability, as well as to fit into a product family, such as custom automated manufacturing. Planning takes place continuously in the electronic design environment (see Fig. 16.3). The data and specifications flow in one direction, from product concept to manufacturing. During the design process, 60 percent of the manufacturing costs are determined in the first stages of design when only 35 percent of the design engineering costs have been expended. The typical response is shown in Fig. 16.4.[1]

FIGURE 16.3 Electronic design environment.

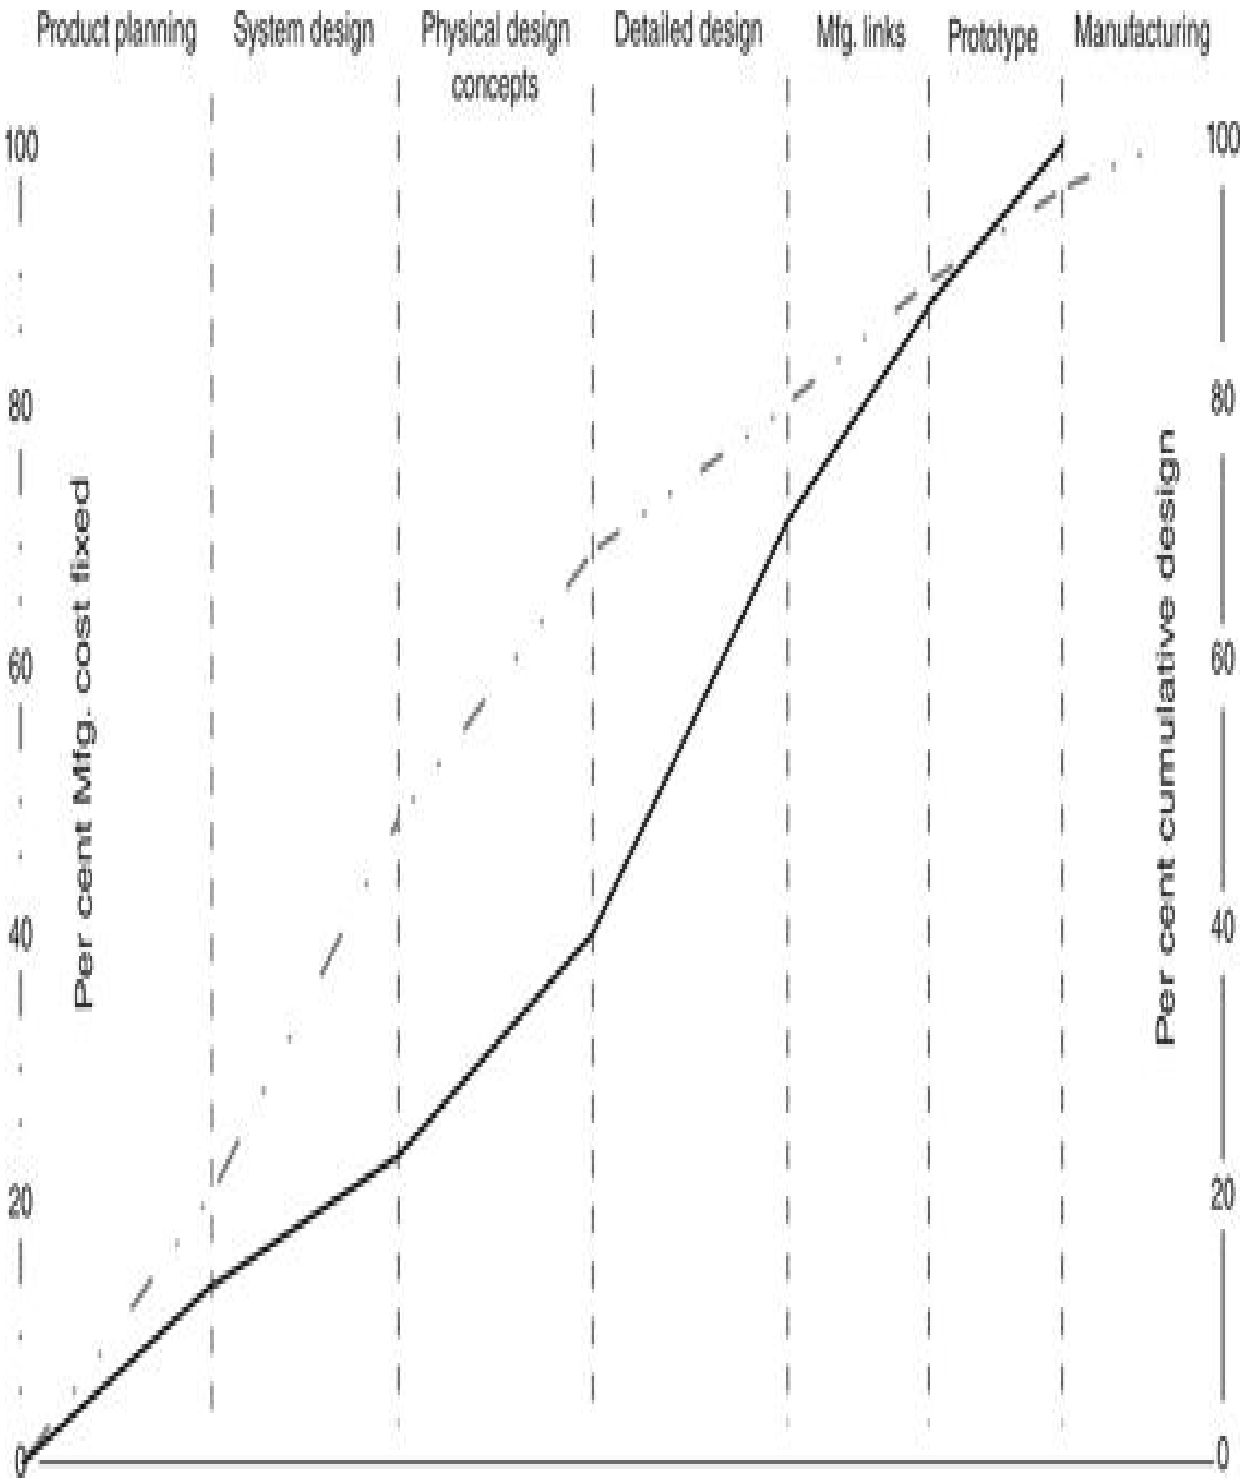

FIGURE 16.4 Design cost accumulation versus intrinsic manufacturing costs.

16.2.2 Producibility

Producibility is now regarded as an intrinsic characteristic of a modern design. Like the concept of quality in manufacturing, such a characteristic must be built in, not inspected in. Producibility must be designed in; it cannot be a “checkpoint” in the design process or inspected in by tooling.

16.3 NEW PRODUCT DESIGN

The keys to superior producibility in new product design can be found in the expanded design process. One of those keys is the role of metrics or data-based analysis of planning trade-offs.

16.3.1 Expanded Design Process

The new expanded design process that incorporates planning, trade-offs, and manufacturing audits is shown in Table 16.1. The process is made up of 12 separate functions that incorporate the planning and trade-offs sections in this book:

TABLE 16.1 The Expanded Electronics Design Process

Function	Purpose
Specification	User-supplied constraints and ideas formulate executable specifications.
Capture of system description	Technology trade-off analysis: balance of loss and gain in various domains' performance versus cost.
Synthesis	Generation of a netlist from the executable specifications.
Trade-off	Selection of layout, fabrication, and assembly features versus cost.
Physical CAD	Conversion of netlists to system and module layouts.
Simulation	Detailed analysis of design structures to support all other design (CAD) activities.
Design advisor	Continuous display of design rated by performance rules.
Manufacturability audit	Check of design to manufacturing design rules and capabilities.
Tooling	Conversion of module layouts to panel layout.
MFG	Conversion of module layouts to physical products (fabrication or assembly).
PDM database	Enterprise wide database containing all product information (product data management, or PDM) including design files, libraries, manufacturing information and revisions, etc.
Internet	Multiteam designs via access over the Internet.

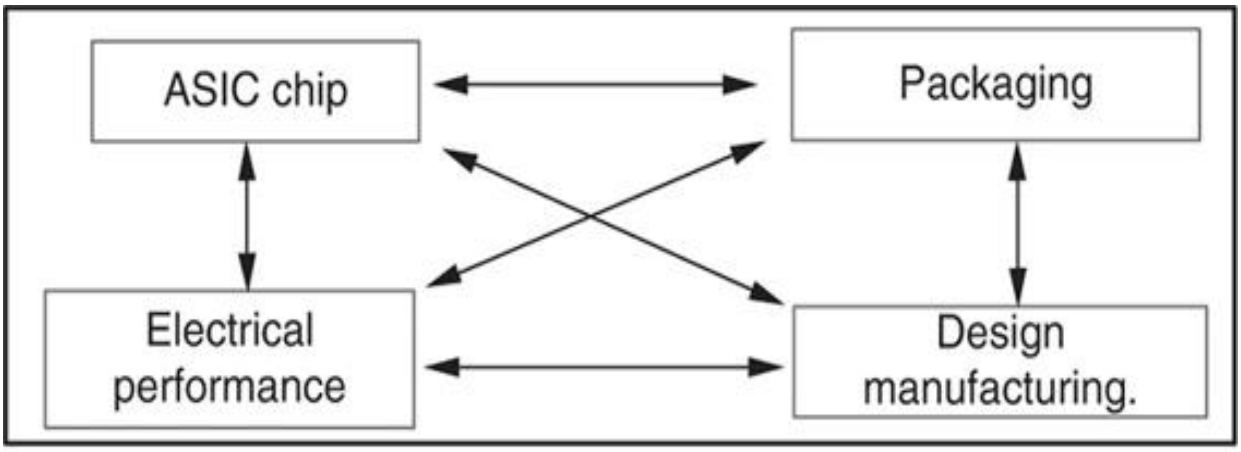
This differs from the more conventional design process (as seen in Fig. 16.3) by the inclusion of four important functions:

- The formal technology trade-off analysis during the specification phase
- Detailed trade-off selection of features for layout, fabrication, and assembly
- Design advice during component placement and routing

- Manufacturing audits to review the finished layout for producibility, time to market, and competitiveness

16.3.2 Product Definition

The initial new product design stage is specification and product definition. This key step takes ideas, user requirements, opportunities, and technologies and formulates the executable specifications of a new product. During this operation, the ability of technologists who may lack any manufacturing experience to predict what will happen in manufacturing can affect both time to market and ultimate product costs. Figure 16.5 shows the technology trade-off analysis that requires the balance of loss and gain in various domains performance versus costs. Size and partitioning for integrated circuits (IC) and application-specific integrated circuit (ASIC) must be balanced with overall packaging costs and the resultant electrical performance. All of these factors affect the manufacturing and product cost.



Technology tradeoff analysis: balance of loss and gain in various domains' performance versus cost.

FIGURE 16.5 Specifications determine product partitioning and producibility.

Another definition of this process could be called a "verified design."[2] A verified design is one that was predicted from models or measures that have been correlated to past designs. This is in contrast to the traditional approach, which is a "nonverified design," or trial and error. This is diagrammed in Fig. 16.6. The advantage of the verified design can be a significant reduction in redesigns to achieve the original product objectives.

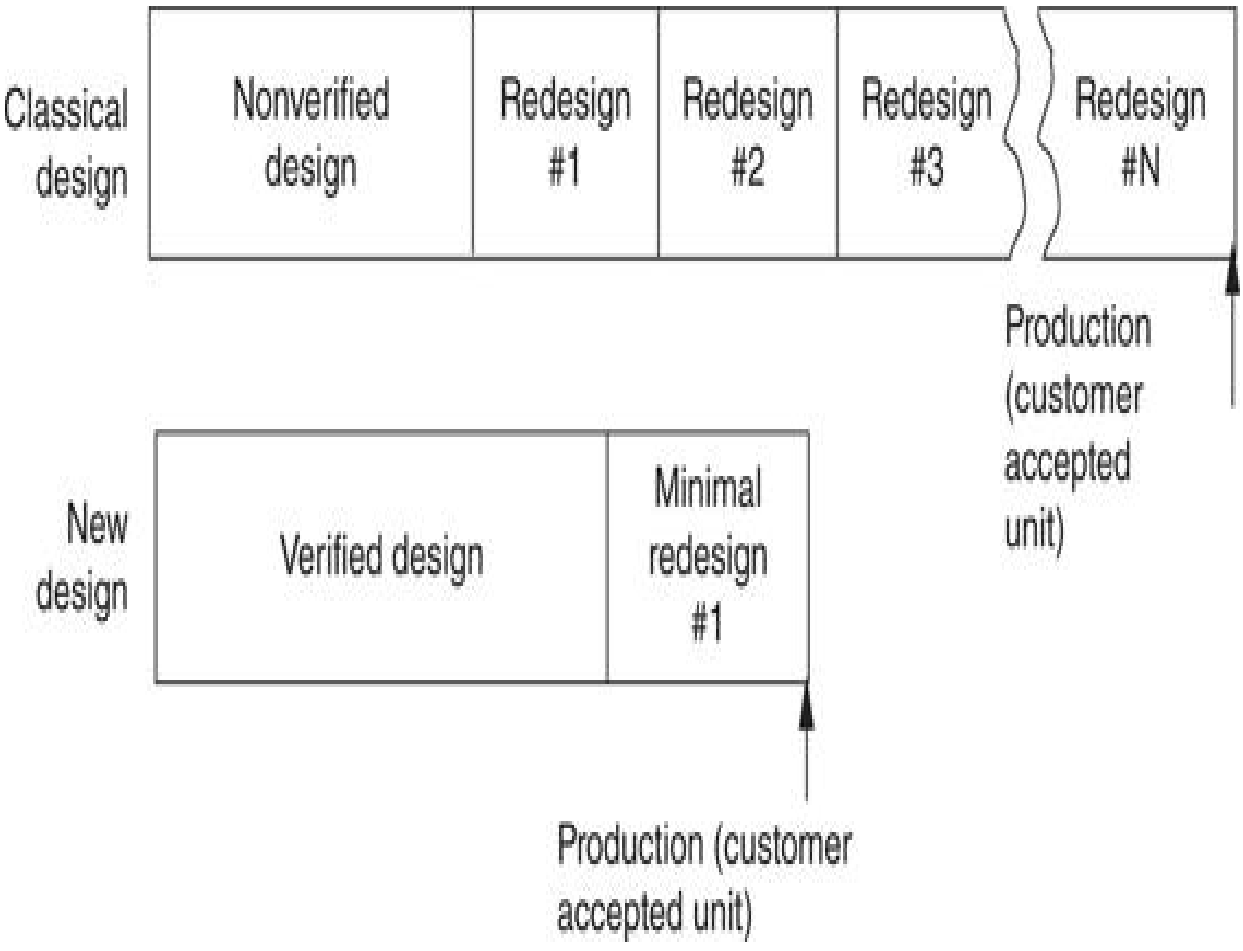


FIGURE 16.6 A design incorporating trade-offs versus traditional design.

16.4 SPECIFICATION: CAPTURE OF SYSTEM DESCRIPTION

16.4.1 Metrics for Predicting and Planning Producibility

Metrics are data and statistically backed measures, such as wiring demand (Wd) (see Sec. 16.5.1). These measures can be density, connectivity, or, in this context, producibility. These measures are the basis for predicting and planning. When such measures are used in the design process, two categories are applied to a product. Only the metrics can be shared by all in the design team. The nonmetrics provide little assistance in design.

16.4.1.1 Metrics

16.4.1.1.1 Metrics. Both the product and the process are measured by physical data using statistical process control (SPC) and total quality management (TQM) techniques (predictive engineering process).

16.4.1.1.2 Figure of Merit. Both the product and the process are scored by linear equations developed by consensus expert opinion (expert opinion process).

16.4.1.2 Nonmetrics

16.4.1.2.1 Opinion. Opinion, albeit from an expert, is applied after or concurrent with design (manufacturing engineering inspection process).

16.4.1.2.2 No Opinions. No attempt to inspect or improve the design is done during the specification, partitioning, or design stage (over the wall process).

Metrics also establish a common language that links manufacturing to design. The producibility scores form a nonopinionated basis allowing a team approach that results in a quality, cost-competitive product (Fig. 16.7).

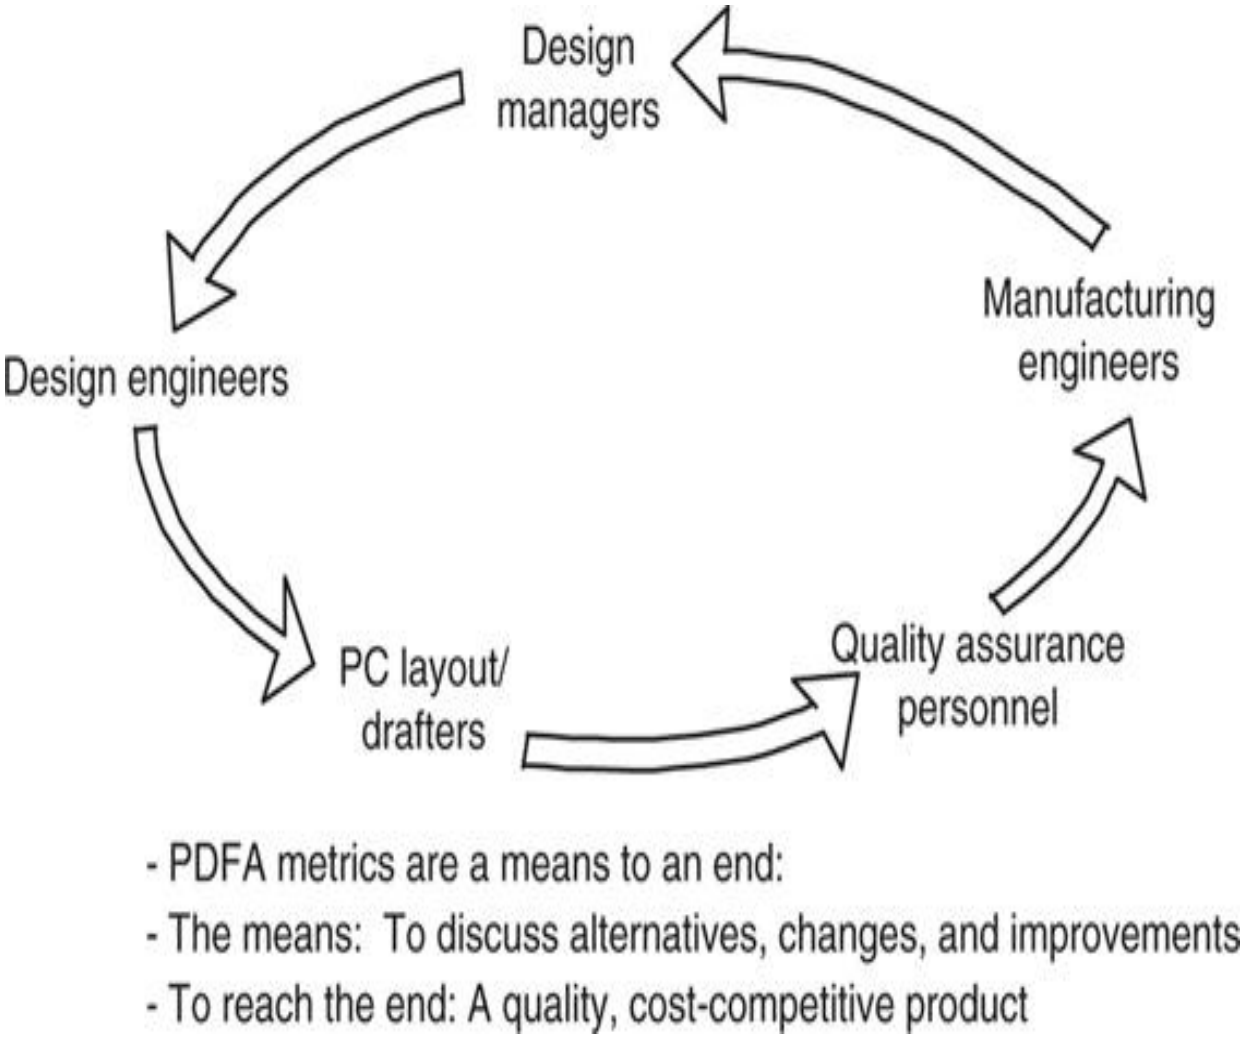

FIGURE 16.7 The benefits of metrics as a common design language.

The strategy in applying these measures is shown in Fig. 16.8. The analysis process is unique to every individual and company, but certain conditions have to be met and considered if the product is going to be successful. If the score meets producibility requirements, then select this approach; if not, then evaluate other opportunities and repeat the process. In the rest of this chapter, measures and metrics are introduced that provide insight for layout, fabrication, and assembly planning.

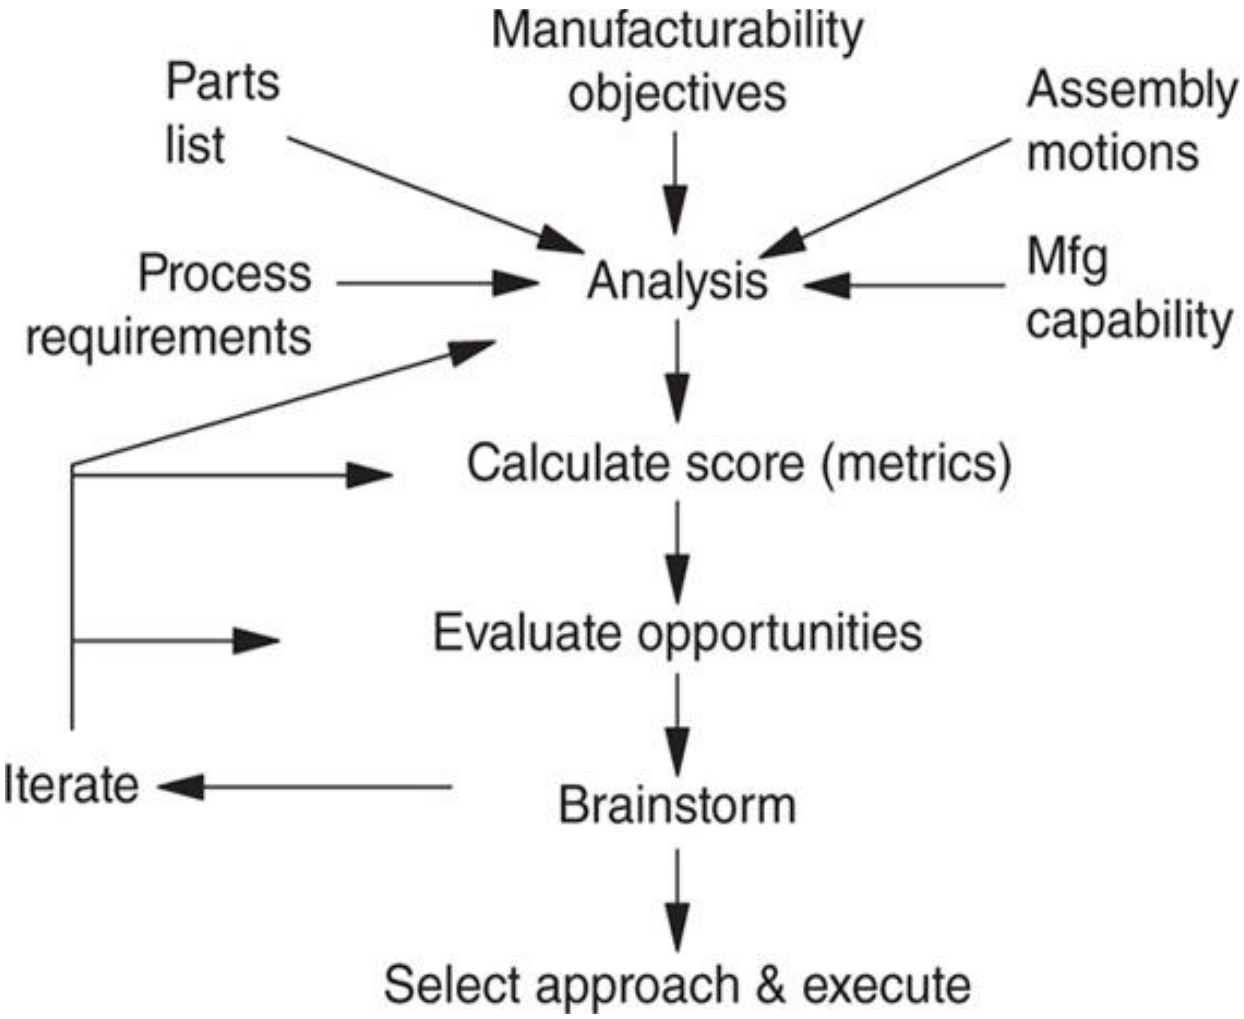

FIGURE 16.8 A process using measures and metrics to obtain a producible product.

16.4.2 Nonmetrics

It is always preferable to have metrics when discussing producibility. But if metrics are not available, then the opinions of experts are better than no opinions at all. The problem with opinions is that they are difficult to defend and explain, and when used in relation to producibility, many times they vary with each person. Sometimes, the opinion process is implemented with good intentions, by having experienced production experts review a new design. This is the *expert opinion process* and although it is sometimes

successful, it is difficult to replicate and often results in building barriers between manufacturing and design. That is why the figure of merit process is so popular. For a small amount of work by experts, it produces a scoring procedure that can be used and understood by all.

16.4.3 Figure of Merit Metric

Metrics are the preferred measures for design planning, but their availability for predicting producibility is often limited. Metrics also can take many months to develop and the amount of experimentation may make them costly. The measure that is much more cost-effective and quicker to develop is the figure of merit. The figure of merit (FOM) is the result of one or two days of work by a group of design and manufacturing experts. The process consists of eight steps:

1. Define or identify the new measure to be developed.
2. Determine why the measure was selected. Ensure the relevance of the measure to communication.
3. Survey the customers. Identify what the measure is that customers need to have communicated.
4. Identify needs and expectations and collect data.
5. Brainstorm contributing factors and variables.
6. Determine the major contributors and normalize scores. Use multivote, paired-ranking, ranking voting, or Pareto techniques to verify data if available. These are the coefficients (Cx) of the equation.
7. Construct FOM factor weightings (FWx). Fill in FOM table values for 1, 25, 50, 75, and 100.
8. Construct a linear equation model (coefficient score × FOM weightings).

16.4.4 Figure of Merit Linear Equation

This FOM procedure uses classical TQM techniques to brainstorm, rank, and formulate an equation that will score producibility, assemblability, or any other measure that can be used in design planning. The two factors used in the producibility score are made up of the (1) the coefficient, Cx, and (2) the factor weighting, FWx.

16.4.4.1 Coefficient, Cx. The coefficients in the producibility score are the result of brain-storming all the possible contributors to producibility that can affect the product (Fig. 16.9*a*). These are grouped into common ideas or factors by such techniques as clouds of affinity or Kay-Jay (Fig. 16.9*b*). These factors are ranked by voting or other Pareto techniques such as paired ranking, as seen in Fig 16.9*c*. Whatever the method of voting, the values are normalized by dividing by the smallest nonzero value. The resulting voting scores form the coefficients, Cx. Those factors with no votes are zeros and drop out of consideration.

FIGURE 16.9 Elements of the figure of merit process: (*a*) brainstorming factors; (*b*) grouping similar ideas; (*c*) ranking factors; and (*d*) assigning values to factors.

16.4.4.2 Factor Weightings, FWx. Each factor that emerges from the ranking process is calibrated by assigning values from one (1) to one hundred (100), as seen in Fig. 16.9*d*. The 1 factors are easy to manufacture, and the 100 factors are impossible today but may only be very difficult in a few years.

The resulting scoring equation will look like and be used as shown in Eq. (16.1).

$$\text{SCORE} = (\text{C1})(\text{FW1}) + (\text{C2})(\text{FW2}) + (\text{C3})(\text{FW3}) + (\text{Cn})(\text{FWn}) + \cdots \tag{16.1}$$

where Cx = coefficients based on ranking
FWx = factor weightings of assigned values (1 – 100)

For example, assume that the producibility of a bare PWB may be scored with the preceding equation if the FOM process established the following factors:

- Size of the substrate: C1 = 1.5
- Number of drilled holes: C2 = 3.0
- Minimum trace width: C3 = 4.0

Now assume that the proposed PWB design specifies the following:

- Size of the substrate: FW1 = 36
- Number of drilled holes: FW2 = 18
- Minimum trace width: FW3 = 31

The producibility SCORE would equal:

$$232 = 54 + 54 + 124 = 1.5 \times 36 + 3.0 \times 18 + 4.0 \times 31$$

The SCORE can be used if it is calibrated based on the prior history of this type of product. Prior products are scored with the FOM linear equation [Eq. (16.1)]. Those products that went into production smoothly and presented minimum problems determine the minimum SCORE that should be sought. The SCORE from products that were a problem, had to be reengineered, or presented delays in introduction determines the SCORE that the design should exceed if problems occur and producibility is to be obtained.

16.5 LAYOUT TRADE-OFF PLANNING

Predicting density and selecting design rules are two of the primary planning activities for layout. The actual layout of a PWB is covered in Chaps. 17, 18, and 21. The selection of design rules not only affects circuit routing but profoundly affects fabrication, assembly, and testing.

16.5.1 Balancing the Density Equation

With the need for more parts on an assembly and the trend to make things smaller for portability or faster speeds, the design process is a challenging one. The process is one of balancing the density equation with considerations for certain boundary conditions such as electrical and thermal performance. Unfortunately, many designers do not realize that there is a mathematical process to determine the routing rules of a printed circuit. Let me briefly explain. The density equation, as seen in Eq. (16.2) and Fig. 16.10, has two parts: the left side, which is the component wiring demand, and the right side, which is the substrate wiring capability.

Component PWB Wiring Demand < PWBs Design Rules & Construction Wiring Capabilities (16.2)

where PWB wiring demand = total connection length required to connect all the parts in a circuit

PWB wiring capability = substrate wiring length available to connect all the components

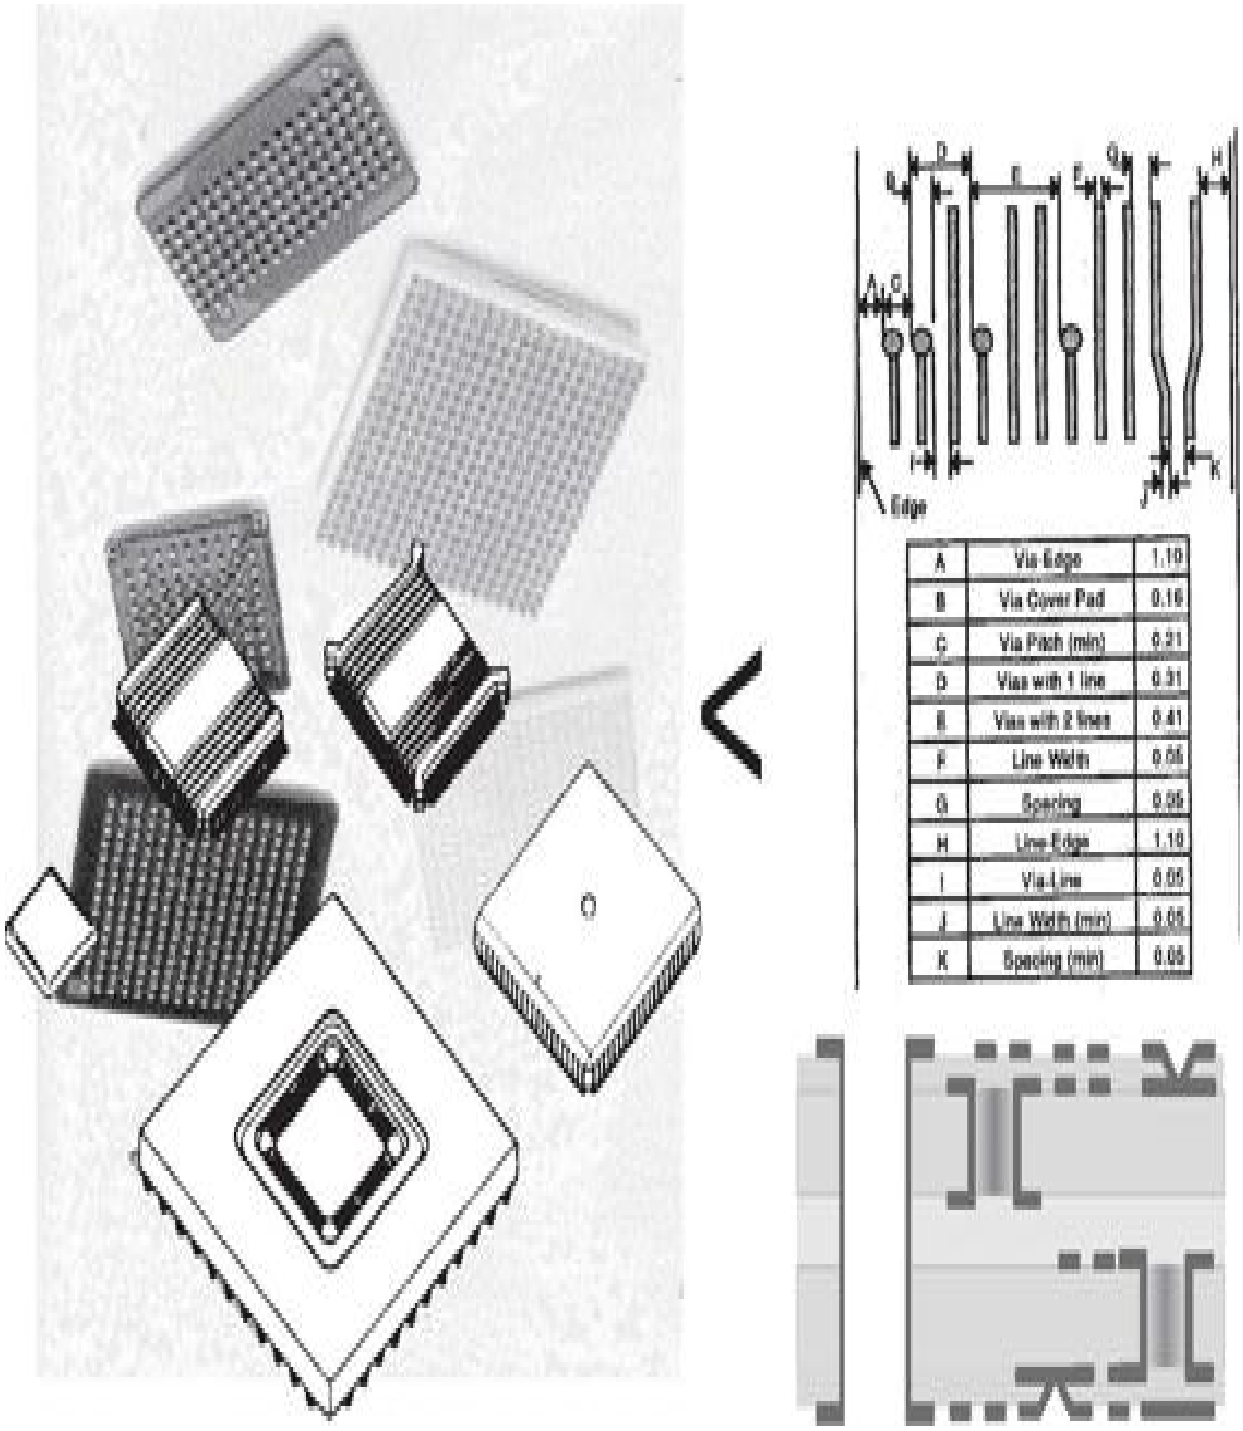

FIGURE 16.10 Balancing the density equations to achieve an optimal layout.

Four conditions can exist between wiring demand and substrate capability:

- *Wiring demand > substrate capability*. If the substrate capacity is not equal to the demand, the design can never be finished. There is not enough room for either traces or vias. To correct this, either the substrate has to be bigger or components have to be removed.
- *Wiring demand = substrate capability*. Although theoretically optimum, this condition leaves no room for variability and it would take an unacceptable amount of time to complete the design.
- *Wiring demand < substrate capability*. This condition should be your goal. There should be enough extra capacity to complete the design on time with only a minimum of over specification and costs.
- *Wiring demand << substrate capability*. This is the condition that usually prevails. By PCB layout, the schedule is tight and timing is all important. Many choose tighter traces or extra layers to help shorten the layout time. This increases the manufacturing costs 15 to 50 percent higher than is necessary, which is sometimes called the sandbag approach. It is unfortunate, as the preceding models would help to create a better-planned environment.

16.5.2 Wiring Demand (W_d)

Wiring demand is the total connection length (in inches) required to connect all the parts in a circuit. If the design specifies an assembly size (in square inches), then a wiring density in inches per square inch or centimeter per square centimeter is created. Models early in the design planning process can estimate the wiring demand. Three cases can control the maximum wiring demand:

- The wiring required to break out from a component such as a flip chip or chip scale package

- The wiring created by two or more components tightly linked, such as a central processing unit (CPU) and its cache or a digital signal processor (DSP) and its input/output (I/O) control
- The wiring demanded by all integrated circuits and discretes collectively

Models are available to calculate the component wiring demand for all three cases; see Sec. 16.5.3. Since it is not always easy to know which case controls a particular design, it is usually to calculate all three cases to see which one is the most demanding and thus controls the layout.

Wiring demand is defined by Eq. (16.3).

$$W_d = W_c \times \varepsilon \text{ (in cm/square cm or in./square in.)} \qquad (16.3)^3$$

where W_d = wiring demand
W_c = wiring capacity
ε = PWB layout efficiency (determined in Sec. 16.4.3)

16.5.3 Wiring Capacity (W_c)

Substrate wiring capacity is the wiring length available to connect all the components. It is determined by two factors:

1. *Design rules*. These rules specify the traces, spaces, via lands, keepouts, and such that make up the surface of the substrate.
2. *Structure*. This factor determines the number of signal layers and the combination of through and buried vias that permit interconnection between layers and the complex blind, stacked, and variable depth vias available in high-density interconnection (HDI) technologies.

These two factors determine the maximum wiring available on the substrate. To figure the wiring available to meet the demand, multiply the maximum wiring by the layout efficiency. The data are straightforward except for layout efficiency. Layout efficiency expresses what percentage of wiring capacity can be used in the design. Equation (16.4) shows the formula for determining wiring capacity for each signal layer. The total substrate capacity is the sum of all the signal layers.

$$W_c = T \times L/G \text{ (in cm/square cm or in/square in)} \quad (16.4)$$

where T = number of traces per wiring channel or distance between two via pads
L = number of signal layers
G = wiring channel width or length between centers of the via pads

16.5.4 Layout Efficiency

Layout efficiency is the percentage of capacity from design rules and structure that a designer can deliver on the board. Layout efficiency is the ratio of the actual wiring density that it takes to wire up a schematic versus the maximum wiring density or W_d divided by W_c. Layout efficiencies, for ease of calculations, are typically assumed to be 50 percent. Table 16.2 provides a more detailed selection of efficiencies.

TABLE 16.2 Typical Layout Efficiencies

Design Scenario	Conditions	Efficiency*, %
Through hole, rigid	Gridded CAD	6–12
Surface mount/mixed	W/wo back side passives, gridless CAD	9–16
Surface mount/mixed	W/back side actives, gridded CAD	8–14
Surface mount only	W/wo back side passives, gridless CAD	Up to 18
Surface mount/mixed	1-sided blind vias, gridless CAD	Up to 20%
Surface mount/mixed	2-sided blind vias, gridless CAD	Up to 28
Built-up technologies	2-sided micro-blind vias, gridless CAD	Up to 35%

*Determined from analysis of printed circuit designs (actual wiring capacity from the CAD system divided by maximum wiring capacity (Eq. 16.4).

16.5.5 Selecting Design Rules

To calculate a potential set of design rules and signal layers, first the wiring demand (W_d) should be calculated. Wiring models help accomplish this.

16.5.5.1 Wiring Demand Models. Seven wiring models are reported in the literature, but the first three are used commonly. The three wiring models include:

- Coors, Anderson & Seward Statistical Wiring Length[4]
- Toshiba Technology Map[5]
- Hewlett Packard (HP) Design Density Index[6]

The other four wiring models include:

- Equivalent ICs per square inch[7]

- Rent's Rule[8]
- Section Crossing[9]
- Geometric Analysis[10]

16.5.5.1.1 Coors, Anderson, and Seward Statistical Wiring Length. This wiring demand model is based on a stochastic model of wiring involving all terminals. The probable wire length is calculated based on the distance of a second terminal and the spatial geometry of all other terminals. This is the most recently determined wiring model and represents the most practical approximation of surface mounting technology. Equation (16.5) presents the mathematical model that results.

$$d = D * N_i/A \text{ (in per sq. in)} \tag{16.5}$$

where D = ave. interconnection distance (in): $D = E(x)*G$

$E(x)$ = expectation of occurrence

G = pad placement grid (in)

N_i = total number of interconnections

A = routing area (sq. in)

Equation (16.6) for $E(9x)$ is the

$$E(x) = -\frac{1}{a}\frac{((S-T)(Sa-2))e\text{^}aS+S(2-(S-T)a)e\text{^}a(S-T)-2T}{(S-T)e\text{^}aS-Se\text{^}a(S-T)+T} \tag{16.6}$$

where $S = M + N$

$T = (M\text{^}2 + N\text{^}2)\text{^}.5$

$a = \ln \alpha$

$\alpha =$ empirically derived constant $= 0.94$

$M =$ board width of grid point $=$ (width/G) + 1

$N =$ board length of grid point $=$ (length/G) + 1

$N_i = 2*Nt/3$

16.5.5.1.2 Toshiba's Technology Map. The packaging technology map is a simple technique to predict a PWB, chip-on-board, or MCM-L wiring demand and its assembly complexity. By plotting components per square inch (or components per square centimeter) against average leads per component on a Log-log graph (see Fig. 16.11), you can calculate the wiring demand W_D in inches per square inch (or centimeters per square centimeters) and assembly complexity in leads per square inch (or leads per square centimeter). Equations (16.7) and (16.8) show the equations for these two metrics.

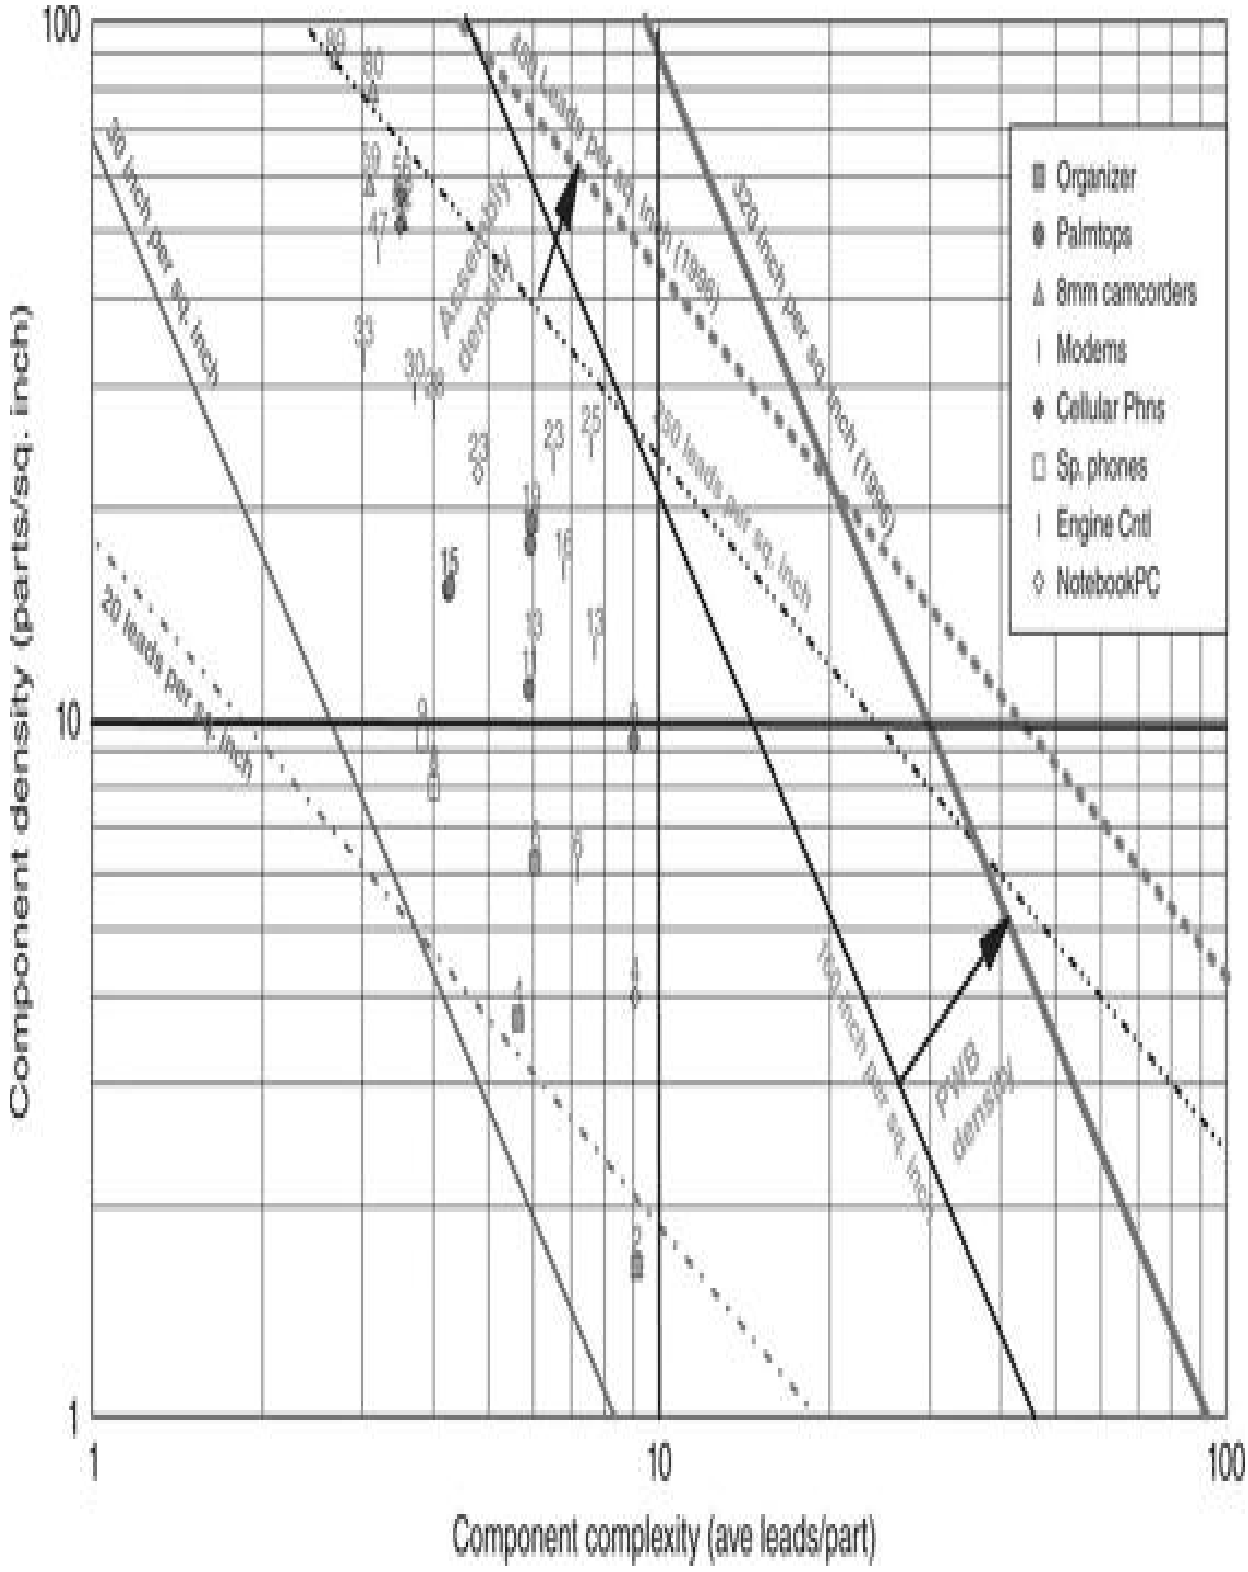

FIGURE 16.11 Packaging technology map.

$$\text{Wiring demand } W_D = \beta \times (\text{comp})^{0.5} \times (\text{leads}) \tag{16.7}$$

where β = wiring coefficient (typically 3.5 but can vary from 2.5 to 4.0 on average; notes/net is a good approximation)
comp = components per board area in sq. in or sq. cm leads = average leads (connections) per component

$$\text{Assembly complexity} = (\text{comp}) \times (\text{leads}) \tag{16.8}$$

where comp = components per board area in sq. in or sq. cm
leads = average leads (connections) per component

Using these two equations, Fig. 16.12 shows lines of constant wiring demand (in cm. per sq. cm or in per sq. in) and assembly complexity (in leads per sq. cm. or sq. in) that can be plotted on this chart (see Fig. 16.11).

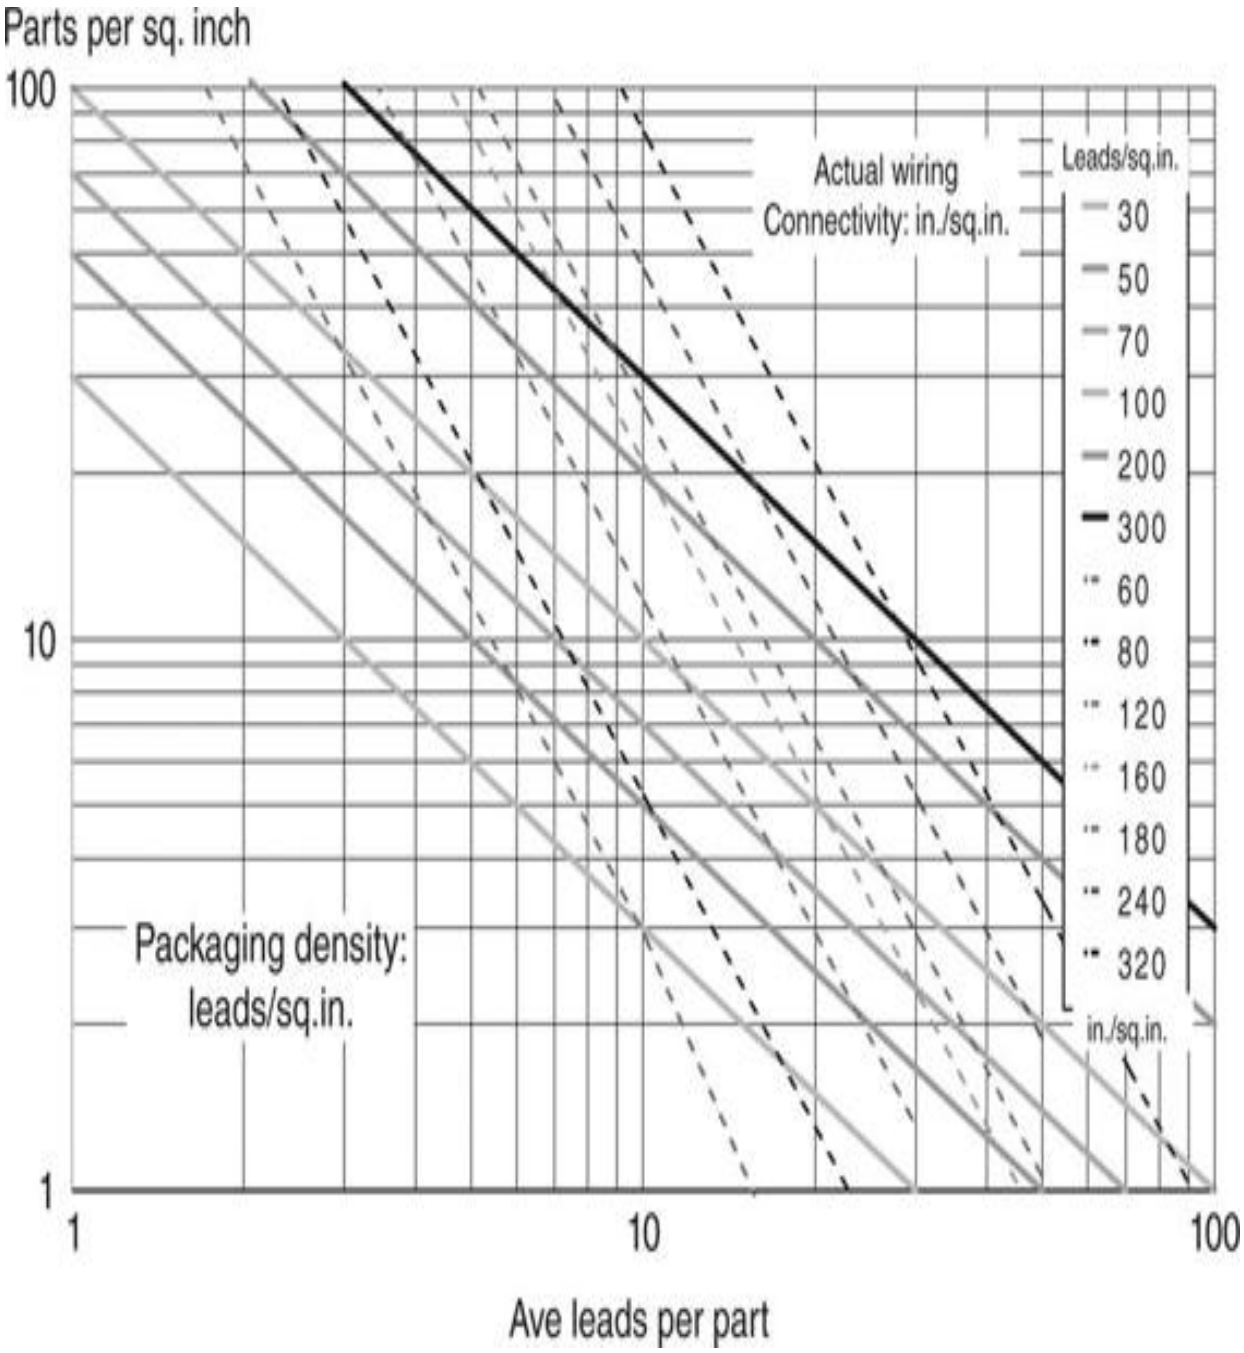

FIGURE 16.12 Wiring and assembly density.

16.5.5.1.3 HP's Design Density Index. Another metric is called the design density index (DDI). It is a correlation of the actual design rules for a PWB compared to the DDI metric. Equation (16.9) gives DDI, and Fig. 16.13 shows a typical calibration chart.

$$DDI = 13.6 \times (EIC/board\ area)^{1.53} \quad (16.9)$$

DDI = 13.6 x [EIC/sq. in.)^1.53]

FIGURE 16.13 Design rules and layer count for various DDIs.

The chart shown in Fig. 9.13 gives a good visual record in PWB layout of a company's efficiency. As various PC boards are charted, their DDIs form a distribution. This distribution is a form of layout efficiency (ε) since at the bottom of the distribution, more EICs are connected than at the top of the distribution.

16.5.5.1.4 Density of Equivalent ICs. EIC per unit area has been a traditional measure of density since the introduction of CAD systems in the early 1970s. A simple measure of the number of electrical connections required per unit area of the board, it remains in use with surface mounting technology and is usually referred to as EIC density. An EIC is the total number of leads of the components divided by 14 or 16, the old number of pins on a dual-inline package (DIP). Many people also use 20 as a divisor. Equation (16.10) defines EIC density mathematically in EIC/sq. in.

$$\text{EIC density} = \text{connections}/16/\text{board area} \tag{16.10}$$

where connections = total component leads

board area = top surface board area (in sq. cm or sq. in)

16.5.6 Typical Example of Wiring Demand Calculation

As an example, take a typical consumer electronic board with these characteristics:

- Design: consumer PCB, all through hole components
- Components: 86
- Leads: 1540

- Size: 16.6 in × 16.5 in = 57 sq. in
- EIC/sq. in = 110/57 sq. in = 1.93 [using Eq. (16.10)]
- DDI = 13.6 × $(1.93)^{1.53}$ = 316.7 ~

Figure 16.13 advises two tracks on two signal layers [using Eq. (16.9)].

16.6 PWB FABRICATION TRADE-OFF PLANNING

The metrics for PWB and chip-on-board (COB) fabrication involve with trade-offs between the performance objectives and the PWB price. Calculating prices requires the PCB characteristics and manufacturing yield. Manufacturing yield requires producibility estimates. Three items are required to predict PCB prices:

- Fabrication complexity matrix
- Prediction of producibility and first-pass yield
- Relative price as a function of a price index

16.6.1 Fabrication Complexity Matrix

The fabrication complexity matrix is supplied by a PWB fabricator. It relates the various design choices on a PWB to design points. These points are based on the actual prices that a fabricator will charge for these features. They are calculated by dividing the actual costs and the values by the smallest nonzero amount. Typical factors that fabricators can use to price a printed wiring board include the following:

- Size of the board and number that fit on a panel

- Number of layers
- Material of construction
- Trace and space widths
- Total number of holes
- Smallest hole diameter
- Solder mask and component legends
- Final metalization or finish
- Gold-plated edge connectors
- Factors specific to the design

A typical fabrication complexity matrix would look like Table 16.3. This is not a complete matrix, but does show the design factors and the design points assigned to each.

TABLE 16.3 Example of Fabrication Complexity Matrix

Factors	Pts.	Highest	Pts.	High Middle	Pts.	Low Middle	Pts.	Lowest
No. of layers	12	8	8	6	4	4	1	2
Trace width (mils)	8	4	5	5–6	3	7–8	1	10
No. of holes	10	5000–8000	5	3000–5000	3	10000–3000	1	>10000

16.6.2 Predicting Producibility

The simple truth about printed circuit boards, multichip modules, and hybrid circuits is that the design factors such as those listed previously can have a cumulative effect on manufacturing yield. These factors all affect producibility. Specifications can be selected that individually may not adversely affect yields but cumulatively can significantly reduce yields. A simple algorithm is available that collects these factors into a single metric, in this case called the complexity index (CI). It is given in Eq. (16.11).

$$\text{Complexity index} = \frac{(\text{area})(\text{holes/unit area})^{\wedge 2}(\text{no. layers})^{\wedge 3}}{(\text{min. trace width})(\text{min. annular ring})(\text{min. hole dia.})} \quad (16.11)$$

where area = top area of the substrate to be designed
holes = total number of drilled holes, blind, buried, and through
holes/unit area = holes divided by board Area
trace width = the minimum trace width on the substrate
layers = the total number of layers in the substrate
annular ring = ½ the difference between the via land and the hole dia.
hole dia. = finished hole size

where area, number of holes, minimum trace width, number of layers, and minimum tolerance (absolute number) are the factors of the board being designed.

16.6.2.1 First-Pass Yield. The first-pass yield equation derives from the Wiebel probability failure equations.[11] Equation (16.12) is of a more general form of the equation typically used to predict ASIC yields by defect density.

$$\text{FPY\%} = \frac{100}{\text{Exp}[(\log \text{CI}/\text{A})^{\wedge}\text{B}]} \quad (16.12)$$

where FPY = first-pass yield
CI = complexity index
A, B = constants

To determine the constants A and B in Eq. (16.12), a fabricator will need to characterize their manufacturing process. Selecting a number of printed circuits currently being produced that have various complexity indexes does

this, ideally some low, medium, and high. The first-pass yield (at electrical test without repair) of these printed circuits for several production runs is recorded. Any statistical software program[12] that has a model-based regression analysis can now determine A and B from the model [Eq. (16.13)].

$$\text{FPY} = f[x] = 100 \div \text{EXP}\{\text{LOG}(\text{complexity} \div \text{PARM}[1])\text{^}\text{PARM}[2]\} \qquad (16.13)$$

$$\text{where PARM}[1] = \text{A}$$
$$\text{PARM}[2] = \text{B}$$

The first-pass yield will follow the examples in Fig. 16.14. Constant A determines the slope of the inflection of the yield curve, whereas constant B determines the *x*-axis point of the inflection.

A=11.5, B=9
A=11.5, B=5

FIGURE 16.14 Estimated first-pass yield as a function of PWB design complexity.

Alternatively, any spreadsheet can be used to determine constants A and B. The [REGR] function in a spreadsheet like Excel™ or Lotus 1-2-3™ is used. The [REGR] function is defined as: (=LINEST(known_y's, known_x's,TRUE,TRUE). To use this function, you must first put the FPY function into the form $y = Ax + B$. This is done by creating two columns: complexity index (which we will call X1) and yield. A third column is created for {log[log(X1)]}, whereas a fourth column is created for {log[ln(-yield/100)]}. Provide the regression function with column 4 as known_ys and column 3 as known_xs. The regression function will return 10 values; FIT (slope & int.), sig-M (slope & int.), r2, sig-B(slope & int.), F,df (slope & int.), and reg sum sq (slope & int.). The constant B is equal to the FIT (slope) and the constant A is 10^[−FIT(int.)/FIT(slope)]. (Remember, to calculate an array, follow these steps: highlight the array on the spreadsheet; type the array formula, making sure that the cursor is in the edit bar; then press CTRL + SHIFT + ENTER.)

16.6.2.2 Yield Calculation Steps. To calculate the first-pass yield coefficients, there are six steps:

1. Collect design attributes of 10 to 15 currently running boards with various size and layers (see Table 16.4).

TABLE 16.4 Example of PCB Part Information and Calculated Complexity Index

P/N	PCS SIZE Length (in.)	Width (in.)	Hole Quantity	Hole Density	Layers	Thickness (mil.)	Min. Trace Width (mil.)	Min. Annular Ring (mil.)	Min. Hole Size (mil.)	Aspect Ratio	Complexity x1

5. Calculate regression coefficients (see Table 16.7).

TABLE 16.7 Example of Excel™ Regression Results

	All Data		AVG Only	
Log-log Fit	Slope	Int.	Slope	Int.
FIT	3.17	−3.48	3.06	−3.38
Sig-M	0.18	0.13	0.34	0.25
R2, sig-B	0.73	0.19	0.88	0.12
F, df	312.60	115	81.75	11
Reg sum sq	11.01	4.05	1.14	0.15
B	3.17		3.06	
A	12.57		12.66	

6. Calculate A and B from regression fits.

16.6.2.3 PCB Part Information. Collect design attributes of 10 to 15 currently running boards with various size and layers (see Table 16.3).

16.6.2.4 PCB Production Yield Data. Collect the first-pass yield information for these selected boards, for at least 10 runs (see Table 16.5)

16.6.2.5 Calculating the Board Complexity Index and Average Yield: Regression Analysis Methodology. To determine the constants A and B in Eq. (16.12), you can use any statistical software program that has a model-based regression analysis. The model is shown in Eq. (16.13). Table 16.6 shows an example of an Excel™ spreadsheet setup, and Table 16.7 shows the regression results.

16.6.3 Example of a Complete PWB Complexity Matrix

This section presents an example of how one company approached this planning process as part of its PWB design for manufacturing program.

16.6.3.1 PWB Fabrication Complexity Matrix. The PWB fabrication complexity matrix (FCM) that this company developed is shown in Table 16.8. This FCM is built on a “per panel” basis of 18 in by 24 in rather than a “per board” basis. Also, volume is assumed to be in a preset amount.

TABLE 16.8 Example of One Company’s Fabrication Complexity Matrix

Fabrication Factors	Pts.	Highest	Pts.	High Middle	Pts.	Low Middle	Pts.	Lowest
Material of construction	147	Polyimide	88	BT	49	FR-4	40	CEM III
No. of layers	196	12 layers	137	8 layers	89	4 layers	36	2-sided
No. of holes/panel	270	<20,001	180	10,001–20,000	90	3001–10000	27	>3000
Min. Trace/spacing	25	2 mil.	10	3–4 mil.	6	5–6 mil.	1	<=6 mil.
Gold tabs	48	3 Sides	32	2 Sides	16	1 Side	0	None
Annular ring	30	>2 mil.	21	2–4 mil.		4–6 mil.	1	<6 mil.
Solder mask	25	2 S Dry film	17	2 S LPI	7	1 S LPI	5	Screened
Metalization	75	Electroless Ni/Au	69	Selective lead-free solder coat	46	Immersion silver	29	SMOBC/ organic coat
Min. hole dia.	166	<= 8 mil.	84	9–12 mil.	69	13–20 mil.	5	<20 mil.
Controlled impedance tolerance	105	+/–5 %	62	+/–10 %	30	+/–20 %	0	None

Points are per PANEL. For board: Divide by no. per PANEL

16.6.3.2 PWB Complexity. Figure 16.14 shows this company's first-pass yield. The curve with $A = 11.5$ and $B = 9.0$ was current for 6 months. Price index is the total points from the complexity matrix divided by the first-pass yield.

16.6.3.3 Relative Costs. The price index data for this company is shown in Fig. 16.15. The price index (PI) can vary from 150, which corresponds to a 70 percent price reduction,

to a PI of 1000 which corresponds to a 275 percent increase in price.

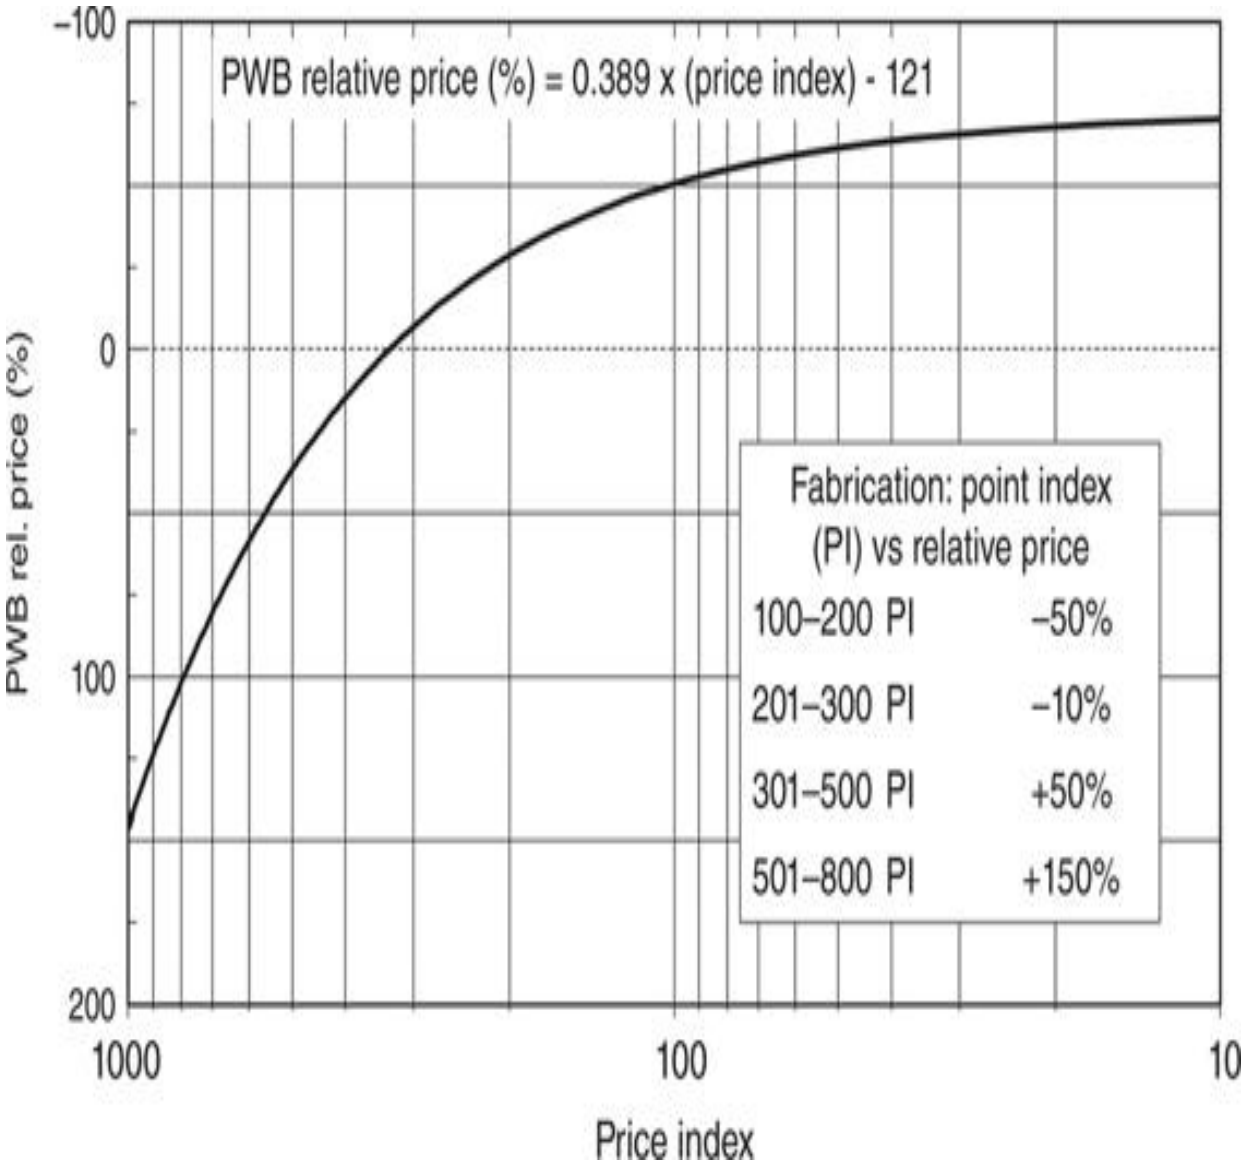

FIGURE 16.15 PWB relative price as a function of the price index.

16.6.3.4 PWB Fabrication Example. Let's continue with the consumer electronics board example from Sec. 16.4.5. Table 16.9 lists the initial design characteristics of the printed circuit and the resultant total design points. Table 16.10 shows the calculation of the complexity index,

estimated first-pass yield, and resultant price index and price adjustment.

TABLE 16.9 One Company's Fabrication Complexity Makeup

Fabrication Factors	PWB Design #1	Points	FCM
Mat'l of construction	FR-4	49	FR-4
No. of layers	six	137	Six layers
No. of holes	$1655 \times 6 = 9930$	90	3001–10,000
Min. trace wd.	0.008 in	6	6–8 mil
Gold tabs	None	0	None
Annular ring	0.010 in	1	<6 mil
Solder mask	2-sided LPI	17	2-sided LPI
Metalization	SMOBC/SSC	69	SMOBC/SSC
Min. hole dia.	0.025 in	5	<20 mil
Cont. impedance	None	0	None
TOTAL POINTS =		374	

TABLE 16.10 One Company's Initial Consumer Board Characteristics

Size	516.0 sq. in
No. of layers	Six layers
No. of holes	1655
Min. trace width	0.008 in
Tolerance (+/−in)	0.003
Complexity index	68.06
First-pass yield	90.7%
Price index	412.3
Rel. price	+ 14.5%

$A = 35, H = 1000, L = 2, T = .01, T_O = .01$

The wiring demand indicates that a 0.007 in trace and a 0.008 in spacing (two track) for a 1.100-in grid (channel) represent more density than is required (see Sec. 16.4.5). A one-track wiring on two signal layers could achieve the required wiring density or a 0.012-in trace with a 0.013 in spacing. The size required a panel layout, as shown in Fig. 16.16*a*, of six per panel. A reduction of 14 sq. in. in the board size would allow eight boards on a 18 in × 24 in panel (see Fig. 16.16*b*).

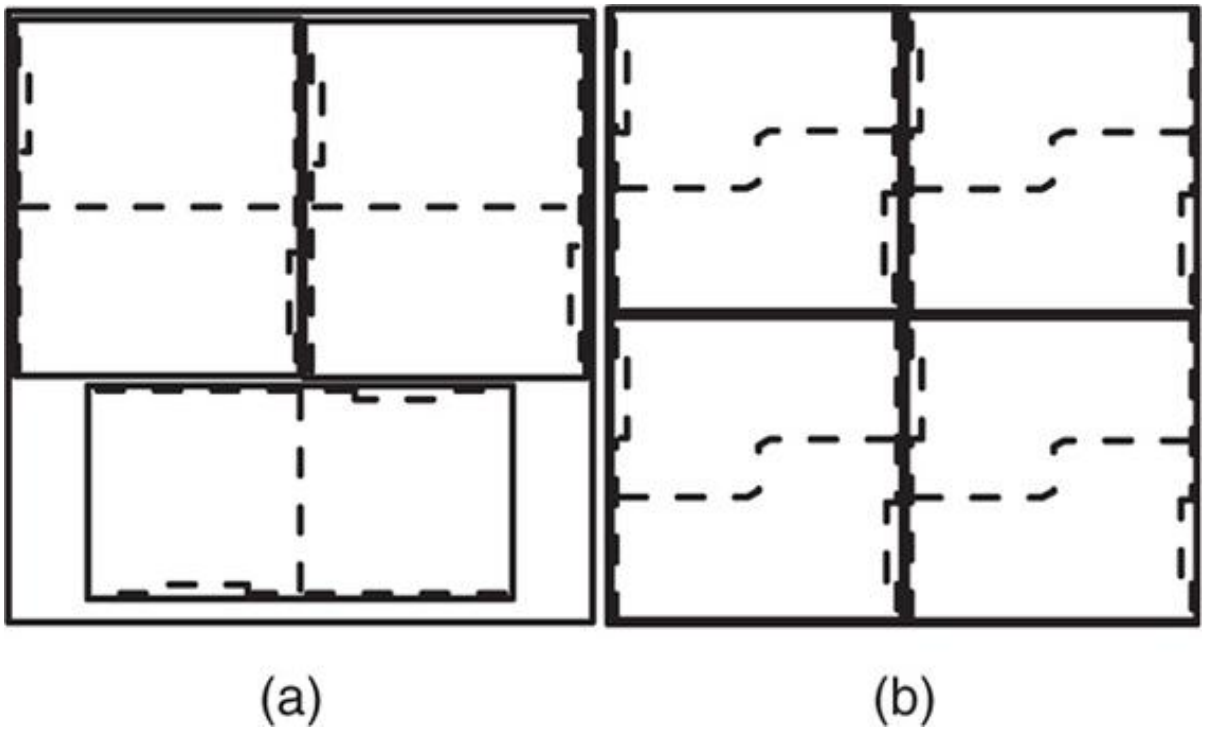

FIGURE 16.16 Fabrication panel layout of the consumer electronics board: (*a*) the original design; (*b*) the final layout.

A simple Gate Array ASIC was employed to reduce the small-scale ICs until 14 sq. in of space was freed up. The final optimized PCB had the fabrication factors seen in Table 16.11. The boards were eight up on a panel (Fig. 16.16*b*) and had a higher producibility by a 18 percent reduction in its complexity and an overall price reduction of 24.7 percent.

TABLE 16.11 One Company's Final Consumer Board Characteristics

Size	43.6 sq. in
No. of layers	Four layers
No. of holes	1156
Min. trace width	0.012 in
Tolerance (+/−in)	0.003
Complexity index	55.8 (24.0)
First-pass yield	96.7%
Price index	331.9
Rel. price	−10.2%

$A = 35, H = 1000, L = 2, T = .01, T_O = .01$

16.7 ASSEMBLY TRADE-OFF PLANNING

The metrics of assembly trade-offs relates factors of process, component selection, and test to assembly prices. Yields and rework are factored into the points of the Assembly Report Card. The point total provides an estimation of the relative prices of assembly and test.

16.7.1 Assembly Complexity Matrix

The PCB assembler supplies the assembly complexity matrix. This matrix relates various process assembly and test choices that the assembler provides along with component size, orientation, complexity, and various other known qualities to the costs of providing for these design choices.

To relate these qualities to the costs, the matrix allocates design points. Typical factors that affect assembly costs are

- One-pass or two-pass infrared reflow
- Wave solder process
- Manual or automatic parts placement
- Odd-shaped parts
- Part quality level
- Connector placement
- Test coverage
- The ability to diagnose tests
- Assembly stress testing
- Repair equipment compatibility

By collecting all the costs associated with assembly, test, and repair and then normalizing these costs with the smallest nonzero value, a matrix such as shown in Table 16.12 can be produced.

TABLE 16.12 Factors in an Assembly Complexity Matrix

Factors	Pts	Highest	Pts	Middle	Pts	Lowest
Solder process	35	1 pass IR	20	2 pass IR	0	IR and wave solder
Placement	8	100% auto	5	99%–90% auto	0	>90% auto
Digital test coverage	9	<98%	3	98%–90%	0	>90%
Manual attachment	8	100% Auto	25	Brackets	0	Post solder assembly

16.7.2 Example of an Assembly Complexity Matrix

An example of the assembly complexity matrix is the Assembly Report Card created by IBM-Austin. This complexity matrix has 10 factors that range in points from 0 to 35. The total points can affect the prices from a 30 percent discount to a 30 percent penalty. Table 16.13 illustrates this assembly complexity matrix trade-offs with design points.

TABLE 16.13 Assembly Complexity Matrix Defined as an Assembly Report Card

Assembly factors	Points	A	Points	B	Points	C	Points	D
Assembly process	35	2-pass IR	25	IR/wave B/S passives	20	IR/wave ≤ 5 B/S actives	0	IR/wave >5 B/S actives

- 2-pass IR is lowest-cost process due to low defect/repair level.
- Maximize SMT content, some PTH OK.
- Back-side SMT attachment with a wave solder process requires the use of adhesive.
- Back-side actives have a high defect level when the wave solder process is used.

Stress tests	15	0 hours	12	≤3 hours in situ	6	≤6 hours in situ and ≤3 hours static	0	<6 hours

- Stress test is a high-cost process step due to cost of chambers, fixtures, and process time.
- Stress test can be eliminated by using robust components, design, and process.

Parts SPQL	10	No high hitters	7	<2 high hitters	4	<4 high hitters	0	>5 high hitters

- Parts SPQL is the quality level of the parts used in the process (shipped product quality level).
- High hitters are parts known to have a high defect rate.

ICT digital test coverage	9	>98% coverage	6	>95% coverage	3	>90% coverage	0	<90% coverage

- The key to high test coverage is the selection of major components that have built-in testability and a PWB design with 1 test point per net.

Diagnosability	9	≤10 min	6	≤20 min	3	≤30 min	0	>40 min

- Effectiveness of diagnostic tools provided by the card designer influences diagnostic time.

Placement/insertion	6	100% auto	4	≥95% auto	2	≥90% auto	0	<90% auto

- Elimination of manual component placement and insertion reduces process time, defects, and process cost.

Manual attachment	6	100% auto	4	Simple bracket	2	Difficult bracket	0	Post-solder assembly

- Simple bracket = <1 min assembly time
- Difficult bracket = >1 min assembly time
- Post-solder assembly = manual solder operation

Connector selection	4	Auto assembly and retention and keyed	2	Manual and retention and keyed	1	Manual and retention	0	Manual

- Manually inserted connectors that are keyed and have retention reduce defects.
- Prepackaged SMT connectors that can be automatically placed are considered equivalent to keyed with retention.

Handling damage exposure	3	No handling list violations	2	<3 handling list violations	1	<5 handling list violations	0	>6 handling list violations

- Single inline packages (SIPs) > 0.5 in high
- Memory SIMM connectors with plastic latches
- Unshrouded headers over 0.5 in high

Repair	3	100% auto	2	≥90% auto	1	<90% auto	0	<90% auto and difficult

- Auto repair refers to the use of semiautomated repair tools for the removal of large components and connectors.
- A difficult repair is one that takes >10 min.

16.7.2.1 SMT Assembly Report Card. The IBM Assembly Report Card's[13] 10 assembly trade-off factors are shown in Table 16.13. The report card was the work of many assembly engineers with the help of the accounting

department. The report card was introduced in early 1990s; within 2 years, through the use of the report card, assembly point scores were averaging around 75 instead of the earlier 50, with its Gaussian distribution. Remember, higher scores indicate more producibility. This effect can be seen in Fig. 16.17. The scores are no longer normally distributed.

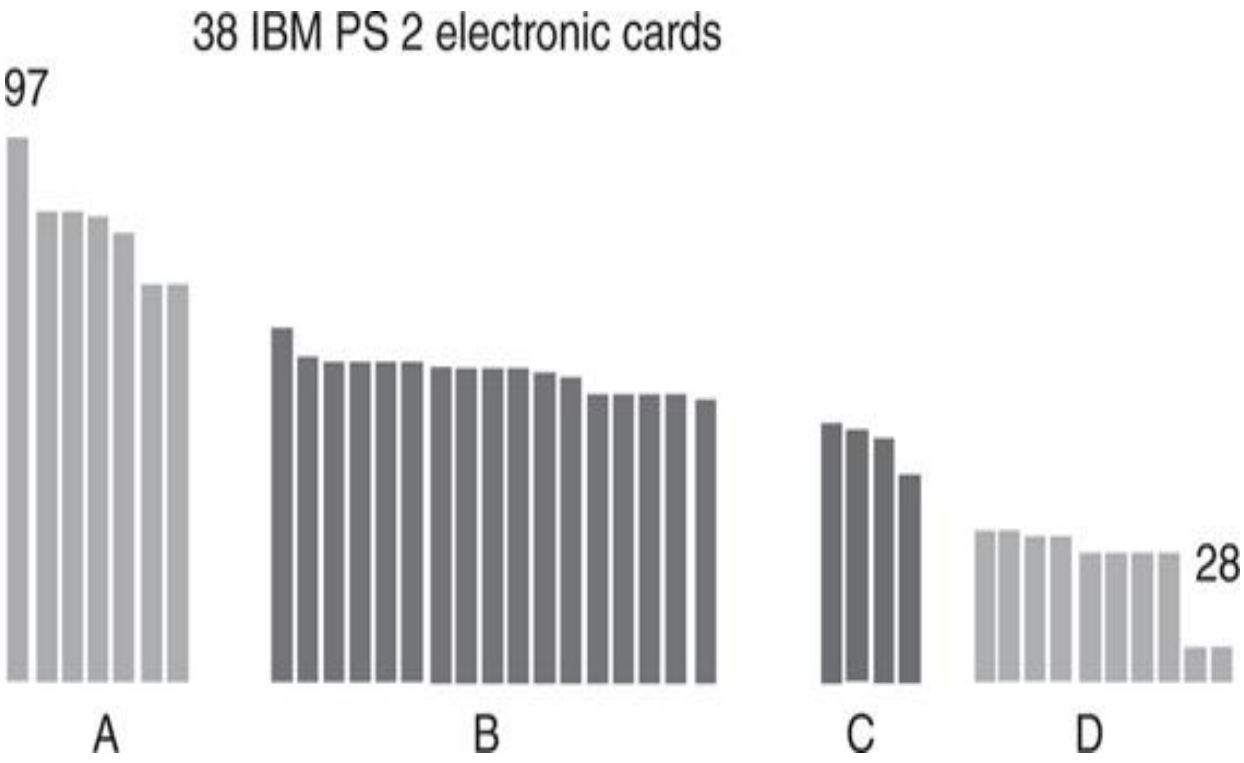

FIGURE 16.17 Improvement in producibility scores as a result of the Assembly Report Card.

CHAPTER 17

PHYSICAL CHARACTERISTICS OF THE PCB

Lee W. Ritchey
Speeding Edge, Napa Valley, California

17.1 INTRODUCTION

Advances in semiconductor technology in the first decade of the 21st century have had a dramatic effect on what can be done in a single integrated circuit. Transistor gate lengths as small as 22 nanometers have made possible integrated circuits with performance at ultra-high speeds and incredible transistor densities.

At the turn of the 21st century the upper limit on transistor count of an integrated circuit was 200 million with data speeds as high as 2.5 gigabit per second (Gb/s) over a single data path. Currently, integrated circuits are commonly made with more than a billion transistors with data rates as high as 28 Gb/s over a single data path.

This advance in integrated circuit technology has made possible products that could only have been imagined a few

years ago. In addition to all of the products that have been in use for many years, two very diverse new product categories have developed around these advances. These are the ultra-density cell phones and tablets that have crept into every aspect of our lives and, driven by these same devices, the ultra high performance routers, switches and servers that provide all of the Internet services.

The first of these has driven component packages to lead pitches as small as 0.4 mm or 16 mils with components on both sides of the printed circuit board (PCB) substrate. This has given rise to buildup PCBs and laser drilled blind vias as small as 0.1 mm or 4 mils. This technology had driven laminate manufacturers to develop ultrathin laminates and prepregs that have glass weaves that are uniformly spread out to improve the quality of laser drilled blind vias.

The effect of these changes is not apparent when one looks at the size of the cell phones and tablets as the external packages remain relatively the same. What these changes have done is make it possible to put entire systems, such as GPS, in the same package with the phone as well as allow the user to surf the Web and watch real-time TV and movies. This is remarkable innovation made possible by improvements in IC technology.

The second of these has driven the performance of routers, switches and servers to unprecedented highs in a very short time period. Figure 17.1 is a terabit router introduced in 2002. It uses half a rack, weights 350 lb (160 kg) and consumes seven kilowatts of power. Figure 17.2 is the same terabit router 5 years later in 2007. It is only 1U high, weighs 22 lb (10 kg) and consumes 700 W.

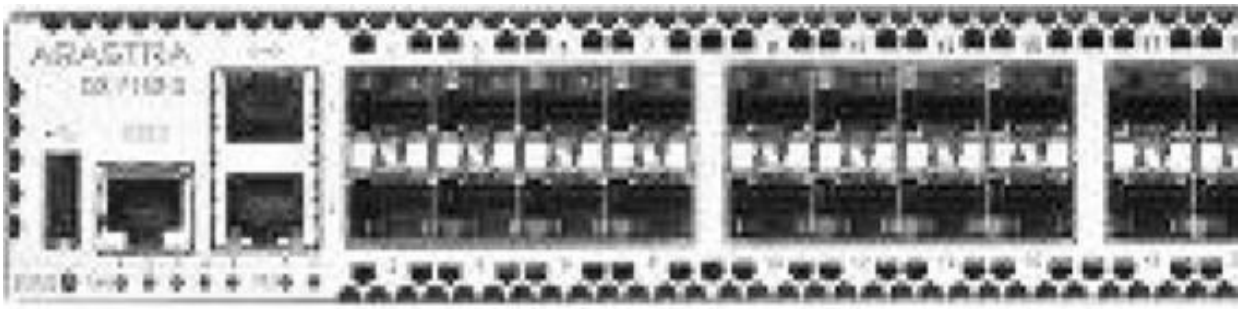

FIGURE 17.1 A terabit router in 2002.

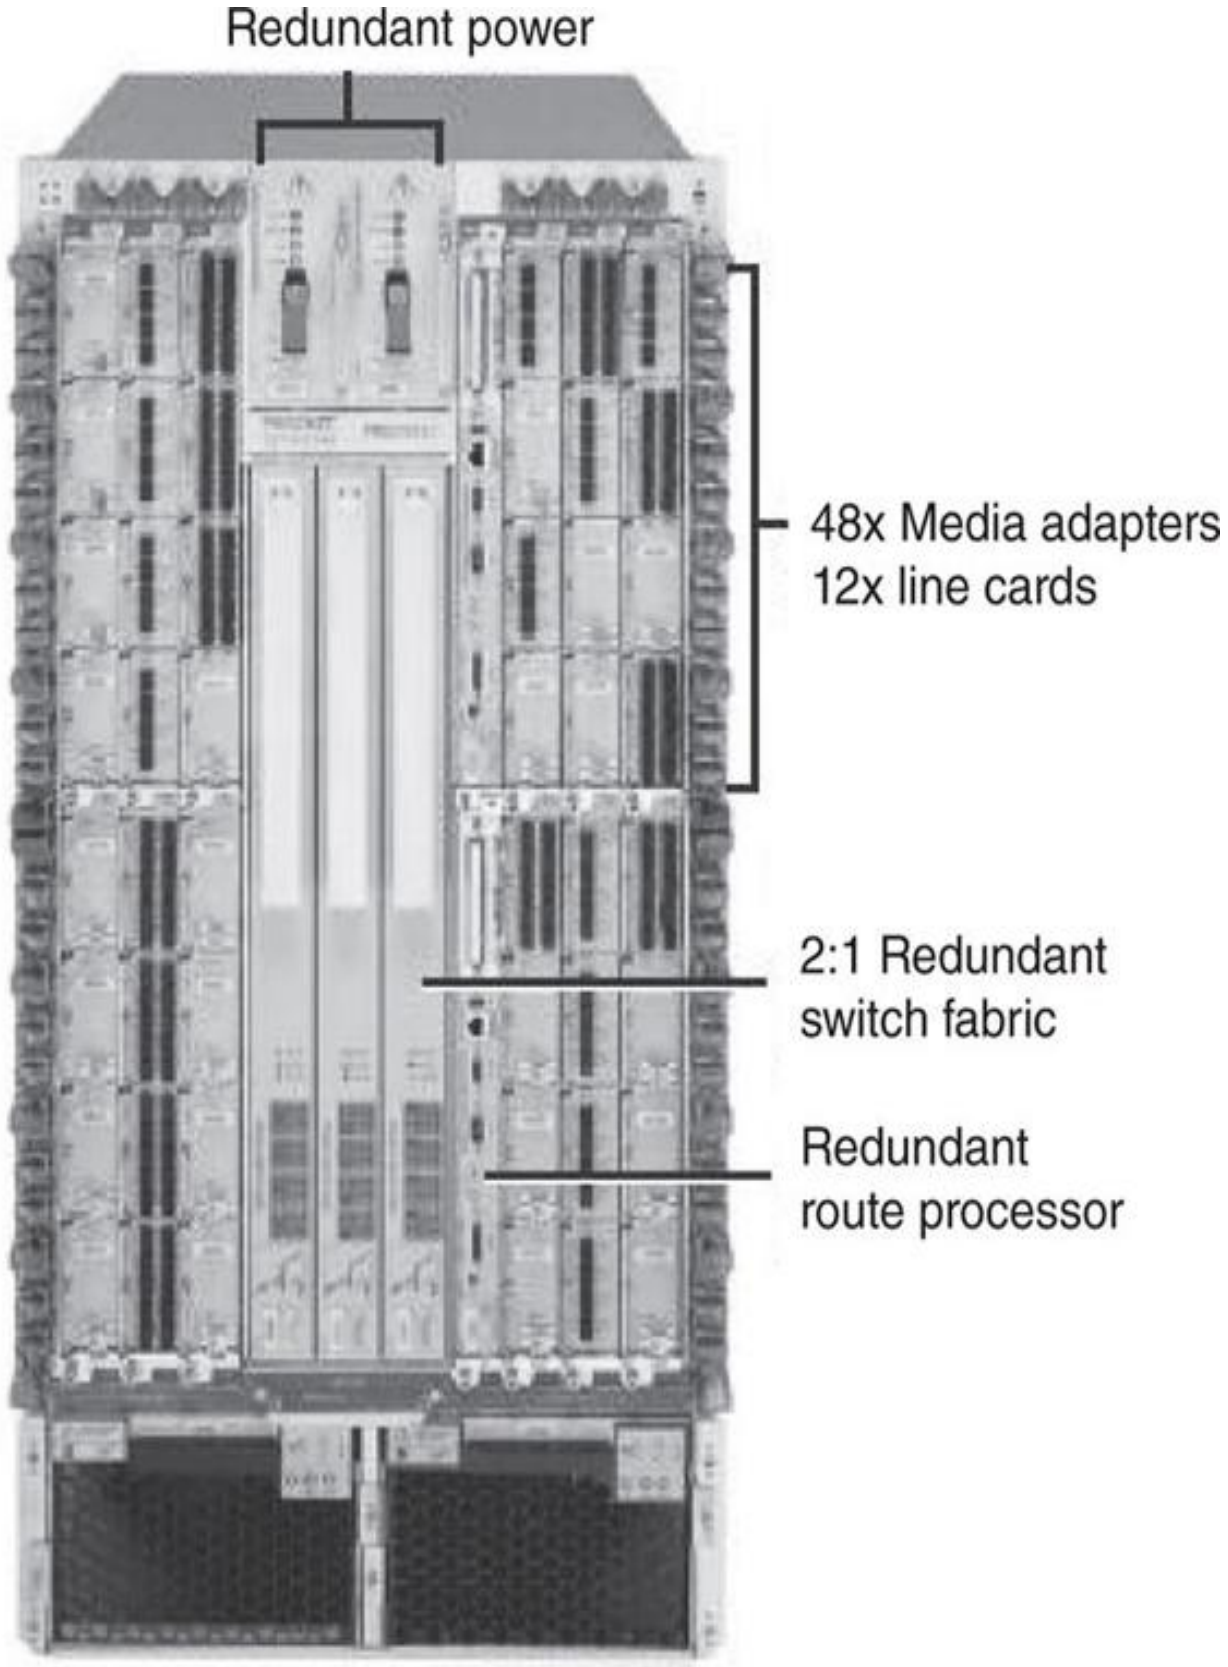

Redundant power
48x Media adapters
12x line cards
2:1 Redundant
switch fabric
Redundant
route processor

FIGURE 17.2 A terabit router in 2007.

More recently, the capacity of the 1U router shown in Fig. 17.2 has increased to 2.5 terabits (Tbs) in the same size package with 32 each 40 Gb/s ports across the front panel. Where technology takes performance seems to have no limits.

The fastest signal on a PCB in the 2002 router was 2.5 Gb/s. The fastest signal on a PCB in the 2007 router is 10 Gb/s. The routers being developed in 2014 will contain signals as fast as 32 Gb/s. These “digital” signals are operating it the frequency band once considered microwave. As a result, laminate considerations that once applied only to RF and microwave are integral to success with these products. Among these are copper loss, loss in the laminates and uniformity of the glass weave, none of which were issues as recently as 2000 with digital products. In fact, demands placed on laminate suppliers by the digital world are more difficult than those by the RF microwave community.

The difference between RF and digital world has blurred as a result of the speed increases in digital electronics. RF and microwave have usually involved signals in excess of a few megahertz while digital was confined to below 100 megahertz. As described above, high performance digital products now operate in the same frequency spectrum as many microwave products, blurring the line between these two technologies.

17.2 TYPES OF PCBs OR SUBSTRATES

Since the last edition of the *Printed Circuits Handbook* many changes have taken place in how PCBs and substrates are made. Some of the technologies such as hybrids, and

multichip modules have nearly vanished from the marketplace. Multiwire PCBs have vanished completely. Others have become commonplace, such as buildup PCBs which are the backbone of every cell phone.

17.2.1 Single and Double Sided PCB

These PCBs have conductor patterns on one or both sides of a base laminate with or without plated through holes to connect circuits on the two sides. These are the workhorse of consumer electronics, automotive electronics, and the RF/microwave industry. They are the lowest cost choice for consumer electronics. Laminate materials range from resin impregnated paper to low loss Teflon™ for RF applications.

17.2.2 Multilayer PCBs

As the name implies multilayer PCBs have more than two layers. Multilayer PCBs with as many as 50 layers have been successfully designed and manufactured. The inner layers may be a combination of signal layers and plane layers used to distribute power to the components mounted on the outside layers. Connections are made between the outer layers and the inner layers with plated through holes or vias. Laminates used to fabricate multilayer PCBs are nearly all composites of woven glass cloth and one of several resin systems. The resin system is chosen to satisfy requirements such as high temperature operation, dielectric loss, dielectric constant, cost and the ability to withstand high humidity or harsh environments such as space or down oil wells.

17.2.3 Flexible Circuits

These circuits are made by laminating copper foil to one or both sides of a flexible substrate such as Kapton® or Kevlar®. They can range from a single conductor layer to multiple layers. They are most often used to replace a wire harness with a flat circuit to save weight and space. Common applications include cell phones, video cameras disc drives and avionics.

17.2.4 Flexible Rigid or Flex-rigid

As the name suggests, these are combinations of flexible circuits and rigid PCBs in a single unit. The flexible portion of the assembly is made first and included in the lamination process of the rigid portion. This process eliminates wiring harnesses associated with connecting PCBs to connectors. The principal applications of this method are aerospace and military electronics where weight and reliability are major concerns.

17.2.5 Backplanes

Backplanes are special cases of multilayer PCBs. In general, the contain large numbers of connectors into which are plugged daughter cards. In most cases, these connectors are press fit into the holes in the back plane as opposed to soldering the pins into the holes. As a result, these PCBs do not get exposed to the high temperatures of soldering and can be much thicker without concern that the plated through holes might fail to *z*-axis expansion.

Most of the backplanes in use at the present time are part of very large routers and switches that are in the backbone of the Internet or server farms. Demands for very high data path bandwidth have driven the signal speeds on these backplanes to as high as 28 Gb/s. At these speeds, the

parasitic capacitance of the plated through holes required by the press fit connectors can degrade performance. As a result, these backplanes are often fabricated by back drilling away the unwanted portions of these plated through holes, further complicating the fabrication process.

Another problem that is encountered with these very high speed backplanes is signal degradation due to the nature of the glass weave used in the laminates as well as loss in the copper due to surface roughness. These will be discussed in the materials section of this chapter.

17.2.6 Buildup Double-Sided PCBs

Buildup PCBs are PCBs that have a multilayer core made using the multilayer fabrication process. Additional layers are added to this core by laminating material to the outside and then connecting circuits on these new outside layers to the inner core using laser drilled or chemically etched blind vias. Figure 17.3 is cross section of a buildup PCB with a six-layer core that has two outside layers added showing the laser drilled blind vias connecting the added layers to the inner core resulting in an eight layer PCB.

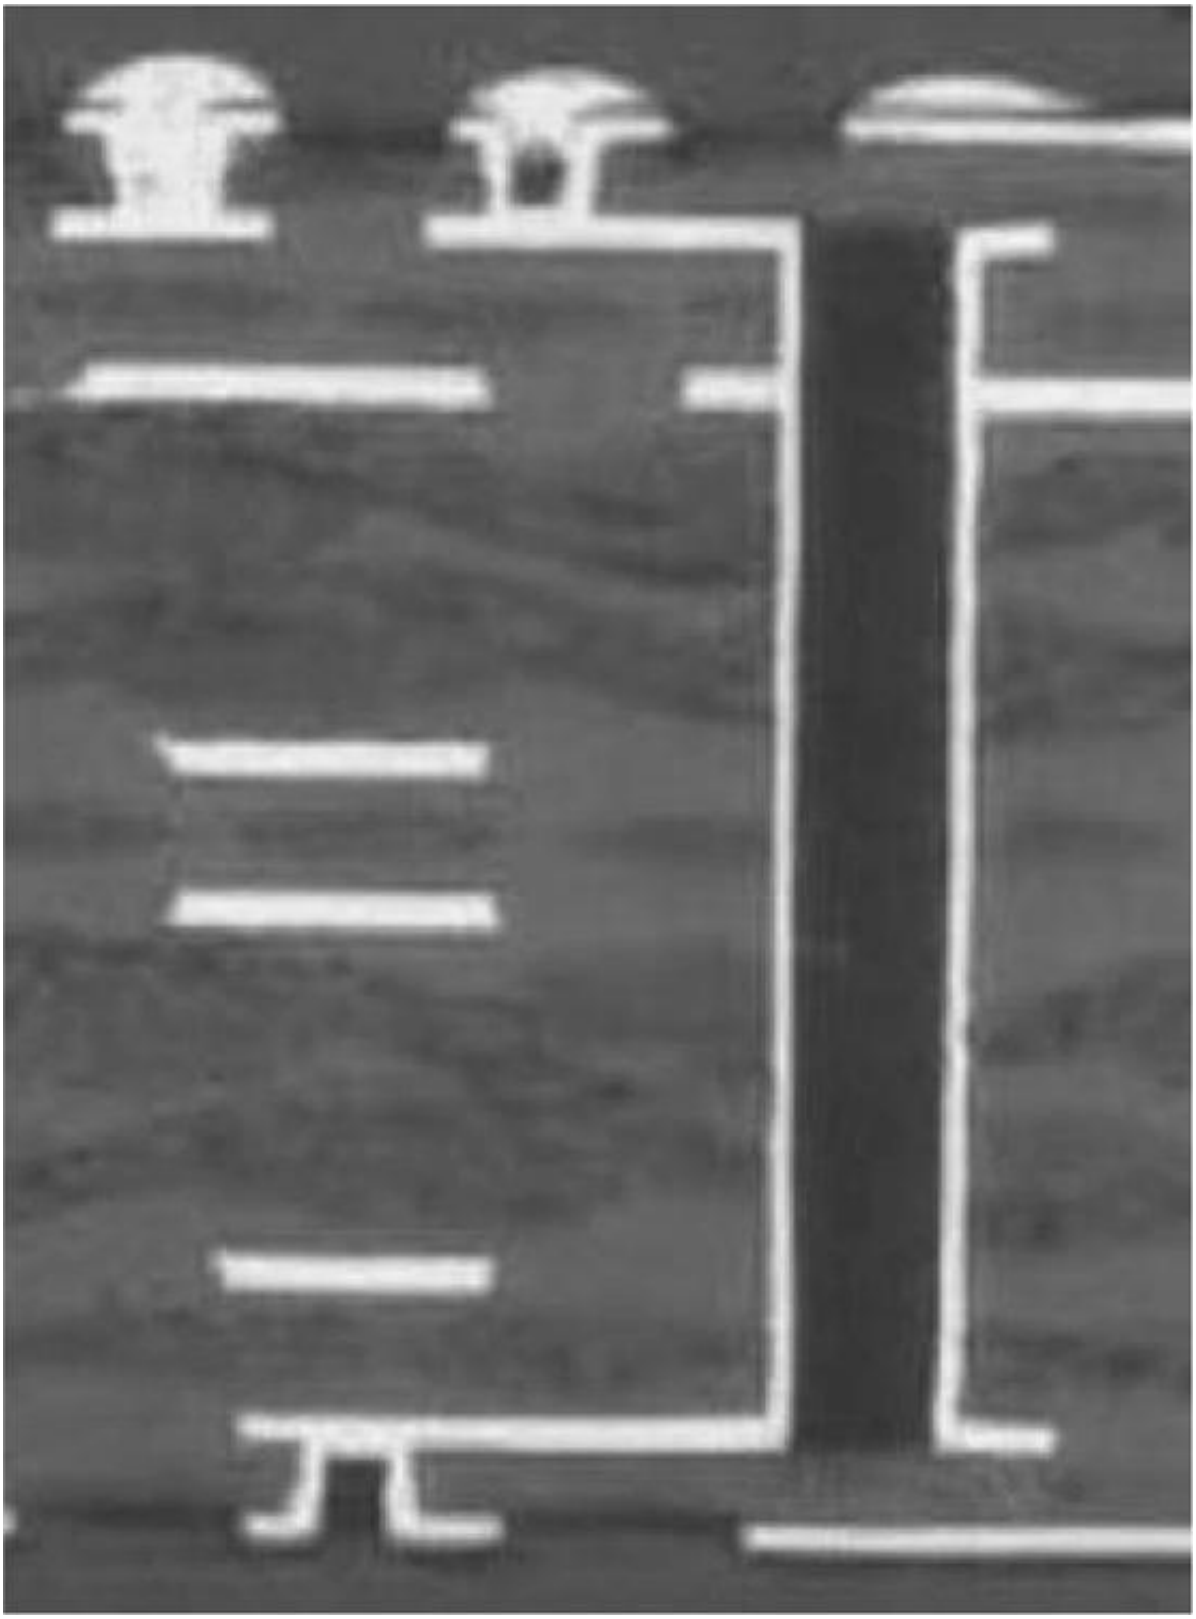

FIGURE 17.3 Cross section of a buildup PCB with a six-layer core and two buildup outer layers.

Clearly, creating an eight layer PCB using this method results in a more expensive assembly than if the eight layers were all created in the assembly process that created the six layer core. The reason that buildup technology is used is to allow components to be mounted on both sides of the PCB so densely that the component leads cannot be connected to internal circuits with through hole vias. This fabrication method is the backbone of products such as cell phones that would not be possible in their current size without it. A second market for buildup PCBs is the multilayer substrates of very high pin count ball grid arrays (BGAs) such as field-programmable gate arrays (FPGAs).

It is common to design buildup PCBs with as many as three buildup layers added to each side of the core.

17.2.7 Multichip Modules

Prior to the recent advances made in integrated circuit manufacturing it was necessary to fabricate analog, RF and digital integrated circuits as different ICs. When a product required a combination of these, they were often mounted as bare integrated circuits in a multichip module. It is now possible to design integrated circuits so that all of these functions are on a single IC. As a result, the need for multichip modules has all but vanished.

17.3 METHODS OF ATTACHING COMPONENTS

A wide range of methods has evolved for attaching components to PCBs. The methods chosen as well as the combinations of methods chosen for a product have a substantial impact on the final cost, ease of assembly,

availability of components, ease of test, and ease of rework. The five basic attachment combinations are: through-hole only, through-hole mixed with surface-mount on one side, surface-mount one side only, surface-mount both sides, and surface-mount both sides with through-hole.

17.3.1 Through Hole Only

All component leads attach to the PCB by being inserted into holes that pass through the PCB. The components may be secured by wave soldering or by pressing into holes that result in an interference fit (press fit). Assembly involves a component placement operation followed by a wave-soldering operation. This method is still the workhorse of the low-cost consumer electronics industry.

17.3.2 Surface Mount Only-Single Sided

This type of package is made up of only surface-mount parts all mounted on the same side of the PCB. Assembly is a one-step process that involves placing all components and soldering them in place using some form of solder reflow.

17.3.3 Surface Mount Only-Both Sides

This type of package contains surface-mount components on both sides. Assembly is a two-step process that involves placing all components on one side and reflow soldering them, followed by placing all components on the other side and reflow soldering them. In addition to more complex assembly operations, designing and testing this type of

assembly is much more complex, as parts often share the same area on opposite sides of the PCB, causing conflicts when trying to locate vias and test points.

17.3.4 Press Fit with Combinations of Above Methods

Components such as connectors and PGAs are attached to the PCB with through-hole technology. All other components are mounted using surface-mount packages. This is the most common method used to assemble electronics products. Assembly is a two-step process that involves placing all surface-mount parts and soldering them in place with a solder reflow system, then inserting all through-hole parts and soldering them in place in a wave-soldering operation. Alternatively, the through-holes may be hand-soldered if the quantity is small.

17.4 COMPONENT PACKAGE TYPES

17.4.1 Introduction

Over time, a wide assortment of packages has been developed to house components. Selecting the correct package type for each component is one of the most important parts of the design process. Package types chosen affect ease of design, assembly, test, and rework, as well as product cost and component availability.

17.4.2 Through Hole–Solder

This class of component is characterized by parts that have wire or formed leads. These leads pass through holes drilled

or punched in the PCB and are soldered to lands on the back side or to plating in the holes. This is the original package type used for electronic components. A major benefit of through-hole components is the fact that every component lead passes all the way through the PCB. Because of this, there is automatic access to any PCB layer to make connections. Further, every lead is available on the bottom of the PCB, so test tooling is easy to construct. With the advent of surface-mount components, through-hole is used primarily for connectors and pluggable devices such as microprocessors mounted in PGA packages.

Through-hole packages are often preferred for ICs and other components that dissipate large amounts of heat, because of the relative ease with which heat-sinking devices can be fitted to them. In addition, it is much easier to provide a socket for a through-hole device. This eases the task of changing programmable parts and microprocessors when it is necessary to upgrade a system.

> *Caution:* Integrated circuits in through-hole packages are becoming difficult to find as they are displaced by surface-mount equivalents and should be avoided in new designs unless a secure supply of components is available for the production life of the design.

17.4.3 Surface Mount

This package type is the mainstream choice for packaging electronic components of every type, including connectors. Its principle characteristic is that all connections between a component lead and the PCB or substrate is made with a lap joint to a pad on the surface of the PCB. This has both advantages and disadvantages. On the advantage side, since there are no holes piercing the PCB, wiring space on inner layers and on the reverse side is not consumed with

component lead holes. Because of this, it is usually possible to wire a PCB in fewer layers than would be true with through-hole parts. Another and larger benefit is the fact that surface-mount components are always smaller than their through-hole equivalent, making it possible to fit more parts in a given area.

The main disadvantages of surface-mount components stem from the fact that there are no leads to easily grip with instrumentation probes and that there may not be access to the leads from the reverse side for purposes of production testing. This gives rise to the need to add a test pad to most nets on the back side in order to perform production test. It also gives rise to the need for very expensive, complex adapters in order to provide access to leads on processors and other complex devices to probe their inputs and outputs when performing diagnostic work.

Yet another disadvantage of surface-mount parts stems from their small size. It is more difficult to remove heat from SMT packages than it is for their through-hole equivalent. In some cases, such as high-performance processors, the heat generated by the IC is too high to permit proper operation in an SMT package.

17.4.3.1 Fine Pitch Leaded. Fine pitch is a special class of surface-mount components. This class is characterized by lead pitches lower than 0.65 mm (25 mils). These fine lead pitches are usually driven by very high lead count ASICs (160 pins and up) or by the extreme miniaturization requirements of PCM-CIA (Personal Computer Memory Card Industry Association) cards, PDAs (personal digital assistants), and other small, high-performance products. The motivation for designating a special fine-pitch-component class of surface-mount parts is the extra difficulty of successfully testing, assembling, and reworking these parts on PCBs, as well as in building PCBs with accurately formed patterns and solder masks to mate with the leads of fine-pitch parts. Fine-pitch

parts are the source of most manufacturing defects in a well-run SMT assembly line. The defects stem from lack of coplanarity of the leads, bent leads, insufficient solder on the joints, and poor alignment of the leads to the patterns on the PCB.

Successful manufacture using fine-pitch components involves very tight cooperation among the PCB designer, the PCB fabricator, the component manufacturer, and the PCB assembler/tester. It almost always involves specialized assembly, test, and rework tooling. Design is most often done by convening a series of meetings of the engineering personnel of all these groups to evolve a set of rules, processes, equipment, tooling, and components. These meetings need to start at the product development stage and continue to be held until the proper pad shapes and sizes have been established and the production process is stable.

17.4.3.2 Ball Grid Arrays. BGA is a relatively new technology that is a cross between pin grid arrays and surface-mount. High-pin-count IC die are mounted on a multilayer substrate made from ceramic or organic material. The die are connected to the substrate using standard wire-bond techniques and encapsulated in epoxy or another form of cover. The bottom side of the substrate contains an array of high-melting-point solder balls which connect to the wire-bond pads through the multilayer substrate. These balls mate with a matching array of pads on the PCB and are reflow soldered during the same operation as all other surface-mount parts. (See Fig. 13.11.)

The appeal of BGA technology is as an alternative to high-pin-count, fine-pitch SMT ICs. As mentioned earlier, assembling high-pin-count, fine-pitch SMT parts is very difficult, owing to the fragile nature of the component leads. BGAs represent a much more robust package during component-level test and during assembly.

As with most technologies, there are some disadvantages to BGAs. Among these are

- The solder joints are hidden from view, so inspecting them requires x-rays.
- The solder joints are not accessible for rework, so the soldering process must have a very high success rate.
- Part removal requires special tooling.
- The pattern on the PCB surface is an array of pads that require one via each all the way through the PCB, hampering routing.
- All component leads are concentrated in a much smaller area than the equivalent part in a fine-pitch SMT package. This concentrates the wiring in a small area pierced with many vias. As a result, the BGA PCB will likely have more wiring layers than the equivalent SMT PCB.
- The BGA package is more expensive than the equivalent fine-pitch SMT package, by as much as three times.

17.4.3.3 Flip-Chip ICs. Flip-chip technology involves plating raised pillars of metal on the bonding pads of ICs, turning them upside down, and attaching them to a matching pattern on a substrate. The substrates are most often silicon and precision ceramics. From this description, it can be seen that this is a very specialized packaging method. To succeed, a source of tested good bare die with plated-on pillars must be available. This situation occurs almost exclusively in very high performance supercomputers where the ICs have been specially designed for the application or in very high volume applications such as pagers and cellular phones.

17.4.3.4 Wire Bonded Bare Die. As the name implies, this method of assembly involves attaching bare IC die directly to a substrate using an adhesive or reflowing solder and connecting the bonding pads to pads on the PCB using

wire-bond techniques. Virtually all digital watches and many other similar consumer products use this assembly technique. It is very inexpensive when used in very high volume products with only a single IC to connect.

17.5 MATERIALS CHOICES

17.5.1 Introduction

The combination of lead-free soldering requirements and the ever increasing frequencies of signals traveling across laminates have resulted in a whole series of new laminate systems that far outperform those that have been in use since the start of PCB fabrication.

17.5.2 Polyimide Systems

Polyimide-based laminate systems were the work horse of applications that required the ability to withstand high operating temperatures and the stress of rework. This is the primary advantage of this resin system. Its disadvantages include more difficult lamination processes, costlier laminate costs and the tendency to absorb enough moisture that an assembly would fail leakage tests unless it was backed dry and coated with a material that served to water proof it. Development in laminate systems have created alternatives that do not have these disadvantages. New designs should not be done using polyimide for these reasons.

17.6 FABRICATION METHODS

A wide variety of fabrication methods has been developed to meet the needs of the electronics industry. The following descriptions are quick summaries of each method intended to acquaint the reader with their advantages and disadvantages and likely applications. Detailed treatments are presented elsewhere in this book.

17.6.1 Punch Forming

Punch forming is used in the manufacture of very low cost, single-sided PCBs such as are used in many consumer electronic products. The process involves printing and etching the conductor patterns on one side of a laminate substrate, usually paper-reinforced epoxy. All holes are punched in a single stroke by a die containing a pin and opening for each hole. The PCB outline is formed in a second die that “blanks” it from the panel in which it is processed.

Often, several PCBs will be contained in a single panel sized to travel through the assembly process. After a PCB is punched out of the panel, it is forced back into the vacant hole and is held in place by interlocking fibers along the edges of the PCB. After assembly and testing is complete, each PCB is pressed from the panel. This is known as *crackerboarding* and is aimed at reducing overall manufacturing costs.

17.6.2 Roll Forming

Roll forming is a process used to manufacture flexible circuits in very large quantities. This is the lowest-cost method for the manufacture of flexible circuits. However, it involves substantial tooling, so it is applicable only for very high volume products. Examples of PCBs manufactured using this method are printer head connections, disk drive head

connections, and the circuits used in cameras and camcorders. The PCBs can be single-or double-sided.

Roll forming resembles newspaper printing in that the process starts with a large roll of copper-clad laminate that is fed through a long process line containing stations which perform each operation on a continuous basis, starting with printing the conductor pattern, etching it, forming the holes, testing, and blanking from the roll itself. The process can include lamination of a cover insulator layer over the conductors as well.

CHAPTER 18

ELECTRONIC DESIGN AUTOMATION AND PRINTED CIRCUIT DESIGN TOOLS

Andy Shaughnessy
Managing Editor, The PCB Design Magazine *and* PCB Design 007, *Seaside, Oregon*

18.1 DESCRIPTION OF PCB DESIGN TOOLS

Electronic design automation (EDA) software tools are used to design printed circuit boards (PCBs), integrated circuits (ICs), and electronic systems. For our purposes, we're primarily concerned with the tools used to design PCBs.

In a nutshell, PCB design software tools are used to turn the concept for a PCB into a finished design, in a data format that manufacturers can use to fabricate and assemble the final PCB.

These are typically Windows-based tools, though a few are native Mac or Linux systems. The tools are built around a

group of software algorithms, detailed sequences of actions that can be used to perform certain tasks. Because algorithms are sequential, processes such as autorouting and simulation can take hours to perform. Graphic processing units (GPUs), made up of hundreds of simple processors, are sometimes used to accelerate specific algorithms.

The underlying code for many of today's PCB design tools was written in the 1990s, and the original code remains. But tool vendors have been updating the software ever since, particularly the graphical user interface (GUI), because of growing demand by PCB designers for more user-friendly systems.

PCB design software tools run the gamut, from free tools that can be used to design simple single-sided boards, to midrange tools in the $10,000 to $20,000 price point, all the way up to enterprise-level tools that cost well over $100,000, not including 15 percent per year for maintenance support.

The free and lower-cost design tools are typically used by do-it-yourselfers and designers of lower-technology PCBs, and they don't have many extra features. Some of these are open-source tools that will never be adopted by a corporation because of security concerns. But the high-end design software suites boast all of the "bells and whistles." Features such as constraint management, DFM functionality, concurrent design, parts library management, and signal integrity and EMC analysis are often integrated into these tools, which are used to design the most complex high-speed PCBs.

PCB design tools have become almost universally modular, allowing customers to purchase only the exact functionality required by the complexity of their PCB designs. For instance, not all companies need the concurrent design function, which allows more than one designer to work on a design simultaneously. But this functionality is critical for larger companies that have design teams working around the clock, and around the globe. See Fig. 18.1.

PCB designers now find themselves working in disciplines that were once firmly in the engineers' realm, such as thermal management, electromagnetic compatibility (EMC), signal integrity, and power integrity. Today, even some of the low-cost EDA vendors are integrating signal integrity capabilities into their tool flows.

18.2 USING PCB DESIGN TOOLS

18.2.1 Schematic Capture Tools

The design process begins when an engineer decides which components must go on the board, and he/she creates a schematic. The schematic can be created with a schematic capture toolwhich is often included in the PCB layout tool platform. This tool has made hand-drawn schematics nearly obsolete.

The advent of modern schematic capture tools has also all but eliminated the need to create a "breadboard" or protoboard before beginning a design. Tools now allow schematics to be created concurrently with the PCB layout. Simulation of the circuit sometimes begins at this early stage.

The design of the entire circuit board is contained in the finished schematic file, which is converted into a netlist. The netlist contains all of the interconnectivity information for the PCB—all of the component footprints, pins and the nets (or nodes) that connect to each pin. The electrical engineer hands off this netlist to the PCB designer.

18.2.2 PCB Layout Tools

The designer loads the netlist into the PCB layout tool. These tools no longer just “connect the dots.” Modern PCB layout software tools prompt users to select the number of layers required, units of measurement (metric or imperial), design constraints, default sizes of copper traces, vias, and clearance, and much more. These tools have become increasingly automated over time.

18.2.2.1 Autorouting. The designer places land patterns (footprints) of critical components and circuits; USB connectors, for instance, must be on the board’s edge for accessibility, while other parts may need to be close to the power source. The rest of the components can then be placed. Many design tools offer advances such as interactive placement replication for components and circuits that are used frequently. Tools often come loaded with components libraries that feature footprints of the most commonly used parts, which minimizes or eliminates the time designers must spend searching third-party sites for components.

After all of the parts are placed, the designer can begin routing the copper traces that will connect the various components. The layout tool’s autorouter software, will take a fraction of the time required for hand-routing but usually only connects about 80 per cent of the nets, with the remaining 20 percent being hand-routed.

On multilayer boards, routing is more complicated because the signal travels from one layer to the next through copper-plated through-holes known as vias. But vias can be routed by hand or with any of today’s autorouters.

18.2.2.2 Design Rules Check. After routing is finished and the board is cleaned up, the designer then checks for errors. Most PCB design tools include a design rules check (DRC) that checks the whole PCB for errors, such as traces that touch, holes that are too small, etc.

18.2.2.3 Data Transfer. During postprocessing the design file is translated intoa data transfer format that PCB manufacturers can use to fabricate and assemble the board. For decades, the majority of PCB designs have been output in Gerber, a machine control language (now owned by Ucamco) that was never intended for this task. As such, Gerbers don't contain all of the information the fabricator needs, so the designer must also send the fabricator separate NC (numerical control) drill files and other documentation.

Relative newcomers ODB++ and IPC-2581are single-file formats which contain all of the information necessary to fabricate and assemblea PCB. ODB++ is owned by Mentor Graphics; IPC-2581 is vendor-neutral. Some OEMs handoff design data in more than one format, but despite its limitations, Gerber is still the most popular data transfer format.

18.2.3 Signal Integrity and EMI/EMC Software Tools

Signal integrity simulation and analysis software tools are relative newcomers to the PCB design community. Until the late 1990s, most PCB designers didn't worry much about signal integrity. Rise times (the time required for a signal to rise from 10 to 90 percent of its final value) were not fast enough to be a problem on most boards. But with today'sincreased rise times and clock speeds, even short traces can become victims of crosstalk, ringing, and ground bounce.

Signal integrity tools allow the user to calculate atiming budget and address impedance mismatches, which contribute to reflections and crosstalk. Now, signal integrity tools provide pre-layout and postlayout simulations, often bundled into the design tool itself, so the designer can begin

simulating circuitsat the schematic level before committing to the final design. These tools can help designers avoid SI problems early in the process by choosing, for instance, the best layer stackup for the board.

Similarly, electromagnetic interference (EMI) was not much of a challenge until fairly recently. EMI on a PCB generally refers to the radiated emissions that emanate from wires, cables, or other parts of the board that serve as unintended antennas. These emissions may interfere with otherelectronic devices, which is frowned upon by the Federal Communications Commission and other regulatory organizations around the globe.

EMI tools include electromagnetic field solvers and circuit solvers. These tools are used to simulate the EMI behavior of rise and fall times, clock frequencies, andswitching rates, across the system’s frequency range. These often-pricey tools allow designers and engineers to make tradeoffs between the drive for EMC and budget-straining design constraints. As is the case with signal integrity, potential EMI challenges are best addressed as early in the design cycle as possible. EMI can keep your end-product from reaching the marketplace if the PCB or system fails the electromagnetic compliance (EMC) testing required by the FCC.

18.3 MAJOR PCB DESIGN TOOLS

The major PCB design software tools are used by global OEMs to design complex PCBs for the most sophisticated electronic products. Some of these enterprise-level tools offer capabilities for multiboard and system design, along with concurrent design and partitioning for companies with geographically diverse design teams. Many of these tools have a fairly steep learning curve. The enterprise-level EDA tool vendors are primarily publically traded companies.

18.3.1 Mentor Graphics—Xpedition and PADS

18.3.1.1 Xpedition. Mentor Graphics acquired Xpedition when Mentor merged with VeriBest in 1999. Formerly known as Expedition, the expanded Xpedition Enterprise platform includes everything from schematic capture through DFM tools. (Mentor also offers the Xpedition Package Integratorplatform for IC packaging teams). Xpedition is a complete integrated design flow platform. It shares a common constraint definition between schematic capture and layout. Features include design data management, an integratedplace-and-route editing environment, interactive sketch routing, and an RF module; it can handle embedded passives, microvias, and flex designs. Xpedition supports concurrent team layout and MCAD collaboration, and is integrated with Valor's DFM flow, including DFF analysis rules. The HyperLynx signal and power integrity tool is integrated into Xpedition. See Fig. 18.2.

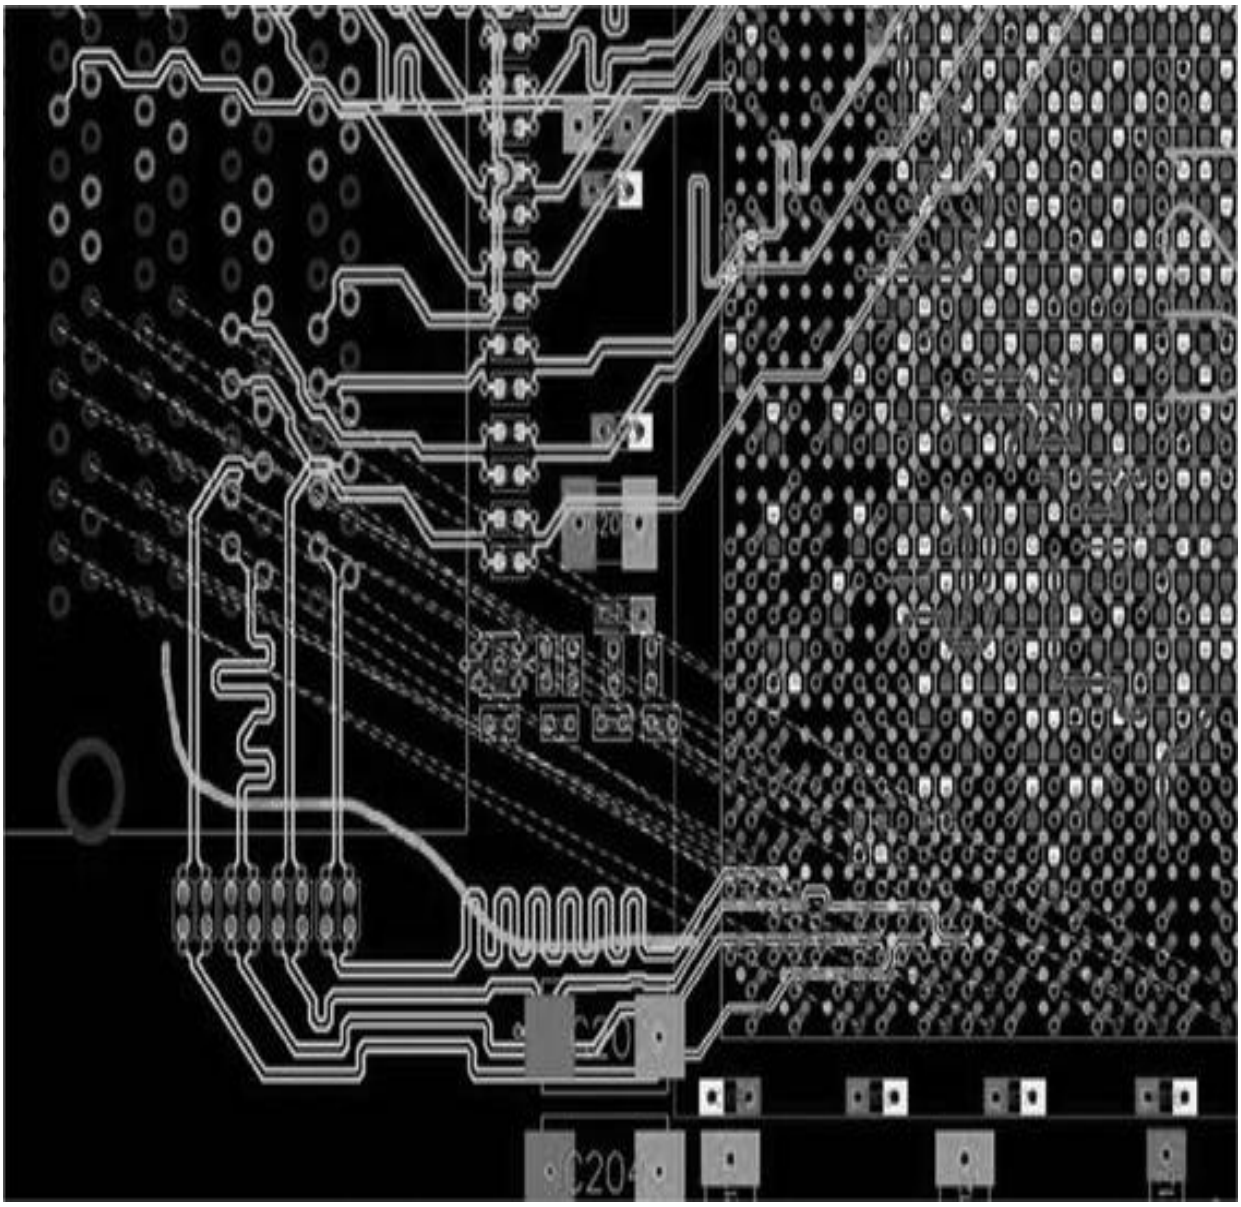

FIGURE 18.2 A screen shot of a PCB design created with Mentor Graphics' Xpedition. (*Courtesy of Mentor Graphics*.)

18.3.1.2 PADS. PADS Software was founded in 1977 by industry icon Gene Marsh, who was also involved in the early years of Racal-Redac. Now part of Mentor Graphics after a series of mergers, the PADS design software tool is still beloved by longtime users for its user-friendliness.

Not quite as sophisticated as Xpedition, PADS can still handle complex designs, though it offers fewer features and options than its big brother. PADS is known for its fairly quick

learning curve, and it's one of the most widely used PCB layout tools today. PADS includes schematic design, library management, constraint management, pre- and postlayout signal integrity analysis, and ECAD-MCAD collaboration tools. The layout tool features push-and-shove route editing, design reuse, cross-probing between schematic and layout, and it supports RF, differential pairs, nested vias, and virtual nets.

18.3.2 Cadence Design Systems—Allegro and OrCAD

18.3.2.1 Allegro. Cadence Design System's Allegro suite was developed to handle the most complex high-speed designs. The Allegro platform includes tools for simulation, design authoring, design publishing, FPGA-PCB co-design tools, and signal and power integrity tools (from the acquisition of SI tool company Sigrity).

Allegro PCB Designer is a scalable constraint-driven design environment. It includes a front-to-back constraint management tool and a complete placement and routing environment with placement replication, advanced interconnect planning, and signal and power integrity simulation. Design tool features real-time plowing/healing with dynamic shape technology, interactive push/shove etch editing, RF/analog and mixed-signal design, interactive floorplanning, hierarchical route planning, and design partitioning.

18.3.2.2 OrCAD. OrCAD Systems Corporation was founded in Hillsboro, Oregon in 1985, developing a line of tools for PCB layout, verification and simulation, and FPGA design. The company gained a PCB layout tool and autorouter from its acquisition of Massteck in 1995, and the PSpice simulation tool from its merger with MicroSim in

1997. OrCAD went public in 1996 and was itself acquired by Cadence in 1999.

The OrCAD lineup includes a variety of design tools, from the free OrCAD Lite through the OrCAD PCB SI signal integrity simulation tool. OrCAD PCB Designer Professional features placement and circuit replication, differential pair simulation and routing support, interactive floorplanning, blind and buried via support, a schematic part and library editor, and pre- and postroute signal integrity analysis. A variety of apps are available for OrCAD. The OrCAD Capture schematic capture tool remains a favorite in the design world, even among designers who use competing tools for PCB layout.

18.3.3 Zuken—CR-5000, CR-8000, and CADSTAR

18.3.3.1 CR-5000. CR-5000 is Zuken's most advanced design software for single board design. Features include concurrent PCB and FPGA design, constraint-driven design with DFM verification, support for design variants and version control, circuit rules check, and EMC, signal and power integrity analysis. The Dragon autorouter was designed to reduce the set-up time required by some autorouters. It generates routing strategies based on checks run by its "routing consultant." The router is optimized for high-performance, high-density routing, and routes differential pairs to reduce skew and uncoupled length.

18.3.3.2 CR-8000. CR-8000 is a system-level, multiboard product-centric design tool built from the core of CR-5000. But CR-8000 allows users to design the whole product, as well as multiple PCBs. CR-8000 adds Design Force, a native 3D graphics tool offering improved product visualization to help designers see the impact of changes upon the final

product. It comes equipped with a tablet for two-handed design, allowing users to pan and zoom with the tablet in one hand while working with a mouse in the other.

18.3.3.3 CADSTAR. CADSTAR started out as more of an entry-level layout environment, but over the years it hasacquired some of the features of its big brothers. Developed for single PCBs, CADSTAR now offers a complete flow from schematic to output, with 3D mechanical integration, signal integrity simulation, power integrity analysis. CADSTAR's place-and-route editor has a grid-free, spatial data structure and rules-driven architecture. It is also available in a free version.

18.3.4 Altium—Altium Designer

Altium's PCB design tools reside on the lower end of the price-point scale, but they manage to offer some capabilities normally seen in higher-end rival tool sets. Its ECAD-MCAD integration permits users to import 3D STEP models directly into the PCB design environment. Altium Designer can handle high-speed, mixed-signal PCBs, and features design verification, validation, and reuse capabilities. It has a unified schematic and PCB design tool, with native 3D modeling, and it's optimized for rigid-flex design as well.

18.3.5 Intercept Technology—Pantheon

Intercept Technology began in 1983 as an R&D company, and moved into EDA by developing CAD translators. Intercept offers a full range of PCB, RF, and hybrid design tools. The Pantheon layout tool was introduced in early 1996 and underwent a full GUI update in 2011. It offers a 3D

design environment, auto-interactive routing, concurrent design capabilities, and DFM verification through design rule checks, engineering rule checks, and manufacturing rule checks.

18.3.6 Keysight Technologies (Formerly Agilent EEsof)—EDA ADS

Agilent, itself a Hewlett-Packard spinoff, spun off its electronics measurement and EDA businesses as Keysight Technologies. Keysight's EEsof EDA Advanced Design System is an RF, microwave and high-speed design environment targeted at wireless communications, networking, and mil-aero companies. ADS offers schematic, layout, electro-thermal co-simulation, X-parameter model generation, and three full-wave, native 3D electromagnetic technologies for laminate/PCB, IC, package, and 3D EM co-design.

18.3.7 National Instruments—Ultiboard and Multisim

The Ultiboard layout tool and Multisim schematic capture tool were developed by the Canadian company Electronics Workbench, which National Instruments acquired in 2005. Multisim was soon integrated with NI's existing LabVIEW graphical programming platform. Primarily aimed at the education market, Ultiboard and Multisim are also available in professional-level packages for PCB designers and researchers.

18.4 LOWER-COST PCB DESIGN TOOLS

These desktop-level design tools offer some of the capabilities of their enterprise-level cousins, but at a fraction of the cost. Usually developed by private companies, these layout tools are a favorite of the “do-it-yourself” and hobbyist communities, but some are even used by PCB designers at the corporate level. These tools don’t typically offer higher-end capabilities such as HDI (high-density interconnect), concurrent design, or multiboard design, but the learning curve is minimal.

18.4.1 Labcenter Electronics—Proteus

Labcenter’s Proteus PCB design platform offers a variety of capabilities, with prices for some packages starting at several hundred dollars. Features include schematic capture, PCB layout, SPICE simulation, a shape-based autorouter, design/connectivity rule checking, and 3D visualization.

18.4.2 CadSoft—Eagle

CadSoft’s Eagle PCB design tool serves both the professional and teaching communities, with prices starting under $100. Eagle (Easily Applicable Graphic Layout Editor) features a schematic editor, layout editor, and an integrated design rules-driven autorouter with ripup-and-retry. Eagle is also popular withthe DIY audience, in part due to its availability in Linux. Also available in a free package for hobbyists and students.

18.4.3 Westdev Ltd.—Pulsonix and Easy-PC

18.4.3.1 Pulsonix. Pulsonix is an integrated schematic capture and PCB design editor. It includes an autorouter, SPICE-based simulation, hierarchical schematics, via stitching, chip-on-board capabilities, the ability to add fanouts to existing BGA footprints, and differential pair broadside coupled pairs. Pulsonix also supports blind and buried vias, embedded components, and rigid-flex designs.

18.4.3.2 Easy-PC. Easy-PC includes some of the capabilities of Pulsonix, but it's targeted more at the educational and hobbyist markets, and at a reduced price point. Features include a bill of materials composer, online DRC, SPICE simulation, integrated autorouter and placement, forward and backward annotation, and cross-probing between schematic and PCB layout.

18.4.4 DEX2020—AutoTRAX

AutoTRAX is the brainchild of one man, Iliya Kovac, who developed the entire design tool himself. Built on an open-format XML file structure, it features schematic capture, PCB layout, a hierarchical project manager, and design reuse capabilities.

18.4.5 Visionics—EDWinXP

Visionics, a subsidiary of Norlinvest Ltd., offers a range of software tools, from EDA to documentation and programming. The EDWinXP design tool features a schematic editor, mixed-mode and SPICE simulation, PCB layout editor, fabrication manager, EM analyzer, 3D library editor, automatic component placement, autorouter, and design rules checking.

18.4.6 IBF—TARGET 3001

TARGET 3001 is a descendant of the company's RULE layout tool, a DOS program released in 1989 and adopted by European hobbyists. TARGET 3001 features SPICE-based simulation, 3D viewing, an autorouter, and a component management system. It supports rigid-flex, chip-on-board technology, assembly variations, and RoHS-compliant design. Toyota used TARGET 3001 to design cable harnesses in their Formula 1 car.

18.4.7 Novarm—DipTrace

Novarm was founded in 2002 by engineering graduates of Ukraine's National Mining University. The DipTrace PCB design suite includes features such as cross-module library management, STEP and IGES 3D import/export, real-time design rules check, shape-based autorouter with support for third-party routers, 3D modeling, and a newly revamped GUI.

18.5 FREE PCB DESIGN TOOLS

Free PCB design tools comprise one of the most interesting segments in EDA tools. It's easy to see why this group continues to grow: Most hobbyists and do-it-yourselfers do not want, or need, to purchase a full-featured PCB design tool, and many PCBs still have fewer than 10 layers. Some of these are proprietary tools offered by fabricators as value-adds to draw manufacturing business; others are developed by open-source software groups, with thousands of members offering feedback. This segment is worth watching.

18.5.1 Altium—CircuitMaker

CircuitMaker is Altium’s big move into the free and low-cost PCB design software market, and some users find it has much of the feel of the full-featured Altium design tools. The free extensible base programincludes 3D design and analysis, and add-ons are available at a cost. Users can collaborate online and comment on designs in real time, and designs are saved to the cloud.

18.5.2 Sunstone Circuits—PCB123

Introduced by Sunstone Circuits in 2002 as value-add to its prototype fabrication business, PCB123 has developed into a full-featured PCB layout tool. It was developed to create designs specifically for Sunstone to build, so PCB123 won’t output a Gerber file that you can take to another fabricator. It provides real-time quotes for parts and fabrication during design, and Sunstone guarantees on-time shipping for orders created with PCB123.

18.5.3 ExpressPCB

ExpressPCB is a prototype manufacturer, and it’s also the name of the company’s free PCB design software. ExpressPCB software includes the ExpressSCH schematic tool, and it allows users to design a two-layer or four-layer PCB, with instant quotes available when the design is finished. Designers can order PCBs directly from the ExpressPCB program.

18.5.4 Advanced Circuits—PCB Artist

PCB Artist is a free PCB design program operated by quickturn fabricator Advanced Circuits. PCB Artist is equipped with a schematic tool, PCB layout tool, backward/forward design integration, autoplacement, single-sided autorouting, DRC error reports, and improved copper pour.

18.5.5 KiCad—EDA Software Suite

KiCad is an open-source PCB design software suite. It runs on FreeBSD, Linux, Windows, and Mac OS X. It works with a variety of component libraries, and can import components from other EDA tools. KiCad includes features such as schematic capture, a PCB layout editor, an autorouter, and 3D viewer.

18.5.6 RS Components—DesignSpark PCB

DesignSpark PCB is a free PCB layout tool available through RS Components and Allied Electronics. The program displays an advertisement each time the program is restarted. It can design PCBs up to 1 sq. m in size. Comes equipped with schematic capture, PCB layout editor, and autorouter. DesignSpark PCB can generate a bill of materials automatically, and it currently boasts over 200,000 users.

18.5.7 ZenitPCB—ZenitPCB Layout

ZenitPCB is freeware for personal or semi-professional use on single- and double-sided PCBs up to 800 pins. It allows hobbyists to import a netlist file from other schematic capture programs such as OrCAD, PADS, Multisim, or Eagle.

Features schematic capture, a PCB layout tool, an online DRC, and a component library with over 1000 footprints.

18.5.8 Osmond—OsmondPCB

OsmondPCB design software is available only for Mac users. It’s free for users creating designs with fewer than 700 pins, with an inexpensive license required to output Gerber files for designs above 700 pins. Allows designers to work in metric or imperial units, and is compatible with DesignWorks’ schematic capture.

18.5.9 gEDA—gEDA PCB

The gEDA project was launched in 1998. The group has created a full, open-source suite of free EDA tools for electrical circuit design, schematic capture, analog and digital simulation, and PCB layout. Each tool is independent of the rest, and some have been developed into more full-featured tools than the others.

18.5.10 Fritzing—PCB View

Fritzing is a publically funded, open-source software group that supports PCB designs up to two layers, primarily for hobbyists. With Fritzing, designers can take a simple breadboard circuit, copy it into the program, and then create a schematic and PCB artwork. Fritzing permits manual routing and autorouting, generates a bill of materials, and can export Gerber files or etchable PDFs for DIY production.

18.5.11 EasyEDA—EasyEDA Editor

Developed by a self-described “tiny hackers team,” EasyEDA is a free Web-based EDA suite. It integrates schematic capture, PCB layout, and SPICE simulation. Because it’s Web-based, there’s no installation involved, and all data resides in the cloud. EasyEDA is integrated with the DangerousPrototypes open-source parts libraries.

18.6 SIGNAL INTEGRITY AND EMC TOOLS

These third-party simulation and analysis tools are primarily targeted at global electronics OEMs. (The major PCB tool companies have all integrated signal integrity capabilities into their design flows, including Mentor’s HyperLynx and Cadence’s Sigrity) These tools are generally sophisticated and costly, and usually used by designers and engineersdeveloping high-speed, complex PCBs for cutting-edge electronic products.

18.6.1 SiSoft—Quantum Channel Designer and Quantum-SI

18.6.1.1 Quantum Channel Designer. Signal Integrity Software (SiSoft) started as a high-speed design consulting company in 1995, and began developing their own tools in-house. Quantum Channel Designer provides system-level design and analysis for multigigabit serial links. It offers statistical, time-domain, and crosstalk analysis, and can run thousands of simulation experiments to investigate design tradeoffs and their impact.

18.6.1.2 Quantum-SI. Quantum-SI offers integrated signal integrity, timing, and crosstalk analysis, providing pre-

and post-layout simulations with waveform processing. It analyzes the whole design for composite effects of SI, crosstalk, and timing. Quantum-SI can conduct SI and timing analysis at the chip's core, the pad of the I/O, or the pin of the package of the source and target components.

18.6.2 ANSYS—HFSS and SIwave

18.6.2.1 HFSS. ANSYS acquired the Carnegie Mellon spinoff Ansoft in 2008, gaining that company's famed HFSS (High-Frequency Structural Simulator) finite element method solver. Used to simulate 3D full-wave electromagnetic fields, HFSS can be used to solve a variety of RF, microwave, and high-speed challenges. It allows engineers to evaluate signal integrity and electromagnetic interference in connectors, transmission lines, and vias on PCBs.

18.6.2.2 SIwave. SIwave is a design platform for signal and power integrity, and EMI analysis of PCBs and packages. It features hybrid field solver technologies, which permit frequency-domain and time-domain analyses in planar structures. It can conduct resonance mode analysis to help determine impedance variations between the planes of a PCB.

18.6.3 Polar Instruments—Si9000e

Polar Instruments offers a wide range of tools for signal integrity and controlled impedance design. The Si9000e is a PCB transmission line frequency-dependent boundary element field solver that models transmission line loss and impedance at given frequencies. It extracts RLGC matrices and plots a range of transmission line information for your PCB. Si9000e is also available integrated with Polar's Speedstack stackup design tool and documentation system,

allowing designers to create the best layer stackup for achieving signal integrity.

18.6.4 CST—CST Studio Suite

Computer simulation technology (CST) has developed a variety of signal integrity and EMC software tools, most of which are available in the company's flagship tool platform. CST Studio Suite allows users to perform signal integrity and EMC/EMI simulations while designing PCBs, cable harnesses, antennas, and filters. It also includes 3D circuit co-simulation and synthesis, and tools for thermal and mechanical stress analysis.

18.6.5 Sonnet Software—Sonnet Suites

Sonnet Software's tools are designed primarily for high-frequency RF and microwave electromagnetic analysis of PCBs and other applications. Sonnet Suites offers electromagnetic modeling of all PCB layout details, including parasitics and cross-coupling. Features include calibrated internal ports and a netlist interpreters, which permit S-parameters to be incorporated into EM simulation.

18.6.6 E-System Design—Sphinx

E-System Design was founded in 2009 around the Sphinx signal and power co-simulator. Sphinx is a signal and power frequency domain solver for PCBs, IC packages, and electronic systems. Based on the Multilayer Finite Difference Method (M-FDM), it takes into account all layer coupling

effects, and lets users perform “what if” analysis by adding layers, vias, and capacitors.

18.6.7 IBM/Moss Bay EDA—EMSAT

IBM’s EMSAT is an EMC rule-checking program for PCB designs; Big Blue requires that all of its new PCB designs be checked with EMSAT. EMSAT EMC and signal integrity tools offer a postlayout check for common violations that lead to EMC and SI degradation. Moss Bay EDA, the exclusive distributor for EMSAT, has partnered with Intercept Technology to pair EMSAT with Intercept’s Pantheon viewer, which displays any violations.

18.6.8 EMS Plus—FEMAS

EMS Plus’ Fast Electromagnetic Analysis Suite (FEMAS) is based on full-wave solutions to Maxwell’s equations. It features a 2D cross-sectional analysis tool, which allows users to find impedance, coupling, and S-parameters for PCB sections. RLGC matrices can be found as a function of frequency and converted to S-parameters. Link path analysis permits S-parameter file concatenation, time-domain analysis, and frequency-domain analysis.

18.7 KEY QUESTIONS TO CONSIDER

The following is a list of questions one might ask the various EDA tool vendors regarding their PCB design tools. When you are benchmarking software within a group of similar EDA tools, or between different groups of tools, keep these points in mind:

- How is the purchase price structured and what features come with each price structure? What are the annual support costs for each tool’s structure?
- How easy is it to enter schematics and electrical net features?
- How easy is it to enter, update and maintain the library of components for the tool?
- How easy is it to update, edit or change the electrical characteristics of each net?
- What other softwaretools (yours and third-party)interface with this tool? Is the transfer interactive, batch or one-way?
- How user-friendly is the user interface regarding toolbars, drop-down menus, short-cuts, etc.?
- What options are available for timing, bus routing and autorouter control?
- What options are available for stackup creation, via constructions, trace entering pads, and impedance calculations?
- How detailed are the DRCs, and do they have various levels to define dimensions?
- Can the DRC used on the final artwork version be sent to vendors?
- Does the manufacturing output cover the three major formats, Gerber, ODB++ and IPC-2581?
- How much work is required to update designs for different software revisions?
- Can designs or parts of the design be saved and reused on other designs?
- Can designs be modified and controlled for different parts or schematic options?
- What tools are available to do gate and pin swaps for FPGAs?

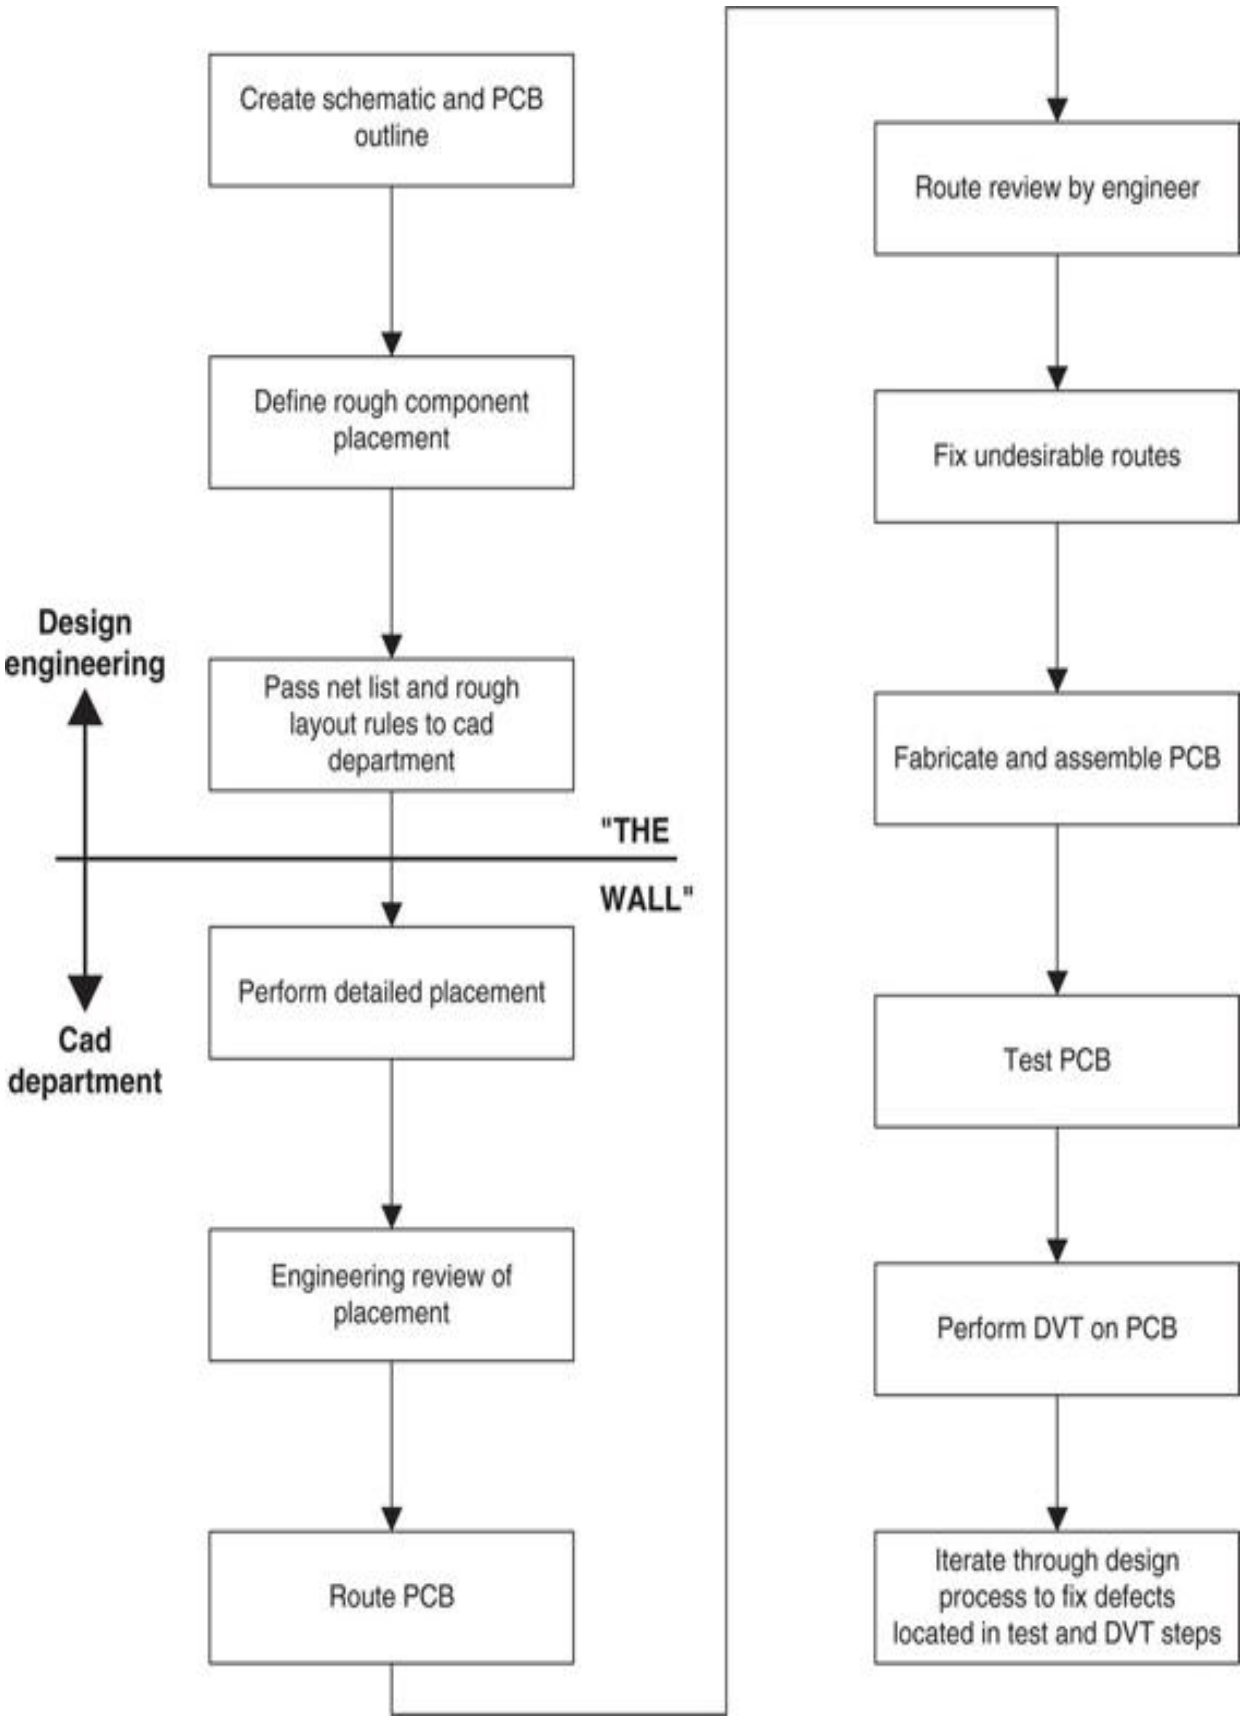
CHAPTER 19
THE PCB DESIGN PROCESS

Lee W. Ritchey
Speeding Edge, Napa Valley, California

19.1 INTRODUCTION

There are two common methods for designing printed circuit boards (PCBs). These are to build a hardware prototype and check it out on the bench to see if it works, or, to simulate all aspects of the design prior to building it to maximize the likelihood that signal integrity, power delivery, thermal management, logic accuracy and timing stability are adequate to assure proper operation over all likely operating conditions. Figure 19.1 is a typical hardware prototyping design process.



Create schematic and PCB outline
Define rough component placement
Design engineering
Pass net list and rough layout rules to cad department
"THE WALL"
Perform detailed placement
Cad department
Engineering review of placement
Route PCB
Route review by engineer
Fix undesirable routes
Fabricate and assemble PCB
Test PCB
Perform DVT on PCB
Iterate through design process to fix defects located in test and DVT steps

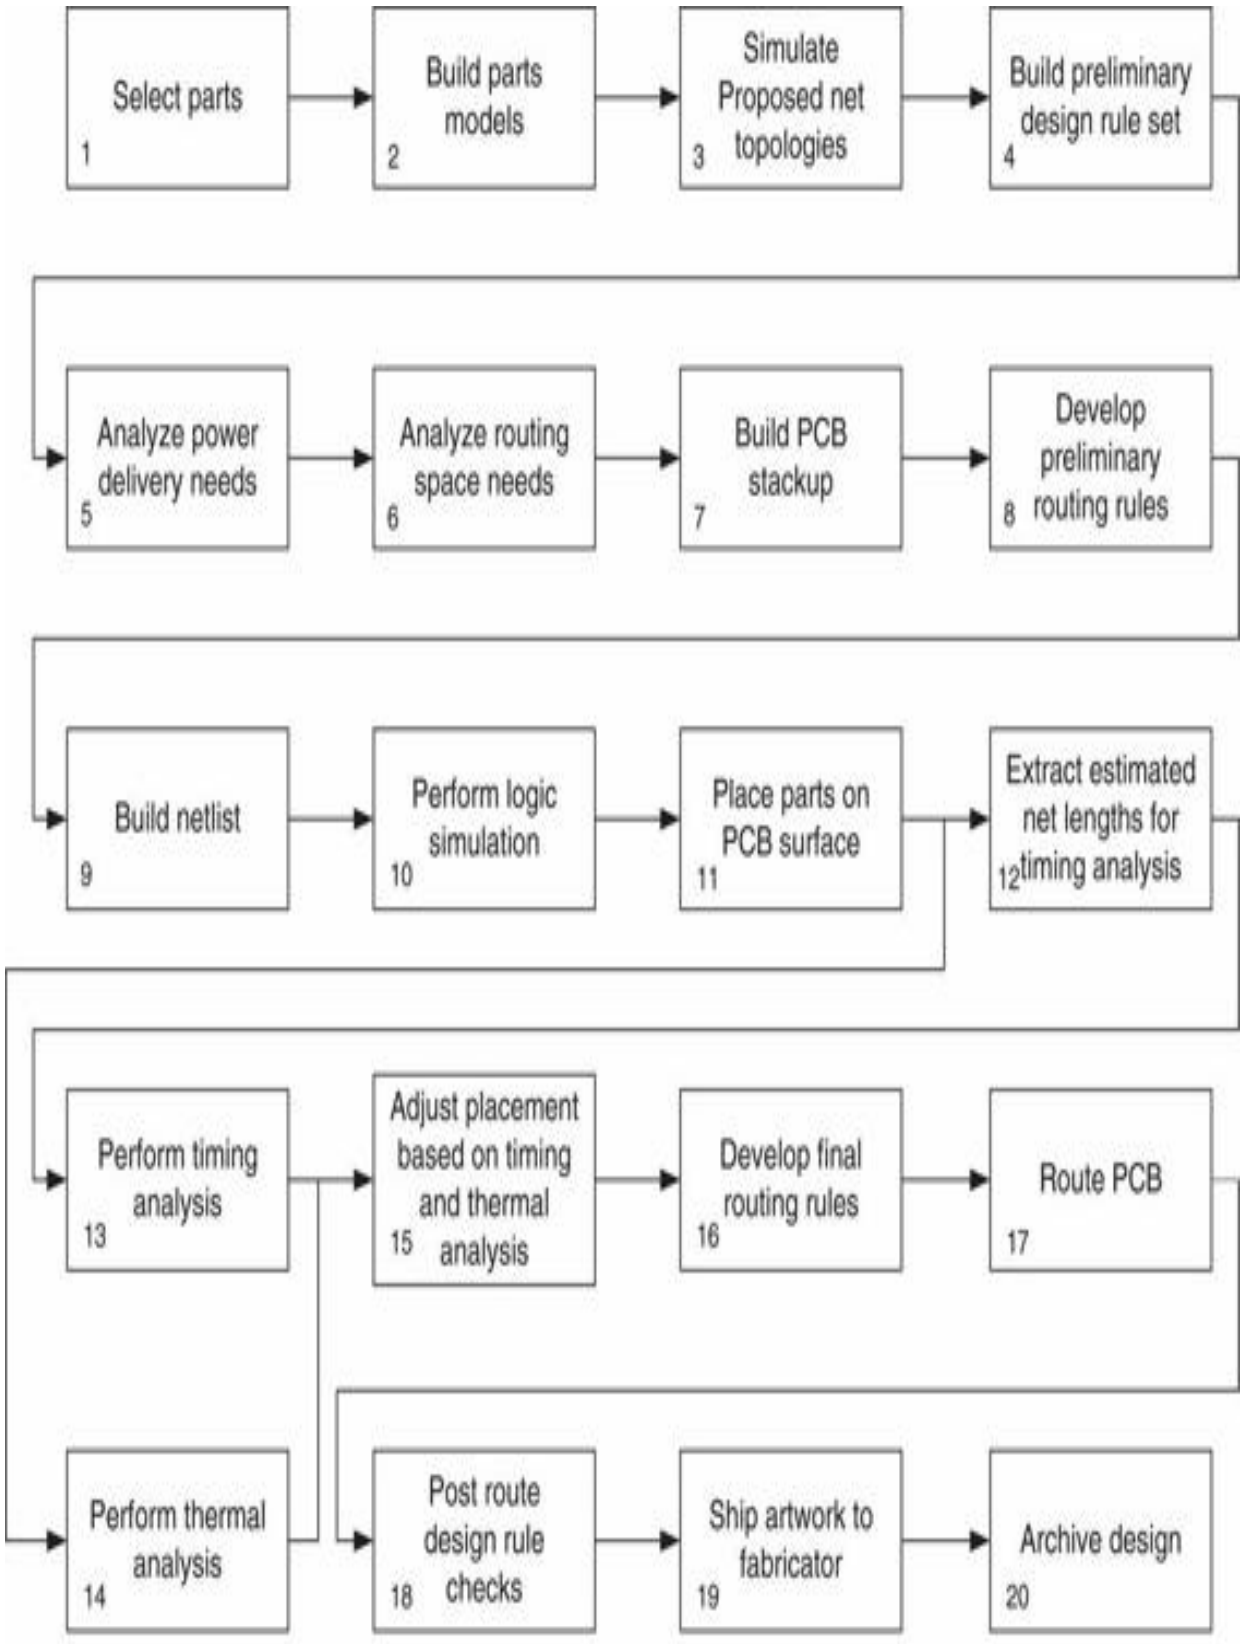
FIGURE 19.1 A hardware prototyping design flow.

This design process is typified by several, sometimes many, iterations of the PCB in order to isolate all of the logic, software and wiring defects until a level of performance is reached that is deemed stable at which point the decision is made to go into volume production and ship product to end users. The weakness of this design process is that there is no easy way to test the wide variations in component speeds, delays, gains and other parameters that occur during normal production. Further, it is often a long, drawn-out process that consumes large amounts of time and technical staff often causing a product to miss its market window. Even when the process results in a prototype that performs properly there is no way to guarantee that the design is stable. All that can be stated is that the units under test meet their specifications. It is not possible to draw the conclusion that the design itself is unconditionally stable. In fact, it is often the case that problems arise in production that must be fixed with engineering change orders (ECOs). Because of this, it is easy to make the case that Design Verification Test (DVT)-style product development testing is worse than no testing at all. The reason is passing a DVT test gives the false impression that the design is stable and that is not always true.

It is easy to argue that hardware prototyping and DVT-style testing are worse than not testing at all. The reason is that passing a DVT test gives the false sense that the design is stable.

Figure 19.2 is a PCB design flow that accounts for all of the variations that may occur during normal manufacturing and operations. It is often referred to as virtual prototyping. This flow has all of the major steps involved in arriving at a

design that is “right the first time.” It focuses on designs that are entirely digital, but could easily be modified to include analog and RF circuits as well.



©Speeding Edge 2006

A PCB design flow with all simulation steps

FIGURE 19.2 A “virtual” prototyping design flow.

Some form of this design flow has been in use for many years in the development of high performance computers as well as complex ICs. In both cases, the original design flows did not include the level of simulation and analysis shown in this flow. The simulation and analysis steps were added one at a time as the complexity and cost of being wrong got higher. This is the situation that most PCB designers find themselves in today with the speed and complexity of modern logic.

When I present this design flow to students in my classes, often one or more engineers will respond with the statements that “there isn’t time to do all that simulation” or that “management won’t let them do that level of design analysis.” Instead, the hardware prototyping process shown in Fig. 19.1 is used. These same engineers will admit that their designs often go through three or four “spins” of the PCB and some have even admitted that 10 spins is not uncommon. When the cost of that time is properly accounted for, the virtual prototyping methodology always proves to be less expensive.

If virtual prototyping is a more reliable and less expensive way to arrive at a stable design, why isn’t it universally used to design PCBs? That is a fair question. In my experience, it is usually due to an engineering department evolving from pure logic design that didn’t require significant electrical engineering to succeed to complex, high-speed designs that could not be made stable without this level of engineering. Two things must happen. One is the design staff needs to acquire significantly different skills in order to operate the design tools in the process and the other is management needs to realize that hardware prototyping is not capable of producing stable designs and that it is necessary to support the design team with the tools and training needed to make

the changes. Sure, this is tough to do, but necessary in order to insure survival.

The design flow shown in Fig. 19.2 suggests a linear flow from start to finish. In actual practice, there are iterations among several blocks as trade-offs are made between things such as routability, thermal stability, timing margins and minimizing layer count. It also shows a single pass at routing the PCB preceded by a large number of analytical steps. The objective of all the steps leading up to routing is to make sure the design rules are well enough developed that routing involves following trace width, trace spacing, trace length and layer specifications. These are the types of input that a PCB layout system works with whether auto- or hand routing is used to place the actual traces on each layer.

19.2 THE VIRTUAL PROTOTYPING PROCESS

As mentioned earlier, the objective of the PCB design process is to arrive at a working PCB with the minimum amount of rework, preferably, none. Figure 19.2 is such a design process. Taking the blocks in Fig. 19.2 one at a time.

19.2.1 Select Parts

In this step, the objective is to select the components, ICs, connectors, capacitors, heat sinks, resistor packs and PCB materials that will make up the final design. As part of this selection process, enough information must be obtained from the manufacturer to allow the analysis and layout process to unfold. Among the information needed is

- IBIS models of all I/O.

- Worst case timing information.
- Mechanical package characteristics.
- Logic models of the parts.
- Power information including current variations during operation.
- Thermal characteristics of the parts and their packages.

19.2.2 Build Parts Models

Each analytical step in the flow-steps 3, 5, 6, 10, 11, 12, 13, 14, and 17 requires an entry into the tool library for each part. Some models, such as IBIS models, logic models and timing models will be supplied by the IC manufacturer. The other models will need to be built by the owner of each tool set.

It should be pointed out that all operations that come after parts model or library creation depend on the accuracy of the models created at this stage. A common error is to assign the task of creating library models to clerical personnel or technicians since it is a tedious task. The risk that is associated with this approach is that library entries will have errors in them that may not be detected until the PCB is built and assembled. An example of this is to build the component footprint as its mirror image. Once a library element has been built, it needs to be checked for accuracy by a second person qualified to detect errors in the model. In some cases, such as IBIS models, it may be necessary to check the model against actual hardware in order to insure the model accurately represents the real part.

The entire design process turns on the accuracy of the parts models created at the start of a project. It is imperative that this task be

assigned to personnel who are technically capable of creating accurate models. This function is usually referred to as library management and has a librarian hired for the purpose of insuring that all libraries are accurate.

19.2.3 Simulate Proposed Net Topologies

At this point it may seem premature to simulate nets in the proposed design since a schematic has not yet been created. However, it is possible to do this as long as IBIS or SPICE models are available for each driver and receiver that will be used in the actual design. As operating frequencies have climbed ever higher it is not only possible to do this, it is imperative that this step be performed as early in the design process as possible in order to insure the drivers and loads will perform properly.

How is it possible to simulate nets at this point? All that is needed to perform simulations is proposed transmission line impedances, driver models, load models, clock frequencies or data rates and estimated transmission line lengths. In almost all cases, the transmission line impedance will be 50 Ω. With this information, any good transmission line simulation tool can be used to examine the behavior of each net type and arrive at termination rules as well as worst-case voltage margins and insights into the effect of loading and termination on timing. Examples of this kind of simulation are shown in Chap. 1 of Vol. 1 of the book set listed at the end of this chapter.

At this stage in the process the number of nets is not known. What are known is the types of nets that will appear

in the design, such as, gigabit Ethernet, SPI-4, DDR, and so on as shown in Fig. 19.3. What is possible is to divide the design into classes of nets where all the members of a class share the same signal integrity needs. Once this has been done, it is only necessary to simulate one member of each net class in order to determine how all of the members of a class are to be terminated and routed. Figure 19.3 is the result of such a simulation exercise. The class name shown for each entry is then added to each net in the net list in a data field provided for this purpose.

TYPICAL TECHNOLOGY TABLE

CLASS NUMBER	CLASS NAME	TECH NOLOGY		FREQ.	QTY	IMPED ANCE	LAYERS	TERM TYPE	STUB LENGTH	TRACE WIDTH	SPACING IN CLASS	SPACING TO OTHER CLASSES	LENGTH TUNE	ROUTE ORDER

Length tuning tolerance is ±.

Differential pair spacing is minimum spacing. Members of a pair can be spaced more than this if needed to.

All ground planes tied together at every device ground pin.

STKUP = See stackup for trace width for each layer.

Layers 1 & 22 are not routing layers.

Routing layers are 2, 5, 6, 9, 10, 13, 14, 17,18,21

Lengths are in mils.

FIGURE 19.3 A typical design rule set presented in the technology table format.

As the IC industry migrates from the "TTL" method of specifying drivers to the transmission line management method, it is not uncommon to discover that some of the drivers that have been used with slower designs are not capable of driving transmission lines. By performing this analysis early in the component selection process, it is possible to avoid using drivers that are not capable of performing at the speeds needed.

19.2.4 Build Preliminary Net List

This step is better recognized as making a schematic. However, it is not always necessary to create a full schematic as is the case with a backplane. This preliminary net list or schematic is used to estimate routing needs, etc.

19.2.5 Analyze Power Delivery Needs

It is not possible to develop a PCB stackup until the power delivery needs of a design are established. Chapters 32 to 37 of Vol. 1 of *Right the First Time: A Practical Handbook on High Speed PCB and System Design* by Lee Ritchey cover how to estimate power delivery needs and arrive at the number of planes required, number and types of bypass capacitors needed and how to place them. Chapters 18, 20, and 21 of this book provide additional design guidance for doing this part of the design task.

19.2.6 Analyze Routing Space Needs

This step involves looking at the number of wires that are needed to connect up all of the devices in a design and estimating how many signal layers will be needed to contain them all. Accurately estimating signal layer needs requires experience with routing similar types of PCBs. It is best done by examining previous designs of similar complexity and extrapolating from there or by conferring with an experienced PCB designer. From experience with many past designs, the signal layer count is usually determined by the highest pin count IC in the design.

19.2.7 Build PCB Stackup and Assign Planes to Power System

Once the number of signal layers has been estimated and the number of power and ground planes has been determined, it is finally possible to create a PCB stackup that has the required number of layers arranged such that they provide an adequate environment for all of the transmission lines and properly deliver power to all components. Chapter 4 of Vol. 1 has a complete explanation of how to design PCB stackups.

19.2.8 Develop Preliminary Routing Rules

Routing rules are the instructions to PCB layout personnel on how to connect all of the signal and power nets in a PCB design. When designs are simple, it is easy enough to make a written list of how to handle each net. However, when designs get complex and devices have hundreds or even thousands of connections, this method breaks down. Over many years, PCB layout tools have been designed that are able to follow predefined rules based on how each net is

labeled. Figure 19.3 is an example of the way rules are recorded for such design systems. The class name is added to each net name in a data field provided for that purpose. The information in the rest of the table is loaded into route control files in the PCB layout system. As routing proceeds, the router, whether manual or automatic, examines the class name and then follows the routing rules listed in the route control files.

The routing rules consist of trace widths allowed; signal layers allowed; spacing to other signals; location of terminations and length matching as needed.

19.2.9 Build Netlist

This netlist is different from that created in step 4 in that it contains the net class information developed in step 8. It will be used with the placed PCB to assess routability and perform timing analysis.

19.2.10 Perform Logic Simulation

Virtually all logic designs have a large amount of software or firmware that must be developed along with them. There is the need to do two things at the same time. These are ensure the logic is correct and ensure that the software or firmware is correct. This creates an immediate conflict for the hardware engineering organization. In order for the software development team to do its job, it needs a logical model or hardware model on which to operate and debug the software. If a hardware model is rushed through the design process, it is certain to have errors in it that will have to be fixed by making design changes in the hardware and building new PCBs—a process that consumes large amounts of schedule time.

The solution to this problem is to build a logic simulator or emulator that represents how the hardware will be built and use that to debug software. If errors are found in the logic model, they can be fixed in minutes instead of days or weeks. In this way, both the software and logic can be debugged with the lowest cost and delay. Once both the software and logic are determined to be error free, the net list from the logic model can be used to correct the hardware net list with the assurance that the hardware will be right the first time.

19.2.11 Place Parts on Surface

Once the above steps have been completed, it is time to place all of the components on the PCB to insure that they will fit properly as well as satisfy routability, timing constraints and thermal needs. It is at this point the PCB design actually becomes physical. Actions taken during this step include creating the PCB outline in the CAD system, defining keep-out areas and placing all of the parts.

19.2.12 Extract Estimated Net Lengths for Timing Analysis

Once the parts have been placed on the surface of the PCB and combined with the net list that defines how the signal pins are to be connected to each other, the lengths of the connections can be estimated. The usual method of estimating potential interconnect length is by assuming that all points will need to be connected using only wires that travel in the *x* and *y* axes. This is what is known as the Manhattan length. (In dense PCBs it is necessary to use only X and Y routing in order to maximize the use of the routing

layers. (This concept is explained in Chap. 46 of Vol. 1 of the *Right the First Time* handbook.)

The Manhattan length of all of the connections can be extracted as a file for use by the timing analysis tools employed in Sec. 19.2.13.

19.2.13 Perform Timing Analysis

Timing analysis consists of estimating the time required for each logic operation to be completed. Time is required for the signals to propagate through the logic elements themselves and along the interconnects or transmission lines. When logic speeds were slow, the time delay through the logic elements was far greater than that on the interconnects. As a result, timing analysis involved only adding up silicon delays, both worst case and best case. Modern logic is so fast that the time delays on the interconnects are often as large as or larger than that in the silicon delays. As an example, one recent large system has a worst-case silicon delay of 3 nSec and a wire delay of 6 nSec. Clearly, checking timing using only silicon delays would not properly account for the overall timing needs of the system.

As a result of the contribution to time delay from the interconnects, timing analysis cannot take place until after the components are placed on the PCB surface and interconnect delays added to overall path delays. In addition, the timing analysis toolset must be capable of adding “wire delays” into the timing model. Timing analysis tools are discussed in Chap. 9 of RTFT Vol. 1.

It is common to discover that timing margins cannot be met if the PCB is routed with the components in their current placement. The placement is adjusted until timing margins can be met. Once this condition has been satisfied, two further analyses must be performed- thermal analysis and routability analysis.

19.2.14 Perform Thermal Analysis

Thermal analysis involves constructing a 3D model of the PCB and its components along with the container in which it will be housed. The devices that generate heat are modeled as heat sources with appropriate body shapes and heat sinks. The flow of cooling air is simulated and the temperature gradients across the PCB are calculated and displayed. If hot spots are detected, actions such as altering the placement of heat sources, adding heat sinks or increasing air flow are taken to eliminate the hot spots.

19.2.15 Adjust Placement Based on Thermal and Timing Analysis

It is common during the previous analysis steps to discover that a design will not meet its timing or thermal goals unless the placement of components is adjusted. Based on the results of these simulations, component locations are changed to improve the results. This is an interactive process that may involve several iterations through the two processes if the design is complex.

19.2.16 Develop Final Routing Rules

Once the component placement has been demonstrated to meet logical correctness, timing margins and thermal goals, the actual routing of the PCB can take place. The first step in this process is to examine the routability by examining the distribution of wires or the wire load. The most common tool for doing this is a plot known as a “rat’s nest.” Figure 19.4 shows the rat’s nest of a typical PCB containing a high pin count FPGA and several other high pin count ICs along with connectors and I/O modules. It is a plot of all the component

pins and the wires that connect them shown in a point-to-point or “as the crow flies” display before the actual routing has taken place. From this display, an experienced PCB layout person can assess the likelihood of connecting up or routing all of the wires in the signal layers available in the stackup. It may be concluded that placement changes would allow the PCB to be successfully routed. If such changes are made, it will be necessary to repeat the timing and thermal simulations to ensure those requirements are not altered by the new placement.

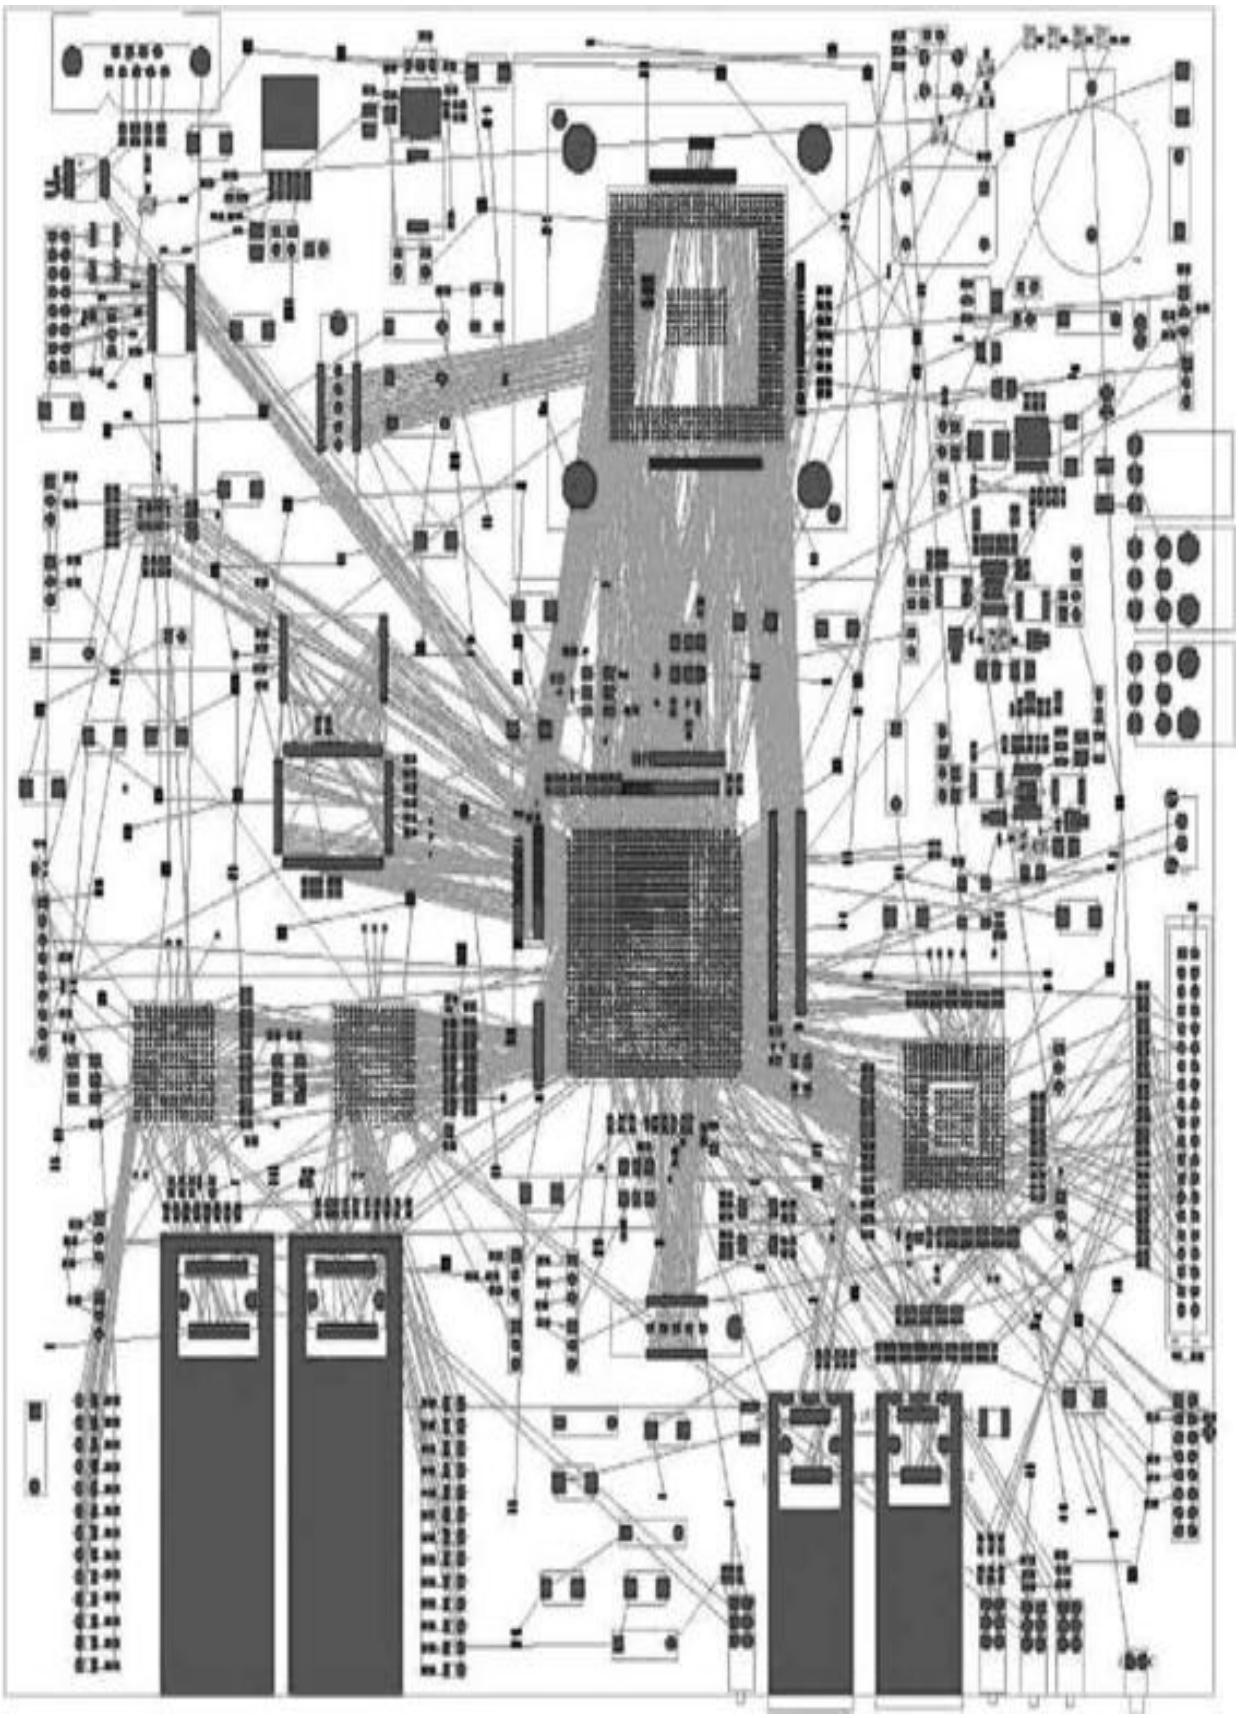

FIGURE 19.4 Typical preroute rat's nest or wire load plot.

Once the routability, timing and thermal goals have been met, it is time to finalize the routing rules that were developed in step 8. The reason this step is necessary is that the best way to connect up some multipoint nets is not obvious from the way they look in the rat's nest. An example of this is given in Chap. 10 of *Right the First Time* handbook. For those cases, it is necessary to extract the proposed net from the placement and simulate it using a good transmission line analysis tool. From this simulation, the best way to connect up the points in such nets can be determined.

Based on what is learned through the above analysis, the specifications in the Technology Table are updated and the design is ready to go through the actual routing process.

19.2.17 Route PCB

Routing a PCB is the process of taking each connection in the net list and resolving it into actual traces in the PCB signal layers. Before performing the actual routing, there are several checking steps that need to be done to ensure the finished route will be correct. The first of these checks is to verify that the net list in the PCB design system is error free. This is done by using checking programs to ensure there are no unwanted connections between different nets; that there are no single pins that should be connected into a net and that the net list accurately matches the schematic. The next check is to ensure that there are no mechanical interferences between components. Other checks are performed that ensure each transmission line has a proper termination and that the termination is located on the net where it should be and that all nets have drivers and loads.

After the checking steps have been successfully completed, the nets or wires are either hand or autorouted following the rules defined in the Technology Table. Of the two, autorouting has the advantage that it is both faster and more repeatable than hand routing and, in the interest of time, is preferred.

A common statement that is made about autorouting is that it cannot be relied on to properly route high-speed signals and, therefore, hand routing is required for all “critical” signals. This statement is usually made by someone who has “thrown” a high-speed design at an autorouter and got an unsuccessful outcome. As I investigate such events, it turns out that the autorouter was given no high speed routing instructions to follow. It is no surprise that the outcome is unusable. In these cases, the user has assumed that “high-speed” autorouters know what to do with all nets. In other words, the assumption has been made that the router has knowledge of what should be done to each net to ensure it complies with appropriate rules. This error is often made when the topic of high-speed design and the tools that are used as part of it comes up. The assumption is made that the skill is in the tool—which it never is.

I often illustrate the difference between hand and autorouting by relating my experiences as I grew up. My father was a master carpenter. When I was very young, all he had to work with were hand tools. With them, he made elegant cabinets. I took the same tools and made irregular little blocks of wood. As time went by, his shop was converted to power tools. Now, he made elegant cabinets much faster and I made irregular little blocks faster! Not having the skill, I chose to go into engineering and spare my father the embarrassment of watching me grow up to be a poor carpenter. So it is with routing PCBs. The skill is in the engineer, not in the tool. When properly used, autorouters produce superior designs in far less time than what can be achieved with hand routers.

19.2.18 Postroute Design Rule Checks

Postroute design rule checking has many steps. The first step is to insure that all of the wires in the net list have been routed in the PCB and that none of them accidentally touches any other wires or any power or ground terminals. Other steps include checking to see that all of the length matching has been done correctly; that spacing between nets is correct and that clearances around component holes and mounting holes is correct. There are specially designed postrout checking tools that are sold for this purpose. These are discussed in Chap. 9 of Vol. 2 of *Right the First Time* handbook.

A popular postroute operation is to perform board-level signal integrity analysis. There are several tool vendors that supply tools to do this. It is possible to do post layout SI on the whole board, but is difficult to do and comes after the horse has left the barn. If SI analysis is delayed until after layout has been completed, the result is likely to be the design has many violations and must be done again. It is far better to do the signal integrity engineering up front, as is described in this book, and arrive at post layout with a “right the first time” PCB.

There will be occasions when a few very critical nets may need to be checked with postroute SI analysis, but in general, this is too late in the process to be making this level of check.

Postroute full board signal integrity analysis is difficult to do and comes too late in the design process. It’s too late to lock the barn door because the horse has already escaped.

19.2.19 Ship Artwork to PCB Fabricator

This step is made up of several operations. They result in a complete document set that will be used to fabricate the PCB; to test it at the bare board level; to assemble it and to test it at the loaded board level. The documents required by a PCB fabricator in order to manufacture and test the bare PCBs are listed in Chap. 47 of Vol. 1 of *Right the First Time* handbook.

The steps involved at this stage are

- Create film layer files needed to plot film for all layers of the PCB. These are often referred to as Gerber files.
- Create bare board test net list.
- Create fabrication drawing.
- Create drill files.
- Create artwork for silk screens and solder masks.
- Create final bill of materials for the assembly.
- Create pick-and-place files to be used to assemble parts onto the PCB.

19.2.20 Archive Design

The design process up to this point has involved large amounts of time to create it. It is a valuable asset that needs to be protected in the event it is needed again to make modifications or to generate new manufacturing documentation. The process of saving a design file for future use is known as archiving. With modern design methods, all of the design records are likely to be in electronic form and are relatively easy to store away. This is a step in the design process that is often skipped or done poorly. When the time

comes to make new manufacturing documents or changes to the design, the records are incomplete or missing.

In order to insure the design files are available when needed, a disciplined archiving system needs to be installed. It is advisable to create at least two copies of the design files, one for on-site storage and one for offsite, secure storage. This latter set of records is the insurance in the event of the loss of on-site records due to fire or other calamitous events.

19.3 MAKING THE CONVERSION FROM HARDWARE PROTOTYPING TO VIRTUAL PROTOTYPING

When an engineering group decides to move from the hardware prototyping methodology to the virtual prototyping methodology described in this book and elsewhere, the size of the task can be overwhelming and it is often difficult to decide where to start. If all of the methods are incorporated at the same time, the design process is sure to grind to a halt and no product development is done, not a realistic choice. How, then, does an engineering group make this conversion?

Adopting the virtual prototyping methodology involves acquiring a new set of design tools. It also involves learning a new set of skills. Because of this, it is advisable that tools be added to the process one at a time. The places in the process where the most failures occur with the present logic technologies are transmission line management and power delivery. Therefore, it is advisable to introduce tools and methods to address these two issues first. As the skill level rises in these areas, the remaining tools can be added.

Note: References are made throughout Chap. 16 to two books written by the author. These are *Right the First Time: A Practical Handbook on High Speed PCB and System Design*, Vols. 1 and 2 by Lee Ritchey and John Zasio. These are available from the website, www.speedingedge.com.

CHAPTER 20

ELECTRICAL AND MECHANICAL DESIGN PARAMETERS

20.1 ELECTRICAL AND MECHANICAL DESIGN PARAMETERS OVERVIEW

Everything that happens in the process of building a printed circuit board (PCB) that transmits signals from A to B and B to A works against signal quality. This is the underlying reason we spend so much time with “signal integrity”—the electrical world and the physical world are fighting against each other. This chapter addresses a number of the issues of concern, with the hopes of helping the reader end up on the winning side of this perpetual scrum.

Signal integrity relates to the quality of an *electrical_signal* that propagates between circuit components. Section 20.2 covers digital signal integrity (SI) in some detail, and a decent grasp of SI will provide a significant advantage with all aspects of electrical integrity in PCB design—including electro-magnetic compatibility (EMC) and power distribution network (PDN) design. As Fig. 20.1 implies, if a hardware engineer or PCB designer makes a design change that impacts signal integrity (SI), it's likely that the change will also have an impact on the power distribution network and electromagnetic compatibility (EMC). Likewise, changes to the PDN will have impacts on both SI and EMC, as well. Their physics are inescapably intertwined.

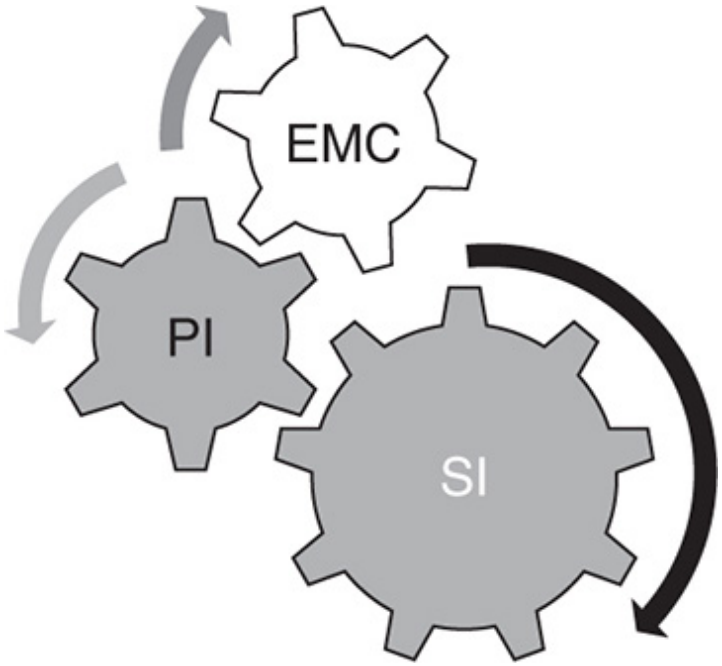

FIGURE 20.1 The physics of PCB signal integrity (SI), power distribution network (PDN) design, and electromagnetic compatibility (EMC) are inescapably intertwined.

The key issue of concern for PCB designers is ensuring both analog and digital signal transmission between circuits and interconnects occur without any loss of signal fidelity.

Power integrity, discussed in Sec. 20.3, is a critical design aspect in any PCB design. Voltage and current levels must be within integrated-circuit manufacturers' margins to ensure that components function as designed. Power integrity analysis must be performed to ensure optimal voltage and current is available at all times—particularly around components that demand a good bit of current.

If the voltage on a power or return plane droops due to lack of energy charge, generally minimized through use of decoupling capacitors, this "bounce" will appear between planes as a propagating RF signal that may cause harmful disruption to other components or radiated from the PCB when this propagating field hits the physical edge of the board, a via or even radiated from the package of an active component in the *z* axis. Both would produce EMI events—discussed further in Sec. 20.4.

Both the direct and indirect relationships between signal integrity and electromagnetic compatibility (EMC) or electromagnetic interference (EMI) are important for designers to grasp. A board or system may pass functional test requirements, essentially meeting SI requirements, but that does not necessarily mean that it will adhere to government EMC standards. Conversely, a PCB that fails EMC testing may function properly, or more likely, will have some serious signal and/or power-integrity issues. For example, a fast driven, long clock signal with improper termination may "ring" like crazy—and EMC engineers will see the results of that high-frequency ringing in the compliance lab months after the clock was improperly optimized for SI. As a result, it's helpful for engineers to be comfortable working in both the time and frequency domains at the same time.

20.2 INTRODUCTION TO DIGITAL SIGNAL INTEGRITY

Before going into signal quality from a voltage versus time standpoint, it's helpful to consider SI at a more foundational level. If you look in a college communications book, you'll see something similar to the basic Communications Model, depicted in Fig. 20.2. A "sender" encodes a message, to be decoded by a "receiver." Whether the receiver receives the intended message is largely determined by the volume (amplitude) of the sender's communication, and how much external noise is competing with it. In the end, whether the communication was successful—where the intended message was sent and received—is determined by the receiver alone.[1]

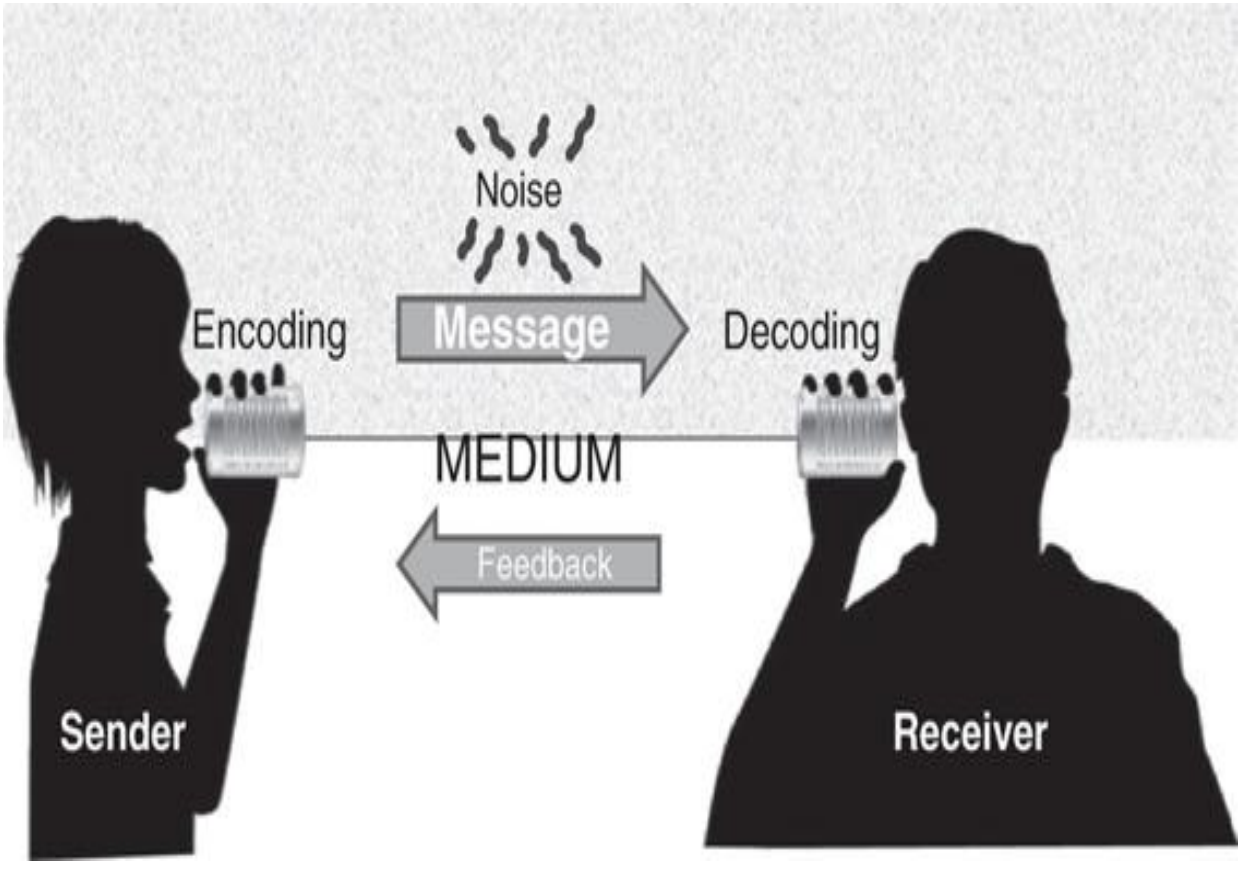

FIGURE 20.2 The communications model—similar to what you might find in a communications textbook—is a good place to start when learning electrical signal integrity.

Carrying the analogy over to the electrical world, the sender is a driver IC, and the medium includes connectors, cables, BGA balls, BGA breakouts, vias, PCB traces, and the dielectric medium.

Unfortunately, everything that happens in the process of building a PCB that transmits signals from A to B and B to A works against signal quality. This is the underlying reason we spend so much time with “signal integrity”—the electrical world and the physical world are fighting against each other.

The quality of an actual electrical signal is determined by its waveform shape. If a waveform shape deteriorates too much, it can cause a number of different problems, including functional failure, “flaky” or intermittent performance, or—worst of all—failure in the field. Figure 20.3 contrasts a representation of a digital signal in an introductory electrical engineering text book versus the same signal in a manufacturer datasheet, versus possible results for a “receiver” waveform on an actual PCB. It’s the non-ideal physical medium between the sender—a driver IC—and the receiver IC that causes delays and functional degradation of the signal.

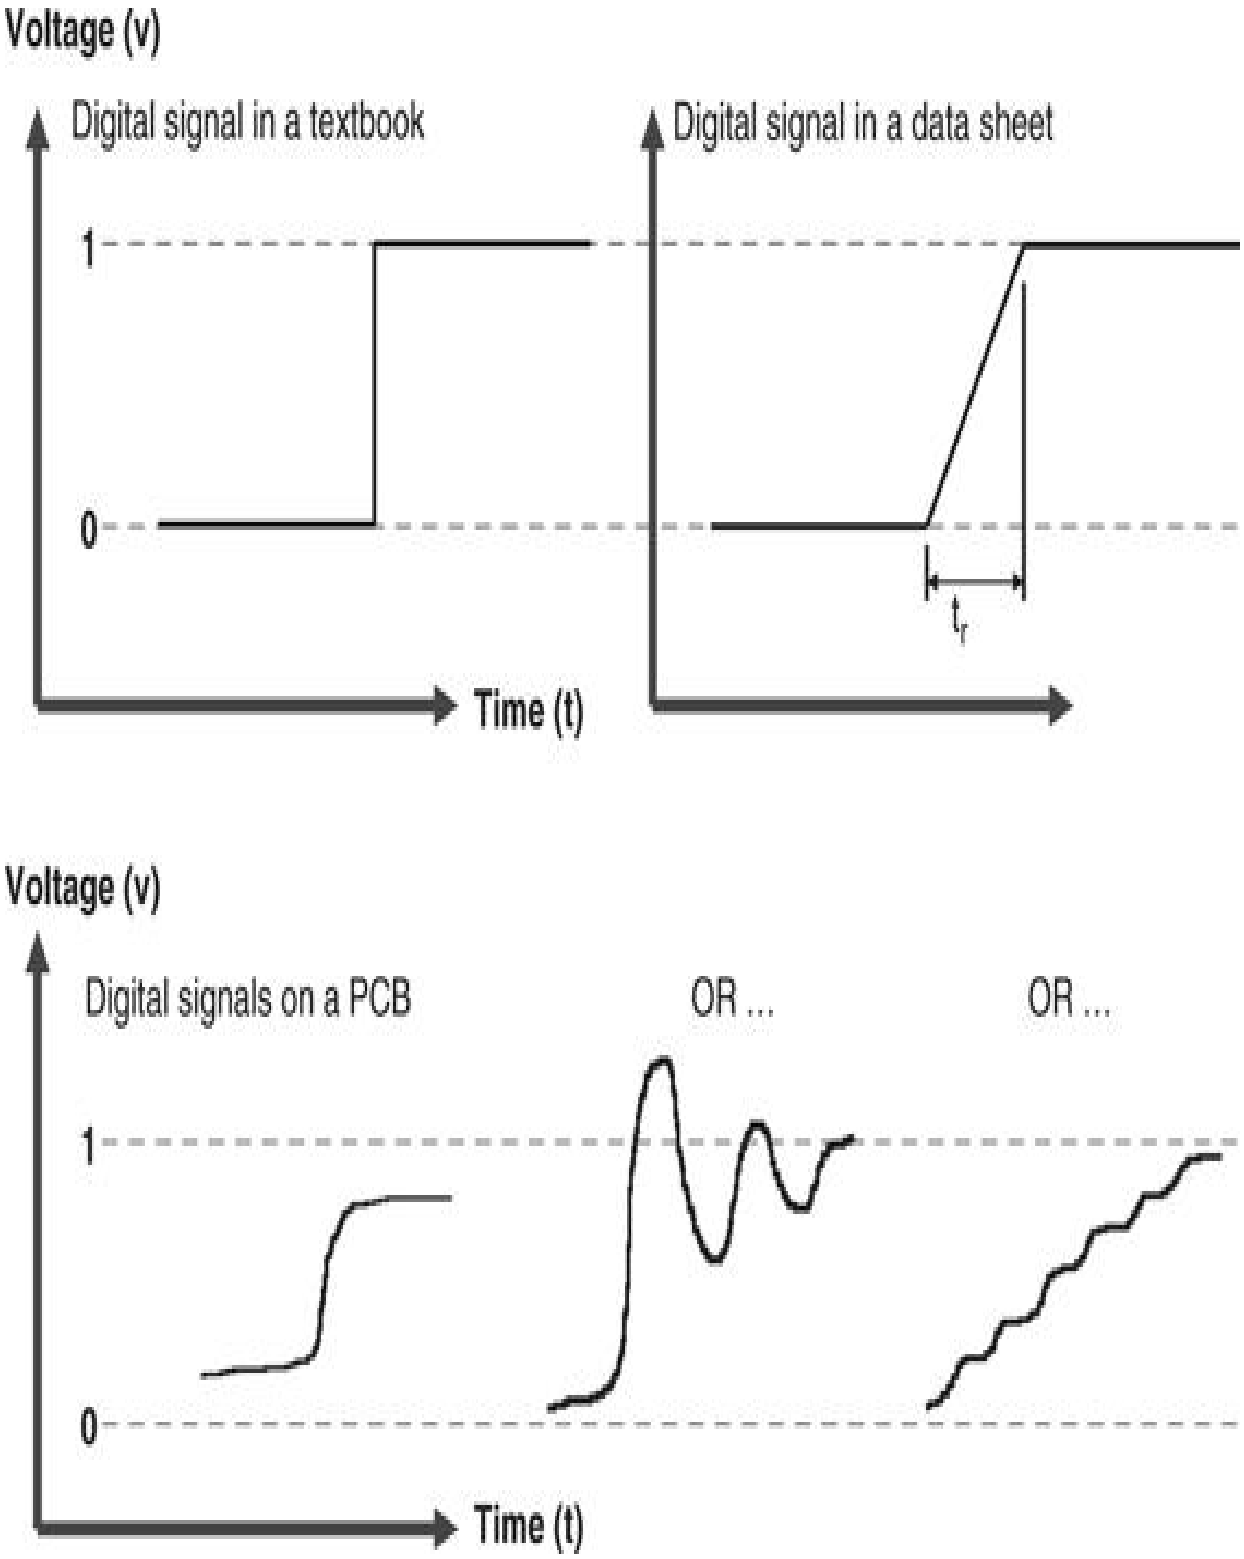

FIGURE 20.3 A representation of a digital signal in an introductory electrical engineering text book versus the same signal in a manufacturer datasheet, versus possible results for a “receiver” waveform on an actual PCB.

20.2.1 Possible Waveform Errors during Signal Transmission

Whenever a signal is propagated between a driver and receiver, degradation of the signal waveform may occur from that of the “textbook signal.” A sample list of issues that may affect the quality of a signal during propagation is provided below. This is not a comprehensive list, but gives an overview of concerns that signal integrity engineers must deal with during a product design. All of the items below occur due to the *physical implementation* on a PCB that includes both core and pregreg material selection, as well. (See Figs. 20.4 and 20.5.)

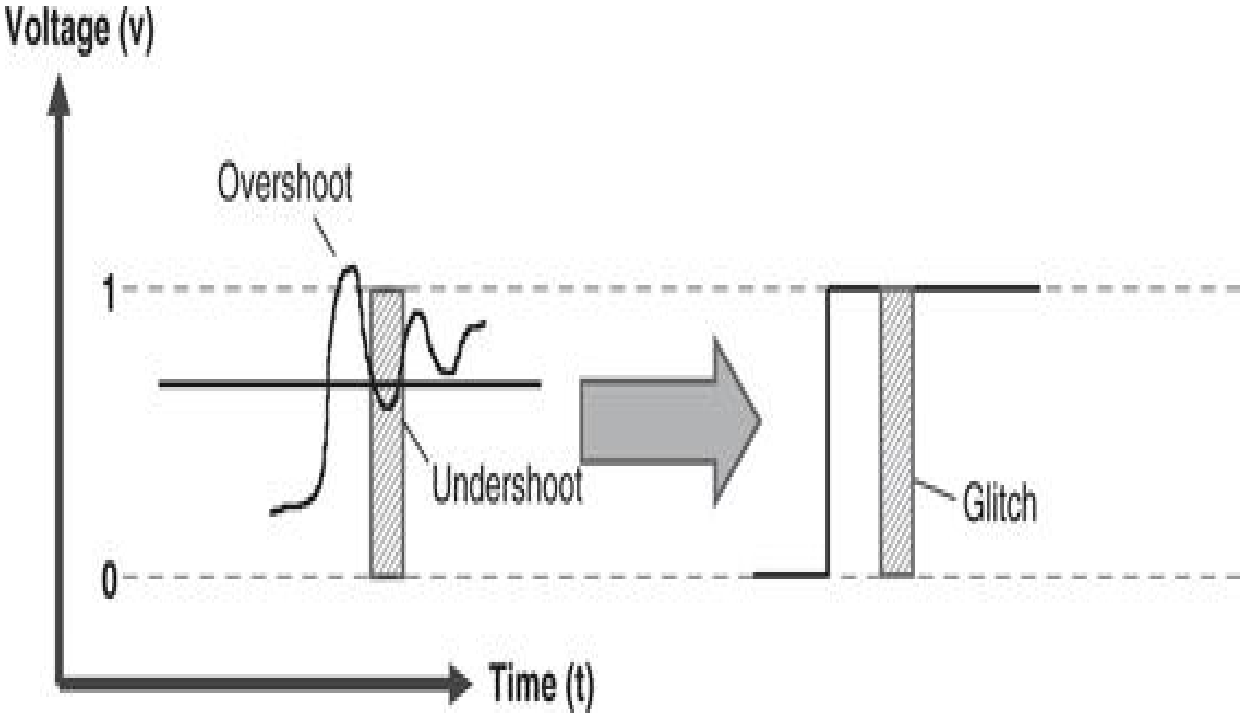

FIGURE 20.4 Ringing at a receiver, leading to an undershoot condition, which results in a threshold error. Also referred to as “false clocking” or “glitching.”

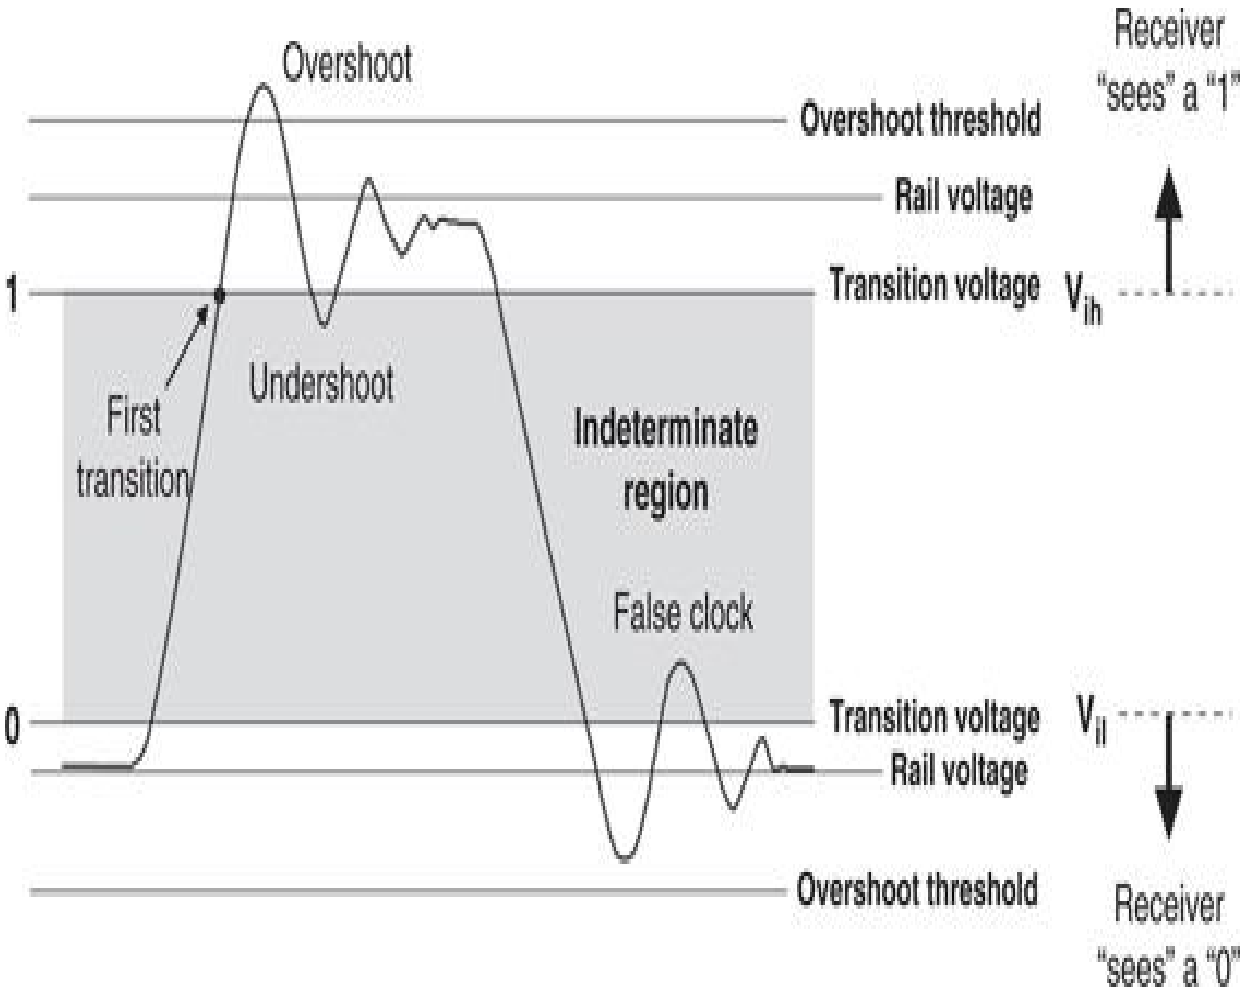

FIGURE 20.5 Receiver voltage thresholds, Vil and Vih, determines whether a receiver "sees" a logic 1 or a logic level 0, and whether the channel performs as intended.

- Threshold errors/false clocking/glitching
- Overshoot
- Undershoot
- Oscillation/ringing
- Delay errors
- Crosstalk
- EMI/EMC problems

Having poor signal integrity can cause PCBs to malfunction, behave intermittently or show performance

variations from different production runs. The waveform in Fig. 20.5 goes into a little more detail on some of the requirements for a signal to produce the intended performance behavior. The first thing to note is the "Indeterminate region" that's grayed out. The upper "transition voltage" on this is referred to as Vih, or "voltage input, high." This is the voltage above which a specific integrated-circuit manufacturer guarantees that the receiver will switch high. Similarly, Vil, or "voltage input, low" is the voltage below which a receiver is guaranteed to switch low. Any voltage states in between Vil and Vih are "indeterminate." If a signal wanders back and forth across that threshold (i.e., undershoot) that's the condition that can lead to false clocking. A detailed timing discussion is beyond the scope of this chapter, but these thresholds are also used in "flight-time" calculations in a timing budget.[2]

20.2.2 What Specifically Causes Signal Integrity Problems?

It's common to think of high frequencies as the main problem—and there are a number of concerns associated with higher frequencies; but it's important to understand signal integrity, specifically, in more detail. At a high level, signal integrity problems are caused by: (1) fast driver edge rates, (2) comparatively long interconnects between driver/receiver pins, and (3) impedance discontinuities or mismatches.

20.2.3 Fast Driver Edge Rates

The "edge rate"—sometimes called the "switching speed," or "rise time" or "fall time"—for a driver IC can typically be found in a component data sheet. Rise time, or T_r, is usually

measured as the time it takes for a driver output to ramp from 0 V to 10 percent of its voltage swing to 90 percent of its upper-rail voltage.

Present switching speeds have made circuit board routing significant. Component packages, PCB traces and vias, connectors and cables all have parasitic inductance and capacitance that are essentially transparent at slow driver switching speeds. (For example, a 10 ns driver edge from 20 years ago.) A circuit board trace simply looks like a resistive load to a driver IC. But, at driver edge rates faster than 2 ns, these inductive and capacitive elements become a much bigger concern, along with the propagation velocity down the trace—and managing signal quality through this maze of inductance and capacitance becomes as big of a job (if not bigger) as laying out and routing the board. Couple this with the fact that many of today's edge rates are below 100 ps (0.100 ns), and it's clear why there's so much concern about SI.[2]

20.2.3.1 What's a Transmission Line? A transmission line is any structure that propagates an electromagnetic field between a source and receiver. Examples of transmission lines include

- Circuit board traces
- Coaxial cable
- Any cable assembly configuration
- Power and return planes
- Free space

Every transmission line is described as a media for signal propagation that includes inductance (L), capacitance (C), resistance (R) and conductance (G) per unit length. These parameters are determined by the transmission-line cross section. The cross-sectional L and C components are used to determine the transmission line's impedance as well as

signal propagation velocity or delay.[2] Above roughly 300 MHz, additional resistive “lossy” elements begin to take on significant value as well.[3]

At any point along the transmission line, a signal requires a complete current loop in order to propagate. The distributed capacitance of the transmission line provides the means of establishing this loop during signal transitions.

20.2.4 Physical Transmission Line Characteristics

There are two primary trace cross-section types found on PCBs shown in Fig. 20.6, and possibly 50 or more derivatives that are beyond the scope of an introduction to signal integrity. The two most common configurations are

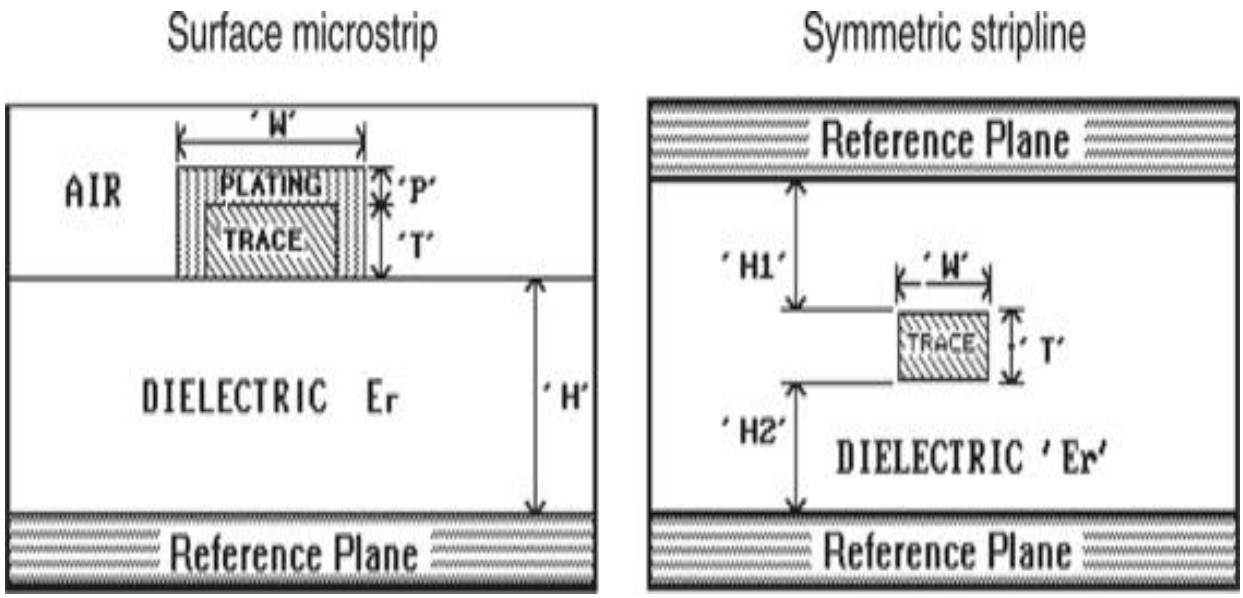

FIGURE 20.6 The two most common signal or transmission-line configurations are surface microstrip and symmetric stripline.

- *Striplines*. The most common trace configuration on a PCB is the stripline, which are traces located on inner layers of

the circuit board stackup, sandwiched between copper reference planes.

- *Microstrips*. Signals on a PCB's outer layers are referred to as surface microstrip or microstrip lines.

Stripline configurations are more common than microstrip lines because on a *multilayer* (*n* layers) board stackup, only two outer (microstrip) layers are available, and up to $n - 2$ stripline layers are possible, assuming each internal layer is considered as a candidate for signal trace routing. There are essentially two kinds of basic stripline configurations: "symmetric" or "balanced," which include one signal layer sandwiched between two reference planes; and "asymmetric" or "imbalanced," which include two signal layers sandwiched between two reference planes. Symmetric stripline routing is recommended for maximum crosstalk immunity.[4]

There are several physical characteristics of transmission lines that determine the four key electrical characteristics discussed in Sec. 20.2.5 below:

1. *Dielectric height (H)*. The thickness of the dielectric material between the signal trace and the nearest reference plane after PCB fabrication in the *Z*, or vertical direction.
2. *Dielectric constant (Er or Dk)*. A measure of the relative capacitance of the transmission medium, as compared to a vacuum. Typical Dk (or Er) values range from 3.5 to 4.3 on a PCB. More expensive materials can have Dk values as low as 3.3, while a vacuum has a Dk of 1.0, which also applies to air. A less common name for the dielectric constant is *relative permittivity*.
3. *Trace Width (W)*. The width of the PCB trace, typically measured in mils, thous, or microns (um). When etched on a PCB, traces take on a trapezoidal shape. To simplify, an estimated rectangular width is often used.

4. *Trace thickness (T)*. This is the vertical thickness of a signal trace in the Z direction. Signal layers that are designed on half once copper, for example, typically start at roughly 0.7 mil thickness prior to etching, and finish at roughly 0.6 mil after etching and cleaning during PCB fabrication. Double these numbers for 1 oz copper. A surface microstrip is usually plated, so the original copper foil of 0.0006 (or 0.0007) inches is usually plated up to three times its original thickness, to a finished thickness of between 0.0018 and 0.0021 in. The finished thickness is used to determine the track impedance, discussed below.

These four physical parameters determine the cross-sectional inductance and capacitance of a transmission line, which can then be used to determine the four key electrical characteristics of a transmission line, outlined below.[5]

From a practical perspective, microstrip signals are usually implemented on the finished printed circuit with a coating of solder mask (Dk ~3.3/3.4). In this case, the structure is that of a coated microstrip and will have a different impedance than the microstrip that assumes air (Dk = 1.0) is above the conductor. Any additional coatings, like conformal coatings or thermal blankets, will also change the transmission lines impedance.

20.2.5 Four Key Electrical Characteristics for Transmission Lines

There are four primary characteristics associated with transmission line routing on a PCB. Each of these characteristics is derived from the cross-sectional geometry of the structure[3]:

1. *Propagation velocity*. Signals do not propagate down transmission lines instantaneously. The speed of a signal varies inversely with the capacitance of the medium, which is tied to the dielectric constant (Dk) of the laminate material as well as the inductance per unit length. The relationship for propagation velocity is shown in Eq. (20.1*a*). As a rule-of-thumb, stripline signals travel about 5.8 in/ns for FR-4 material with a Dk around 4.0, roughly half the speed of light. Signals travel a bit faster on microstrip lines because air has an $E_r = 1.0$, roughly ¼ that of a standard FR-4 dielectric material.
2. *Time delay, or "propagation delay."* Signals traveling on a PCB trace experience propagation in addition to logic delays, which can be significant in high-speed systems. Propagation delays are affected by the length of the trace, anything affecting the inductance or capacitance related to the geometry of the trace, the location of the trace within the PCB stackup, and the materials in the PCB stackup. The delay per unit of trace length is the inverse of the propagation velocity relationship, as shown in Eq. (20.1*b*). The easiest way to calculate propagation delay through a stripline is to multiply the speed of light, 85 ps/in, by the square root of the dielectric constant of the material. For a 10-in (25.4 cm) stripline trace through a material with a Dk of 4.0, the total "propagation delay" would be 1.7 ns.
3. *Characteristic impedance (Z_0) of the transmission line*. PCB traces look just like a resistance until a reflected wave comes back. With typical values for PCB traces that range from 40 to 65 Ω, Z_0 (Z zero) determines ratio of current and voltage propagating through a trace, both forward and return. Detailed IPC-4121 equations have been documented and modified over the years to approximate Z_0, but—at a high level—Z_0 is generally represented as shown in Eq. (20.1*c*). Field-solver software

can calculate Z_0 to within an ohm, typically, for single-ended signals.

4. *Reflections*. Energy reflections occur at the end of a transmission line, or at any impedance change along the way. Impedance changes can come from any number of physical changes along the signal path. Managing this is often called “impedance matching.”[6]

(a) Propagation Velocity (b) Propagation Delay (c) Characteristic Impedance

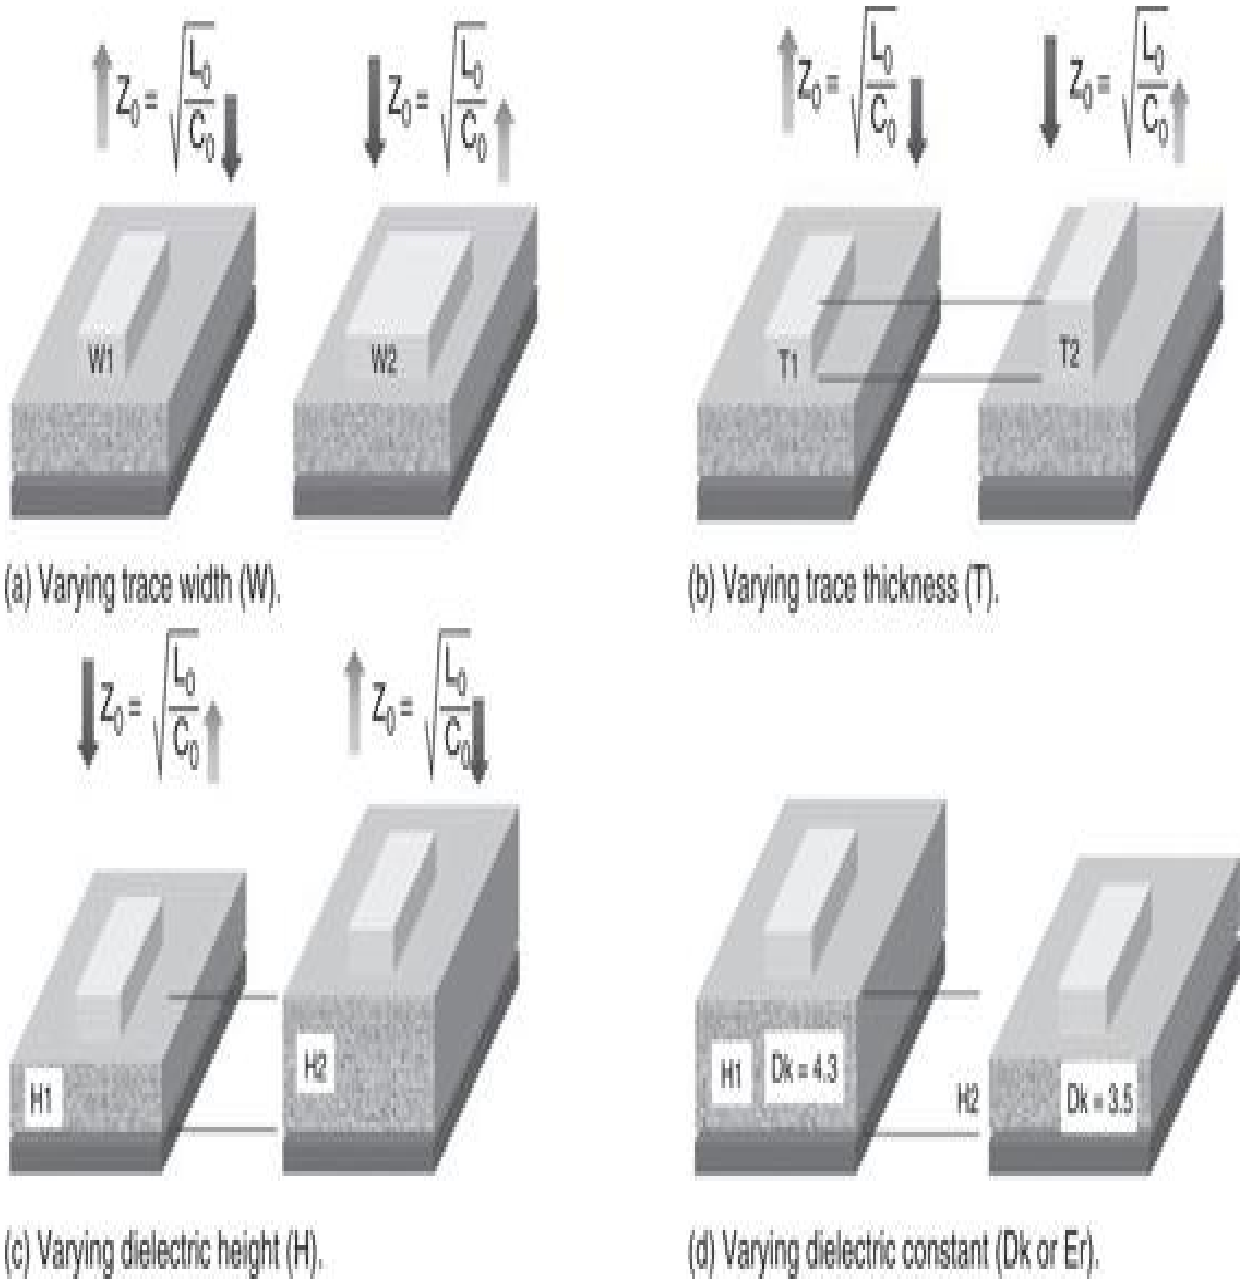
$$v = \sqrt{1/LC} \qquad \text{Delay (Td)} = \text{Length} \times \sqrt{LC} = \text{Length} \times 85\sqrt{DK} \qquad Z0 = \sqrt{L/C} \tag{20.1}$$

Equation (20.1*a–c*) shows three key electrical relationships for transmission lines.

20.2.6 Characteristic Impedance (Z_0)

Correctly calculating single-ended signal impedances is a key step in the PCB design process. The IPC-4121 specification includes some general approximations for determining trace impedance. There are a number of commercial, software-based field solvers available for the task, as well.[7]

Impedance planning is most easily performed with a capable, easy to use electromagnetic field solver that automatically solves Maxwell’s equations.[1,4] When planning a specific transmission-line’s cross section impedance, it is very helpful to consider the *capacitance* of the copper trace in reference to its closest reference plane(s). Figure 20.7 a–d highlights some of the trade-offs.[8]



(a) Varying trace width (W).

(b) Varying trace thickness (T).

(c) Varying dielectric height (H).

(d) Varying dielectric constant (Dk or Er).

FIGURES 20.7 *a–d* Four ways to adjust trace impedance—primarily considering capacitance. (*Adapted from Rod Strange, Fast Edges*.)[8]

- Widening a signal trace from W1 to W2 will *increase the capacitance* in the denominator of the generic characteristic impedance relationship, resulting in a lower impedance.
- Increasing trace thickness from T1 to T2 will also *increase the capacitance* in the denominator of the generic

characteristic impedance relationship, resulting in a lower impedance.

- Increasing dielectric height from H1 to H2 results in a *reduction in the effective capacitance* of a trace, and therefore a higher impedance.
- Reducing capacitance with a relatively low-Dk dielectric material will increase the impedance if the same cross section is used, but enables designers to use thinner dielectrics to achieve the same target impedance.

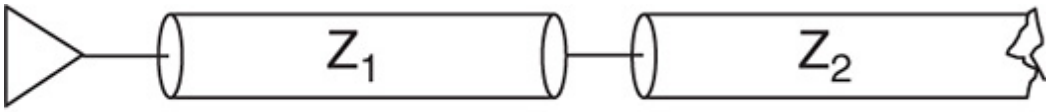
Some rules of thumb exist for “ball park” impedance planning, as well. A quick approach is to consider that the ratio of the line width to dielectric thickness is 2:1 for a 50-Ω microstrip in FR-4.[5] If the dielectric thickness is 3.5 mils, the line width is roughly 7 mils for a 50-Ω line. Again, this relationship is corroborated by Fig. 20.7*a*.

20.2.7 Signal Reflections on a Transmission Line

If you have ever dribbled a basketball in an empty gym, you’ve heard the sound waves bouncing off the six parallel surfaces of the gym. Echoes are reflected sound waves. Water surface waves created by wind that bounce off a floating bridge, forming similar waves that move away from the bridge are reflections, as well. Both examples are similar to reflected voltages on a transmission line, except the solid wall would be represented by an open circuit at the end of a line, just like a receiver in its default, high-impedance state.

A signal reflection, the root of most signal integrity, crosstalk and EMI issues, occurs whenever a signal sees an impedance discontinuity, or a change within the characteristic impedance of the transmission line. Figure

20.8 and the associated equation show the simple relationship that predicts signal reflections.[6]



$$\% \text{ Voltage reflection} = \frac{(Z_2 - Z_1)}{(Z_2 + Z_1)}$$

FIGURE 20.8 The % voltage reflection relationship. Any time a signal passes through a change in impedance, a voltage reflection will occur.

There are three possible voltage reflection scenarios:

1. When $Z_2 > Z_1$, reflection is *positive*.
2. When $Z_2 = Z_1$, reflection is 0 percent.
3. When $Z_2 < Z_1$, reflection is *negative*.

Anything causing a delta between Z_2 and Z_1, including variations in board stackup, changes in trace width, BGA breakouts, stubs, vias, loads, connector transitions, or large power plane discontinuities will lead to a voltage reflection. Careful pre-layout impedance planning is a critical part of a proactive impedance-control process.

At the source, reflection from the far end reflects again. Source reflections are usually antireflections because driver impedance is lower than line impedance. Signal reflections cause the overshoot, undershoot and ringing seen on receiver waveforms.

The relative significance of a reflection is impacted by a number of factors, including the actual impedance difference, as outlined above, the length over which the impedance difference occurs relative to the overall length of the transmission path, and the technology's tolerance for noise. Detailed attention to each of these issues is beyond

the scope of this introductory chapter, which will assume that care has been given to minimize unnecessary impedance discontinuities wherever possible.

20.2.8 The Length at Which a Trace Becomes a Transmission Line

There are a number of different opinions, as to when a trace reaches the “critical length,” and becomes a transmission line—where designers need to worry about all of these effects, like parasitics, impedance matching and reflections. Rules have been suggested, stating that the length of a line in nanoseconds can be no more than 1/3, ¼, 1/6, or 1/10 the driver’s switching speed. Before discussing any of these “rules” in detail, it’s helpful to be reminded that the answer all depends on the receiver. If the receiver can “understand” a signal clearly, with a high level of confidence, that’s a good answer.

One rule of thumb is to make the line length in nanoseconds no more than 1/6 the driver’s switching speed. As discussed earlier, in FR-4, a signal propagates at 5.8 in/ns (round to 6 in/ns).

Let’s look at our driver’s edge rate to determine this rule-of-thumb’s recommended line length. Signal propagation during first incidence of waveform down a transmission line is sometimes called the “transition electrical length” or TEL.[6]

$$\text{Transition electrical length} = T_{\text{rise}}\ (\text{ns}) * 6\ (\text{in/ns}) = 1.0\ (\text{ns}) * 6\ (\text{in/ns}) = 6\ \text{in}$$

This means that the initial transition of the signal travels six inches down the line before the signal finishes switching. Multiply this by 1/6 (the rule-of-thumb) to produce the maximum (recommended) line length using this driver. Of course, for a 1 ns driver edge, and assuming the 6 in/ns approximation, the sixes cancel, and the result is a

maximum line length of 1.0 inch in the unterminated case. (More on that later.) If you simulate this configuration—with a 1.0-in driver edge—you will see some still ugly ringing, as shown in the “1 in” waveform in Fig. 20.11. Clearly, this puts the 1/3, ¼, and 1/6 rules for the maximum route length for a transmission line in question. Simulating high-speed signals of concern is always advisable over naively applying rules of thumb. The remainder of this chapter—including the “3 T’s”—will help with the basic concepts. (Note: For FR-4, rather than doing all of the multiplication above, just use the rise time in nanoseconds as the maximum line length since 6 × 1/6 = 1.)

20.2.9 Impedance Mismatches

Before going into detail on using the “3 T’s” to address signal-reflection problems, it’s important to address impedance mismatches at a more general level. Reflections occur at any impedance discontinuity according to the following relationship[6,3]:

$$\%\ \text{Voltage reflection} = 100 \times \frac{z_2 - z_1}{z_2 + z_1} \tag{20.2}$$

Anything causing a delta between Z_2 and Z_1, including variations in board stackup, trace-width variations, changes in trace width, BGA breakouts, stubs, vias, loads, connector transitions, or large power plane discontinuities will lead to voltage reflections. Some of these reflections—if significant enough—cannot be resolved using the 3 T’s. For this reason, careful pre-layout impedance planning is a critical part of a proactive impedance-control process.

The relative significance of a reflection is impacted by a number of factors, including the actual impedance difference, as outlined above, the length over which the

impedance difference occurs relative to the overall length of the transmission path, and your technology's tolerance for noise. Detailed attention to each of these issues is beyond the scope of this chapter, which will assume that care has been given to minimize unnecessary impedance discontinuities wherever possible.

20.2.10 The "3 T's"

The techniques for managing these effects on digital signals can be broken into three broad categories, sometimes referred to as "the 3 T's"[9]:

1. *Technology*. Select driver technology that's fast enough to meet your functional needs, but as slow as possible.
2. *Topology*. Select topologies that meet timing requirements while minimizing the impact of signal reflections.
3. *Termination*. Manage signal reflections using passive components.

The challenge is that there are thousands of such choices to be made when designing a PCB, and trade-offs must also be managed vis-à-vis timing requirements, and electro-magnetic compliance (EMC)—discussed further in Sec. 20.4.

20.2.10.1 The First "T": Triage by Technology. There are several strategies for dealing with nonideal routing. The first is to know which nets can afford to suffer from arbitrary routing and which truly cannot. A three-tier "technology triage" strategy, as outlined in Fig. 20.9 works best.[10]

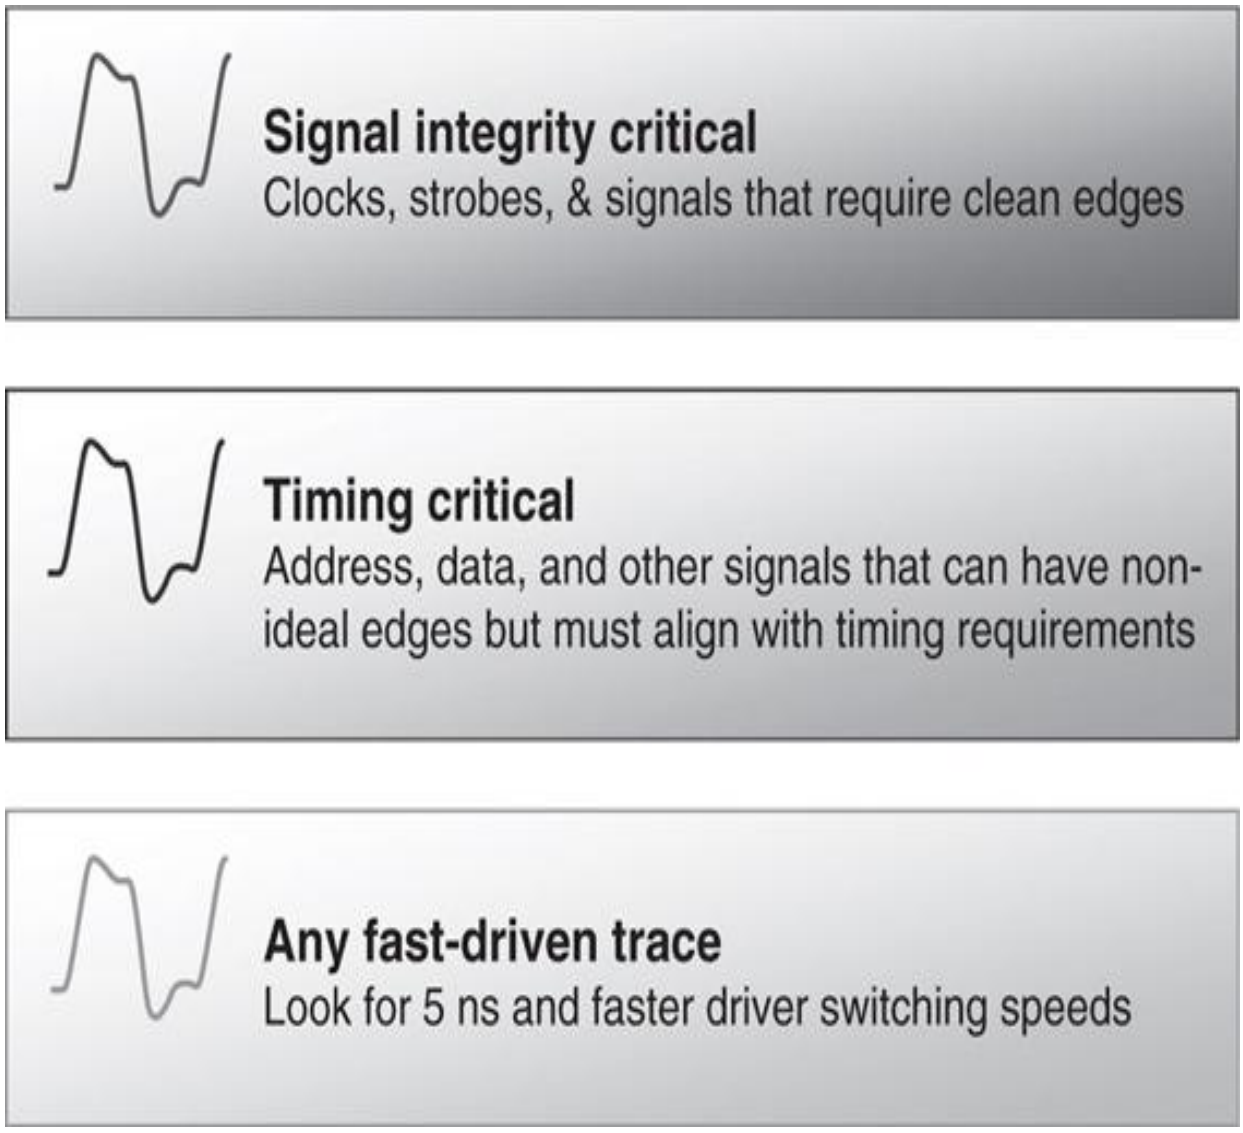


FIGURE 20.9 A three-tier “technology triage” strategy.

1. Nets that are “signal-integrity-critical” (clocks, strobes, and other signals that must have clean waveforms).
2. Nets that are “timing-critical” (address, data, and other signals that can have nonideal waveforms but must align with your timing requirements).
3. Signals with driver edge rates that are faster than 5 ns. The remaining slower-driven signals can be ignored from a signal integrity standpoint.

Figure 20.10 shows the effect of increasing driver edge rates on a 5-in (127-mm) trace. The 10 ns and 5.0 ns drivers produce clean receiver waveforms. The faster 2.5 ns and 1.0 ns drivers, however, produce reflections and ringing on their respective receiver waveforms.

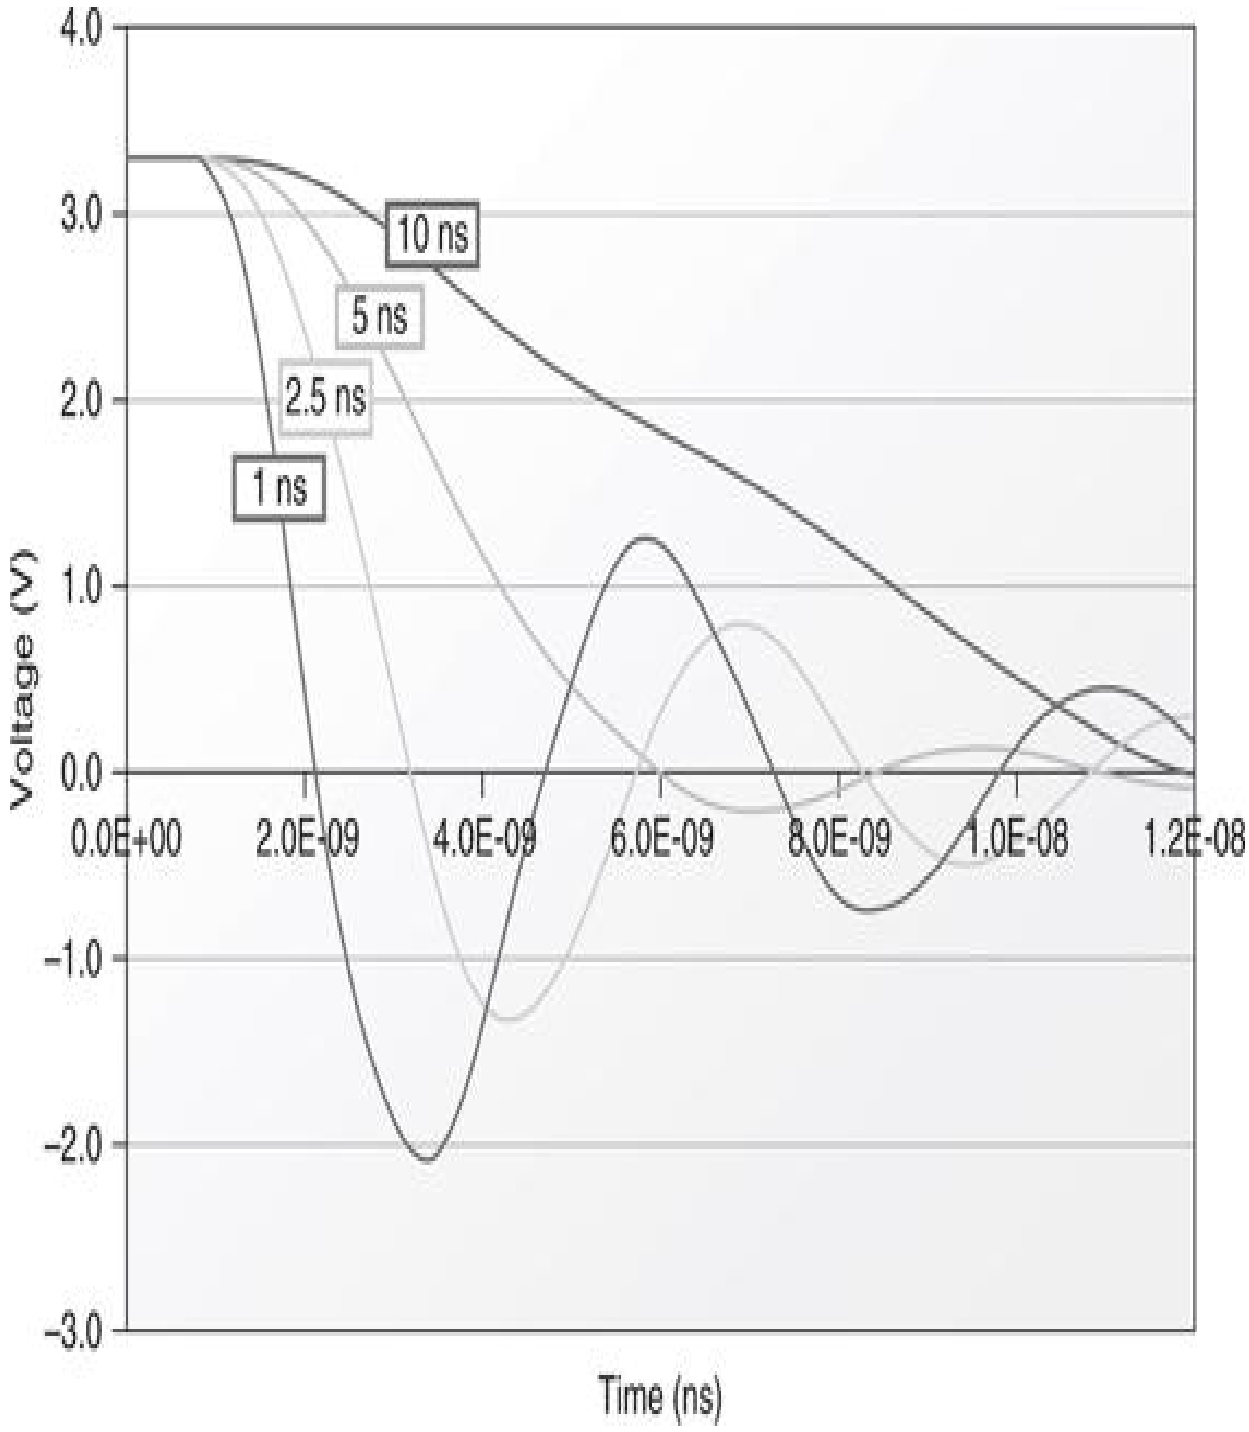

FIGURE 20.10 The effect of driver edge rates on a 5-in trace.

The 10 ns and 5 ns edges look fine, with reflections and ringing effects appearing on the receiver waveforms for the faster 2.5 ns, and 1 ns drivers. For subnanosecond driver switching speeds, receiver waveforms get progressively worse.[9]

20.2.10.2 The Second "T": Topology, Signal Integrity and Timing. Signal integrity problems tend to disappear when nets are short relative to how fast they are driven, as reflections settle much more quickly. Figure 20.11 illustrates this clearly. The 1-ns receiver waveform from Fig. 20.10 provides a point of reference. Recall that the net was 5 in long (127 mm), with a 1.0-ns driver switching speed. Shortening this point-to-point topology to 1 in (25 mm) produced a much better-looking waveform. Shortening this trace to a one-half inch (12.5 mm) produced an even better-looking signal. Though academically instructive, an engineer certainly wouldn't want to specify more than a few carefully planned high-speed nets with a half inch maximum length requirement! Additional alternatives are discussed in the next session, the third "T."

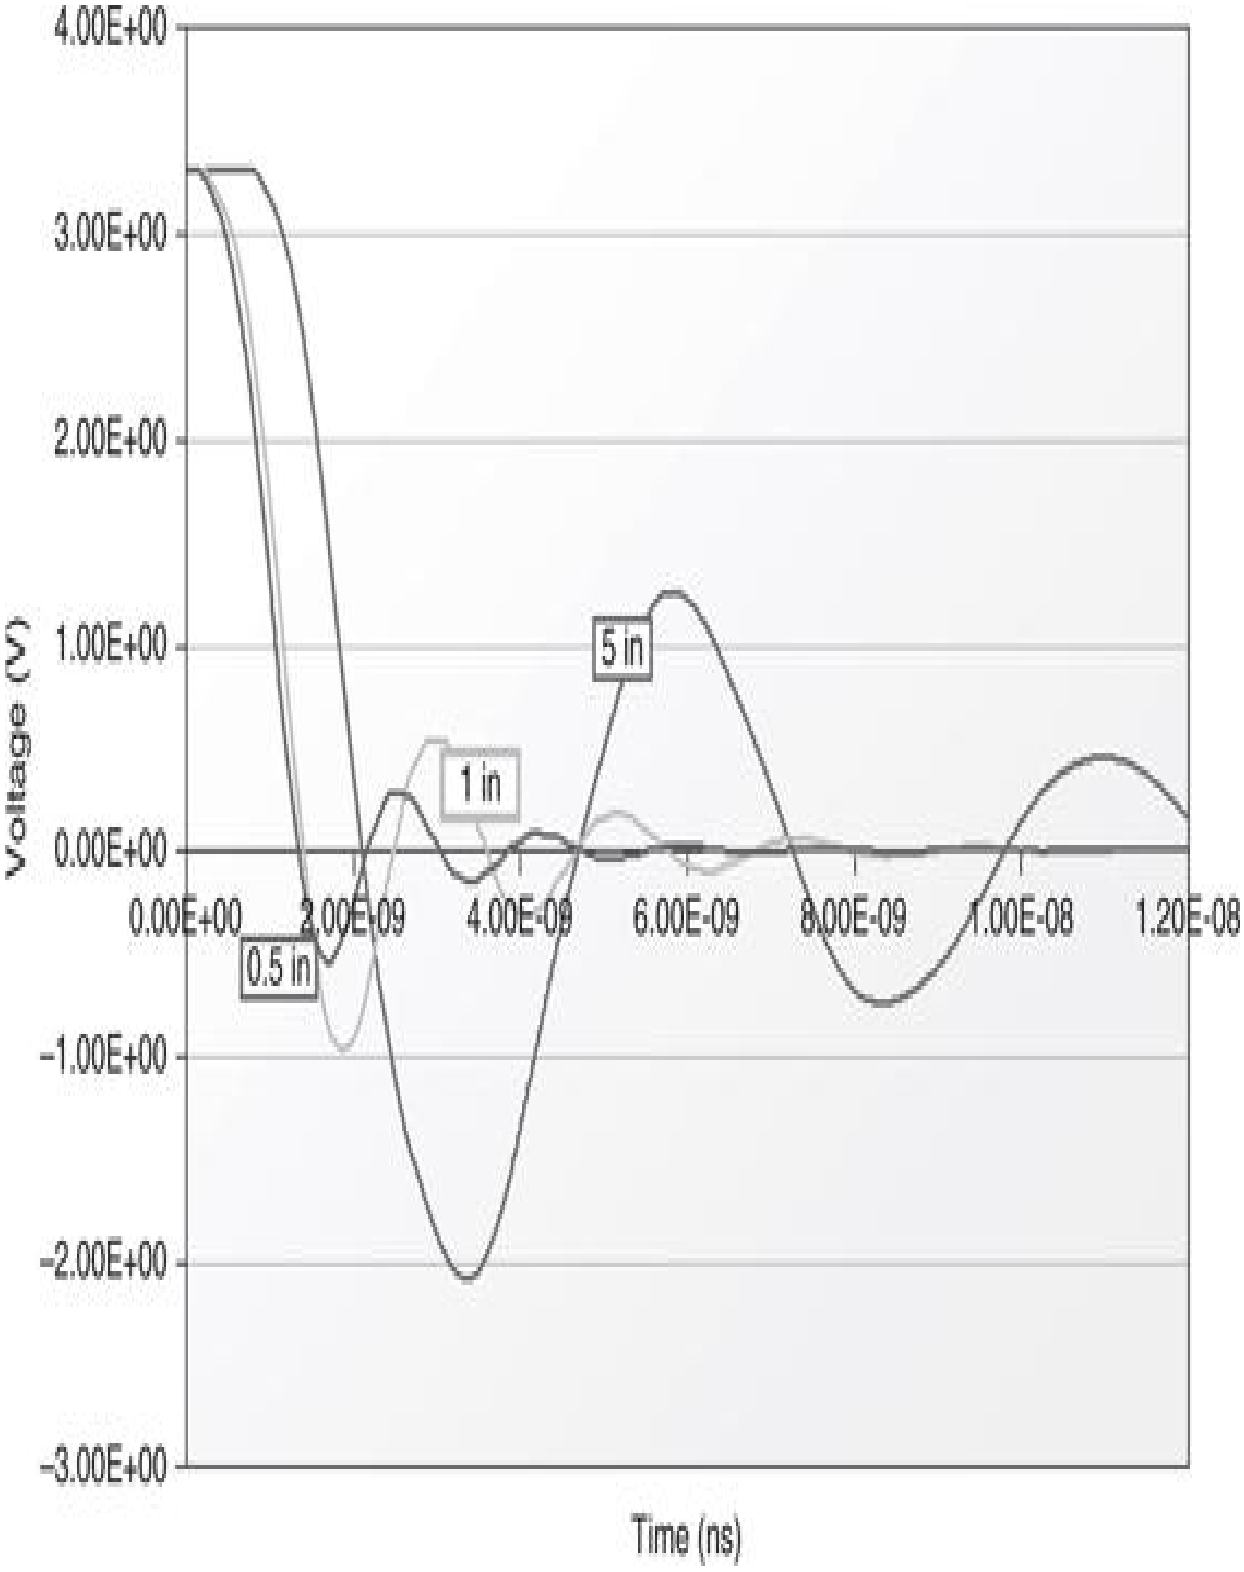

FIGURE 20.11 Shortened trace lengths reduce the impact of reflections on receiver waveforms for a 1-ns driver output.

Sometimes, departures from normal “good-practice” routing can actually be a key to solving tough signal-integrity problems. For example, consider the case of a clock net with multiple receivers, each of which is skew-sensitive (i.e., the clock must arrive at each receiver at very close to the same time). In this case, a daisy-chain route may not be ideal because it delivers the signal to each receiver in a serial fashion, inherently creating skew. Figure 20.12 shows this clearly.

FIGURE 20.12 Daisy chain routing, shown in this transmission-line view, often leads to skew between receivers. (*Simulation courtesy of Mentor Graphics HyperLynx*.)

For cases like this, a superior routing scheme may be a “star” pattern in which each receiver, or small subsets of receivers, has its own routing branch with all branches meeting at or very near the driver IC. Note the advantages of this topology: each receiver can be placed approximately the same delay length from the driver (no skew), and each receiver is considerably more isolated from other receivers than on a daisy chain (reduced susceptibility to receiver-to-receiver reflections).

On the other hand, star routing introduces several new problems. Underscoring the interrelationship and trade-offs associated between the 3T’s, the parallel (star) combination of multiple branches presents the driver IC with a low impedance, meaning that the driver must be capable of dynamically sinking and sourcing a considerable amount of current. In practice, one may need to use a stronger driver technology for this routing topology. For example, a 24-mA driver instead of an 8-mA, as shown in Fig. 20.13. More on this topology in the next section, termination.

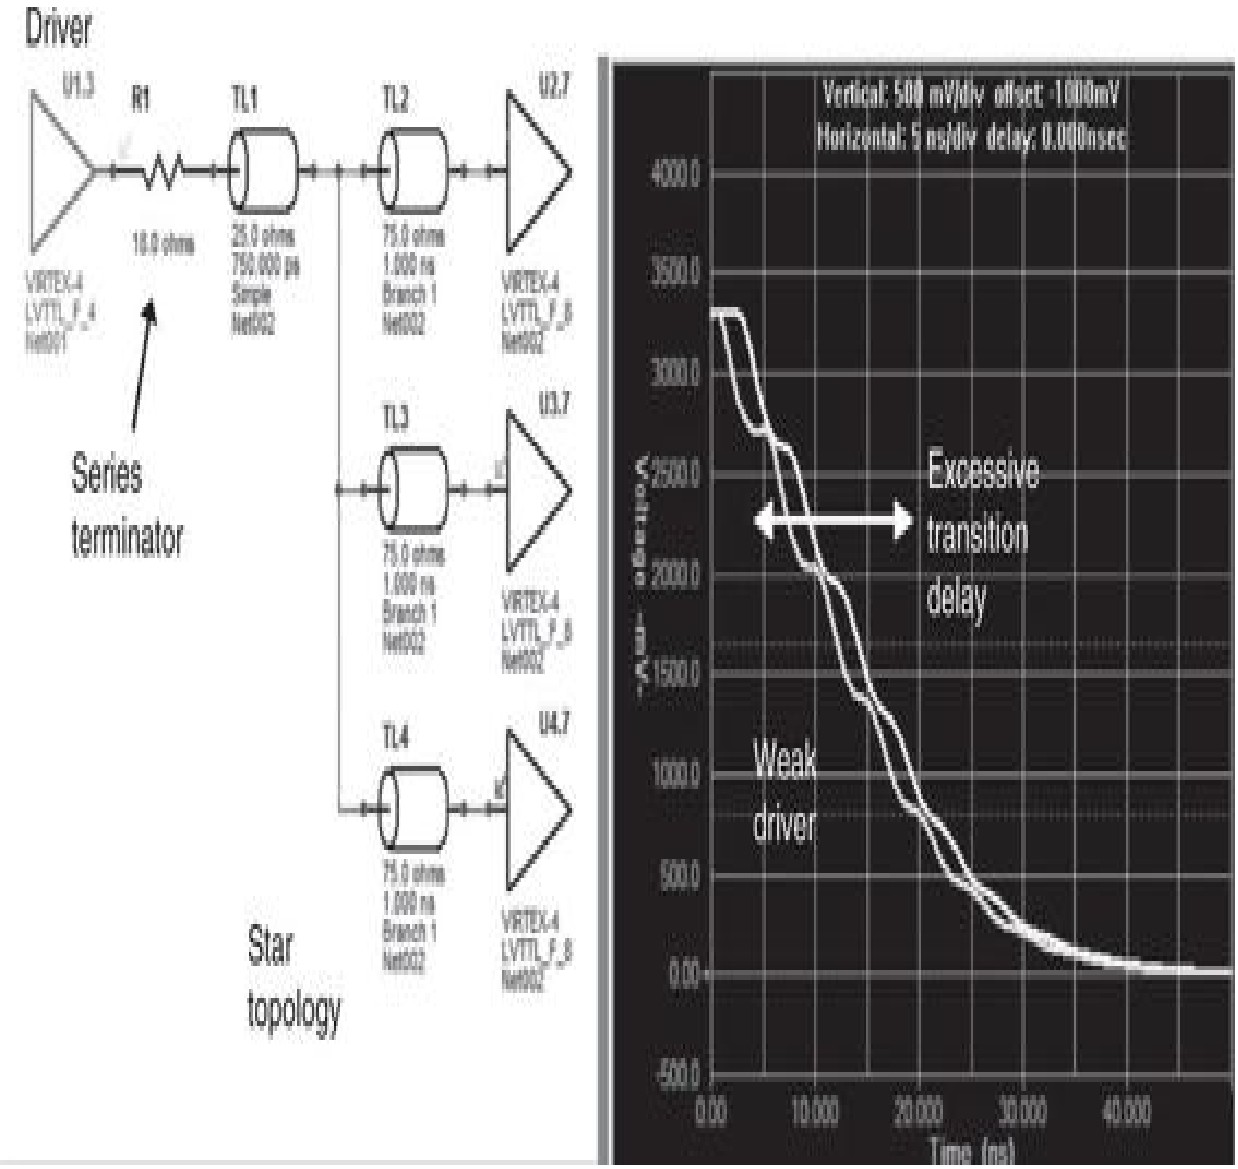

FIGURE 20.13 Loading and trace length determine the drive strength required to reach the desired signal transition at each receiver. Here, we see a driver that is too weak for the parallel, low-impedance star topology. It would be better in this case to use a stronger 24 mA buffer.

20.2.10.3 The Third "T": Termination. The benefits of improved signal quality from optimizing termination schemes on fast-driven signals is absolutely critical—impacting whether the product works at all. When providing termination we must consider:

- Which nets to terminate?

- *Termination strategy*. What type of termination to use is based on routing topology and design requirements?

20.3 WHICH NETS TO TERMINATE AND WHAT TYPE OF TERMINATION TO USE

As a general rule, any line with an edge rate faster than about 5 ns on nets running longer than an inch should be considered a candidate for termination.[1]

The classic methods of terminating transmission lines—where the nets on a digital PCB constitute the lines—are fairly well known. Designers can terminate the source, the far end, both, or employ “distributed” terminations at several locations—for example, in the case of multidrop or daisy chain connections.

Using parallel DC termination, the transmission line is pulled at its far end to a power-supply voltage through a resistor equal in value to the impedance of the line. Parallel AC termination adds a capacitor in series with the DC resistor, to eliminate the DC loading.

Series or “source” termination replaces the end-of-the-line terminator with a resistor at the driver end of the line; the resistor’s value should add to the driver’s impedance to equal the line’s characteristic impedance.

Variations on these methods are possible, too. For example, Thevinin terminations involve two parallel DC terminating resistors pulled to opposite power supplies, to reduce DC current.

There are some basic guidelines when selecting a termination methodology:

- Source termination is useful in point-to-point/one-directional connections.
- Far-end termination is useful in multipoint connections.
- Distributed termination can be helpful if you have a plug-in system with variable configuration.

Each of these techniques has advantages and disadvantages. Parallel DC termination is the simplest scheme, both from the standpoint of component count (only one), and the choice of value (equal to the line impedance), but it burns the most power and may unacceptably load the driver IC. AC termination requires an additional component (more expensive), and additional engineering effort—to find the optimal capacitor value. But the addition of the capacitor does reduce power consumption.

Series termination seems simple (only one component), but it is not always trivial to find the optimal component value because it depends on the driver impedance, which may be unknown, and varies with semiconductor processing. Also, series terminators do not work properly unless the receiver ICs are clustered near the end of the net, because series termination works by creating a voltage “plateau” that persists until a reflection is received back from the end of the line. Receivers midway or near the beginning of a line may experience unacceptable timing results.

Consider the daisy chain topology presented in Fig. 20.12. The waveforms in Fig. 20.14 show a series topology leading to unacceptable skew between the first receiver and the one at the end of the net in a daisy-chain configuration.

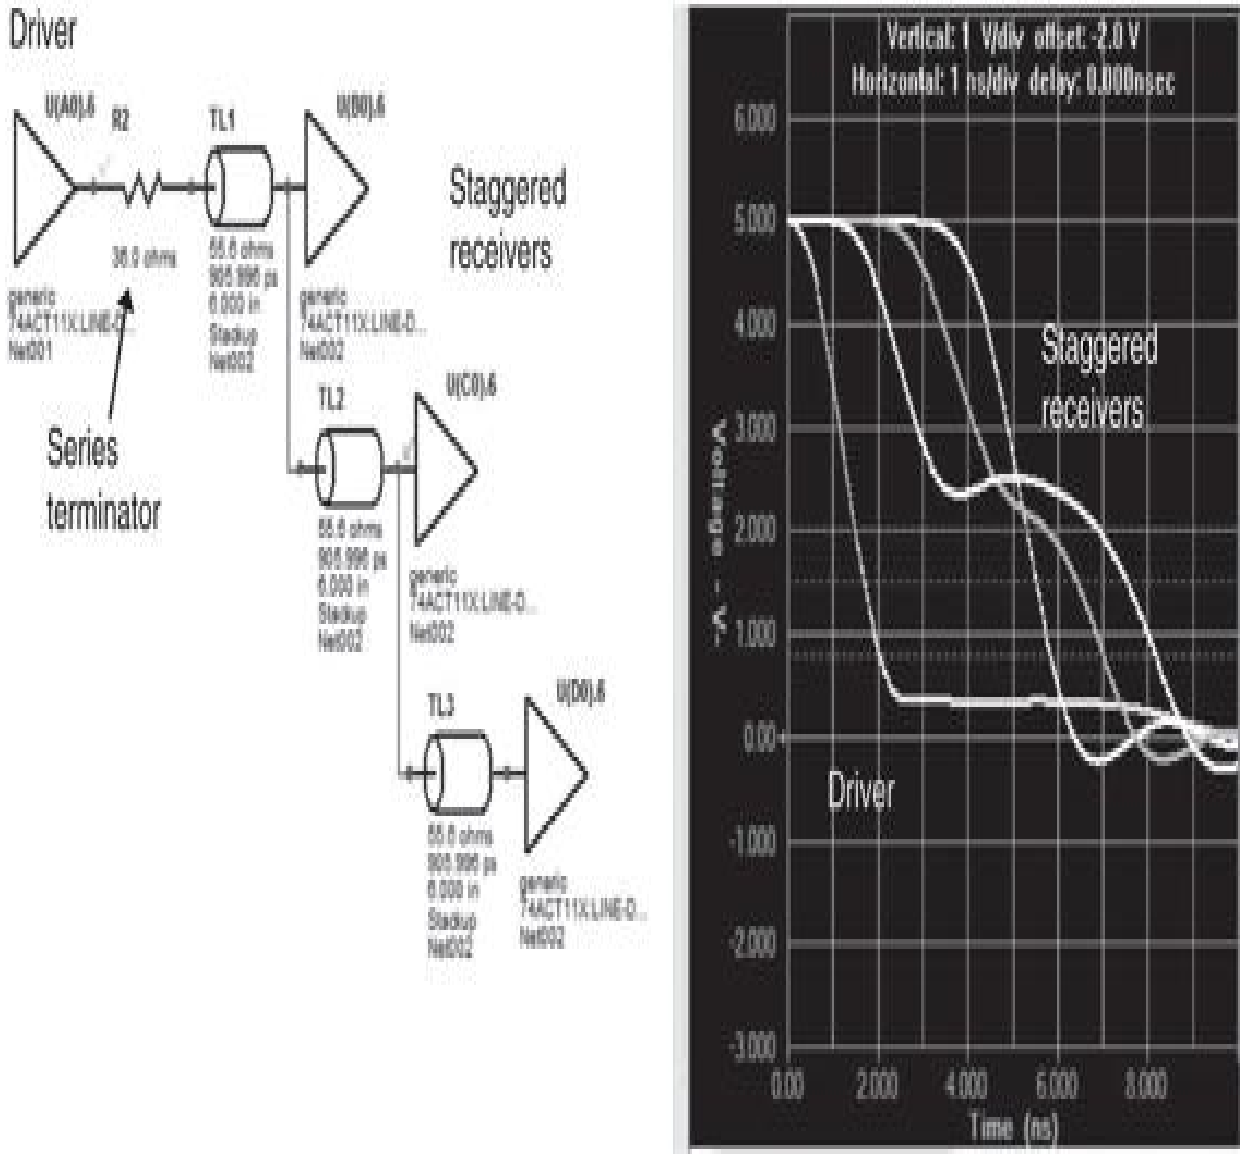

FIGURE 20.14 Series termination causes a voltage plateau at intermediate receivers. Parallel AC termination is generally better suited for daisy-chain topologies.

There are several ways to terminate at a junction or star connection that was introduced earlier. One possibility is a series termination at every driver. This has the advantage of reducing settling time at the receiver, while consuming a minimum amount of power. Several conditions must be met for a single series termination strategy to be effective. First, each branch must be close to the same length in delay terms; otherwise, reflections coming back from each branch

are not in sync and end up “bleeding” from branch to branch. Also, each branch must be the same impedance (or close), or it will not be possible to choose an effective single resistor value. If branches are longer than three-quarters of an inch, it makes sense to make their parallel impedances equal to the inbound line impedance from the driver. If driving from multiple I/Os, consider the distributed termination strategy.

PCB designers can also terminate at the junction itself by changing the trace impedance, or by using parallel DC termination. This method will damp reflections quickly, but will also attenuate the signal.

The appropriate choice of termination depends on network topology and signal direction. For nets that have complex routing patterns where it’s not been possible to conform to a pure daisy-chain route, or where multiple drivers are involved, it may be difficult to find a termination scheme that works, even in theory. This is where a “what if” simulation software can be an indispensable ally in quickly comparing alternatives.

20.3.1 Digital Crosstalk

Crosstalk is unwanted electromagnetic field coupling generated *between* transmission lines—causing unwanted noise generated between signals. It occurs when two or more nets on a PCB are coupled to each other electromagnetically (even though conductively, they’re not connected at all). Such coupling can arise any time two nets run next to each other for any significant length. When a signal is driven on one of the lines, the electric and magnetic fields it generates cause an unexpected signal to also appear on the nearby line, as shown in Fig. 20.15.

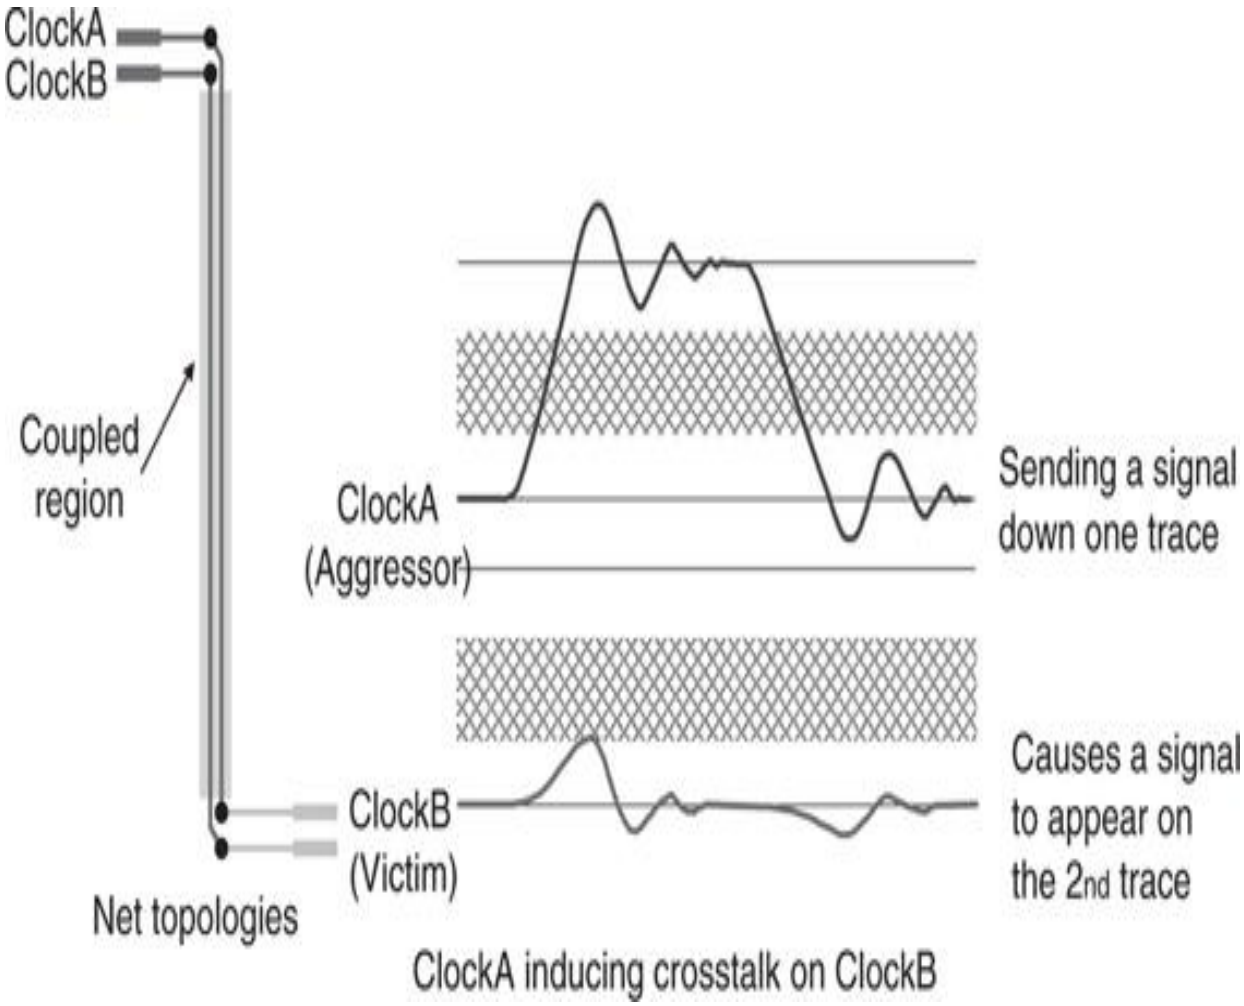

FIGURE 20.15 Crosstalk occurs when two or more neighboring traces couple together.

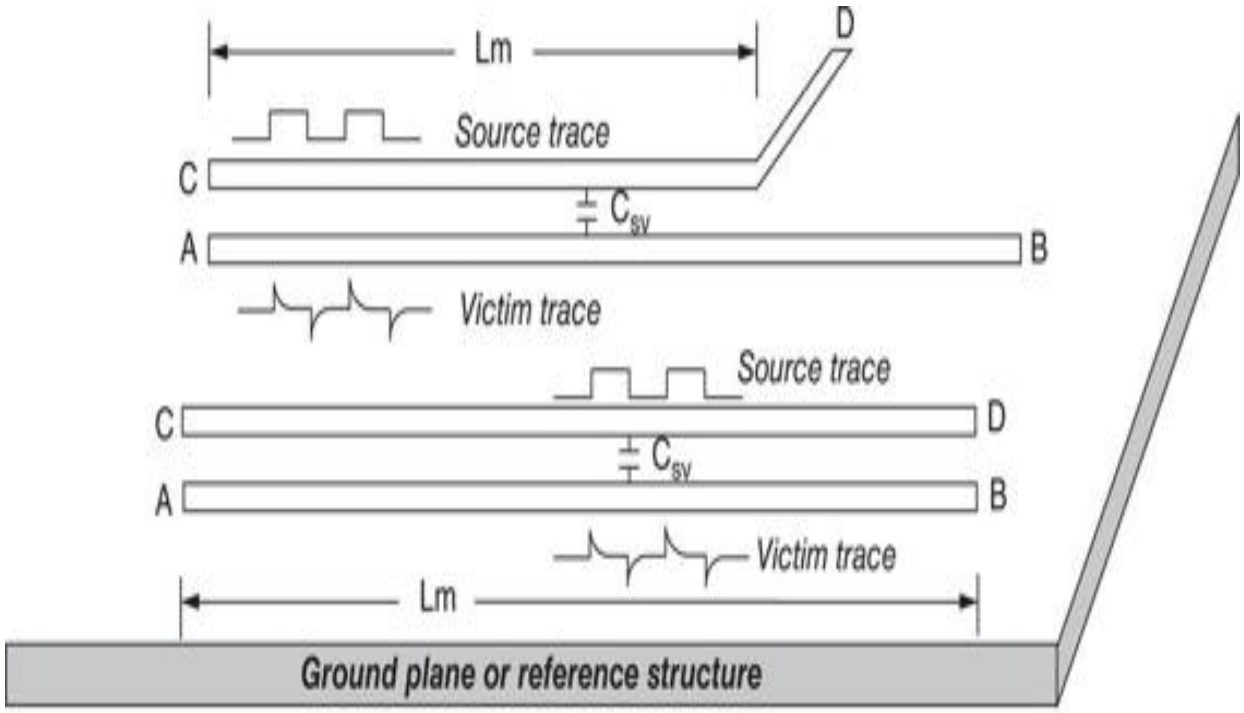
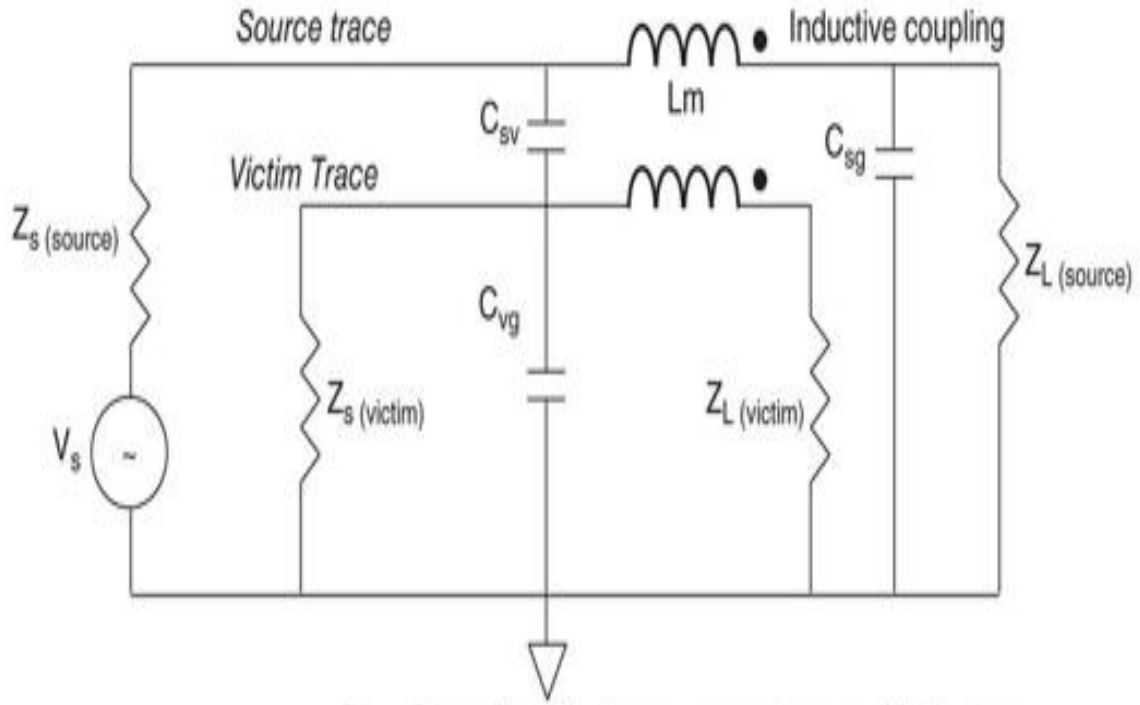
Crosstalk includes a capacitive element—known as "capacitive crosstalk," and an inductive component—known as "conductive crosstalk."[3] Each of these elements is illustrated in Fig. 20.16.[11] "Source," in this figure, denotes the source of the unwanted crosstalk, or the aggressor signal.





$$Z_v = \frac{Z_{s\,(v)} \times Z_{L\,(v)}}{Z_{s\,(v)} + Z_{L\,(v)}}$$

C_{sv} = Capacitance between source trace and victim trace
C_{vg} = Capacitance between victim trace and ground
C_{sg} = Capacitance between source trace and ground

FIGURE 20.16 Physical and electromagnetic representation of transmission lines that cause crosstalk to occur.[11]

A number of factors combine to create an unwanted crosstalk signal: the length over which the traces are coupled, the distance between the traces, their positions in the PCB stackup, what driver ICs are used on both the "aggressor" and the "victim" lines, whether or not the lines are terminated, and so forth.[2]

Crosstalk is a particularly hard phenomenon to anticipate and control unless you're able to simulate it, because there is almost no way of *intuitively* knowing how much crosstalk voltage and current will develop due to a given coupling. Nevertheless, there are semi-conservative design guidelines that can be useful—though almost always at the expense of board real estate.[10]

Examples include the "3H rule," where traces are spaced at three times the dielectric height, relative to the nearest reference plane; and the "3W rule," where trace spacing is held to three times the trace width. Each of these approaches can widen a bus width considerably.

20.3.2 Description of Crosstalk in a PCB

In crosstalk parlance, the "aggressor" signal or trace switches logic states and may cause a crosstalk event to occur. The "victim" transmission line responds by developing an unintended signal. The effect is three dimensional in nature. Victims can be adjacent, above or below the aggressor, as shown in Fig. 20.17.

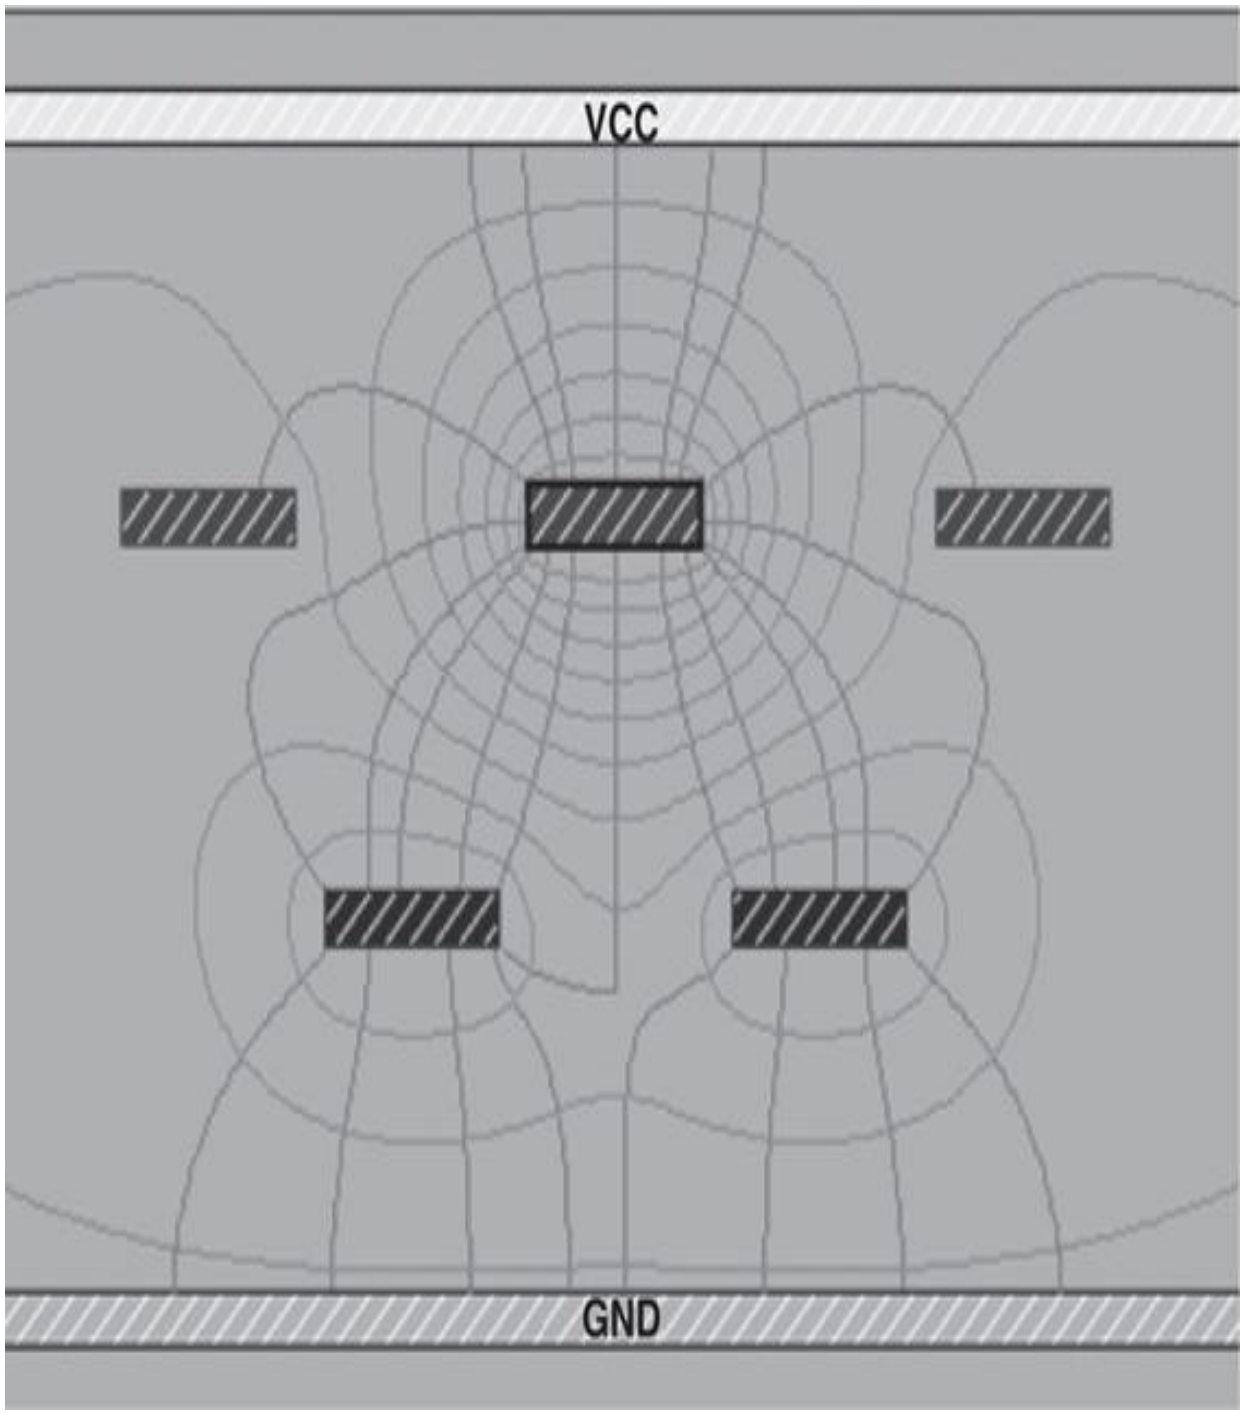


FIGURE 20.17 Victim nets can be above, below, or adjacent to an aggressor net.

Two coupled signals are imposed upon the victim net: a forward signal, and a backwards signal. The “forward” pulse travels along with the aggressor’s signal; and a “backward”

pulse travels back from the aggressor signal. Crosstalk at the victim's far end is called "far end crosstalk," or FEXT, and coupled voltage at the near end is called "near end crosstalk" (NEXT). Figure 20.18 shows both forward and backward crosstalk scenarios.

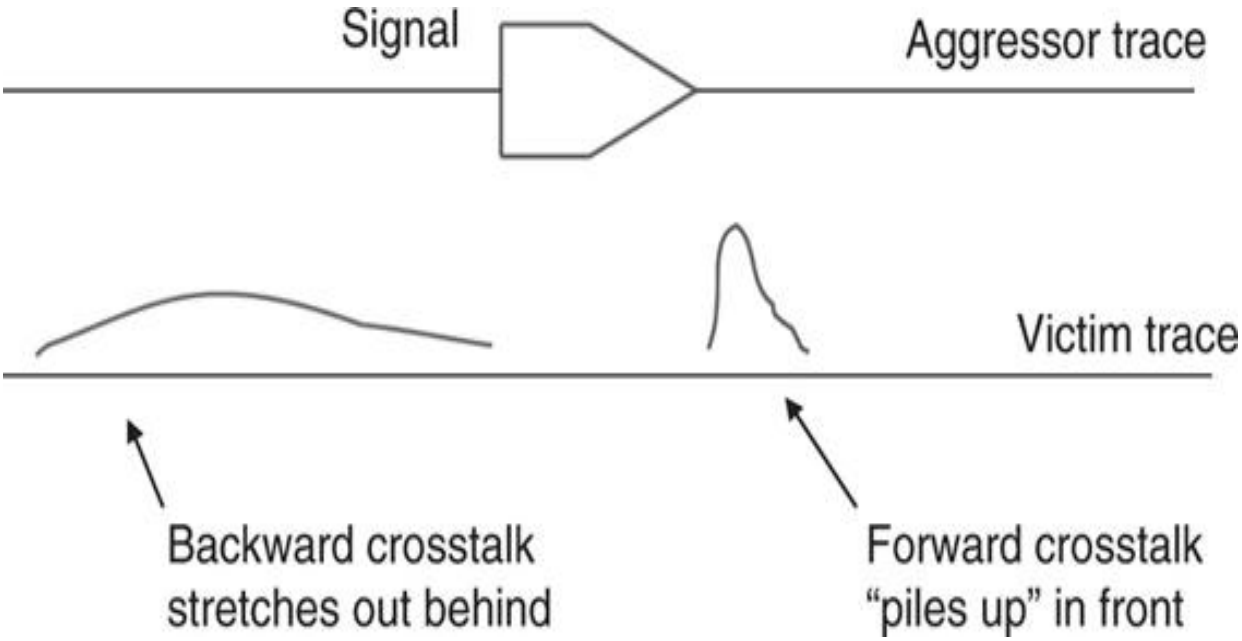

FIGURE 20.18 An illustration of both forward and backwards crosstalk on a victim trace.

The backward signal often ends up traveling forward after reflecting off of a driver. *Current* is injected into the victim by electric fields (the lines that run orthogonal to the traces in Fig. 20.17) that are caused by capacitive coupling interactions traveling between the aggressor to the victim nets. These interactions are effected by surface area and distance, and generally terminate at adjacent conductors.

Voltage is induced upon the victim by magnetic fields. These are inductive (transformer) coupling interactions, which are somewhat circular—surrounding the aggressor and victim nets. These interactions are *not* generally stopped by conductors, and can therefore extend around multiple adjacent conductors.[10]

20.3.3 Guidelines to Minimize Crosstalk

The most common crosstalk design rules involve trace to trace separation. A PCB designer might, for example, set an auto-router to 4-mil trace width, and 4-mil spacing. This will, of course, maximize router completion; but the resulting design will result in 20 to 60 mV of crosstalk. Adjusting noise-sensitive victims to more than 6-mil trace-to-trace spacing can help avoid this problem, as shown in Fig. 20.19.[10]

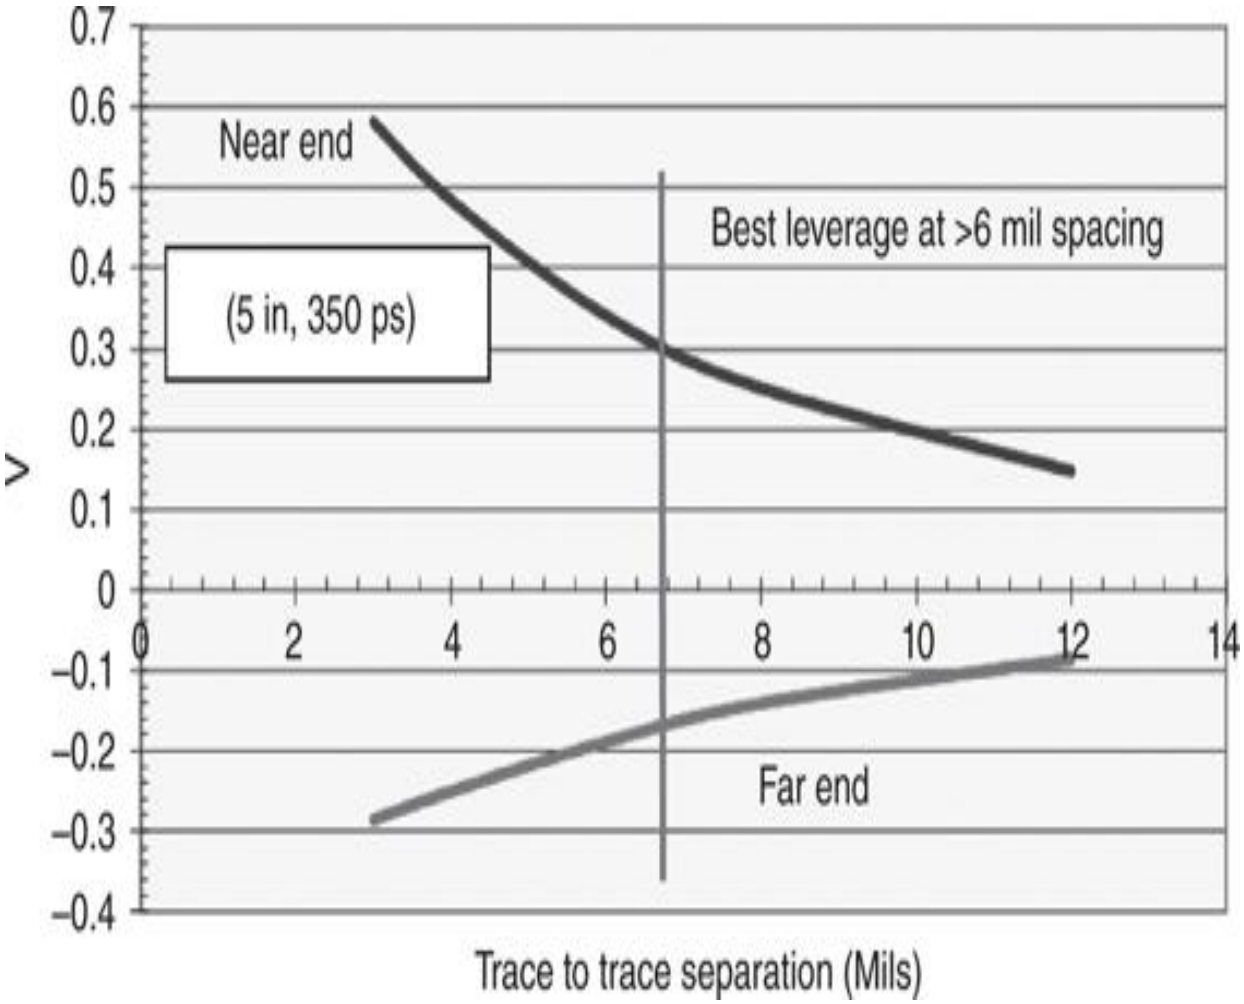

FIGURE 20.19 Using two parallel, 5-in lines, the graph shows the curves for NEXT and FEXT beginning to flatten out at around 7-mil spacing between aggressor and victim nets. Tighter spacing, to the left of the vertical line, results

in more crosstalk, and wider spacing—to the right side of the vertical line will result in diminishing benefit.

20.3.4 Dielectric Effects and Reference-Plane Distance

Since electric fields terminate at reference planes, traces physically close to reference planes have reduced crosstalk. Capacitive trace-to-trace coupling drops off quadratically with the distance from the reference plane(s)—so traces within 4 mils of a reference plane will be much more immune to crosstalk than a trace 6 or more mils from the nearest reference plane. And symmetric striplines—because of their relative proximity to not one, but two reference planes—have relatively higher immunity than microstrip signals.

Moreover, there's a dielectric constant effect to consider. High dielectric constants (Dk), concentrate the electric field, resulting in relatively poorer crosstalk performance, in a roughly linear relationship between Dk and capacitive crosstalk.

20.3.4.1 Example: Crosstalk on a Bus. The following process ensures no more than 200 mV of crosstalk can occur between transmission lines.

A typical bus in a modern digital system contains many physically parallel traces—16, 32, 64 or more. To analyze crosstalk on such a bus, you can narrow the scope to a single "victim" trace, with "aggressor" nets on either side.

Starting with coupled, coplanar 6.0-mil wide (W) (0.15 mm) stripline traces running parallel for 12 in (305 mm) with trace-to-trace separation of 8.0 mils (S) (0.208 mm), the dielectric constant (Dk) is 4.3, with a height (H) of 5.0 mils (0.127 mm), as shown in Fig. 20.20.

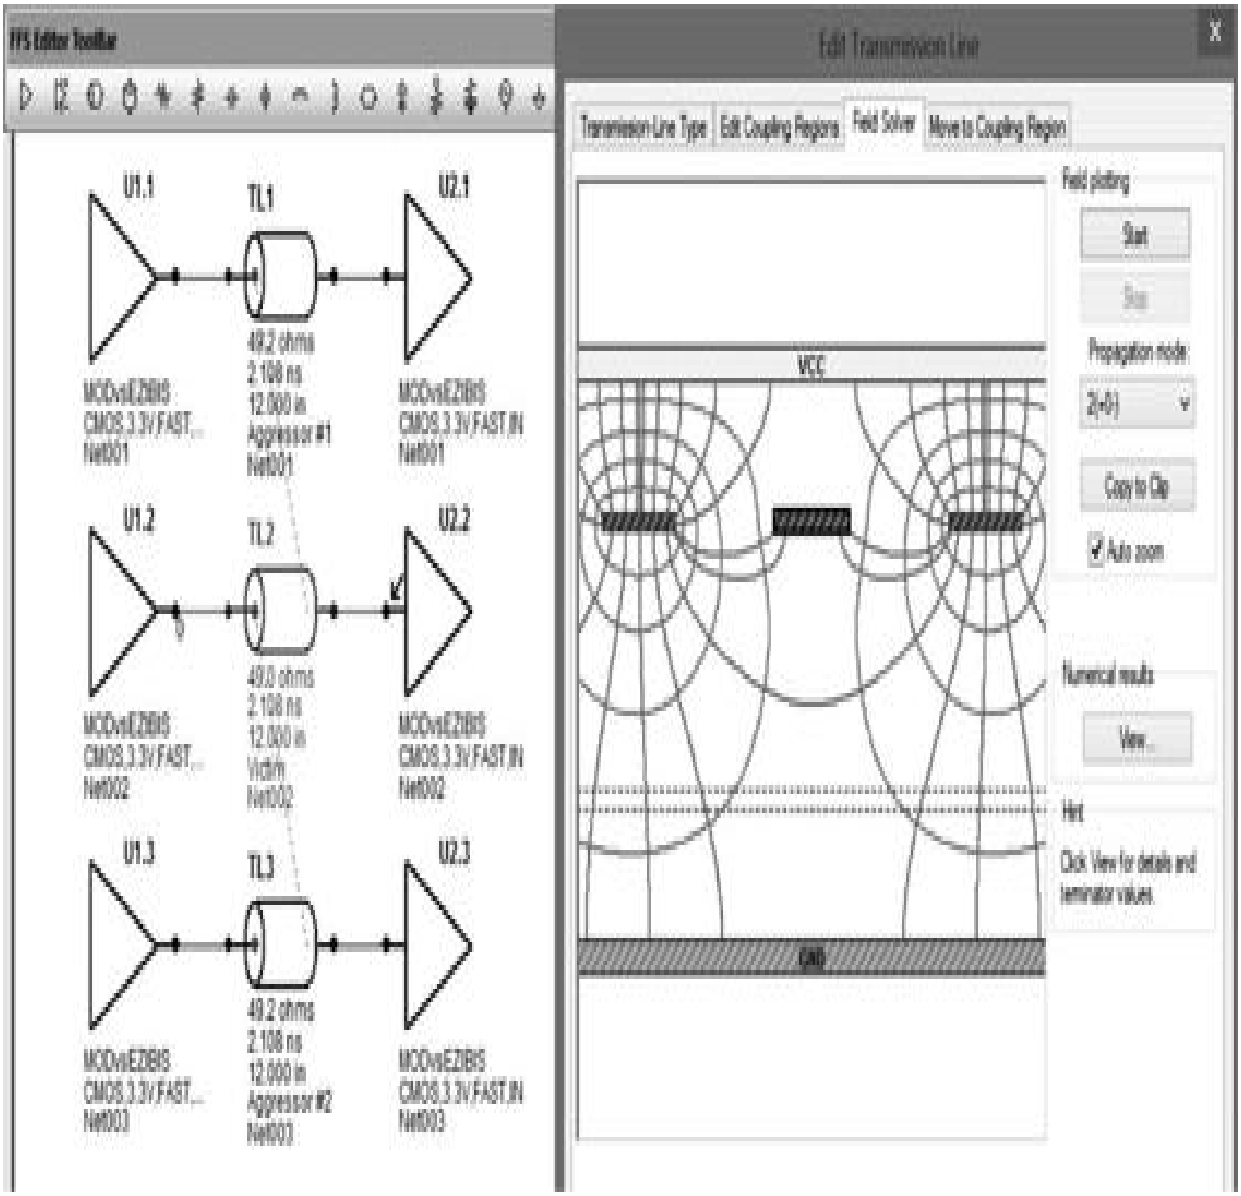

FIGURE 20.20 Crosstalk is easily illustrated with the aggressor-victim-aggressor example shown. (*Shown with Mentor Graphics LineSim*.)

Simulation results from Mentor Graphics LineSim, are shown in Fig. 20.21 using the parameters above. In the figure we clearly see far-end crosstalk based on this configuration.

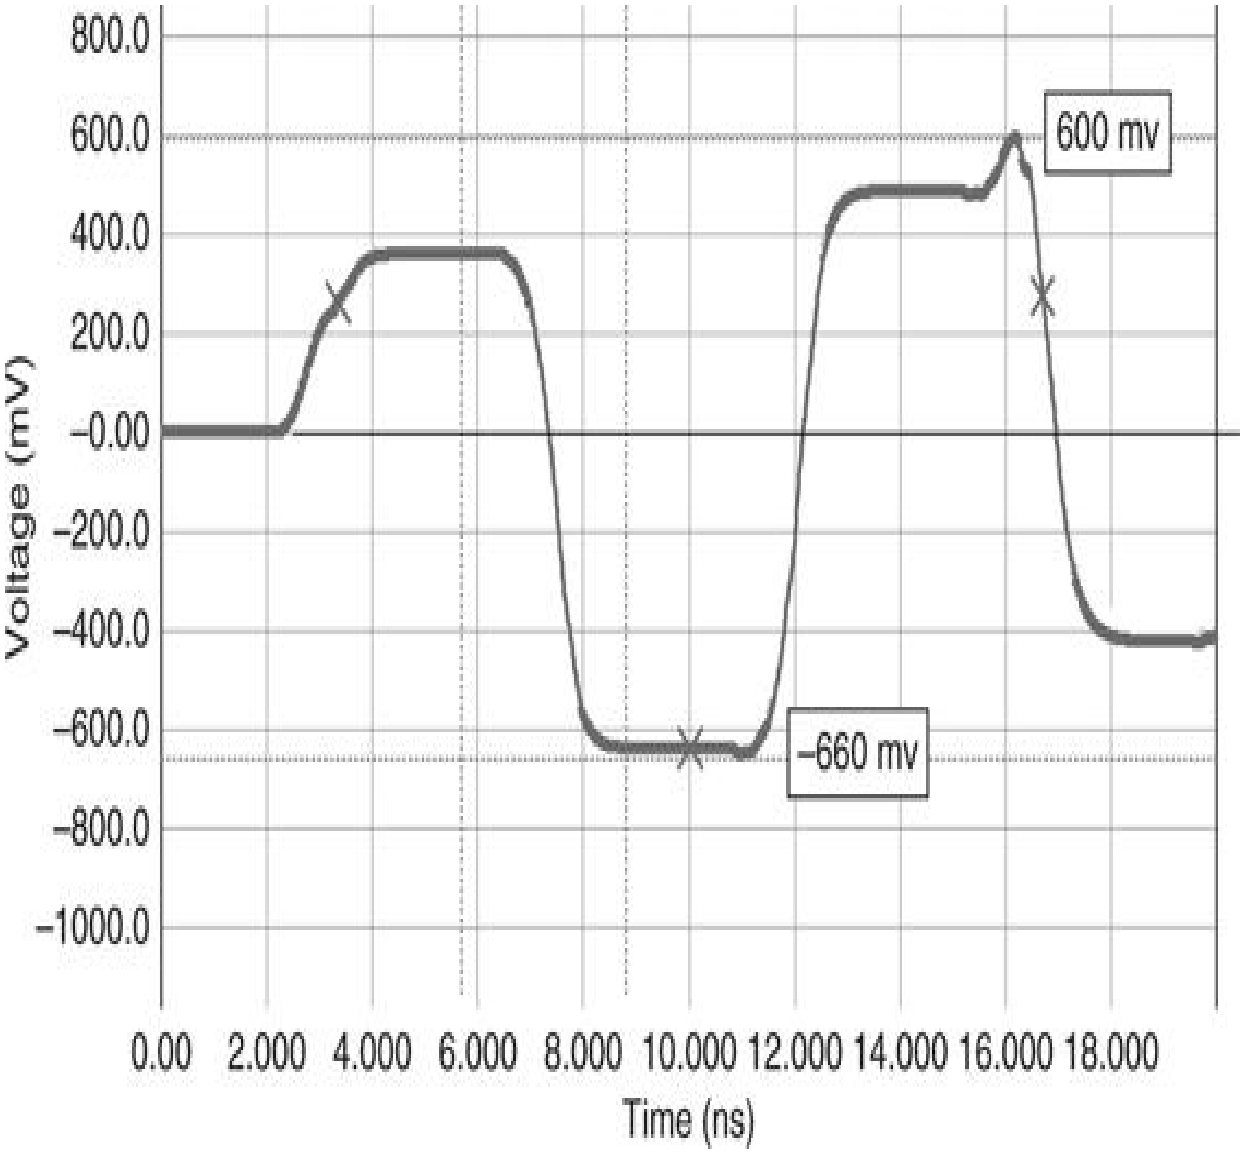

FIGURE 20.21 Far end crosstalk (FEXT) on the victim net shown in Fig. 20.20.

With 590 ps (0.59 ns) driver-switching speeds on the two aggressor nets, and no signal injected on the victim net, we have about 600 mV on the positive side that will be injected into the far-end victim waveform; and 660 mV on the negative side—both well beyond our design criteria of 200 mV maximum crosstalk.

Crosstalk is a complex effect that is influenced by many different geometric factors: for example, driver-IC technology (Tr, Tf, output impedance and drive strength), trace width

(W), copper weight (T), parallel-line length (Lp), trace separation (S), PCB stackup (layer ordering, Dk, and dielectric thickness, H), and line-end termination (crosstalk generally requires more-complex termination than single-line reflections).

Rules-of-thumb exist for controlling crosstalk, but if you really want to know how to minimize crosstalk while controlling cost on your specific design, you need a good simulation tool. In the following section, we'll go through an iterative process for dealing with crosstalk on the design in Figs. 20.20 and 20.21.[10]

20.3.5 Copper Thickness

A crosstalk lever that might be overlooked sometimes is the copper thickness. Up until now, signals have used 1 oz copper. One might think that reducing copper thickness will reduce capacitive coupling, though simulation shows that the result doesn't turn out to be significant in practice. Nevertheless, for the remainder of this discussion, we'll half-ounce copper in the analysis.

20.3.6 Reducing Parallel Coupling Length to Decrease Crosstalk

One common technique for reducing crosstalk is to reduce the length over which aggressors and victims run parallel to one another. This poses some practical problems on the routing side—as those traces ended up being parallel on a board for a reason—but it's instructive to see what happens when the parallel coupling region is reduced by 50 percent, from 12.0 in (305 mm) to 6.0 in (152 mm). Surprisingly, this change does not end up reducing crosstalk at all—simply moving peak crosstalk amplitudes to the left in the time

domain. Reducing parallelism alone, as a crosstalk lever, isn’t quite as powerful as we might think it is.

20.3.7 Increase Trace Separation to Decrease Crosstalk

Another common technique to decrease crosstalk is to increase the separation, S, between the traces. Increasing trace separation from 8 to 12 mils results in a reduction of crosstalk to 400 mV on the positive side, and −400 mV on the negative side—still well beyond where we would like to be; and in the process of making this change we’re using up a good bit more board space.[3]

20.3.8 Modifying the Dielectric Material

There are many ways besides trace separation and parallelism to affect crosstalk values. One that is sometimes overlooked is the PCB stackup assignment and where the trace is routed relative to a reference plane. Recall that we started with a Dk = 4.3. What happens if we try to reduce capacitive crosstalk by using a lower-Dk material, say D = 3.8?[3] Through simulation, it turns out that the improvement from this change alone is negligible; however, in the process of using half-ounce copper, and reducing the capacitance (Dk) of the dielectric, trace impedance increased from roughly 50 Ω to just under 57 Ω. (Remember: Impedance is inversely related to the square root of trace capacitance, which is tied to the capacitance of the dielectric.) So, reducing the dielectric thickness (H) from 5.0 mils to 4.5 mils between the stripline layer of interest, and the nearest reference plane increases the capacitance again, pulling the impedance back to around 50 Ω. The combination of these

factors gets us much closer to our goal, resulting in 211 mV on the positive side down to about 230 mV—more than a 60 percent improvement, but still above our target of 200 mV.

Reducing trace width (W), which increases impedance (Z_0), and then narrowing the dielectric thickness (H) to pull the impedance back down to around 50 Ω is another potential way to reduce crosstalk. Reducing width (W) to 5.0 mils (0.127 mm), and height (H) to 3.75 mils (0.95 mm) results in roughly 200 mV of both positive and negative crosstalk.

By narrowing trace width (W) to 5.0 mils (0.127 mm), the overall bus with will decrease by the number of bits minus 1. With an interest in gaining more margin—while keeping the overall bus width in line with the original width—adding another mil to the spacing [i.e., taking S from 8.0 (0.203 mm) to 9.0 mils (0.228 mm)] results in plenty of margin: 160 mV on the positive side, and 170 mV on the negative side.

Table 20.1 summarizes effects on the topology in Fig. 20.20, and their relative impact on FEXT—ranked by relative reduction in worst-case crosstalk.

TABLE 20.1 Simulation Results for Reducing the Crosstalk Shown in Figs. 20.20 and 20.21

Rank	Description	FEXT Reduction, %
	Original configuration: W = 6 mils; T = 1 oz; Lp = 12 mils; S = 8 mils; Dk = 4.3; H = 5 mils	0
	Reduce copper thickness (T) to ½ oz	~0
	Reduce parallel length (Lp) from 12 to 6 mils	~0
4	Increase trace separation (S) from 8 to 12 mils	~33
	Reduce capacitive crosstalk: Dk = 3.8	~0
3	T = ½ oz; Dk = 3.8; H = 4.5	~60
2	Reduce W from 6.0 to 5.0 mils, and H to 3.75 mils	~65
1	Reduce W from 6.0 to 5.0 mils, H to 3.75 mils, and increase S to 9.0 mils	~75

Reducing trace width (W), which increases impedance (Z_0), and then narrowing the dielectric thickness (H) to pull the impedance back down to around 50 Ω is another potential way to reduce crosstalk. Reducing W to 5.0 mils (0.127 mm), and H to 3.75 mils (0.095 mm) results in roughly 200 mV of both positive and negative crosstalk. By narrowing trace width (W) to 5.0 mils (0.127 mm), the overall bus with decreased by the number of bits minus one.

Figure 20.22 shows the top four ways of reducing crosstalk on this particular bus design. The resulting design rule is to use W = 5.0 mils (0.127 mm), Dk = 3.8, H = 3.75 mils (0.095 mm), and S = 9.0 mils (0.228 mm).

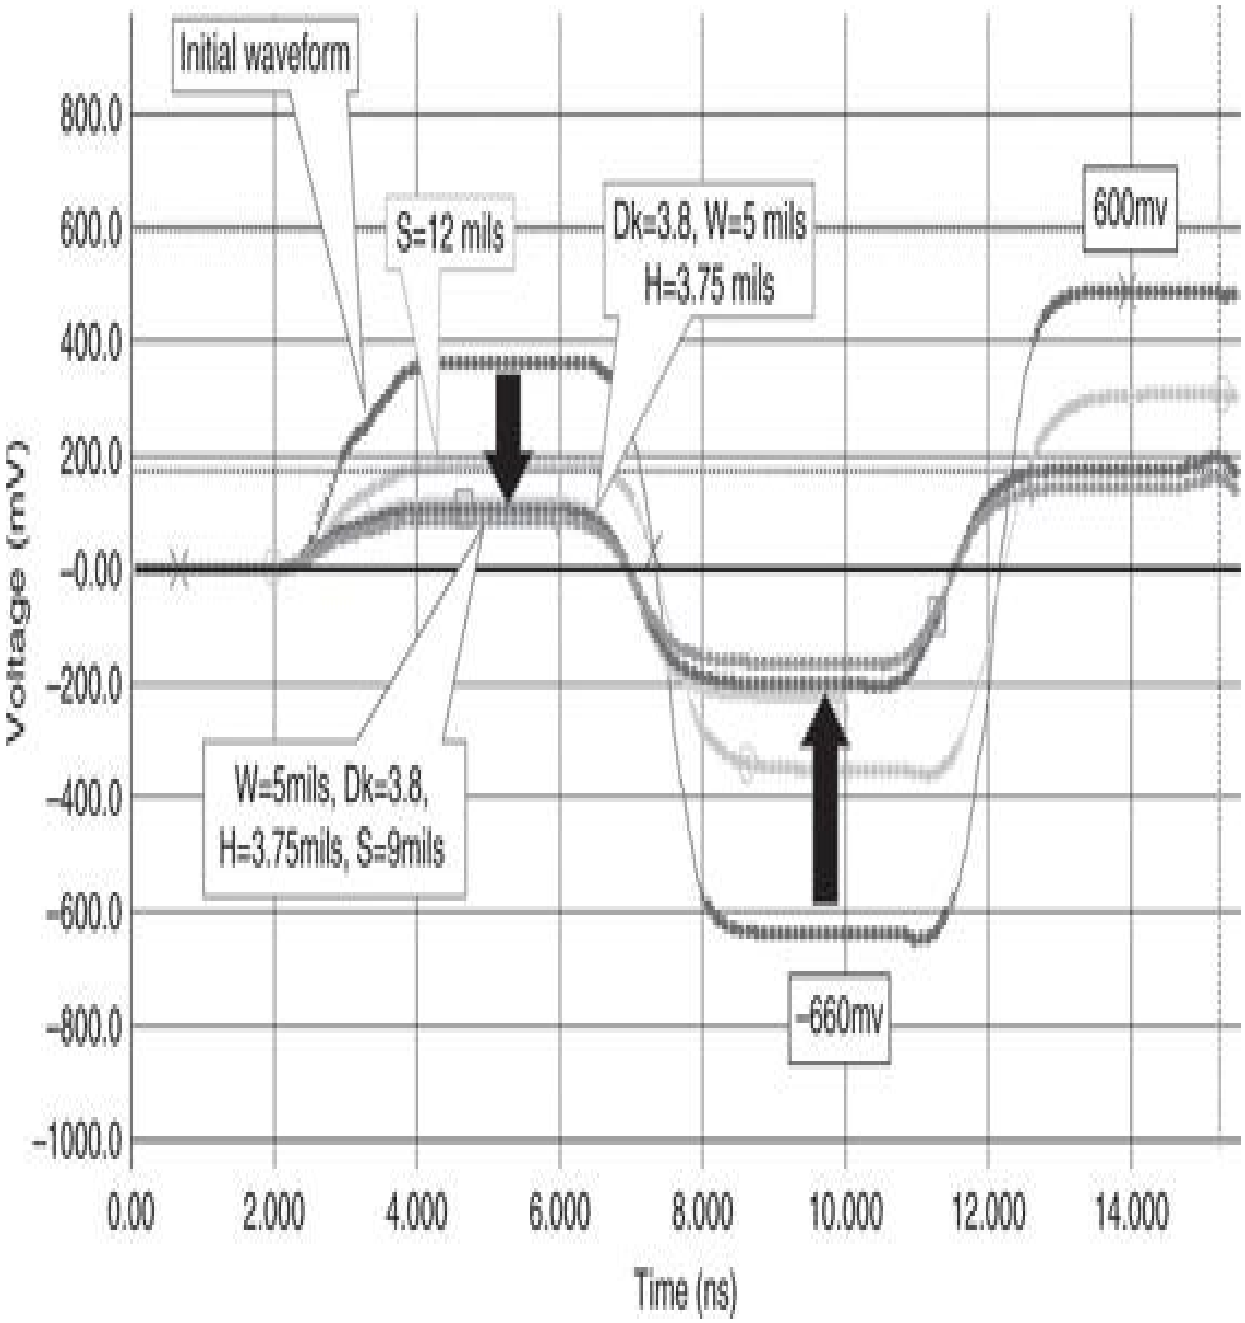

FIGURE 20.22 Top four ways of reducing crosstalk on Fig. 20.20 bus design. Resulting design rule is W = 5.0 mils, Dk = 3.8, H = 3.75 mils, and S = 9.0 mils.

20.4 INTRODUCTION TO DIFFERENTIAL SIGNALING

The single-ended, high-speed buses that have been discussed in this chapter so far persistently became wider and faster over the years until signal integrity issues, such as skew, crosstalk, SSN, and similar concerns forced a fundamental change in signaling strategy in the mid-1990s. This is when *low-voltage differential signaling* (LVDS) was introduced by integrated-circuit manufacturers as an alternative to "single-ended signaling," primarily for the rejection of common-mode noise.

In a differential signal, the driver IC, ideally, sends perfectly matched signals of opposite polarity down two well-matched lines, or as close to identical as possible. The *difference* in amplitude between these two signals, one positive and the other negative, is what the receiver sees as the incoming signal. A key reason for this approach is to combat *common-mode noise*. It is the same principle used with a noise-canceling microphone, which picks up ambient noise, inverts it, and feeds it into the microphone with the sender's voice to cancel it out.

The goal is for near-complete symmetry between the incoming signals, both in terms of timing (propagation delay) and voltage. To achieve this, the following factors should be considered:

- Trace-length matching is important.
- External noise, such as crosstalk should be symmetrical.
- The glass weave under each half of the "differential pair" should be the same … If it's not, we refer to the timing difference as "glass-weave skew" (typically measured in ps).

Figure 20.23 shows single-ended receiver waveforms that a differential receiver reads as V_{diff}, the difference between D+ and D−. If everything is designed properly, the AC common-mode noise at the bottom of the figure will be minimized.[12]

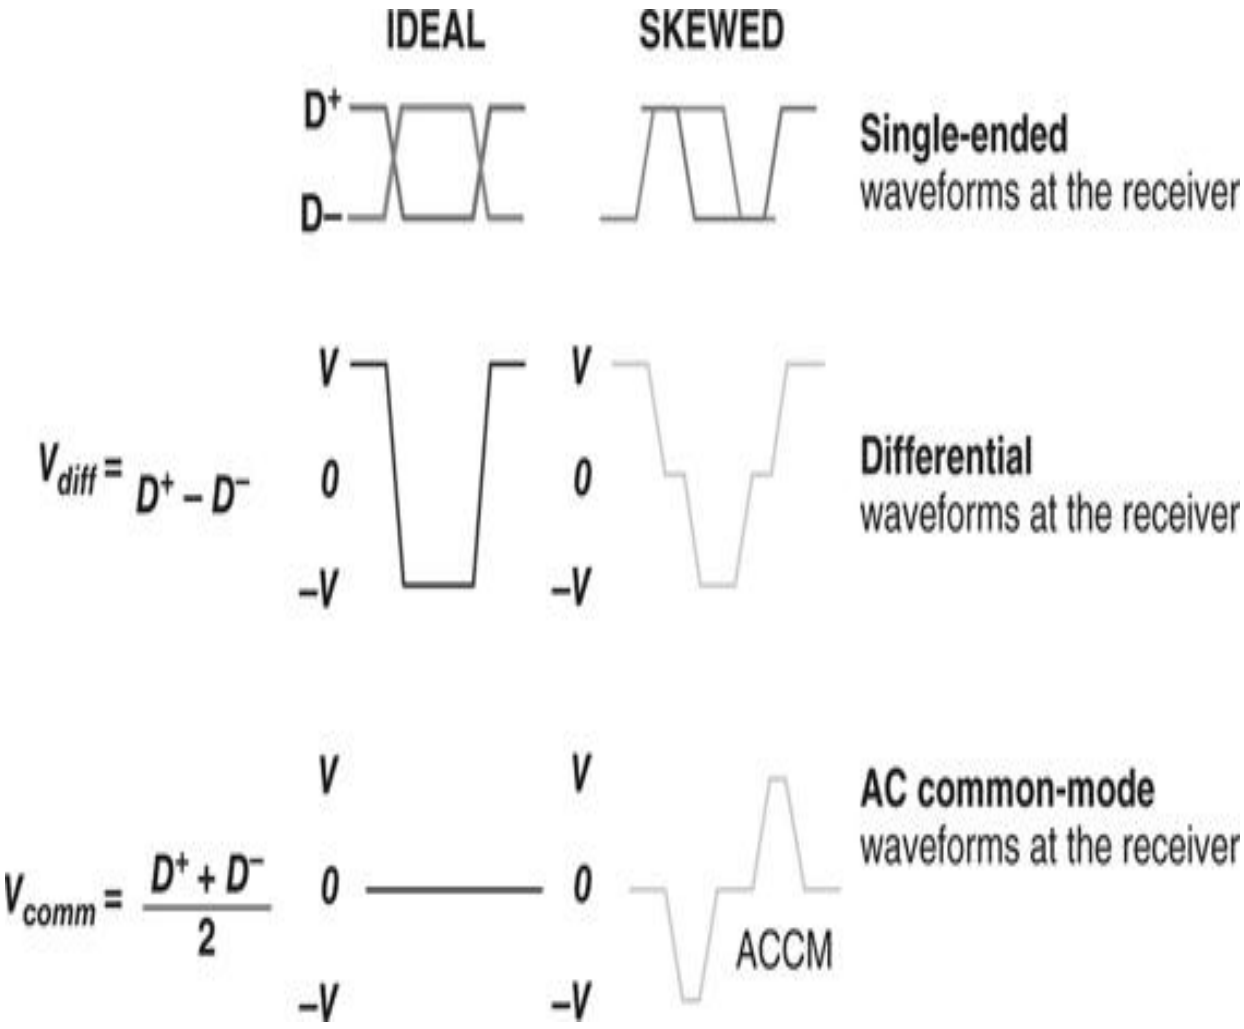

FIGURE 20.23 Single-ended receiver waveforms that the differential receiver read as V_{diff}, the difference between D+ and D−. If everything's designed properly, the AC common-mode noise at the bottom of the figure will be minimized.

With a differential signal, an external noise source such as a CMOS driver in close enough relationship for crosstalk to occur will couple into both halves of the differential pair (roughly) equally. Most differential component providers recommend differential impedances (Z_{diff}) at 100 or 85 Ω for optimal noise cancelation and performance.

20.4.1 Introduction to Multi-Gigabit-per-Second SERDES Signaling

The common-mode noise rejection benefits provided by LVDS were helpful, and differential signaling became an industry standard as a result, however differential signaling alone was not enough to solve the growing speed problem.

Initially, only clocks used differential signaling; when source-synchronous logic like early DDRx architectures began to become prevalent in the late nineties—data lines went differential, and data paths became narrower—presenting a hybrid form of signaling between old parallel (single-ended) architectures and fully asynchronous approaches.[13]

As a result, the networking/computer industry began turning away from parallel signaling to asynchronous serial interconnects—with embedded clocks—utilizing techniques that have been used in telecommunication and military applications for years.

Figure 20.24 shows a contrast between a wide, parallel bus interface, with an external clock, and a differential, serial architecture—with the clock embedded in the bit stream.[13]

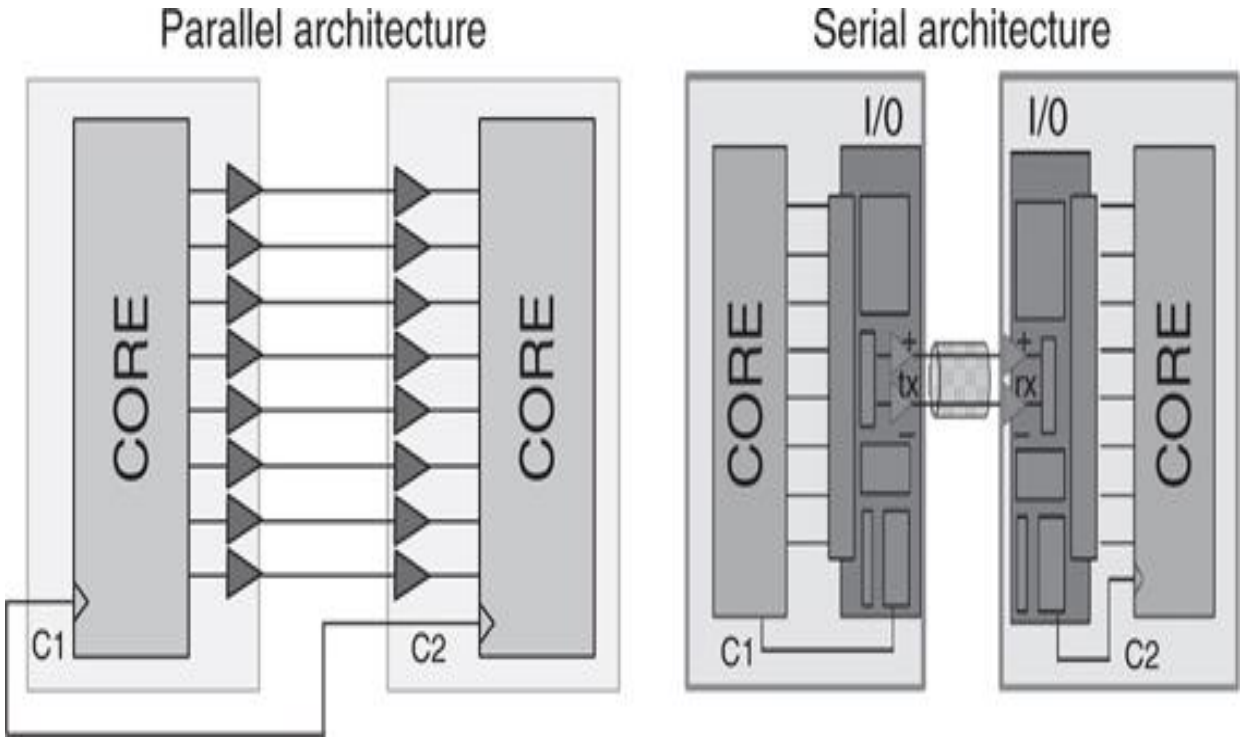

FIGURE 20.24 A graphical representation of the architecture of a wide, parallel bus is compared to a differential, serial architecture.

For signals faster than 1 GHz, transmitted for distances longer than 10 in (25.4 cm), loss is the principal signal-integrity concern. A super-fast driver edge will emerge from the end of the transmission path with reduced amplitude and a slower rise time. This effect becomes particularly serious when the degraded rise time is comparable to the bit period of the signal. Inter-symbol interference (ISI) results when the shape of the received waveform becomes dependent on the prior combination of bits.

20.4.2 Balancing a Loss Budget

The most general way to control loss on a backplane is to avoid impedance discontinuities through transitions. This means keeping the same ratio between *L* and *C* throughout the signal path.

Every link needs a link budget, with typical end-to-end attenuation budgets for multi-gigabit-per-second SERDES links ranging from 10 to 15 dB, or lower with equalization at the receiver.[14]

As with any budgeting exercise, exact (dB) figures for each item are not required, but it is important to have a budget for each major element. If you are hunting for the last decibel, just knowing that one part of the system is twice as important as another. This provides a huge design benefit as far as knowing where to focus engineering resources.

A component manufacturer will typically explicitly specify a loss budget for the component. It is also possible to derive the budget. The relationship for estimating an interconnect loss budget is[15]

$$\text{Attenuation budget (dB)} = 20 \times \log\left(V_{\text{RX,min}}/V_{\text{TX,min}}\right)$$

This loss figure reveals attenuation requirements before employing preemphasis or equalization. At a high level, there are two areas on a backplane interconnect where loss can occur:

- Transition regions that include the BGA package, vias, and connectors
- The line card and the backplane itself

20.4.3 Loss at Backplane Interconnect Transitions

A BGA package represents a very small piece of the overall loss budget, typically 0.5 dB or less on each end at frequencies below 2 GHz. At 3.0 GHz, each package would contribute 0.8 dB to total channel loss.

Connectors in a high-speed system take another chunk out of the loss budget. As a general rule, look for connectors with

a differential impedance of 85 to 100 Ω, this will result in well under 3 dB of loss at the target frequency.

At gigabit rates, poorly designed vias can contribute 0.5 to 1.0 dB of loss, each, against the total loss budget. The degradation effects posed by vias are influenced by the unique characteristics of each individual via, including the proximity of nearby return paths, the number and location of pads in the pad stack, pad size and shape, the layers on which the traces connect and the associated via length (through, blind or buried), spacing between differential vias and "stubs" (that is, any portion of the via that is not necessary for signal transmission).

Approaches for mitigating the negative effects of vias include blind and buried vias (shorter than through-hole vias), backdrilling, using smaller pads and only the pads that are needed, using large antipads, and carefully locating bypass capacitors and stitching vias close to vias on high-speed nets. These techniques can reduce via effects to less than 0.25 dB.[14]

20.4.4 PCB Interconnect Loss

There are three primary ways to control PCB interconnect loss:

1. Reduce resistive loss by widening traces. "Skin effect" is the result of reduced cross-sectional area in a trace, so this solution is somewhat self-explanatory. Trace width changes tend to be relatively more effective at reducing loss at frequencies below the cross-over frequency discussed below.
2. Reduce dielectric loss using low-loss dielectrics. To reduce dielectric loss, consider more expensive materials with lower loss tangents—typically represented as "Df," or "dissipation factor."

3. Reduce dielectric loss and resistive loss by shortening lines. Dielectric loss is a function of the material used and the length over which a signal is transmitted. Resistive loss is tied to the line width and the line length. An example of this is shown on the left in Fig. 20.25.

FIGURE 20.25 *Top*: Loss (dB) as a function of frequency for two differential, stripline channels with different materials, lengths, and slightly different stackup cross sections. The view to the left has a total stripline loss of 5 dB (not including vias and BGA breakouts), and the view to the right shows a higher-loss material with 10 dB of total loss. *Bottom*: The resulting eye diagrams, with a PCI Express eye mask for reference. (*Simulations with Mentor Graphics HyperLynx*.)

Figure 20.25 shows two sets of loss curves, as a function of frequency, and consideration for a few of the different types of loss, resistive, which includes skin effects; and dielectric loss, which is tied to material properties. The view to the left shows 5.0 dB of total loss through a 12-in differential pair. The second example shows 10.0 dB of total loss through a similar stripline, but using a higher-loss dielectric material, and 17-in differential traces. This view of a transmission-line cross-section is useful for tasks such as stackup planning, loss budgeting, and material selection. Using this or a similar software tool, a designer can quite easily gain an understanding of the PCB trace components of your loss budget. Depending on the trace properties, it's reasonable, as these examples show, to design in trace losses that vary pretty widely, resulting in eye patterns that are quite different. The open eye shows quite a bit of margin with respect to the diamond shaped PCI Express eye mask.

5.0 dB Example: 12-in stripline trace, *W* = 4.5 mils, Er = 3.75, loss tangent = 0.009*
Loss results (at 4 GHz): Loss_{TL} = 5.0, loss_{Res} = 2.9, $\text{loss}_{\text{Dielectric}}$ = 2.1 dB
Crossover frequency = 7.86 GHz
*Nan Ya NPG-170D halogen free

10.0 dB Example: 17-in stripline trace, *W* = 4.5 mils, Er = 3.9, loss tangent = 0.02*
Loss results (at 4 GHz): Loss_{TL} = 10.0, loss_{Res} = 4.0, $\text{loss}_{\text{Dielectric}}$ = 6.0 dB
Crossover frequency = 1.78 GHz

*Nan Ya NP-175F FR-4

Below the crossover frequency (the point at which dielectric loss begins to dominate), increasing trace width provides more loss-reducing leverage than reducing the loss tangent. This is important when you are searching for ways to trim a few decibels from your total loss budget. Note, too, that the frequency at which these two loss curves cross is about 75 percent lower for the standard loss FR-4 on the right in Fig. 20.25.

PCB material changes can be considered—to drive down dielectric loss. However, when considering material changes to balance your attenuation budget, you need to carefully consider impacts on manufacturing costs. Lower loss materials almost always come at a higher cost.

20.4.5 Compensating for Loss at the Chip Level

At high frequencies and across long backplanes, it is likely that you will still need some help at the end of the design process. That is where the FPGA or ASIC itself can compensate for loss outside your budget.

There are two primary ways to control loss at the chip level:

1. *Transmitter preemphasis*. Boost the initial voltage of each edge to compensate for high-frequency loss.
2. *Receiver equalization*. With equalization, the incoming signal's high-frequency components are amplified to compensate for loss.

In practice, you can build fairly long, inexpensive channels ranging from 12 to 18 dB while leaving additional margin for crosstalk and reflections, correcting these losses with TX and

RX equalization for low bit-error-rate performance. Although it is possible to estimate rise-time degradation and loss, the only way to get a realistic prediction of actual results—including crosstalk and reflection effects—is to use a software simulator with these capabilities.[14]

20.5 INTRODUCTION TO POWER INTEGRITY

Every electronic product, regardless of application, requires a carefully planned power distribution network (PDN) to ensure functional operation while achieving EMC compliance—particularly at today's high operating frequencies. Many components on PCBs are sensitive to fluctuations in the power distribution system. Without a stable power distribution system, issues may develop from switching noise on planes, affecting nearby components based on charge storage, power fluctuations, spikes, voltage droops, blackouts, along with a host of other items that may cause functional disruption in addition to undesired EMI that radiates from the edges of the PCB. Additional background on PDNs is found in Ref. 11.

In this section, the word "*ground*" is sometimes replaced by the word "*return*" or "0V." There is no "true ground" in a PCB with regard to power distribution. We have voltage and 0 V reference. Voltage travels from the power generating section, and according to Ampére, must "return" to its source.

20.5.1 The Need for Optimal Power Distribution

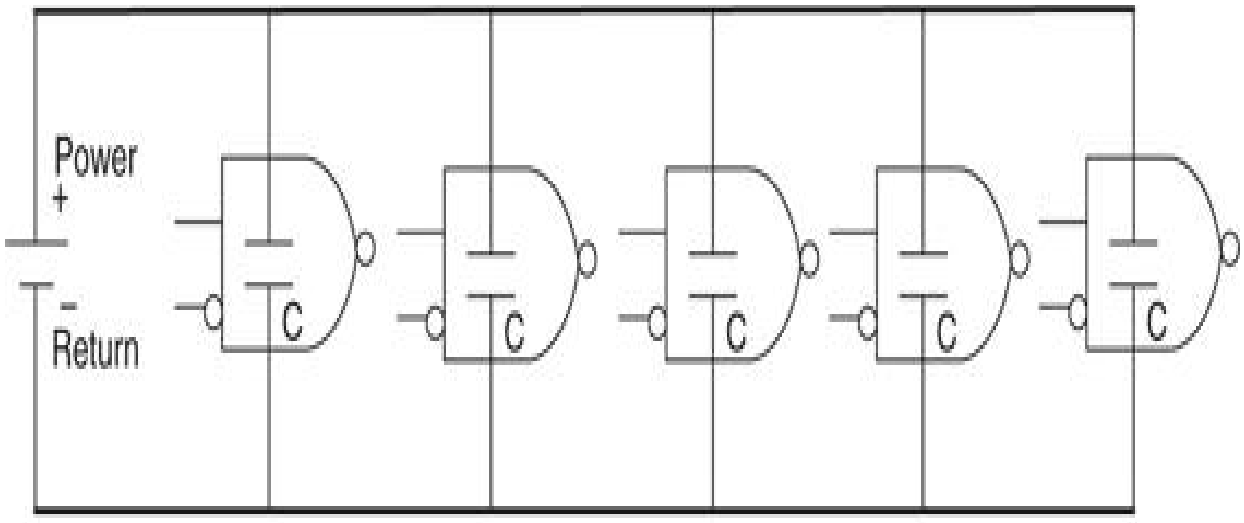
An optimal power distribution system is required to provide stable operating voltages, typically with 5 percent or lower voltage ripple, with minimal switching noise for all components to ensure functional operation.

Key concerns when designing a PDN include

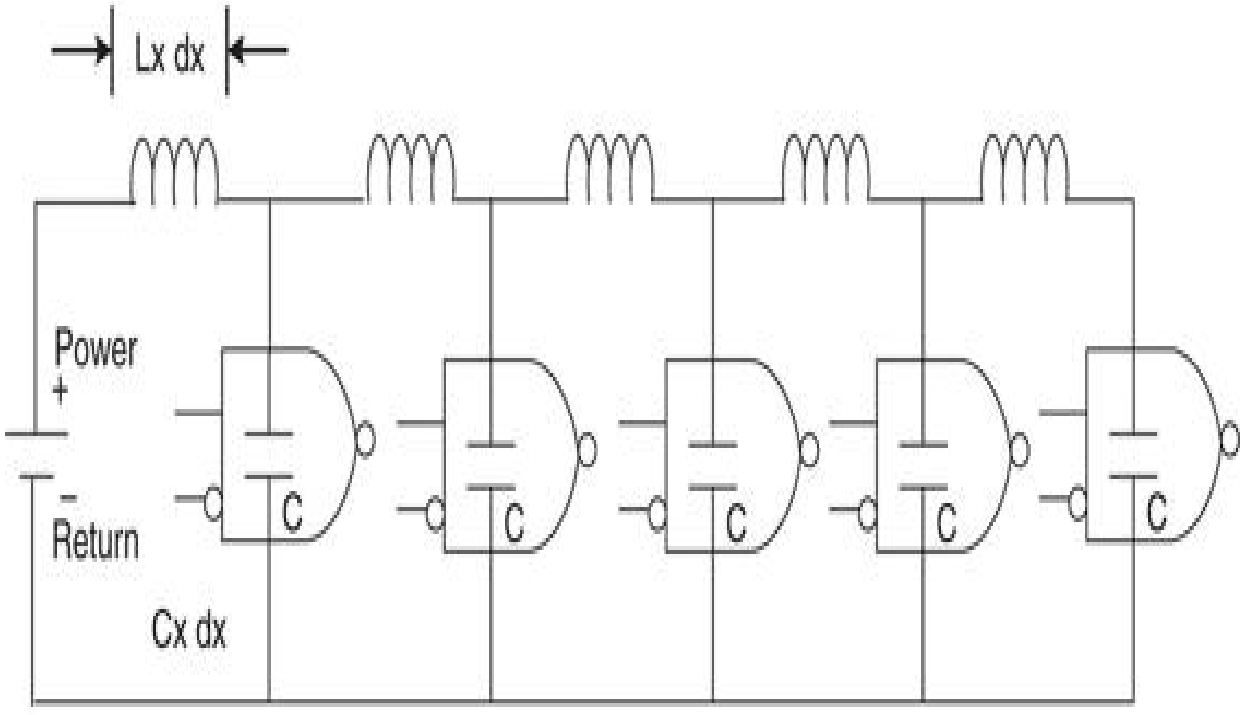
1. Use of a low-impedance connection between circuits to minimize voltage drops in the power transmission path.
2. Between components there is always a finite physical distance to transfer charge. This means a finite voltage drop will occur across this interconnect due to transmission path inductance. Depending on the inductance of this interconnect, significant fluctuations of power may occur, potentially affecting signal integrity and causing an EMI event.

20.5.2 Power Distribution Network as Transmission Lines

Power distribution networks can be represented as a two conductor transmission line with inductance, capacitance, impedance and propagation delay—just like transmission lines. The differences between a plane and trace are in physical dimensions only. Planes are wide in both the *x* and *y* axes while signal traces are, of course, narrow. Both transmission structures propagate a signal, or power, between devices. And a return path must also be present in both cases, as illustrated in Fig. 20.26.



Ideal Power Distribution Network–Multiple Loads



Real-Life Power Distribution Network–Multiple Loads

FIGURE 20.26 A power distribution network is in reality a transmission line system with inductance between each item connected to the power and return rail.[11]

In order to provide optimal power integrity, there must be very low impedance within the PDN interconnects between components using either trace(s) or plane(s). The reason we must have low impedance is easily described by Ohm's law (20.3), shown in both time and frequency domain format for the impedance portion of the equation. The subscript (*t*) refers to "with respect to time." If we have less impedance (*Z*) in a transmission line, with a fixed voltage requirement, a maximum amount of current is available to the component, with minimum voltage bounce and switching noise.

$$\Delta V = \Delta I \times Z$$

where

$$Z_o = \sqrt{\frac{L_o}{C_o}} = \frac{V(t)}{I(t)} \qquad (20.3)$$

The easiest way to lower total transmission plane impedance is to minimize inductance (numerator) or increase total capacitance (denominator). We can thus reduce impedance on a PCB through the process of

- Reduction of total loop area between conductors—including the *Z* direction—minimizing total loop inductance in the transmission line structure.
- Putting power and return planes very close to each other in the layer stackup—to achieve greater capacitance and reducing loop inductance.
- Increasing a conductor's width reduces inductance and increases capacitance, with respect to another conductor or its associated return path.

The key thing to remember is that minimizing ripple on the voltage rail is best achieved by reducing Z_{PDN}, the

impedance of the PDN. Lowering interconnect impedance also allows for greater drive current to components.[16]

20.5.3 Different Types of Discrete Capacitors Used in Power Distribution Networks

There are two basic applications to consider when choosing a capacitor to ensure a stable PDN; bypassing and decoupling. These two terms are sometimes interchanged when discussing the need to have a high quality PDN. Proper understanding of the differences is an important key to successful PCB layout.

- *Bypass capacitors*, or “bulk bypass” capacitors have larger capacitance values, such as 1 to 1000 µF, that helps maintain constant DC voltage and current levels within a PDN. Bypass capacitors ensure there is sufficient “bulk” power, both voltage and current, available to all components within a specific radius of operation. Consider them as very large charge storage reservoirs. These capacitors provide a valuable function up to about 10 MHz. Bulk bypass capacitors are recharged by the power supply.
- *Decoupling capacitors* minimize or decouple switching energy from digital components from being injected into the power distribution network with every edge transition, both low and high. Digital components both source and sink current, and with each transition, a finite amount of charge must be available to ensure the PDN does not drop below operational voltage levels—typically targeting 5 percent or lower fluctuation. Decoupling capacitors provide a localized source of DC power—particularly useful in reducing peak current surges propagated across the board up to around 200 MHz.

Above 200 MHz, instantaneous, localized power delivery then comes from the power and return plane pair located somewhere within the stackup of a multilayer PCB, or from on-die capacitance. Decoupling capacitors are recharged from the bulk capacitor(s). The planes directly under the component are then recharged by both the bulk and decoupling capacitors, strategically located throughout the layout. An overall view of a PDN is shown in Fig. 20.27. The key to providing maximum power delivery is to minimize spreading as well as the interconnect inductance between both component and capacitor to the PDN, which is commonly performed with breakout traces and vias. This interconnect inductance combines the equivalent series inductance, or ESL, of all of the loop elements in Fig. 20.27.

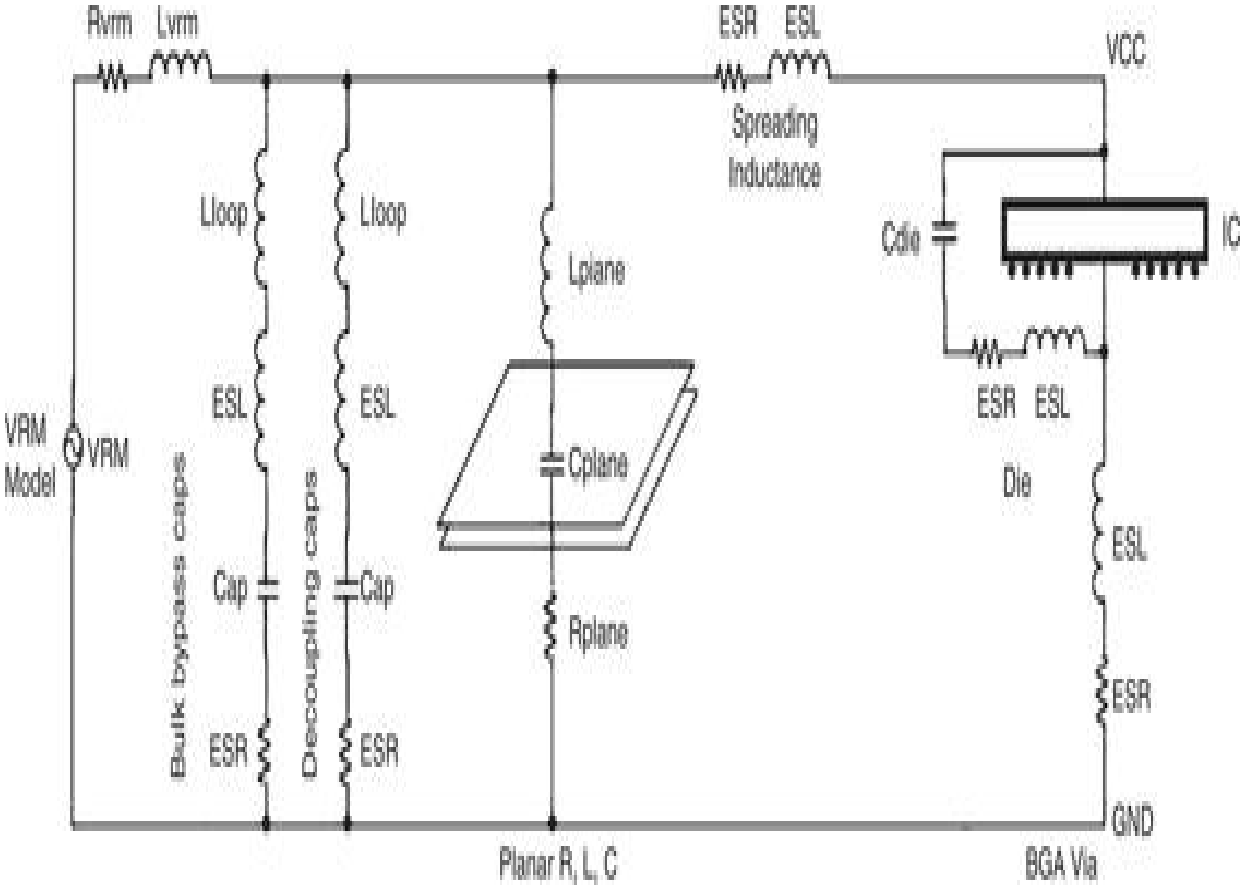


FIGURE 20.27 Power distribution network illustrating various internal capacitance structures.[17]

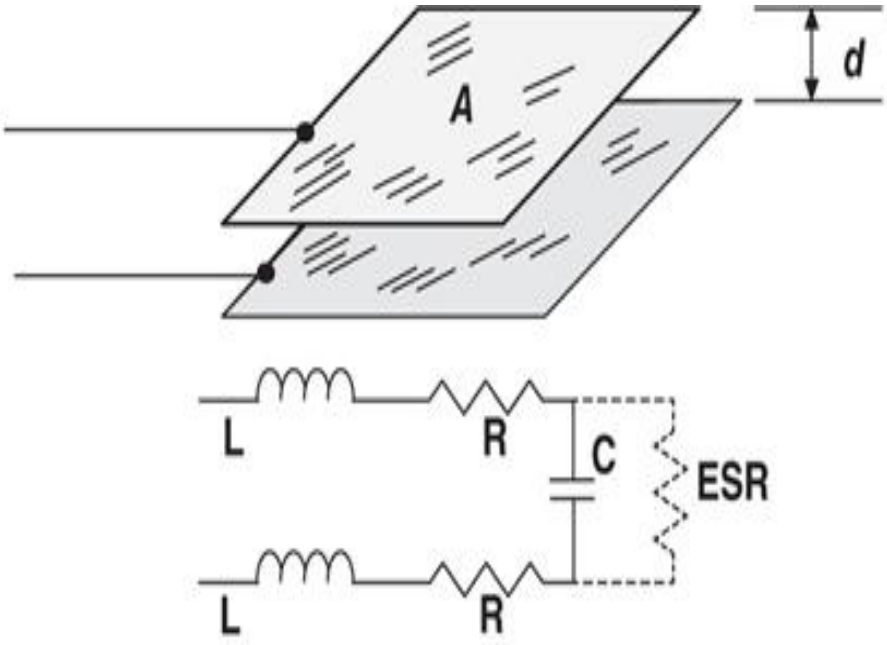
20.5.4 Physical Characteristics of a Capacitor When Applied to PDN Applications

Capacitors are modeled as an *RLC* circuit, where *L* (inductance) relates to both external lead length interconnect and body construction, *R* (resistance) inherent within the dielectric material between the plate, and *C* (total capacitance). A schematic representation is shown in Fig. 20.28, with variable "*d*" representing the physical spacing between the two plates.



Interconnects internal to the capacitor plates contain both inductance and resistance – *ESR* is mainly the resistance inherent within the dielectric material

FIGURE 20.28 Capacitor model with resistance, inductance and capacitance.[11]

At a calculable frequency (20.4), the series combination of *L* and *C* becomes resonant, providing very low impedance and effective RF energy shunting at that specific frequency.

At frequencies above self-resonance, the impedance of the capacitor becomes increasingly inductive and performance, especially when used in decoupling applications, becomes less effective. Both bypassing and decoupling applications are significantly affected by lead inductance in addition to the physical trace length interconnect between capacitor and the PDN though vias, so anything that a PCB designer can do to minimize these “loop elements” is advantageous.[17]

$$f = \frac{1}{2\pi\sqrt{LC}} \tag{20.4}$$

where f = self-resonant frequency, or where the impedance of the capacitor is at a minimum (Hz)
L = total inductance of the circuit (includes trace interconnect through vias to internal planes) (henrys)
C = value of the capacitor (farads)

Capacitors reach their minimum impedance at their self-resonant frequency (SRF), which is determined by total capacitance and *ESL*. This includes the interconnect inductance between the component and PDN, including vias, and is shown in Fig. 20.29, where the capacitor performs as a capacitive structure up to its SRF. Above its SRF the capacitor behaves inductively. Inductance restricts the flow of charge delivery.[17]

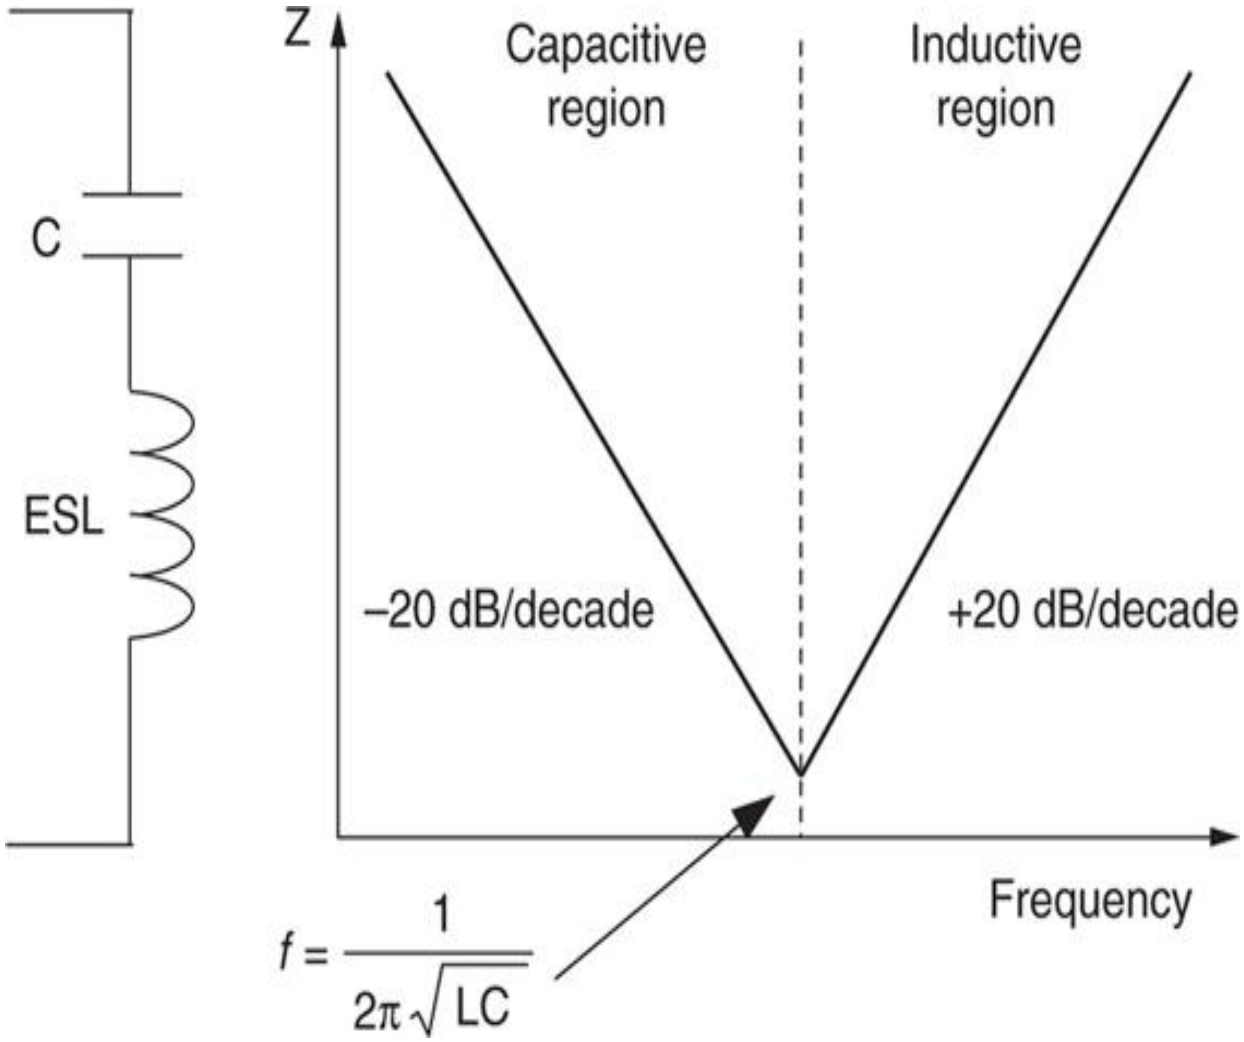


FIGURE 20.29 Impedance plot of a capacitor showing both capacitive (left of the SRF frequency, f) and inductive (right of SRF) regions of performance. The capacitor provides charge in the capacitive region but is inductive above self-resonant, and useless for the purpose of providing local charge storage energy.[11]

To meet the target impedance at a particular frequency, a capacitance value can be chosen that will resonate at the desired frequency per (20.4). At this frequency, its impedance will be equal to its *ESR* (equivalent series resistance).[17]

When many capacitors with the same value are placed in parallel, both *ESL* and *ESR* are reduced in proportion to the number of devices provided. Total capacitance also increases, which is highly desirable—though these benefits

come at the expense of both the components and more importantly, board space.

A serious concern when using two capacitors of different values lies in the belief that they provide a large spectral distribution of decoupling deals with their combined antiresonant frequency. Using typical values of 100 nF and 1 nF caps in parallel means they have a SRF at 16 MHz and 170 MHz respectively, but with an antiresonant frequency at 120 MHz, shown in Fig. 20.30. If there are any switching frequencies at 10, 20, 30, 40, or 60 MHz, a harmonic of these frequencies can cause a serious radiated EMI event to occur at 120 MHz. Balancing between pulling the PDN impedance curve, Z_{PDN}, down across a wider frequency band versus the battle with antiresonant effects has been the subject of many PCB engineering discussions over the years. Unfortunately, panaceac solutions do not exist for making all of the trade-offs.

20.5.5 Lead Length Inductance Related to Mounting Configuration

The mounted inductance, or ESL of a capacitor, has three components that describe the loop in which current must flow: (1) capacitor footprint; (2) distance from the plane; and (3) power plane spreading inductance. The footprint for a capacitor consists of via placement with respect to the pad, the length and width of connected traces, as well as characteristic inductance that dominates the total ESL value.

The key to successful PDN design when using discrete capacitors for energy delivery below 200 MHz lies in minimizing loop inductance in the interconnect. This interconnect includes the breakout trace and the physical distance to planes internal to the stack assignment through a highly inductive via. Typical mounting configurations are provided in Fig. 20.31.

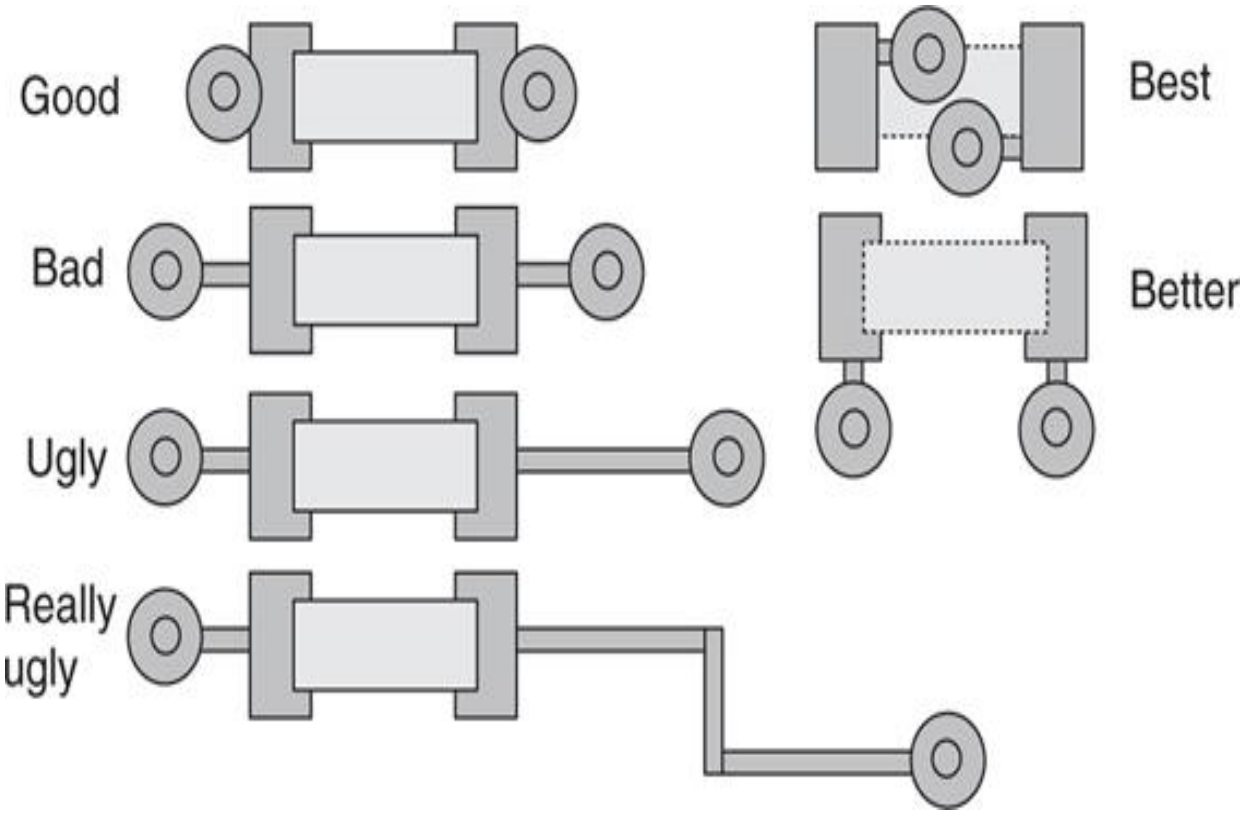

FIGURE 20.31 Inductance associated with mounting a capacitor for decoupling purposes.[11]

Using numerical analysis, calculated decap inductance is on the order of

- Surface traces 10–15 nH/in (25.4–38.1 nH/cm)
- Vias for capacitor to plane interconnect 0.40–1 nH (200–500 pH each)
- Plane inductance 0.1 nH

When determining total amount of charge that a capacitive system has, which includes discrete components and a power/return plane pair, there are basically three variables: (1) total area between the metal plates; (2) distance or separation between the plates; and (3) the dielectric constant between the plates.

In Fig. 20.32 we have a simplified illustration of a capacitor with two metallic plates having a finite area (A), separation (d), and dielectric constant (ε_r), which is a frequency-dependent value of the material used to create the capacitor, whether the capacitor is a discrete component, or parallel planes on a circuit board.

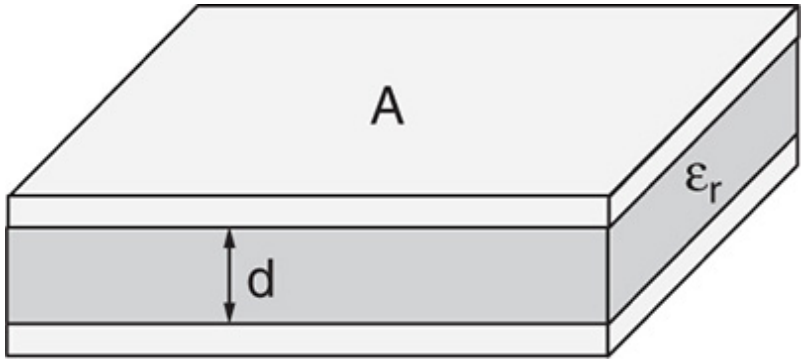

FIGURE 20.32 Typical capacitor configuration with the two plates acting as the power and return planes with a dielectric material between the plates. This material has a frequency dependent dielectric value.

Internal plane capacitance, used in conjunction with discrete decoupling capacitors to provide a stable power distribution network can be calculated by Eq. (20.5).

$$C_{pp} = k\frac{\varepsilon_r A}{d} \tag{20.5}$$

where C_{pp} = capacitance of parallel plates (pF)
ε_r = dielectric constant of the board material
A = area between the parallel plates (square inches or cm)
d = distance between the plates (inches or cm)
k = conversion factor (0.2249 for inches, 0.884 for cm)

The least inductive means of providing a large amount of energy charge is through use of power and return planes embedded internal to a multilayer PCB stackup. These planes provide energy from 150 MHz and up into the GHz

range. Discrete capacitors cease to provide their energy storage function due to inductance at an upper limit of around 250 MHz. By the time capacitors go inductive, the planes have already started to provide charge—with very little additional inductance.

The use of ultra-thin, high dielectric constant (Dk) dielectrics can significantly improve the effectiveness of the PDN. Standard FR-4 technology is limited to 2-mil thickness, dielectric constants of around 4.0, and a capacitance density of only 49 to 68 pF/cm^2 (0.31 to 0.43 nF/in^2). Thinner, less than 1.0-mil (<25-um) cores, especially those filled with high dielectric ceramic particles such as barium titanate, are now being used for the power distribution in today's high-frequency designs.

Some of these laminates have a dielectric thicknesses in the range of 8 to 14 microns (0.31 to 0.55 mil) and dielectric constants up into double digits. In combination, these features deliver a higher capacitance density of 0.3 to 3.6 nF/cm^2 (2 to 23 nF/in^2), and much lower loop inductance. A list of example materials for distributed capacitance can be seen in Table 20.2. Each offers many benefits when used for decoupling high speed digital electronics, including:

- Lowering impedance of power distribution network
- Dampening board resonances
- Reducing noise on power planes
- Reducing radiated emissions
- Possibly replacing large numbers of discrete decoupling capacitors
- Possibly replacing discrete SMT filter capacitors

There are a lot of nuances to the design of optimal power distribution that are beyond the scope of this introduction. Reference 11 provides details on the design of power distribution networks across a broad spectrum of PCB layouts.

20.6 INTRODUCTION TO ELECTROMAGNETIC COMPATIBILITY[18,19]

Every electronic product, with few exceptions, must comply with international requirements related to electromagnetic compatibility (EMC). What is not recognized by many is that the field of electromagnetics is the foundation of everything that uses electricity or the movement of time-variant electrons in a transmission line, both at AC and DC potential. James Clerk Maxwell published a series of equations that describes the propagation of electric and magnetic fields within a transmission line with respect to time. His four equations are based on two from Gauss, one from Faraday (a.k.a. the Right Hand Rule) and Ampére's law. All four equations are in both differential and integral form of calculus. The reference from Ref. 11 provides an easy way to

understanding field propagation without going too deep into the math.

The field of EMC is defined as the ability of electrical and electronic products to operate within their intended environment of use (e.g., industrial, commercial, residential, military and the like) without causing harmful interference to other electrical systems, and conversely must be able to withstand any external electromagnetic event that could cause functional harm to itself. EMC is a highly specialized field of electrical engineering divided into two parts: emissions and immunity.

Emissions. The first aspect of the field of EMC is the unwanted generation of harmful radio frequency (RF) emissions called electromagnetic interference (EMI) or simply “emissions.” This unwanted energy is generated by digital components located on a PCB assembly though a complex process that creates both radiated fields and/or conducted currents. The frequency range of RF energy covers the electromagnetic spectrum from anything greater than DC to light (300 GHz). PCBs are utilized in applications within this frequency spectrum and beyond, including terahertz communication systems.

The main concern regarding propagation of undesired RF energy is to protect telecommunication systems such as commercial broadcasts from harmful disruption in addition to other electrical systems containing components susceptible to electromagnetic field disturbance. This includes itself along with internal circuitry located near unintentional radiators on the same PCB.

International requirements are legally mandated in North and South America, the European Union, most of the Asian continent and many other countries worldwide. Failure to meet legally required emission limits, both radiated and conducted, with a certified test report from an assessed or accredited EMC test laboratory, means it is illegal to market,

merchandise, sell or install a product within the country’s borders.

Immunity. The second part within the field of EMC related to immunity or susceptibility. Both words refer to the same electromagnetic principle. One refers to aspects of a system, viewing it as protecting components internal to an enclosure from outside interference (immunity), or viewing aspects of harmful RF energy outside the unit penetrating to the inside (how susceptible the system is to electromagnetic field disruption).

With regard to immunity, this concern is always at the component level. Most analog components are sensitive to high levels of electromagnetic field disturbance. PCB construction has minimal effect related disruption of operational circuits thus, further discussion on immunity is outside the scope of this chapter. Excellent resources exist to learn more about immunity requirements at the system level.

20.6.1 How EMI Is Generated from a PCB

There are three primary areas of concern when designing a PCB to ensure EMC compliance and that the system does not cause harmful interference to not only the outside environment, but to adjacent circuits and components through the process of crosstalk. (Crosstalk can be viewed as EMI at a very localized level.)

1. Proper transmission line routing based on numerous design requirements.
2. Ensuring optimal power distribution to all components, which minimizes transient-voltage fluctuations in both the power and return (a.k.a. ground) planes.

3. Ensuring proper referencing of signals to power and ground planes.

20.6.2 Transmission Line Routing to Ensure Optimal Signal Integrity

Using transmission line theory, traces are used to send signals between components. The signal propagated is actually an electromagnetic field that travels from source to load along with a return for the current to satisfy Ampére's law. Any losses within a transmission line become the magnitude of undesired common-mode current that is developed and which propagates as either an unintentional radiated field or conducted currents.

There are two modes of signal propagation, differential and common. Differential-mode is the signal of interest between source and load along with its return path. No loss of electromagnetic energy occurs. The electromagnetic field in the source path is 100 percent identical to the electromagnetic field in the return path travel, however the return path is in the opposite direction. With equal and opposite magnetic field propagation between the two transmission lines coupling to each other, we have optimal signal integrity and no EMI.

However, if there is a loss of electromagnetic energy in either the source or return path, this loss within the electromagnetic field must still return to its source based on Kirchhoff's law. A portion of the electromagnetic field, the loss portion, will take an undesired propagation path through parasitic capacitive coupling to an adjacent transmission line such as free space or a metallic interconnect. These unintentional, common-mode currents, are at the root of all emissions problems.

Thus, to minimize emissions is to ensure optimal signal integrity—minimizing or eliminating unnecessary energy loss

in transmission line structures. Ringing on a periodic signal, for example, is a guaranteed emissions source. Any impedance discontinuity, in fact, associated with transmission line routing results in common-mode energy transfer from the transmission line to the outside world.

20.6.3 RF Return Paths[20,21]

All signals require a source transmission line and return path for the electromagnetic field that propagates within every transmission line. Very frequently, the signal conductor is easily seen on the schematic and the return is neither shown nor mentioned. It is implied that the return current magically returns to the source through the power and ground pins of components, which is true for strictly DC systems. As soon as there is current changing with respect to time with units of hertz, we enter the AC domain. Once the frequency is above 100 kHz, all components are considered to be propagating RF signals with an electromagnetic field and not with steady state voltage levels. The rise and fall times of digital components are the AC portion of a signal, while logic level “0” and “1” are DC. Therefore, there are two types of current present at the same time, AC and DC. There is a significant difference between how AC current (the electromagnetic field), and DC current (steady state) flows in every transmission line.

RF current, or signals operating above 100 kHz, must propagate between components using any transmission line path possible, generally the one with the lowest impedance. This transmission line path includes transference of the electromagnetic field due to parasitic capacitive coupling to a nearby metallic structure (adjacent trace or plane) or system enclosure through free space. If there is no low-impedance conductive path (<377 Ω), free space (at 377 Ω) becomes the transmission line. *Free space is exactly what*

we do not want, especially with regulatory compliance concerns and EMC compliance.

Return currents at DC voltage levels travel through either the power and/or 0 V return plane. While single-sided PCBs may be a cost-effective implementation for a simple design, the probability is high that this configuration will not pass various EMC test requirements if digital components are utilized, unless the digital rise and fall times are very slow such as >1 microsecond, with a very short transmission line route between source and load. Adding a 0-V reference plane, or making the stackup of the PCB a multilayer assembly, will enhance overall performance related to signal integrity and EMC compliance.

Any physically large copper or metal laminate in a multilayer stackup provides an optimal return path with minimal impedance for RF return currents. The DC voltage potential of the plane (i.e., +3.3 V, +5 V, +12 V) is not a major concern. Multilayer boards obviously cost more, but the functionality gains in SI and PDN performance, as well as improvements in EMC, more than compensate for the additional expense in manufacturing the board, typically.

Figure 20.33 illustrates the return path for both low- and high-frequency signals. At lower frequencies, the return current for DC referencing is through the path of *least resistance*, which in this case is a direct path back to the source using the power plane for signals transitioning to the logic level high state; and the return plane for transitions to logic level low.

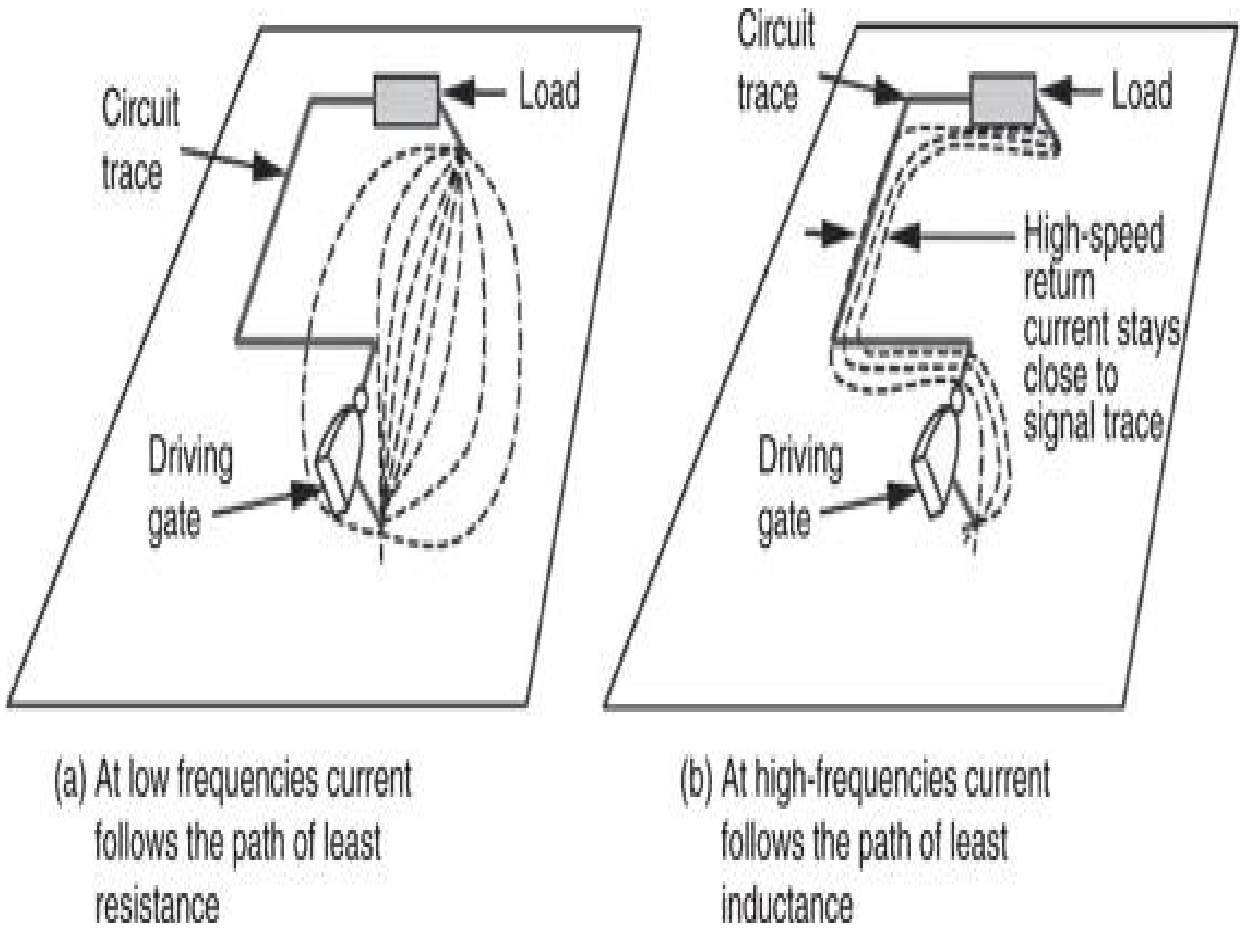

FIGURE 20.33 Current return path, both high and low frequency.[4]

For higher frequencies, generally above 100 kHz, the RF or AC return current takes a different path or the path of *least inductance*. Every electromagnetic field requires a mirror image of itself using a return path that is physically located as close to the source path as possible in order to couple its magnetic field lines, per Faraday and Ampére's law. This return path exists as a result of partial mutual inductance, a complex topic reserved for discussion in books listed in the Reference section requiring extensive use of high-order math.

To simplify discussion on the difference between the path of least resistance and least inductance, Eq. (20.6) illustrates the concept.

$$Z = R + jX_L \tag{20.6}$$

where Z = total impedance of the transmission line
R = resistance of the transmission line (a fixed value) [DC current]
X_L = inductive reactance (a variable value) [AC current]

$$jX_L = 2\pi fL$$

where f = frequency of the signal
L = inductance of the transmission line

Assume the characteristic resistance of a trace is 10 mΩ. This is very low and DC current flows easily in the return path (the path of least resistance).

The inductance of this same transmission line is 100 nH, a typical value for a short trace route. When the frequency of the electromagnetic field propagating in the transmission line increases, the value of X_L starts to become very large in direct portion to frequency. For example, at 1 MHz, X_L = 630 mΩ. At 100 MHz, X_L = 63 Ω. At 1 GHz, X_L = 630 Ω. The impedance of free space is 377 Ω. The total impedance of the transmission line is the combination of both DC resistance and AC inductive reactance. Above 100 kHz, the resistive portion essentially falls out of the equation and is a variable we can ignore.

Per Ohm's law, $V = IZ$, where Z is from (20.x). The AC return current at higher frequencies is unable to return in a direct manner if the transmission line is >377 Ω, so, for the 1 GHz case, the AC return current must then propagate through free space as unwanted radiated EMI, regardless of the path the DC return current takes.

By physically bringing a signal-transmission line closer to an adjacent plane or ground pour—regardless of DC potential

—the inductance becomes lower by a significant amount through the process of partial mutual inductance, a topic beyond the scope of this discussion. With carefully planned current return paths in close proximity to the original signal, electromagnetic field lines for the original signal and its return cancel each other at higher frequencies, thus minimizing unintentional, common-mode currents.

20.6.4 Violations or Splits in an RF Return Path

For an RF return plane to be effective, all signal traces must be physically located adjacent to a solid, undisturbed return —generally, copper planes and signal paths. No high speed, digital signal should cross an isolated or open area such as slots or gaps in adjacent planes. If any signal, or even a power/return trace is routed across such a gap, the result is typically a larger physical loop area for RF return current to flow toward getting back to the source. RF loop currents now created can then couple to an adjacent signal layers across this absence of copper area, resulting in unintended common-mode currents—a key element in crosstalk emissions, PDN noise, and differential.

Figure 20.34 illustrates a violation of the image plane or disruption of the RF return path for AC signal propagation. The return plane can now no longer function as a solid, undisturbed RF return path. The signal trace in Fig. 20.34 is the solid line going horizontal and the RF return path with a longer route is the dashed line. The percentage of RF current flow is directly proportional to distance from the impedance discontinuity area. The vertical lines are slots located in the adjacent return plane.

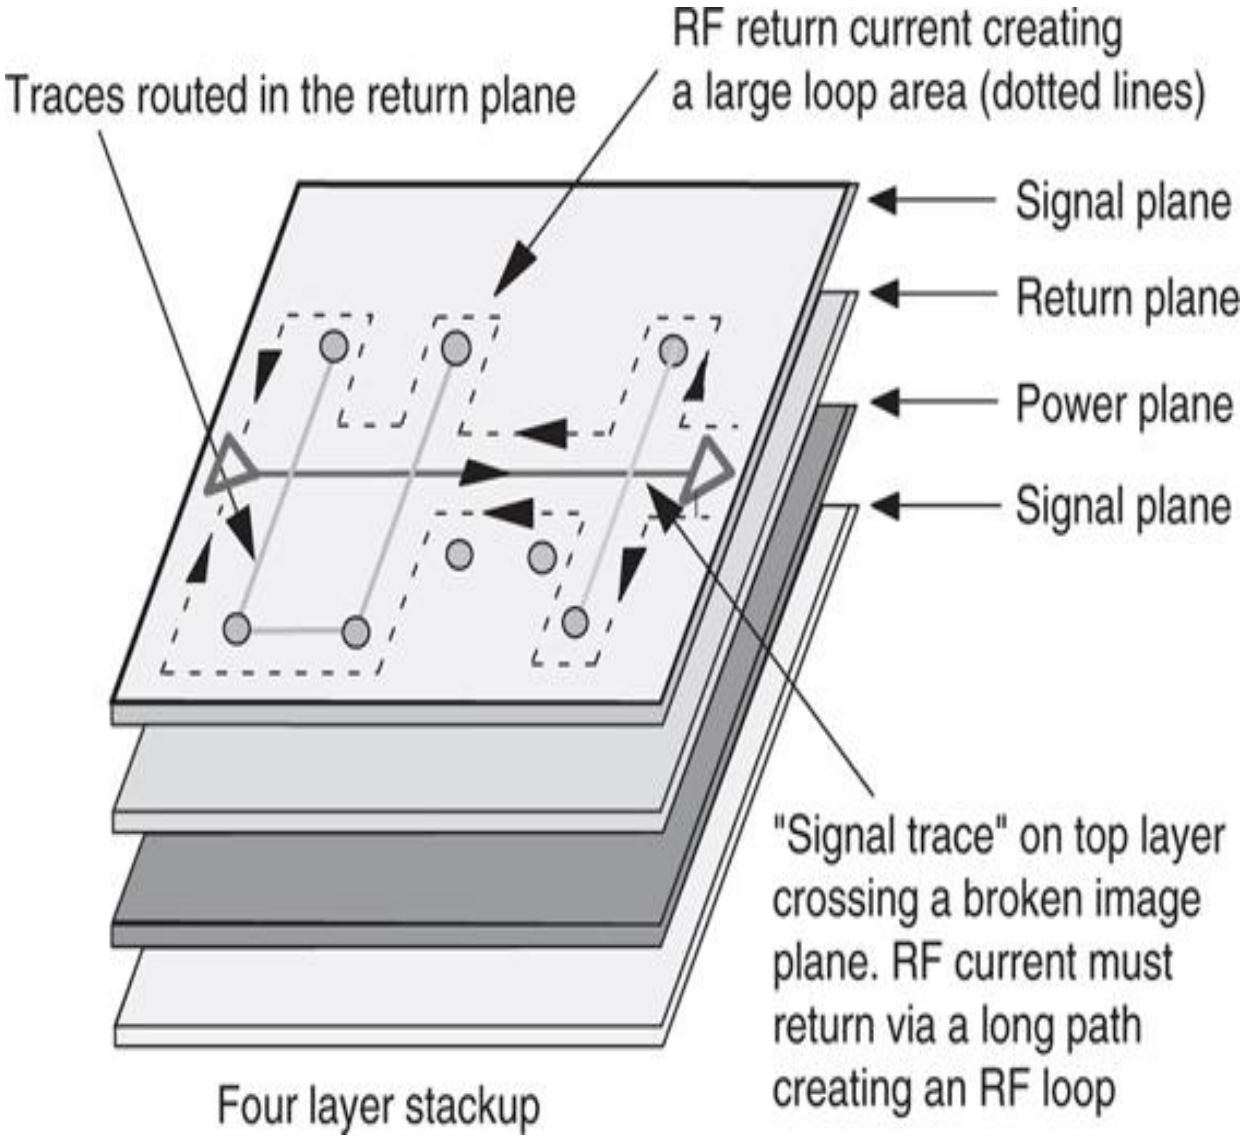

FIGURE 20.34 Image plane violation with a single trace.[11]

Should any transmission line have a disturbed RF return path, undesired EMI will develop. This is easily visualized with a coaxial cable with the braid removed, but not the center conductor. The return current on the braid will find a discontinuous path at infinite impedance and make the jump through free space, at 377 Ωs, which is less than infinity, and find its return path on the other side of the split. Once this energy enters free space to make the jump, we now have an EMI problem, and yet the circuit itself may still function without degradation.

20.6.5 Grounding Concepts and Methodologies

The word “ground,” when used alone, is ambiguous.[3] In reality, both digital and analog circuits operate off a voltage potential difference between a 0 V reference (a.k.a. ground) and a nominal power supply voltage. To be accurate, we should use the term “0 V” or “return” for power distribution since there is no literal “earth ground” on a PCB. If the word ground is to be used, preceding it with by an adjective makes sense. When someone says they have a ground plane, it’s helpful to know whether it’s a “digital” ground plane, “analog” ground plane, “ESD or chassis” ground plane, “thermal” plane, “protective earth for functional safety” ground, or another type of ground plane.

The subject of grounding is fairly involved. A number of high-quality textbooks have been written on this topic, some of which are noted in the Reference section at the end of this chapter. Nevertheless, a brief overview on grounding and referencing associated with PCBs is presented here.

20.6.6 Signal Referencing

When a PCB signal travels between transmitter and receiver pins, either the power or ground plane acts as the RF return, as seen in Fig. 20.35.

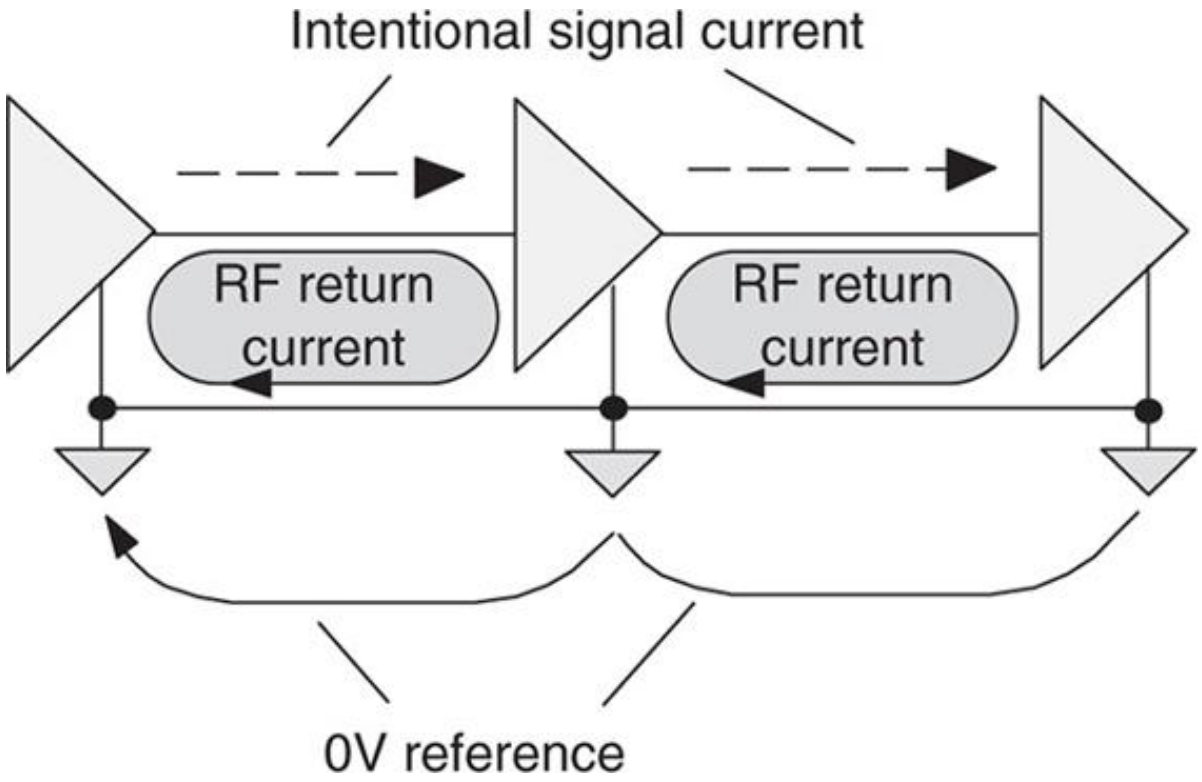

FIGURE 20.35 Referencing signal propagation for functional operation between components.

The majority of design concerns associated with EMC lie in referencing circuits to each other. All components must be at a specific voltage reference above a-0 V reference for functionality reasons. With regard to a PCB, components are referenced to a common point, typically a plane in order for logic circuits to determine a valid transition state. If the reference level between two circuits is not at the same potential, functionality concerns may occur, such as noise margin erosion and unpredictable threshold levels required for optimal logic switching. This is in addition to possible creation of a ground-noise voltage potential or undesired common-mode current.

20.6.7 Grounding System Methodologies[22]

When implementing a referencing methodology on a PCB, several types are commonly used. For each methodology, a hybrid combination may exist. Different methodologies may be used at the same time, but only if the designer understands the concept of RF current flow and RF return paths, differentiating between RF return and safety or chassis ground, which are at a completely different potential.

20.6.8 Single-Point Grounding Methodology

The single-point grounding methodology is one in which all returns are tied to a common reference point, usually at the power source, either AC or DC. This grounding methodology prevents RF currents from propagating between dissimilar circuits, usually at different voltage or reference levels or even different bandwidths of operation. Single-point grounding also prevents sharing of common RF return paths for undesired RF loop currents that produces common-impedance coupling.

There are two primary topologies when using single-point grounding—series and parallel, as shown in Fig. 20.36. Depending on the application, either will provide the same functionality. Single-point grounding is optimal when the switching speed of all components is below 100 kHz and 1 MHz! If signals are above 100 kHz to 1 MHz, multi-point grounding becomes the methodology of choice. This is because the interconnect between the PCB and chassis ground contains minimal inductance (e.g., PCB is screwed and secured to a standoff) versus a very high inductive wire with several orders of magnitude higher inductance.

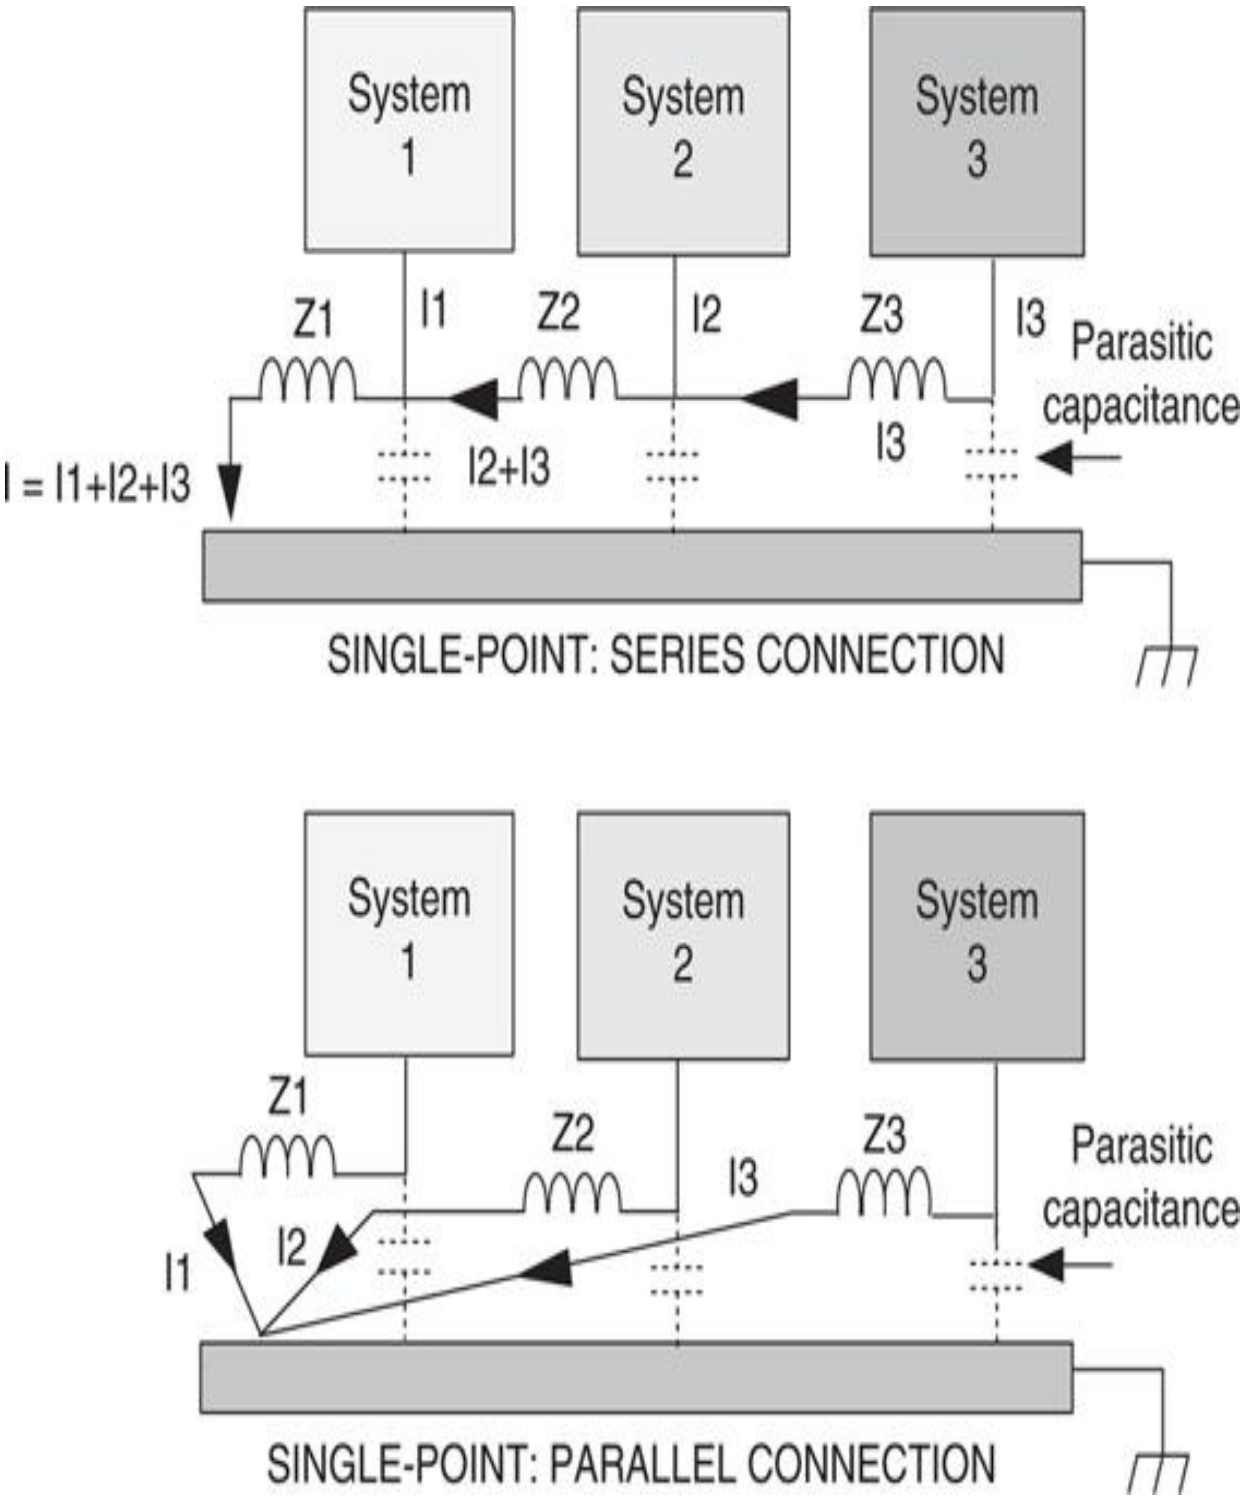

FIGURE 20.36 Single-point grounding methods. (Note: Inappropriate for high frequency operation, generally above 100 kHz to 1 MHz.)[11]

20.6.9 Multiple Connections to Single-Point Reference (a.k.a. Multi-point Grounding)

Higher frequency PCBs generally require all 0 V reference plane(s) be connected to a common reference point, usually a metal chassis or enclosure, or a plane internal to a PCB assembly commonly called the ground plane. The correct definition of multipoint grounding should be "*multiple connections to a single point reference*." This definition will become obvious with the discussion that follows.

Multiple connections to a signal-point reference, or multipoint grounding, minimizes plane impedance present for all RF current return paths. This is because there are no wires or physically long interconnects to tie functional subsystems together. Loop inductance is also minimized significantly. Loop inductance is the primary reason why single-point grounding starts to become ineffective above several 10's of kHz. When a bond connection occurs between a 0-V reference plane and a metal enclosure, the entire system is essentially at one reference potential. This one reference potential is shown with the *chassis ground* symbol in Fig. 20.37, lower right corner. Regardless of the number of circuits identified on a schematic using a symbol such as digital ground, analog ground, chassis ground, ESD ground, and the like, they must eventually connect together somewhere which means there is only *one* 0V reference in the system, or true single-point referencing. Proper connection of different ground or reference potentials is thus critical for both signal integrity and EMC compliance.

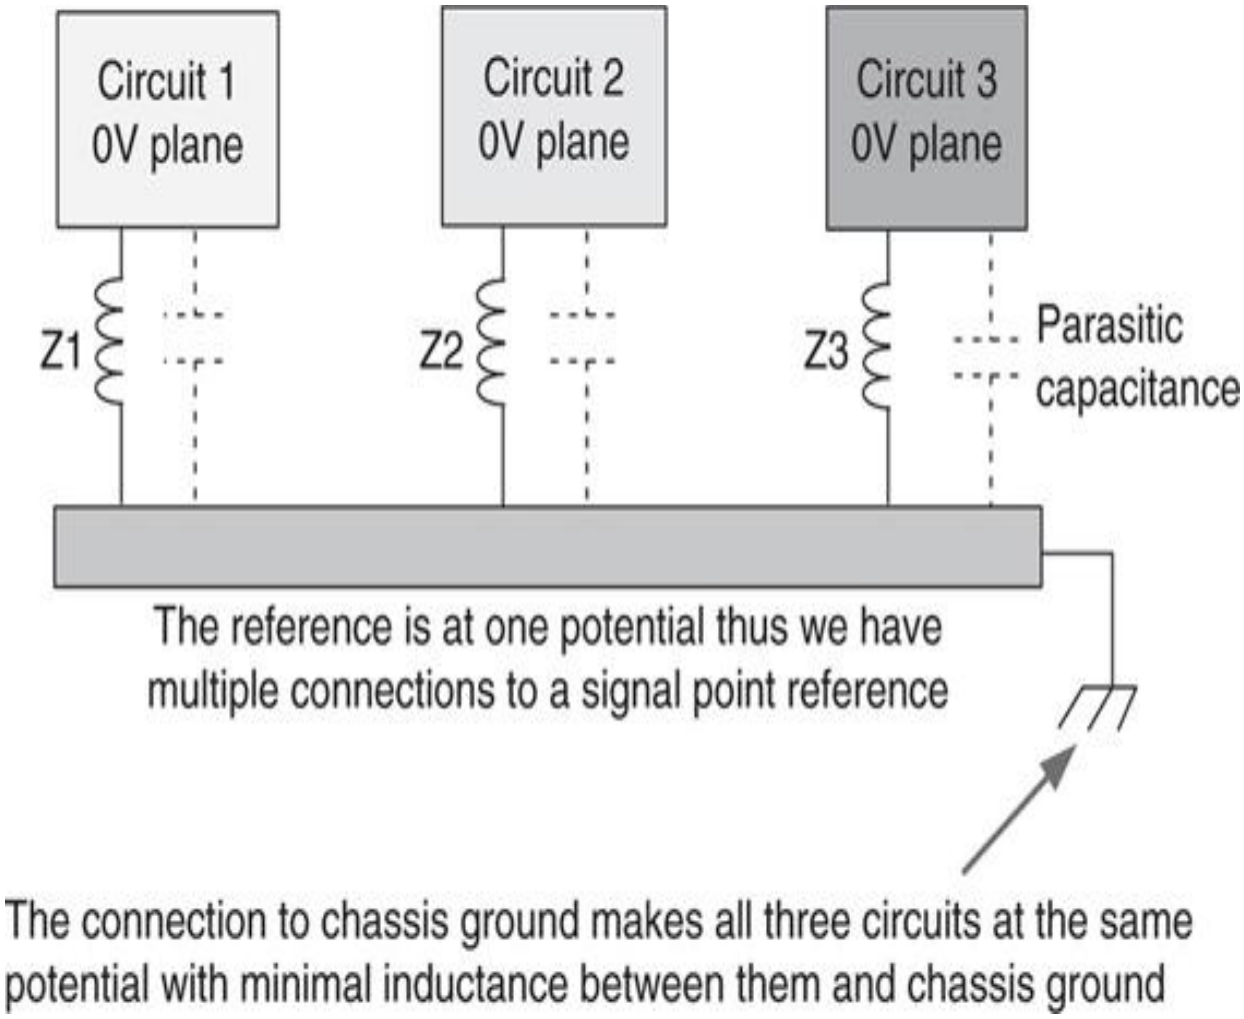

FIGURE 20.37 Multiple connections to a single point reference methodology (a.k.a. multipoint grounding).[11]

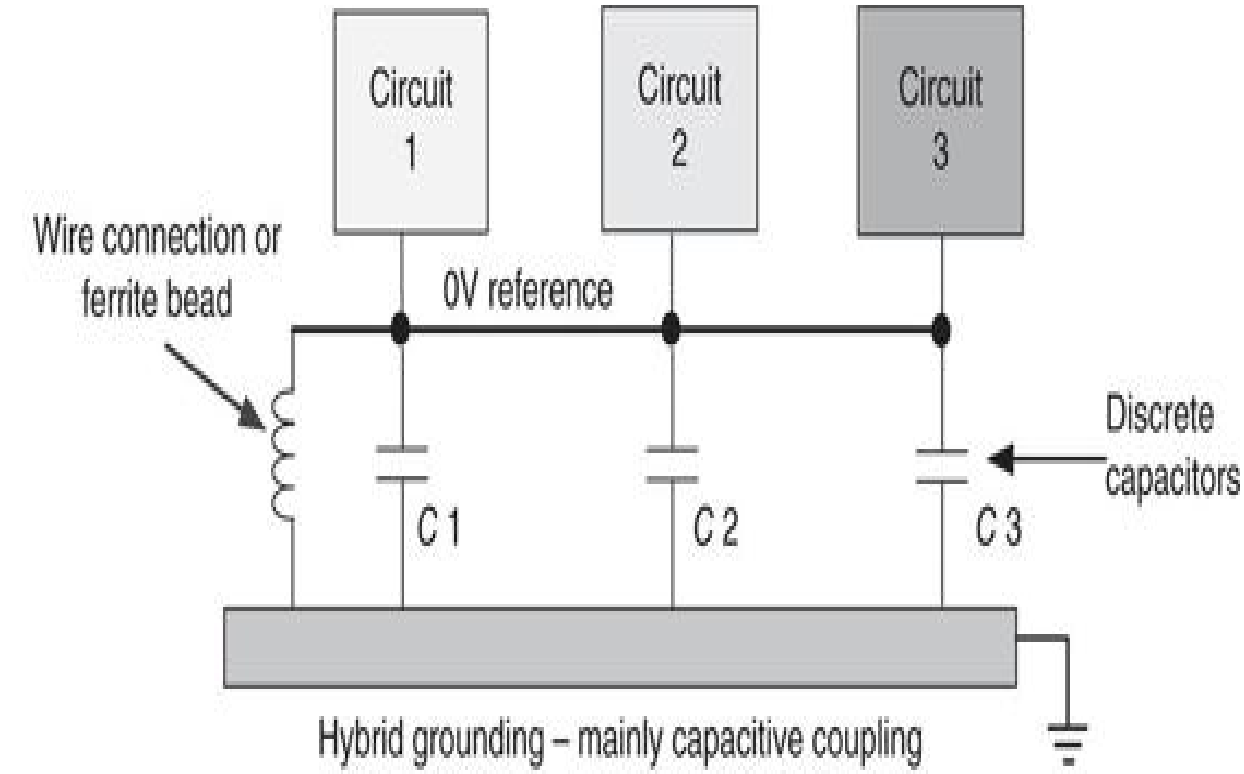
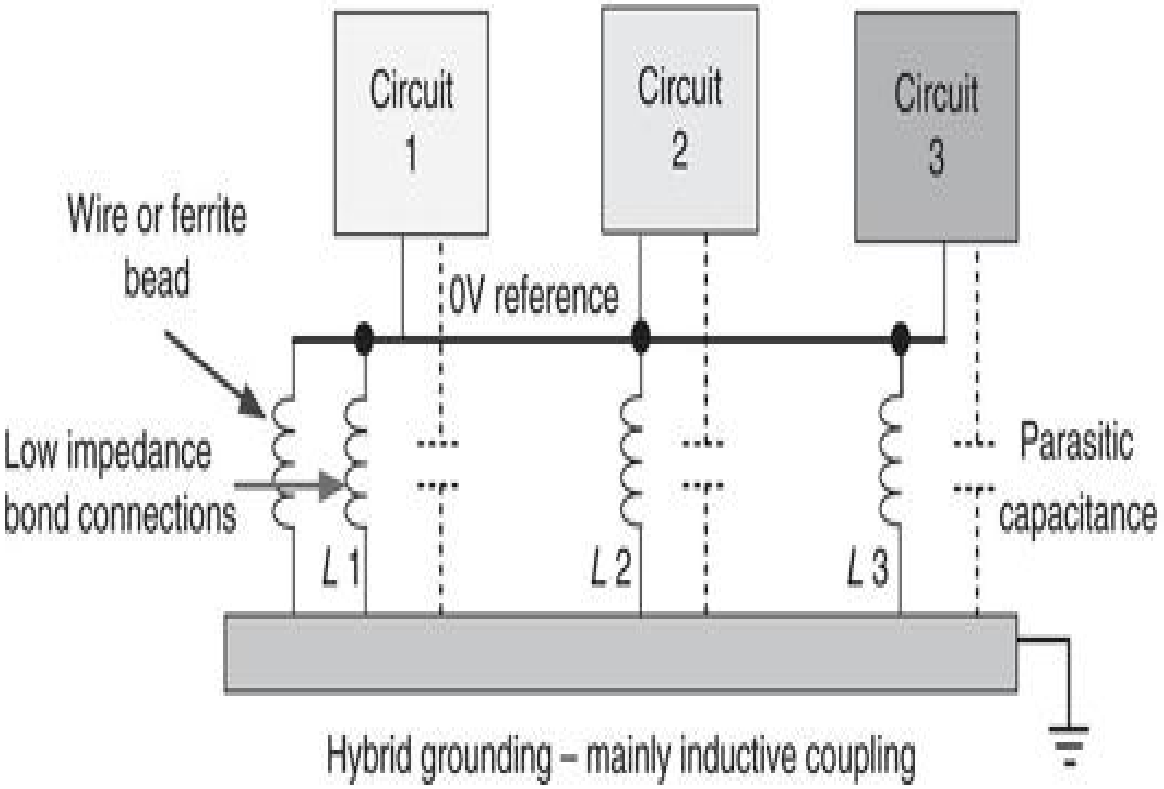
20.6.10 Hybrid Grounding

A hybrid ground system is a combination of both single and multiple connections to a single point reference, also called multi-point grounding. This configuration is used when mixed frequencies and assemblies are utilized in the same enclosure. This enclosure may contain several PCBs, each with a separate power supply, as well as separate, remotely located disk-drive assemblies, as an example. Figure 20.38 shows two hybrid topologies. For the capacitive coupling version at lower frequencies, the single-point configuration is

dominant, whereas the multi-point configuration works better at higher frequencies. This is because of parasitic capacitance present that shunts high-frequency RF currents to a 0-V reference after the single-point interconnect goes inductive. The key to success is to understand or know all frequencies present and the desired path of RF return current flow.



Hybrid grounding – mainly capacitive coupling



Hybrid grounding – mainly inductive coupling

FIGURE 20.38 Hybrid grounding methodology.[11]

The inductively coupled version is utilized when multiple ground-stitch locations must be connected to a chassis-ground reference for safety reasons, and lower-frequency connections for operational purposes. Parasitic capacitance still exists, which could cause a resonance condition to occur, along with undesired EMI by allowing eddy currents to propagate between each loop area.

20.6.11 Two Reasons for a Ground Reference in a PCB—Electrical Product Safety

A primary reason related to grounding is to ensure that a protective earth-bond connection exists in systems having hazardous voltage levels that can cause a shock hazard or electrocution. This is a legally mandated international requirement if the product has any hazardous voltage equal to or greater than 42.2 VAC or 60 VDC. Many units are connected to an AC mains network that carries 115 or 230 VAC, which makes them hazardous. If any hazardous voltages exist, the system must be connected to a true earth ground external to the assembly. This solid earth ground connection reduces the voltage difference between the exposed conducting surface, or a metal enclosure, and person physically touching the energized chassis enclosure.

Safety ground is achieved by the proper connection and routing of a permanent and continuous, low impedance, adequate fault capacity conductor that travels between an energized power source and load, or earth ground, as shown in Fig. 20.39.

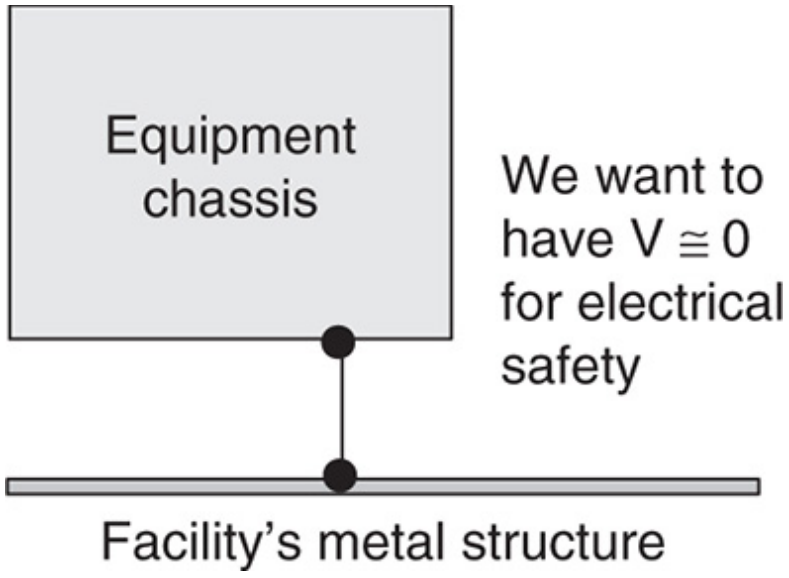


FIGURE 20.39 International creepage and clearance distance requirements between conductors.

International product safety requirements have certain tests to ensure leakage or abnormal currents are not present. This is because PCBs may contain hazardous voltages. These include power supply assemblies, telecommunication circuits, relay-driven instrumentation control units, power switching modules, etc.

When routing AC or high-voltage traces, one must use sufficient trace width and spacing to comply with legally mandated creepage and clearance requirements, as well as current carrying capability and heat dissipation. Maintaining physical distance between two elements at hazardous voltage potential requires compliance with *spacing requirements* published in safety standards. These spacing requirements are referred to as "creepage and clearance." The following definition of creepage and clearance below is identical between all international product safety standards. Illustrations of creepage and clearance measurement distances are shown in Fig. 20.40.

Creepage
Insulation

FIGURE 20.40 International creepage and clearance distance requirements between conductors.

- Creepage is the shortest path between two conductive parts, or between a conductive part and the outside, bounding surface of the equipment, measured along the surface of the insulation.
- Clearance is the shortest distance between two conductive parts, or between a conductive part and the bounding surface of the equipment, measured through air.
- The bounding surface is the outer surface of the electrical enclosure considered as though metal foil was pressed into contact with the accessible surface of insulation material.

When dealing with ground currents, it's important to remember that current must always return to its source, per Ampere's law. This return current may take numerous paths with various amplitudes proportional to the finite impedance within each path, including free space through parasitic coupling, both inductive and capacitive. This fault current could injure people or domestic animals.

20.7 INTRODUCTION TO MECHANICAL DESIGN REQUIREMENTS

The design intent of PCB is to physically support active and passive components to perform a useful function. PCBs are almost always provided in some enclosure, either metal or plastic. Regardless, everything electrical is based on its mechanical structure used to physically support both components and transmission lines.

There are three general configurations of PCB assemblies, related to mechanical assembly:

1. *Functional module*. A section of a PCB where various assemblies are interconnected to provide a functional use. These modules may be separate or integrated into one assembly. Examples of a functional module is a power supply, digital interfaces, analog processing, I/O interconnects, plug-in disk drive assemblies, adapter cards, wireless modules, and a host of other items used at the same time on one assembly. Both electrical and mechanical interconnects occur between modules.
2. *Plug-in module*. This may or may not be an optional module used to extend the capabilities of a system. A plug-in module typically plugs into a motherboard, a backplane or external interconnect. A plug-in module must be mechanically supported on one edge by some type of connector along with other physical support on the other sides.
3. *Mechanically mounted module*. This is a module mounted and/or supported in a mechanical assembly or housing with a number of mechanical fasteners around its periphery. The most common mechanically mounted module is a motherboard frequently found in personal computers and communication equipment using one or more mechanical fasteners, such as screws, clips and standoffs.

All forms of PCBs have common requirements necessary to meet their functional requirements, although there will be significant variations due to product definition requirements. For example, the requirement for board flatness due to bow and twist may be different for a plug-in module than for a mechanically mounted assembly. The requirements for number and location of mounting fasteners for a mechanically mounted module will be different for a relatively thick PCB with low-mass components than for a simpler assembly with high-mass components.

The following list of factors must be considered and evaluated during the design and assembly process:

- Configuration of the physical structure; size, and form factor
- Need for mechanical attachment and mountings
- Compatibility with EMC and other environmental concerns
- Method of mounting such as horizontal or vertical as a consequence of other factors such as dust and moisture
- Other factors requiring special attention, such as thermal management, shock and vibration, humidity, salt spray, dust, altitude, and radiation
- Degree of support
- Retention and fastening
- Ease of removal

20.7.1 General Mechanical Design Requirements

The general mechanical design requirements for PCBs and the assembly include the methods of dimensioning, mounting, insertion and removal of plug-in components or assemblies, retention and extraction. Frequently, the mounting method is predetermined as a design requirement with existing hardware. In other situation, the printed board designer has a choice in determining which mounting method is more suitable after considering such design factors as the following:

- Physical size and shape based on form, fit and functional requirements
- Input/output locations for connectors
- Area and volume restrictions

- Accessibility requirements
- Ease of repair/maintenance
- Modularity requirements
- Type of mounting hardware
- Thermal management
- Electromagnetic compatibility

20.7.2 Dimensioning and Tolerancing

Dimensioning and tolerancing for PCBs and their assemblies must ensure that the product is appropriately designed for proper form, fit, and functional requirements for the complete product life cycle. This includes manufacturing to end use or disposal. Dimensioning and tolerancing is critical during the design, manufacturing, assembly, inspection, test and acceptance phases.

Regardless of the dimension and tolerance standards used, there should be at least two primary data references called datums (Fig. 20.41). The purpose of a datum is to ensure the integrity and accuracy of alignment during the manufacturing of a multilayer assembly. In general, it should be a nonfunctional hole or a surface feature that is used as the primary datum reference for final dimensional measurements. The datum reference should not be a machined edge that is formed in the last phases of the manufacturing, fabrication or assembly process in a secondary machining operation.

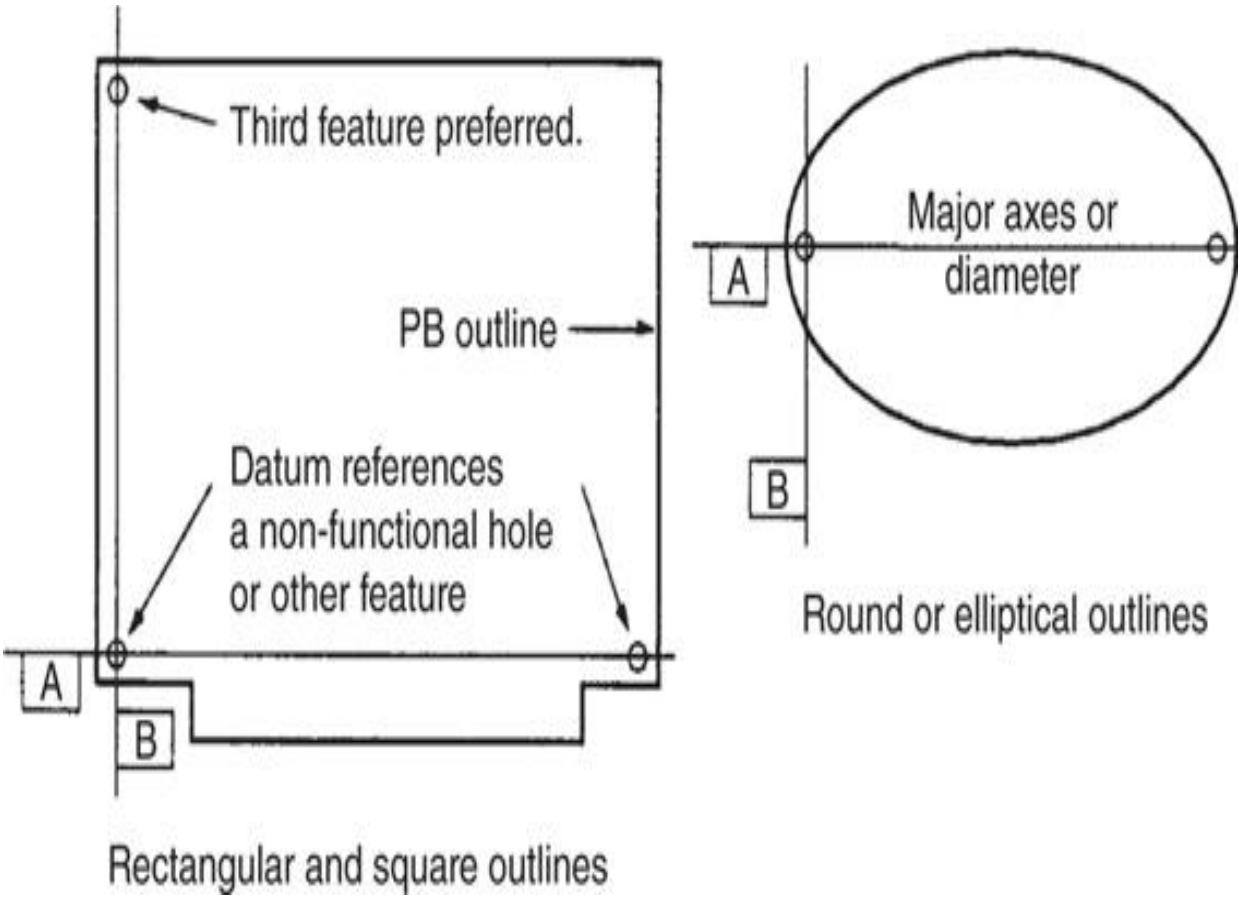

FIGURE 20.41 Illustration of a PCB using datum as a references to ensure accuracy of manufacturing.

20.7.3 Mechanically Mounted Printed Board Assemblies

PCB assemblies should be designed to ensure that both mechanical and electrical grounding requirements remain unchanged throughout its product life cycle. The following are generally accepted requirements and practices for mechanically mounted assemblies:

- The PCB assembly should be supported within 25 mm of the edge of on at least three sides.
- Fabricated printed boards having a thickness from 0.7 to 1.6 mm should be mechanically supported on 100-mm or

lower intervals. Assemblies thicker than 2.3 mm or less should use 1.3-mm intervals.

- Fasteners should not be located on less than assembly with a small thickness, or a fastener’s head diameters, whichever is less, from the edge of the assembly.

20.7.4 Physical Support for PCB Installed in a Card Cage

One advantage of using plug-in printed board assemblies (PBAs) is the ability to add or remove a board within an enclosure for manufacturing or maintenance purposes. Use of mechanical card guides makes it easy for changing configurations and upgrading functional performance. There are many hardware designs available for the purpose of providing a card guide securement method. The design is predetermined or may be developed based on the size and shape of the board assembly. The degree of dimensional accuracy needed to ensure proper mating alignment, along with the mating connector system is important for operational performance and in some application, is used to minimize board edge radiated emissions between the power and return planes. The metal card guide thus functions as an EMI shield.

20.7.5 Retaining PBAs

Shock, vibration, and normal handling requirements necessitate that any assembly be secured or retained in the system by some form of mechanical device. Some retaining systems are attached as hardware to the board during assembly. Other retaining systems are built into the mounting hardware when the board is installed in a card cage. The selection of a proper retaining system is

important, since the retaining devices may reduce the amount area on the board for component mounting and interconnections, and can add significantly to the cost of the electronic equipment.

20.7.6 Extracting PBAs

A number of unique methods have been developed and applied to solve the various problems of extracting board assemblies from their enclosures. The most common industry-standard extractor is injection-molded plastic hardware that is free to partially rotate when attached with a pressed-in pin. Many of these extraction tools use a minimum of space, thereby maximizing available area for components and conductor routing. They also protect both the board and the associated mating connector(s) from damage during the extraction process.

The following should be considered when selecting among the many different types of extraction tools:

- The area available for attachment
- The extractor’s effect on the mounting pitch of the assembly
- The need for special provisions such as mounting holes, mounting clearance holes and notches
- The size of the extractor, especially if the extractor is to be stored in the equipment with which it is used
- The need for an extraction device that is permanently attached to the assembly, usually by riveting
- The need for specially designed considerations, such as load-bearing flanges, in the assembly mounting chassis or cage hardware
- The suitability of the extractor to be used with a variety of board sizes, shapes, and thicknesses

- The cost of using the extractor, both in piece price and added design costs
- Degree of access required to engage and use the extraction tool

20.7.7 Shock and Vibration

Shock, vibration, flexing, and bowing can be functional performance and reliability concern especially for larger sized assemblies. For many board assemblies, the worst-case exposure to shock and vibration occurs in nonfunctional or operational usage during shipping and other forms of transportation from one location to another, or possibly during functional use when the product containing is inadvertently dropped on the floor. Other board assemblies are designed to withstand specified levels of shock and vibration in transportation. The design requirements for shock and vibration vary, depending on each family of general requirements. For example, there are nonoperating shock and vibration requirements for vehicular, train, ship, and air transportation which include various procedures and requirements for packaging. The shock and vibration functional design requirements vary and are dependent on the application. Some sources of shock and vibration are very obvious while others are not. The levels and duration of shock and vibration vary significantly in each application: An electronic sensor mounted on a vehicle’s axle is different from the radio mounted in the dashboard. There are also differences among ground-based, rack-mounted, industrial control equipment, aircraft, aerospace, and munitions applications. Some vibrations are subtle, low-level continuous, and are frequently caused by electric or gas motor-driven rotating machinery and equipment. Continuous low-level vibrations can induce *mechanical fatigue* in some electrical/electronic equipment.

20.7.8 Mechanical Shock

Mechanical shock is be defined as a pulse, step or transient vibration where the excitation source is nonperiodic. Shock is a suddenly applied or increment of force by a sudden change in the direction or magnitude of a velocity vector. With few exceptions, shocks are not easily transmitted to electronic equipment due to their relatively light mounting frames and structures. Most shock to electronic equipment in the consumer, commercial, and industrial markets are due to dropping during handling or transportation, the exceptions being electronic sensors or equipment mounted to heavier mounting frames such as vehicle axles and punch-press-like equipment, or military equipment subjected to air dropping or to explosive forces such as munitions. Most shock impact forces result in a transient type of dampened vibration, influenced by the natural frequencies of the mounting frame. Generally, shock either results in instantaneous failure or functions as a stress concentrator by reducing the effective strength of the connection or lead for subsequent failure due to additional shock(s) and vibration.

20.7.9 Vibration

Vibration is a term that describes oscillation in a mechanical system, and is defined by the frequency or frequencies of oscillation and amplitude. Board assemblies that are subjected to extended periods of vibration will often suffer from fatigue failure, which can occur in the form of broken wires or component leads, fractured solder joints, and cracked conductive patterns or broken contacts on electrical connectors. The frequency(s) of vibration, resonances, and amplitude(s) all influence the rate of failure.

Flexing and bowing is the result of induced shock and vibration into the printed board assembly (PBA). Different

mounting methods have differing susceptibilities to shock and vibration. In general, most small functional modules are manufactured as components and are frequently encapsulated with a polymeric potting material into a solid mass. They therefore have minimal shock and vibration requirements within the module. The plug-in modules are restrained on one edge by the edge-board connector(s) and to some extent along the two other sides by mechanical guides. This leaves only one edge of the assembly free to flex from shock and vibration or to bow from residual manufacturing or assembly stress.

However, a handle along the free edge of the PBA or a restraining bar can be located across the center of the free edge of the assembly and mechanically attached for support at the ends of the restraining bar to mounting hardware such as a card cage. Generally, the mating edge-board connector has a molded-plastic body that provides mechanical support to the mated edge-board connector and has sufficient compliance in the electrical contacts to maintain good electrical connections within the connector’s performance specifications. Mechanically mounted PBAs can be more of a shock and vibration concern for three main reasons:

1. The board assembly can be very large, physically.
2. The board assembly is misused as a mechanical support structure for high-mass components, such as magnetic components that include iron-core transformers and inductors, power supplies, and large functional modules.
3. The board assembly is not included in the mechanical design definition.

20.7.10 Major Shock and Vibration Concerns

Major shock and vibration concerns include the following:

- Flexing between assemblies may cause shorts between adjacent boards or to the enclosure.
- The fundamental mode is the primary mode of concern because it has the large displacements that cause fatigue damage to solder joints, component leads, and connector contacts.
- Continuous flexing of an assembly will fracture component leads and, more important, surface-mounted component solder joints due to mechanical fatigue failure.
- Movement of an assembly within its mechanical guides will be amplified due to shock and vibration or harmonic resonance.
- Fatigue life modeling mounted components has become significantly more complex due to in-use simultaneous application of both vibration and thermal cycles. Vibration strains and thermal strains should be superposed for more representative modeling.

20.8 TYPES OF EDGE MOUNTING FOR CIRCUIT BOARDS

Methods of analysis and minimization from effects of shock and vibration on PCB assemblies are the same as in other engineering applications. Similar solutions can be used. PCB assemblies are designed and manufactured in a wide range of shapes and sizes, with rectangular being the most common. PCBs are a multi-degree-of-freedom system, the fundamental mode which is of primary importance because it has the large displacements that are the primary cause of fatigue failure in solder joints, component leads, and connector contacts. Most vibrational fatigue damage occurs at the fundamental or natural frequency as displacement is highest and stress is maximized. Edge or boundary

conditions are terms used to define the method of attachment of the assembly to a fixed structure, or more generically to a panel on a mounting frame. The term *free edge* is used to define those edges that are not restrained and are free to move and/or rotate outside of their normal mounting structure. The terms *supported edge* or *simple support* is sometimes used to define an edge that is restrained in out-of-plane movements but is allowed rotational movement around the board's edge. The terms *fixed edge* or *clamped edge* are used to define an edge that is restrained in both out-of-plane and rotational movements. Illustrations of both definitions for fixed edge, supported edge, and free edge, and their applications, are shown in Fig. 20.42.

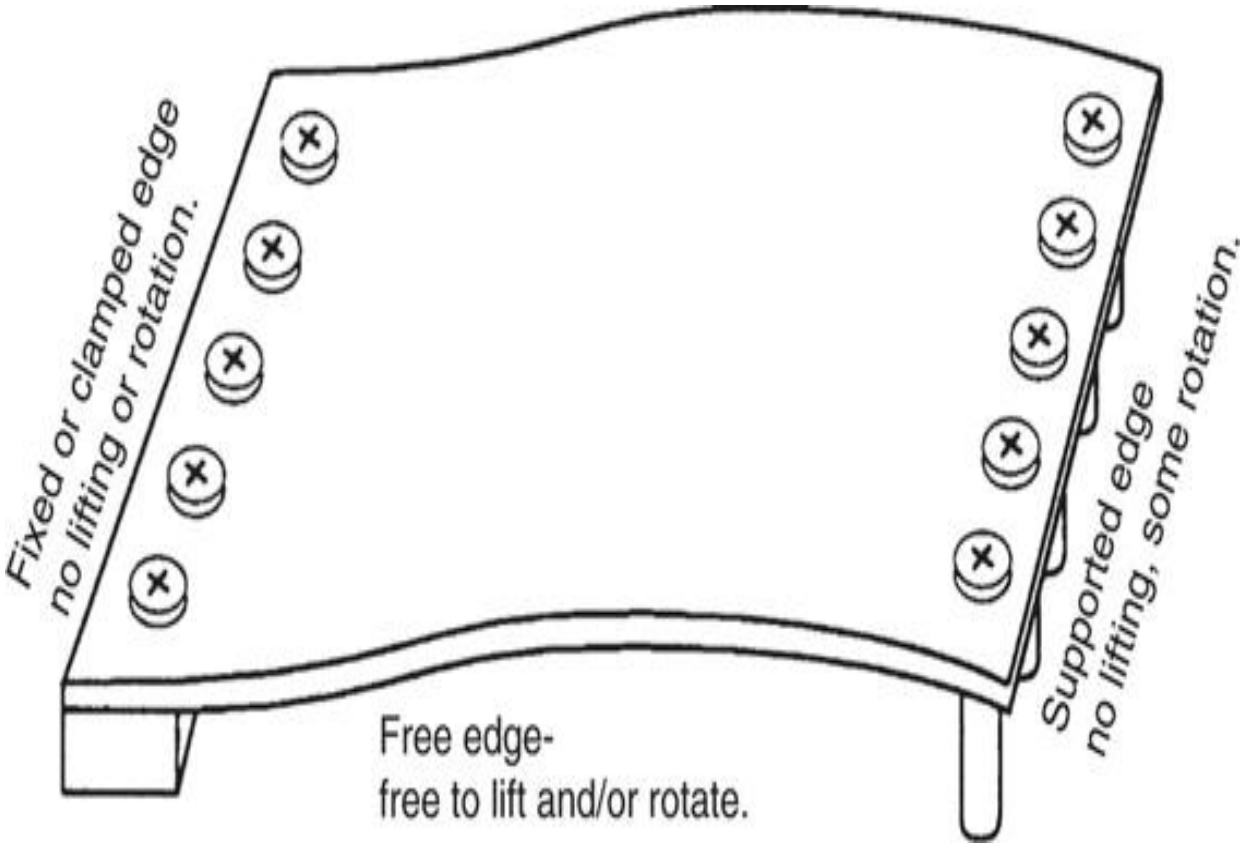

FIGURE 20.42 The method of mounting contributes to shock and vibration concerns.

20.8.1 Board Deflection

The amount of strain on a physical component is a function of the maximum deflection of the assembly when subjected to shock, vibration, twisting, and bending. Components mounted closest to the center of the assembly are subjected to the greatest strain, illustrated in Fig. 20.43.

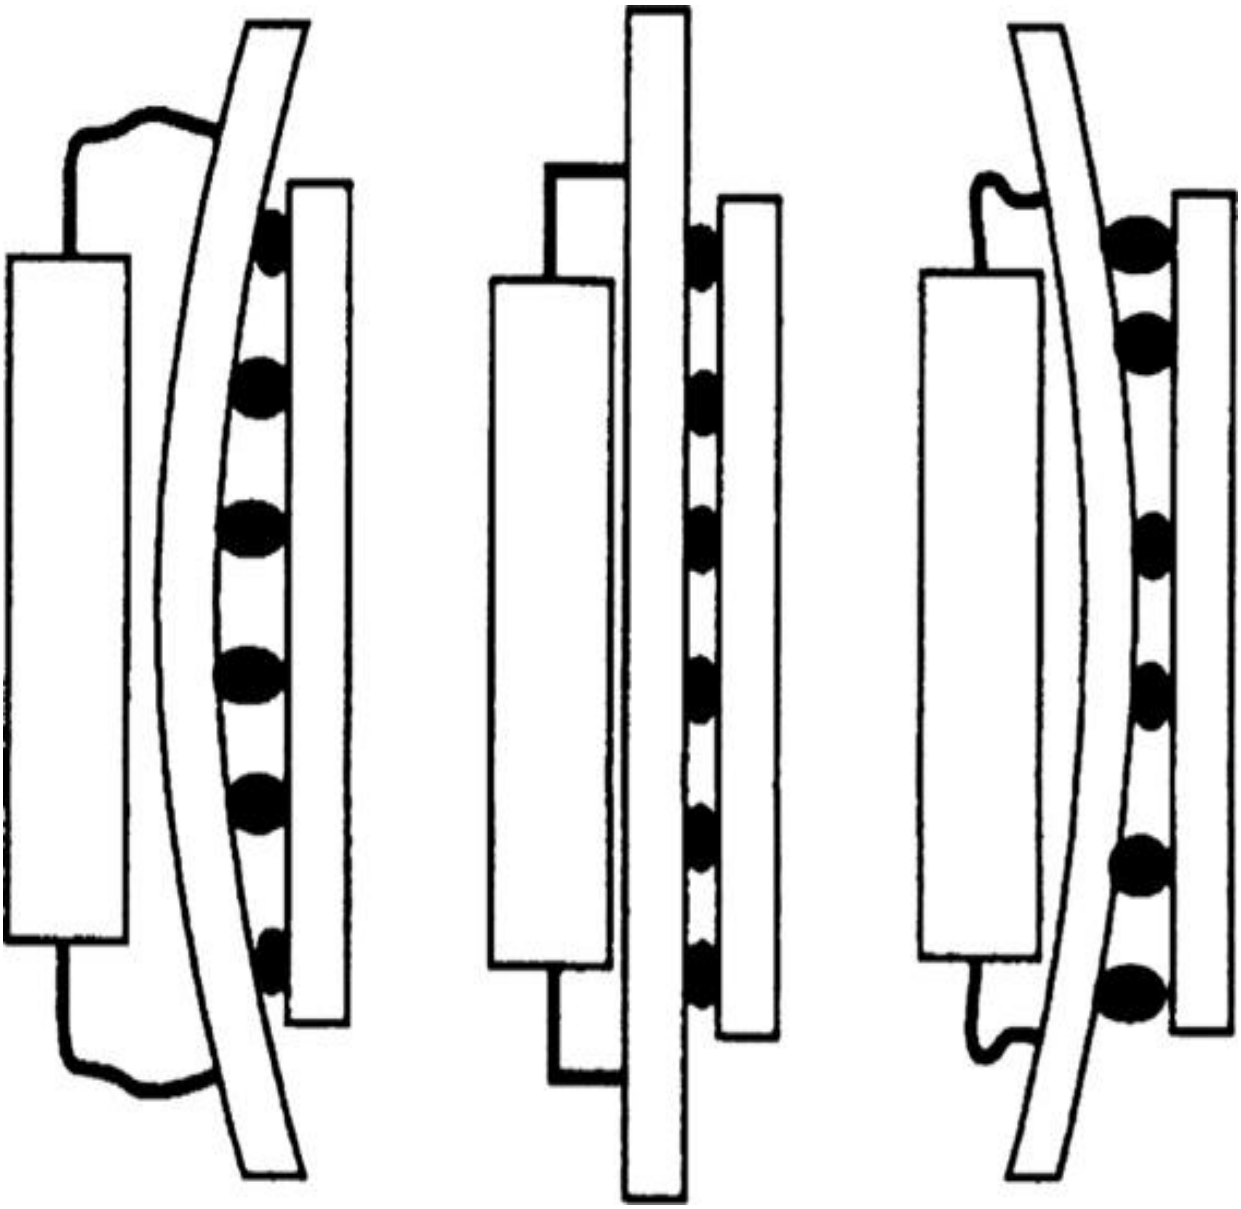

FIGURE 20.43 Bending in a printed circuit board during shock and vibration, with the most severe stresses applied to the components mounted centermost on the assembly.

A set of empirical maximum deflection (d) calculations has been developed by Steinberg. His latest equation[7] has more parameters than previous equations, reflecting the sophistication and requirements for modern PCB designs. These new equations have units adjusted from inches to mm [Eq. (20.7)].

$$\delta = \frac{k\,0.00022B}{ct\sqrt{L}} \tag{20.7}$$

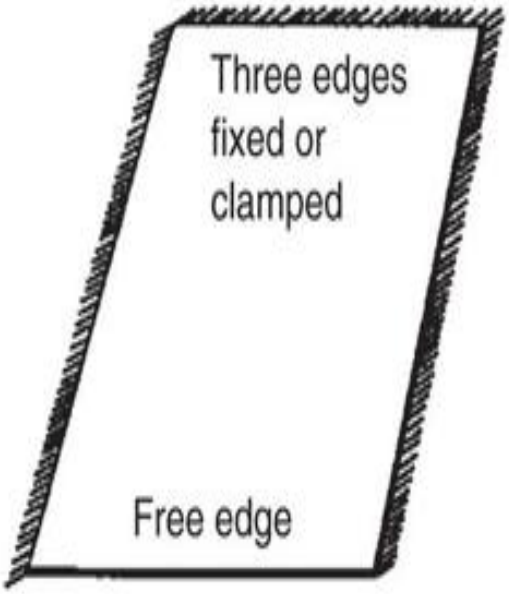
where k = units conversion coefficient; for inches $k = 1$, for mm, $k = 25.4$
B = length of PB edge parallel to component located at center of board (worst case), mm
L = length of component, mm
t = thickness of the board material, mm
c = 1.0 for standard DIP
= 1.26 for DIP with side brazed leads
= 1.0 for PGA with four rows (one row extending along the perimeter of the edge)
= 2.25 for CLCC

Analysis of the maximum deflection calculation formula reveals that components with some compliance built into their component mounting and electrical terminations can be subjected to about twice the vibrational deflection as packaging, provided component size, the PCB dimensions and thickness are equivalent. The latest equation for maximum deflection calculations is rated for 10 million stress reversals when subjected to harmonic (sinusoidal) vibration, and 20 million stress reversals when subjected to random vibration. It must be understood that this equation is a first approximation for predicting solder joint life.

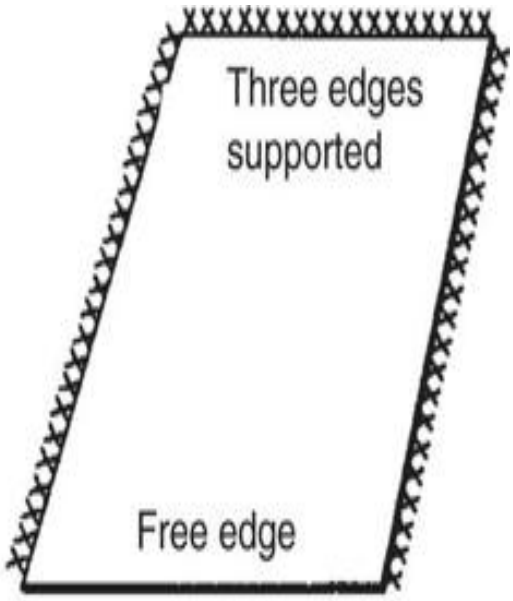
20.8.2 Natural (Fundamental) Resonance of Printed Board Assemblies

The mechanical mounting of a PCB and their components is a key design consideration in the ability of the assembly to withstand shock and vibration. The overall size of the assembly is not a major factor, provided a suitable mechanical support structure is included as a part of the product definition requirements. There numerous ways to mount panels using various combinations of free edges, supported edges, fixed edges and point supports and by calculating fundamental resonances. The following four examples compare the fundamental natural resonances of the same rectangular shaped assembly using different edge-mounting techniques.

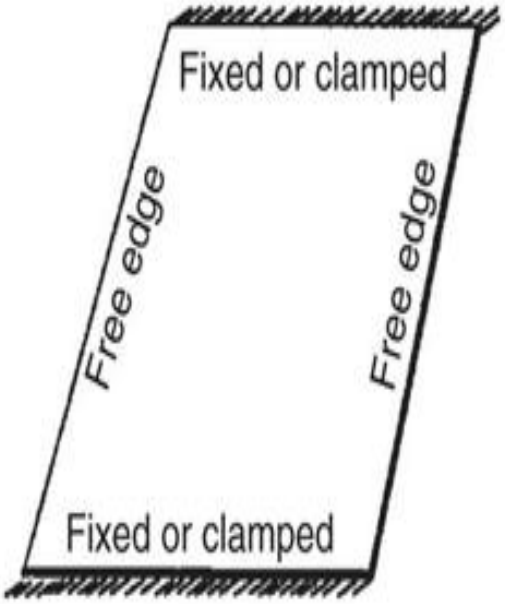
In the following examples—demonstrations of the sensitivity of assemblies to their methods of mounting is provided for comparative purposes (Fig. 20.44). The following are the design requirements and material parameters that were used for the calculations:



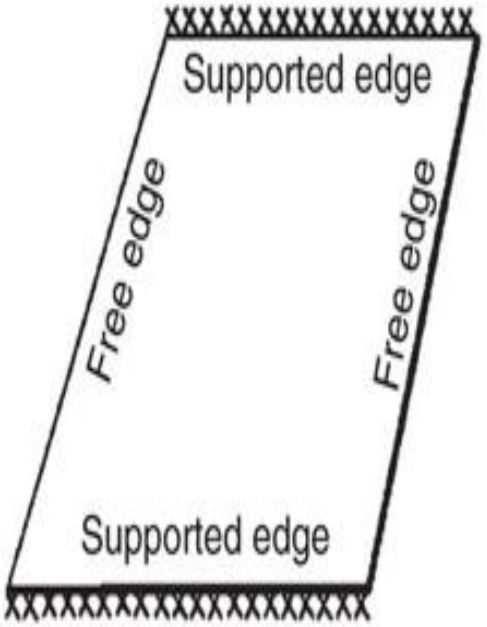
Fundamental resonance frequency
128 Hz



Fundamental resonance frequency
53 Hz



Fundamental resonance frequency
67 Hz



Fundamental resonance frequency
30 Hz

FIGURE 20.44 The same assembly can have a wide range of natural resonances depending on the mounting method, which is why shock and vibration concerns are a critical design consideration.

$$D = \frac{Et^3}{12(1-\mu^2)} \tag{20.8}$$

where D is the plate bending stiffness.

$$M = \frac{w}{g} \tag{20.9}$$

$$f_n = C_o P_o \sqrt{\frac{Dab}{M}}\ Hz \tag{20.10}$$

where f_n is the natural resonant frequency.

20.8.2.1 Methods of Reinforcement and Snubbers. PBAs are stiffened using one or more methods to raise the natural resonant frequency sufficiently above the shock and vibration threat. The most obvious means to achieve this is to change the method of retaining or mounting in the next higher level of assembly. Frequently, though, this may not be an acceptable option due to the resources and schedule changes that may be necessary for extensive redesign. However, some simpler modification in the design may meet functional requirements. Sometimes changing the plug-in guide from a loose supportive guide to a tighter spring-loaded or clamping-type guide may be sufficient. Other methods are to add ribs or stiffeners, additional single-point mounting locations, or *snubbers* across the surfaces of the assemblies.

20.9 ACKNOWLEDGMENTS

The authors extend their appreciation to the industry and many who contributed to the progress of signal integrity activities. Sincere thanks also goes to Ralph J. Hersey, Jr., at Lawrence Livermore National Laboratory for his authorship of this chapter in the previous (6th) edition of *Printed Circuits Handbook*.

THE BASICS OF PRINTED CIRCUIT BOARD DESIGN

Susy Webb

Design Science, Sugar Land, Texas

There are mountains of information one must gather and understand in order to design any printed circuit board (PCB). Interested parties may be coming from any of a number of different places with any amount of information they know about board design. The purpose of this chapter is to introduce those interested parties to the concepts involved in designing a PCB, without being either overly simplistic or complicated in the approach. It will cover as many of the concepts as possible, while assuming that there is at least some knowledge of the subject matter. Also, there are sometimes different terms in the industry that mean the same thing, so there is a listing of terms at the end of this chapter to use as a cross-reference.

21.1 SOFTWARE SELECTION

The first thing that is needed is the computer software to do the job. There are many different kinds to choose from for both schematic entry and PCB design with additional add-ons that will do an increased level of layers and constraints, auto routing, simulation, even work with the company's MRP system. The PCB designer must evaluate what the needs would be for the types of PC boards to be designed. If only the most basic boards will be produced and they will be a minimum number of layers, one of the free computer softwares on the Web might work for that company. Those softwares are extremely fundamental, however, and should be considered only for the most basic of boards. If the designs will be complex with many parts, many constraints and many layers, one of the higher end software tools may be needed. Even the major software vendors have a range of different levels of what their software will do, and they can help the designer work out which version of the tool might work best for them. It would be most prudent to gather information from several different software vendors before making a decision as to which one will work best for the company's needs.

21.2 STANDARDS

There are standards for almost everything that is done in the design world, and they are generally set up by volunteer committees of experts. They are compiled by subject matter and available in written or electronic forms from IPC (Association Connecting Electronics Industries, Bannockburn, Ill. www.ipc.org). The IPC serves all the disciplines associated with PCBs. Designers should get copies of all the standards that apply to the kind of work they will be doing, become familiar with them, and refer to those standards often. If the information or terminology contained therein is confusing,

the first publication on the designer's list of must haves might be IPC-T-50, which is the "Terms and Definitions" document. Most of the IPC documents have a cost associated, but they may save the designer from a world of problems they might otherwise encounter.

Examples of design standards are as follows:

- IPC 222x—Generic Standards on Designing Printed Boards (including flex and MCM)
- IPC-2611—Documentation Requirements
- IPC-A-600—Acceptability of Printed Boards
- IPC-A-610—Acceptability of Assemblies
- IPC-6011—Generic Performance Specification
- IPC-6012—Qualification and Performance for PCBs
- IPC-SM-840—Solder Mask
- IPC-4101—Materials for Rigid Boards
- IPC-ET-652—Electrical Testing

21.2.1 Classes of Board by Application

The IPC also has devised classes and levels to help users determine the type of board they are designing as compared to others. IPC performance classes set the standard for how well the product must work. They are as follows:

Class 1 are general electronics like toys, games, and general products. If these products fail, there are no large ramifications.

Class 2 are dedicated service electronic products like business and industry machines and communications equipment. Uninterrupted service is desired, but not life threatening.

Class 3 are high reliability electronic products like military and medical where interrupted service could be life threatening.

21.2.2 Producibility Levels

IPC producibility levels communicate the degree of difficulty of manufacturing the features of the board in production. Those levels are:

Level A General Design Complexity—preferred

Level B Moderate Design Complexity—standard

Level C High Design Complexity—reduced producibility

21.2.3 General Standard Objectives

There are other industry standards that may be required for a specific type of board such as computer, telecom, medical, etc. These standards might have requirements for boards such as size, shape, mounting, and connector location that determine whether that board will properly interface into any like system. The military has its own set of very tight standards that govern how those boards will be built and assembled. There are even standards from American National Standards Institute (ANSI) and the Electronics Industries Alliance (EIA), which governs dimensioning and tolerancing of electronic components. That is done so that when a part says it is an SOIC, for example, it actually matches that tolerance standard set up and can be used as a replacement for another SOIC.

Some companies set up standards for the way work is done within that company as well, in order to insure that the flow of information is the same for every project and every

person in the department. Companies that are interested in standardizing might include

- The flow of work
- Library issues
- Processes and responsibilities
- Input, output, and saving specifications
- Notes, stackups, naming, and numbering
- Reference information
- Anything else that is important to that company

Additionally, some companies choose to set up their own standards for fabrication and assembly that cover issues like exactly what is expected from the fabricator, what are the deliverables? Are repairs, modifications, or X-outs allowed? What are the panelization, and electrical testing issues? What permissions are needed?

Since PCB design is very precise work, all of these types of standards (and more) may be necessary to ensure consistent quality. If the designer is involved in setting up these standards within his or her company, they might choose to set up checklists to remind them of the important issues on that or any project. An input checklist might include all mechanical, electrical, organizational and testing criteria, while an output checklist can be used as a reminder for any items needed to complete the project.

Standards are important because there are many ways to achieve the same goals in PCB design, and there are many people to communicate with. The designers, purchasing agent, fabricator, assembler, technician, etc. all have to speak the same “language” so there is less chance of misunderstanding and miscommunication. The design methods and documentation used will be the most clear, concise and understandable for all involved if they all reference the same set of standards. Many of the

illustrations contained in this chapter were inspired by information from the IPC standards.

21.3 THE SCHEMATIC

Occasionally, the PCB designer is asked to enter the schematic, or make modifications to it, so it is helpful to have an understanding of the way it flows. The connectivity information for the PC Board comes from the schematic. The schematic designer creates drawings of symbols representing the parts to be connected on the board to perform the electrical functions that are needed. The pins on those symbols represent the pins on the parts and the connectivity between those pins represents the connections, or nets, to be made on the board.

21.3.1 Standards for Schematics

Not surprisingly, there are standards for drawing schematics too. One of the most important is that the circuits should flow from left to right on the page (see Fig. 21.1). This means that is it helpful when reading the schematic if the inputs are on the left side of the symbol or page and the outputs are on the right. It helps if the pieces of a connector are brought out to the edge of the page, as they are easier to find there. Also, the power connections are generally kept to the top of a symbol, and the ground connections are kept to the bottom. It is very helpful if all pins on every symbol are shown whether used or not so that there is never any guess as to whether a pin was not used or was forgotten. If a symbol has multiple parts, called gates, they must all be shown for the same reason. It is very helpful for the board designer if the circuit designer places all the decoupling capacitors near the part they will be used on so that he or

she knows which pins the circuit designer planned to decouple. And lastly, a grouping of symbols on a schematic will generally correlate to a desired grouping of parts on a board.

21.3.2 Schematic Software

The schematic software may output several other helpful bits of information. As mentioned, the main purpose is to correlate each symbol to a part and each part will correspond to a footprint on the board. The software can be used for a block diagram, which is very helpful for getting an overview of the entire circuit with a minimal amount of information. It will also assign a different reference designator to each part based on the kind of symbol it is and the number of them on the schematic. A list of all the parts contained in the schematic called a parts list or bill or materials (BOM) can be extracted for help in ordering everything for the board. Special groupings of parts, design rules, and other bits of information may also be extrapolated. The software will also compile all the parts and connectivity into a net list that will translate everything into the PCB software.

21.4 PARTS

There are a multitude of parts that may be used on a PCB and each has its own needs for mounting, soldering, cleaning, etc. The parts that connect into holes through the board are called through hole devices (TH). Their leads connect through the holes with solder or pressure. See Fig. 21.2. The PCB goes through many heating expansions and contractions as it is being assembled and used, and the bends in many of their leads (called strain relief) help to account for the difference in thermal expansion between the

board material and the part. Those bends can flex slightly back and forth to keep the device from cracking.

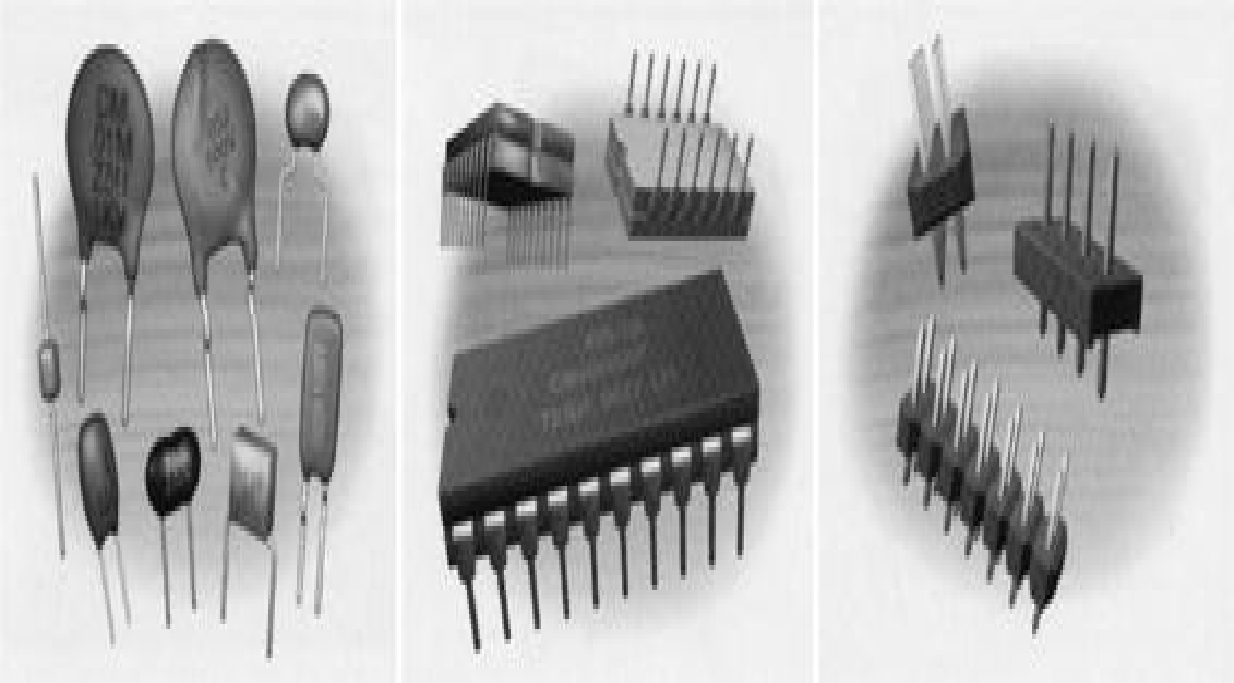

FIGURE 21.2 Examples of through hole devices.

Another type of device connects to the board by soldering the leads onto a pad on one side only. Those are called surface-mounted devices. These devices are generally smaller than their through hole counterparts, so the strain relief is not as needed as on the larger parts. Some surface-mounted parts do have strain relief though. See Fig. 21.4. The majority of the newest parts made are in this surface-mount category. See Fig. 21.3.

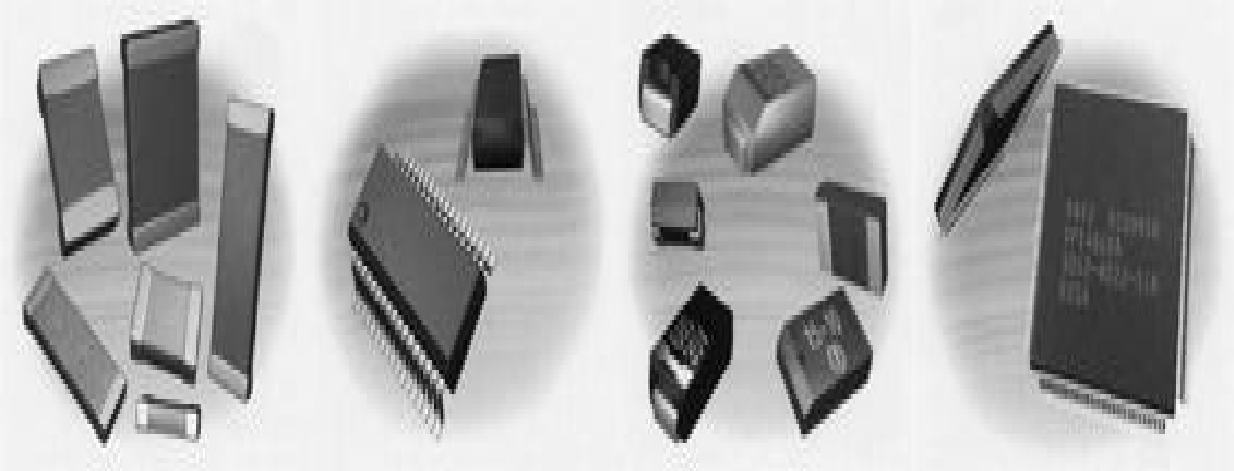

FIGURE 21.3 Examples of surface-mounted devices.

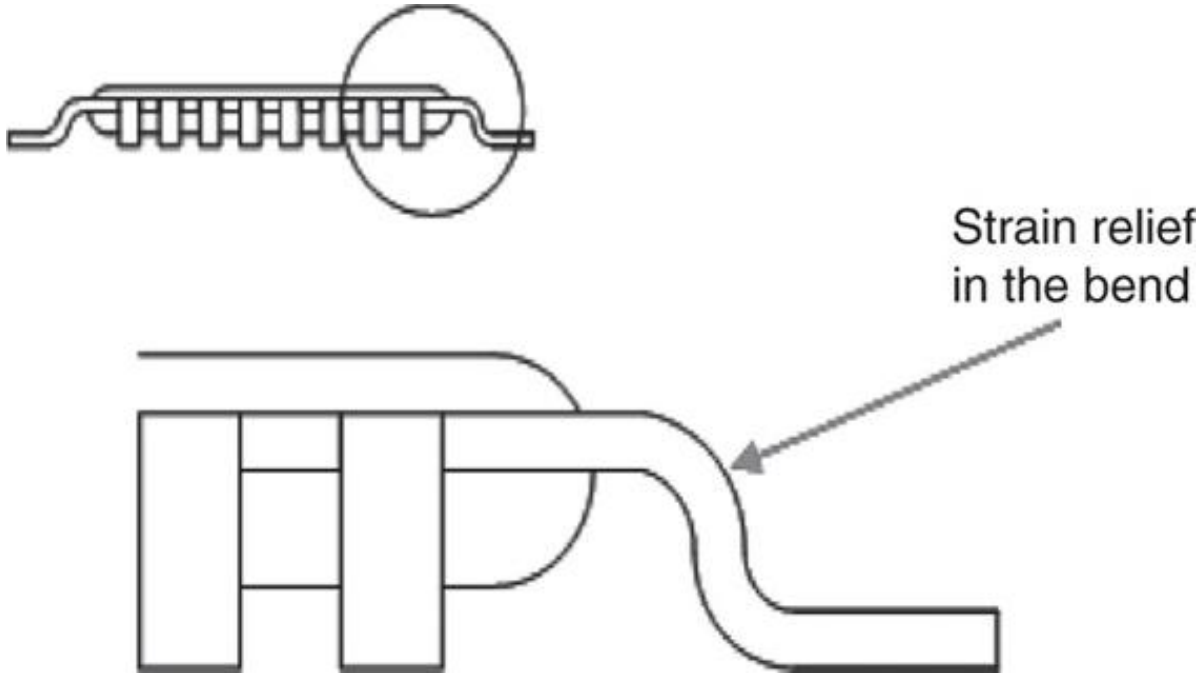

FIGURE 21.4 A surface-mounted device with strain relief.

21.4.1 FOOTPRINTS

The footprints are the actual landing pattern for the leads of the electronic parts. This is where they will be placed and soldered into place on the board. The footprint will consist of the pad and solder mask opening for each connection point

(lead, ball, etc.) in a pattern set up by the device. The footprint may also contain silkscreen information, assembly information, reference designator, pin numbers, placement boundary, paste mask, an origin, and orientation information. See Fig. 21.5.

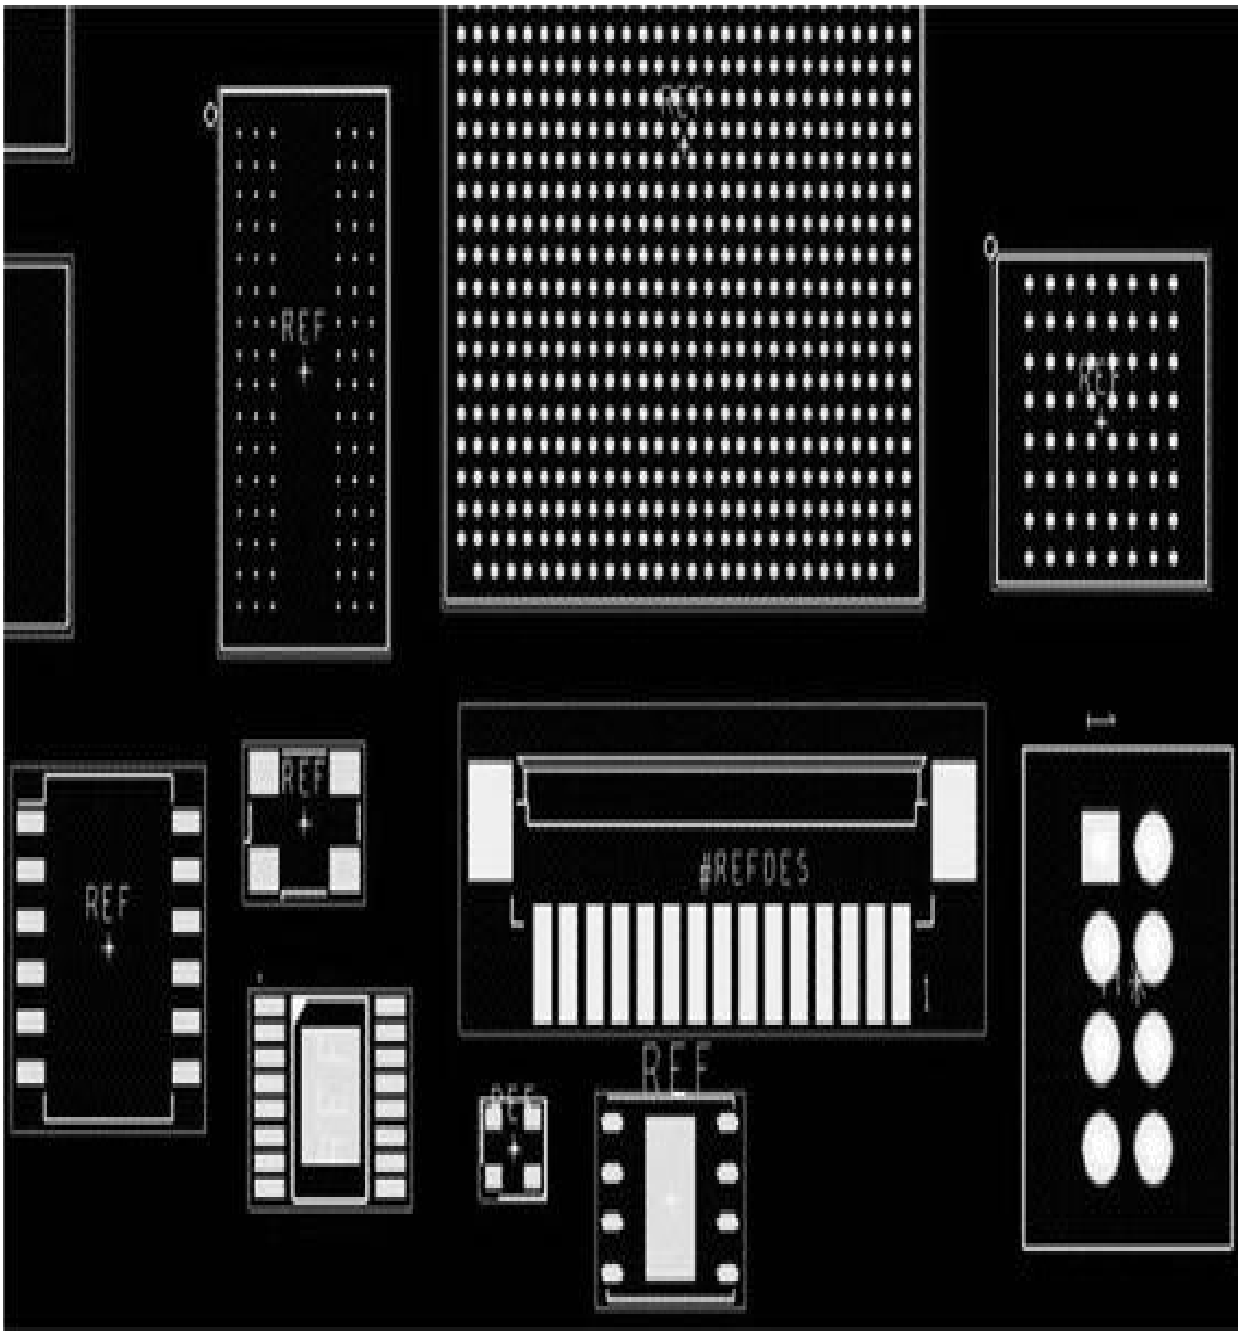

FIGURE 21.5 A few example footprints.

The footprints are usually made generically without ties to a particular part, pin function, or connection and that information is then assigned when the schematic net list pulls the footprints and connections into the PCB database. In other words if there are two or more symbols on the schematic that have different functions but their electronic body size is *exactly* the same, they might each use the same footprint. The pins on part A would take on the net list properties from its schematic part and the pins from part B would take on the net list properties from its schematic part and they might be completely different. Each individual part's needs must be considered carefully before assigning it to a footprint.

Several things are very important in footprint design. Obviously it needs to have the correct number of pads in the correct locations. The origin of the footprint will tell the assembly machine where to pick up the part for placing it onto the board. And the orientation of the footprint will lead assembly to install the part in the correct position. The height of the part will affect the size of the pads that will be used because of the amount of solder needed, and the board designer can use included information on the height of the part to check where things will fit in a 3D manner. The footprint will also need the correct silkscreen outline so the designer will know where the edges of the part are, and the correct placement boundary so that they will know how close other parts can get to that part.

Attributes are helpful to include in part information. They might include things like the manufacturer's part number, what the part is or does, special layout needs, whether the pin is a source or load, and the signal's rise time. These bits of information keep the important information right at hand when using a part. They might be placed on a "construction" layer of the part, or entered into it as part or pin attributes when the netlist comes into the PCB.

Using a naming convention is for all parts makes it very easy to find parts in the library. IPC has a naming convention that includes part type, lead span, size, height and number of pins. Other part libraries available on the Web have other naming conventions, or the designers can choose one of their own that works for them as long as it meets all of their needs.

21.5 PADSTACKS

Each connection on a footprint will be made with a padstack, and those will be very different for through hole and surface-mounted leads. The through hole padstacks must accommodate connection pads for each layer of the board, solder mask for the top and bottom, antipads and thermal pads where necessary. The antipad completely isolates a pad on a plane layer from the plane so there is no short, while the thermal pad makes a small connection to a plane. See Fig. 21.6. The surface-mounted pads are simpler, needing only one connection pad on the outer layer, a solder mask and solder paste pad. The solder paste pad will become the opening for the solder paste to be applied for soldering the part to the board. See Fig. 21.7.

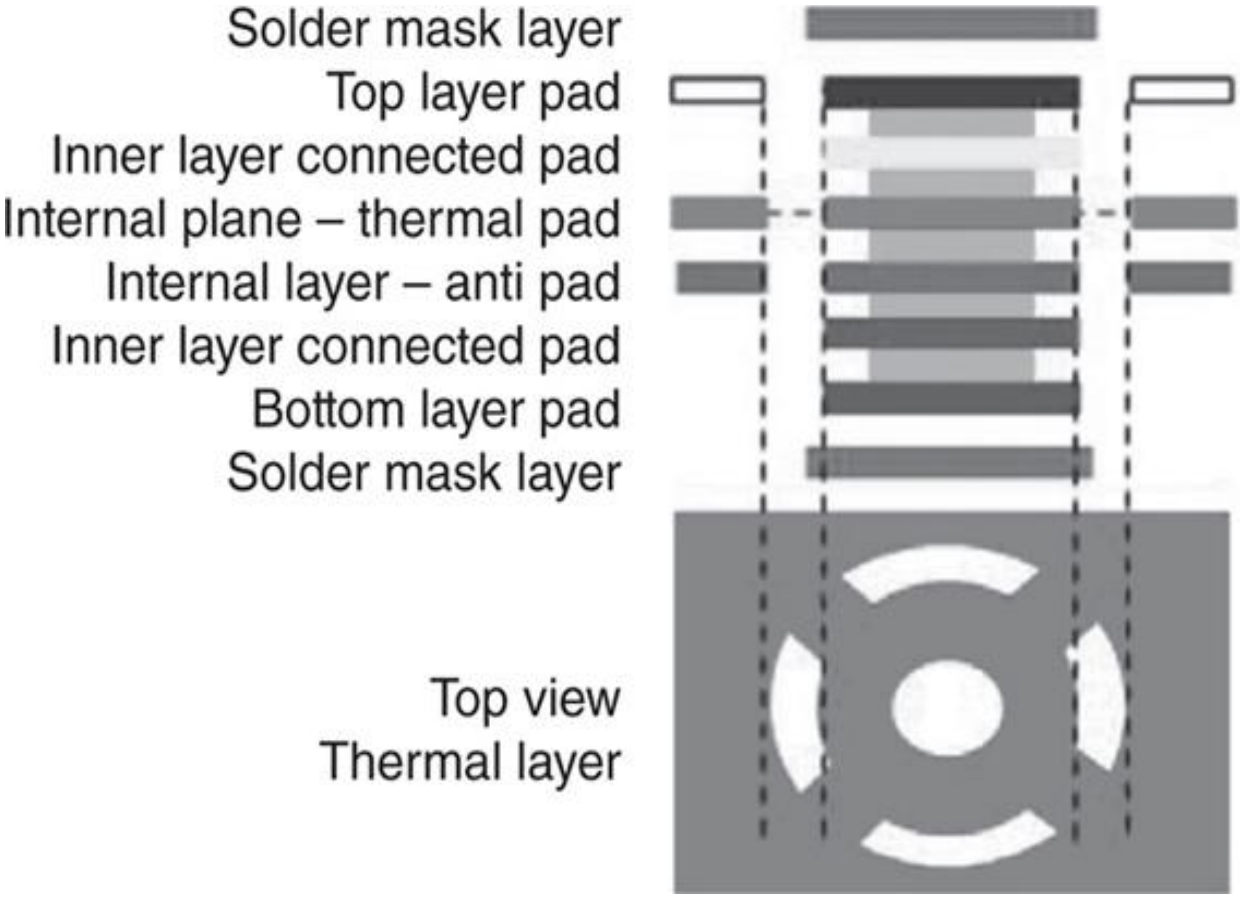

FIGURE 21.6 Through hole padstack.

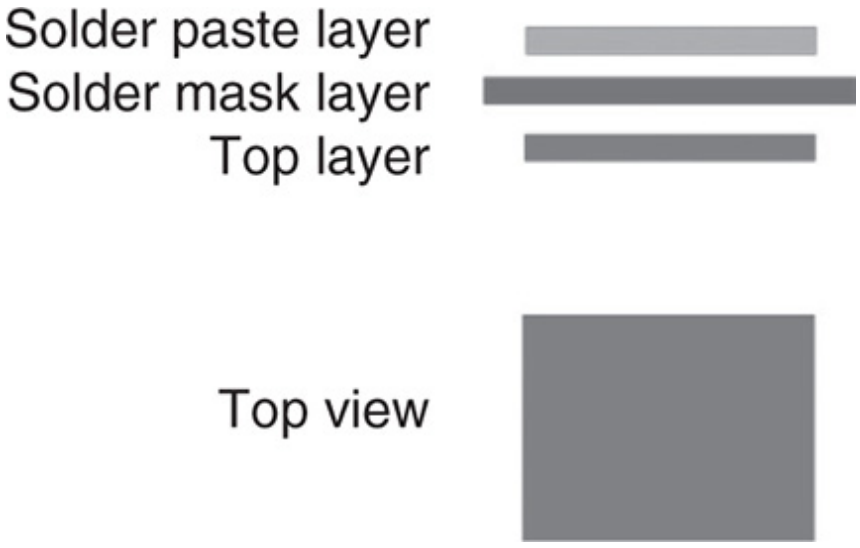

FIGURE 21.7 Surface-mounted padstack, side and top view.

It is a good idea to have a standard for the padstack design too. The size, shape and pad to hole ratio can vary fairly dramatically depending on the source of the information used to make them. IPC has set up standards for these issues as well, and they can be used for every footprint built. For surface-mounted parts, they have set up three categories—minimum sized, nominal sized, and maximum sized which allows for designers to use a more personalized approach to the IPC standard depending on the normal density of their boards. Whichever standard is chosen, it is a good idea to always follow it. Consistency in the way things are done helps multiple designers working together, fabricators, testers, and assemblers.

The choice of an individual part for inclusion into a board can be based on many things besides just function. Among other things, the size, shape, voltage, pitch, and ease of use should be considered. The physical shape and pin location of the pins can be less than clear and can cause problems with assembly if not clarified. If the part is high speed, it can be very important that the power and ground pin locations are very close together. See Fig. 21.8 for some physical part comparisons.

Footprint	Positives	Negatives
SMT	Small, low impedance, power/ground pins	Fanout
Thru	Easy route any layer	Larger, hi imp, P/G
BGA	Lg. amt of info	Rework issues
QFP	Lg. amt of info	Size/pin count ratio
Discrete	Place where needed	More physical parts
R-Pak	Less space, better tol	Distance to route
Embedded	No space, good place	Complexity of design

FIGURE 21.8 Part comparisons.

21.6 STARTING A NEW BOARD

When starting to design a new board, the mechanical issues of the entire project should be fully understood. Any mechanical limitations like height restrictions, rounded corners, cutouts, external connectors, etc. must be considered from the very earliest moments of design. This will ensure that everything fits into its allotted space. Is this board a part of something larger, or is it the complete set of electronics involved? One must understand how and when the board will fit into its area. That will affect the orientation of the board (which side is top) and whether cables and plugs will need to be installed prior to installation. The text on the board should be aligned with the top edge of the

board. That will make it easy to read any text on the board while it is in operation.

One way to be absolutely certain that the board being designed will fit into the size and space expected is to interact closely with the mechanical people and their files. All corners, curves, cutouts, dimensions, and keepout areas must be considered. A way all this mechanical interaction with other boards or devices can be brought into the PCB database is with a .dxf, .emn file or something similar from the mechanical drawing. That can be placed on a nonfunctional layer and converted into the board outline and hole location so that there is no possibility for error. Since the mechanical people are generally the ones that make the connectors, switches, and plugs fit perfectly together, all that information can be brought into the PCB in the same way the board outline was for a sure fit of those items as well. See Fig. 21.9.

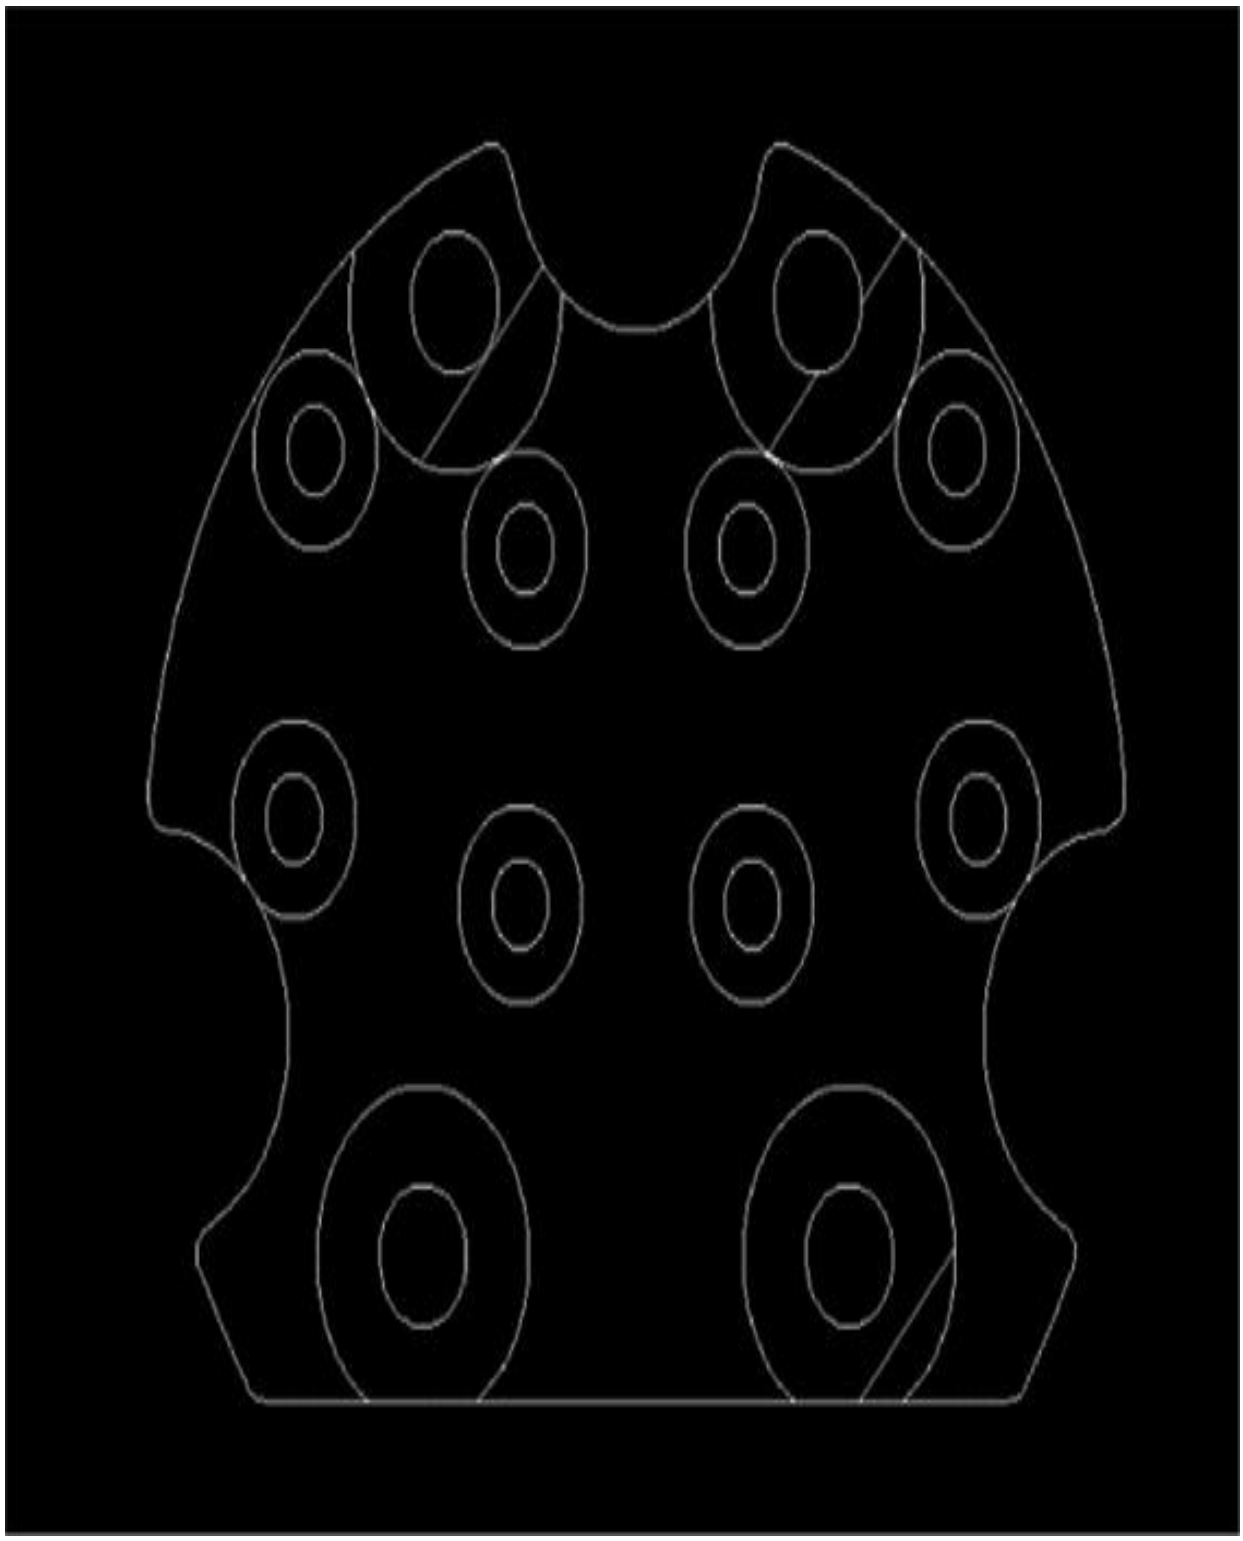

FIGURE 21.9 Bring in a .dxf file for accuracy.

Another early consideration is to understand the parts involved. The designer should gather data sheets and reference information for all the major components on the board. They can provide information about the part and pin function, the signals and their rise time, the need for timing constraints leading to matched length, any and all critical signals and busses, and the size and shape of the part. Many times they will also contain suggested footprint, cleaning, soldering, and lead-free information. While the information contained therein my not always apply to every PCB design, it should always checked for consideration.

This is also a good time to look at the footprints used for the parts chosen. Some of the things to look for would be: will the parts route well together for the flow of a signal or bus (see Fig. 21.10), do they have good indication of how the pins are numbered for testing, are they easy to place when manufacturing, can the programmable pins be changed for best routing, and are there other parts of the same density on the board so that one single part is not driving the board to a higher complexity unless absolutely necessary.

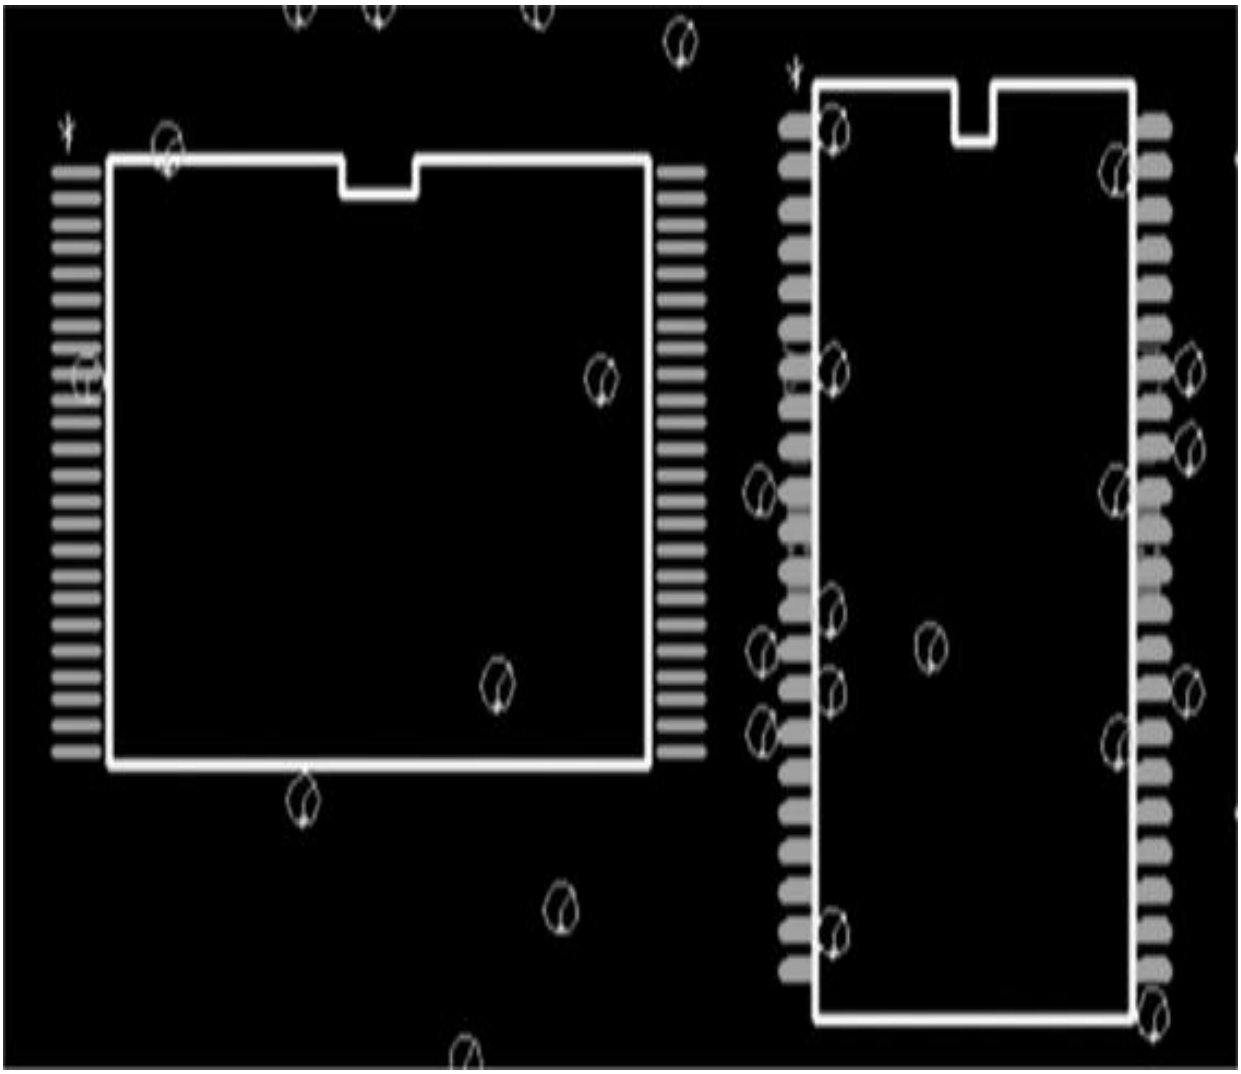

FIGURE 21.10 Will parts work together for the flow of a bus?

Now is the time to begin the setup of the new board within the software. Lots of input is required to do that, and many decisions have to be made. The schematic must be ready to make a “clean” netlist and import into the board with all the parts and library paths set up correctly. The board size and shape must fit into its enclosure, so clearances, tolerances, and keepout areas must allow for those things. The basic software information like grids, precision needed, via sizes, constraints, etc. must be set up. The designer will need to know some information about the board like mounting, air flow, testing. And they will need to know certain bits of

electronics like high current, important, noisy, differential, or high speed signals and impedances needed in order to start the process.

As mentioned, other things that may be important to a board are its orientation, mounting, and testing. The parts on the board may require that there is access to them or that there is cooling, and if there is a fan or venting, those parts must be placed for maximum cooling. It may be important to note the way the board will be mounted to its enclosure for keepout areas and grounding. Mounting holes or rails and anything that will be in a “fixed” location should be brought in and locked into place now too. A designer should know before starting a board if it will be subjected to testing such as shock and vibe, temperature, EMI, HAST, and any of many more tests, so that he or she may set up the board rules accordingly.

A brief discussion of the grid system might be useful. Usually a grid system is used for placing parts as that is the easiest way to line them up in rows and columns which is the best way to build channels for lots of signals to flow through an area. As large a grid as possible makes it is easy to align the parts.

However, some designers use a grid system for routing and vias, and some do not. If the proper constraints are input into the board database, the software will keep the signal routing the correct distance from everything else, or flag it with an error if it does not, but that will not necessarily be centered on a grid. This could allow a signal to route between two rows of pins or vias in an uncentered way which could easily become a signal integrity problem when any of those signals or pins are the higher speed signals of today’s current technology. A grid system of routing also allows any extra room in an area to fall to bigger spacing which is good for manufacturability.

At this point, the software can then be set up in the way that best accommodates this particular board. If more of the

parts are built in a metric grid system, then a metric grid should be set up on the board to use for placement and routing. The precision is the number of decimal places used or allowed after the whole number. Metric boards are often set up for 4 decimal places and boards in mils (Imperial) are already on the small grid of 0.001 in (1 mil), so the number of decimal places after that is often 2. The density of the board will help to set up the default via size that will be used in routing. If the board will be fairly wide open, the via size may be larger than if the parts and routing will cause space to be very tight. It is a good idea to talk to the manufacturer about their “normal” size via and pad and the smallest via hole that they allow without an up-charge. Before any placement or routing occurs, the most basic constraints will be entered. These might include the default trace width and spacing, any signals with critical length or spacing, and differential signals.

It is also important to decide the board thickness at the start of the process in order to design the board’s stackup. While manufacturers can make up numerous board thicknesses, there are some that are used a lot more often than others. The most common by far is 0.062 in thick. The intended number of routing and plane layers should be decided, and the copper thicknesses planned based on current need. The stackup will help determine how the signals will travel through the board and also help determine impedance control and return current because those are partially set up by the distance between the trace and its closest plane. Now is also the time to determine if any special board material will be needed for lead free, high speed signaling, heat dissipation, or any other reason.

At this point, bringing a netlist into the board will bring all the parts and their connections into the database. Most softwares have a quick way of placing all those parts in a more or less random arrangement outside the board outline

(see Fig. 21.11). There, they are available for the designer to begin his or her placement.

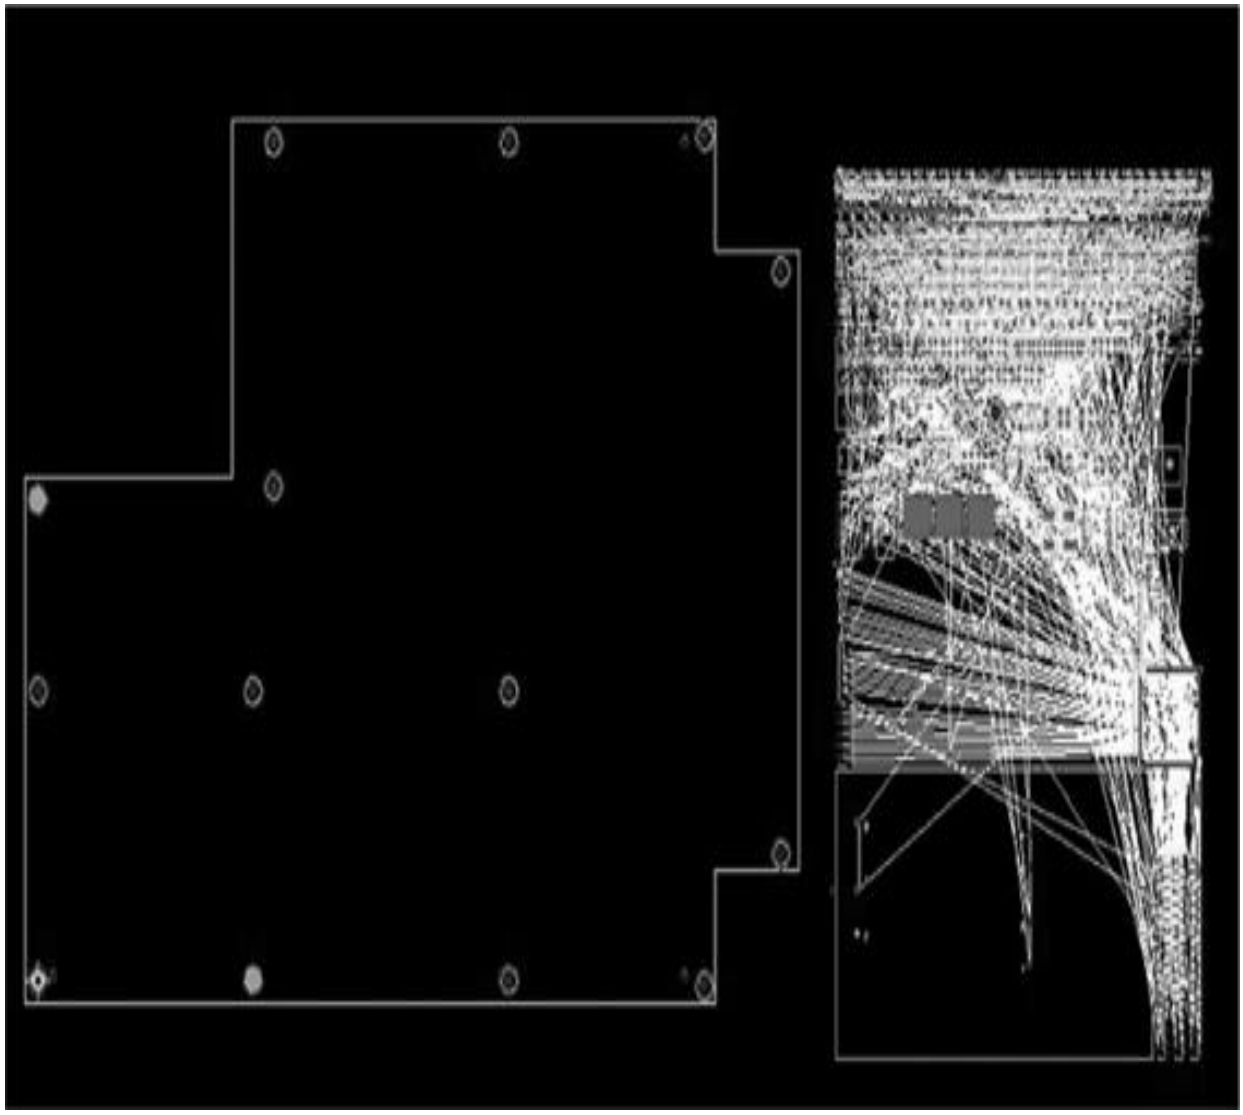

FIGURE 21.11 Netlist brings parts into random locations outside the board outline.

There are many ways to organize all the information given to us from the schematic into something understandable and manageable prior to placement on the board. Sometimes, groupings are done at the schematic level that will carry over into the board. Some people like to organize the parts as they are placed into the board. Others prefer to organize the

parts into “blocks” or regions outside the board outline to see what goes together and how it fits with other groupings of parts (see Fig. 21.12). The added benefit of this grouping step is that the designer gets familiar with the schematic, parts, and circuit, and how they all fit together in the bigger picture. The methodology used for this organizational step really only needs to make sense to the designer as long as things get grouped as they need to be electrically on the board.

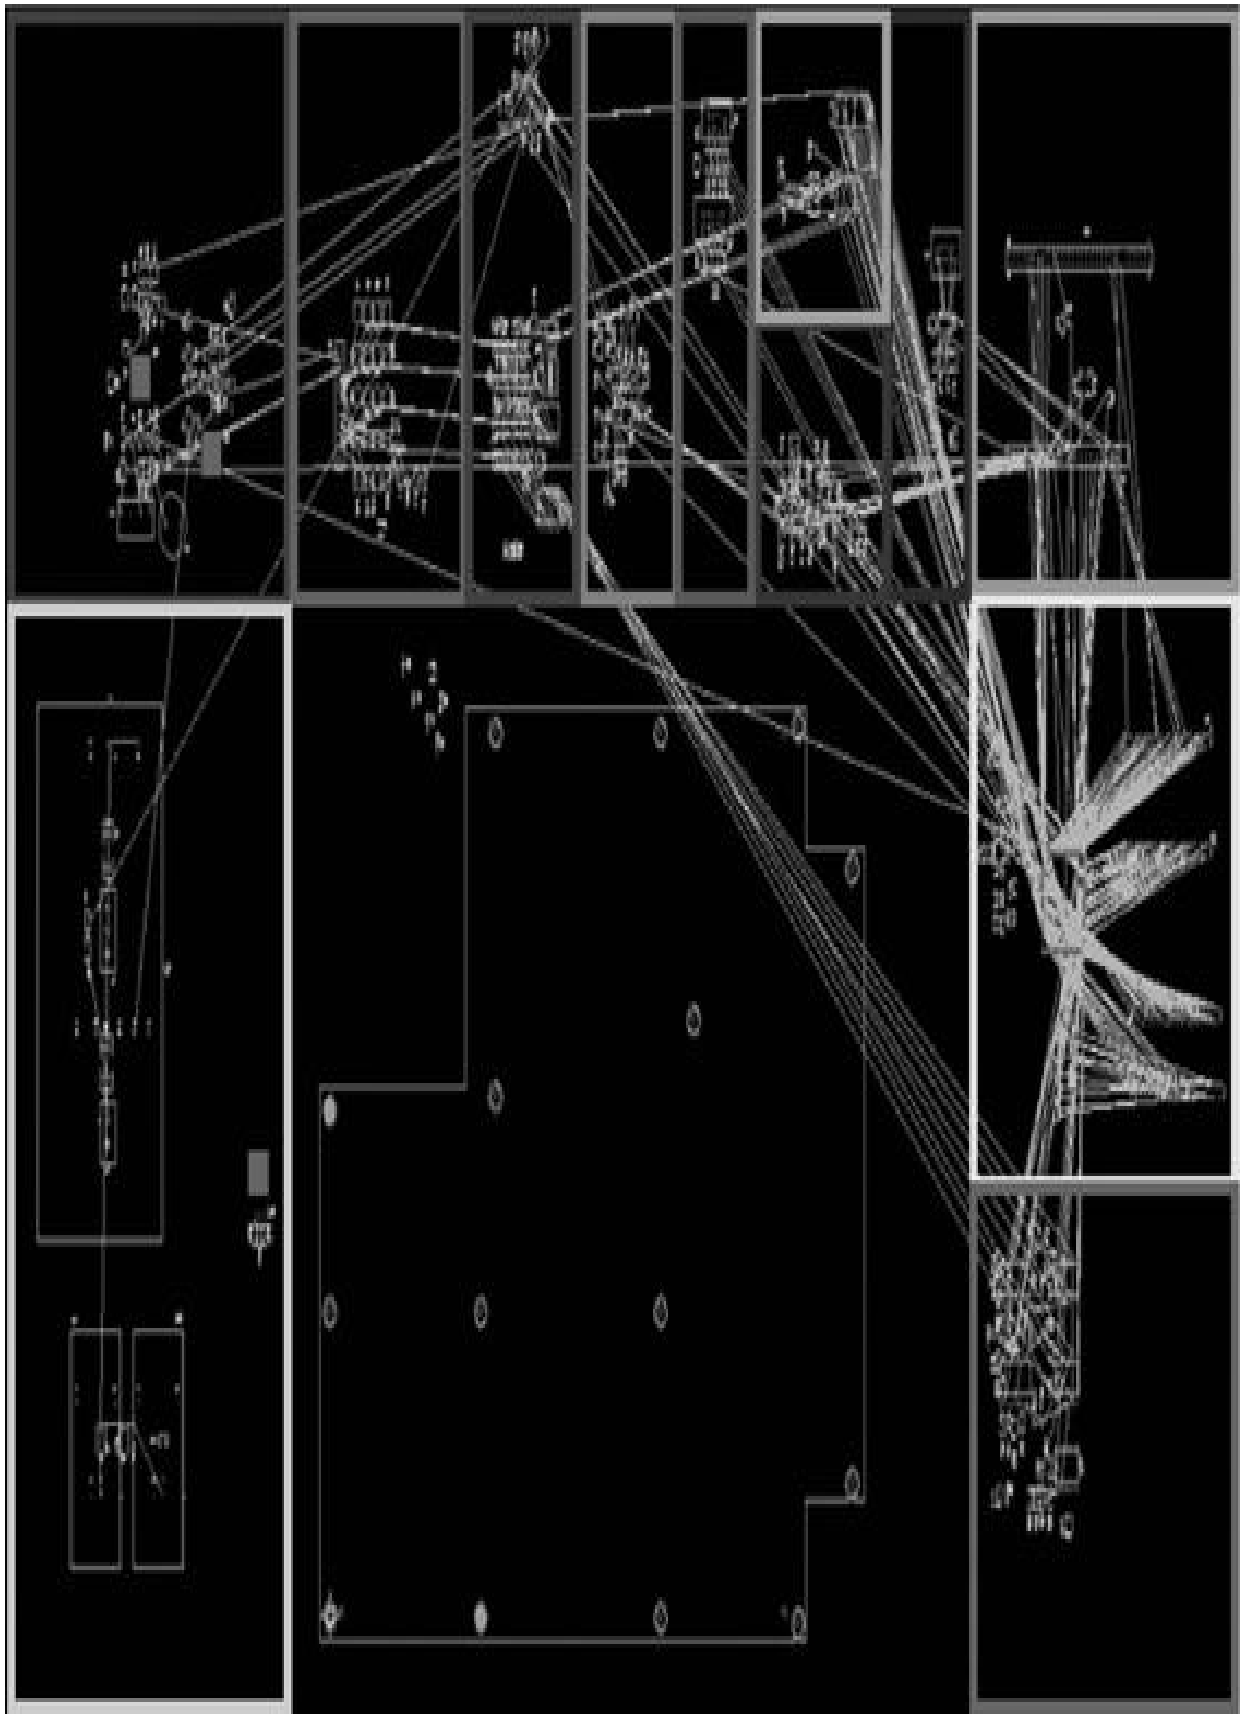

FIGURE 21.12 Group parts outside board outline.

21.7 PLACEMENT

It is helpful at this point to study the total space allotment on the board. Just as a block diagram helped to simplify and understand the schematic, making a block diagram for the PCB can be helpful. One can choose the size and shape of the sections on the board that will be used for each section of analog, digital, high speed, I/O, filtering and ESD, power supplies, etc. (see Fig. 21.13). A little planning on how these parts and sections will interconnect can easily be used for placing parts and later when routing them. The groups of parts can then be moved around as needed and collapsed closer and closer until they fit within the designated area and the board outline.

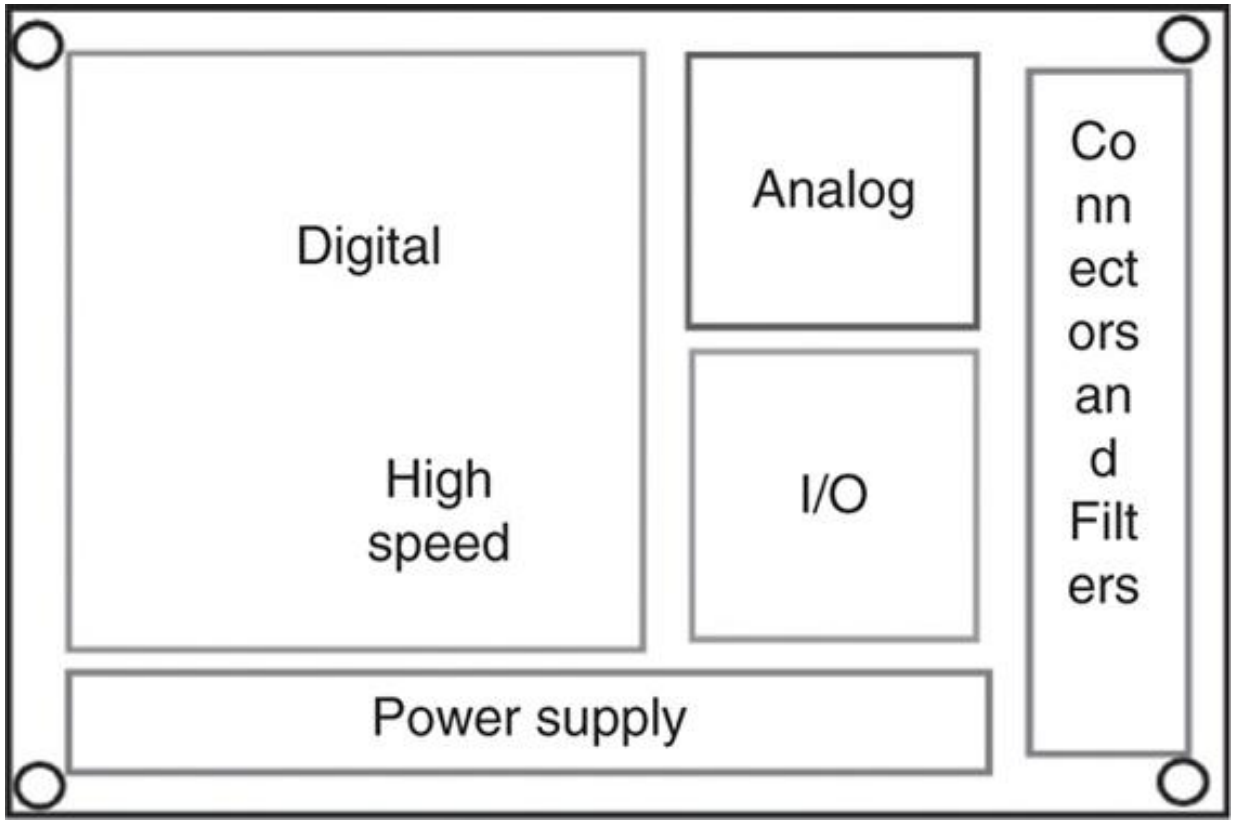

FIGURE 21.13 PCB block diagram.

When placing parts inside the board outline, understand that there is no ONE right way to place parts on a board that always works best. One of the first issues to decide is whether the parts will be placed on one side of the board or both sides. It is helpful to manufacturing if parts are only placed on one side of the board, but it may be helpful for the electronics if they are placed on both sides. For example, capacitors and termination resistors can get very close to ICs when placed on the opposite side, and connectors may have their cables turn and orient themselves correctly just by placing them on the back side of the board. If some of the major parts were built on metric grid and some on an imperial grid, then one grid or the other should be chosen for all the interconnecting signal routing between them. The grid with the most complex parts (like BGAs) may work very well for the fanout and routing of all those parts.

There are benefits to following electronic rules for placement, so parts should always be placed for best signal integrity and load distribution. That means that the placement should probably follow the schematic placement (if grouped there) as much as possible because the circuit designer generally places parts in functional groups on a page or pages in the schematic. If the circuit designer does not do that, knowledge of good signal integrity practices is a must for the board designer. Additionally, if the parts are grouped by logic family and voltage, one power plane layer can easily be subdivided for all the voltages needed on the board. That is helpful for keeping signals routed to return against that power plane within one enclosed area where they don’t cross splits in planes. The next priority would be to minimize trace length where possible because the signals should not have to travel farther than necessary because they can pick up or deliver noise to/from other signals. Lastly

the parts might be placed for the best fit and flow on the board.

Some people like to find and place all the parts that are in fixed location and then work from the outside edge in toward the center to place the parts, but it is almost never a good idea to place parts solely by using the netlist because that gives no priority to important parts and nets over less important ones.

There are a few tricks that will help the designer have a better picture of what is going on as he is placing and routing the board. These include BGA placement, color coding, alignment, “rough in” routing, and grouping parts.

BGAs are generally placed on a grid that is ½ their ball grid. In other words, when a 0.8-mm pitch BGA is placed on a 0.4-mm grid, it is quite easy to fan out the signals to a via and have that via be a uniform distance from all other pads and vias within the part boundaries. The routing for the signals will then be placed on a 0.2-mm grid which will also space them uniformly between the BGA pads and vias. That is very good for the integrity of those signals and all the ones around it, as we never want signals too close to other vulnerable signals or pads that might accept some energy from a noisy trace.

Color coding has the designer assigning a different color to each major bus or net so that it is easy to identify where each one begins and ends, and any parts that are connected together. If those colors are matched to colors applied to the schematic or block diagram, the designer’s eye can quickly move back and forth from one to the other without searching. It also makes it very easy to see where different nets are on major components like BGAs so that they can be placed to optimize routing. See Fig. 21.14.

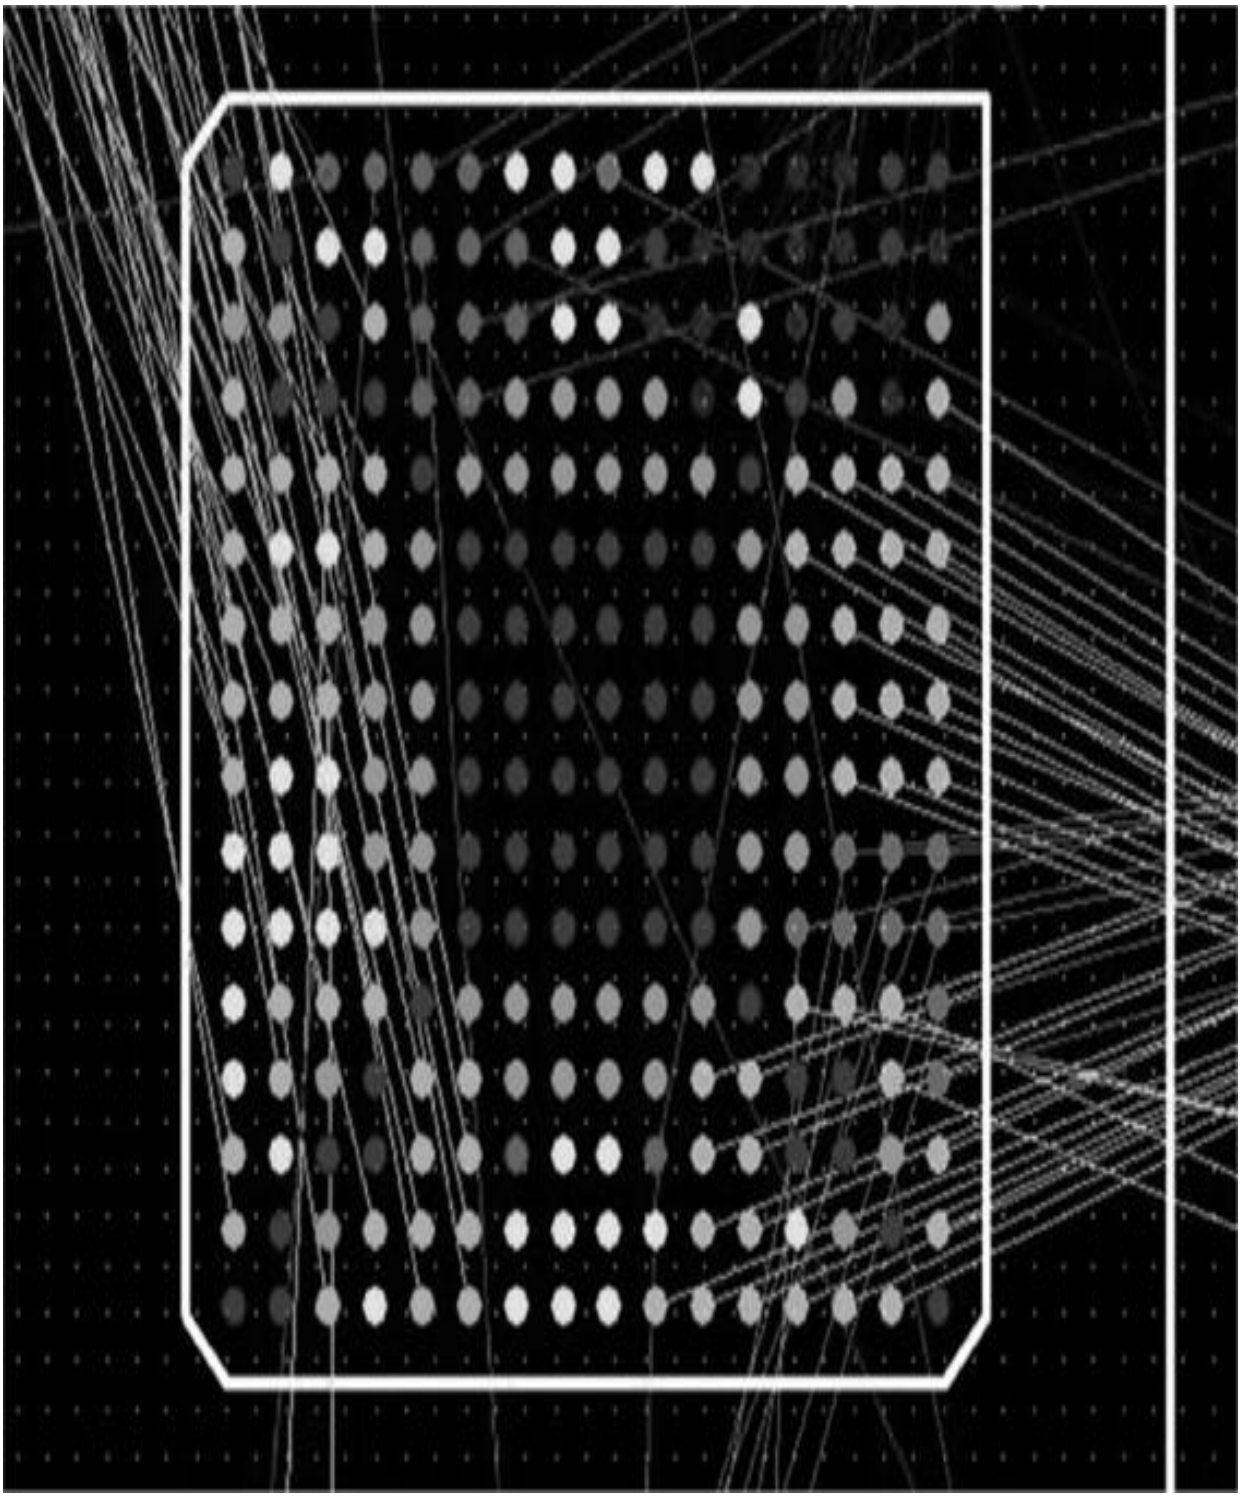

FIGURE 21.14 Color coding of nets.

When placing parts, alignment is very helpful for routing too. See Fig. 21.15. If the edges of the parts are in rows and

columns, it’s easy to get entire busses to flow nearby using the space available. The fanout vias can also be lined up in rows and columns to allow for routing between one part and another.

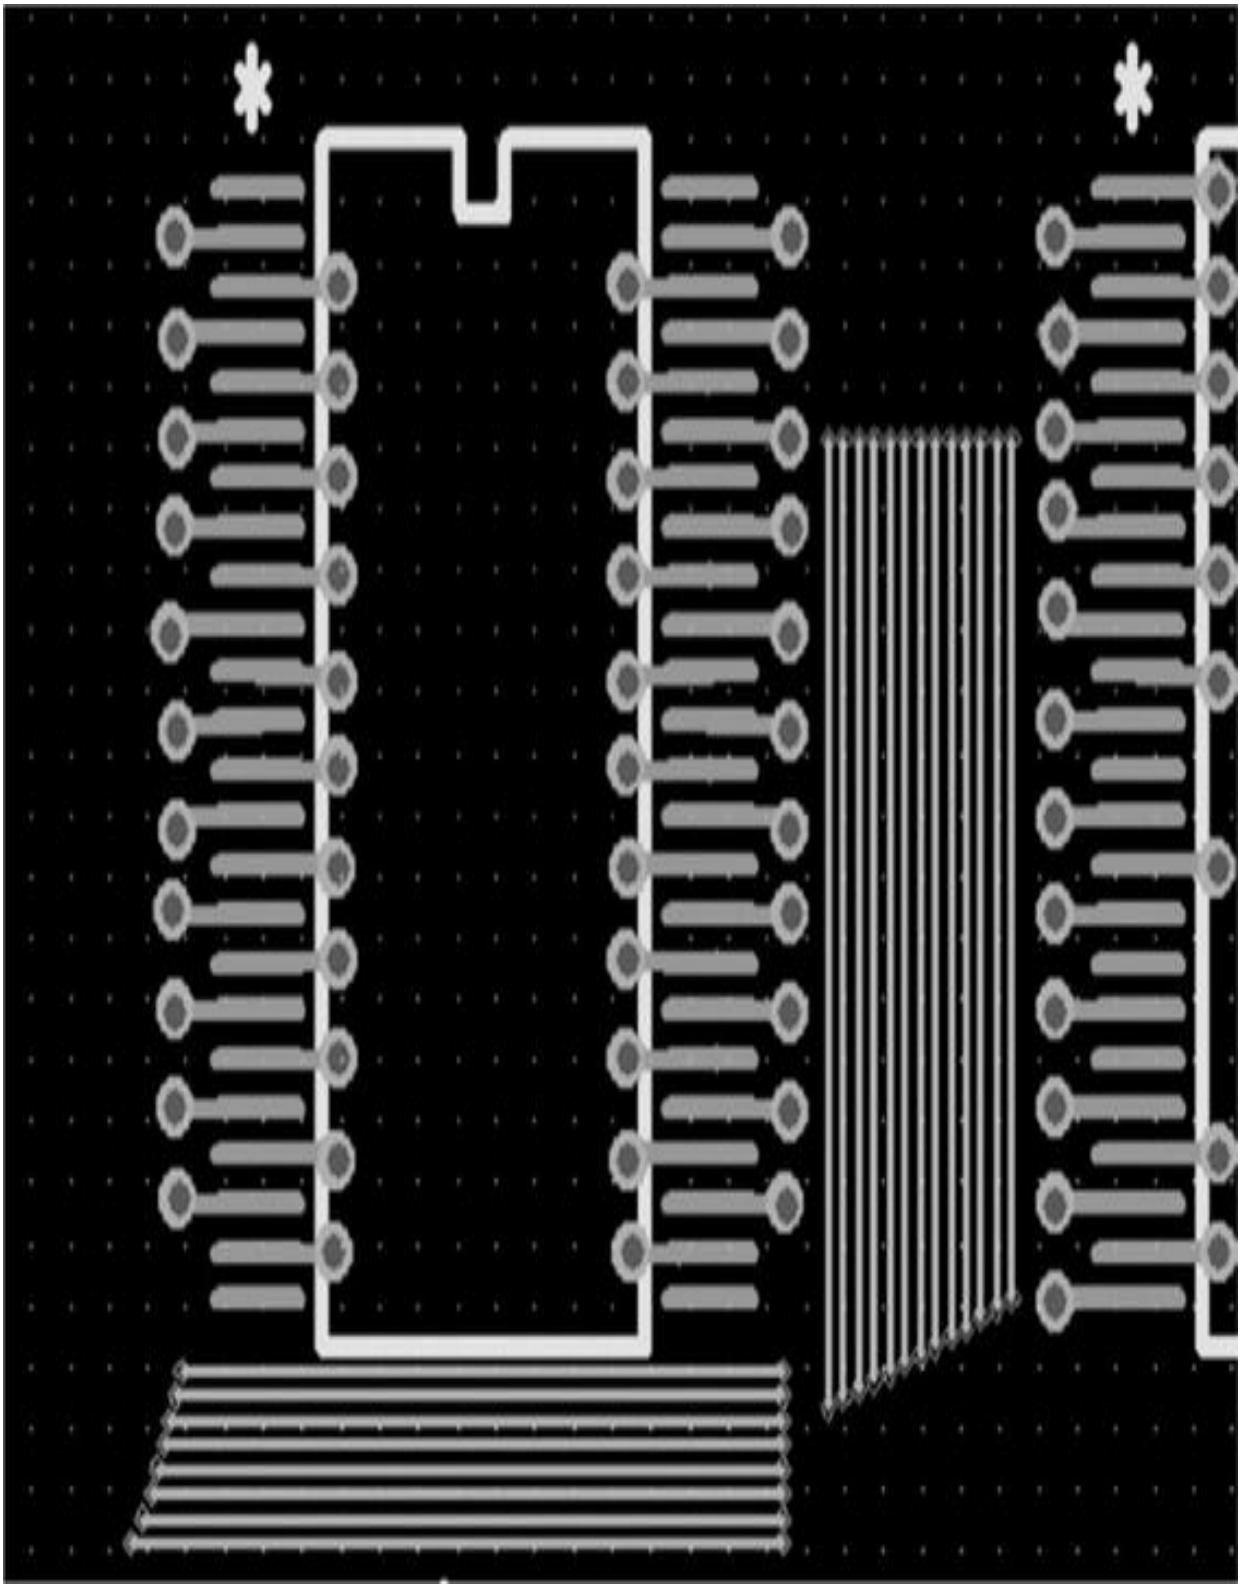

FIGURE 21.15 Alignment of parts and vias.

Figure 21.15 also shows an example of “rough in” routing. When there are a number of signals to go between parts or rows of vias, those parts or vias can be placed with “placeholder” signals routed between them with the proper spacing to see exactly how much room is needed between those placed parts before they are put onto the board. That is especially helpful when a board will be dense with components. And it is good for an area that has clocks or differential signals passing through it as they both will need extra spacing around them because of interference possibilities. The parts can then be moved closer or farther away as needed to accommodate the spacing needed. Another example of this process would be to bring a number of signals through (or out of) a small area or connector, to see exactly how much room the group of signals will take.

Orientation of the parts in a N-S or E-W direction is not very important because the pick and placement machines will be able to place them automatically no matter what. While it used to be an issue of concern on a board, it no longer carries any real weight in the placement of the design.

A few words must be said about analog component placement which can be much more critical than digital. Analog signals are very sensitive and can easily be corrupted, so their parts and signals should be kept in their own region of the board, away from digital parts and signals. They should be placed very close to one another with the connections as short as possible so there is no chance of them picking up noise. It is a good idea to start at the input device to a group of analog parts and place the parts working toward the output device. That way, the input and output devices are not close to one another. Many people use what is called the “clothesline” method to place analog parts. In that scenario, the signals that go through the parts “are” the clothesline, and all others parts and signals hang

off the clothesline. See Fig. 21.16. *No* digital parts or signals should be placed in or go through an analog region.

FIGURE 21.16 Use the clothesline method for analog parts.

As the designer is placing parts, he must be thinking about how he is going to route those parts. We don't want signals flowing through areas that have nothing to do with those signals as that may cause interference. Routing needs can also affect the location of parts, the grouping and orientation of parts, and how the connections are made between parts. One of the ways people keep track of their routing plans is with a routing map. Basically, that is a picture of the board with the parts placed, and lines drawn in a different color for each the routing layers to indicate the intended routing. Every route line is not needed so a single line can indicate the intended flow for a whole bus.

Once a designer has taken the time to place parts close together, making his own grouping of them helps to keep them together. This ensures that if one item gets moved, all parts in the group move with it. That way, an IC doesn't get moved across the board with its decoupling caps or termination devices left behind accidently.

Placement should not be considered a rigid or inflexible thing. It should always be somewhat flexible so that when routing requires that one or more parts have to move, they can. The integrity of the placement and routing is by far the most important issue.

21.8 PLANES

It is very beneficial to plan the planes very early in the design process. This will help the designer know how many layers are needed in addition to the routing layers and in what order they should be placed in the stackup. Every signal is a closed loop and the energy that is a signal must return back to its source. So, each power plane and every routing layer must have a return plane (normally ground)

placed right next to it in the stack so the signal energy has a place to return that will not interfere with anything else. The designer must pay as much attention to where the return path will be as he does to where the signal routing is since it is not actually drawn as a trace as a routed trace is.

The signals will return on the closest layer to their routing in the stackup as this is the path of least impedance. This is called transmission line routing. The digital signal and its return will flow very close together between the routing and return layers and should not be separated in any manner. If either one crosses a split in a plane they will be separated, and signal integrity problems very likely will result. Since the ground planes are not split, these layers give a good clean return path to the signals on the adjacent layers. That is not to say that signals cannot return on the power layer, they can. However, if the power layer is used for return, the signal must be the same voltage as the area it is traveling through AND it must not cross the splits in the planes. These plane layers should be of a solid copper plane as opposed to a cross hatch pattern.

Since the parts should have been grouped as much as possible by their power needs, a separating line can be drawn between the different power areas creating multiple shapes on one single power layer that is split for as many powers as needed. See Fig. 21.17. In general, the ground layers should not be split. If digital and analog parts are segregated into their own areas, and their signals stay routed within those areas, their return current will stay in those areas too.

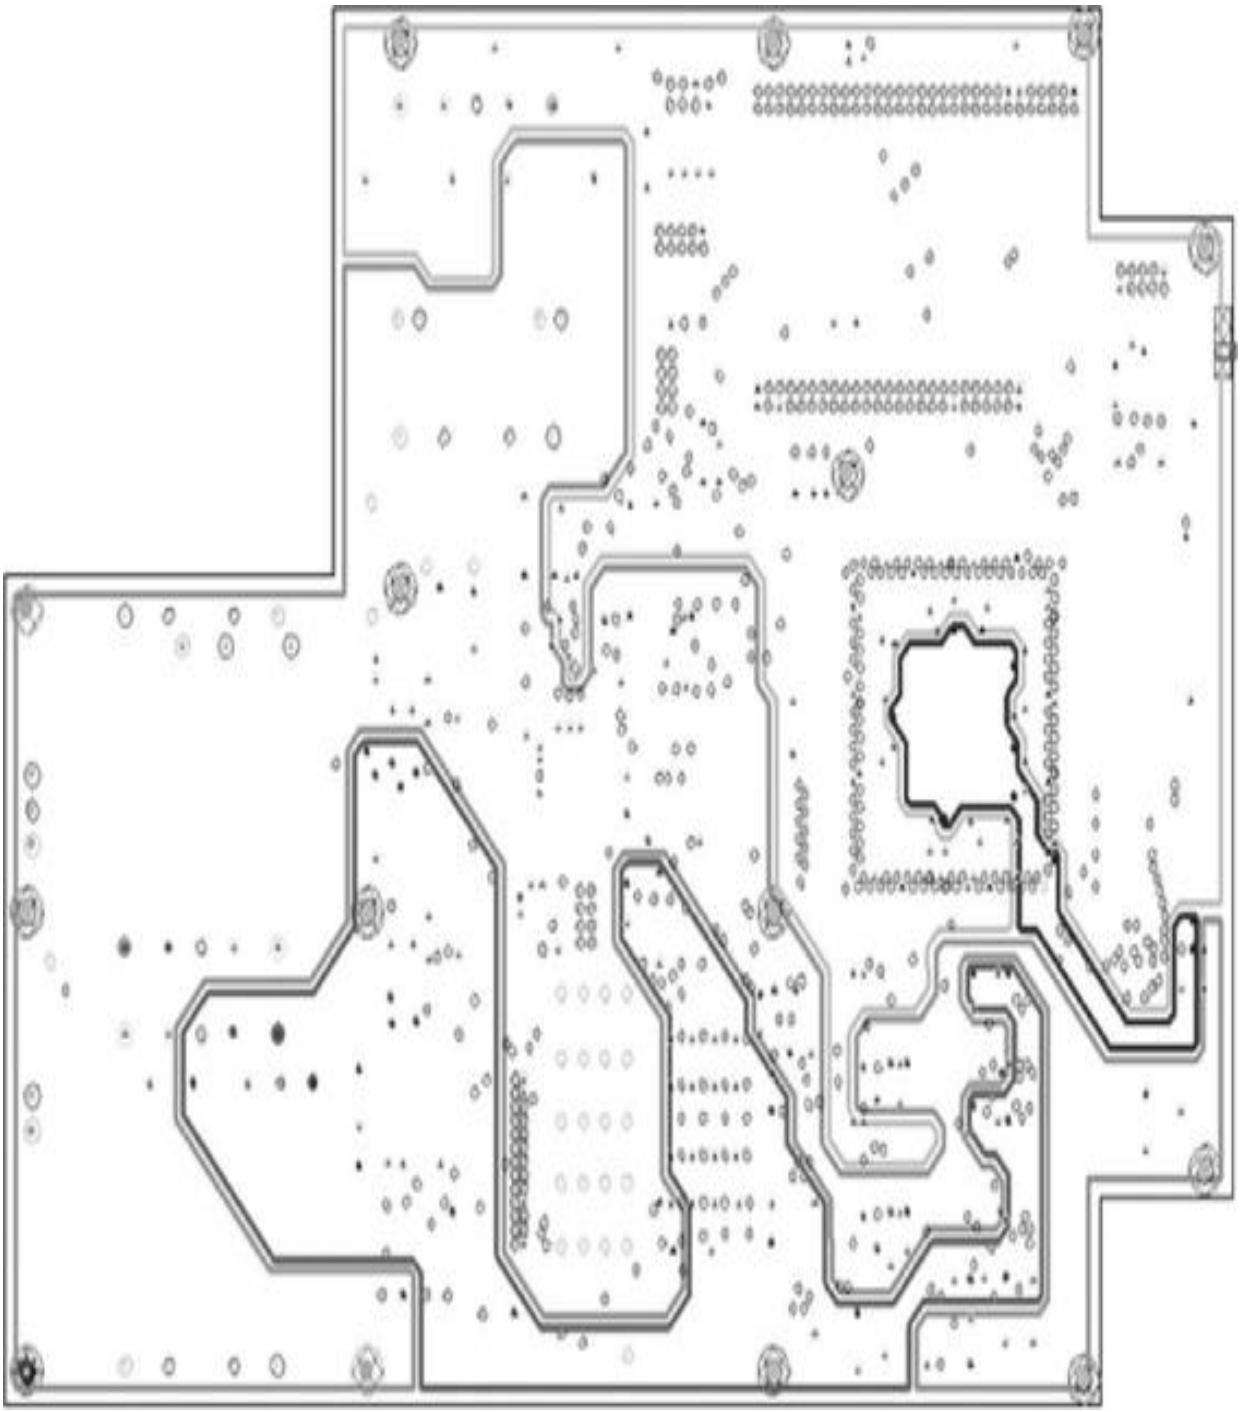

FIGURE 21.17 A power plane with separation drawn for different voltages.

21.9 STACKUP

The materials that constitute most PCB boards are thin sheets of copper and dielectric material. The dielectric can be either core material which is fully cured dielectric material and usually has copper adhering to one or both sides, or prepreg material which is only semi-cured dielectric material and is used as a filler between core layers and often as an outer layer. Because it is semi-cured, the prepreg material will melt when the layers are pressed together and so it will act as a glue.

Fabricators prefer to build stacks in a “foil construction” with the thin layer of copper foil and prepreg material as the outer layers and core layers alternating with prepreg layers internally. That is less expensive for them because there are fewer core layers of material to buy and there are fewer etching steps in the processing. Core material can be used as outer layers if needed, but there are time and cost issues involved. Figure 21.18*a* shows a routing layer as an outer layer in foil construction while 21.18*b* shows a routing layer as an outer layer on core construction.

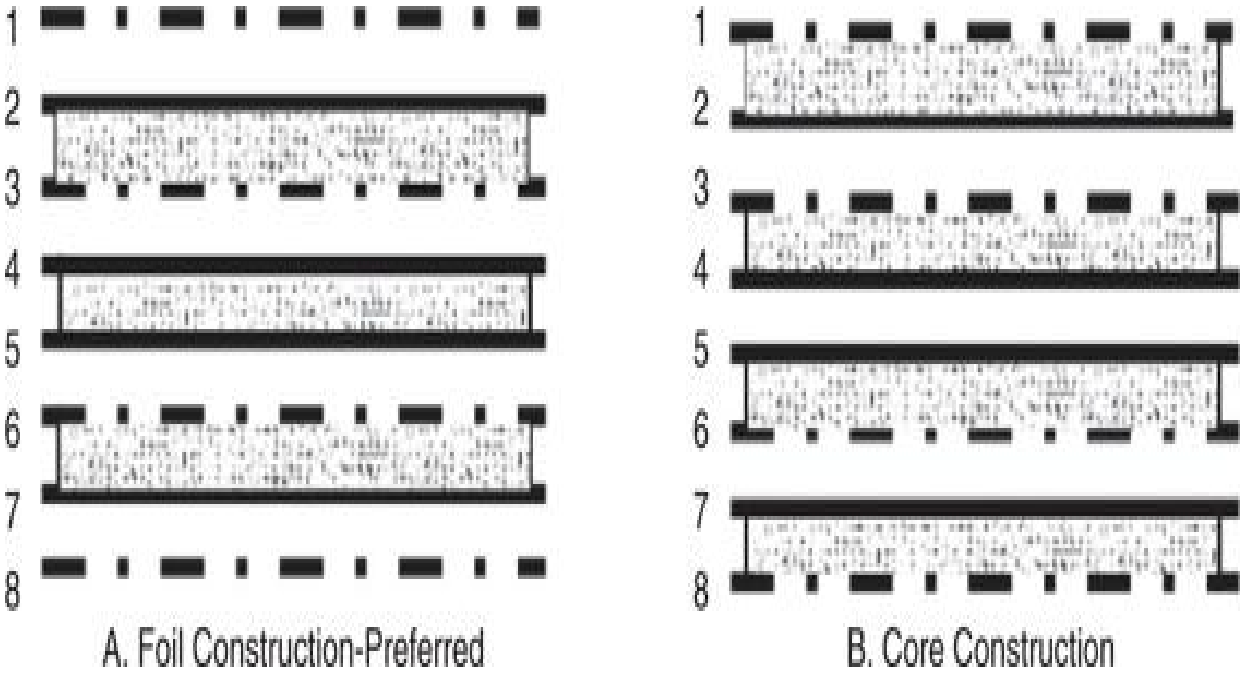

FIGURE 21.18 Foil construction versus core construction.

PCB Boards should always have an even number of layers in their stack with the same type of layer (routing or plane) above the center line as below the center line. This makes a balanced construction for the fabricator that will help to keep the boards from warping. Another thing that helps to balance the board is adding poured planes into any open areas on any layer. That will help keep over etching to a minimum in areas that have few traces or pads on a given layer. Tying those poured planes to power or ground has the added benefit of creating extra built-in capacitance for the ICs to use and keeps an unconnected plane from picking up noise from some other signal in the area.

Setting a PCB stackup can be a complex procedure, but there are a few more general “rules” that are helpful.

It is almost always a good idea to have a power and ground plane right next to each other in the center of the stack, so that is a good place to start. This sets up useful capacitance to help the power distribution system work properly. These two planes should have a minimum spacing between them of 0.003 to 0.010 in to provide the maximum capacitance. The exception to this rule is that it cannot be done this way in four-layer designs.

The placement of routing layers is also important. Two signal routing layers are allowed next to each other in the stack as long as they have return planes on either side of them. That way, the return planes will be the lower impedance path and will keep the signal from trying to return on the other signal layer. There should never be more two signal layers next to each other in the stack though. And there should not ever be more than one signal layers as the outer layer on the board. If there are two routing layers as the outer layers, there is no place for the signals on the outermost layer to return and it is very difficult to control impedance. See Fig. 21.19.

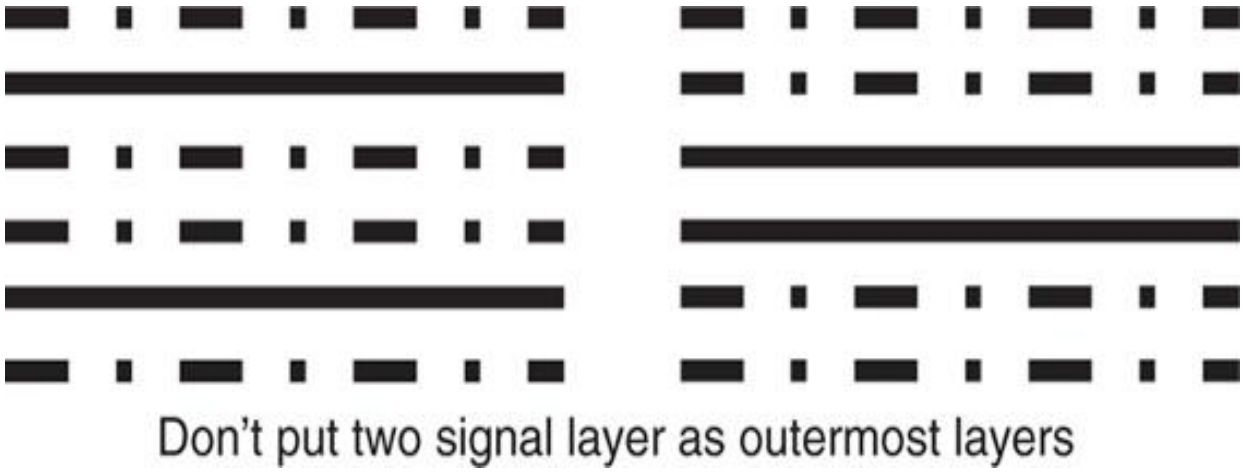

FIGURE 21.19 Routing and plane configurations.

It is important to understand that impedance control is partially set up by the copper thickness and the distance between the trace and the nearest plane. So, any boards that have controlled impedance traces or differential pairs should have their stackup coordinated with a fabricator who can help with traces, spacing, and distances between layers. In fact, it’s always a good idea to have a fabricator check out a proposed stackup to make sure it will accomplish what is needed.

21.10 ROUTING

As mentioned earlier, there are many IPC standards that are available to help with designing, fabricating, and manufacturing PCB boards. The entire IPC-222x series is about design and there are many pictures and charts to reference there. One chart in IPC-2221 in particular is the “PWB Design/Performance Tradeoff Checklist Considerations.” This chart lists a feature (like dielectric thickness to ground, for example), tells a parameter that is affected by it (in this case, crosstalk) and if that parameter increases or decreases if the feature is increased. This is a

particularly helpful chart for people who are not used to the way PCB items affect each other.

One of the first things to think about after placement is entering constraints. Even simple boards will need constraints to determine the default trace widths and spacing. Complex boards will need many more items controlled. Classes can be set up in the constraint manager to group any nets that will need the same constraints like trace width, spacing, layer control, sequencing, length matching, etc. Any net that needs to be controlled for any reason should be given a name because that will protect them from future edits accidently destroying their constraints. Designers will want to add in enough constraints to do what is needed, but no more than necessary. It may be helpful to have a discussion of the rules to be set up with the circuit designer to be sure everyone's needs will be met.

Pin and gate swapping must also be considered before routing can begin. Many components have gates inside them whose connections can be swapped to provide a better flow for signal integrity and routing.

These components range from simple groups of "like" gates like the 74LS00 and the 74LS04 shown in Fig. 21.20, or very complex programmable devices. Either way the pins in the gate and the gate in the device must be identical in function in order to be swappable. In the gate is like the 74LS00, the input pins [example 1 and 2 (1A and 1B)] can be swapped with each other, or one whole gate of three (1A, 1B, and 1Y) can be swapped with another gate within the device. Programmable gates are only internally accessible and must be programmed into the part in the pin order that is needed and available. Color coding is very useful for the board designer when organizing how to swap the gates.

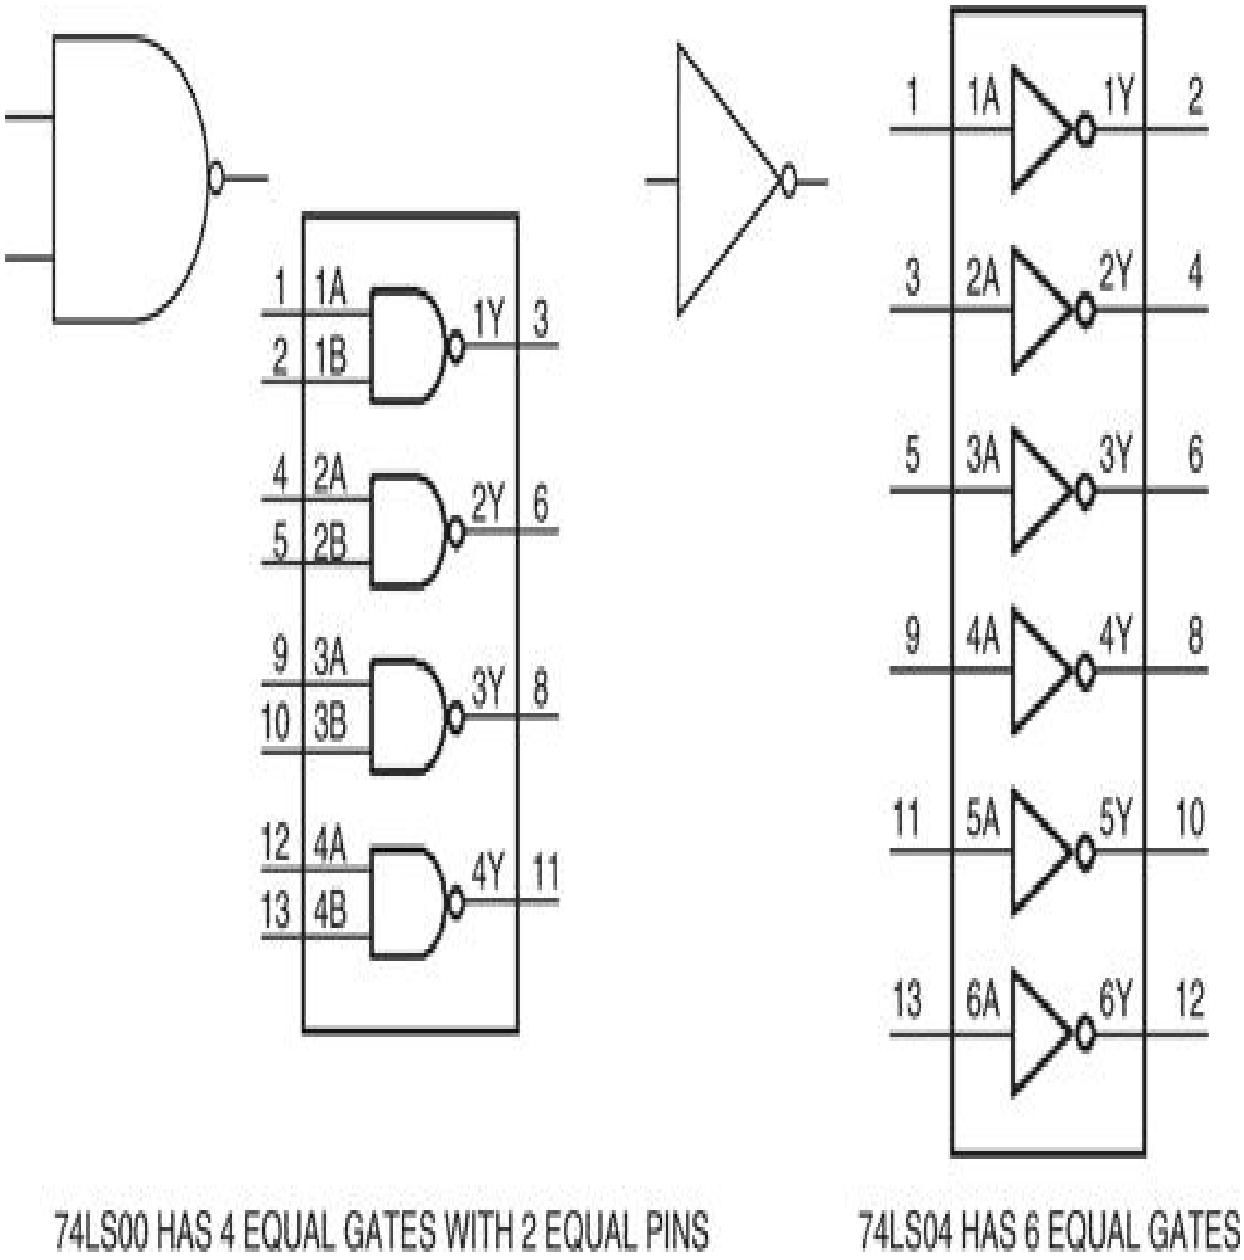

FIGURE 21.20 Simple parts with gates.

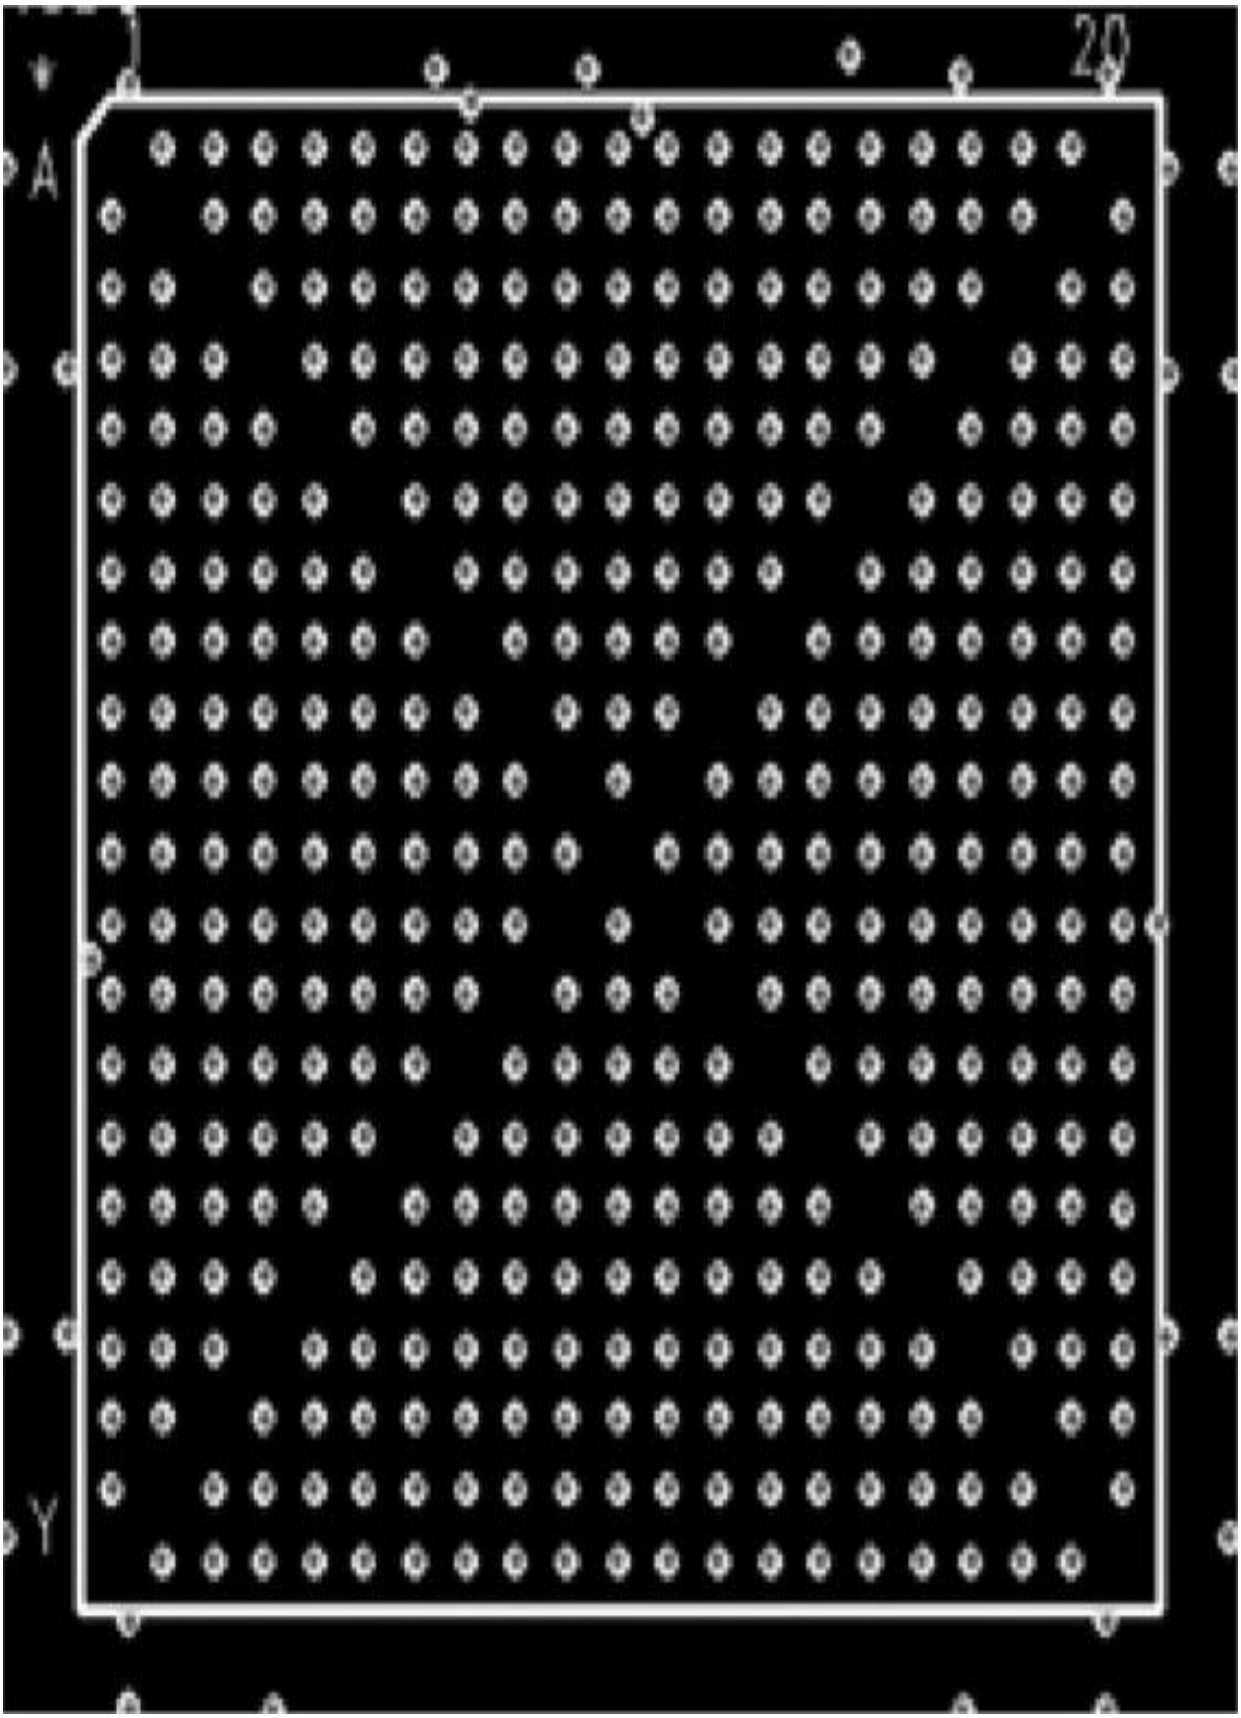
Now is the time to plan what widths the traces will be. Some things that help determine trace width are desired impedance, stackup, current carrying capacity, temperature rise allowed on the traces, and the ability of the fabricator. Even if a particular impedance is not needed for the signals, it is still a good idea to control the trace impedance layer to layer. That way when a signal changes from one layer to

another there is not an impedance mismatch, which can cause a reflection. For normal routing, pick an impedance number near 50 to 60 Ω (ohms) and stick to it on each layer of the board. That might prove to mean different trace widths are needed on internal layers in order to achieve the same impedance, but that is generally pretty easy to set up to do automatically within the software. The trace width and spacing are generally equal values. If there is any extra room available, it should go to spacing rather than trace width to make the fabrication easier. It is always important to keep those trace widths within the abilities of the fabricator for the project, and not to use smaller trace widths than necessary. It may also help to look at the distance between the leads on the parts and try to set the chosen trace width to something that can go between the leads or balls of the ICs or BGAs.

Often when surface-mounted components are placed on a board their signals cannot route away from the pads on that same layer. Those signals will need to be fanned out to a via that will take them to connections and routing on another layer of the board. At a minimum, the power traces should be fanned out early so that their vias secure their place before any other routing starts and fills up the space. The fanout vias on BGAs and some other complex parts might also be placed early because it’s easier to take them off if they are not used rather than try to add them later when the area is filled. BGAs are often fanned out into either an X or a + pattern so that the power and ground planes can get into the center of the part and provide good power integrity. See Fig. 21.21.



1
20
A
Y

FIGURE 21.21 A BGA that is fanned out into an X pattern (only the vias are visible).

The signal vias can also be placed in an “as routed” manner or set up in a fan out grid pattern such as the one in Fig. 21.22 where the vias are lined up in rows and columns. If the board will be fairly dense with lots of parts and routing, the gridded pattern is probably the best option. Routing and return would then go around or between those gridded vias in a north-south or an east-west pattern, as needed. Again only one grid, either Imperial or metric, should be used for fan out patterns so that the vias and routing will line up correctly.

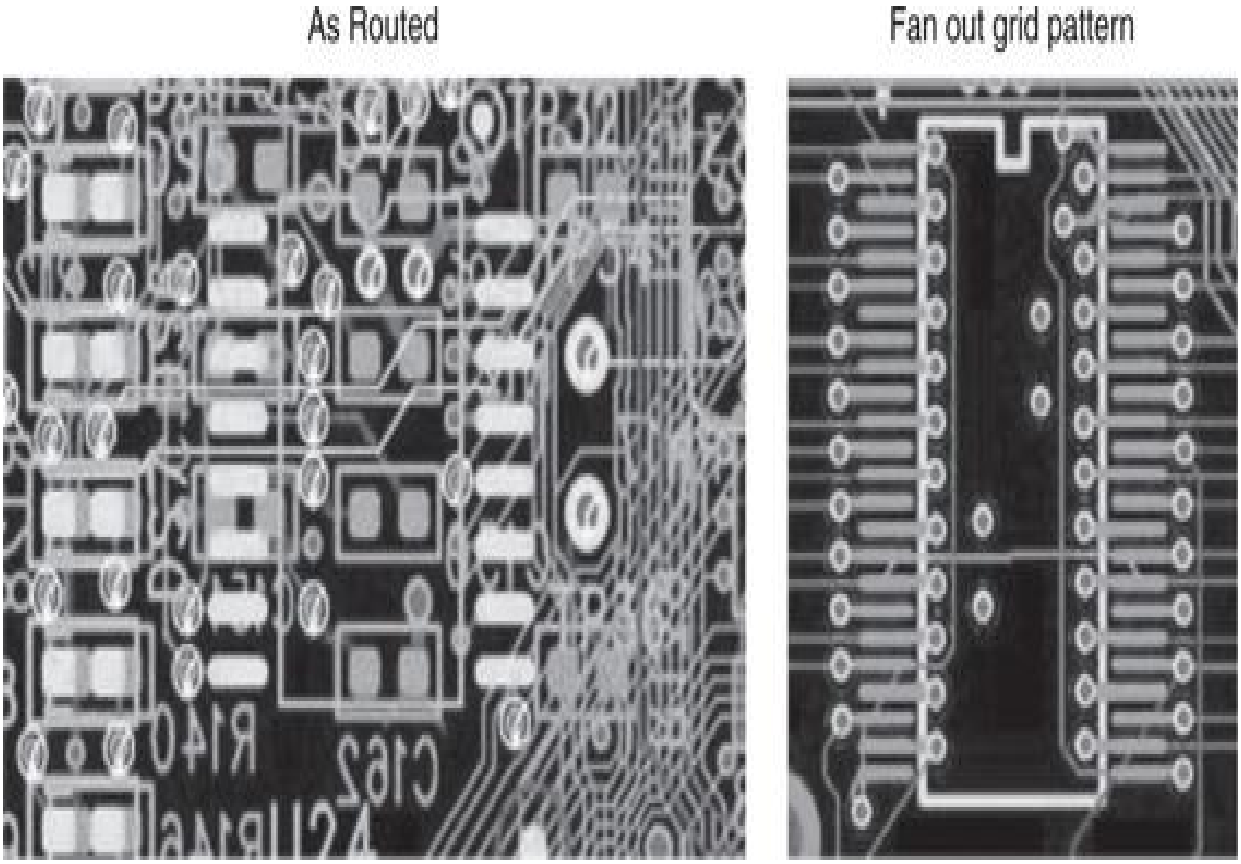


FIGURE 21.22 An “as routed” pattern and a simple fan out grid pattern.

The fan out grids can get much more complex and set up many routing channels as shown in Fig. 21.23 or with a

dominant flow in one direction over the other as shown in Fig. 21.24.

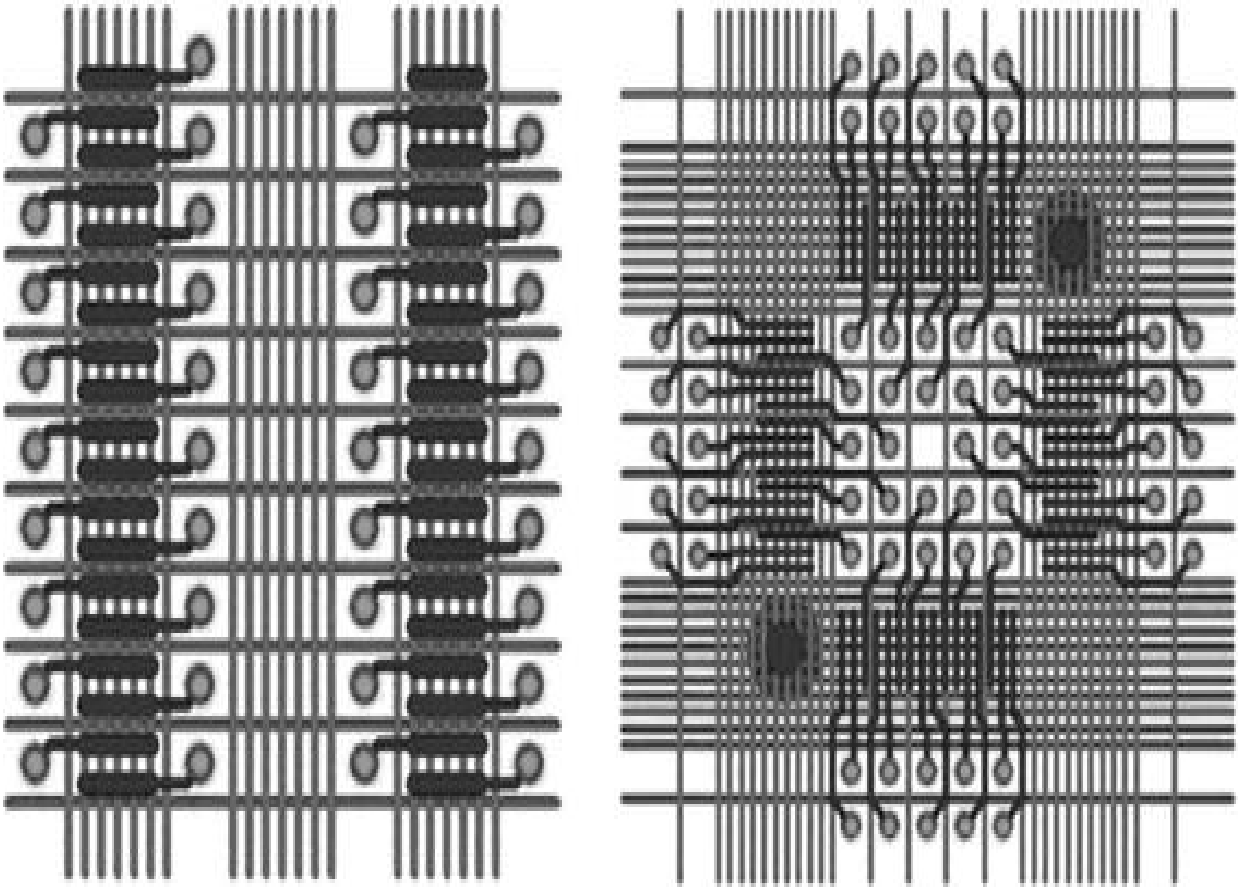

FIGURE 21.23 Via grid setup for routing channels.

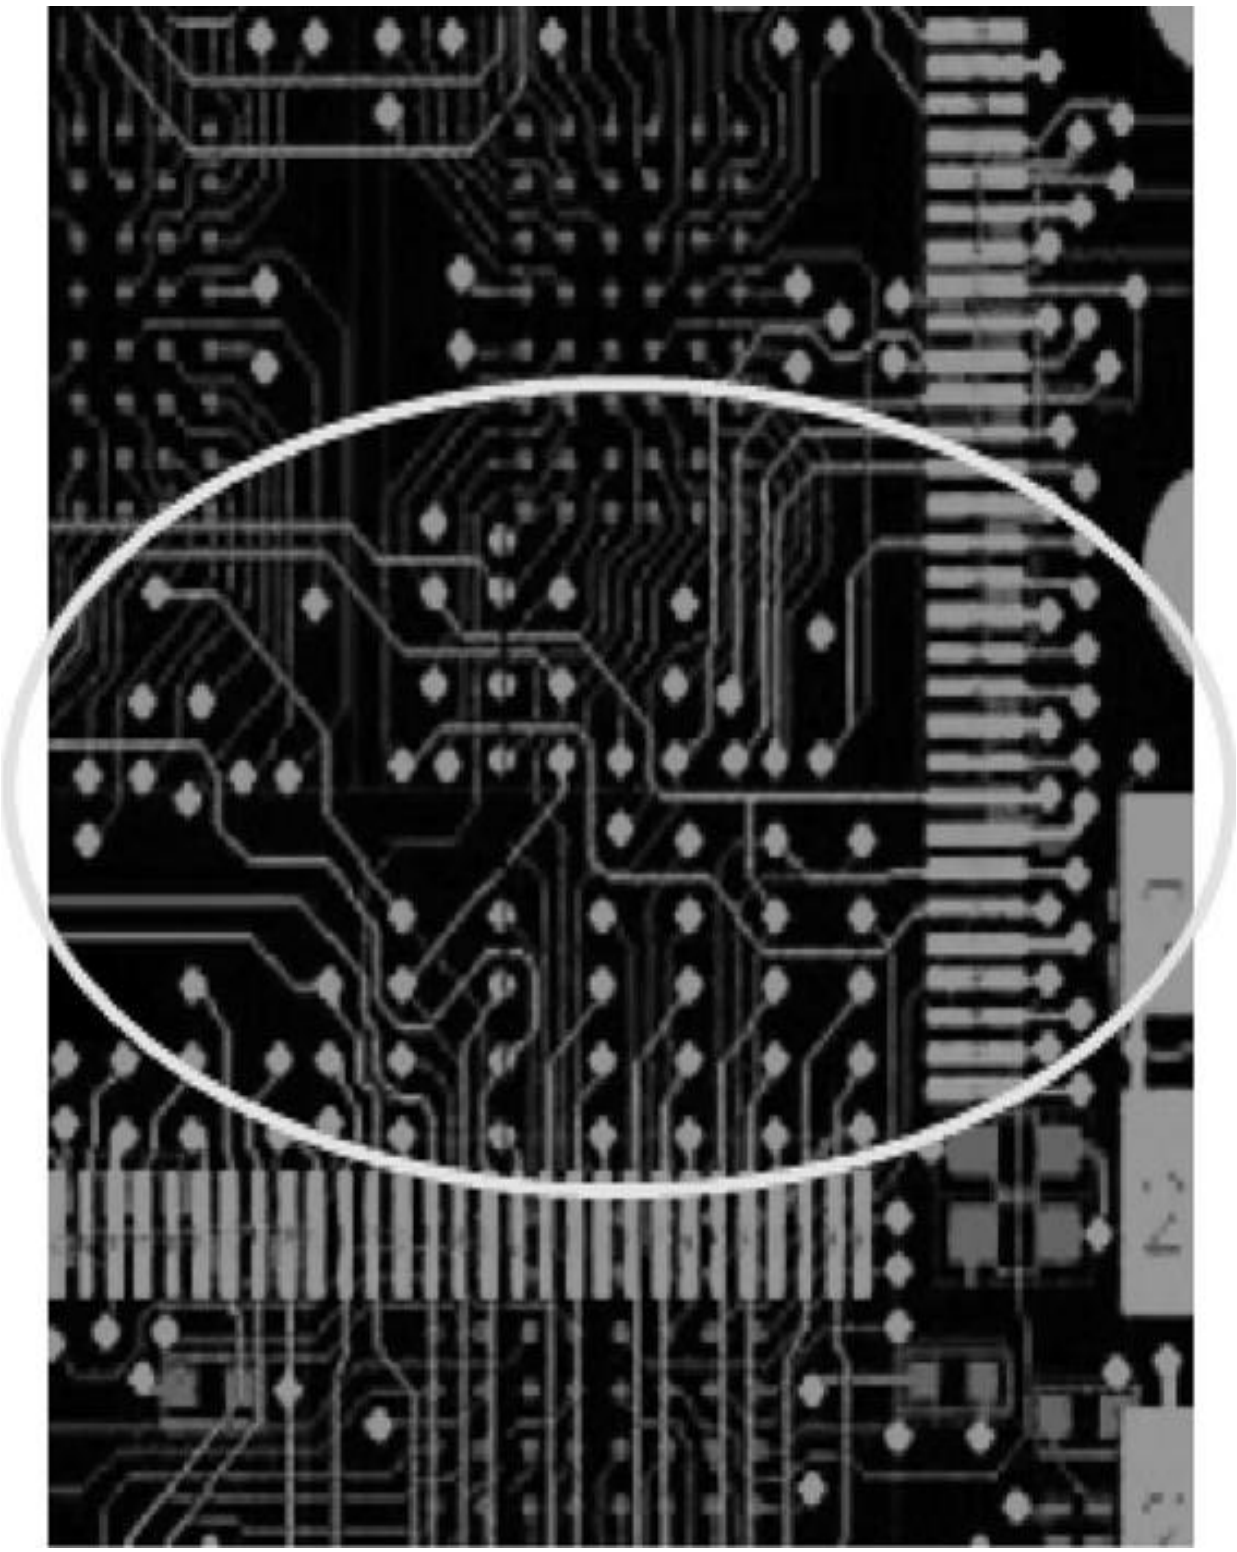

FIGURE 21.24 Via grid setup for north-south dominant routing.

One way to start the routing process is to go to the densest area of the board and work there first. That area will help determine layer count because it will need the most routing. The BGA escape pattern is an example of this because there are a limited number of channels to route out of a BGA on any given layer. This area will also help to show if the placement will need to be tweaked a little here or there to accommodate the density of routing there. It is also a good idea to plan to minimize routing on outer layers where possible because it is best for signal integrity to route all important signals internally. Slower signals can probably route on outer layers.

To begin the process, establish the routing direction for each layer in those dense areas. Any time signal layers are next to each other, the routing should be in perpendicular directions so that they can't interfere with each other. Look at the rats on the parts in those dense areas to see if they lead to an obvious routing direction. If not, check the size and shape of the board to see which layers might more likely lend themselves to more routing out and away from that dense area. Above all, remember to route according to the routing map established earlier.

Check into which signals are considered important or critical. These usually include clocks, strobes, high-speed signals, noisy signals, and any major busses. It is important to understand what is important about these signals and how to control them. Read and understand the data sheet and reference information and discuss it all with the circuit designer.

As mentioned, it is important to think about how the parts will be routed as they are being placed. There are several routing schemes that are commonly used. See Fig. 21.25. Busses are generally routed in a daisy chain pattern from driver to load(s). Clocks generally route in a star or 'branch by n' pattern. T-routing is used for a group of loads that are lumped together. Termination and decoupling devices will

probably need careful placement and routing to ensure that they work as needed.

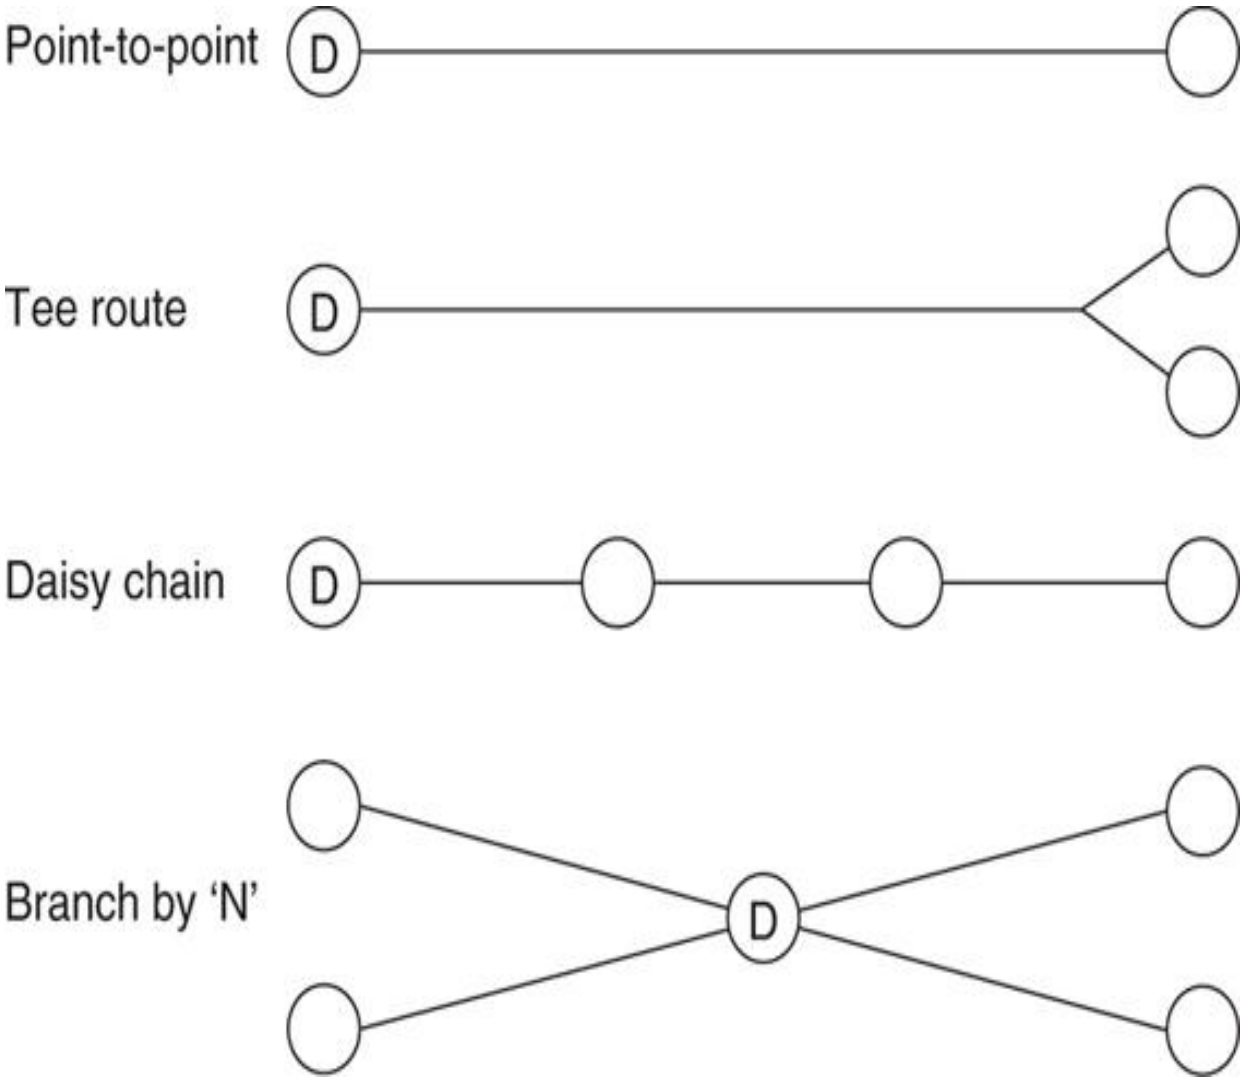

FIGURE 21.25 Most common routing schemes.

There are many ways to accomplish routing. One approach that may work well is to route in the order listed below:

1. Route power connections in a fanout to vias
2. Route I/O connections
3. Route critical nets
4. Protect or "lock" criticals until/unless changes are necessary

5. Analog signals (and parts) next, and isolate from digital
6. Any location specific signals
7. General routing

If there are like signals (like a bus) that need to flow from one region of the board to another, they can be grouped together into routing channels. Since they are probably all switching at the same time, the spacing between them can be the same as the trace width without much concern for crosstalk. See Fig. 21.26. However, if signals are put into channels that are different from each other, there can be crosstalk from one signal to another if there is minimum spacing.

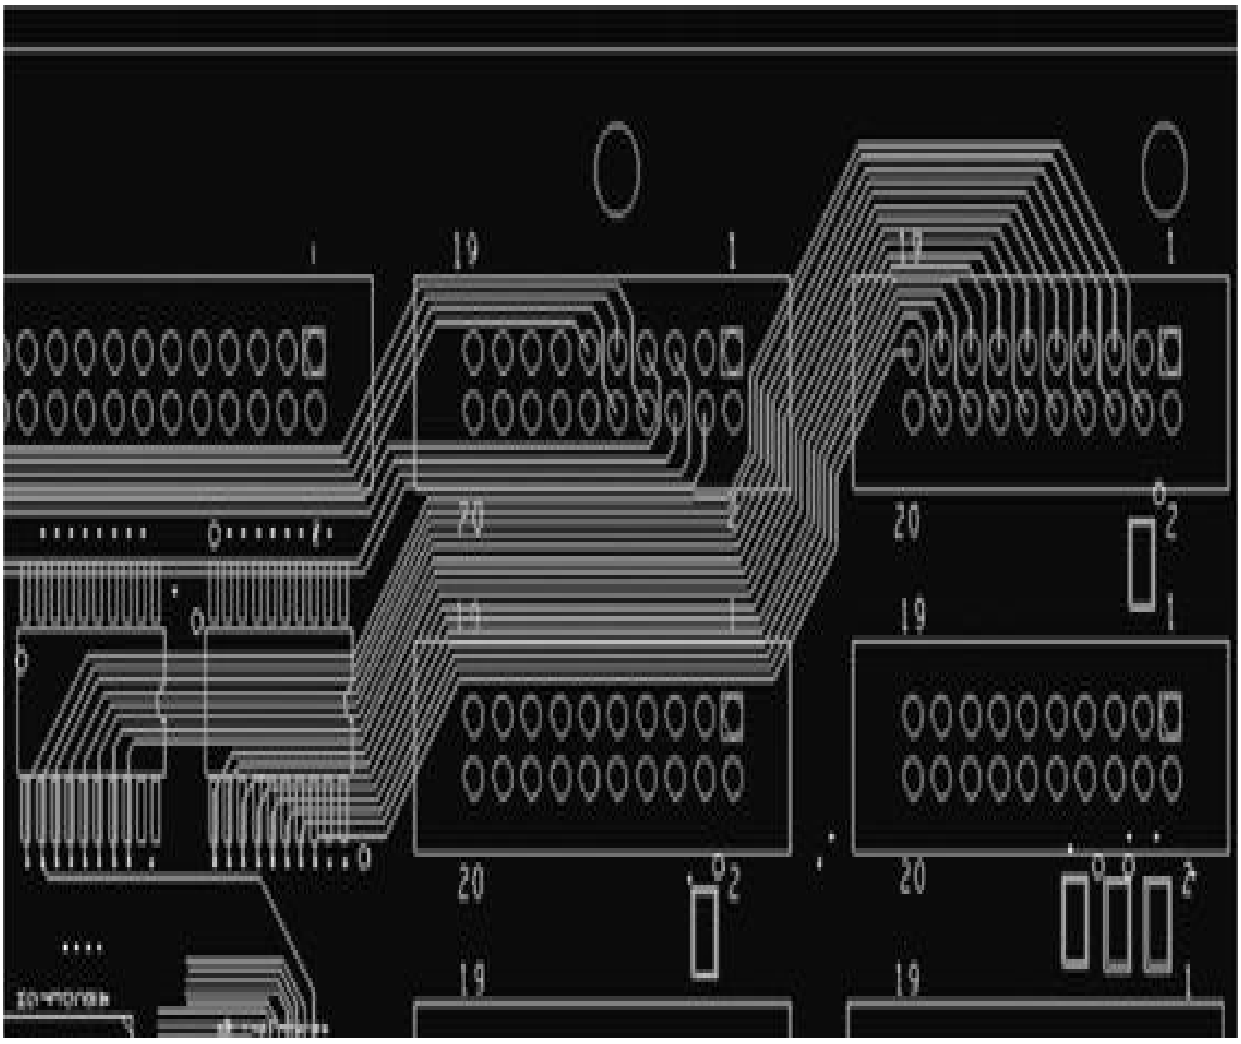

FIGURE 21.26 Routing channels.

Additionally, room must be left during routing for any vias, turnaround room, and changes of direction that are necessary. And one must plan for the return current for each and every signal. One way to do that is to turn on only the routing layer being used and its return plane. Look for any splits or roadblocks to the return current and fix them or reroute the signal.

Here are a few general tips that may help with routing:

- One should be able to discern a noticeable routing direction on any given layer, meaning that most of the signals on that layer would route in the same general direction (E-W or N-S).
- Trace entry into pads should not leave an acute angle which may cause fabrication issues.
- Trace width should be no more than approximately 60 percent of the pad size it is entering for heating reasons during assembly.
- Keep all routing within its own power or ground region for return purposes.
- Do not route traces across splits in planes as that cuts off signal return possibilities.
- Do not route any traces on the power or ground layers. They could cut off return current in that region of that layer.
- Via the caps and ICs to the planes if they are more than 0.100″ apart for best power connection.
- Keep input and output signals separated so they cannot interfere with each other.
- Don’t route high speed traces near the edges of the board for best EMI control.
- The use of slightly larger vias for power connections may be helpful to move current from layer to layer, when

needed.

- Look for ways to route signals on one layer, without any vias. That keeps other layers clear of via holes and so is good for routing on that layer.
- Keep extra spacing between noisy signals like clocks or strobes and any other routing to minimize interference from the clock to other signals.
- Keep extra spacing between differential pairs and any other routing or vias to minimize any routing interference on the pair.
- Copy and paste repeating circuits or routing where possible to reduce time needs.
- When adding serpentine routing to match lengths, be sure there is three to four times the trace width between loops to keep the signal from jumping across segments and ignoring the loops.
- Don’t route signals through a BGA that have nothing to do with that BGA. They may cause or collect interference.
- Spread out routing whenever possible to minimize crosstalk.
- Change routing layers only when necessary … but change layers when necessary.

Some people choose to work with an autorouter. There are some pros and cons to doing that. In general, an autorouter is much faster than a designer at making connections. An autorouter might be fairly accurate at suggesting how many layers a board may need or if the placement set up by the designer will work effectively. They are very good at fanning out signals from complex devices. However, they often fail to complete their task on high density, low layer count boards. This is because autorouters work by taking a signal along a certain path and when there is a road block, changing layers. If there are not many layers to change to, the router will have problems. There is also a fair amount of time needed to

set up the rules for an autorouter, and to do the cleanup after routing.

On the other hand, a good board designer will design a board with much greater signal integrity because the will not necessarily route to change layers at a road block, but rather might consider all the options and ramifications to routing a signal in a certain way and will choose the best path. These traces tend to be shorter and have fewer vias, which often helps to keep a board to a lower layer count. A board designer can also do layer paired routing which is very good for containing the high speed energy of most current technology. Basically, layer paired routing means that a signal routed on a layer that returns on a certain plane switches to the signal layer on the other side of that same plane when it needs to change direction. See Fig. 21.27. This contains the energy to that particular area of those particular layers of the board, rather than letting it spread out all over the board.

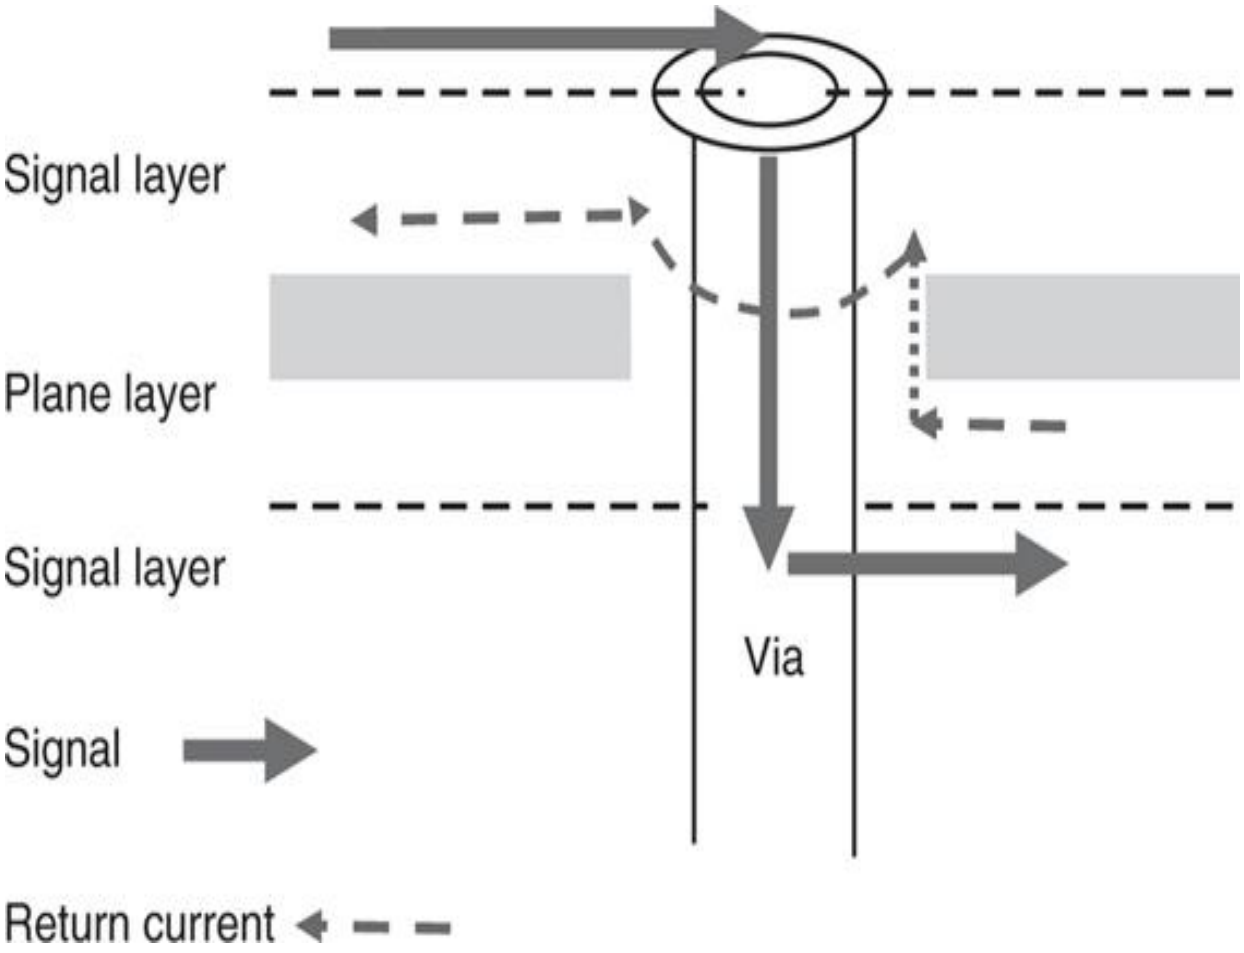

FIGURE 21.27 A close-up of layers involved in layer paired routing.

Some choose to route all the important or critical connections by hand, and then place the board into the autorouter to finish things up.

Notes placed into a blank layer of the database may be helpful in several scenarios. They may cause a person remember what they were doing if they are pulled off the project to work on something else. When they return to the original project, they will know exactly what they were doing. They may help with notes about placement or routing changes that are needed but haven’t been accomplished yet. And if someone has to make changes to the board as an ECO later on the notes can explain why things were done a certain way.

When routing, remember that every board is different and each will have its own set of priorities. One set of rules will not work for every board! Find out all you can about the parts and signals on the board at hand and what might work best for that particular board.

21.11 FINISHING

After the board is routed, there is still work to do….

One of the steps between designing and finishing a board is to run Design Rule Checker (DRC). It is always ideal to have a clean DRC report with no errors at all. There are occasions, however, when there will be errors that cannot or will not be cleared. (This might be something that you would document in text in the board design file.) All the constraints that were entered into the software should be checked to make sure that they were accomplished. Also, there should be a check for unconnected nets or pins, any differential pairs, noisy signals next to any other signals, same net trace spacing, and anything else that might be particular to this board.

At this point, the board might be resequenced. This is done so that when people are checking, testing or working with the board it is easier to find components. Most boards are resequenced in a gridded pattern of left to right and top to bottom on the top side and then the bottom side is done the same way. See Fig. 21.28. This renumbering can then be annotated back to the schematic so that the two are in sync. At that point, it is a good practice to import the newly resequenced schematic netlist one more time into the newly resequenced board to make sure that they are the same.

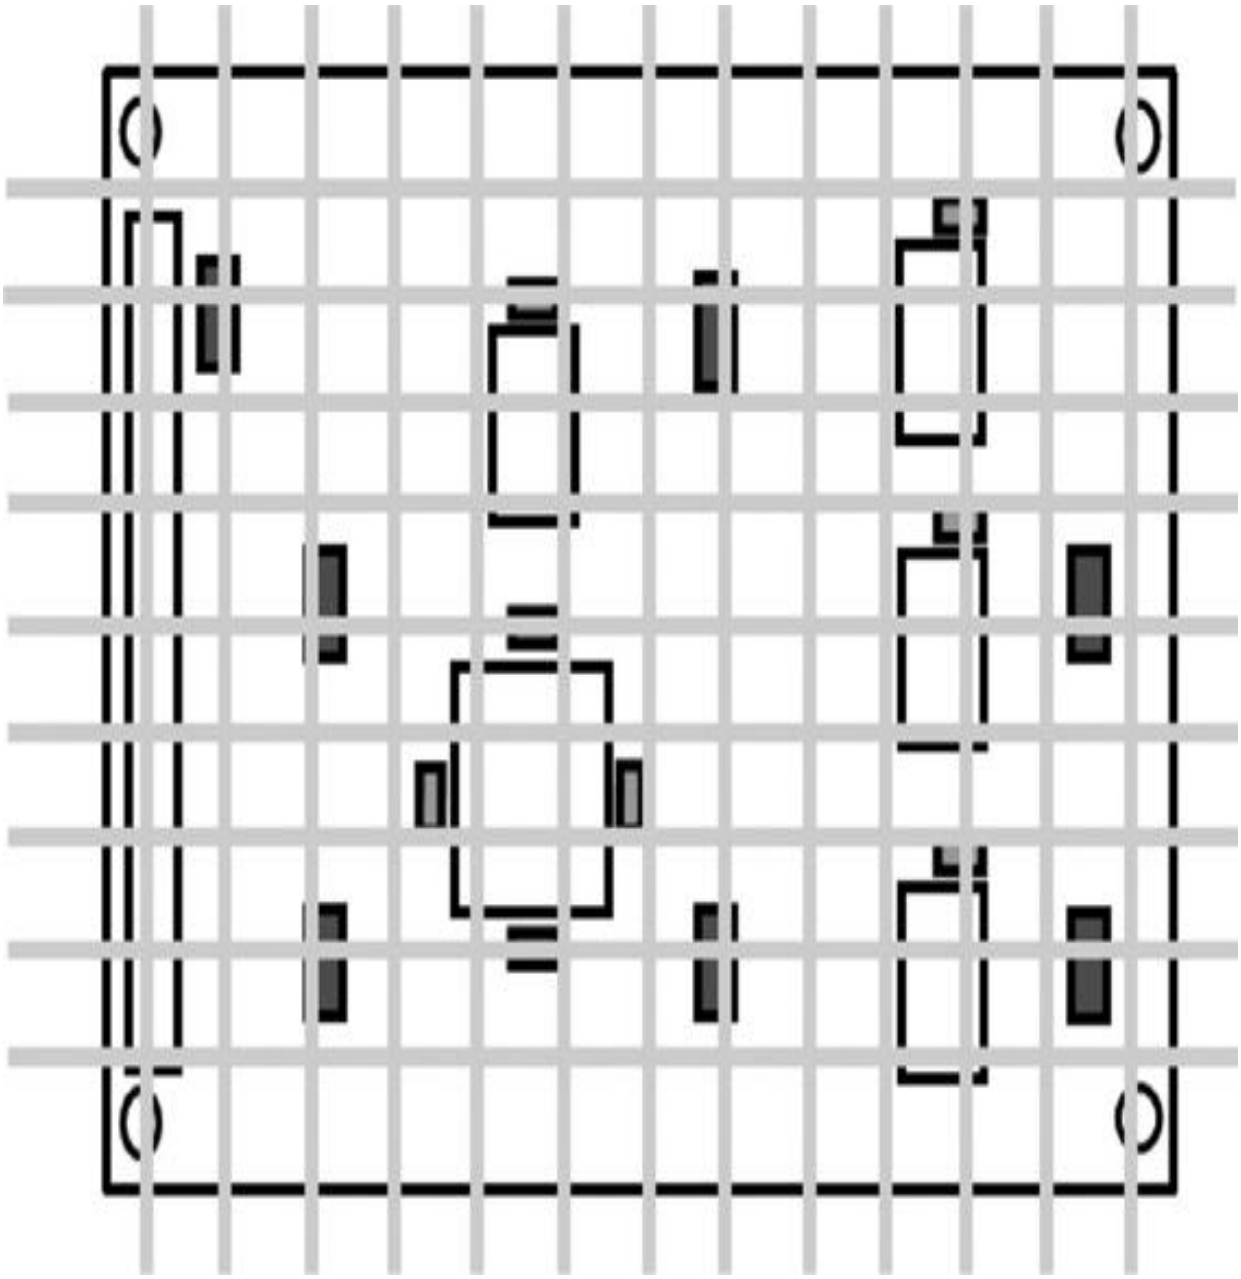

FIGURE 21.28 Gridded resequencing pattern.

Since the reference designators have been resequenced, their position might have changed. Now is a good time to move the text and reference designators so that they are easy to read, easy to see which component each belongs to, that they are placed outside the component area, and that they don’t fall on top of any pads or vias. If it is placed on pads or vias, it will be deleted during the fabrication

processes and so will be useless. If there is no room for the reference designator right next to the part but there is room close by, a line or leader can be drawn between them as shown in Fig. 21.29. Some designs are just too complex for reference designators and so the Assembly drawing must be carefully drawn to show which components are located where.

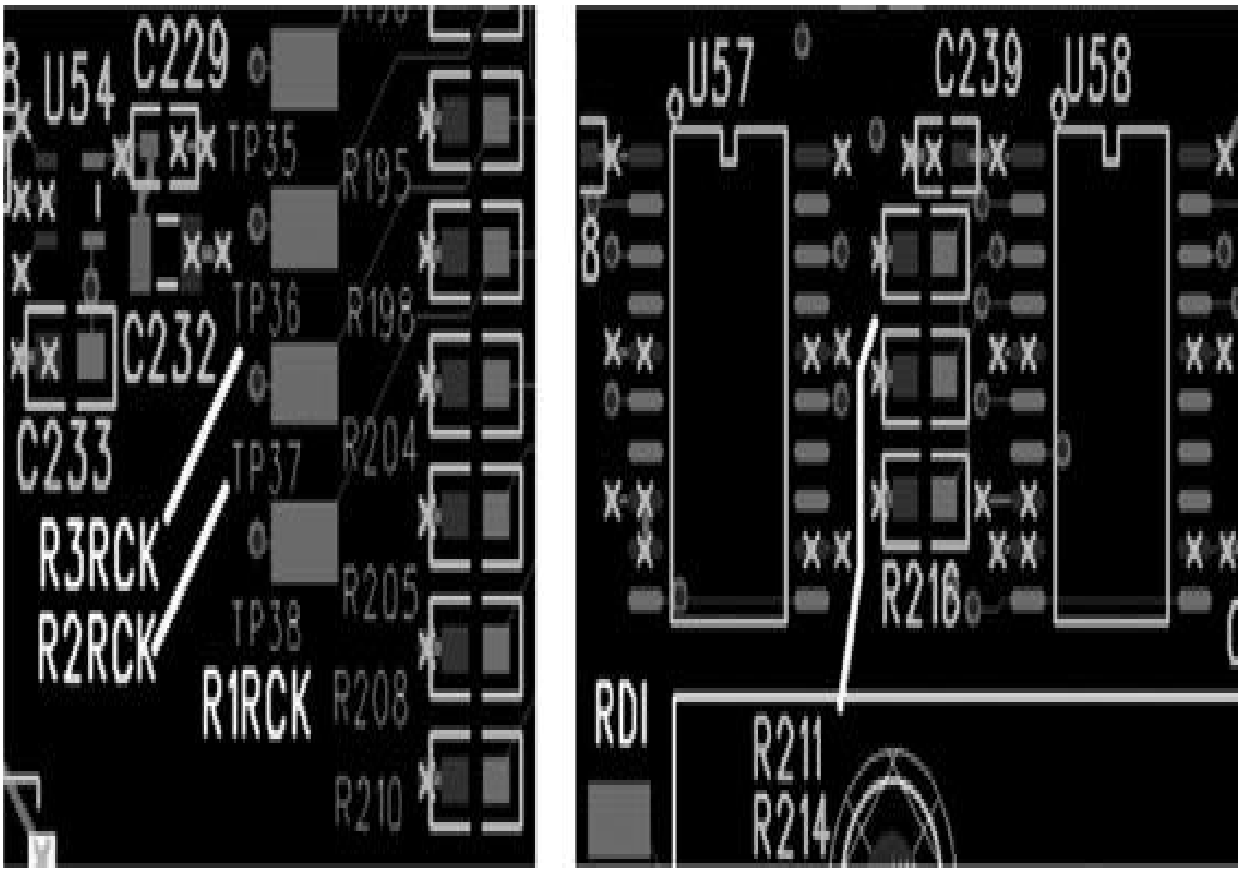

FIGURE 21.29 Reference information with a leader to location.

In addition to the reference designators, there may be other documentation that will be needed on the board. That might include company name, board name, assembly number, test point names, made or assembled in USA, pin or polarity indicators, and of course the complete outline of the part, all in silkscreen. Once again, make sure that the new silkscreen information does not fall onto pads or vias.

The board can then be set up for its fabrication drawing information. Outline dimensions and tolerances can be added to the “fab” layer. It is important that any notes that are added on the fab drawing be checked out by the fabricator to ensure that they mean the same thing to them as they do to the board designer. The drill schedule should include every individual size of hole to be drilled, the tolerance for each (usually ±0.003 in), whether plated or nonplated, and the quantity. There should also be a detailed drawing of the stackup for the board that includes layer name, copper weight, the amount of plating, dielectric thickness between layers, and the impedance if control is required. There will need to be good communication with the fabricator to be sure they have everything they need to complete the board.

The output files from the PCB software will be Gerber files, ODB++ files, or IPC 2581 files. The fabricator may want to give his preferences as to which kind of files he prefers to receive. At a minimum, the individual layers of the output files should be looked at carefully to ensure that they are the same as the board files after the translation. And it is also helpful to check an individual layer with its associated layers (example top layer with top silkscreen layer) to be sure that they will work together as expected. A list of all the files that are sent to fabricator helps him know what he has received. When questions come up, it is also good that they have contact information for the board designer. Anything the designer can do to make fab or assembly easier, will lower the cost of the board.

The output files might include, but are not limited to, fab and assembly documents, auto insertion files for the pick and place machines, IPC-D-356 file of the netlist connections, an ascii file of the database (if appropriate), and any special fab or assembly information. If there is a company standards document, it may be included as well.

21.12 SAVING

Make a new copy of the database every day while working and include the date in the name. That way, if any problem occurs, the most that will be lost is a single day's work. It would be good to save a minimum of a few days' worth of data so that one can revert to an older way things were done, if necessary. It's also a good idea to save a copy of the board at certain milestones. For example, if it is saved as XXXB4resq, the database is still available if something goes wrong in the process of re-sequencing.

When the project is completed, everything should be copied to its permanent home on the network, and possibly make that directory read only so nothing can arbitrarily be changed. This will be the "master" information for starting any changes (ECOs) to the board and all other documentation and databases might be deleted so that there is never any question as to which copy of the database is the latest or correct one.

21.13 CONCLUSION

This is by no means meant to be everything that is needed to design a PCB, but it is only a beginning. Hopefully it is a reasonable start. There are many sources of information available to the novice designer for questions that are not answered here. They might include user's forums, conferences, IPC Designer's Council meetings, technical support personnel, fabricators and assemblers, and anyone in your network of PCB designers.

Antipad—an opening in a plane that is larger than the pad so that the pad will not make connection

BGA—a component called a Ball Grid Array

BOM—Bill Of Material or parts list

DXF—a mechanical file format

EMI—ElectroMechanical Interference

ESD—Electro-Static Device

FANOUT—the process of bringing a trace from a surface-mounted pad to a via to change layers

FLEX—a PCB made on flexible material

HAST—Highly Accelerated Stress Test

I/O—a connection that flows onto or off of the board

IPC—Association Connecting Electronic Industries

MCM—MultiChip Module

MRP—Manufacturing Resource Planning system

Netlist—a compilation of all the parts and interconnections on the schematic

Padstack—a group of pads, each used on a different layer of a PCB for interconnect

PCB—Printed Circuit Board

QFP—a component called a Quad Flat Pack

R-PAK—resistor pack

Schematic—the document that contains the symbols and their interconnects to all the other symbol

SM—Solder Mask

SMT—Surface Mount Technology—parts that solder directly to pads on one layer of the PCB

SOIC—Small Outline Integrated Circuit

TH—Through Hole—parts whose leads solder through holes in the PCB

Thermal pad—a pad connecting a TH to a plane with small copper spokes

Via—a through hole on a board that is solely meant to move a signal from one layer to another

X-out—a board in a panel or array that has been identified as imperfect

CHAPTER 22

CURRENT CARRYING CAPACITY IN PRINTED CIRCUITS

Mike Jouppi
Thermal Management Inc., Centennial, Colorado

22.1 INTRODUCTION

Current carrying capacity refers to the steady state temperature rise of a conductor in a printed circuit board (PCB) when current is applied. When multiple conductors have a simultaneously applied current, the rules for sizing traces changes and the parallel conductor rule must be followed.

This chapter assumes that the reader has some experience with conductor sizing charts. There are many charts found in various sources. This chapter concentrates on charts presented in IPC-2152, Standard for Determining Current Carrying Capacity in Printed Board Design, and the charts they replaced. The charts that were replaced have a long history dating back to the mid-1950s and were last published in IPC-2221.

There are many claims through using the Arrhenius function that electronics reliability is directly related to its operating temperature. Each 10°C temperature rise reduces component life by 50 percent. Conversely, each 10°C temperature reduction increases component life by 100 percent. Regardless of whether this is exactly true or not, it is still worth keeping electronics as cool as possible and optimizing reliability and the return on investment.

An accurate estimate of component temperatures requires consideration of all heat sources. Current carrying capacity and the temperature rise of the PCB traces is one aspect of electronics thermal management.

This chapter is written to help provide a basis of understanding for current carrying capacity in printed circuits and bring attention to IPC-2152. The purpose is to discuss how certain aspects of a circuit board affect the temperature rise of a trace. PCB thickness, dielectric material, number of copper planes, distance from trace to copper plane, size of the copper plane, environment and more, all impact the temperature rise of a trace.

It is not possible to collect test data and create charts for every variation of dielectric material, board thickness, number of layers, and all other ways that a PCB can be constructed. What is presented in IPC-2152, by the IPC-1-10b task group,[a] is a standard configuration. The standard configuration is called a baseline, which is used to compare how certain aspects of the board change the temperature rise of the trace when compared to the baseline. The baseline is for a specific material (polyimide), specific thickness [1.78 mm (0.07 in)], and specific size board with only traces that is defined in IPC-TM-650 2.5.4.1a.

22.2 CONDUCTOR (TRACE) SIZING CHARTS

There is very little public information that defines conductor sizing charts. Therefore, the first part of this chapter discusses the data that was used to create the external conductor sizing chart last published in IPC-2221. The importance of this discussion is to draw attention to some of the variables that impact trace temperature rise, which will then lead into the internal conductor sizing chart in IPC-2221. Following that discussion will be information used to create IPC-2152 and why there is such a significant difference between the old and new charts.

22.2.1 Conductor Sizing Chart Development

Conductor sizing charts were first introduced in 1956. Work performed at the United States National Bureau of Standards from January to December 1955 is documented in NBS Report 4283, dated May 1, 1956.[1] This work was the first data set published when printed circuit techniques were first gaining widespread acceptance for military and industrial applications. The work documented in that report was not considered complete and the design guide was labeled tentative; see Fig. 22.1. The charts in that report were published in a multitude of Mil-Std-275 revisions, which were then continued in IPC-D-275 and last published in IPC-2221. This history is captured in the appendix of IPC-2152.

Design chart
(Tentative)

For use in determining current carrying capacity and sizes of etched copper conductors for various temperature rises above ambient.
(Note: See design guide on preceding page for use of this chart).

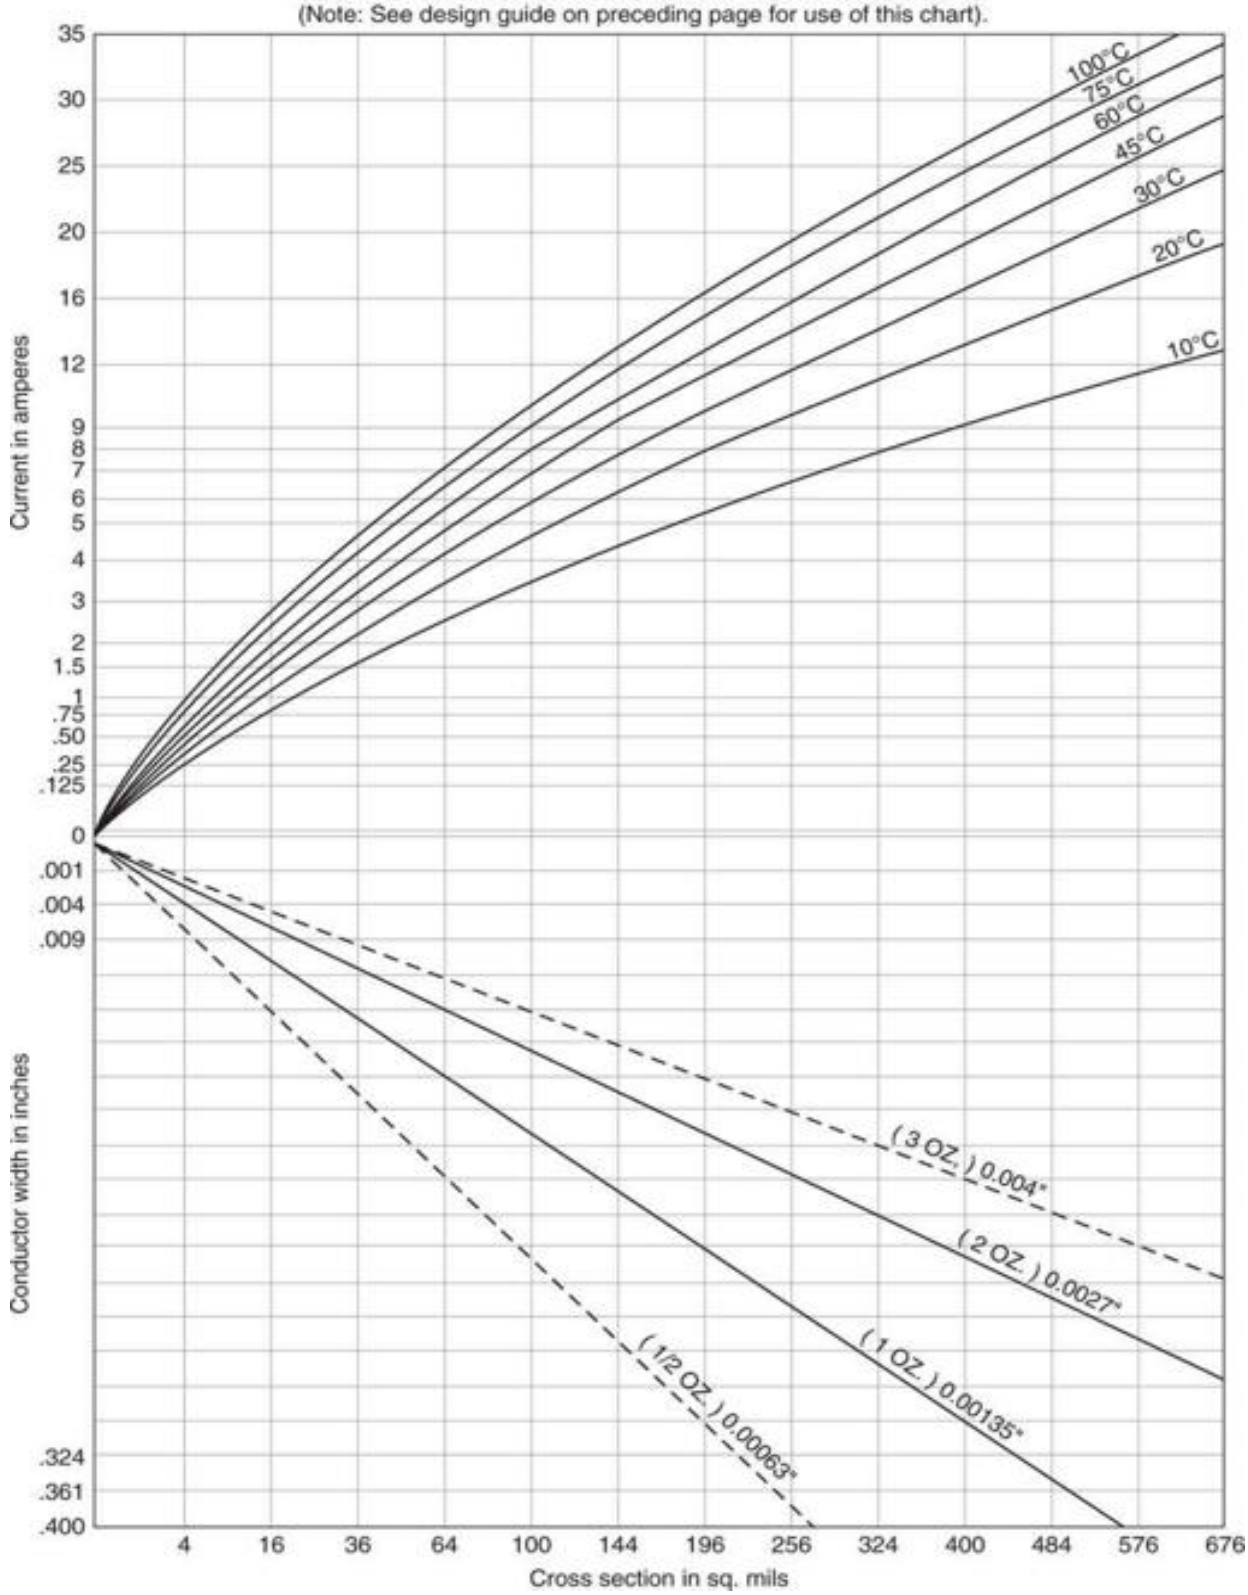

FIGURE 22.1 National Bureau of Standards tentative chart (1955).

The old charts were developed by applying current to traces and measuring the temperature rise of the trace in many different types of boards. The boards varied in thickness, board material, conductor weight, and some with copper planes on the back side of the board. The copper planes have a significant impact on trace temperature rise. A curve fit through all of these mixed sets of trace heating data skews the ability to accurately predict a trace temperature rise or a group of parallel traces.

The original trace heating data was collected only on external conductors. The trace heating data included traces on phenolic and epoxy boards, board core thicknesses of 0.03125, 0.0625, and 0.125 in, with ½, 1, 2, and 3 oz copper weight traces, as well as from boards with and without copper planes on the back side of the board. A plot of some of the original data is shown in Fig. 22.2. The test vehicle description for the data points shown in Fig. 22.2 are listed in Table 22.1. Figure 22.1 was used to create the old external chart that was last published in IPC-2221; see Fig. 22.3.

(For use in determining current carrying capacity and sizes of etched copper conductors for various temperature rises above ambient.)

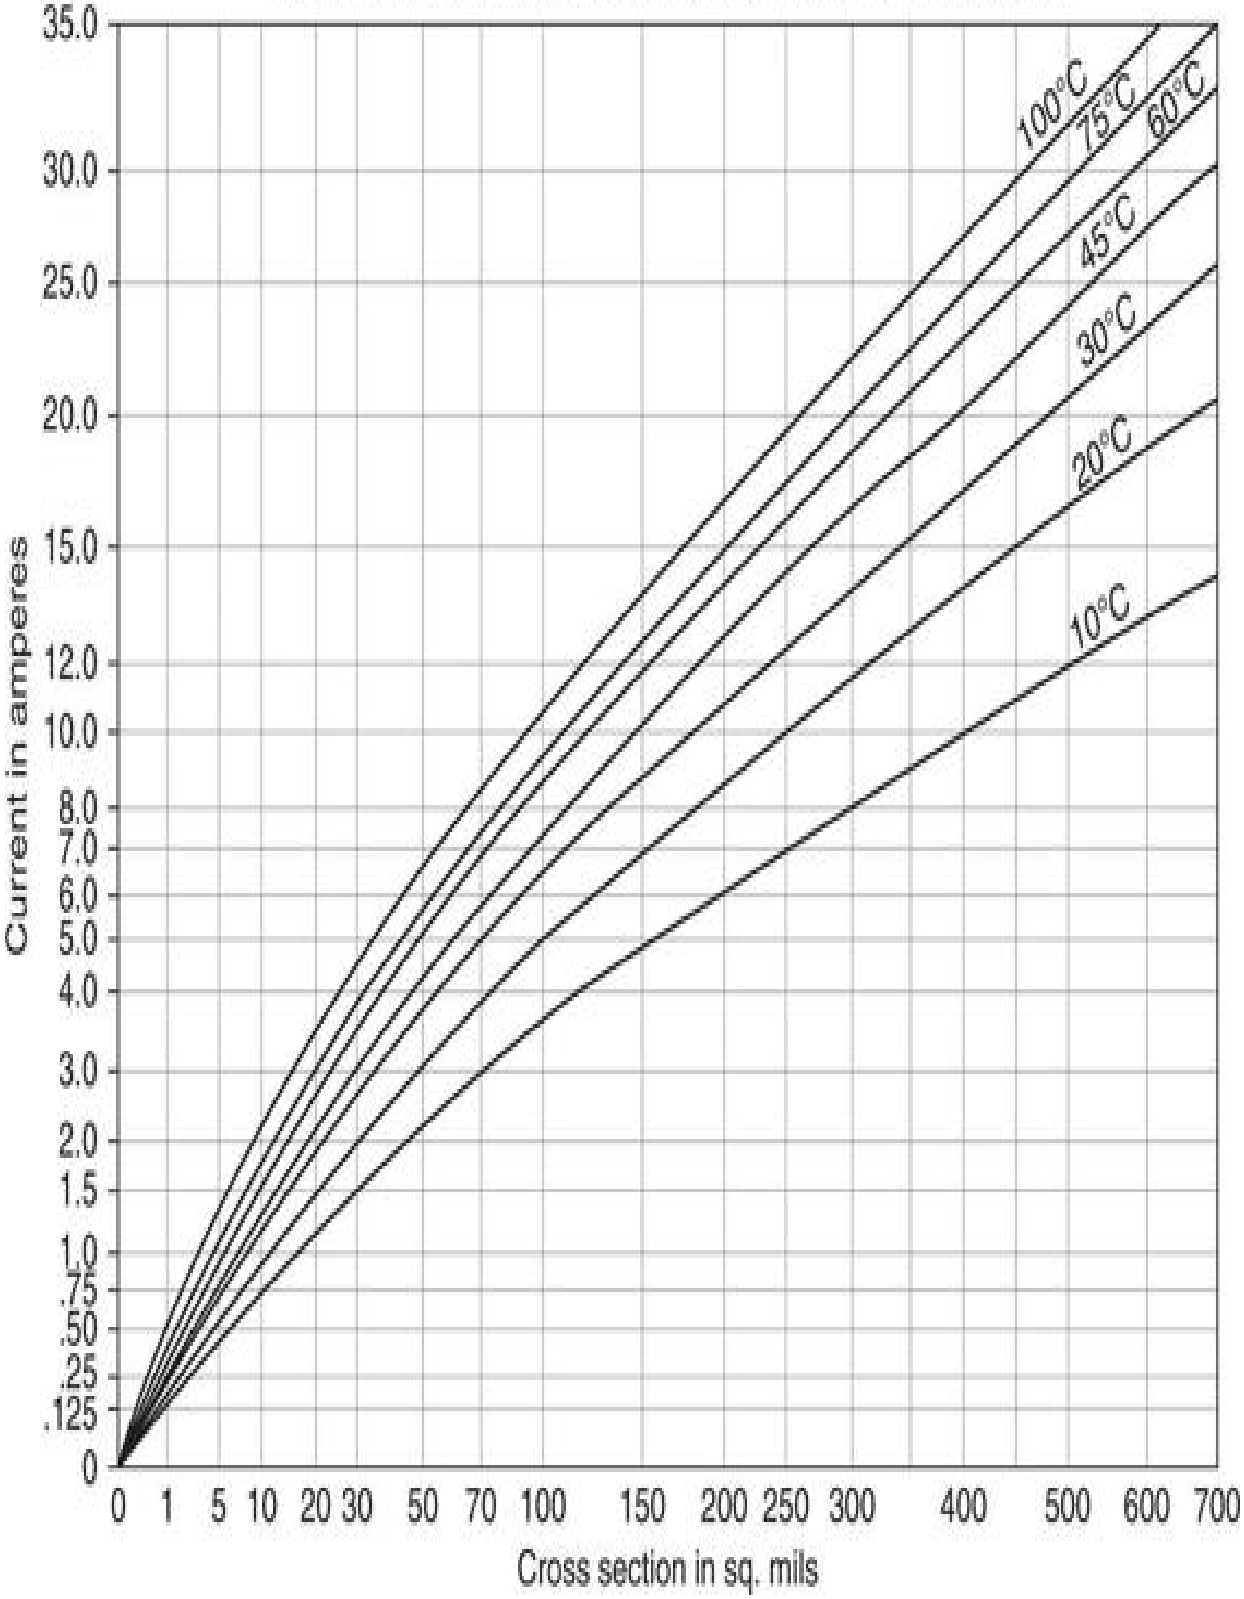

FIGURE 22.3 IPC-2221 external conductor sizing chart (old chart).

There are many observations to be made when looking at Fig. 22.2 and Table 22.2. When making the observations one must keep in mind the time period (mid-1950s), the instrumentation available and accuracy of the data. Four observations are discussed:

1. The first observation is that the dominant characteristic for current carrying capacity is the cross-sectional area.
2. Second, a noticeable reduction in current carrying capacity is seen for the thinner core material (L) at 1/32 in. Data collected for IPC-2152 observed a reduction in current carrying capacity as core thickness decreased, which although is not discussed in this chapter, brings attention to flex circuits.
3. Third, the influence of a copper plane on the core is shown to have significant impact for the thinner core (O). This influence of the copper core is less pronounce for the thicker boards where the distance from the trace to the plane is a greater distance. Data and thermal modeling of conductors for IPC-2152 clearly shows that there is a significant drop in the conductor temperature rise as the distance from a conductor to a copper plane decreases.
4. The last observation is that conductors in free air have the least current carrying capacity. The thermal conductivity of the epoxy and phenolic cores were not reported, although have a value that is approximately 0.354 W/m-K. Air has a thermal conductivity of approximately 0.026 W/m-K. The point here is that a trace conducts more energy into a core with high thermal conductivity than air with low thermal conductivity, neglecting any discussion on the convective and radiative losses.

TABLE 22.2 Dielectric Thermal Conductivity

Material	kx (W/in-C)	ky (W/in-C)	kz (W/in-C)
FR-4	0.0124	0.0124	0.0076
Polyimide	0.0138	0.0138	0.0085

In general, many people believed that internal conductors ran hotter than external conductors for a given cross-sectional area and current level. This fallacy was created by the old internal conductor sizing chart shown in Fig. 22.4. The casual observer would believe this internal conductor sizing chart was developed by performing current carrying testing on internal conductors, when actually the current is just ½ the current from the external conductor sizing chart; see Fig. 22.3. Testing from 2001 to 2004 show internal conductors operate at a similar temperature, but slightly cooler than external conductors for current carrying capacity (see Figs. 22.7 and 22.8).

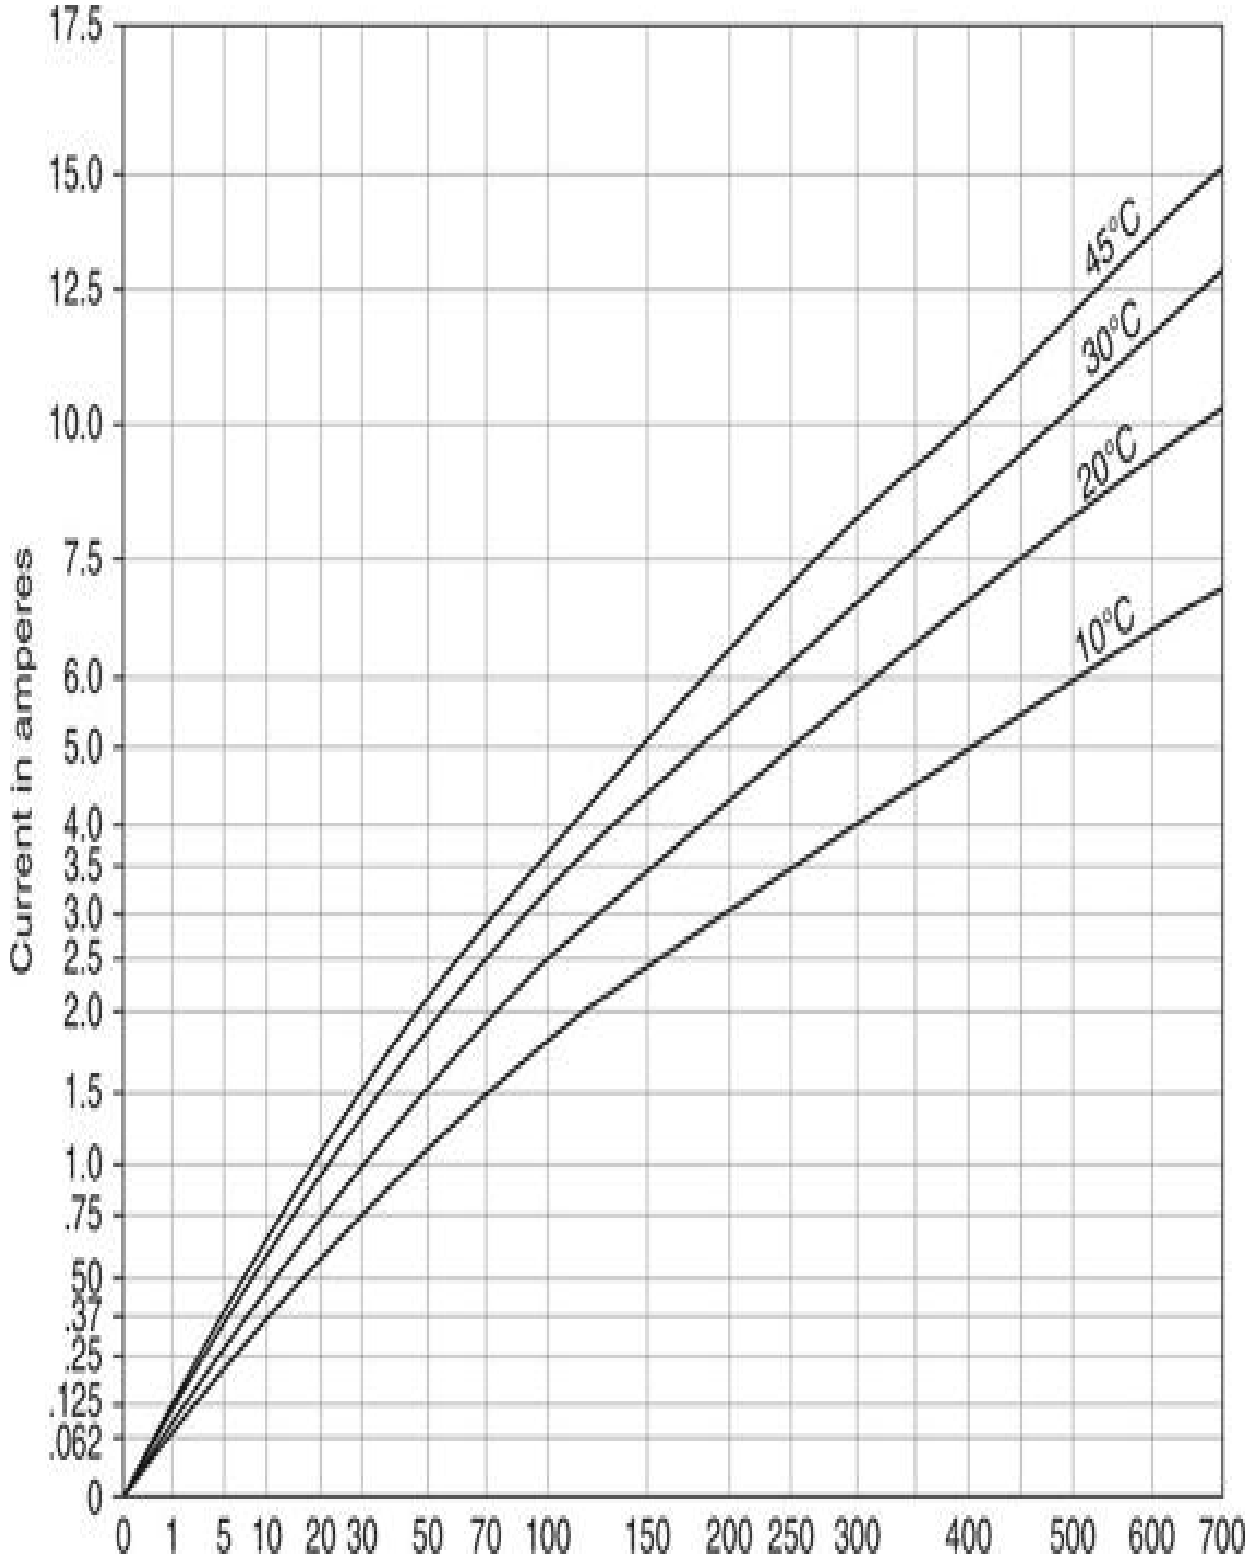

FIGURE 22.4 IPC-2221 internal conductor sizing chart (old chart).

22.3 BASELINE CHARTS

IPC-2152, “Standard for Determining Current Carrying Capacity in Printed Board Design,” was developed by the IPC-1-10b task group.[b] They defined a set of charts called baseline charts that are used to determine the temperature rise of a trace and assess variables that influence that trace temperature rise. An example of the difference between what is calculated using the old internal trace sizing chart and the new is shown in Fig. 22.5.

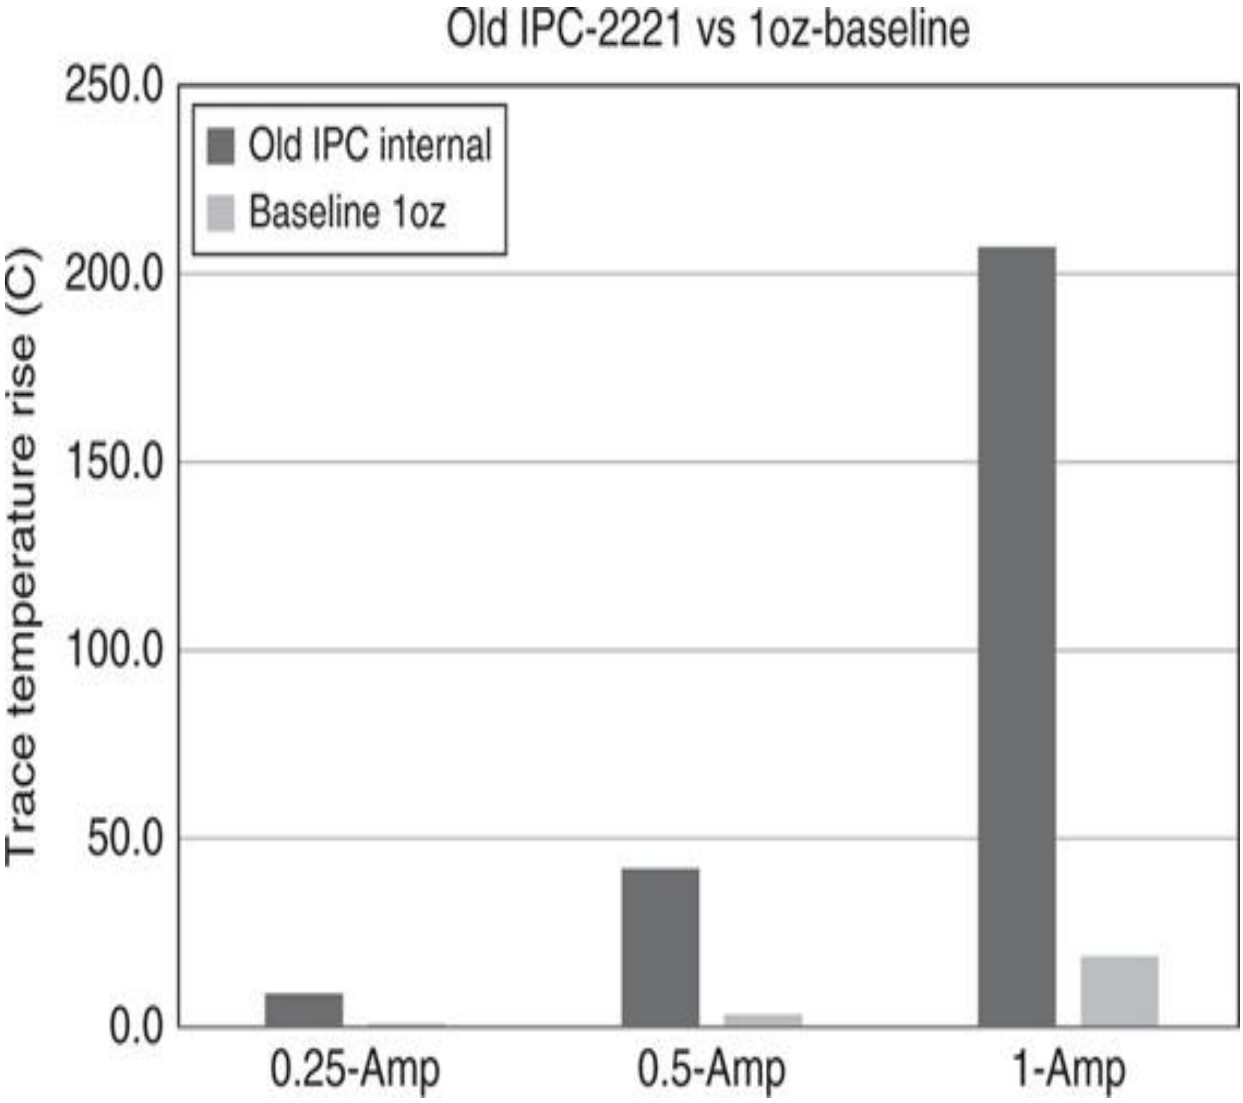

FIGURE 22.5 Old chart versus new baseline for a 0.005-in-wide, internal 1-oz trace.

The *baseline charts* were developed from current carrying capacity testing using polyimide PCBs, 1.78 mm (0.07 in) thick, with no internal copper planes. Test vehicles were developed and current carrying capacity testing was performed following IPC test method, IPC-TM-650-2.5.4.1a, “Conductor Temperature Rise due to Current Changes in Conductors.” An advantage of using a baseline chart is that it provides a more accurate trace temperature estimate in general, as well as when extrapolating the data for higher current estimates and trace cross-sectional area greater than 700 sq. mils.

Two internal baseline charts, 1 oz and 2 oz internal traces, and one external baseline chart are presented; see Figs. 22.6 through 22.8. These charts represent a subset of data collected for ½-, 1-, 2-, and 3-oz copper weights, FR-4 and polyimide boards, and printed wiring boards (PWB) with board thicknesses of 0.965 mm (0.038 in), 1.498 mm (0.059 in), and 1.78 mm (0.07 in), all of which are discussed in IPC-2152.

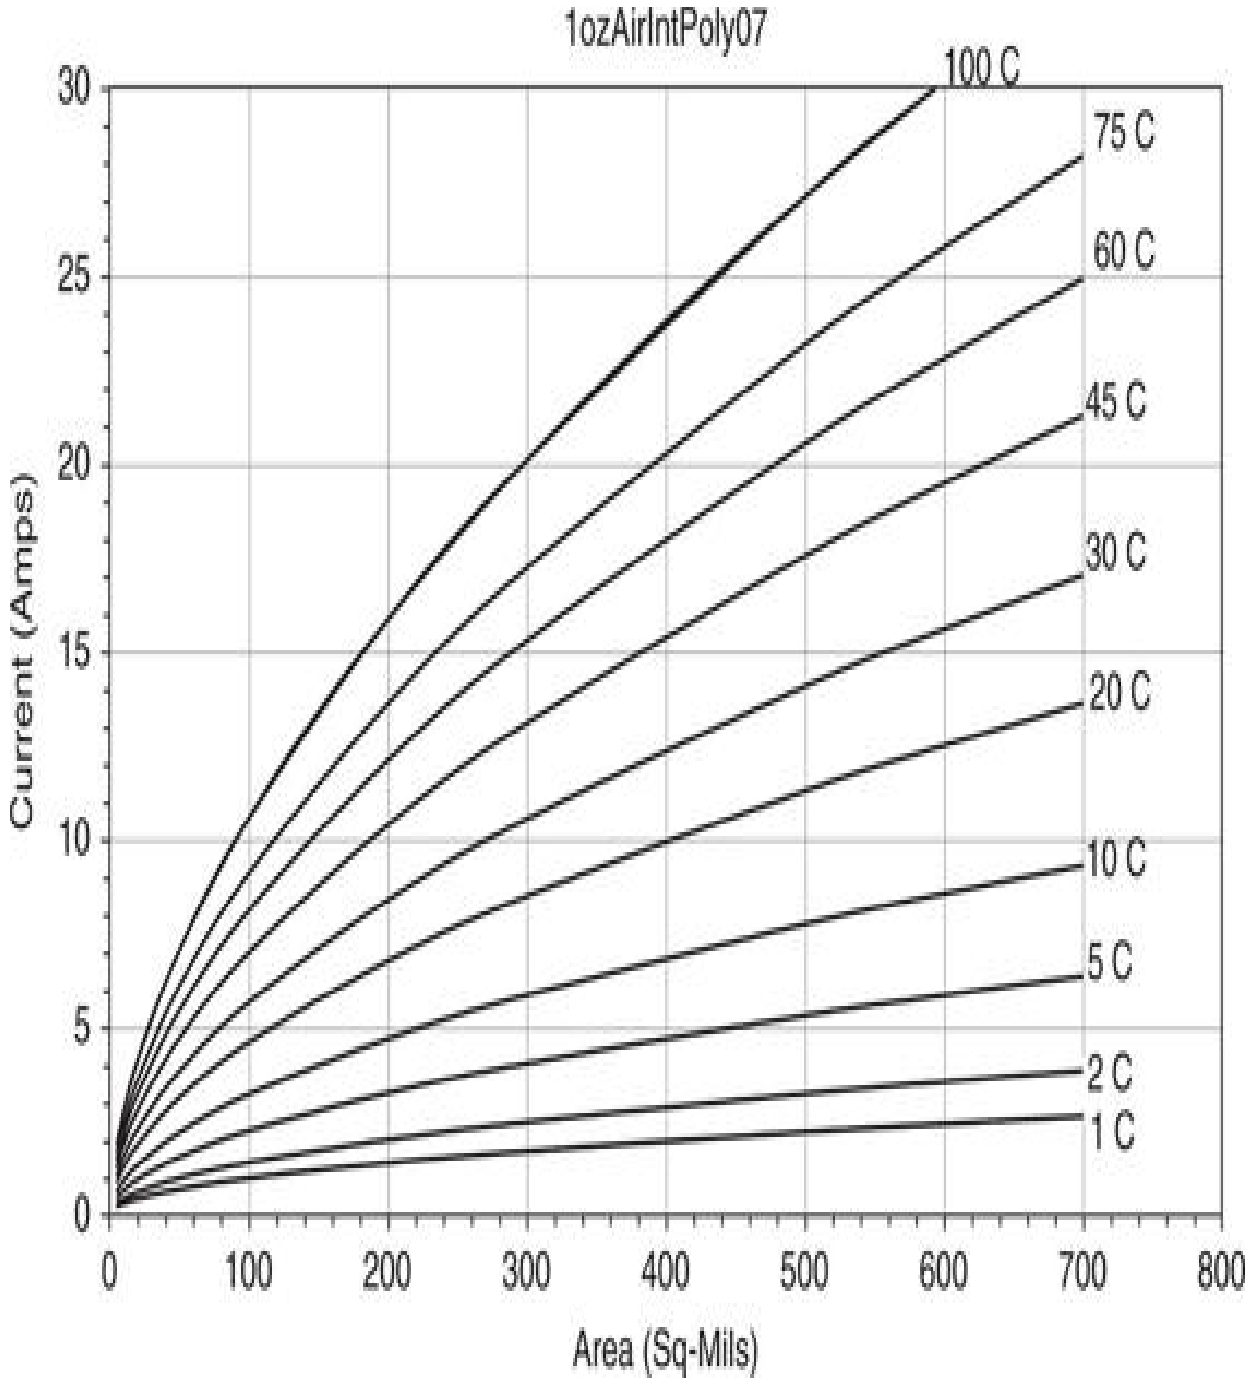

FIGURE 22.6 One-ounce internal conductor chart (new IPC-2152).

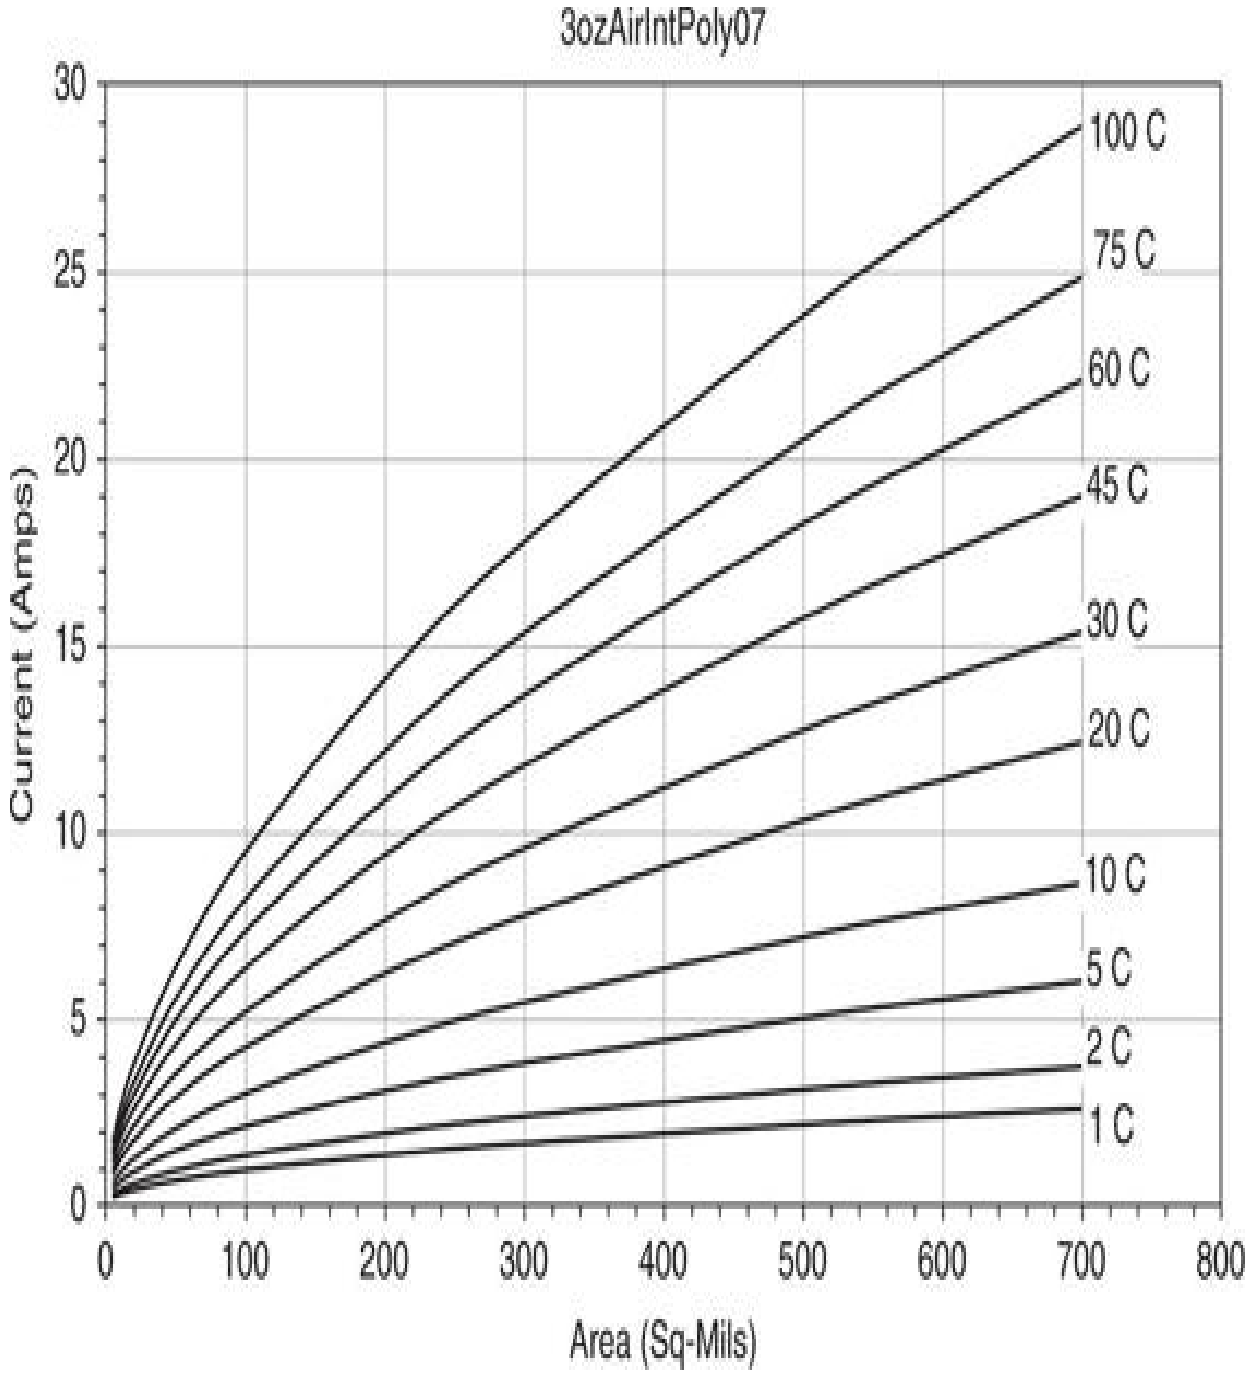

FIGURE 22.7 Three-ounce internal conductor chart (new IPC-2152).

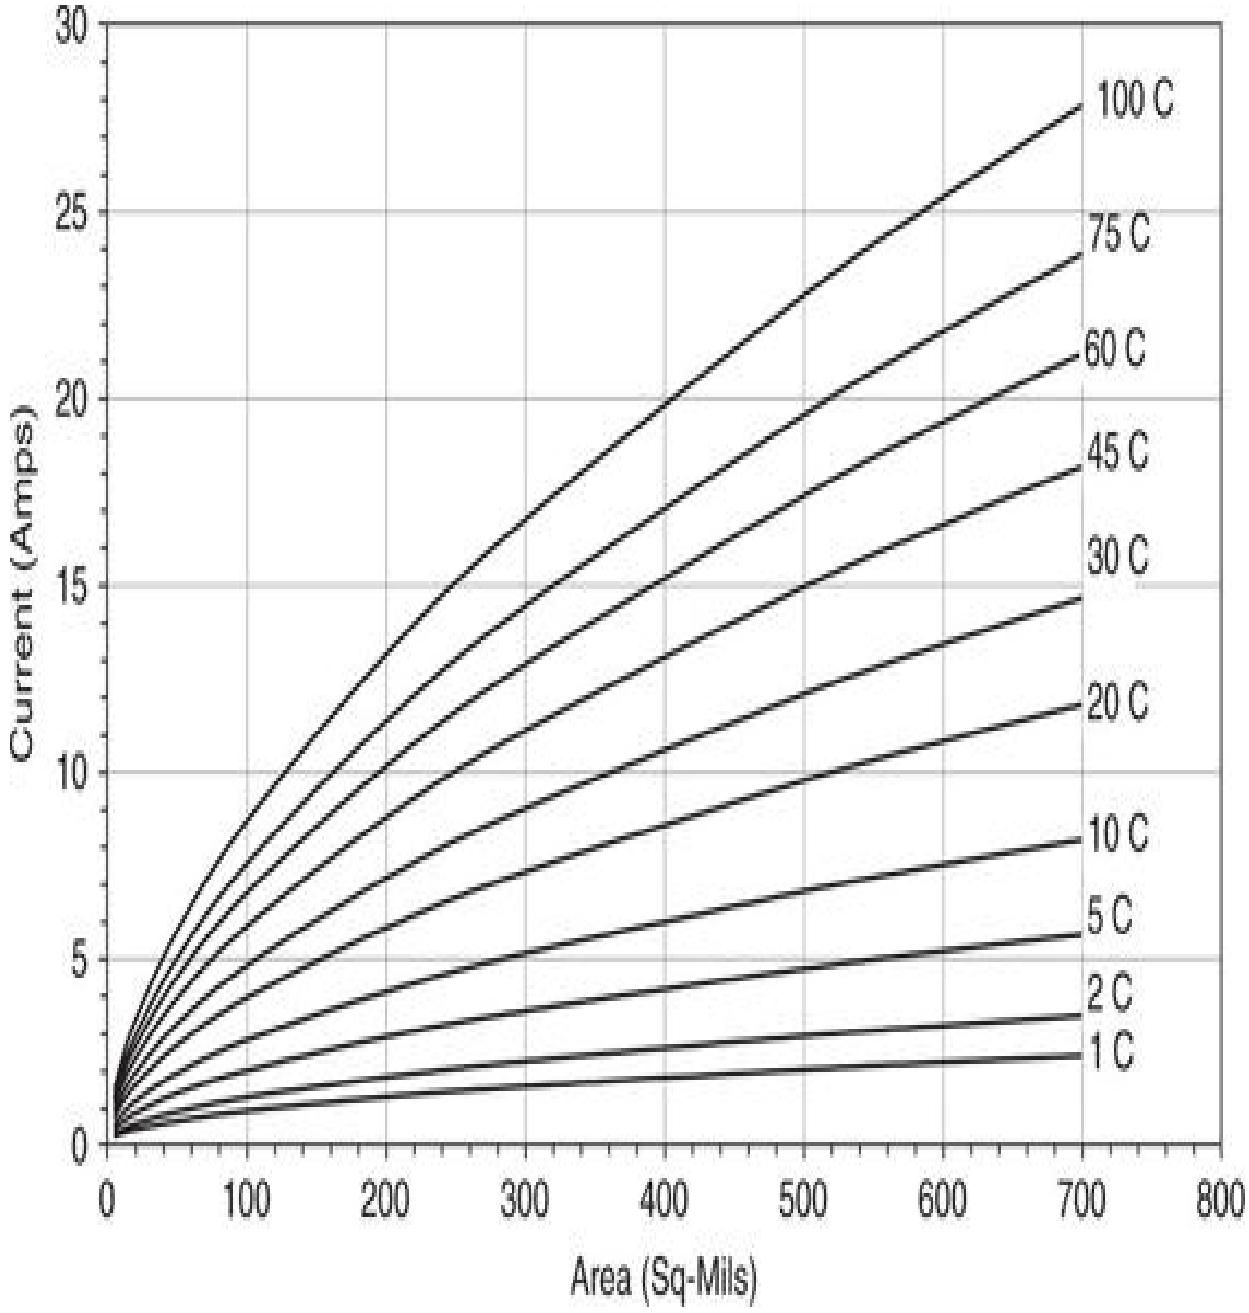

FIGURE 22.8 Three-ounce external conductor chart (new IPC-2152).

22.3.1 Baseline Testing

The baseline test vehicle is a polyimide PCB that is 1.78 mm (0.07 in) thick, designed, and tested following IPC-TM-650-

2.5.4.1a. The steady-state conductor temperature rise was investigated as a function of the following parameters:

- Current level
- Cross-sectional area of the trace
- Copper weight
- Board thickness
- Board material
- Environment (still air, vacuum)
- Distance from a trace to a copper plane

The IPC-2152 baseline charts are

- 3 oz external (0.07 in polyimide in air)
- 2 oz external (0.07 in polyimide in air)
- 3 oz internal (0.07 in polyimide in air)
- 2 oz internal (0.07 in polyimide in air)
- 1 oz internal (0.07 in polyimide in air)
- ½ oz internal (0.07 in polyimide in air)

Examples of the baselines charts are presented in Figs. 22.6 through 22.8. Figure 22.6 represents the data set for 1-oz internal conductors with a 0.07-in thick polyimide core in an air environment. Figure 22.7 is for the same core and environment, although the copper weight is 3 oz. There is a small effect on trace temperature rise as conductor weight increases, it can be seen in the charts for the 1 oz and 3 oz traces, most noted at higher temperature differences. Figure 22.8 represents data collected for 3 oz external conductors. Temperature differences are observed between internal and external traces, for the same board material, board thickness, environment and cross-sectional area; when comparing Figs. 22.7 and 22.8.

22.3.2 Copper Planes (Modeling)

The baseline test vehicle has no copper planes in the core. This is not representative of a large percentage of designs, therefore computer modeling was used to investigate the impact of copper planes on trace temperature rise. Copper planes help spread the heat and lower the temperature rise of what would otherwise be a hot spot created by the trace.

Copper planes add another dimension to trace heating, because the trace temperature is then dependent on the size of the copper plane and the distance from the trace to the plane. The modeling assumes an ideal copper plane with no holes or cutouts. Charts are provided in IPC-2152 to account for the influence of copper planes and an estimate for the reduction in trace temperature rise. They are not recommended as a trace sizing tool, but rather an approach toward estimating margin in a design. An example of the influence of a 1-oz internal copper plane on a 5-mil trace is shown in Fig. 22.9.

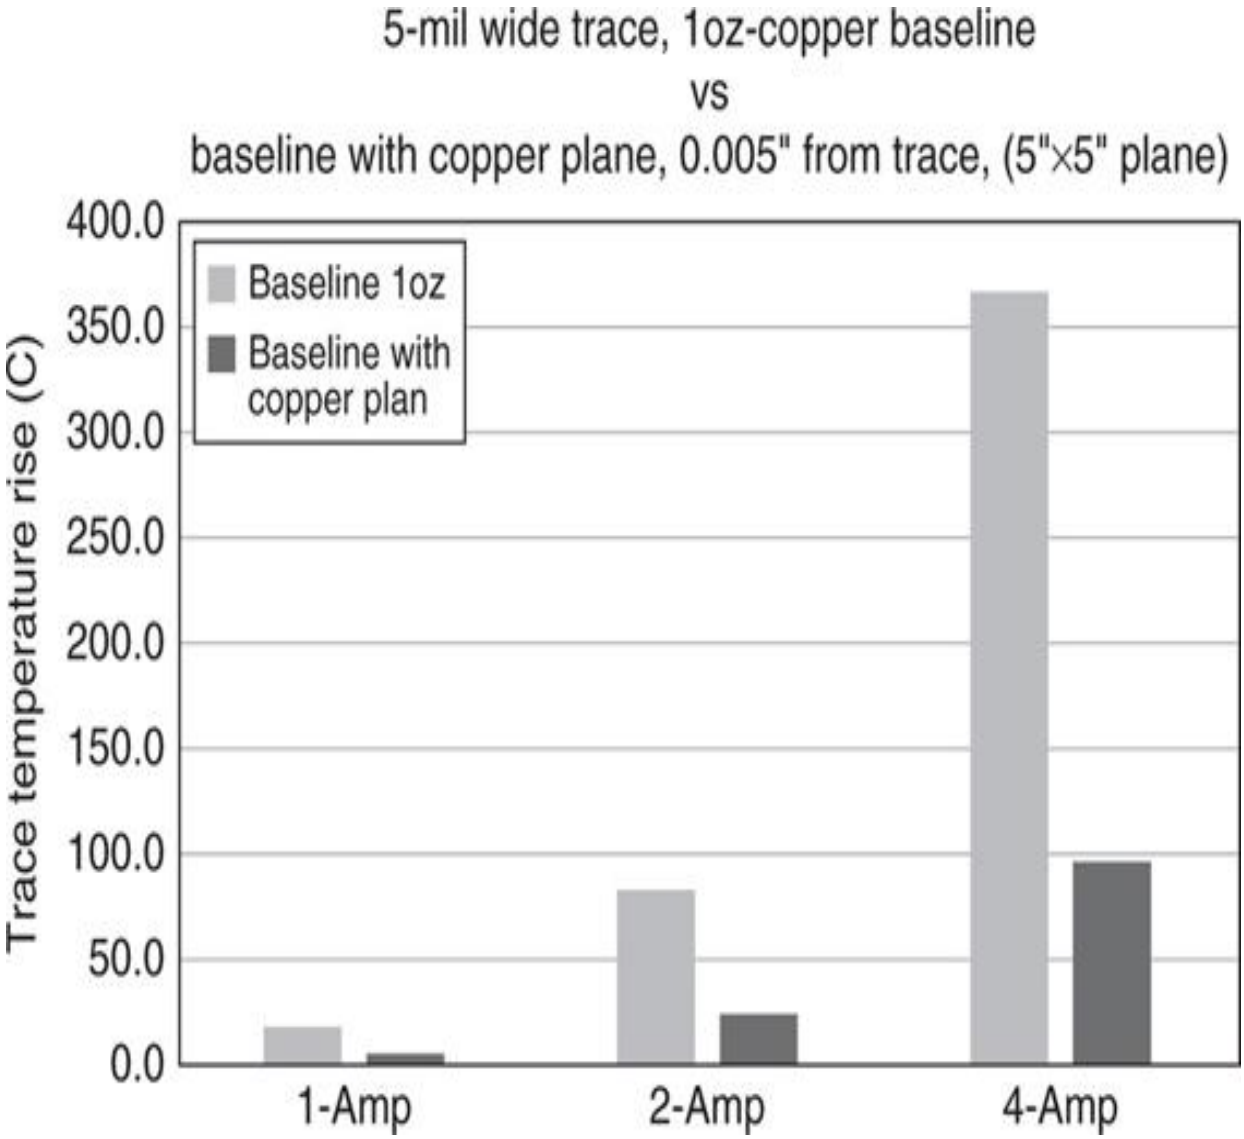

FIGURE 22.9 One-ounce baseline for a 0.005-in-wide, internal 1 oz trace versus with 1 oz internal plane (new IPC-2152).

22.3.3 Board Material

FR-4 boards were tested in addition to the 0.07-in core polyimide boards. The FR-4 board core material was 0.038 in for one set and 0.059 in for the other. The thermal conductivity had a secondary effect compared to the board thickness. The measured thermal conductivity for the two laminates tested are listed in Table 22.2.

22.3.4 Board Thickness

The thickness of the board affects the trace temperature rise. When comparing test results for the 0.038-in and 0.059-in-thick boards to the baseline board, 0.07-in thick, as the board thickness decreased the trace temperature rise increased. For example, using the 1 oz, air, baseline chart; a 0.0088-in-wide trace, carrying 1 amp, produces a 10°C rise in trace temperature. That same trace in a 0.059-in-thick test board had a 12.1°C rise and a 0.038-in-thick board had a 13.3°C rise.

22.3.5 Environments

Data was collected in a still air environment and in vacuum for the baseline charts (Fig. 22.10). Results in a vacuum environment run hotter than in an air environment as expected. In a vacuum, the internal and external traces run approximately at the same temperature.

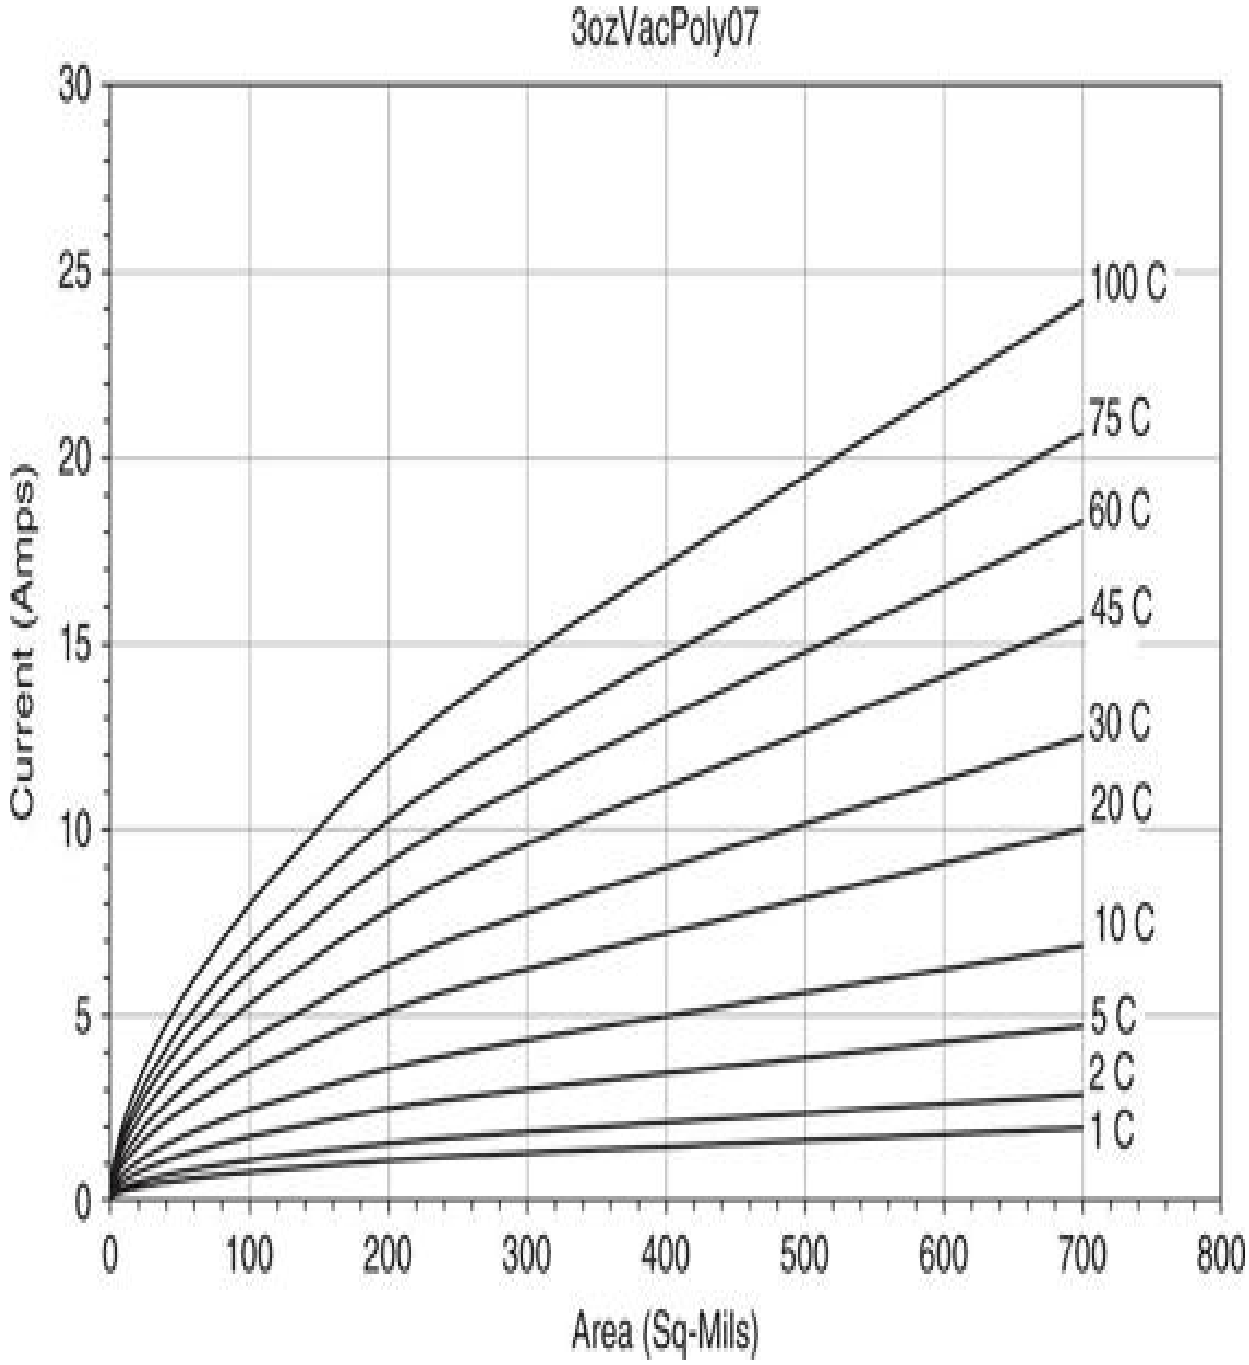

FIGURE 22.10 Three-ounce external/internal conductor chart (vacuum, new IPC-2152).

22.3.6 Copper Thickness

Copper thickness should be considered when sizing electrical traces. IPC-2221 specifies the minimum acceptable copper

thickness for internal and external layers as shown in Table 22.3 and 22.4,[2] The IPC printed circuit Process Capability, Quality, and Relative Reliability (PCQR[2]) database identifies end process copper dimensions for conductors. When sizing traces for a given current level, consideration should be given to the end product.

TABLE 22.3 Minimum Internal Copper Foil Thickness[c]

Internal Conductor Thickness after Processing

[d]*Ibid., Table 10-2*

22.3.7 Parallel Conductors

“Parallel conductors” is an evolving term. They were first defined by the following: “For groups of similar parallel conductors, if closely spaced, the temperature rise may be found by using an equivalent cross-section and an equivalent current. The equivalent cross-section is equal to the sum of the cross-section of the parallel conductors, and the equivalent current is the sum of the currents in the conductors.” No definition was given to closely spaced and this led to a lot of confusion about what conductors should be considered. IPC-2152 has color plots that are provided as

an aide to help get a sense of the heat spreading in an effort to illustrate and define “closely spaced” conductors.

All conductors that are simultaneously carrying current are heat sources that should be evaluated together as a part of the PWB thermal management design plan. Observe the number of traces that are above and below each other, from side to side, as well as throughout the rest of the PWB. Using those conductors the total current can be summed and a cross-section can be defined.

Estimating power losses for all conductors, simultaneously carrying current, is a simple way to start estimating any areas of concerns for conductor sizing. If the wattage for the specific design starts to become a significant percentage of the total power dissipated on the board, it becomes apparent that some design choices should be made.

Managing the temperature rise of traces by accounting for their power dissipation, and power density, in a preliminary thermal analysis prior to final layout is a time saving step in the design process.

Some of the most difficult areas to manage are when there are odd shaped geometries, such as around connectors where traces may be necked down to get around power pins, and copper planes that have a lot of cutouts and keep-outs for vias. These areas have potential for significant heating and are best solved with a thermal analysis tool.

22.3.8 Other Areas of Study

There are many areas of current carrying capacity that deserve more study, such as flex circuits, edge effects, mounting configurations, vias, microvias, high-speed effects, neck downs around connectors and the conduction path through the connector, and high-current pulses.

Recent investigations into high-current pulses have shown interesting results, where the trace was fusing earlier than

expected. These studies were preliminary, but help shed light on the need for understanding the limits to approaches we take to solve problems that may or may not have the research performed to support all of our assumptions.

22.4 Summary

New charts have been developed to help determine current carrying capacity in printed circuits. The new IPC-2152 baseline charts are conservative for most applications. They can be used to determine a trace temperature rise for a given current level for other board thicknesses, environments, and when copper planes are present. The flexibility of using the IPC-2152 charts is determined by how well the user understands the baseline charts.

Large differences are found between the old and new charts primarily due to collecting data for both external and internal traces. The difference that is observed between the old and new charts is a significant step and as the development of IPC-2152 continues there will be additional significant steps.

CHAPTER 23

PCB DESIGN FOR THERMAL PERFORMANCE

Mike Jouppi
Thermal Management Inc., Centennial, Colorado

23.1 INTRODUCTION

The reliability and electrical functionality of electronic components is partially determined by the temperature at which they operate. As such, control of the component temperatures in the system is an important design consideration. Factors that impact device temperatures include the power at which they operate, the air flow surrounding them, heat generation upstream to them, the environment in which the system operates (either indoors or outdoors), the system orientation (either vertical or horizontal), and a variety of printed circuit board (PCB) layout and design properties. These PCB design factors include the design of the copper (Cu) traces contacting the components, the number and area of Cu planes that are connected to them, any thermal vias that might be designed between them and the spreading planes, the proximity of

other devices that dissipate power, and any cuts in the thermally conducting layers. Additional PCB features that impact the thermal performance of components include chassis screws, connectors, edge guides, and shields.

To control component temperatures, PCB factors that impact thermal energy flow must be considered in the design phase of the PCB layout. These factors include many complex interactions that make application of simple equations to calculate system temperatures impossible. For example, the historical equation used to calculate component temperatures from a thermal resistance parameter called theta-*ja* (θ_{ja}) as shown in Eq. (23.1) is not applicable in modern systems. This is stated clearly in the Joint Electron Device Engineering Council (JEDEC) standard for θ_{ja}.[1] θ_{ja} is not a constant. It is a function of the PCB onto which the component is placed and can vary by a factor of two or more as a function of the PCB design layout. Therefore, if component temperatures are calculated using Eq. (23.1), wildly erroneous estimates may be accepted, which might lead to a system design that fails thermally.

$$T_{\text{junction}} = T_{\text{ambient}} + (\theta_{ja} * \text{power}) \tag{23.1}$$

where T_{junction} = the temperature of the active portion of the component
T_{ambient} = the temperature of the air at a specified location
θ_{ja} = the thermal resistance of the component as defined by JEDEC
power = the power of the component

This chapter describes best-design practices that enable the PCB designer to achieve the best possible thermal performance for a given design. As there is no method to calculate analytically the combined impact of the methods described, the designer is encouraged to use sophisticated tools to model the final component temperatures.

23.2 THE PCB AS A HEAT SINK SOLDERED TO THE COMPONENT

The PCB can be considered to be a heat sink that has been soldered to the leads or solder joints of the electronic component. The physical design of the PCB dramatically impacts its efficiency as a heat sink and the temperatures at which the components operate. Figure 23.1 helps to illustrate this point. Here, a packaged component (shown in cross section) is attached to the PCB. Heat is generated by current flowing through electrical resistances on the active surface of the die. This raises the temperature of the surface, resulting in a thermal gradient. Thermal energy (heat) flows from regions of high temperatures to regions of lower temperatures. For the component illustrated in Fig. 23.1, heat flows from the die through the die attach, then through any Cu metallization in the package substrate, then through the solder joints into the PCB. If there are good thermal conduction paths in the PCB, the heat spreads out over a large area of the PCB, allowing the potential for efficient convection and radiation into the environment. If there are few heat transfer paths in the PCB, the component is insulated and the temperature increases.

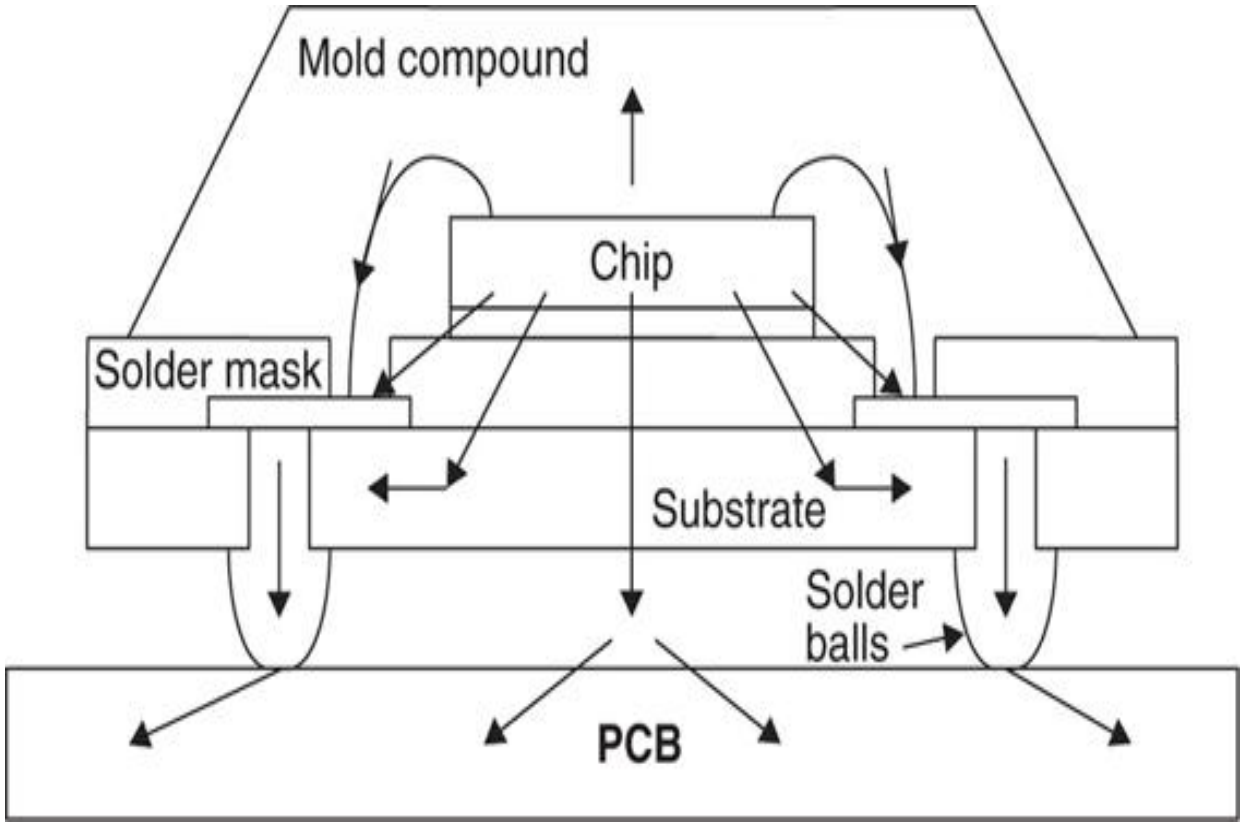

FIGURE 23.1 Cross-section of an electronic component on a PCB. The arrows indicate heat conduction paths.

How important is the PCB to the thermal performance of components? Depending on the PCB design, up to 60 to 95 percent of the thermal energy can be dissipated by the PCB. This type of performance can be achieved by PCBs that meet the following criteria:

- Large spreading planes to conduct heat away from the components
- Sparsely populated PCBs with large areas for convection and radiation
- Long traces interconnecting the components, again to conduct heat away from the components
- Sufficient spacing of PCBs in a system rack to enable adequate convection

Failure to meet these conditions will result in reduced thermal dissipation from the PCB, higher component operating temperatures, degraded device reliability, and perhaps even lack of electrical functionality.

23.3 OPTIMIZING THE PCB FOR THERMAL PERFORMANCE

To optimize the PCB's thermal performance, it is important to consider the trace layout, the thermal planes, and the thermal vias. Component spacing on the PCB and the maximum PCB power dissipation (thermal saturation) are also critical.

23.3.1 The Impact of the Trace Layout

The thermal conductivity of a material is a measure of the thermal energy that can flow through the material under an applied temperature gradient. Figure 23.2 shows a plate of material where two sides are held at different temperatures, T_1 and T_2. Experimentally, the one-dimensional thermal energy transferred through this material is found to be governed by Eq. (23.2).

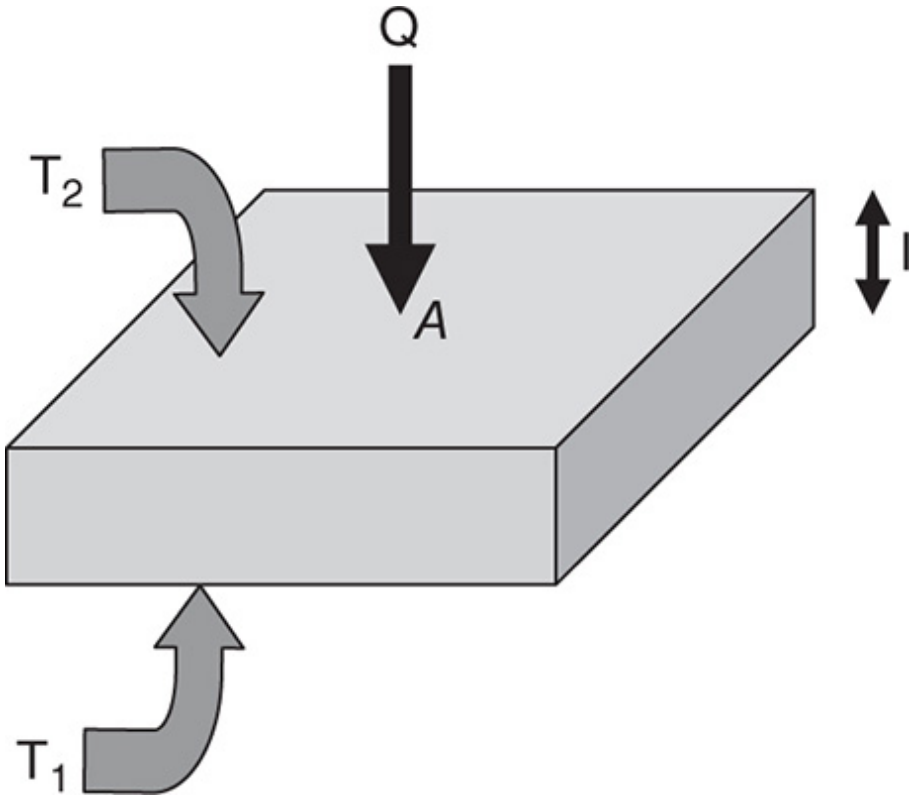

FIGURE 23.2 Typical thermal conductivity test schematic showing a block of material with area A constrained by two different temperatures, T_1 and T_2, on opposing faces. Q indicates the heat flow direction when T_2 is greater than T_1.

$$q = \frac{kA}{l}(T_1 - T_2) \qquad (23.2)$$

where q = the heat energy
A = the area of the plate
l = the thickness of the plate
k = the thermal conductivity of the material
T_1, T_2 = the applied temperatures on the plate's opposing faces

Table 23.1 lists typical thermal conductivity values important to PCB and electronic components. Where a range of material properties is given, multiple factors determine the exact thermal conductivity value. These factors can

include the filler percentage and composition in a polymer, or in the case of silicon (Si), the doping type and level. Material property measurement or vendor data should be used to determine the thermal conductivity of the specific material of interest. One alloy of Cu is shown to demonstrate that the Cu alloy composition can play a role in the thermal conductivity of metals. These material properties are valid at room temperature (~23°C). Due to the temperature-dependent nature of thermal conductivity, further references for these properties should be pursued when operation is expected at temperatures above 85°C or below −25°C.

TABLE 23.1 Typical Thermal Conductivity Values[2,3]

Material	k(W/m-°C) at 25°C
Air	0.0026
Copper (pure)	386
Copper EFTEC-64T	301
FR-4 (in-plane)	0.6–0.85
FR-4 (out-of-plane)	0.25–0.3
Solder mask material	0.15–0.5
IC encapsulant	0.6–1.0
Silicon	110–149

It is critical to note that the thermal conductivity of Cu is three orders of magnitude greater than the conductivity of most polymers such as PCBs and solder mask materials. This means the majority of the thermal energy will be conducted through the Cu, which implies that the layout of the Cu traces and power planes will be critical to the thermal performance of the PCB as a heat sink. Figure 23.3 shows this graphically. In this model, an eight-pin small- outline

integrated circuit (SOIC) package dissipating 1 W was soldered to a single-layer FR-4 PCB of 1.57 mm thickness. The temperature rise above ambient is plotted as a function of the trace length connected to the device pins. As shown, the device temperature changes by ~40 percent for this variation in trace length. The data show that to get the lowest possible temperatures, the longest possible traces should be used to spread heat away from components. Equally important, the widest possible traces should be used. These thermal design optimizations need to be made within the constraints of the electrical performance requirements such as the system time delay budget.

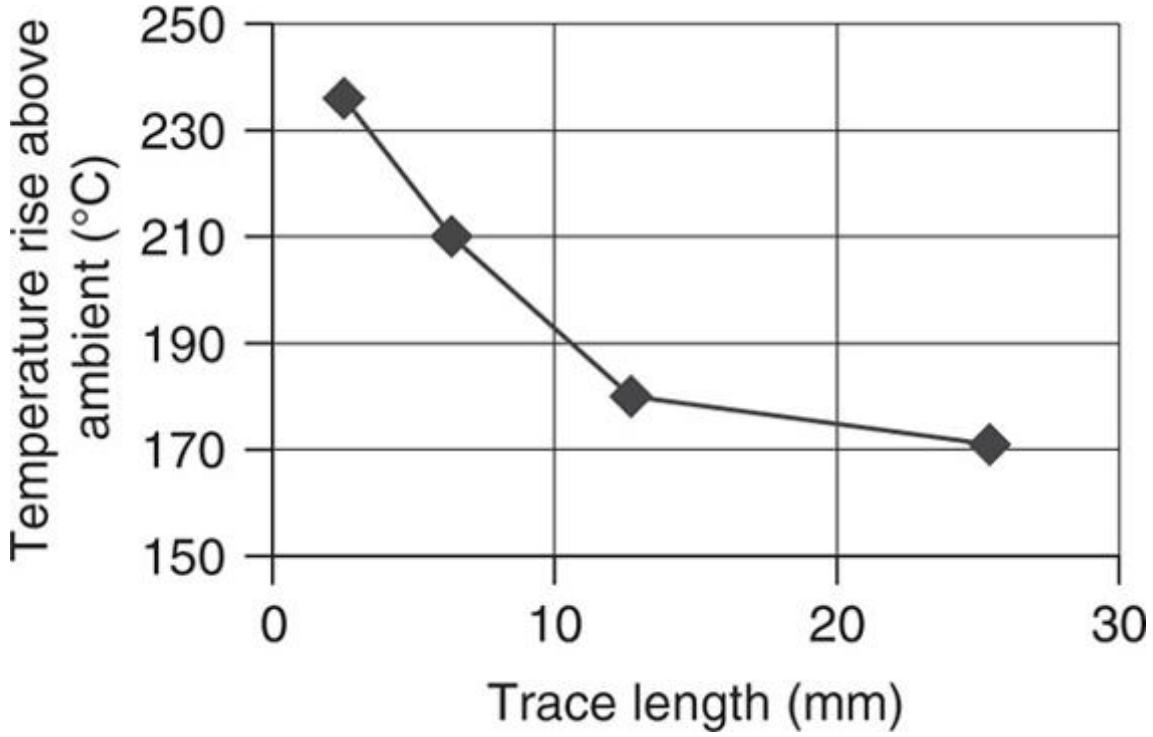

FIGURE 23.3 Modeled temperature rise above ambient thermal performance of an 8-pin SOIC powered at 1 W as a function of the trace length.

An important feature of thermal management is evident from this chart. After a trace length of about 15 mm, there was little additional improvement as the trace lengthened further—seeking thermal optimization by increasing the

trace length had reached a point of diminishing return. Often, once a specific parameter has been optimized, further changes in that parameter lead to little additional efficiency gain. Intuitively, heat flow can be thought of by analogy to fluid flow through pipes of different diameters. The pipe with the smallest diameter limits the fluid flow rate for a given fluid pressure. If the diameter of this constriction is made larger, the next smallest pipe diameter becomes the next constriction. Thermal resistance is analogous to the resistance to fluid flow in this pipe illustration. Once a thermal resistance restriction has been minimized, the thermal conduction “bottle neck” moves to a different portion of the problem.

The PCB trace thickness is another important parameter that interacts with the trace length and width. If the traces are thick, they offer less thermal resistance to heat transfer. If the traces are thin, their thermal resistance is increased and the heat will not spread as far. For best thermal performance, use the thickest possible Cu foil material with the thickest possible electroplating. Unfortunately, the trace thickness is often specified to achieve the best possible etch performance for tight pitch routing, which in turn gives the smallest PCB with the fewest signal layers and lowest cost. Within these limits, ensure that Cu traces are as thick as possible. Use them to provide direct thermal conduction paths to thermal features such as thermal vias, thermal side rails, or thermal conduction screw holes.

23.3.2 Thermal Planes

Cu planes in the PCB can provide very effective heat spreading for the electronic components. The intent is to conduct the heat over as large an area as possible in order to optimize convection and radiation heat loss from the PCB. Figure 23.4 shows a cross-sectional view of a PCB

highlighting features that make good thermal planes. These include

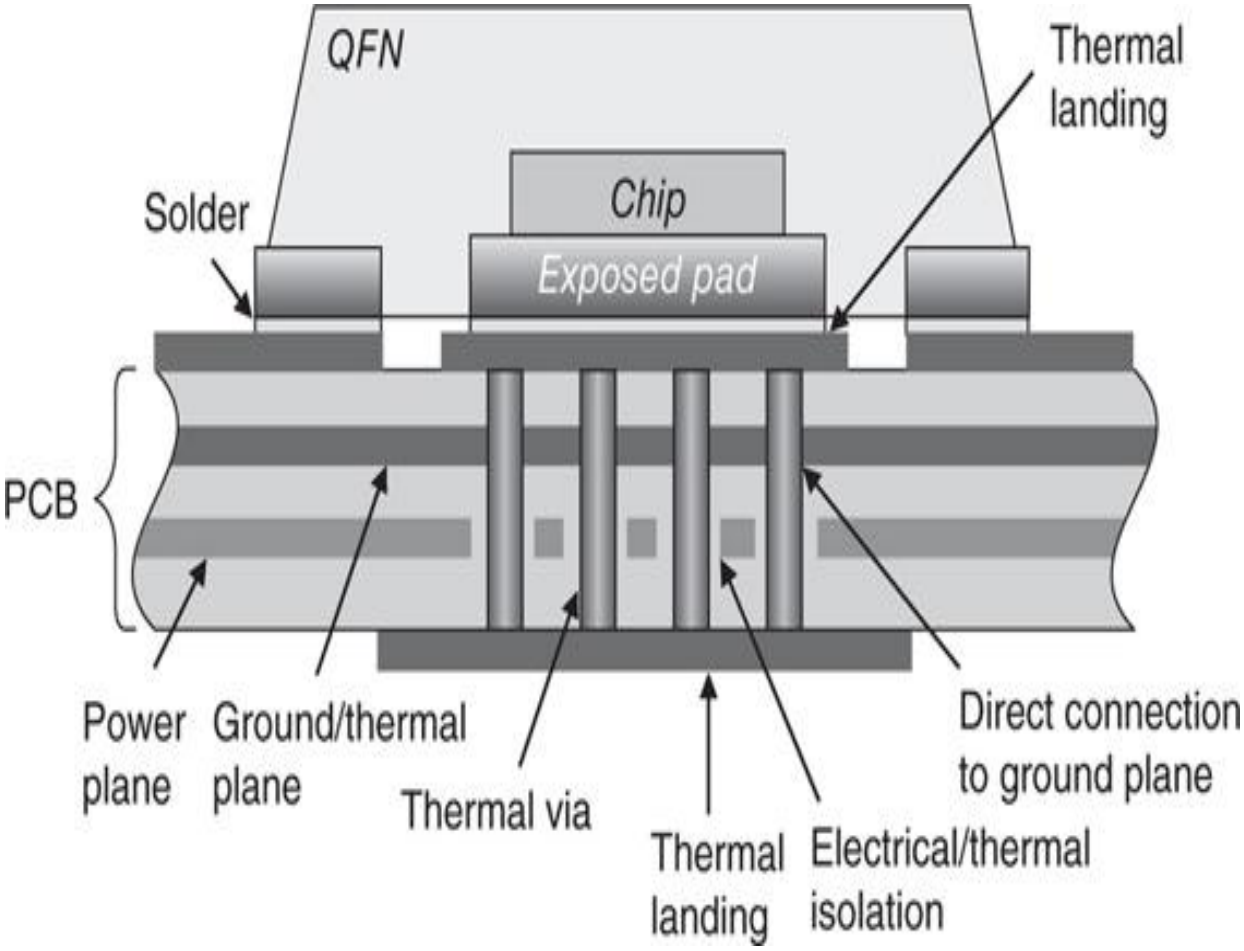

FIGURE 23.4 A typical four-layer PCB cross section showing a package with an exposed pad soldered to a thermal landing that is in turn connected to the PCB ground plane through thermal vias. The vias are isolated from the power plane for electrical reasons. In this figure, the ground plane would become the thermal spreading plane assuming it was continuous over a large area.

- A thermal landing (sometimes called a thermal collection plate) or solder land to gather the heat that the device is shedding
- Thermal vias to conduct heat from the thermal landing into a buried plane (most often either the power or ground plane)
- Continuous Cu to spread the heat

- A possible thermal landing on the bottom side of the PCB where an indirect heat sink might be attached
- Isolation areas to ensure that the thermal vias don't short all planes in the PCB

Many integrated circuit (IC) packages are optimized to "dump" power into such thermal planes in the PCB. Figure 23.5 shows images of packages with exposed pads that are intended to be soldered to thermal collection plates on the PCB. The die of these packages are glued directly to these exposed pads, giving a very low thermal resistance into the PCB. This thermal resistance can be found from vendor data sheets and might be listed as theta-*jc* (θ_{jc}), for junction to case, or as theta-*jp* (θ_{jp}), indicating junction to pad resistance. Ball grid array (BGA) packages often include thermal balls that are designed with optimized thermal conduction paths to the die inside the package. These balls should be soldered to thermal collection lands for spreading heat throughout the PCB. Often, thermal ball arrays include both power and ground balls, allowing at least two PCB planes to be used for spreading, thereby increasing the spreading efficiency of the PCB.

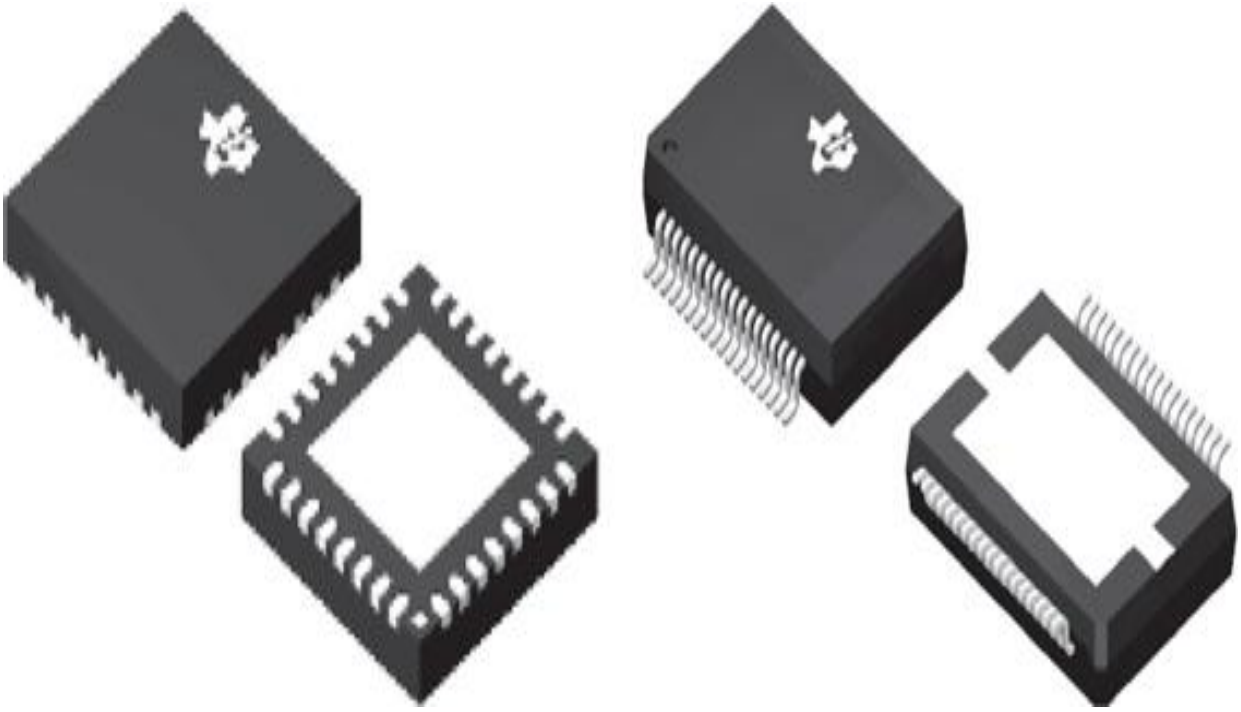

FIGURE 23.5 Two package types with exposed thermal “slugs” on the bottom of the package intended to be soldered to thermal spreading elements on the PCB.

Large thermal spreading elements that must be soldered to the PCB can sometimes present manufacturing problems. Improper control of solder paste leading to too much paste under these large thermal pads can result in “floating” the components on a pool of molten solder during reflow. When this happens, continuity yield suffers as the package tends to tilt one way or the other, lifting high side leads off their solder lands. Some users faced with this problem eliminated the solder between the exposed thermal pad and PCB, which led to high operating temperatures and severely degraded reliability in the field. The solution to the floating package problem is to optimize the solder paste volume, not to eliminate the thermal conduction path to the PCB. Always connect thermal management features of electronic components to the appropriate thermal collection pattern, which should then be connected through thermal vias into a

thermal plane. Failure to do so will result in devices not running at the expected thermal efficiencies.

Figure 23.6 shows the impact of thermal spreading plane area on the thermal performance of a 12- × 12-mm chip scale package (CSP) BGA-type package with 49 thermal balls. When the thermal plane size is small, the thermal performance is poor, whereas when the thermal plane size is large, the thermal performance improves by a factor of two or more. Often, suppliers of components with exposed thermal attach pads will also provide guidance as to the recommended size and shape of the thermal planes. It is best to ensure that the maximum plane area be close to the component; there shouldn’t be a large thermal resistance getting from the component into the plane. Maximize the area of the thermal spreading planes to maximize thermal dissipation.

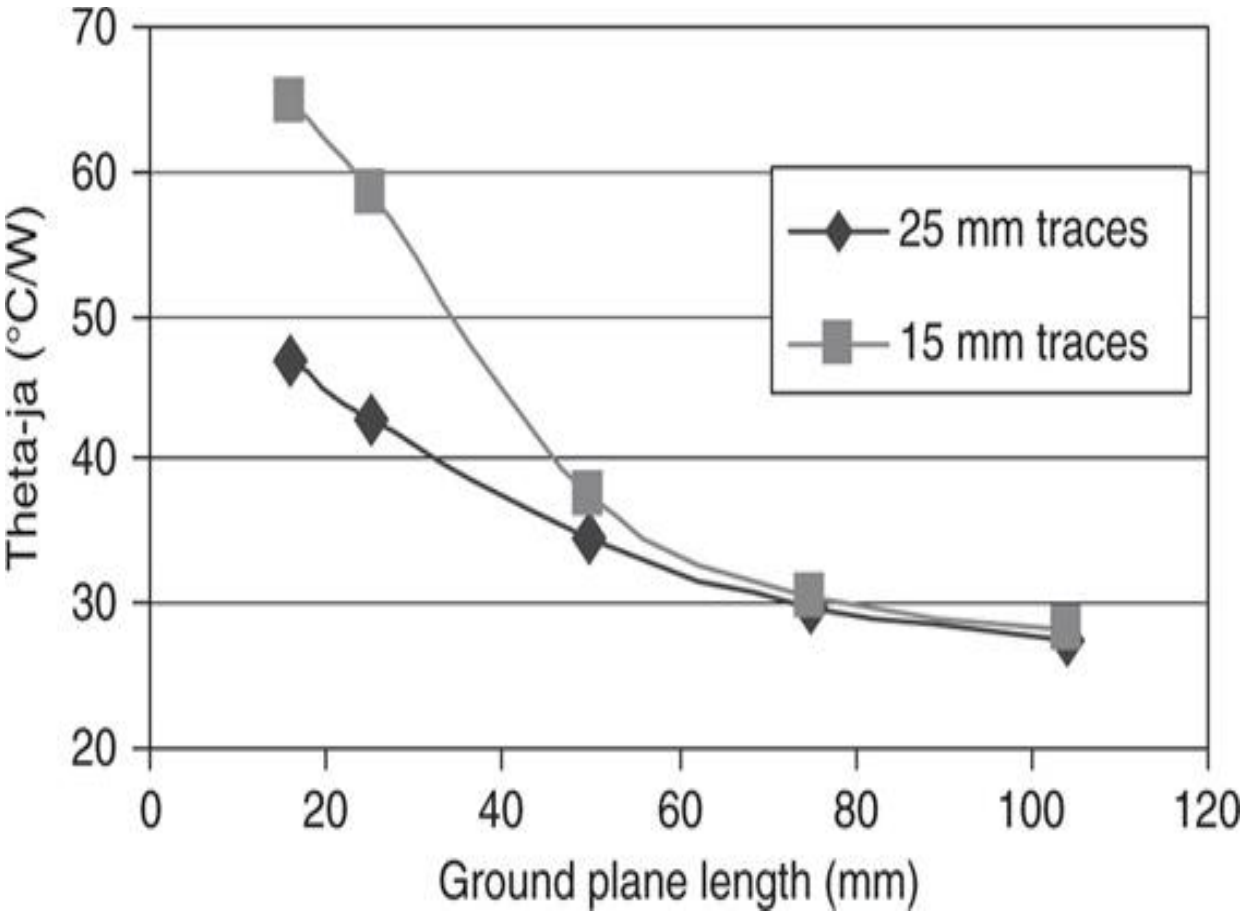

FIGURE 23.6 The effective θ_{ja} of a 12- × 12-mm chip scale package (CSP) with 49 thermal balls as a function of the (x, y) length of a continuous thermal plane under the package. Two trace lengths were assumed, showing different amounts of coupling of heat from the traces into the plane.

It is important to point out that the plane must be continuous, that is, with few or no isolation breaks in the Cu area. Since the thermal conductivity of Cu is about 1000 times higher than that of the FR-4, a 1-mm FR-4 break in a plane offers about the same thermal resistance as a 1000 mm span of Cu. A model result showing the impact of an electrical path break in a thermal plane is shown in Fig. 23.7. Here, a small 7- × 7-mm device with an exposed solder pad was intended to be cooled by a specific size of PCB area. However, due to electrical constraints, a 0.25-mm electrical noise isolation break was placed halfway down the plane to produce a quiet island. The PCB designer didn't think this

would have much impact, but thermally, it cut the plane size by half. As shown in the figure, there was a 29°C temperature drop across this single 0.25-mm break in the thermal plane and the component temperature increased by 33°C. For best thermal performance, don’t hamper thermal spreading in a thermal plane with continuous electrical isolation cuts.

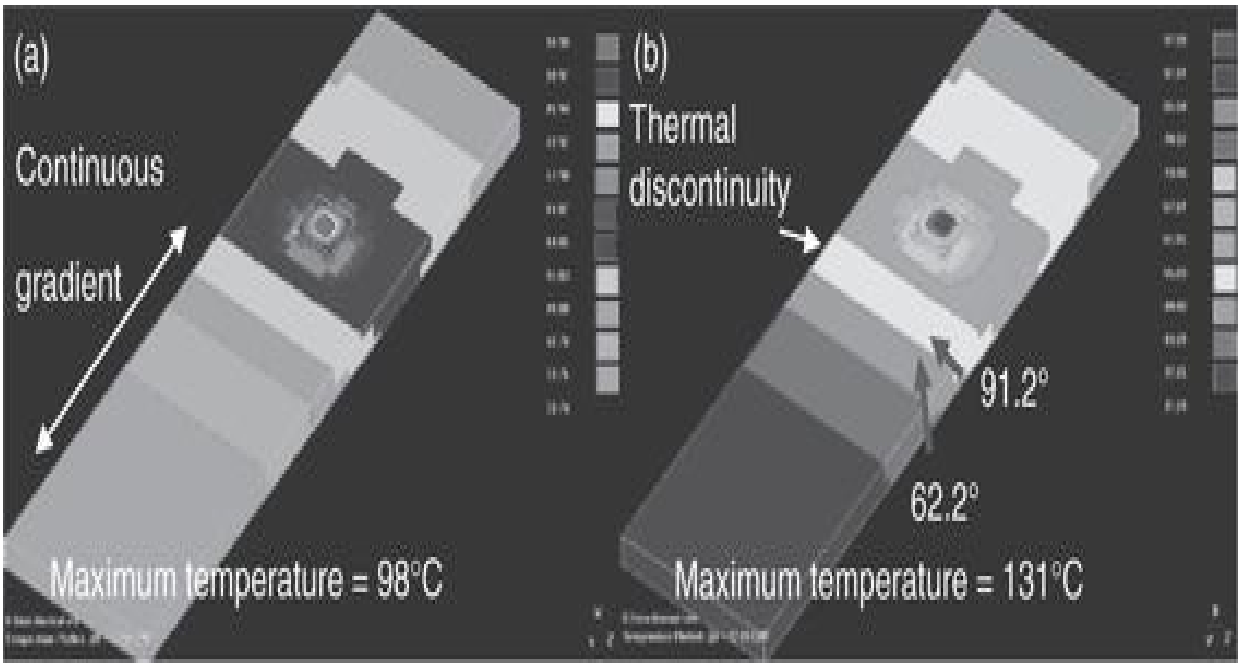

FIGURE 23.7 Thermal contours of a component on an isolated section of PCB in two configurations: (*a*) with a solid thermal plane over the section of PCB, (*b*) with a 0.25-mm electrical isolation zone in the thermal plane. The isolation zone increased the component temperature by 33°C.

Sometimes, the overall thermal performance of a PCB can be enhanced by carefully utilizing isolation cuts in the PCB to thermally segregate components that can afford to run at higher operating temperatures. For example, if a series of power regulator components can operate at junction temperatures of 150°C but are dumping so much heat into the PCB that the digital components’ maximum junction temperatures are exceeded, it might be effective to cut the thermal plane between the power regulator components and

digital portion of the PCB. This design technique will cause the temperatures of the power components to rise, but will lower the temperatures of the digital components. Of course, care must be taken to ensure the Cu connecting to the power regulation devices can carry the required current, so judicious application of this design technique is advised.

For the best spreading performance, the thickest possible Cu should be used in the construction of the thermal planes. If a thermal plane is to be 0.5 oz Cu thickness (23.8 µm), it is wise to double this plane with another thermal plane, giving an effective 1 oz layer of Cu to spread the heat over the PCB surface. Little additional advantage is gained when the thickness of all planes for spreading thermal energy is greater than 2.8 oz Cu.

23.3.3 Thermal Vias

Thermal vias are simply those that connect the thermal lands or thermal collection plates to the thermal planes. They are formed using the same processing techniques that are used for the PCB's electrical vias. However, unlike electrical vias, the primary intent of a thermal via is that it conducts thermal energy efficiently into the thermal planes. As such, a number of conditions should be met:

- There should be at least one thermal via associated with each thermal ball of a BGA package.
- The density of thermal vias under a thermal landing should be maximized within the limits of what can be allowed without degrading the PCB mechanical integrity.
- If the PCB uses through hole vias, the plating thickness should be maximized to optimize thermal conduction.
- If the PCB uses build up technology and nested vias are possible, nested vias should be used to connect to the thermal plane.

- If the PCB uses build-up technology but nested vias are not allowed, the shortest possible path between vias should be used to route the thermal energy into the spreading planes.

Figure 23.8 shows the proper way to connect thermal vias to power or ground planes. A web or spoke via connection is not recommended, as either constricts heat flow into the thermal plane. The exit side of the thermal via should have a Cu ring to anchor it to the PCB. Common thermal via dimensions for exposed pad packages are 1.0 to 1.2 mm center-to-center spacing, 0.3-mm drill diameter, with 0.025-mm Cu plating thickness or higher. Through hole thermal vias should be filled with solder, epoxy, or solder mask to avoid wicking solder from the thermal joints or thermal balls that might otherwise create an open or a reliability hazard.

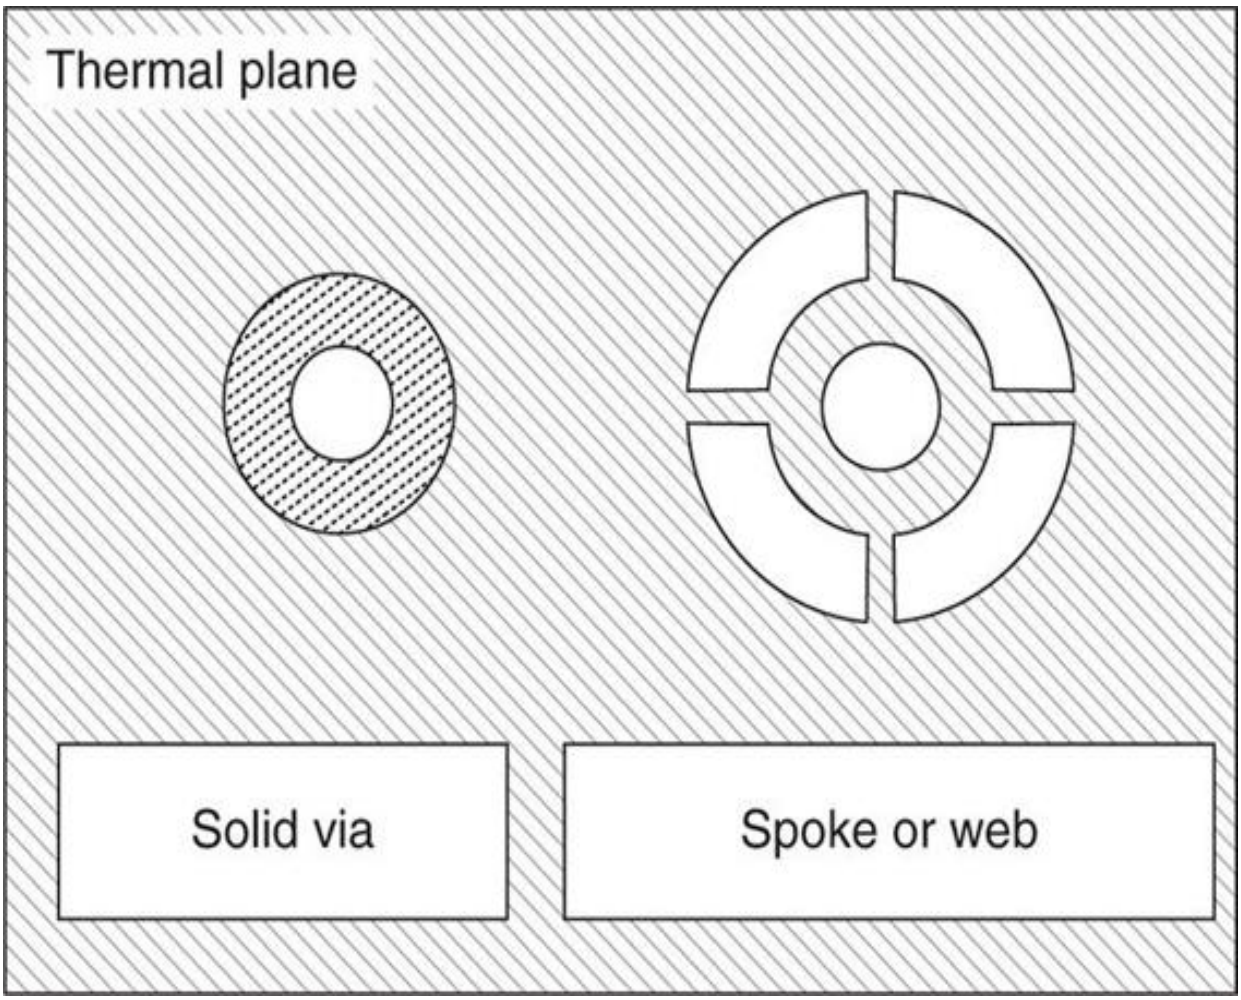

FIGURE 23.8 An illustration of two possible thermal via connections to the thermal spreading plane. The first via is a solid connection, which is recommended. The second via connection is made with a spoke or web connection to the thermal plane. This is not recommended for a thermal via.

The thermal resistance of an individual thermal via can be easily calculated from the via diameter, the via plating thickness, and the via length between the thermal land and thermal plane using Eq. (23.3).

$$\theta_{via} = \frac{l_{via}}{k * \pi * \left(\left(\frac{\text{diameter}_{via}}{2} \right) - \left(\frac{\text{diameter}_{via} - (2 * T_{plating})}{2} \right)^2 \right)} \tag{23.3}$$

where θ_{via} = the via's thermal resistance (°C/W)

k = the thermal conductivity of Cu (W/mm-°C)

diameter_{via} = the via's drill diameter (mm)

$T_{plating}$ = the Cu plating thickness in the via (mm)

l_{via} = the via's length between the thermal land and thermal spreading plane

Substituting some typical values such as a drill diameter of 0.3 mm, a plating thickness of 0.025 mm, a via length of 0.38 mm, and a thermal conductivity of 0.389 W/mm-°C, the typical thermal resistance of a thermal via is found to be 45°C/W. Since a thermal resistance is analogous to an electrical resistance, equations for calculating parallel resistance can be used to calculate the effective thermal resistance of a thermal via array. Using Eq. (23.4) below, a 4 × 4 array of vias is found to give a thermal resistance of 2.8°C/W. It is evident that the thermal performance of a component can be optimized with a relatively small number of thermal vias [see Eq. (23.4)].

$$\frac{1}{R_{\text{total}}} = \sum_{i=1}^{n} \frac{1}{R_i} \tag{23.4}$$

where R_{total} = the total resistance of the via group

R_i = the resistance of each individual via

Evaluating the thermal via resistance as a function of trace plating variability, a 0.015-mm-thick plated via with the same dimensions as the preceding will have a thermal resistance of 73°C/W. Thus, the thermal performance of a PCB is sensitive to variations in the plating thickness of its thermal vias. To ensure thermal via performance, the plating thickness in the via should be checked. This is usually performed by parallel polishing down from the surface of the

PCB rather than through a cross-sectional polishing of the via. When cross-sectioning a via, if sectioning plane does not intersect the exact center of the via, an incorrect plating thickness will be measured; this problem does not occur when parallel polishing into the depth of the PCB.

23.3.4 Component Spacing on the PCB

There is a finite spreading thermal resistance to any PCB as a function of its thickness and the number of planes in the PCB. Eq. (23.5) is a simple equation to calculate the in-plane thermal conductivity of a PCB as a function of the spreading plane thicknesses versus the FR-4 material layers. For example, if a 1.57-mm-thick FR-4 board has a single solid thermal spreading plane that is 0.036 mm thick, the effective in-plane thermal conductivity of the plane is 8.9 W/m-°C. This is substantially lower than the thermal conductivity of pure Cu, which is 386 W/m-°C. Therefore, thermal spreading through the PCB with a single plane will be worse than thermal spreading through a plate of Cu with the same thickness as the PCB.

$$k_{\text{effective}} = \frac{\sum_i k_i t_i}{\sum_i t_i} \tag{23.5}$$

where $k_{\text{effective}}$ = the PCB's effective in-plane thermal conductivity
k_i = the thermal conductivity of the ith layer
t_i = the thickness of the ith layer

The net effect of the limited spreading resistance of a PCB is that component temperatures will rise as they are clustered more tightly on a PCB of a given size and

construction. For example, Table 23.2 shows the maximum component temperature of four small devices on a 100- × 100-mm PCB containing two buried planes. As the components were moved closer to each other, the device temperatures increased from 81.6 to 98.4°C, representing an increase of 30 percent compared to the ambient temperature of 25°C. To make the best use of a PCB as a heat sink spreader, the power of individual components should be distributed as evenly as possible on the PCB to minimize hot spots.

TABLE 23.2 Case Example of Component Temperature versus PCB Spacing

Component Spacing, mm	Maximum Temperature, °C
50	81.6
25	84.4
12.5	92.9
8	98.4

The location of a component with respect to the air flow is also important. As air flows across power sources on a PCB, it picks up heat and increases in temperature. Components in the air flow downstream from high-power devices are heated by the warmer air. Air temperatures can easily rise 10 to 30°C just past a high-powered component such as a microprocessor, power amplifier, or power regulator block. If a component is running too hot, one possible solution is to move it as far upstream in the air flow as possible such that it receives the coolest air.

23.3.5 Thermal Saturation of the PCB

When the power of individual components has been evenly distributed over the PCB surface such that further geometrical rearrangement of the components or further optimization of the trace and thermal plane design is ineffective in cooling the components, thermal saturation of the PCB is said to have occurred. At this point, the power dissipation capability of the PCB becomes the factor limiting the component temperatures. The maximum power dissipation of a PCB with good thermal planes and evenly distributed power sources is in turn limited by a number of geometrical and system-level factors. These include

- The air stream velocity
- Any air ducting or shrouding around the PCB
- The configuration of heated surfaces around the PCB
- The altitude at which the PCB is operating
- The orientation of the PCB with respect to gravity

Each of these parameters impacts either the convection or radiation from the PCB. Convection is the heat transfer mechanism whereby heat is removed from the PCB through conduction of thermal energy into the gas or fluid that surrounds the PCB. In a natural convection environment, the heating of the air around the PCB causes its density to decrease. In the presence of a gravitational field, the less dense air will rise, carrying away heat with it—fresh, cool air moves in to replace the heated air. In a forced-air environment, the heated air is “blown” away from the surface by cooler air, which in turn becomes heated through the conduction of thermal energy from the PCB. The heat removed from a surface of area *A* due to convection, either natural or forced, can be represented by the simplified one-dimensional Eq. (23.6).

$$q = hA(T_{\text{surface}} - T_{\text{ambient}}) \qquad (23.6)$$

where q = heat
h = convection coefficient
A = surface area
$T_{surface}$ = the average temperature of the surface
$T_{ambient}$ = the temperature of the ambient air

Equations to calculate the convection coefficient *h* are beyond the scope of this chapter. Convection is a function of (1) the PCB size, with smaller PCBs having higher convection efficiencies; (2) the PCB orientation, with vertical PCBs being more efficient; (3) altitude, with lower altitudes being more efficient than higher altitudes; and (4) air ducting, with ducting tending to make the PCB more efficient in forced air environments.[4]

Radiation is the removal of heat from a surface by the emission, or “radiation,” of photons. These photons are generated when thermally excited atoms collide with each other, resulting in overlapping electron energy states. Since electrons are fermions, meaning no two electrons can occupy the same energy band, when the energy states of two electrons overlap during the collision, one electron is forced into a higher, empty energy state. This reduces the momentum of the colliding atoms, ensuring that energy is conserved. After collision, the displaced electron decays back to its initial energy state, giving up a photon of energy in the process. At the surface of the object, this photon is emitted, carrying away some of the thermal energy, while in the bulk of the material, this photon is reabsorbed by neighboring atoms. The simplified one-dimensional equation that describes the total energy loss from a surface due to radiation is shown in Eq. (23.7). This equation for radiation neglects heat that the PCB might reabsorb from heated objects such as power supplies around it, but does include an ambient temperature radiation reabsorption.

$$q = \varepsilon \sigma A(T^4_{\text{surface}} - T^4_{\text{ambient}}) \tag{23.7}$$

where q = heat

ε = the emissivity of the surface

σ = the Stefan-Botzmann constant (5.67×10^{-8} W/m^2-K^4)

T_{surface} = the PCB surface temperature

T_{ambient} = the ambient temperature

The emissivity of the object is a unitless number that describes how efficiently a surface radiates. It varies from 0, which is a surface with no radiation that is perfectly reflective, to 1, which is a perfectly radiative and absorptive black surface. The emissivity of the surface is a function of both the type of material that composes the surface as well as the roughness of the surface. Typical solder mask material has an emissivity ranging from 0.85 to 0.95. Typical exposed Cu trace has an emissivity ranging from 0.1 to 0.3 depending on the roughness and oxidation condition of the Cu.

It is important to note that the area of the PCB plays a major role in both of these equations. This is intuitive; the larger the PCB, the more heat it can dissipate. In combination, the preceding equations can be used to estimate the power that a given PCB at a given temperature can dissipate. For example, Fig. 23.9 shows the best-case power that can be dissipated by a series of PCBs ranging in size from 10 × 10 cm to 20 × 20 cm. The PCBs were assumed to be oriented horizontally in an unobstructed natural convection environment of 25°C with no significant neighboring radiating surfaces. Convection was allowed to vary as a function of temperature. Most importantly, the power was assumed to be uniformly distributed over the PCB such that there were no thermal gradients on the PCB. This is a major assumption, meaning that the power dissipation figures in the chart are best-case, a condition that no

practical PCB will attain. The chart indicates that 50 W can't realistically be dissipated in natural convection from a PCB that is 10 × 10 cm, but it can be dissipated by the 15 × 15 and 20 × 20 cm PCB. The 15 × 15 cm PCB will rise 80°C above the ambient to dissipate 50 W, while the 20 × 20 cm PCB will rise only 50°C to dissipate the same power. This graph has been formatted to look the same as typical heat sink curves that are available from many vendors.

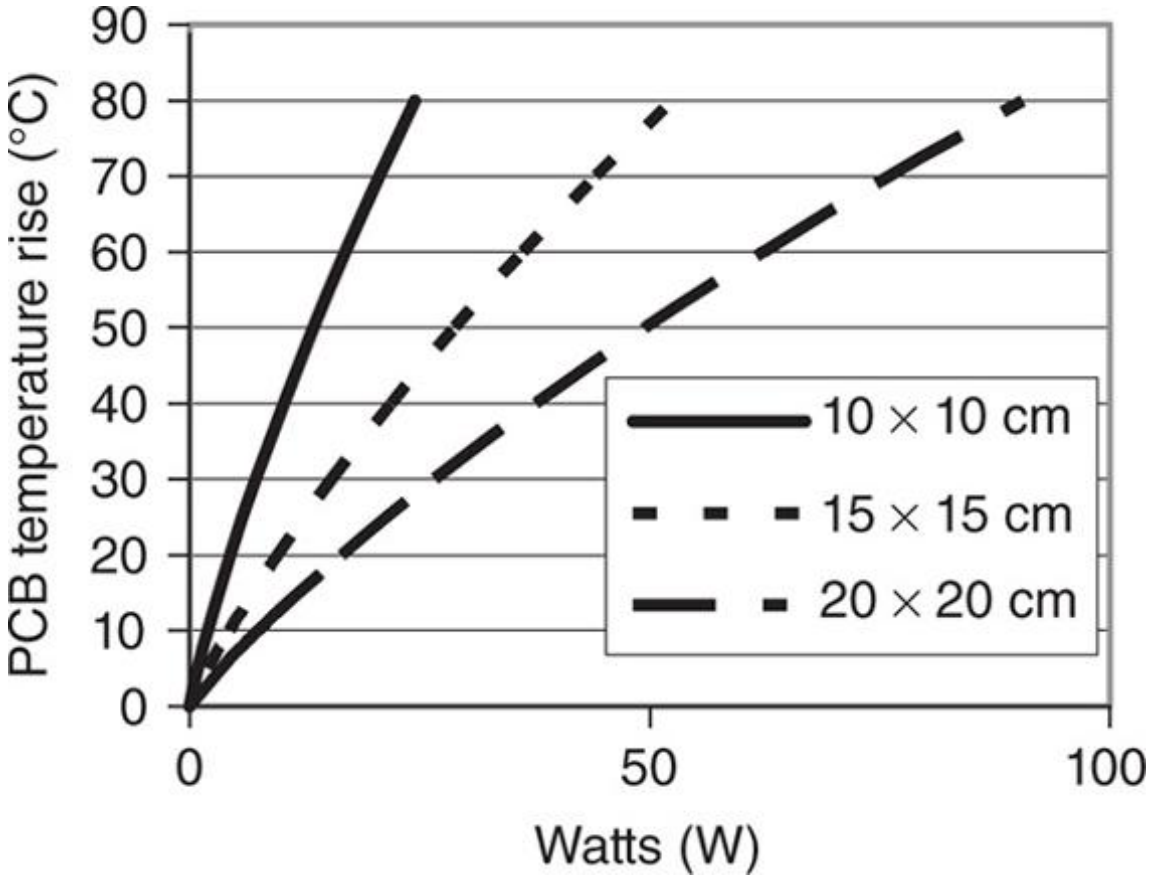

FIGURE 23.9 Temperature rise above 25°C of a horizontal PCB in natural convection as a function of PCB size and power dissipation. Both convection and radiation are dissipating the power.

23.4 CONDUCTING HEAT TO THE CHASSIS

When the PCB is thermally saturated and the component temperatures are still too high to be tolerated at the maximum obtainable system air velocity, other means of conducting heat from the PCB to even larger area system structures are required. The chassis of the system is often the largest surface area structure in the system, is exposed to the ambient air, and often makes a good sink for heat that cannot be dissipated by the PCB alone. Mechanisms to conduct heat into the chassis include chassis screws, gap fillers, connectors, and side rails. Sometimes, radio frequency (RF) shields that are appropriately connected to components can provide additional heat sinking.

23.4.1 Chassis Screws

A properly designed chassis screw thermal sink connection in a PCB includes connection to the thermal spreading plane of the PCB, through hole plating, and a thermal contact area for the screw and stand-off sleeve to clamp onto. This configuration is shown in Fig. 23.10. The thermal screw should be as close to the hot electronic component as possible to minimize thermal resistance into the chassis. As well, the chassis where the thermal screw attaches should have a high thermal conductivity to spread the heat away from the screw. Preferably, the chassis should be made of metal. If a plastic chassis is used, molding a plate of aluminum (Al) into the plastic will improve its thermal heat spreading capability. A plastic chassis alone is usually a poor thermal spreader and may not provide substantial thermal performance enhancement.

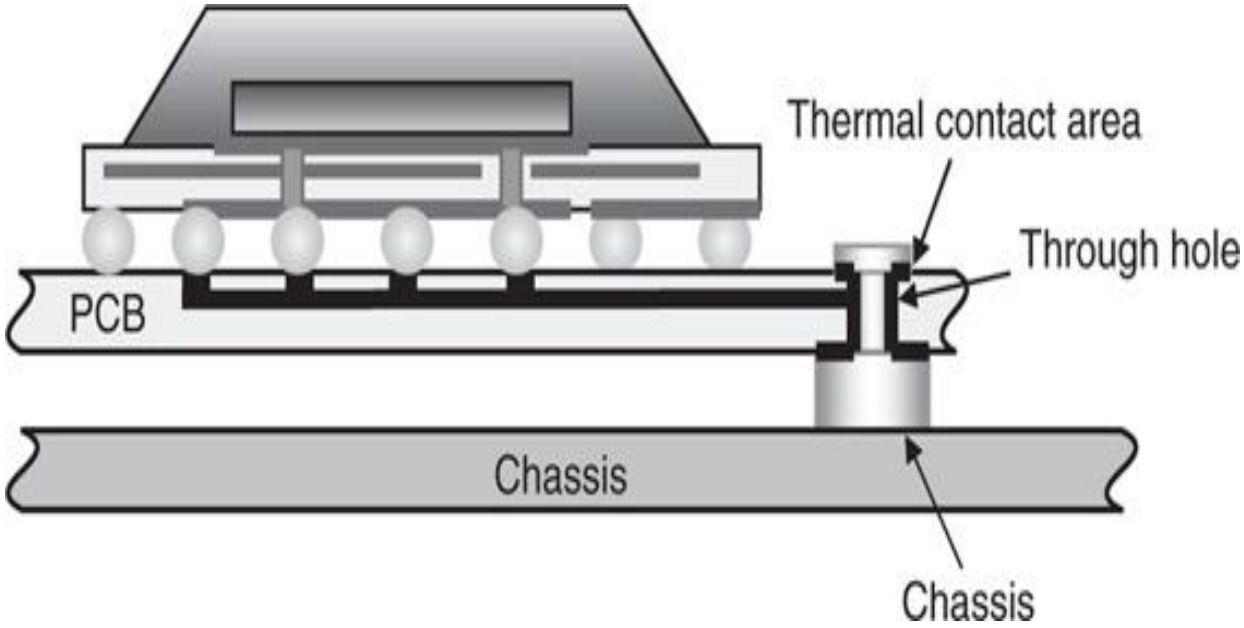

FIGURE 23.10 Schematic of a chassis screw implementation for sinking heat to the chassis. The thermal screw mounts through a plated through via that is shorted to the thermal plane as shown. The thermal plane conducts heat from the thermal balls of the PBGA package.

How much improvement might be expected from using the chassis of an enclosure for cooling? This depends substantially on the enclosure construction and the location of the chassis screw with respect to the hot component. In one example, a device was cooled with a thermal screw that connected between a hard drive PCB and the hard drive enclosure. Connecting the device thermally to the hard disk drive resulted in a 10 percent thermal enhancement.

23.4.2 Gap Fillers

It is sometimes not possible to use screws for conducting heat to the chassis. In other cases, large areas of high-power density might need to be sunk into the chassis. In these instances, another type of thermal conduction path is available that lends itself to conducting heat to the chassis: gap fillers. Gap fillers are thermal compounds that fill the gap between the PCB and chassis whose sole purpose is to

conduct heat to the chassis. There are many different types of gap fillers. The most common is a soft, flexible silicone rubber material that has been filled with thermally conducting particles to enhance its bulk thermal conductivity. Sometimes, thermally filled foams are used. When the soft, compliant material is compressed between the PCB and chassis, it conforms to the protruding components on the PCB, making a good thermal connection. Important criteria to consider in selecting elastomeric gap fill materials are the thickness needed, the thermal conductivity required, and the pliancy of the material. A variety of materials with varying compositions are readily available on the market. There is normally a trade-off between the pliancy of the material and the thermal conductivity, with higher thermal conductivity materials exhibiting less compliancy.

Plastic sacks filled with a thermal fluid are sometimes used as gap filler materials. The fluid is usually optimized to produce convection in the gap of interest. The convection in the fluid can give an effective thermal conductivity that is substantially higher than the conductivity of the fluid alone.

23.4.3 Connectors

Connectors can either provide a direct or indirect means of conducting heat from the PCB. Direct conduction occurs in those system configurations where the PCB is plugged into an edge connector or back plane socket, or is held in place with an edge guide. To take advantage of these direct connect thermal features, it is necessary to extend thermal planes into the areas where the connection or clamping occurs. The connector, clamping, or edge guide should have as large a contact area as possible to optimize thermal conduction of heat from the low thermal conductivity PCB material. In some military applications, the PCB is built

around a thick Cu core that is clamped by the edge rail of the card cage. The thick Cu core provides very effective thermal conduction from the PCB into the edge rail, which is then cooled by a system of channels containing either moving air or moving water.

Indirect conduction of heat from the PCB can occur when cables are plugged into connectors on the PCB. These indirect conduction paths are much harder to include accurately in system-level thermal analyses, but can provide some margin in a PCB thermal design. Care must be taken, however, to ensure that these plug-in cables don’t block critical airflow paths that would lead to overheating.

23.4.4 RF Shields

RF shields are used over sensitive RF and analog circuits to minimize electrical interference with the circuit function or to minimize electrical radiation from the circuit into the surrounding environment. RF shields are usually made of a thin metal which is soldered to ground on the PCB. In most instances, the RF shield is a continuous plate or box that encloses the circuits. Unfortunately, this continuous box creates a dead zone in the air flow directly above the components within the box, degrading natural convection for those components. To enhance the thermal performance of components within RF shields, perforations or meshing of the RF shield cage is recommended. If these perforations are kept less than 1/10 the wave-length of the shielded electromagnetic radiation, the RF shield will function adequately to quiet the circuit and block out extraneous signals while allowing air flow through the shield to cool the interior components.

If additional steps are taken, the shield can be used to spread heat from hot components inside the shield over a larger section of the PCB, thereby maximizing convection

and radiation cooling for the heated components. Figure 23.11 shows a schematic of a shield over a stacked package component. It is normally difficult to conduct heat from the top device in such a stack to the PCB, but when the RF shield is brought into contact with the top device, heat can conduct into the shield and down to the PCB. It is suggested that the thermal connection between the shield and the electrical components be made with a thermal epoxy or thermal grease after the shield is soldered in place to avoid issues with mechanical tolerances or interference between the shield and the components. If the high-powered components to be cooled reside immediately outside the shield, it is possible to conduct heat from them into the shield such that the shield behaves as a heat sink.

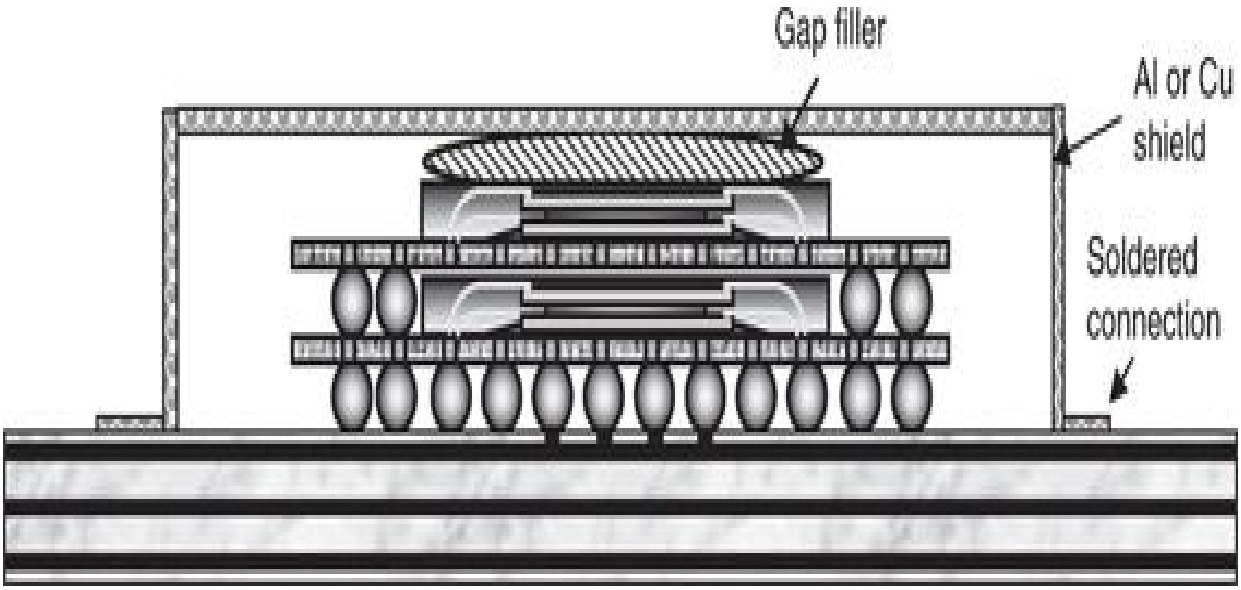

FIGURE 23.11 A stacked package configuration on a PCB with a perforated RF shield that is being used to spread heat from the top package. Thermal gap filler material such as thermal grease is used to conduct the heat from the top package into the RF shield.

23.5 PCB REQUIREMENTS FOR HIGH-POWER HEAT SINK ATTACH

Most IC components with power dissipations of 2.5 W or higher require attached heat sinks to dissipate the power. These heat sinks are often glued or clamped to the components with few special constraints placed on the PCB. If a large number of components requiring heat sinks are placed on the PCB, it is important that the PCB be thick enough to handle the weight of the attached heat sinks, especially if the system environment subjects it to vibration or mechanical shock. High-powered components in the 50 to 300 W range require special PCB design features to handle the high-loading force of the heat sink against the electronic component. Clamping forces of 20 to 200 lb are possible for these high-power heat sinks in order to get the best possible thermal contact between the heat sinks and components. One such high-power heat sink configuration is shown in Fig. 23.12.[5] Here, the heat sink is spring loaded against the package with tensioned screws which tighten into a bolster plate. The bolster plate provides the rigidity needed to avoid bending and damaging the PCB under the spring loading. A mylar film between the bolster plate and PCB minimizes electrical shorting of the fixture to the PCB. For such heat sink constructions to work, no components can be placed between the PCB and bolster plate.

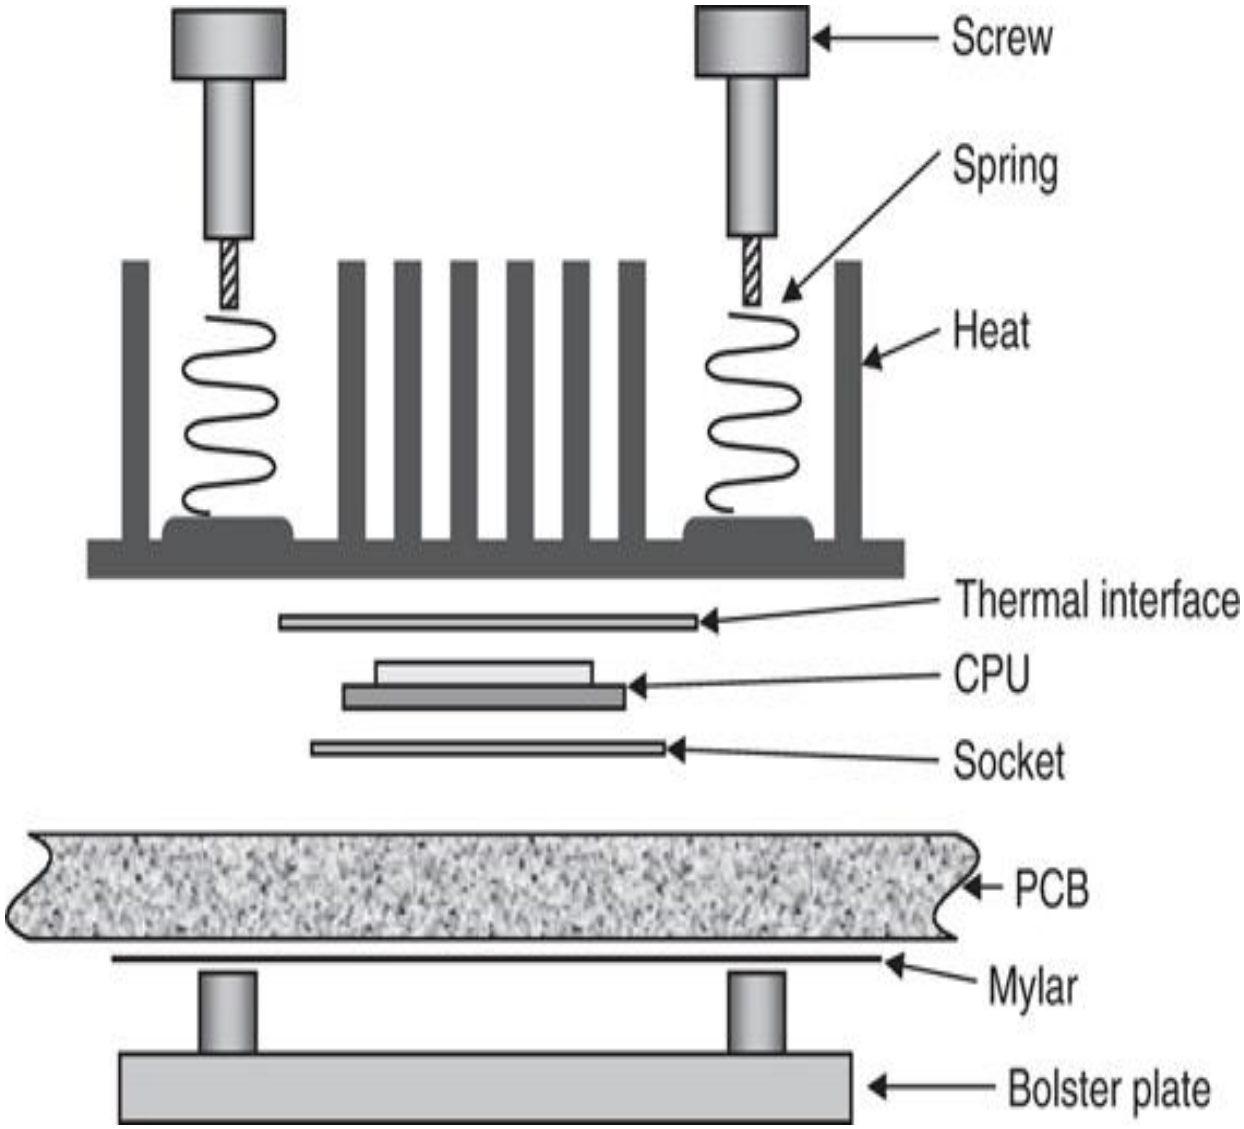

FIGURE 23.12 Cross section of a mechanical design for a high-power heat sink clamped on a microprocessor. The bolster plate on the bottom of the PCB minimizes PCB warpage and breakage.

23.6 MODELING THE THERMAL PERFORMANCE OF THE PCB

Each of the many PCB thermal optimization techniques described in this chapter will have some amount of impact on the thermal performance of the system. Determining the relative impact of a single optimization is difficult to perform

analytically. When an entire ensemble of optimization techniques is employed across multiple devices operating at a variety of powers, analytical solutions of the thermal problem become impossible. The simplicity of system-level temperature calculations implied by Eq. (23.1) is misleading unless the effective θ_{ja} of each component in the specific system is known a priori. Since the impact of the PCB design on the thermal performance of the system must be determined before design completion and tooling, the question becomes how to quantify the impact of the PCB thermal features. Relayout and redesign of the PCB to fix thermal issues once tooling is generated is prohibitively expensive and leads to noncompetitive design cycle times. The only predictive method currently available that addresses this need is computer simulation, which can incorporate all relevant PCB design features, perform a thermal analysis, and report back the component temperatures to identify problem locations.

Many commercial computer simulation tools exist, ranging in complexity, accuracy, and cost. Computational fluid dynamics (CFD) programs incorporate equations that solve the problems of air flow around the PCB, thermal conduction from the PCB into the air, and thermal conduction within the PCB. Solutions using CFD don’t require special knowledge of convection coefficient equations, thereby making the modeling process easier and less prone to convection coefficient calculation errors. Accuracy of CFD analysis can be as high as ±5 percent. CFD codes tend to be slow, however, taking substantial computer resources to run a reasonably complex model. A step down from CFD are codes that employ user supplied convection coefficients that are applied to the PCB and component surfaces. These solutions can be quite accurate, though no more than ±10 percent precision can be projected without substantial correlation to experimental data.

Whichever analysis code is selected, it should be capable of reading in data from the user's PCB layout tool and should be capable of incorporating the specific thermal conduction paths that were optimized for component performance. It should be able to handle relatively complex system-level structures and should be capable of inputting a variety of thermal characteristics of the components. Postprocessing identification of PCB regions and components above limit temperatures is a plus. The code should run fast enough to enable multiple design iterations to optimize the PCB layout without slowing down the design cycle.

23.6.1 System-Level Thermal Modeling Phases

System-level thermal analysis normally includes three phases due to the complexity of the task and the difficulty of inputting a fully detailed system design into a tool. The first phase concentrates on airflow optimization through the system to minimize any dead zones in the cabinet. The PCBs, cables, fans, and other air blockages are included in the analysis during this phase. The second phase includes dissipation of power on the PCB by applying power areas to the PCB. During this phase, it is fairly easy to change locations of power sources to optimize the air cooling paths. The final phase is the fully detailed phase, which includes the PCB layout geometries and details of the electrical components. By the time phase three is reached, there should be few remaining major iterations for thermal optimization.

During each phase of thermal modeling, the solids of the components, PCB, and system enclosure must be defined to the code. These solids are meshed by the code, a process through which the objects are broken into tens of thousands of discrete nodal points. The computer calculates thermal

parameters such as temperature and heat flow at each of these nodal points as a function of neighboring nodal points rather than trying to solve analytical equations for the thermal fields. If the meshing is fine enough, the calculated solution will be very accurate. If the meshing is too coarse, errors will creep into the model. There is a trade-off between accuracy and run time in computer simulations; models with coarser meshes usually run much faster than models with fine meshes. It is best for users to become familiar with the mesh sensitivity of their chosen modeling tool to optimize run time versus accuracy before running critical analyses.

When performing a CFD system-level analysis to determine temperatures on a PCB, it is important to include all airflow obstructions that might change the convection on the PCB and its components. Common airflow obstructions include cables, RF shields, daughter cards, brackets, air filters, capacitors, transformers, memory single in-line modules (SIMs), power regulators, and hard drives. Failure to include these air blockages in the modeling process can result in systems that run too hot or that suffer from thermal shutdown. External blockages should be accounted for as well. Cabinet vents should not be located where a user might carelessly toss a magazine or CD cover. The impact of accumulated dust over the lifetime of the system should also be considered, as the dust can substantially reduce convection.

From a PCB layout standpoint, the highest velocity air stream on the board may well occur between two tall components if they block the airflow path. The blockage causes the air to be channeled through the gap, resulting in higher air velocities. High-power electronic components can sometimes be more effectively cooled by placing them in this channeled air stream. Locations to avoid for high-power components are the leeward side of air blockages, immediately downstream of high-power components, or on the bottom center of a natural convection-cooled PCB.

23.6.2 Required Component Thermal Parameters

Thermal models of a PCB loaded with detailed models of components in a system can become very complex with many nodes. Such analyses can run for days and weeks, making them impractical. As well, it is often impossible to get detailed models of each component to be used in a system. To address these issues, the industry has developed two levels of component thermal abstraction. The first method reduces the electrical component's thermal behavior to two thermal resistances, θ_{jc}, which represents the thermal resistance from the active portion of the component to the top component surface, and theta-*jb* (θ_{jb}), which represents the thermal resistance between the active portion of the component to a point on the PCB at the edge of the component. The component is then represented to the system as shown in Fig. 23.13. The thermal resistance from the top of the component to the ambient, R*a*, is calculated either through CFD or from the convection coefficients. It also includes radiation heat losses. Thermal conduction through the PCB to other components and to the air is calculated by the simulation tool. Accuracy of a two-resistor component thermal model temperature delta with respect to the ambient is in the ±20 percent range, even when using CFD. The parameters θ_{jc} and θ_{jb} are usually available in the component supplier's data sheets. If not, the supplier should be contacted for the information.

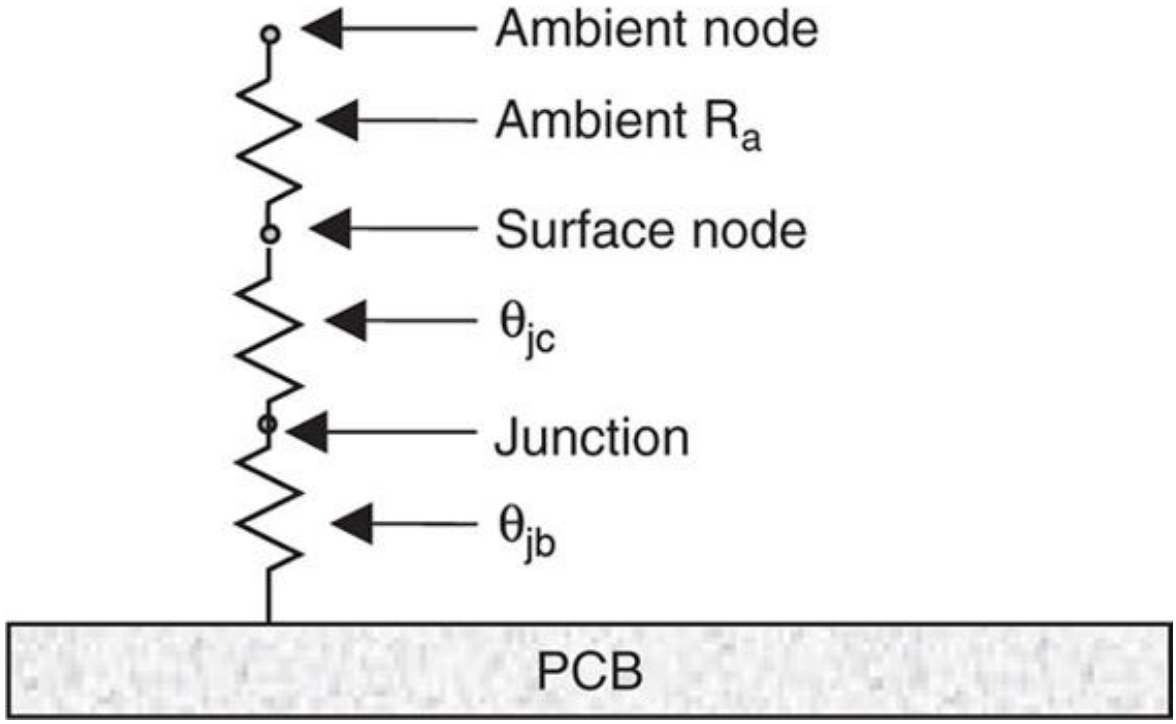

FIGURE 23.13 Thermal conduction representation of an electrical component by two thermal resistances, θ_{jc} and θ_{jb}. The resistance to ambient (R_a) is the result of convective and radiative heat loss.

A more complex modeling configuration has been developed to improve thermal estimations from ±20 percent to ±5 percent. Called a *compact model*, these resistor network topologies better represent heat flow within the package and from one side of the package to another. Compact models should therefore be used whenever they are available. Often, the system design engineer must ask the component supplier for them since they are not commonly printed in data sheets. Many tools allow the user to mix compact component models with the simpler two-resistor models.[6]

23.6.3 Handling Cu Traces and Power Planes

Due to the complexity of meshing the fine geometries of a PCB trace layout, many if not most modeling tools include the ability to “smear” Cu layers into solid sheets. A smeared layer is a single sheet whose average thermal conductivity is equivalent to the thermal conductivity of the detailed trace layer. Unfortunately, most tools use an incorrect averaging technique to determine the effective thermal conductivity of a layer. The tool asks for the percent Cu coverage in the trace layer. Based on this input, the tool then calculates the thermal conductivity of the trace layer as the weighted average between the Cu conductivity and the insulator conductivity. For example, if a 100 percent coverage of Cu layer has a thermal conductivity of 380 W/m-°C, a 95 percent coverage of Cu would have an effective conductivity of 360 W/m-°C, and a 0 percent Cu coverage layer would have a conductivity of 0.8 W/m-°C. Smearing in this fashion neglects critically important details such as isolation regions that might cut through thermal spreading planes. Therefore, trace smearing using a conductivity averaging scheme should be avoided.

If the modeling tool can’t represent the PCB in full complexity, some attempt should be made to perform a better estimation of the thermal conductivity in Cu spreading layers connected to critical components. The overall smeared thermal conductivity of the plate should be replaced with patches of thermal conductivity that account for heat flowing either parallel or perpendicular to the Cu conductors. Equations (23.8) and (23.9) can be used to estimate parallel and series thermal conductivities in Cu layers respectively. Figure 23.14 shows graphically what is meant by a parallel thermal conductivity. Here, multiple stripes of thermally conductive materials pass thermal energy from the top to bottom. Each material channel can be considered as a thermal resistor. The thermal resistance of each resistor can be calculated as a function of its cross-sectional area (thickness × width) and thermal conductivity,

and the effective parallel resistance can be backed out [Eq. (23.8)].

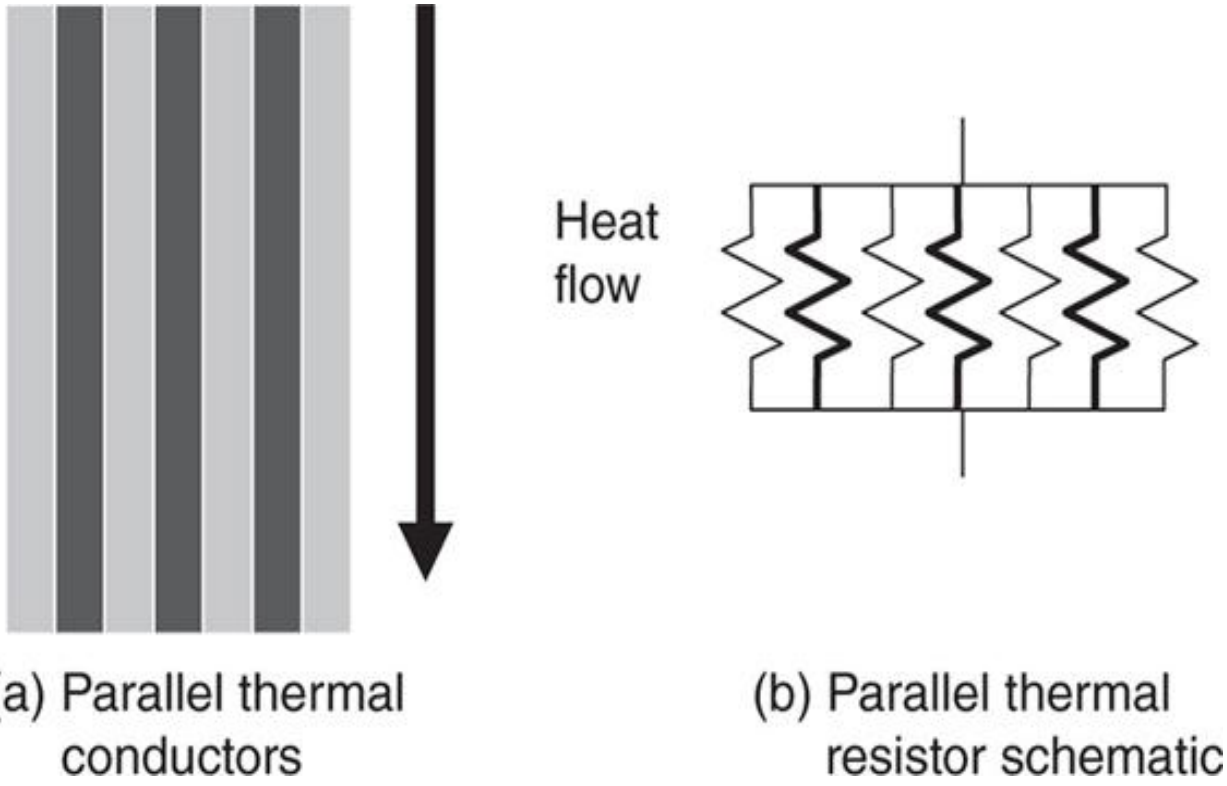

FIGURE 23.14 A diagram to illustrate how heat flowing along parallel conductors can be represented through electrical analogy to electrical resistors in parallel. The parallel resistance representation is used in the derivation of Eq. (23.8).

$$k_{\text{parallel}} = \frac{\sum_i k_i \cdot \text{Area}_i}{\sum_i \text{Area}_i} \tag{23.8}$$

where k_{parallel} = the effective thermal conductivity of a plate where the heat flows parallel to the conductors
k_i = the thermal conductivity of the ith material
area_i = the area of the ith material (thickness of stripe × width of strip)

In the case of series thermal resistances, the dimension of interest is the length of each section of material in the direction of the heat flow [see Eq. (23.9) and Fig. 23.14].

$$k_{series} = \frac{\sum_i \text{Length}_i}{\sum_i \frac{\text{Length}_i}{k_i}} \tag{23.9}$$

where k_{series} = the effective thermal conductivity of a plate where the heat flows perpendicular to the conductors

k_i = the thermal conductivity of the ith material

length_i = the length of the ith stripe parallel to the heat flow path

23.7 HEAT SOURCES

When performing any thermal analysis one must consider all the sources of energy into a system and how all the energy leaves the system. Thermal management of printed circuit assemblies (PCAs) involves assessing all the energy inputs and outputs. Components are the most common energy input. Although, traces and planes, connectors and sometimes energy input from other PCAs require consideration when evaluating a given design.

Many components need to be evaluated at both steady state and transient conditions. JEDEC standards address many of the conditions necessary to evaluate the heat transfer from the component junction-to-board in air environments. Unfortunately, this is not performed for components in a vacuum environments. The component junction-to-case thermal resistance is considered valid, more or less for vacuum environments, but the case-to-board thermal resistance is negatively impacted in vacuum compared to air environments. Conduction through the leads can be a large thermal resistance and must be evaluated on a component-by-component basis. In most cases, the

radiation losses between the component and board are assumed negligible.

Traces and planes can be a challenge to evaluate. Traces require more attention now than ever due to higher density designs and the introduction of IPC-2152, Standard for Determining Current Carrying Capacity in Printed Circuits. IPC-2152 introduced new conductor sizing charts that are used by PCB designers to size electrical conductors in printed circuit boards (PCBs). Many companies have not changed their design practices as a process from when they used the conductor sizing charts last published in IPC-2221.

Chapter 22 includes a history behind the IPC-2221 charts. It also discusses the difference that is observed between the IPC-2221 charts and new charts published in IPC-2152. One reason that electronics have not had heating issues as a result of trace heating is that the old charts used for sizing internal conductors was not only conservative, but it was not based on trace heating data. See Chap. 22 for further discussion. Circuit Board Designers, Electrical Engineers, Mechanical/Thermal Engineers and Managers should be required to understand these topics.

CHAPTER 24

EMBEDDED COMPONENTS[a]

Vern Solberg
Solberg Technical Consulting, Saratoga, California

24.1 INTRODUCTION

Historically, electrical components have been mounted on the outside of printed circuit boards (PCBs), either with through hole leads or with terminations all on a single side (surface mount) with the interconnection traces embedded inside the board. Technology, however, has been developed to embed electrical components inside the board also. The earliest component to be embedded were resistors, which are made by etching a pattern on a sheet of resistive material and then connecting them with the rest of the circuit through the standard multilayer process. In addition, capacitors are formed from thin dielectric material between closely spaced copper-foil planes, and inductor elements are formed by etching coils of the copper conductive foil during innerlayer manufacture. These fabrication techniques have expanded to include the ability to “place” very thin and small outline discrete passive components inside the board.

This allows the normal multilayer board pressing operation to encapsulate these placed components.

24.2 DEFINITIONS AND EXAMPLE

Components. The following are the electrical units that make up all electrical devices.

Passive components. These components––including resistors, capacitors, or inductors—influence electrical flow in a circuit, but do not cause a gain in current or voltage.

Active components. In contrast, these components can provide gain in an electronic circuit.

Integrated passive arrays. Multiple passive devices may be packaged in either a leaded or surface-mount technology (SMT) package or sometimes in arrays of all the same value. *Integrated passive component* is a general term for multiple passive components that share a substrate and packaging. Most typically, integrated passives are on the surface of a separate substrate that is then placed in an enclosure and surface-mounted on the primary interconnect substrate, in which case they are called *passive arrays* or *passive networks*. This chapter discusses only embedded components.

24.3 APPLICATIONS AND TRADE-OFFS

Embedding components are not appropriate for all electronic packaging. A board designer must consider several factors when deciding whether to use embedded components or not. Use of discrete components, whether on the surface or placed inside the board, involves incremental costs in that

the more components that are used, the higher the cost. However, the trade-off is that the cost of fabricating one formed embedded component is about the same as that of forming an entire layer of those components. Another factor to consider is that surface-mount components can have the same size and shape for widely differing electrical values. Formed embedded components on a single layer are larger and can increase electrical value. Widely differing electrical values may require more than one layer of embedded formed material.

24.3.1 Advantages

Advantages from embedding components inside the board include

Reduction in board area (enabler). Reduction in surface area results in more circuits per fabrication panel. Reduction in board size can yield a smaller board for the same functions, as components are now inside the board.

Increase in functionality, higher density (enabler). The surface area is the same, but some other function can be added. For example, the designer can increase cell phone capability by adding a Bluetooth connection to the ear piece receiver.

Improvement in performance (enabler). Higher speeds, shorter paths, and lower noise are possible. For example, cell phones can be enhanced with built-in digital cameras or even video cameras.

Improvement in total assembled costs. System cost is key; the higher board price is often offset by a lower bill-of-materials purchased for the system, as fewer standard components are needed.

24.3.2 Disadvantages

Disadvantages of embedding components include

- Quality can be affected; in particular, meeting tolerances can be more difficult.
- Trimming embedded resistors is slow and expensive.
- The design is “parametric” where designer sizes components.
- Technology implementation does not give all values needed.
- Some capacitance values are not obtainable commercially (>100 nF/cm^2).
- Manufacturers of sheet resistor materials make only one decade of values.
- The cost of prototypes can be high.
- Resistors cost the same whether one or thousands are made per layer.
- Test tools are lacking.
- Test voltages may cause dielectric breakdown.
- Charge-up time for capacitors may limit test speed.
- Rework is not possible inside the board.
- Additional capital investment is required.

24.3.3 Principles of Cost Trade-Off

The circuit design tools identify the resistors and capacitors that must be added to make an electronic circuit functional. The tools simulate circuit operation and “size” the resistors and capacitors as appropriate. Whether a resistor is purchased and mounted on the board surface or formed inside the board from a layer of resistive material has little effect on the electrical operation of a circuit. Therefore, if

many resistors can be formed inside the board from the same series of chemical steps, the inclusion of perhaps thousands of internal resistors costs no more than adding one internal formed resistor. The critical economic analysis is to find the cost of adding internal formed resistors and then dividing by the number that can be used internally to see whether embedded resistors inside the board make sense.

24.4 DESIGNING FOR EMBEDDED COMPONENT APPLICATIONS

24.4.1 Resistors

Resistors were the first component to be embedded in a multilayer board, making it a truly three-dimensional interconnection and circuit system. While early designs were custom for each application, over time design standards and “best practices” have been developed, which allow for successful inclusion of resistors, and other components, without the need to start from the beginning. The following discussion provides these for resistors, with subsequent. Sections providing similar information for other components.

24.4.1.1 Resistor Terminology. The designer must size embedded formed passive resistors. This is in contrast to the “library selection” of conventionally manufactured resistors that are selected from a table of available components. The principle of embedded resistors is given by the following formula for a term ohms per square; this means that any square area defined in the material will have the same resistance and that by grouping squares appropriately, the designer can define the resulting resistance.

Resistance in any resistor is determined by Eq. (24.1):

$$R = \rho L/A \qquad (24.1)$$

where R = resistance in ohms
ρ = resistivity
L = length of the resistor
A = cross-sectional area (resistor thickness times resistor width)

Note: Resistivity (ρ) is a material property. It is a constant at a given temperature and expressed in resistance units (ohms) for area and length. For example, the resistivity of copper is $\rho = 7.09\ e^{-7}\ \Omega\ in^2/in$.

Sheet resistance (R) is a commonly used term to describe raw materials used in embedded formed resistors. These materials are manufactured in sheet form with a constant thickness, giving a uniform R value for any square resistor. Therefore, the material is specified by its sheet resistance value, given in ohms/square (Ω/). Resistance of a specific resistor is simply designed by changing the ratio of length to width. For example, 100 Ω material forms a 100-Ω resistor in any square configuration while a resistor element that is three squares long by one square wide would be 300 Ω, as illustrated in Fig. 24.1. On the other hand, a resistor element that is two squares wide by one square long would provide a 50-Ω resistor element.

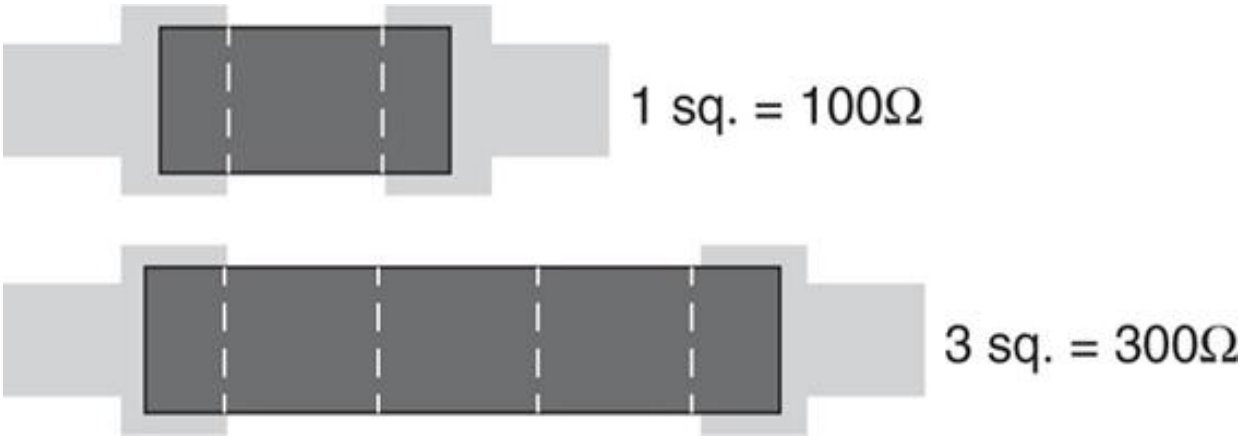

FIGURE 24.1 Printed resistor elements using 100-Ω ink or paste material.

24.4.1.2 Resistor Design Parameters. The circuit board designer is responsible for sizing the resistor to give the appropriate value. Material suppliers have given their sizing parameters to computer-aided design (CAD) software companies for entry in their component libraries. Additionally, the manufacturing tolerances for each supplier product have been communicated to computer-aided manufacturing (CAM) suppliers. Figure 24.2 gives typical design parameters for sizing both the active embedded formed resistor area and the termination pads for the traditional copper innerlayer upon which the resistor is built.

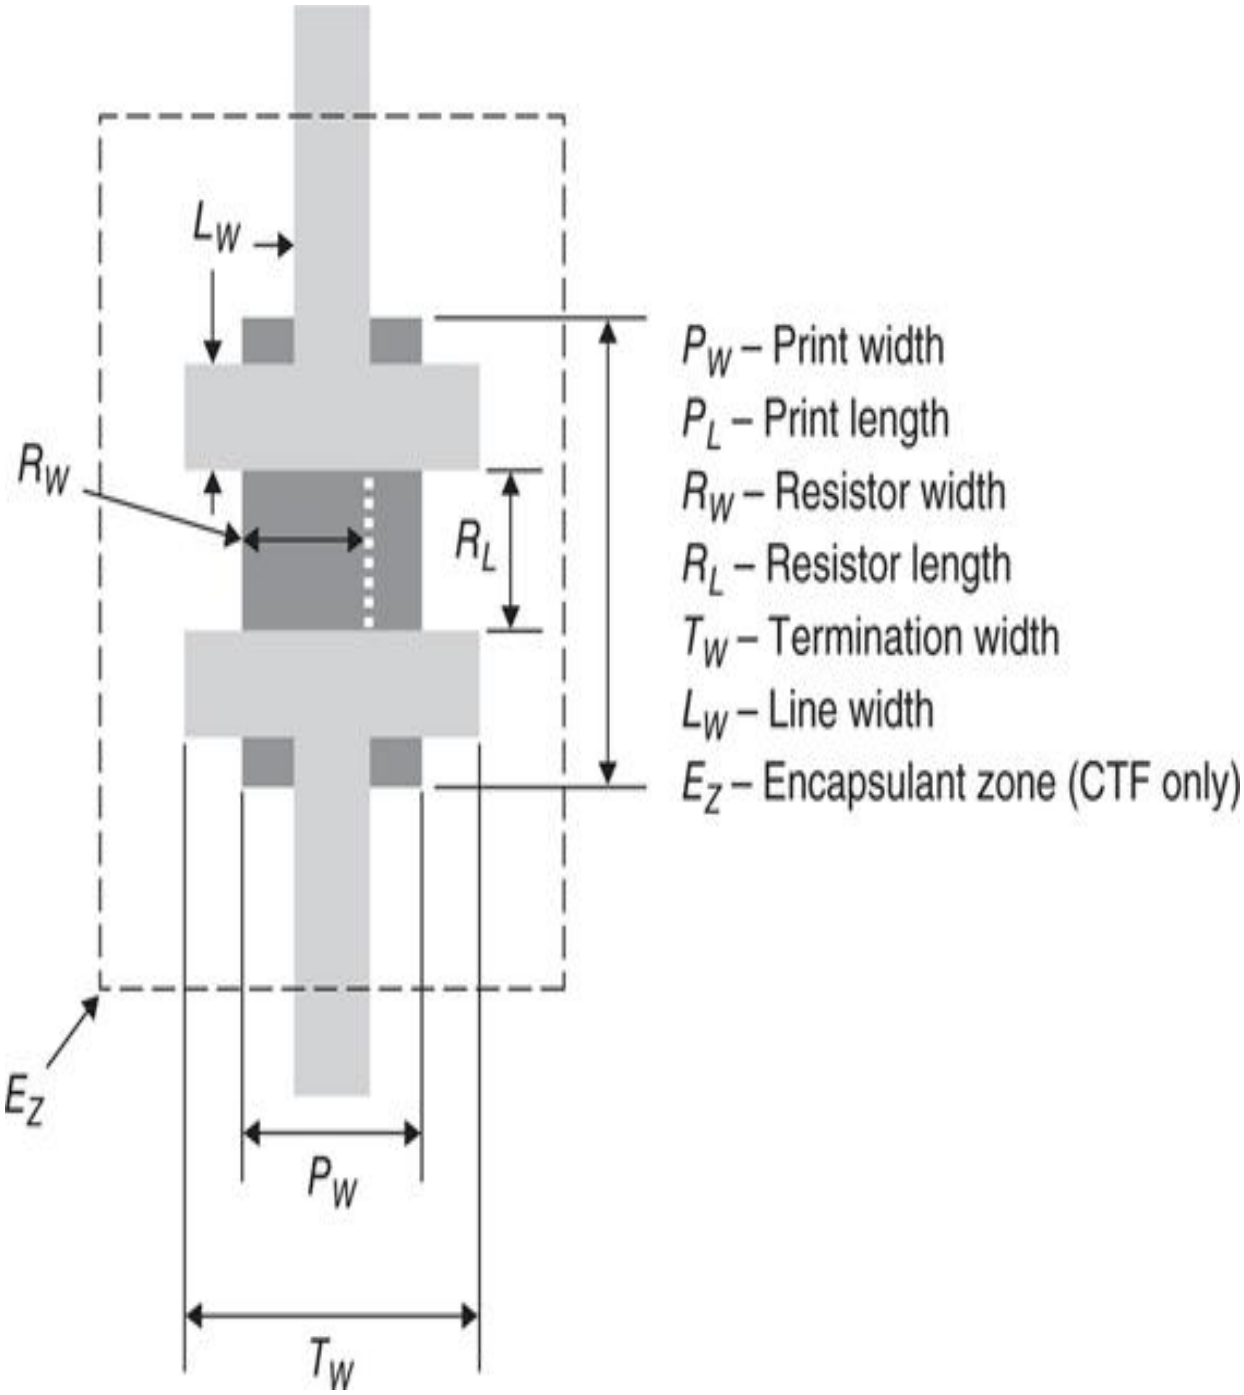

FIGURE 24.2 Resistor terminations.

24.4.1.3 Serpentine Resistor Design. The examples previously furnished exhibit very basic value geometry requirements. To maximize the number of resistor elements on the circuit layer and achieve greater utilization of the

process, alternative techniques can be considered. By adjusting the geometry of the resistor element, the designer is able to create a relativity wide range of values. The serpentine resistor example shown in Fig. 24.3 demonstrates the flexibility in designing resistor elements requiring more complex values.

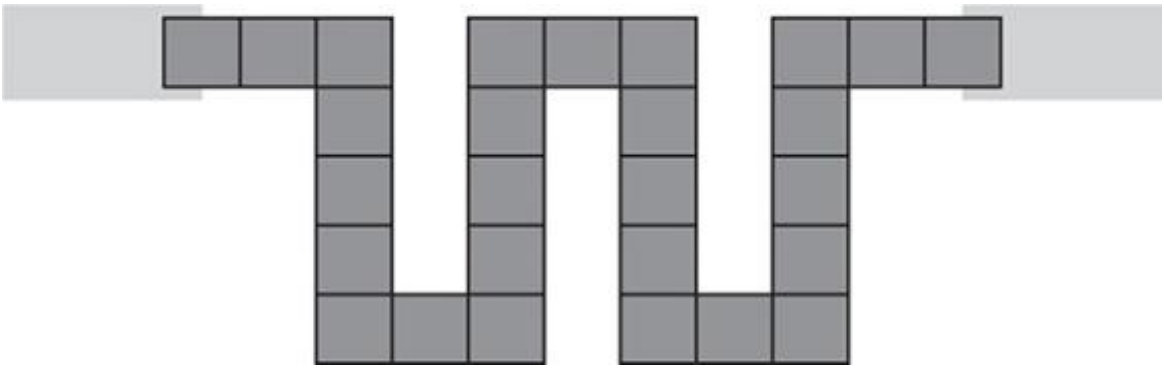

FIGURE 24.3 Printed serpentine resistor element.

A serpentine resistor value can be calculated as a bar resistor (1.0R value per square) with the exception of the corner squares (right-angle bends). Due to the change in current density at right-angle paths, the effective value number of the corner square is 0.56R.

24.4.2 Capacitor Design

All production formed capacitors use laminate-like materials. Most typically, the capacitor manufacturer starts with an especially flat copper foil on at least one side. This copper foil is precisely coated with the dielectric material: filled polymer. Either the top foil electrode is then laminated or two layers of coated foil are bonded polymer to polymer.

24.4.2.1 Capacitor Terminology. Capacitors are electrical elements that store charge on parallel electrode plates. They are not batteries that operate chemically.

Capacitors store more charge with closer parallel electrode plates. The higher the dielectric constant between the plates the more charge is stored. The value of embedded capacitors will be defined by dielectric area as well as dielectric thickness. The Eq. (24.2) will aid the designer in calculating formed capacitor values.

$$C = A \times D_k \times K/t \tag{24.2}$$

where C is the value of the capacitor, A is the area of the formed planar capacitor $L \times W$ D_k is the dielectric constant of the capacitor material t is the thickness between the capacitor plates K is a conversion constant = 8.854×10^{-14} farads/cm.

24.4.2.2 Capacitor Design Parameters. Similar design tolerance for capacitor design parameters (compared to resistors in Sec. 24.4.1) is available for capacitors, as shown in Fig. 24.4.

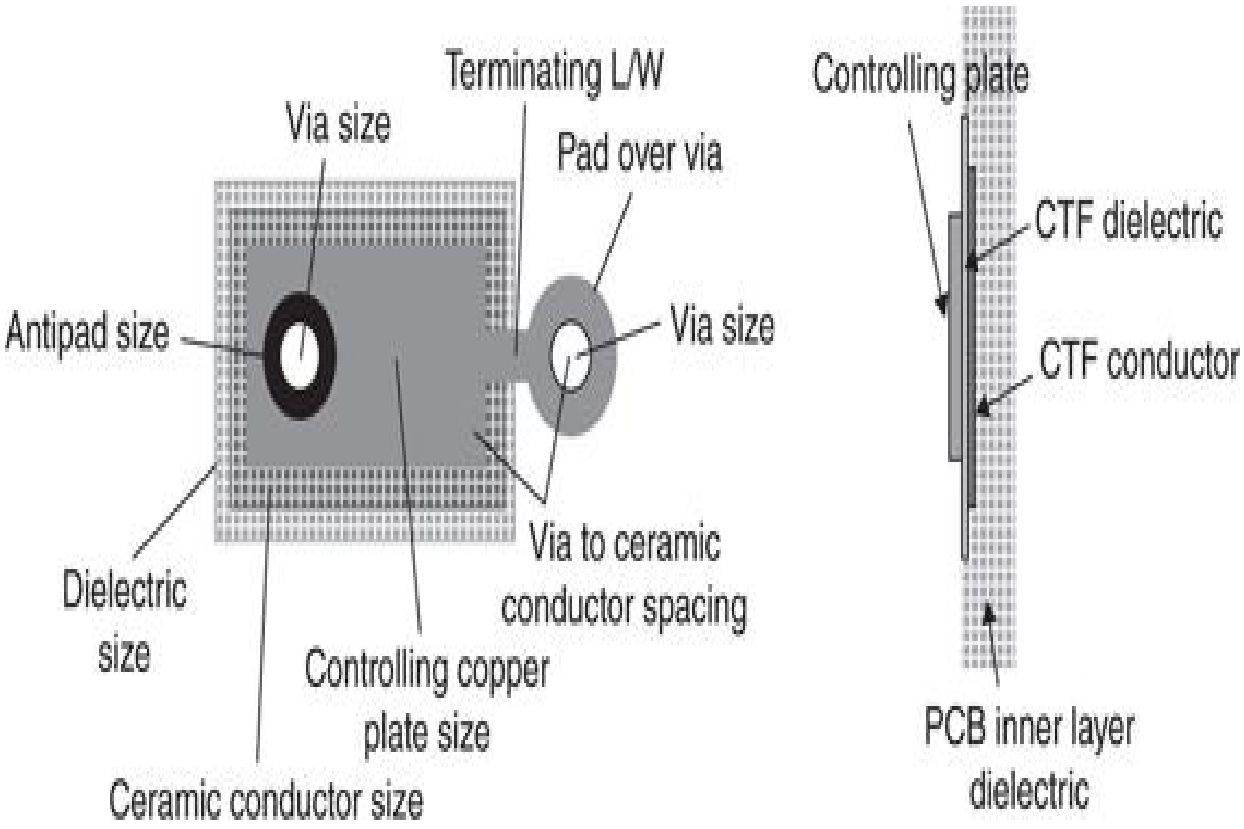

FIGURE 24.4 Capacitor design features.

Even conventional epoxy glass laminate has some capacitance value, and the oldest formed embedded capacitors were carefully controlled using thin conventional glass/epoxy laminate layers. Both epoxy resin and E-glass have dielectric constants of about 4 D_k, not a particularly large value. Eliminating the glass and adding compounds such as barium-titanate to the epoxy or polyimide resin, however, dielectric constants can be expanded into the 10 to 20 D_k range. When higher capacitance values are needed, dielectric containing ceramic or inorganic compositions must be adopted. More advanced technologies demonstrate dielectric constants in the 100 to 2000 D_k range to enable the forming of larger value capacitors inside the circuit board layer system. These larger capacitors are useful for decoupling, one of the primary uses of capacitors.

Thickness is the divisor in the capacitance formula. The thinner dielectric layer between copper planes will yield a higher device capacitance value. Early formed embedded distributed capacitors simply used the readily available 100-micron (4-mil) epoxy/glass innerlayer construction, common in multilayer circuit boards. Then, thinner woven glass allowed 50-micron glass/epoxy layers, doubling the device capacitance. Finally, polymer only or barium-titanate-filled polymer enabled further reduction of the dielectric layer thicknesses (as thin as 8 microns). This improved dielectric provides 6 to 20 times higher capacitance value of the original 100-micron epoxy glass. Because of the special fabrication and handling required for manufacturing the thinner dielectric material, there is increased cost. A cost/benefit analysis will help illustrate the trade-offs between common dielectric material and the more premium materials. Key factors the designers must weigh are overall cost against the area gained using the smaller-size-for-higher-capacitance values of the filled polymers.

24.4.3 Inductors

Inductors use the magnetic effects of electrons traveling in wires to influence the travel speed of other electrical signals. Typically inductors are a coil configuration. No special material technology has been demonstrated for inductors. These spirals of copper circuitry are typically formed similarly to the copper-conductive traces of innerlayers. Formed inductors are current loops configured to induce a magnetic field for storing and controlling inductive energy. Inductance (measured in henry) is an effect that results from the magnetic field that forms around a current carrying conductor. Current flowing through the inductor creates a magnetic field that has an associated electromotive-field that opposes the applied voltage. This counter

electromotive-force (emf) generated opposes the change in voltage applied to the inductor and current in the inductor resists the change but does rise. This is known as *inductive reactance*. It is opposite in phase to capacitive reactance. Routing the circuit conductor into a spiral creates a larger magnetic field that can increase inductance.

The energy (measured in joules, in SI) is stored by an inductor is equal to the amount of energy required to establish the current flowing through the inductor, and therefore the magnetic field. This is given by the following equation:

$$E_{\text{stored}} = \frac{1}{2} LI^2$$

where L is inductance and I is the current flowing through the inductor.

A combination of line width, number of turns, shape and conductor length define the inductance value. A spiral inductor can be formed on a single layer for simple low value applications (Fig. 24.5) or by employing two or more circuit layers for the more complex requirements.

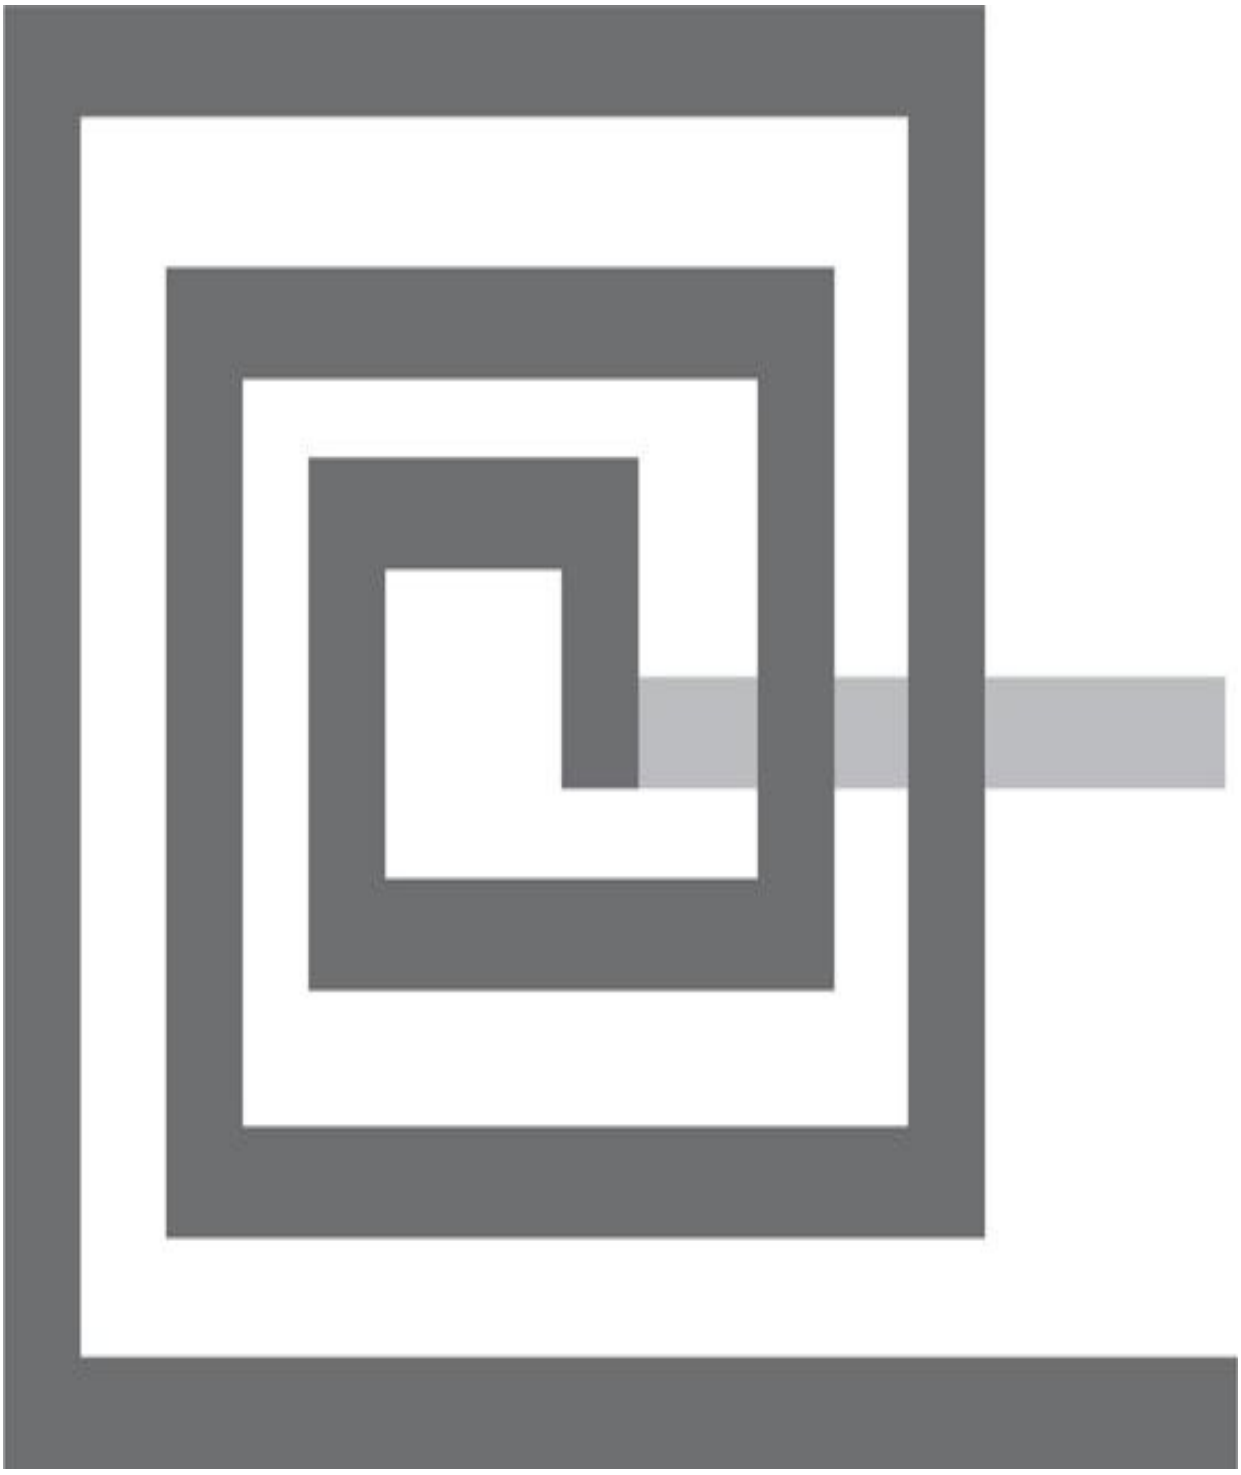

FIGURE 24.5 Printed or etched spiral inductor element.

Software tools are available to refine the inductor pattern development process. Spiral inductor layout traditionally relied on approximate quasi-static models and verification

using electromagnetic field solvers. Software developers have created interface tools for high-performance EM simulation. The software also enables optimization of the inductor as well as facilitating the design of spiral circuit components.

24.5 MATERIALS

24.5.1 Resistor Materials

Resistors, discrete or formed, are actually very poor electrical conductors when compared to copper. Their function is to restrict the flow of electricity in a circuit. Common compositions of resistors include metal oxides, carbon particles, or small conductive particles separated widely by an organic polymer. Conventionally, the value of a resistor is rated in ohms, with higher values restricting more current. Also, resistors are sized by tolerance in percentage, allowable maximum current, and parameters that deal with the electrical frequency of operation.

Material suppliers have designated the range of resistance values that are optimum for their material. The designer determines the length and width that is allowable in the design, and then determines which material to specify for manufacture so that the final resistor value is achieved in the allocated circuit board space.

Formed embedded resistors of similar values are designed on one specific layer so that the maximum economic value is achieved for that layer.

Materials are also available that can combine mixed values of resistance on one layer. Polymer thick films (PTF) are applied by successive screen print/cure cycles so that all the desired resistance values can be made on one layer. Also, some sheet capacitance manufacturers laminate a layer of

resistor foil as one electrode in their construction. Therefore, a fabricator can mix resistance and capacitance on one sheet type raw material.

24.5.2 Resistor Fabrication Details

Several different raw materials and processing systems are used to fabricate embedded resistors. The most commonly used are listed in this section.

24.5.2.1 Photoprint. Photoprint involves a supplier coating a thin, resistive layer on a copper-foil sheet and selling this to either a laminate supplier or directly to the board fabrication shop. The fabricator uses two imaging and etching steps: the first to image the copper conductors on the layer, and the second to size individual resistors by using a second, different etchant solution, specifically for the resistor composition. Typically, alkaline etchants are used in step one, and acidic etchants are used in step two.

24.5.2.2 Screen or Stencil Print. Screen or stencil print is the operation of adding specific resistive paste compositions directly to the etched innerlayer. Polymer compositions (PTF) are cured directly at normal board exposure temperatures (150 to 200°C). Ceramic compositions cure at much higher temperatures (900°C), so the sequence of manufacturing operations is changed. Copper foil first has the uncured ceramic paste screened. Then firing of the paste occurs in a nitrogen blanketed oven. The foil, with cured ceramic resistors, is laminated to B stage epoxy, and the epoxy layer cured to C stage with resistors pressed into the resin. Finally, the innerlayer copper traces are etched, exposing the embedded ceramic resistors.

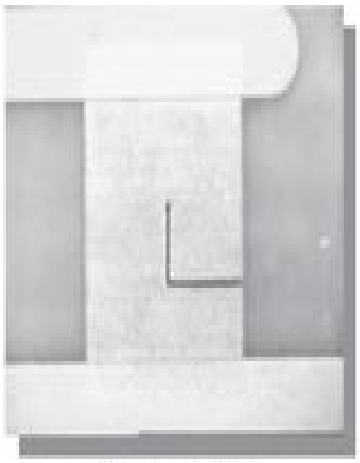
24.5.2.3 Plating. Plating is an additive process where the copper layer is first etched. Then the layer is catalyzed for electroless plating, and photoresist is applied. Resistor

locations are imaged into the resist and the pattern developed. Exposed catalyst in the proper areas then initiates plating of the resistors. The resist is stripped, background catalyst is removed, and the resistors are in the proper locations.

24.5.2.4 Inkjet Printing. Inkjet printing is the additive process of applying appropriate resistor materials (usually PTF-type compositions) directly to etched innerlayers. Resistors are applied one at a time, in contrast to the mass screening of conventional PTF. It is also possible to print several resistor value compositions before a final single cure step.

24.5.2.5 Photoimageable Discrete. In a photoimageable discrete process, resistive compositions have been dispersed in traditional solder mask–like materials, which are applied to the surface of an etched layer. Imaging and development leave the desired geometry resistor after the development step.

24.5.2.6 Resistor Trimming. Resistor trimming is a necessary step. All of the resistors given here have been shown trimmable to very precise values. This is normally done in with a modified laser machine, adapted from trimming ceramic surface mount discrete resistors. Either the machine uses a probe card pattern to measure the values of a number of resistors at one time or it uses a flying probe technology from electrical test to measure and trim a single resistors. The flying probe system is used in hybrid circuit manufacture and the probe card system is standard for arrays of resistors from discrete component suppliers. An interpretation of the laser trim process is shown in Fig. 24.6.



Finished trim

Pulsed laser machining

FIGURE 24.6 Resistor trimming.

24.5.3 Capacitor Fabrication

Formed capacitors can be planar or discrete. Capacitance value is achieved using materials of different dielectric constants and different dielectric thicknesses. The planar capacitor simply sandwiches a dielectric material between two layers of copper foil typical of that illustrated in Fig. 24.7.

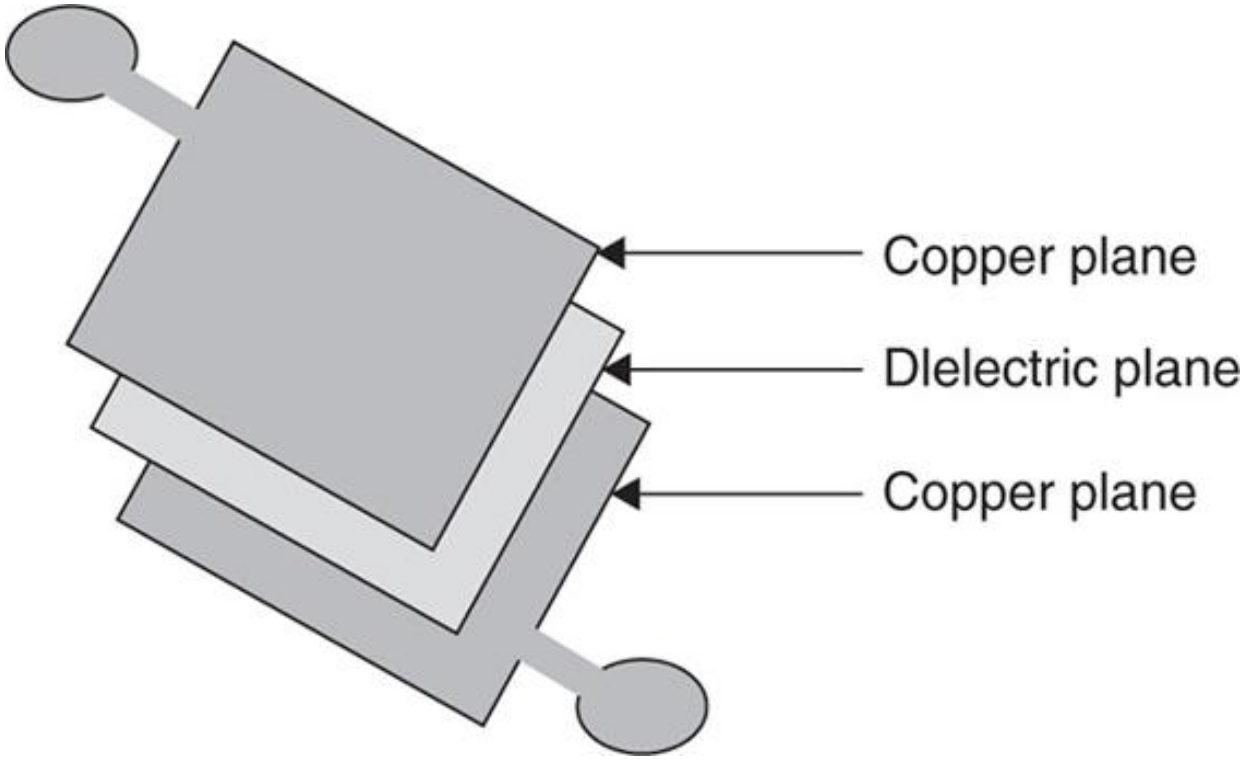

FIGURE 24.7 Planar capacitor.

The dielectric layer may be a common organic composite, polyimide, an organic polymer thick film or ceramic thin film (CTF) composite. The polymer thick film or ceramic thin film (CTF) composite dielectrics can be applied for both discrete and planar capacitors. The PTF material density is equal to 20 pF/mm^2 while CTF materials will have a density rating of approximately 24 nF/mm^2.

The most common commercially available capacitor technology is a laminate structure that relies on a thin glass reinforced epoxy composite that is furnished with copper foil on both sides. Companies are also supplying a barium titanate filled polyimide and epoxy material that can provide a much broader and higher capacitance density. Also supplied as the laminate, the fabricator simply places a layer within the printed circuit board structure. Because it is a para-electric material, it furnishes a relatively low capacitance density compared to a crystalline ferroelectric material. In this case, the total capacitance available is limited only by the area of the circuit board and given a suitable sized board the materials can be used for decoupling where higher capacitance density is required.

24.5.3.1 Planar Capacitors. Power and ground planes within the EPCB structure are often used to furnish a common capacitance value to the entire circuit, providing both current and voltage to enable the power supply in meeting the demands of the active components. The power source can be either AC or DC. Power and ground planes are commonly furnished as adjacent layers in the layer stack-up. When required, the designer can add additional power and ground planes or pairs of power and ground planes within the board.

The general description of a planar capacitor is basically two copper layers separated by a thin (~25 µm) dielectric layer. Because these Cu planes extend across the entire substrate, the plated through-hole vias or micro-vias connecting to the power and ground planes can be placed very close to the power and ground inputs of teach device. This close coupling results in lowering loop inductance. Low inherent inductance will deliver current to the device on a very short time scale, greatly damping fluctuations of the voltage at the device input.

Normally, embedded formed polymer capacitors are made from purchased sheet materials. It is difficult for the board fabricator to apply a liquid dielectric formulation precisely to laminate, but one photolithographic capacitor formation technique has been developed. Unneeded dielectric is removed with a developer solution similar to liquid photoimageable solder mask.

24.5.3.2 Formed Discrete Capacitors. A majority of the capacitors designed into an electronic circuit will function as a decoupling element. In regard to forming capacitor elements within the circuit layers, the industry has developed a number of buried capacitor materials with high dielectric coefficients. In most cases, a higher dielectric coefficient is desirable since the strength of the capacitor is directly proportional to its dielectric coefficient. The 'planer' capacitor in particular, is one that basically separates parallel copper foils. These foils generally provide the power and ground layers of the substrate.

24.5.3.3 Thin Film Capacitor Dielectrics. The capacitor dielectric selected for separating the copper surfaces of the power and ground plane are most likely to be either an organic polymer thick film (PTF) or ceramic thin film (CTF) composite. These dielectrics can be applied for both discrete and planar capacitors. The PTF material density is equal to 20 pF/mm^2 while CTF materials will have a density rating of approximately 24 nF/mm^2.

There are a number of companies supplying polyimide (PI) as the dielectric for capacitors. Polyimide dielectric laminate can be processed like thin flexible circuit laminate through the develop/etch/strip process steps. Although furnished with copper foil on both sides, the dielectric remains somewhat flexible and can be imaged and etched with conventional PCB fabrication processes to define the capacitor outline.

24.5.4 Inductor Fabrication Process

Formation of inductors simply involves the design in copper circuitry, and then careful imaging and etching to ensure close tolerance conductors. PCB planar spiral inductors can be used as antennae or components for forming high frequency matched filters in a RFID system.

The term “spiral” is not always a literal description of the formed inductor element. The spiral inductor, depending on their specific application, can be designed in a number of different shapes Sizing of inductors is dependent on a number of parameters:

- Line width
- Spacing
- Geometry

Single layer copper spiral inductor can only reach about 10 nH; however, multilayer spiral inductor can reach up to 30 nH. Adding a ferromagnetic material either as a core within loops of copper or lying beneath or sandwiching a spiral can possibly extend the inductor value into the 100 nH range. The detail in Fig. 24.8 furnishes the basic physical parameters for designing the spiral inductor on the embedded PCB structure.

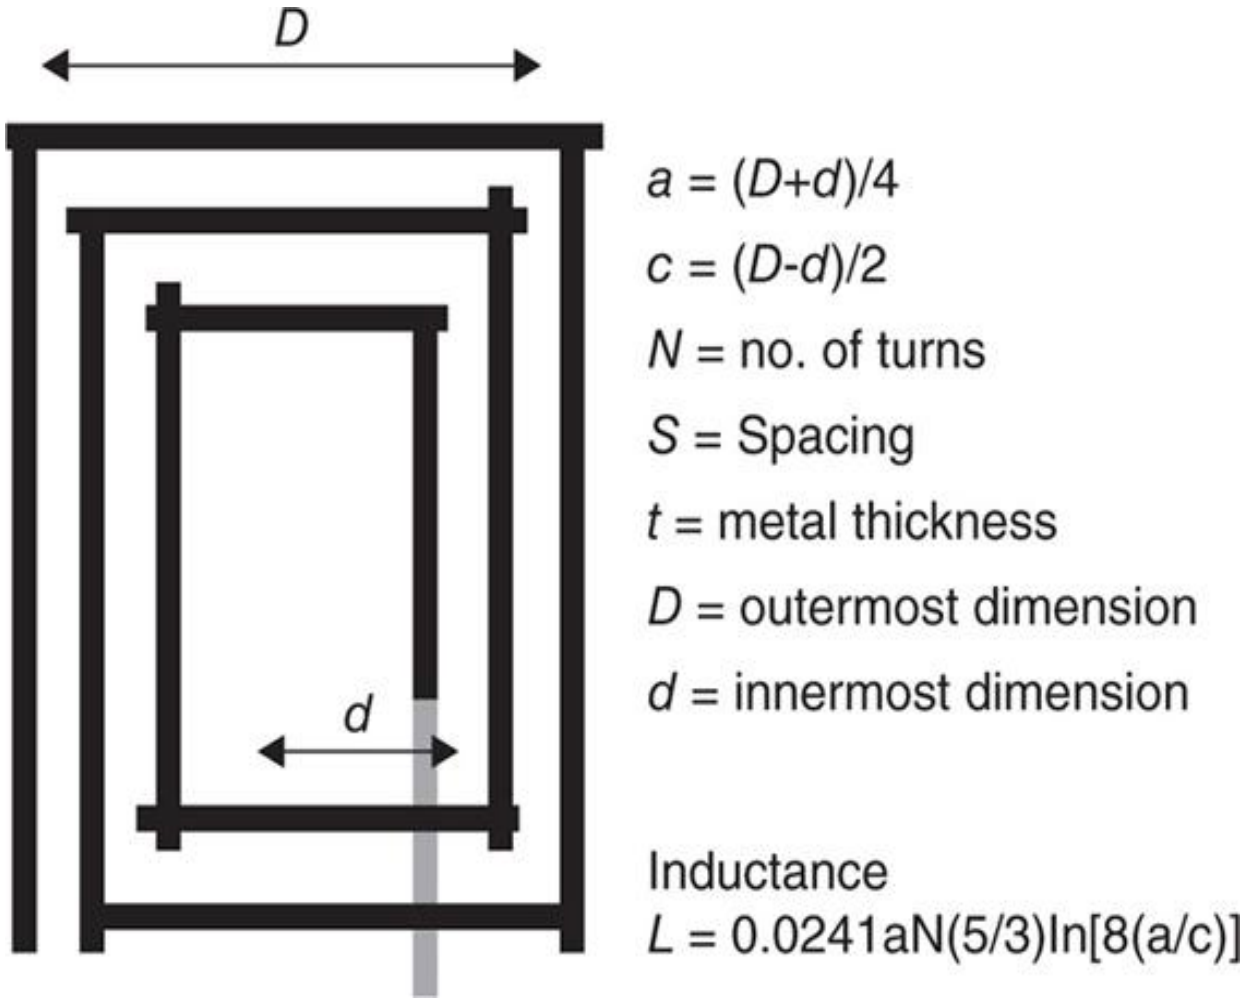

FIGURE 24.8 Spiral inductor design parameters.

As noted, the resistances and inductances of a formed spiral inductor can also be calculated using a number of commercially available software tools.

24.5.5 Active Integrated Circuit Fabrication

Forming active elements: transistors, memory, integrated circuits (ICs) within the circuit structure is possible but the processes and materials are not as widely available to the commercial PCB fabricator. Semiconducting polymers make

up the source, drain, and gate of the integrated circuit and are applied by inkjet or screen printing.

24.5.5.1 Formed Transistors. Discrete elements can be integrated into the circuit structure using thin films of organic or inorganic compounds. One printable inorganic semiconductor adapts an amorphous combination of InGaZnO that can be cured at low temperature. Electrodes in these transistors are typically metal but they may consist of conductive organic compounds.

24.5.5.2 Formed Memory. Based on the use of functional polymer material and flexible films, memory functions have been developed to provide data storage within the circuit structure. These unique materials are ideally suited for consumer products such as personalized toys and online-enabled game cards, authenticity identification, smart packaging, displays and all-printed RFID applications.

24.5.5.3 Formed Logic. The “printing inks” used in creating semiconductor functions consist of conducting and semiconducting conjugated polymers and/or other nano materials that are formulated into solvents. Printing is done one layer at a time (semiconductor, conductor, insulator, resistor, and dielectric). Each deposited using advanced printing systems enabling feature sizes as small as 10 µm and the layers must align precisely for the device to function properly.

There is continued development for a wide range of components for embedded printed circuit board (EPCB) applications. Most of these active component-forming processes rely on proprietary methodologies and material sets and will likely require licensing from the developing companies.

24.6 MATERIAL SUPPLY TYPES

24.6.1 Resistor Materials

Formation of the resistor by the designer, working with the board fabricator, involves making a material selection. All resistor values are not possible with each raw material technology. Table 24.1 shows the various forms of the raw resistor material.

TABLE 24.1 Embedded Formed Resistor Supplier Types

Process	Technology
Photoprint (sheet resistor material)	Thin-film etch (NiCr, Pt, NiP)
Screen or stencil print	Polymer thick-film addition (PTF)
	Ceramic thick-film addition (CTF)
Plating	Selective addition
Inkjetting	Selective addition
Photoimageable discrete	Photopolymer (filled)

Table 24.2 gives the range capability of the various resistor manufacturing technologies.

TABLE 24.2 Embedded Formed Resistor Ranges

Resistance, Ω	10	100	1000	10e4	10e5	10e6
Photoprint (NiCr, NiP)	X	X	X			
Photoprint (Pt)		X	X	X		
Screen or stencil print (PTF)	X	X	X	X	X	X
Screen or stencil print (CTF)	X	X	X	X	X	X
Plating	X	X	X			
Inkjetting	X	X	X	X		
Photoimageable discrete	X	X	X	X		

Where materials are sold in foil form or plated, only one value of resistors can be produced per layer. Since the resistive material is consistent across the panel, the final value of the finished resistor is determined by the length-to-width ratio. If the resistive material is made at 100 Ω per square properties, a resistor that is one unit wide and five units long will have a value of 500 Ω. Or, if the resistor is one unit long and five wide, the value will be 20 Ω. Practical resistor ranges evolve from the basic properties of the starting foil material.

Paste compositions, both polymer and ceramic, can have different dispersions of resistive particles and can yield widely variable resistance values. However, to limit manufacturing steps, selection of certain paste values, usually 10 to 15 times apart, are used. Thus, a design with resistors from 10 to 100,000 Ω could use pastes of 100 Ω per square, 1000 Ω per square, and perhaps 50,000 Ω per square.

A graphical representation of various formed resistor configurations is shown in Fig. 24.9.

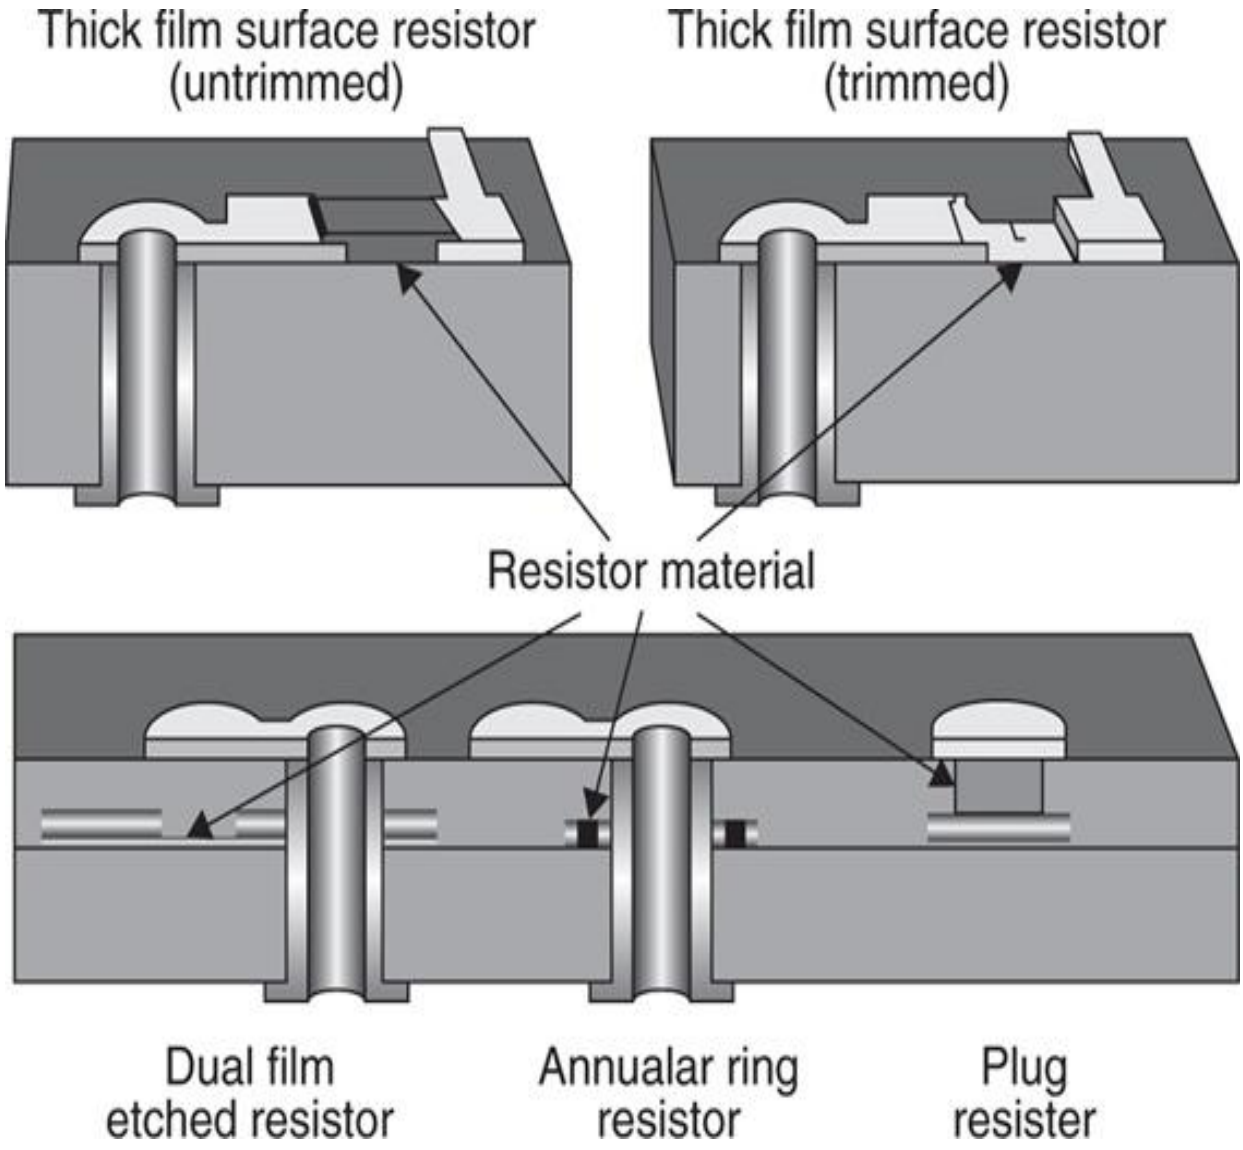

FIGURE 24.9 Embedded formed resistor configurations.

24.6.2 Capacitor Materials

Capacitors are needed in a great range of values. Capacitors may be the conventional “discrete” or a whole capacitance sheet may be used—*distributed capacitance*. Distributed capacitance is quite useful electrically, when high-speed integrated circuits need voltage immediately to turn on or off. The distance to voltage planes may be too long in some

designs and will not allow efficient electrical operation of very fast integrated circuits.

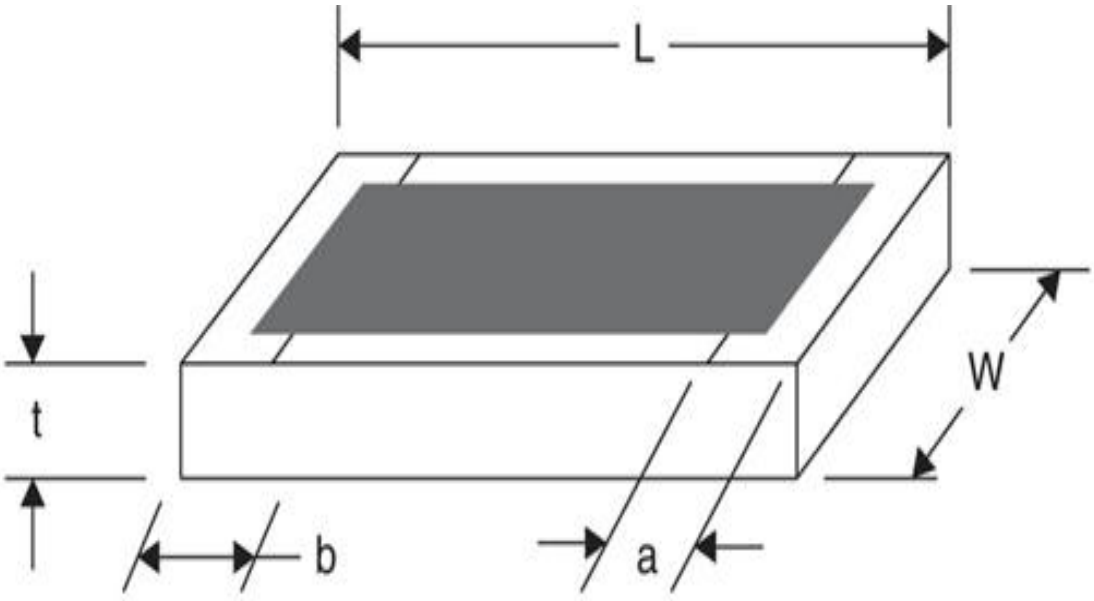
Depending on the technology applied, the area used to make the formed embedded capacitor can vary. Both area and dielectric will determine capacitor values. The value of capacitor can vary from a pico-farad to a few micro-farads. Low pico-farad elements are best suited for the formed embedded capacitors for applications generally associated with timing, decoupling, and filtering.

TABLE 24.3 Embedded Formed Capacitor Technologies

Process	Technology	Dielectric Constant	Micron Thick	Capacitance of a 1 sq. cm Area
Etched copper planes	FR-4/glass, copper clad laminate	4.5	50	78 pF/cm^2
			25	156 pF/cm^2
	Polyimide (filled) copper-clad laminate	11.0	14	700 pF/cm^2
	Polyimide (unfilled) copper-clad laminate	3.5	25	122 pF/ cm^2
	Proprietary dielectric (filled) copper-clad laminate		24	140 pF/cm^2
		4.2	12	310 pF/cm^2
	Epoxy (filled) copper-clad laminate	15	16	850 pF/cm^2
Screen or stencil printed discrete	Ceramic thick-film	1500	25	93 nF/cm^2 (93,000 pF/cm^2)
Photoimageable discrete	Photopolymer (filled)	22	11	1.5 nF/cm^2 (1500 pF/cm^2)
Emerging	Sol gel formation	150	0.5	150–300 nF/cm^2

An alternative to forming component parts, many companies are placing discrete passive components within the multilayer circuit. Although a majority of the discrete passive devices may remain mounted on the outer surfaces of the interposer or substrate, embedding passive component elements within the innerlayers of the structure will enable greater utilization of the outer surfaces for larger passive and packaged semiconductor component mounting.

24.6.2.1 Discrete Resistors. Discrete resistors are commercially available in the standard 0201 and 01005 type package outlines. In regard to the value range available in the smaller package outlines, ceramic based thick film SMT resistors are available in all of the standard values with tolerances of 5 percent for thick film resistors and 0.5 percent for the thin film type resistors. The overall thickness specified for the commercially available discrete resistor is 0.13 mm for the 01005 outline device and 0.23 mm for the 0201 outline variation (Fig. 24.10).



Type (Inch size)	Dimensions (mm)				
	L	W	a	b	t
01005	$0.40^{+0.02}$	$0.20^{+0.02}$	$0.10^{+0.03}$	$0.10^{+0.03}$	$0.13^{+0.02}$
0201	$0.60^{+0.03}$	$0.30^{+0.03}$	$0.10^{+0.05}$	$0.15^{+0.06}$	$0.23^{+0.03}$

FIGURE 24.10 Thin small outline resistor.

The resistors described above are considered standard and have a relatively broad source of supply. Thinner passive components than those shown may be available from companies with specific interest in supporting the embedded component market.

24.6.2.2 Discrete Capacitors. The discrete SMT capacitor family also includes 01005 and 0201 outline. The dielectric type, working voltage and value range for the

smaller device outlines, however, is somewhat limited. The 01005 and 0201 type capacitors with a C0G dielectric, for example, are available in a value range between 5.0 and 100 pf. The X7R dielectric capacitors, on the other hand have a value range 68 to 470 pF for the 01005 type and 68 to 10,000 pF. A number of companies are supplying the small outline capacitor with thickness of 0.20 mm for the 01005 type component and 0.30 mm for the 0201. A very thin (0.15 mm) capacitor family is available from some sources but the value range may be limited.

A unique and very thin (0.13-mm-thick) chip capacitor family is available that utilizes a silicon technology and a tightly controlled wafer fabrication process to produce capacitors that are said to have excellent placement loss and consistent capacitance. Described by the manufacturer as a metal-insulator-semiconductor (MIS) the chip capacitors are primarily designated for use as DC blocks in wire-bond assembly. These components are available with capacitance values from 0.8 to 1000 pF and are useful from VHF to millimeter wave bands. The outline of the component grows progressively with the specific capacitance value from a tiny 0.23 × 0.30 mm outline for the 0.8 pF capacitor to 1.5 × 1.70 mm outline for the 1000-pF capacitor.

24.6.3 Placing Active Component Elements

Progress in developing high density embedded component substrate capability has accelerated through the cooperation and joint development programs between a number of government, industry and technical universities. In addition to these joint development programs, several independent development laboratories and package assembly service providers have developed proprietary processes for specific applications. Embedding active components within the

substrate interposer will require the adoption of a methodology that is well outside the more traditional multilayer PCB fabrication processes. Some semiconductor components are easy candidates for integrating into the substrate while other may involve more complex processes.

24.6.3.1 Attachment and Termination. Semiconductor elements may be mounted on the core structure with their active face up or down. There are a number of methods being used for interconnecting uncased semiconductor components. The face-up attachment method will likely require the fabricator to provide a cavity within the laminate structure to compensate for the die thickness and termination profile. The initial mounting of the die traditionally adopts an adhesive material (liquid or film) for securing the die element to the substrate interposers' surface. Both wire-bond and ribbon-bond processes may be applied for completing the die-to-substrate interface. Following the die attach and termination process the die element is commonly encapsulated with an epoxy compound that, when cured, becomes a homogeneous part of the substrates structure. For some applications, the prepreg resin coating may furnish enough material during the lamination press cycle to flow into the cavity to complete the encapsulation process (Fig. 24.11).

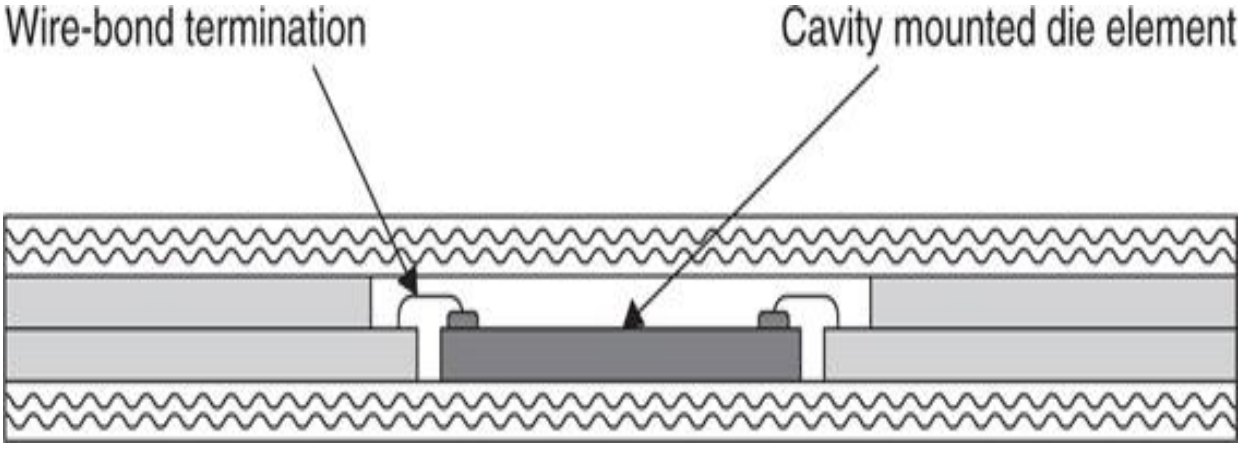


FIGURE 24.11 Cavity-mounted die element.

24.6.3.2 Flip-Chip Attachment. Mounting the semiconductor in the facedown orientation (flip-chip) requires additional preparation to the die element. The most basic process provides a solder compatible copper metallization to each wire-bond site. The bond sites are then furnished with a small volume of solder alloy that, when heated to a liquid state, form a raised bump feature for subsequent soldering onto mating lands provided on the substrate surface (Fig. 24.12).

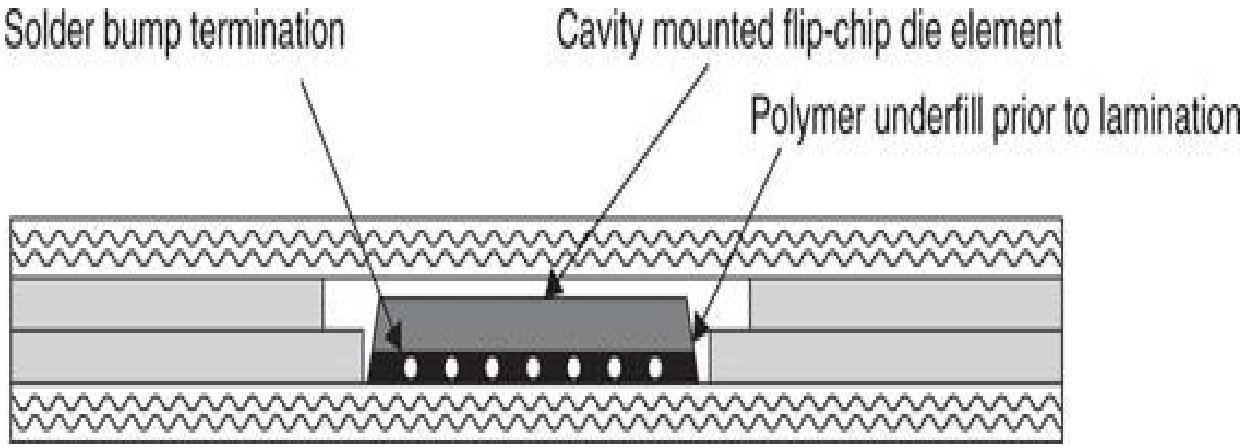

FIGURE 24.12 Cavity-mounted flip-chip die.

Reflow solder processing is the most common technique for flip-chip assembly and a substantial infrastructure already exists for supplying systems for both high and low volume manufacturing. Common methods for mass reflow soldering include hot air/gas convection, infrared, conduction, and vapor phase.

To ensure long-term reliability, the solder alloy composition selected must be compatible with the contact alloy and surface finish supplied on the mounting structure. In addition, both temperature and the cycle time required for soldering the lead-bearing solder and the lead-free solder can differ a great deal. The tin/silver/copper alloy compositions, for example, become liquidus at a

temperature range that is much higher than the eutectic tin/lead alloy and the time duration for completing the joining process may need to be extended as well.

24.6.3.3 Micro-via Terminated Die Element. Many companies favor attachment of the semiconductor die with the active surface facing away from the substrates core or base structure. In preparation for direct micro-via to die bond pad interface the bond sites on the die element must be prepared with a compatible Cu alloy contact surface. Typical of the passive device shown above, it is common to provide a recessed cavity in the substrate to compensate for the semiconductors thickness. This allows the semiconductor to be completely encased by the substrate resin materials during the lamination process (Fig. 24.13).

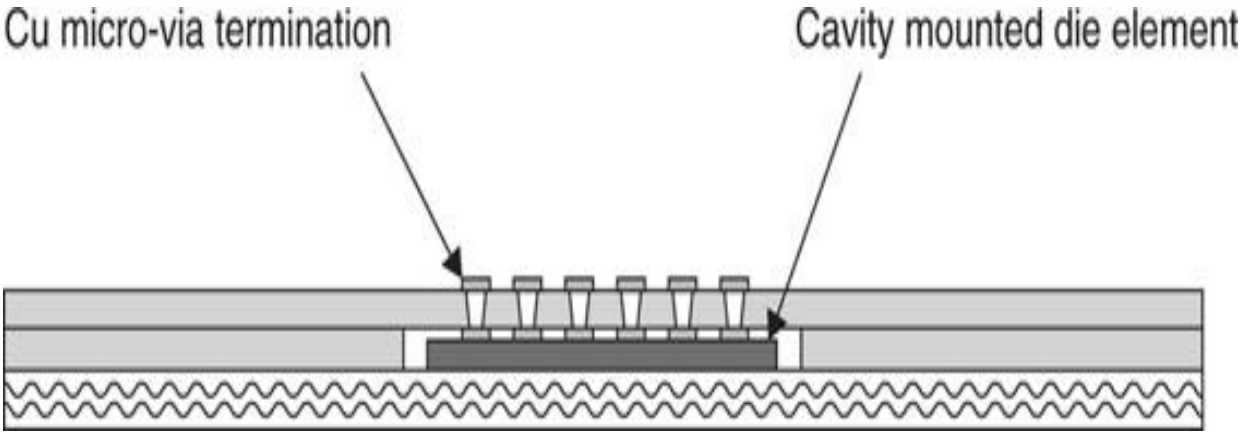

FIGURE 24.13 Micro-via terminated die element.

One key benefit of the face-up mounting option is improved thermal dissipation. When the die element is mounted onto a solid copper plane, any heat generated by the semiconductor during operation can be distributed over a wider area.

24.6.3.4 Combining Formed and Placed Components. When combining formed components and

placed components the designer must consider economic and performance goals:

- The formed passive components are generally very economical because they can be easily implemented during PCB fabrication. The main drawback is the limitation of value range. Beginning with a single base value, the designer will be limited to a single resistance per square and the stability of the target values will be impacted by the effects of aging of the substrate material, operating temperature and any conditions that would promote excessive moisture absorption. The general consensus is to ‘form’ the non-critical value components and “place” the components requiring closer value control.
- The placed passive components will have the greater latitude for value and tolerance stability. Placing components, however, requires a number of processes considered well outside the normal PCB fabrication process flow. Systems will need to be available for depositing solders or conductive materials, precise placement of the components, and capability for reflow soldering or thermal curing the attachment material. If plated copper via’s will be used for component interface, they too will require copper plating on their terminal features.

24.6.3.5 Process Planning for Formed and Placed Components. In the event that both formed and discrete placed components are to be combined within the same embedded PCB structure, there are a few ground rules regarding component location. Mixing formed and placed components on the same layer should be avoided. This is because the processes for forming and the process for discrete component termination are quite different. Because the formed components require unique printing curing or photoimaging and developing processes, they can be easily

damaged if not protected. The protection may be a coating of polymer or the lamination of glass reinforced clad with copper foil or resin coated copper foil. The discrete components selected for embedding should be on separate layer(s) of the PCB (Fig. 24.14).

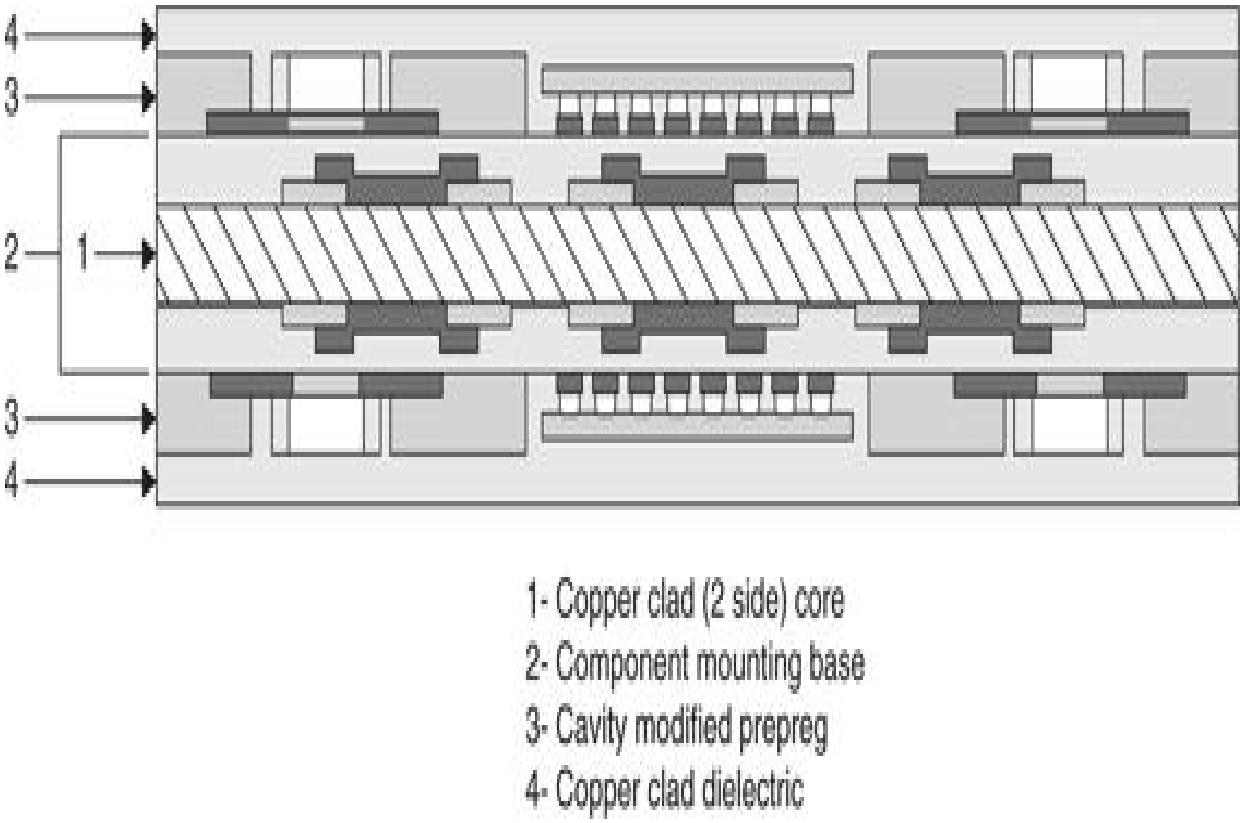

FIGURE 24.14 Combining formed and placed components *(source: IPC-7092)*.

When planning the embedded component PCB the designer must consider the fabrication process flow. The process flow will go well beyond the sequence typically applied to conventional multiple layer PCB fabrication. Embedding formed components will have very little impact on the fabrication sequence, however, placing and terminating discrete components with in the PCB structure will require processes not typical of those commonly available in PCB shops. An example of a process flow

combining formed and placed components within the same PCB structure is shown in Fig. 24.15.

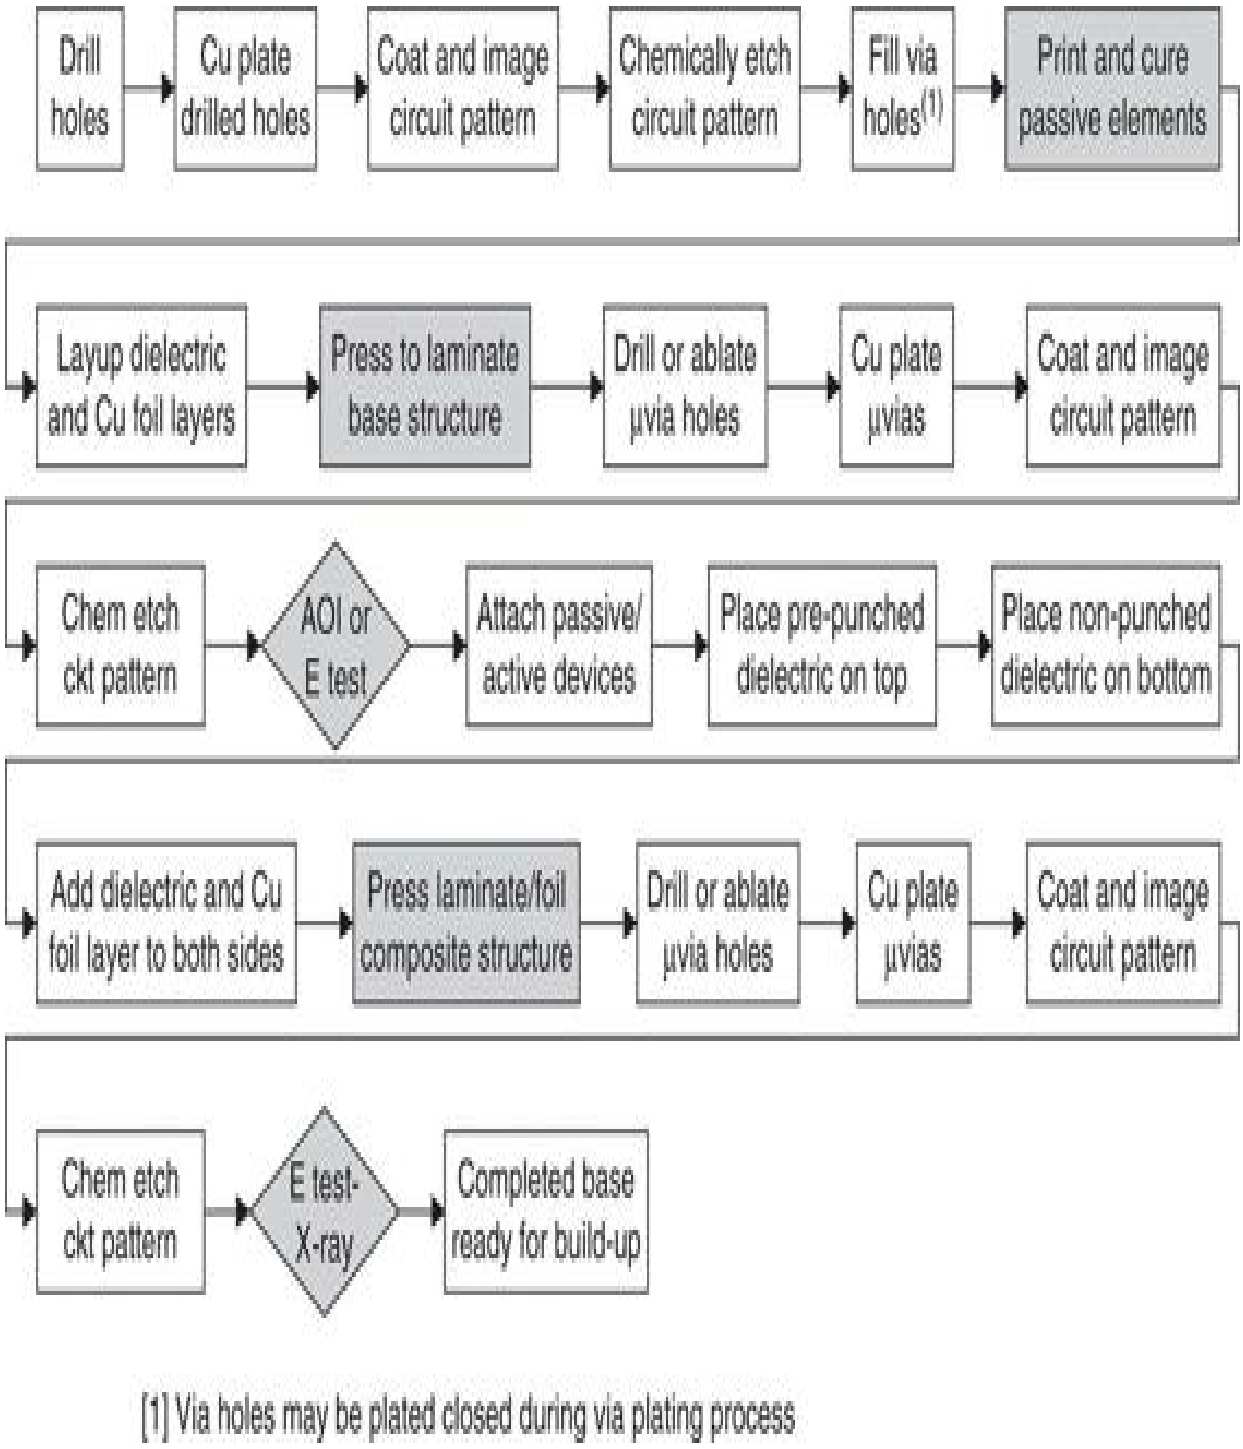

FIGURE 24.15 Embedded component process flow diagram *(source: IPC-7092)*.

24.6.3.6 Bill of Material Preparation. The BOM for the embedded component substrate or PCB will be segmented to reflect the location or layer where the component parts are mounted or formed. To assist in identifying each components location it is recommended that the designer establish a reference designation system on the schematic diagram that corresponds to the circuit layer on which the component it is located. Furthermore, when creating a BOM the designer should consider who would be using it. It may be used internally or for communication between several manufacturing partners and suppliers or confined to a single suppliers manufacturing facility.

24.7 CONCLUSION

Further reading and standards are available in the newly completed IPC-7092, Design and Assembly Process Implementation for Embedded Components. This 150-page document covers embedded discreets and formed components as well as embedded active devices.

PART 5

HIGH-DENSITY INTERCONNECTION

CHAPTER 25

INTRODUCTION TO HIGH-DENSITY INTERCONNECTION TECHNOLOGY

Happy T. Holden
Co-Editor-in-Chief, Printed Circuits Handbook, *and PCB Technologist, Zeeland, Michigan*

25.1 INTRODUCTION

The use of more complex components with very high input/output (I/O) counts has pushed the board fabricator to reexamine techniques for creating smaller vias, and many new or redeveloped processes have appeared on the market. These processes include revised methods of creating holes, such as laser drilling, micro-punching, and mass etching; new methods for additively creating dielectric with via holes using photosensitive dielectric materials; and new methods for metallizing the vias such as conductive adhesives and solid post vias. All of these methods share some common traits. They all allow the designer to increase significantly routing density through the use of vias in surface-mount

technology (SMT) pads, to reduce size and weight of product, and to improve the electrical performance of the system. These types of boards are generically called high-density interconnects (HDI). An HDI board typically will have, as an average, over 110 to 130 electrical connections per square inch (20 connections per sq. cm) on both sides of the board.

25.2 DEFINITIONS

Printed wiring boards (PWBs) with microvia hole structures are called different names, such as HDI, sequential build-up (SBU), and build-up multilayer (BUM). However, HDI covers a broader range of high-density wiring boards such as extremely high-layer-count multilayer boards (MLBs) without microvia holes. MLBs with microvia holes are not necessarily built sequentially, nor do they necessarily have build-up structures. These definitions are not appropriate for the discussions in this chapter, and therefore we shall address MLBs with microvia holes simply as *microvia hole boards* (all microvia hole boards are essentially multilayer boards).

Some trade and academic organizations define the microvia hole to be a hole of a certain diameter or less. For example, the Association Connecting Electronics Industries (IPC) defines a microvia hole as a hole with a diameter equal to or less than 150 μm. However, when a surface blind via (SBV) hole is formed between layer 1 (L1) and layer 3 (L3), the diameter of such a hole is typically 250 μm in order to facilitate reliable plating, but the hole is still considered a microvia hole. Since all microvia holes are essentially SBVs and are normally small in diameter in order to increase circuit density, it seems more appropriate to define the microvia hole as an SBV without limiting its diameter. As long as a hole has SBV structure, it is defined as a microvia hole throughout this chapter.

The first microvia PCB in general production, Hewlett Packard's FINSTRATE, was put into production in 1984 (see appendix a at the end of this chapter). It was a copper-core, build-up technology that had direct wire- bonded integrated circuits (ICs). After laminating layers of plasma-metalized polytetrafluoroethylene (PTFE) to the copper core, vias were mechanically drilled through the copper core and then insulated with PTFE. Additional through holes were then drilled along with 5 mil blind vias. The first photodielectric microvia board was produced in volume in Japan by IBM-Yasu (see appendix b). This is the SLC technology with two build-up layers on one side of the four conventional FR-4 layers. These can be seen in Fig. 21.1 in the 5th edition of *Printed Circuits Handbook*.

25.2.1 HDI Characterization

This generation of printed boards is characterized by very small blind, buried, and through vias made by techniques other than mechanical drilling. To turn blind vias into buried vias, these process techniques are repeated and the layers are "built up," hence the name *build-up* or *sequential build-up circuits* (SBU).

This type of printed circuits actually started in 1980, when researchers started investigating ways to reduce the size of vias. The first innovator is not known, but some of the earliest pioneers include Larry Burgess of MicroPak Laboratories (developer of LaserVia), Dr. Charles Bauer at Tektronixs (who produced photodielectric vias)[1] and Dr. Walter Schmidt at Contraves (who developed plasma-etched vias). Laser-drilled vias were used in mainframe computer multilayers in the late 1970s. These were not as small as the laser-drilled vias today and were produced only in FR-4 with great difficulty and at great cost.

The first production build-up or sequential printed boards appeared in 1984, starting with the Hewlett Packard laser-drilled FINSTRATE computer boards, followed in 1991 in Japan with Surface Laminar Circuits (SLC)[2] by IBM and in Switzerland with DYCOstrate[3] by Dyconex. Figure 21.1 in the 5th edition of *Printed Circuits Handbook* shows one of those first Hewlett Packard FINSTRATE boards and one of the first IBM SLC boards (see this chapter's appendix).

Since the introduction of SLC technology in 1991 (see Fig. 2.5), many variations of methods for mass producing HDI wiring boards have been developed and implemented. However, if one technology is to be picked as a winner judged in terms of volume produced, laser-drilling technology is the one. Other methods are still used by a number of PWB manufacturers, but in a much smaller scale.

The purpose of this chapter is to examine a variety of microvia hole formation technologies, structures, and materials.

However, a greater emphasis will be placed on the laser-drilling process (*laser via* hereafter) since it is the most popular process today and it seems its popularity will grow in the future. It must be understood that via hole formation is just one element of fabricating HDI wiring boards. Fabrication of HDI wiring boards with microvia holes involves many new processes not common to conventional board fabrication. Therefore, additional emphasis will be placed upon these new fabrication processes that are common to other microvia technologies.

25.2.2 Advantages and Benefits

Four main factors drive printed boards to require higher wiring densities:

- More components can be placed on both sides of the printed circuit.
- Components are closer together.
- Size and pitch of components are smaller while the number of I/Os is increasing.
- Smaller geometries allow faster transmission of signals and reduce signal crossing delay.

At the same time, enhanced performance is required for faster signal rise times, reduced parasitics, reduction of radio frequency interference (RFI) and electromagnetic interference (EMI), fewer layers, and improved high-temperature performance and reliability. HDI provides all of these advantages and more.

25.2.3 HDI Traditional PCB Comparison

The interactions among PCBs, components, and assemblies are best seen by the packaging technology map (see Fig. 1.2). Components are characterized by the average I/Os per part, assemblies by the components per sq. cm and I/Os per sq. cm, and the printed circuit by its wiring density in cm per sq. cm. Figure 25.1 shows the approximate crossover between the traditional printed circuit board and the next generation with microvias.[4]

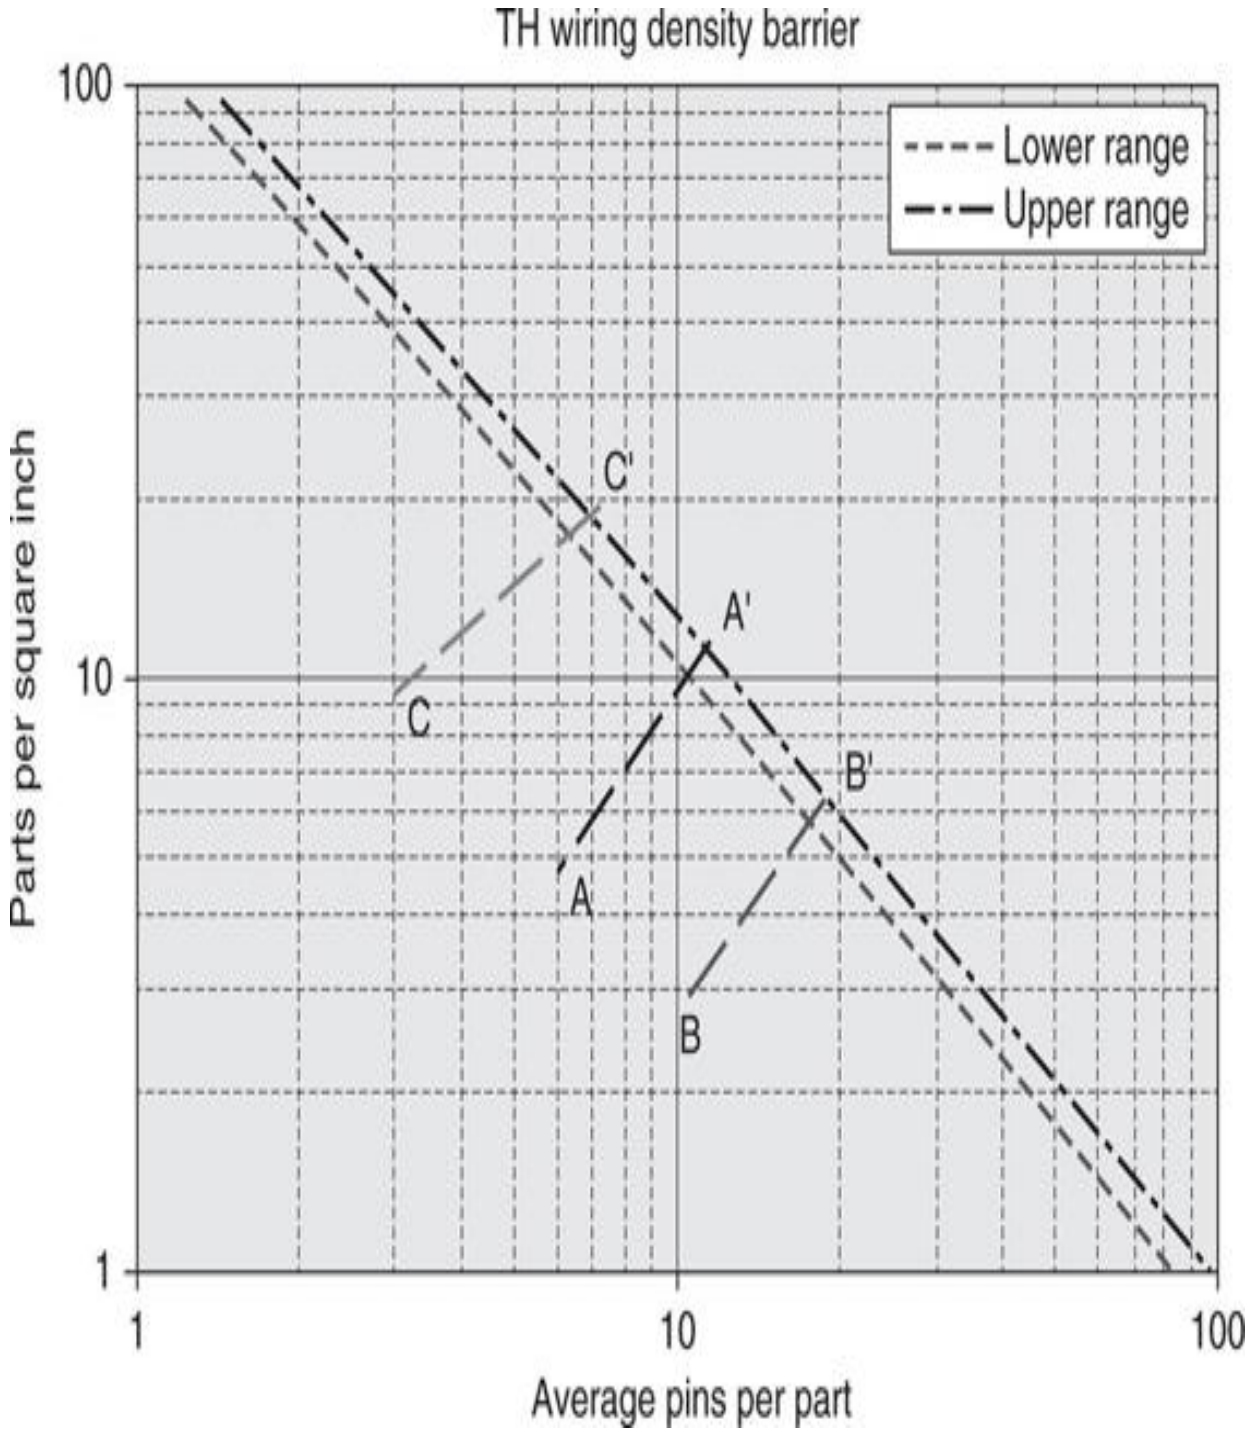

FIGURE 25.1 The through-hole density barrier. If the ends of an electrical net contain an SMT pad connected by a trace and a via hole, then there is only so many such connections (using conventional design rules' spacing) that can be placed in any square area. This *through-hole barrier* is shown crossing this technology roadmap. To cross the barrier (and prevent via starvation), the fabricator must stack vias using blind and buried vias and such.

25.2.4 Design, Cost, and Performance Trade-Offs

The HDI structure is cost-effective for higher-density assemblies shown throughout this chapter. The relative price of HDI versus relative density is depicted in Fig. 25.2. Cost parity (for similar wiring densities) is achieved with a four-layer HDI microvia at approximately an eight-layer, through-hole printed circuit multilayer. Wiring capacities and densities greater than an eight-layer multilayer can be achieved at a lower price with a properly designed HDI substrate. At very high densities, there are no through-hole multilayers that can meet the wiring capacities and density demand necessary, whereas HDI can easily meet the requirements.

FIGURE 25.2 (*a*) Relative price and density comparison between conventional through-hole (TH) boards and HDI microvia boards with different structures. The relative cost index (RCI) is actual production pricing of boards normalized to the eight-layer price. The density (DEN) is a measure of the maximum average pins (leads) per sq. in (for both sides of the PCB). The diagonal lines are equivalent density boards. These are for FR-4 printed circuits; (*b*) relative price and density comparison for conventional TH boards and Stacked HDI microvia boards.

25.2.5 Specifications and Standards

The Institute for Interconnecting and Packaging Electronic Circuits (IPC) has been working on standards and specifications for high-density interconnecting structures. Three standards and a guideline are the documents that are available from the IPC. The four documents are

- *IPC-2315*. "Design Guide for High Density Interconnecting Structures and Microvias"
- *IPC-2226*. "Design Standard for High Density Interconnecting Structures and Microvias"
- *IPC-4104*. "Standard for Qualification and Conformance of Materials for High Density Interconnection Structures and Microvias"
- *IPC-6016*. "Standard for Qualification and Performance Specification for High Density Interconnection Structures"

The IPC standards that cover HDI design rules, materials, and specifications are

- *IPC-2226*. This specification educates users in microvia formation, selection of wiring density, selection of design rules, interconnecting structures, and material characterization. It is intended to provide standards for use in the design of PCBs utilizing microvia technologies.
- *IPC-4104*. This standard identifies materials used for high-density interconnection structures. A series of specifications (slash sheets) are defined for specific available materials. Each sheet outlines engineering and

performance data for materials used to fabricate high-density interconnecting structures. These materials include dielectric insulator, conductor, and dielectric/conductor combinations. The slash sheets are provided with letters and numbers for identification purposes. For example, if a user wishes to order from a vendor and reference the specification sheet number 1, the number “1” would be substituted for the “S” in the preceding designation example (IPC-4104/1). To start the ordering process, one can use the slash sheets in the IPC-4104 document in combination with relevant IPC documents for each material sets (e.g., IPC-CF-148, IPC-MF-150, IPC-4101, IPC-4102, IPC-4103, etc.).

- *IPC-6016*. This document contains the general specifications for high-density substrates not already covered by other IPC documents.

25.3 HDI STRUCTURES

The IPC HDI Structure Subcommittee, which is responsible for defining performance requirements, used the following methodology to specify HDI products. Since a microvia can be any shape—including straight wall, positive or negative taper, or cup—determining the methods used for producing microvias can be segmented into three methodologies (A, B, or C), as noted in Table 25.1.

TABLE 25.1 Ten Process Methods Utilized to Produce Microvias

Hole Formation	Microvia Process*
Mechanically drilled	A
Dry-etched (plasma)	A
Mechanically punched	A
Abrasive blast	A
Laser-drilled	A
Post-pierced	B
Photo-formed	A
Insulation displacement	B, C
Wet-etched	A
Conductive bonding sheets	C

*A: create hole, then make conductive; B: create conductive via, then add dielectric; C: create conductive via and dielectric simultaneously.

All of these technologies provide approximately the same high-density design rules. These design rules endow build-up technologies with four to eight times the wiring density of conventional, all-drilled through-hole vias. The ten via profiles are depicted in Fig. 25.3.

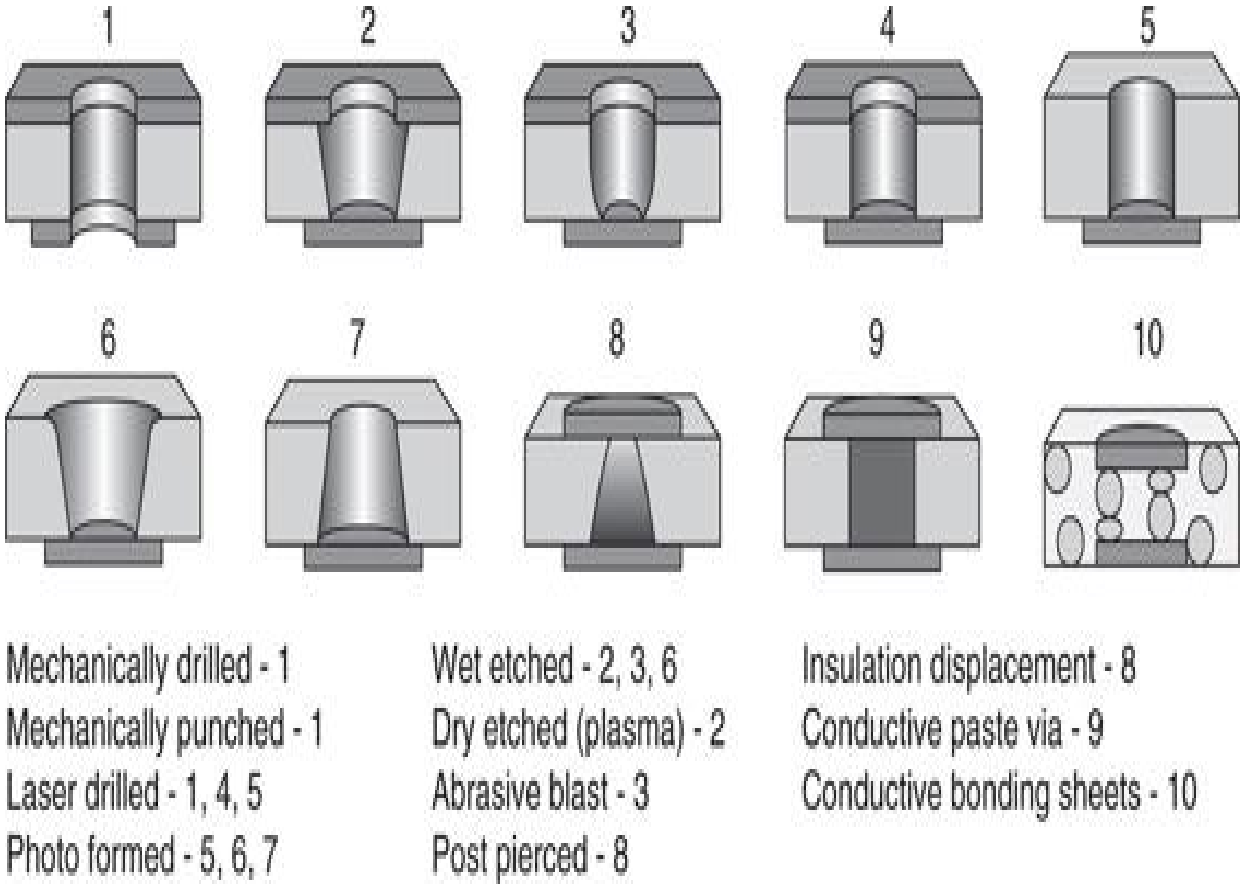

FIGURE 25.3 Representative microvia profiles and the processes that produce them.

The structure of the high-density interconnection is by type: Type I, Type II, Type III, Type IV, Type V, and Type VI (see Table 25.2). However, some of these type constructions are based on which microvia material is to be used. Thus, the following definition applies to all high-density interconnect substrates (HDIS).

TABLE 25.2 Description of the Six IPC HDI Type Structures of IPC-2226

Type I	1[C]0 or 1[C]1, with through-vias from surface to surface
Type II	1[C]0 or 1[C]1, with through-vias buried in the core and from surface to surface
Type III	≥2[C]≥0, 2 or more HDI layers added to through-via in core or from surface to surface
Type IV	≥2[P]≥0, where P is a passive "substrate with no electrical connecting functions"
Type V	Coreless construction using layer pairs
Type VI	Alternate construction using conductive pastes

[C], printed circuit core; [P], passive substrate core; 0, 1, and 2, number of build-up layers on each side of the core [C] or [P].

The core, defined as [C], can be identified as an A, B, or C type core. Thus, [CA] is a core with internal vias only; redistribution makes contact with the surface. [CB] is core with internal and external (through microvia structures). High-density interconnecting structures make contact with the innerlayers of the core. [CC] is passive core, in which there are no interconnections.

25.3.1 Construction

Type I to Type VI constructions currently describe all known HDI build-up structures, but as the technology evolves, new ones are likely to be created. The notation used is as follows:

x[C]x

where x = 0, 1, 2, 3, etc. (that is, the number of build-up layers on that side of the core) [C] = a standard laminated core of materials, with or without vias of *n* layers

25.3.1.1 Type I Constructions. This construction (1[C]0 or 1[C]1) describe an HDI in which there are both plated microvias and plated through holes used for interconnection.

Type I constructions describe the fabrication of a single microvia layer on either one side (1[C]0) or both sides (1[C]1) of an underlined printed circuit substrate core. The printed circuit core substrate is typically manufactured using conventional printed circuit techniques. The substrate may be rigid or flexible and can have as few as one circuit layer or be as complex as a prefabricated multilayer printed circuit with buried vias. A single layer of dielectric material is then placed on top of the core substrate. Microvias are formed in the dielectric connecting layer 1 to layer 2 and layer n to layer $n - 1$. Through holes are then drilled, connecting layer 1 to layer n. Then the microvias and through holes are metallized or filled with conductive material. Layer 1 and layer n are circuitized and fabrication is completed. Figure 25.4*a* shows this construction as illustrated in IPC-2226.

FIGURE 25.4 IPC-2226 microvia structures from Type I to Type VI.

25.3.1.2 Type II Constructions. Type II (1[C]0 or 1[C]1) has the same HDI layers as Type I. The difference is the core, [C]. Type II allows through vias to be placed in the core before the HDI layers are applied. The processes are the same except for the cores through vias being filled before the HDI layers are applied. Figure 25.4*b* shows this construction as illustrated in IPC-2226.

25.3.1.3 Type III Constructions. This construction (2[C]0) describes an HDI in which there are both plated microvias and plated through holes used for interconnection. Type III constructions describe the fabrication of two microvia layers on either one side (2[C]0) or both sides (2[C]2) of an undrilled or drilled printed circuit substrate core. The printed circuit core substrate is typically manufactured using printed circuit techniques. The substrate may be rigid or flexible and have as few as one circuit layer or be as complex as a prefabricated multilayer printed circuit with buried vias. A single layer of dielectric material is then placed on top of the core substrate. Microvias are formed in the dielectric, connecting layer 2 to layer 3 and layer $n - 1$ to layer $n - 2$. This first microvia layer is either metallized or filled with conductive material and then circuitized. A second layer of dielectric material is then placed on top of this circuitized layer and microvias are formed connecting layer 1 to layer 2 and layer n to layer $n - 1$. Through holes are then drilled connecting layer 1 to layer n. The microvias and through holes are then metallized or filled with conductive material. Layer 1 and layer n are circuitized and fabrication is completed. Figure 25.4*c* shows this construction as illustrated in IPC-2226.

25.3.1.4 Type IV Constructions. This construction (1[P]0 or 1[P]1 or >2 [P] > 0) describes an HDI in which the build-up layers are used over an existing drilled and plated

passive substrate. The printed circuit or metal core substrate is typically manufactured using conventional printed circuit techniques. This substrate may be rigid or flexible. Figure 25.4*d* shows this construction as illustrated in IPC-2226.

25.3.1.5 Type V Constructions. The Type V construction describes an HDI where there is no core. Both plated and conductive paste layer pairs are interconnected through a colamination process. The multilayer is created with an even number of layers (two-sided flex or rigid layer pairs) laminated together at the same time that the interconnections between the even and odd layer are made. This is not a build-up process; it is essentially a single-lamination-parallel process. Figure 25.4*e* shows this construction as illustrated in IPC-2226.

Layer pairs are prepared using conventional processes of etching, plating, drilling, and so on, or by conductive paste processes. The layer pairs are laminated together using B-stage resin systems or some other form of dielectric adhesive into which conductive paste vias have been placed.

25.3.1.6 Type VI Constructions. Type VI describes constructions of HDI in which the electrical interconnections and wiring can be formed simultaneously. Another variety forms the electrical interconnections and the mechanical structure simultaneously. The layers may be formed sequentially or colaminated. The conductive interconnect may be formed by means other than electroplating, such as anisotropic films/pastes, conductive pastes, dielectric piercing posts, and so on. Figure 25.4*f* shows this construction as illustrated in IPC-2226.

25.3.2 Design Rules

The designer should be aware that not all fabricators have equal capabilities in the areas of fine-pitch imaging, etching, layer-to-layer alignment, via formation, and plating. For this reason, the HDI design guide categorizes design rules into two categories: the preferred producibility range and the reduced producibility range. For simplicity of design, this handbook will further divide the design rules into three category ranges: A, B, and C, with A being the easiest to produce and C being the most difficult. If more stringent design standards are selected, the number of fabricators that can produce such a board is limited. Circuits produced with design rules in the A category will be easier to produce, will have higher yields, and therefore can be fabricated at lower cost. To keep costs at a minimum, you should select the design rules most appropriate for the application:

- *Category A*. This specification allows conventional HDI processes to be used with relaxed tolerances. It should have the highest yield and lowest cost. It is estimated that 100 percent of HDI fabricators can meet these design rules.
- *Category B*. This is the conventional HDI process. It is estimated that 75 percent of HDI suppliers can meet these design requirements under production conditions.
- *Category C*. Top-level fabrication shops, representing 20 percent of the total HDI fabricators, can meet these design rules. Panel sizes are often reduced to increase yield, which increases the final cost. Production volumes are presently limited, with special attention required during the production process. These rules require smaller panels and more exotic fabrication techniques. They are generally required only in electronic packages, chip-on-board (COB), flip-chip interposers, or MCM applications. At present, yields are lower and costs are high. It is estimated that fewer than 20 percent of all fabricators can achieve these design rules in limited production or prototype volumes.

Typical HDI design rules are given in Fig. 25.5. This figure bridges the two design categories from the specification IPC-2226, “Design Standards for HDI and Microvias.”[5] This is a Type III HDI structure.

Symbol	Feature	Category A micron [mil]	Category B micron [mil]	Category C micron [mil]
a	Microvia hole diameter at target land (as formed)	125-200 [5-8]	100-200 [4-8]	75-250 [3-10]
b	Microvia diameter at capture land (as formed, no plating)	350/14	300/12	250/10
b-1	via in SMT pad width	300/12	250/10	250/10
c	landing pad diameter	350/14	300/12	250/10
d-1	conductor/landing pad spacing on rigid innerlayer	125/5	100/4	75/3
d	pad to pad spacing on innerlayer	125/5	75/3	75/3
e-1	conductor line width on landing layer	125/5	100/4	75/3
e	conductor width on innerlayers	125/5	75/3	75/3
f	min. finished hole size - fhs (plated through-hole)	250/10	200/8	150/6
g, o	surface via pad (fhs + annular ring x 2) min.	fhs+350/14	fhs+300/12	fhs + 250/10
	through-hole pad diameter	600/24	500/20	400/16
h	trace spacing on rigid outerlayer	125/5	100/4	87/3.5
l	trace width on rigid outerlayer	125/5	100/4	87/3.5
k	fhs drill hole plane clearance on innerlayer (fhs + annular ring x 2)*	fhs + 700/28	fhs + 66/24	fhs + 500/20
	surface conductor to unplated hole	250/10	200/8	200/8
n	min. unplated hole diameter	350/14	300/12	300/12
m-1	min. HDI dielectric thickness	75/3	62.5/2.5	50/2
ar	Min. aspect ratio, (m-1)/a	< 1.0	1.0	1.0
z	min. board thickness	725/29	600/24	500/20

25.4 DESIGN

HDI and microvias place a new burden on printed circuit design. The various IPC types impose significant changes in the multilayer stack-up from a conventional board. But additionally, microvias can be implemented in many different ways and with different design rules. This section presents just a few of the design issues.

25.4.1 Multiple Layers of Microvia Holes

For interconnecting IC substrates with hundreds of I/O terminals, a single layer of microvia holes may not be sufficient to satisfy interconnection requirements. Double, triple, or even quadruple microvia hole layers may be necessary whether the board is a motherboard or a chip package substrate. When microvia holes are made only between adjacent layers (see Fig. 25.6), all three microvia processes—photovia, plasma via, and laser via—can be used. However, when a design requires microvia holes that must connect beyond adjacent layers—such as L1 and L3 (skipvia)—laser via processing is the only practical option.

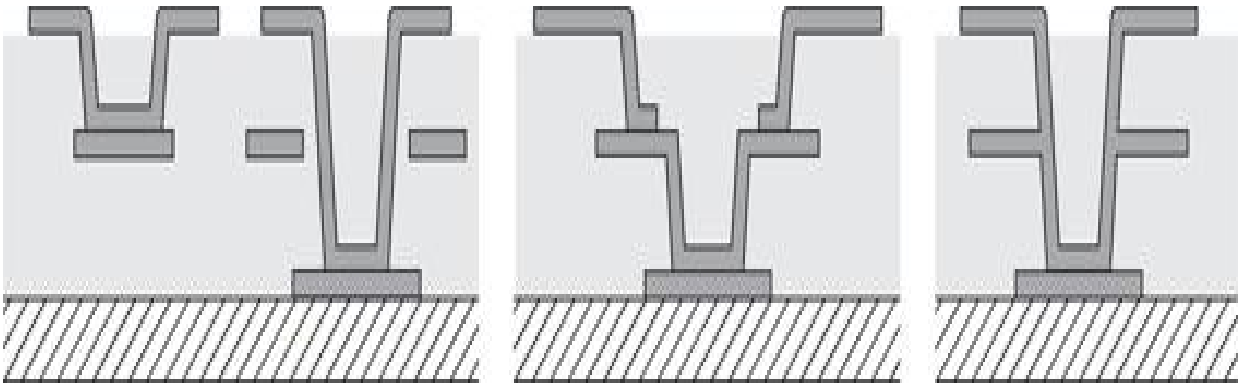

FIGURE 25.6 Microvia connections beyond adjacent layers.

25.4.2 Design Tools

Printed circuit design has become one of the most important functions in the electronic product realization process.[6] The demands on printed circuit design keep mounting. The reasons for this increasing demand include the following:

- To regain time for product schedules
- To lower the cost of fabrication and assembly
- To enable new area-array components, such as chip scale packages (CSPs), micro-BGA, and flip-chip interposers
- To decrease the time to market
- To improve electrical performance for high frequency and to reduce EMI

Bringing the process back under control requires a methodology that involves planning the printed circuit layout process with predictive wiring density models. The other benefits include reducing printed circuit fabrication and assembly costs.

25.4.2.1 Required Features of HDI CAD Toolsets and Autorouters. A partial list of features that computer-aided design (CAD) tools require to design HDI boards includes the following:

- Optimization of a mixed via by a router
- Autorouting of cost budget for mass via generation
- Buried or blind via control on the layer
- Via padstack control (landless)
- Staggered via control
- Pad within pad
- Blind via push/shove during manual routing
- Any angle routing
- Manufacturing process rules at all design phases
- Buried components

Some of these features have already been discussed in previous chapters.

25.4.2.2 Autorouters. Autorouters have been a part of printed circuit design systems for many years. An autorouter will automatically place vias and traces on the printed circuit based on the schematic and part geometries. Elaborate configuration menus drive the appropriate placement of these features. A special autorouter is required for HDI structures, because many HDI processes employ mass via generation as used for SLC technologies. These processes produce all the vias simultaneously and at any desired diameter. Since the cost of vias is rather insignificant, the autorouter should have the capability of achieving a near-zero via cost. When the routing is done, a different but more optimized design results.

25.4.3 Trade-Off Analysis

After a product has been partitioned, the circuit has been designed, and the components have been selected, the physical design must be planned with an eye toward achieving the lowest manufacturing cost while meeting all

performance and operating boundary conditions. This is especially true for HDI designs. Conventional through-hole printed circuit design has not changed too much over the years. Finer geometries, more layers, and surface mounting have been added, but the conventional design process remains essentially the same. Microvias and HDI, however, introduce many changes to the design process and require new design rules and layer structures. Experience and history will not help here. The unfortunate truth about printed circuit layout is that there is an almost infinite number of combinations of layer structures and design rules that can satisfy the schematic and bill of materials. With all these choices, especially the new ones that HDI offers, a trade-off tool is required to find the best set of design rules and features that allows the rapid design of a printed circuit board, is producible, and meets all the performance expectations while providing the lowest total manufacturing costs. When used early in the design process, before the actual physical design of the printed circuit, the tools require predictive models that can anticipate cost and performance. Information and processes for planning a HDI design can be found in Chap. 19 of this handbook. Trade-off information of through-hole density and relative costs can be seen in Fig. 25.2.

25.5 DIELECTRIC MATERIALS AND COATING METHODS

This section provides an overview of the dielectric and applied conductive materials used in microvia and via filling. Some of these materials can be used in both IC chip carrier and PWB HDI applications. The discussions are focused on the HDI PWB arena and on materials for which information is readily available. In Sec. 25.5.2, cross-references are made

to the relevant material specifications of the IPC/JPCA-4104 specification for HDI and microvia materials. A brief material roadmap discussion is included to illustrate material property trends.

Figure 25.7 shows the compatibility of laser via, photovia, and plasma via methods with four basic surface dielectric structures on which microvia holes are to be formed. Although laser via methods can cope with all four dielectric structures, photovia and plasma via methods are applicable to only one structure, respectively, as shown in the figure. This is one reason why laser via is more widely used today. Another wiring layer is built over the existing microvia holes, which become buried via holes (BVHs).

	Standard configuration 	RCC	Thermally curable resin	Photoimageable resin
Photovia	X	X	X	O
Laser via, CO_2	O	O	O	O
Laser via, yag	O	O	O	O
Plasma via	X	O*	X	X

FIGURE 25.7 Compatibility of via hole formation methods with four basic dielectric layer structures.

The specification IPC-4104 will define material requirements for HDI applications. This IPC specification applies only to the *surface HDI layers*, the conventional multilayer core materials are covered by IPC specification IPC-4101B.

25.5.1 Materials for HDI Microvia Fabrication

Figure 25.8 shows a material and technology selection flowchart for use when choosing dielectric materials. In using the flowchart, you should ask the following questions regarding the dielectric you are considering:

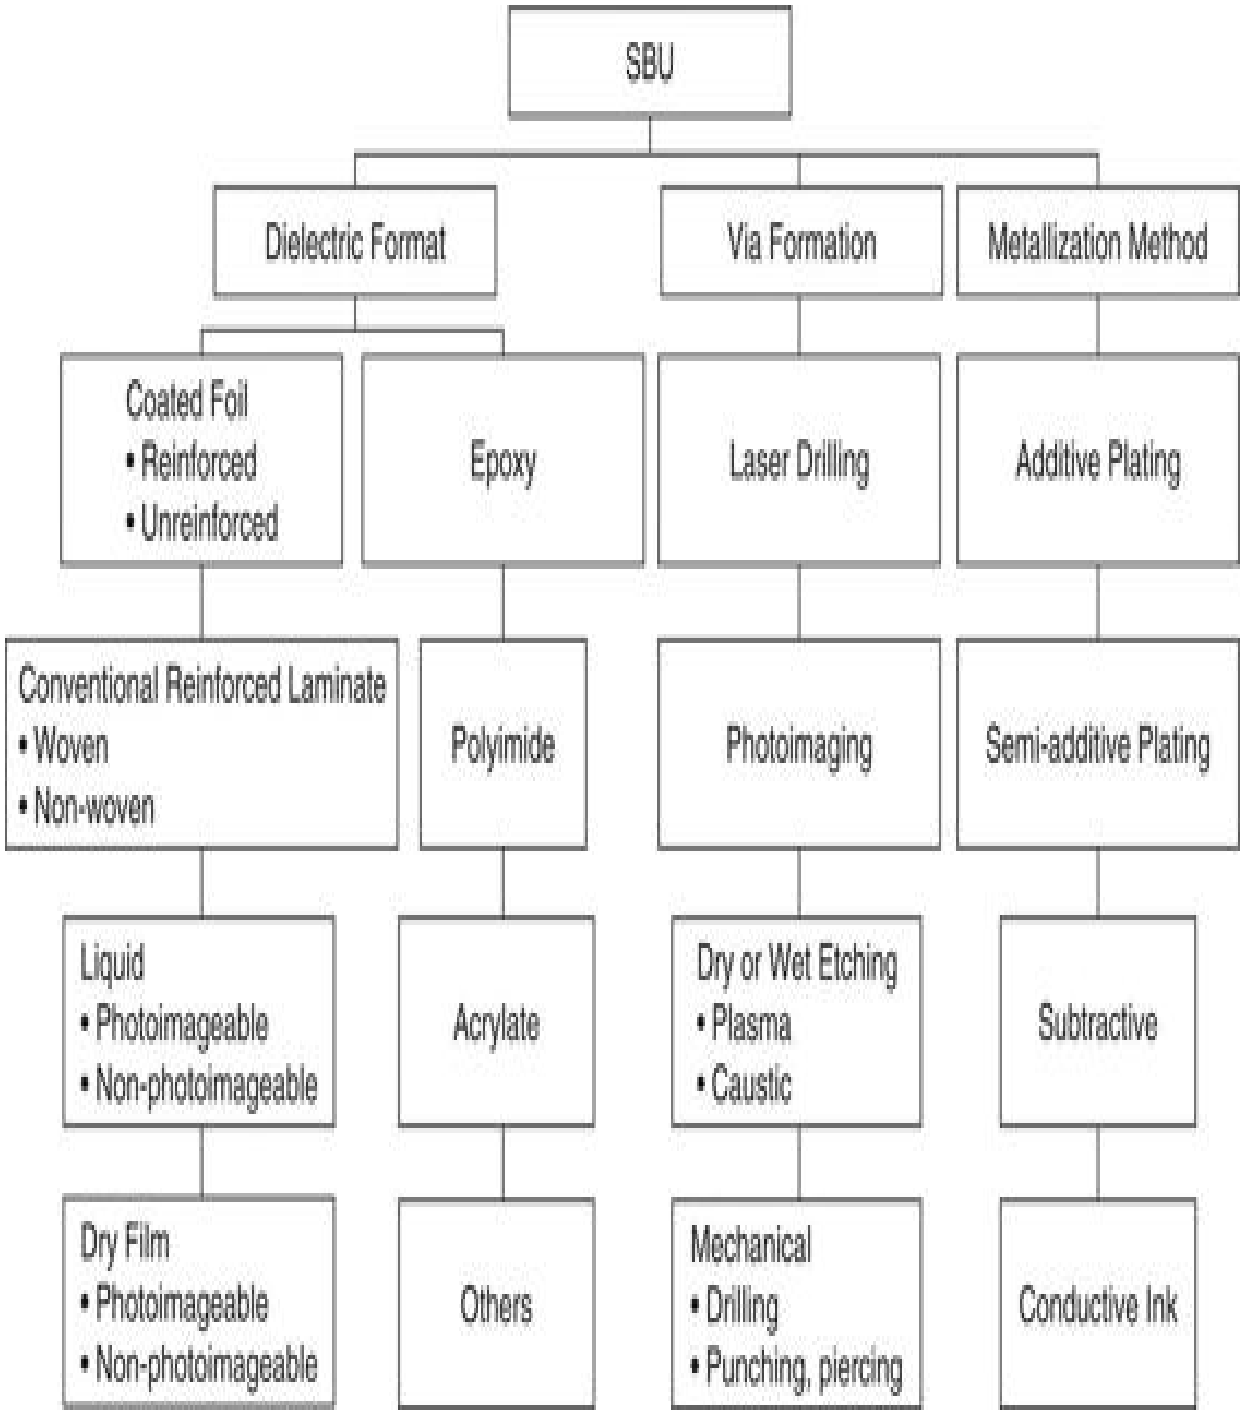

FIGURE 25.8 Material and technology choices for SBU fabrication. (*Courtesy of DuPont*.)

- Will the dielectric use chemistry compatible with current chemistry used by core substrate material?

- Will the dielectric have acceptable plated copper adhesion? [Many original equipment manufacturers (OEMs) want ≥6 lb/in (1.08 kgm/cm) per 1 oz (35.6 μm) copper.]
- Will the dielectric provide adequate and reliable dielectric spacing between metal layers?
- Will it meet thermal needs?
- Will the dielectric provide a desirable "high" T_g for wire bonding and rework?
- Will it survive thermal shock with multiple SBU layers (i.e., solder floats, accelerated thermal cycles, multiple reflows)?
- Will it have platable, reliable microvias (i.e., will it have latitude to ensure good plating to the bottom of the via)?

25.5.1.1 Copper-Clad Dielectric Materials. Due to relative ease of implementation, copper-clad dielectrics are used on a larger scale than unclad dielectrics. Copper-clad dielectrics provide a method that requires the least number of changes in manufacturing flow because they typically use the same dielectric and reinforcements found in standard PWBs. Copper-clad-based materials have a longer history in making blind vias than any other method. This makes many designers, OEMs, and PWB fabricators more comfortable with copper-clad-based materials.

These materials can be nonreinforced or reinforced. The reinforcement can be woven or nonwoven and can be aramid, glass, and so on. These dielectrics are suitable for via formation by laser or other mechanical removal methods.

Due to its wide availability and familiarity, FR-4 material is often initially evaluated in laser-drilling microvias. Reinforced with thin 106 or 1080 woven glass (since thicker glass is more difficult to vaporize with lasers, but there is 1086 uniform-woven glass just for laser ablation), one- or two-ply

laminates are selected with a resin content close to 70 percent. The “laser drilling” is done by ablation of the via using a conformal mask or a directly focused beam, with either an ultraviolet (UV) Nd:YAG or a CO_2 laser. These materials may also be coated on a copper foil. Typical applications use single-side-clad material where the copper clad is used as the outer layer and the C stage is bonded to the subcomposite. These materials are suitable for via formation using methods such as plasma or laser. To meet fine circuitry and smaller via needs, very thin copper is available. Another approach, practiced by many Asian PWB fabricators, is to thin down incoming copper clad by etching and/or planarizing the copper surface precisely.

25.5.1.2 Unclad Dielectric Materials. If the dielectric is reinforced, microvias are formed by laser drilling or other mechanical means. If it is nonreinforced, it can be photoimageable in addition to the previous choices. To add conductivity, subtractive processing is the standard manufacturing practice in the United States and Europe. Semi- or fully additive techniques have been practiced in continuous high volume only in Asia, most notably Japan. In Japan, which leads the world in microvia production, about 22 percent of manufacturing begins with a non-copper-clad dielectric material.

Japan has long accepted the additive manufacturing methodology for creating circuits on the board surface as well as the through-hole connection.

The trade-off between clad and unclad dielectric materials follows a benefit analysis similar to that used for subtractive versus additive processing. Copper-clad-based material is fabricated using standard practices familiar to most shops. However, it innately generates more waste and has a higher cost due to the subtractive nature of the manufacturing sequence. In addition, copper-clad materials demonstrate

limitations in fine-line capability similar to those seen with standard manufacturing methods used today.

Unclad dielectrics require considerable resources for optimized plating of copper to achieve reliable and consistent copper peel strengths. Unclad dielectrics and thin copper-clad dielectrics, however, gain in importance as the requirements for line and space geometries reach ≤75 µm and required via sizes are lower than 75 µm in diameter. Figure 25.9 depicts the influence of base copper on the aspect ratio of a via. The base copper increases the aspect ratio, making it more difficult to plate the via, and can cause issues with bottlenecking whereby the via plates shut at the top without sufficient plating in the bottom. Other data show that thinner copper etches more uniformly, which helps the cause for controlled impedance.

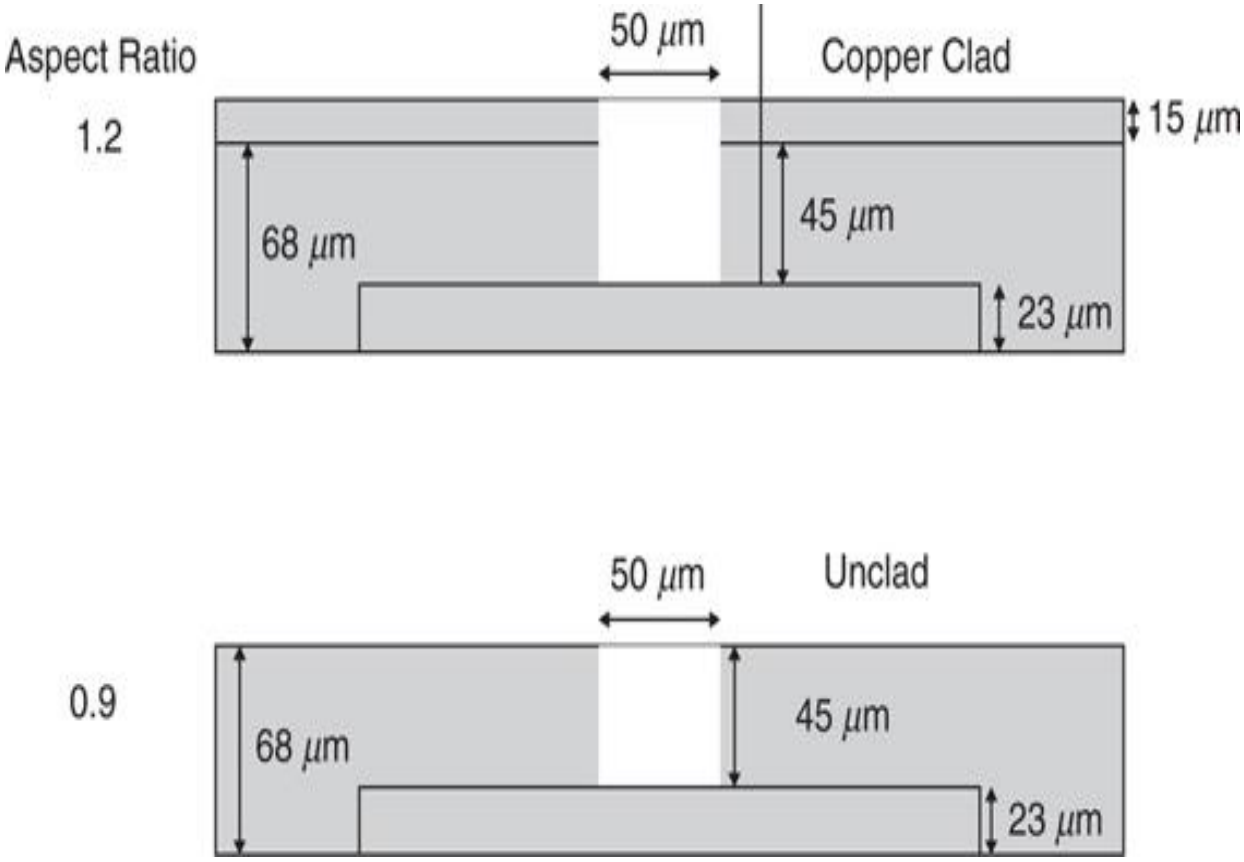

FIGURE 25.9 Impact of 1.2 oz base copper on the aspect ratio of a 50-µm via. (*Courtesy of Vantico*.)

25.5.1.3 Clad versus Unclad Dielectric Materials.

Table 25.3 compares the utilization of clad versus unclad dielectric materials as circuit geometry shrinks. This table shows that as the technology requirements get tougher, the trend toward using unclad dielectrics increases. As line and space requirements get denser, and via diameters get smaller, requirements for chip package substrates to use unclad or thin copper dielectrics increase. In the case of mobile phones and other portable applications, for example, it is foreseen that by the year 2015 lines and spaces will be down to 5 to 15 µm, respectively, and via sizes to 10 µm, with a subsequent high usage of unclad material.

TABLE 25.3 Utilization of Unclad Dielectrics by Key Market Segments[4]

	Chip Package substrates	Cellular, Camcorder, PDA	Computer/ Telecommunication*
HDI penetration	High	High	Low
Line/space and via diameter (year 2013)	10-µm lines and spaces; 25-µm via diameter	50-µm lines and spaces; 100-µm via diameter	100-µm lines and spaces; 125-µm via diameter
Use of unreinforced dielectrics	High	High	Low
Use of unclad dielectrics	High	Med, but increasing	Low

*Excluding laptop computers.

25.5.2 Examples of HDI Microvia Organic Substrates

From a mechanical standpoint, materials may be grouped as reinforced and nonreinforced laminates and prepregs, as in Fig. 25.8. Reinforced materials are generally better in dimensional stability, lower in coefficient of thermal expansion (CTE), and less sensitive to thermal cracking, whereas nonreinforced materials often have a lower dielectric constant (D_k) and may be photoimageable. This can be seen in Fig. 25.10, which shows the D_j versus D_k (at 1 MHz) of various resins and reinforcements.

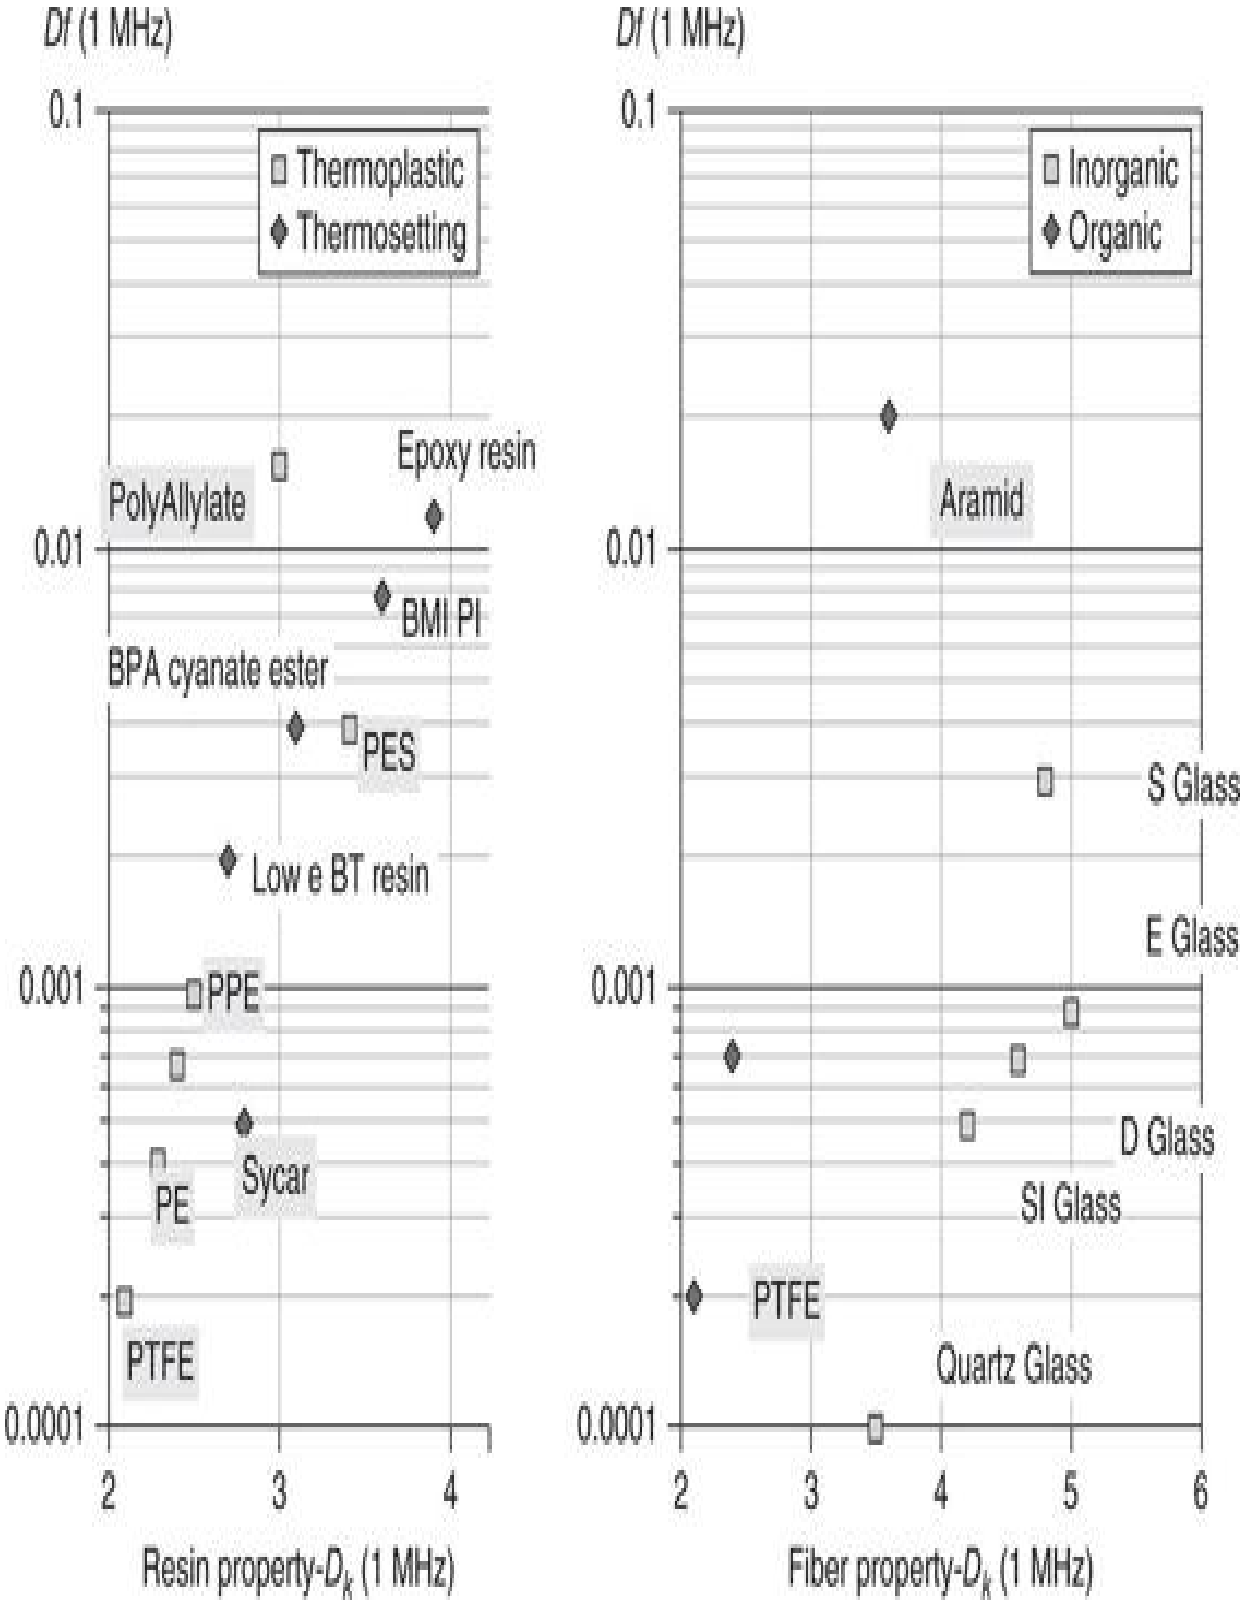

FIGURE 25.10 Dielectric options of resins and reinforcements by dissipation factor (D_j) versus dielectric constant (D_k). (*Source: Holden Consulting*.)

25.5.2.1 Nonreinforced Dielectric Materials. Nonreinforced dielectric materials include resin-coated copper foils, unclad photoimageable dielectric materials, and non-photoimageable dielectric materials.

25.5.2.1.1 Resin-Coated Copper Foils. Resin-coated foils are the most common materials used for build-up multilayer microvia applications. Many product variations are available and fit well within the existing multilayer-manufacturing infrastructure. Epoxy-based coated foils are the most common and have performance properties similar to FR-4 but with no glass reinforcement. Peel strengths, thermal performance, and electrical properties are excellent. A variety of other resin systems are also being developed and starting to be used for coated foil build-up applications. Resin-coated foils come in two general types with either one or two resin layers. One-pass coated foils have a single B-stage layer designed to flow, fill, and provide thickness control at the same time. Two-pass-coated foils have a C-stage resin layer adjacent to the foil and a B-stage layer for flow and fill. The fully cured C-stage layer acts as a “stop” during the lamination process, typically enabling better thickness control. Resin-coated foils are available in a variety of thicknesses, yielding between 1.0 mil (25 micron) and 3.0 mil (76 micron) thick, finished dielectric layers. Copper foils most commonly used are 1/2 oz (18 micron) and 3/8 oz (13.34 micron), but there is substantial interest in thinner copper foils for improved laser efficiency and better fine-line circuitry definition.

25.5.2.1.2 Other Resins. Since build-up technology is still in its relative infancy but evolving rapidly, many different and diverse approaches are being investigated for the resins used and variations on the via-formation process. Low-D_k/D_j resins such as polyphenylene ether (PPE) are being used to address signal speed and integrity demands in resin-coated foil build-up structures. Another approach is to use additively plateable resin and use the copper as a sacrificial carrier,

eliminating the need to laser through copper. An additively plateable resin has the characteristic of high surface adhesion to electroless copper or direct metallization. The sacrificial foil makes it compatible with normal multilayer lamination processes, saving the need for expensive coating machinery, while also protecting the thin dielectric from harm until it is laminated to the printed circuit. This also gives excellent surface topography for good peel strength. The properties of a resin-coated foil are given in Table 25.4. See IPC- 4104 specification sheets 12, 13, and 19 through 22 for more complete material performance information.

TABLE 25.4 General Properties of Resin-Coated Copper (RCC)

	Units	Via Foil	Conditioning
Dielectric constant at 1 MHz	—	3.4	C-24/23/50
Dissipation factor at 1 MHz	—	0.0205	C-24/23/50
Electrical strength	V/mil	1776	D-48/50
Insulation resistance	MΩ	2.65×10^5	C-96/35/90
Surface resistivity	MΩ	6.60×10^8	E-24/125
Surface resistivity	MΩ	4.71×10^8	C-96/35/90
Volume resistivity	MΩ-cm	7.17×10^7	E-24/125

Source: Allied-Signal.

Laminate suppliers should be contacted when special needs arise, as the resulting composite will require understanding of fabrication and design issues.

Resin-coated foils come in two general types:

- One-pass coated foils have a single B-stage layer designed to flow and fill and to provide thickness control,

all at the same time.

- Two-pass coated foils have a C-stage resin layer against the foil and a B-stage layer for flow and fill. The fully cured C-stage layer acts as a “stop” during the lamination process, typically enabling better thickness control.

With the exception of the laser process, all the basic technology to produce SBU using resin-coated foil is the same as, and found in, most multilayer PWB production operations.

Another alternative is to use additively platable resins. In this approach, the copper foil acts as a sacrificial carrier. The process is similar to that described earlier, but the first step after lamination is to etch off all the copper chemically. This eliminates the need to laser through copper and makes acquisition of registration targets simpler. The structure left behind by the copper also gives excellent surface topography to the resin for good peel strengths from the subsequent additive plating step. This approach allows for extremely fine feature definition and much greater laser efficiency.

25.5.2.1.3 Unclad Nonreinforced Photoimageable Dielectric Materials. Material chemistry options for this group include epoxies, epoxy blends, polynorbornenes, and polyimides. They can be applied as liquid or dry film, negative or positive imaging, and can be solvent or aqueous developable. To improve the dielectric’s adhesion to copper, most dielectric suppliers require a copper pretreatment with a black oxide or conversion coating (oxide replacement) prior to application of the dielectric. Most of these materials are either epoxy or epoxy- and novolac-based to provide high T_g and good plating, and most provide adhesion values for plated copper of at least 1.1 kg/cm at a 25-µm copper thickness. Typically these dielectrics are metallized using conventional solvent swell and permanganate etching techniques. The liquid materials use only safe solvents

(those not known to lead to harmful health effects with prolonged exposure. Typical microvias are seen in Figs. 23.27, 29.5, and 29.12.

A unique advantage for photoimageable materials is that the speed used to make small or large vias is the same. With the growing need to make embedded reactives (passives), large rectangular areas need to be opened up to place these devices. Currently, this is only economical with photoimaging. Most photoimageable materials are easy and fast to laser-drill because they are nonreinforced. See IPC-4104 specification sheets 1, 2, 7 through 10, and 16 for more complete material performance information. A partial list of available materials is shown in Table 25.5. Properties of photodielectrics can be seen in Tables 25.6 and 25.7.

25.5.2.1.4 Nonphotoimageable, Nonreinforced Dielectric Materials. This group can be laser-drilled, plasma-etched, and/or mechanically treated to form microvias. As stated earlier, many of the photoimageable dielectrics are laser-drillable.

As with the photoimageable group, to improve the dielectric's adhesion to copper, most dielectric suppliers require a copper pretreatment with a black oxide or

conversion coating (oxide replacement) process. See IPC-4104 specification sheets 6, 11, 17, and 18 for more complete material performance information. A partial list of materials is seen in Table 25.8.

25.5.2.2 Reinforced Dielectric Materials. Copper-clad dielectrics for HDI can be rein- forced, as in FR-4, or unreinforced, as in coated copper foil. The dielectrics can be epoxy, as in FR-4, or polyimide, cyanate ester, bismalene-triazine (BT), PPE, or PTFE. Reinforcements are typically glass cloth, but there are a variety of glass as well as aramid paper and exotic fibers such as quartz or carbon fiber.

25.5.2.3 Laser-Drillable, Woven-Glass Laminate. A new family of prepregs for HDI consists of uniform-glass prepregs such as 1086 and 1087 glass. This glass is a thinner fabric than the typical 1080 glass cloth; it has more glass plies but they are spread uniformly across the fabric. Table 25.9 describes the differences between the conventional 1080 glass cloth and the 1080 LD (laser-drillable) and the new 1086 LD prepreg. Figure 25.11 shows these two glass prepregs. Table 25.10 compares the performance of RCC, conventional 1080 prepreg (PP), and the new 1086 LD

prepreg, whereas Fig. 25.12 shows laser-drilled microvias in the two different prepregs. Additional details can be found in Chaps. 10, 11, and 12 of this Handbook.

25.5.2.4 Aramid-Reinforced, Nonwoven, Nonglass Laminate.

In 1965, scientists at DuPont discovered a method for producing an almost perfect polymer chain extension using the polymer poly-p-benzamide. The key structural feature of this molecule is the paraorientation on the benzene ring, which allows it to form rod-like structures with a simple repeating molecular backbone. The term *aramid* now refers generically to organic fibers in the aromatic polyimide family. Kevlar was the first para-aramid fiber to become familiar, due to its use in bullet-resistant vests and as a lightweight, high-strength structural reinforcement. Aramid- reinforced prepregs and laminates have proven their functionality for a number of years in high-reliability applications and more recently in consumer electronics.

The low CTE of aramid non-woven reinforced prepreg and laminate provides a closer match to the CTE of the silicon chip. Depending on the type of resin and the resin and copper content of the laminate and the prepreg, the CTE of the PWB can be tailored to between 10 and 16 ppm/°C (Fig. 25.13). This allows the designer the option of finding a best fit of the CTE of the PWB to the CTE of the components.

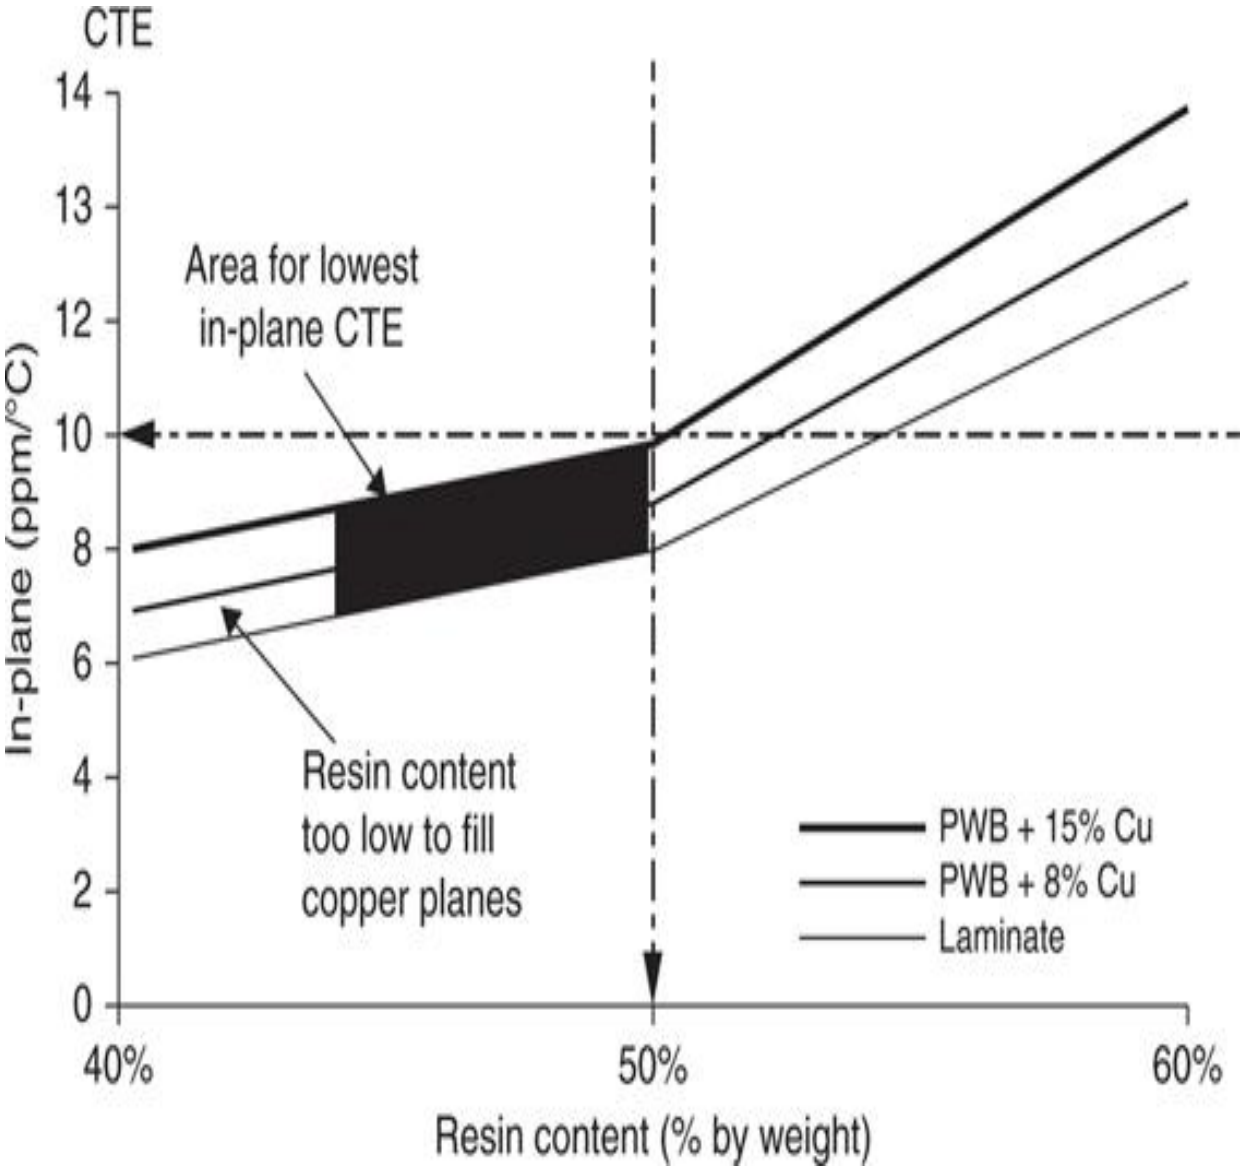

FIGURE 25.13 Impact of copper and resin content on in-plane CTE. (*Source: DuPont*.)

Reliability can be designed in by PWB designers, as they know which component packages are used, what the CTE requirements of these packages are, and what the life-expectancy requirements of the electronic equipment are. The ability to tailor in-plane CTE has made nonwoven aramid-reinforced PWBs one of the most favorable material options for avionics, satellites, and telecom applications where long life expectancy and high reliability are needed. In

mobile phone applications, where chip scale packages (CSPs) are commonly employed, low-CTE nonwoven aramid reinforcement extends solder joint life as much as three times over FR-4 and resin-coated foil (RCF). After more than 1000 thermal cycles (−40 to +125°C), nonwoven aramid-reinforced epoxy resin does not crack, as is common with nonreinforced dielectrics.

Aramid-reinforced laminate and prepreg allow fast microvia hole formation and at the same time maintain the performance characteristic of a smooth surface for fine-line conductor imaging. The ablation speed of nonwoven (aramid) laminates and prepregs is close to that achieved when using nonreinforced materials such as resin-coated foil, dry film, or liquid dielectrics. Since aramid laminates are very stable, they allow the fabrication of double- sided, very thin, etched innerlayers, which are then pressed to a multilayer package in a single pressing cycle. Thus, these thin innerlayers can be processed in parallel. Aramid-reinforced material is a cost-effective alternative when laser hole formation is used to form single- and multiple-layer interconnects, and is compatible with FR-4 materials used in the core of aramid–FR-4 mixed constructions. Laser drilling of stepped microvia holes is accomplished in one subsequent operation (see Fig. 25.14). This allows the designer to interconnect up to four layers on each side of the inner core without sequential processing—a substantial productivity advantage for the PWB fabricator that results in the lowest possible manufacturing cost. See IPC-4104 specification sheets 5 and 23 for more complete material performance information.

25.5.3 Via Filling

The demand for filling of through holes with epoxy resin or conductive paste has been rising ever since surface-mount technology became widely adopted in the PWB industry.

25.5.3.1 Basics. Following are the traditional examples of the types of applications that require via filling processing capability:

- Preventing acid residue from attacking the Cu plating at the through-hole opening, which can in turn cause an open circuit
- Averting mishandling due to loss of vacuum during board-level assembly or during vacuum- assisted transport in production
- Avoiding blowout of flux and/or solvent residue during assembly and solder reflow
- Stopping flux from dripping from the through holes to the opposite side of the PWB
- Keeping solder resist ink from migrating into through holes during screen printing, which can cause formation of nodules at the through-hole opening during solder plating and/or gold plating
- Enhancing the planarity of solder resist on the surface of filled through holes and the planarity of core layer for SBU PWBs
- Improving the stability of solder paste printing volume for via-in-pad designs
- Preventing the migration of solder into through holes in via-in-pad designs

The filling of through holes with nonconductive resin and conductive materials using dispensing, screen-printing, and roll-coating methods has been extensively evaluated and tested. Of the three basic methods described earlier, screen printing is the most common process. It allows for efficient, selective filling of large numbers of through holes.

25.5.3.2 Via-Filling Materials. Selection of the proper resin-based material is the most important objective when using a screen-printing process to fill through-hole vias in build-up multilayer cores. In particular, the primary issues to be considered when choosing an appropriate fill material are

- Ease of printing

- Ease of grinding (planarizing)
- Adhesion to hole wall and panel surface

The most commonly used materials for permanently filling through holes include single- cure (thermal) resins, photoimageable dielectrics, conductive pastes, and the dual-cure (UV + thermal) epoxy resin utilized in the Noda screen flat plug process. Following are brief descriptions and comparisons of the characteristics of each of these types of via-fill materials.

25.5.3.2.1 Conventional Prepregs and RCC. In fabricating a base core with a pattern, the core panel is usually panel-plated and the pattern is made with a dry-film tenting process. Some fabricators seem to prefer pattern plating, however. The choice depends on the fabricator's familiarity with these processes. After the pattern is formed, dielectric material is laminated over the core (in the case of prepreg, with copper foil) and the holes can be filled with resins, depending on the plated hole diameter and the thickness of the core. It is generally agreed that when the diameter of plated holes is equal to or less than 0.3 mm *and* the core thickness is equal to 0.6 mm or less, these holes can be filled effectively by the lamination process (although the resin thickness of 80 µm is preferred in the case of RCC). See Fig. 25.15.

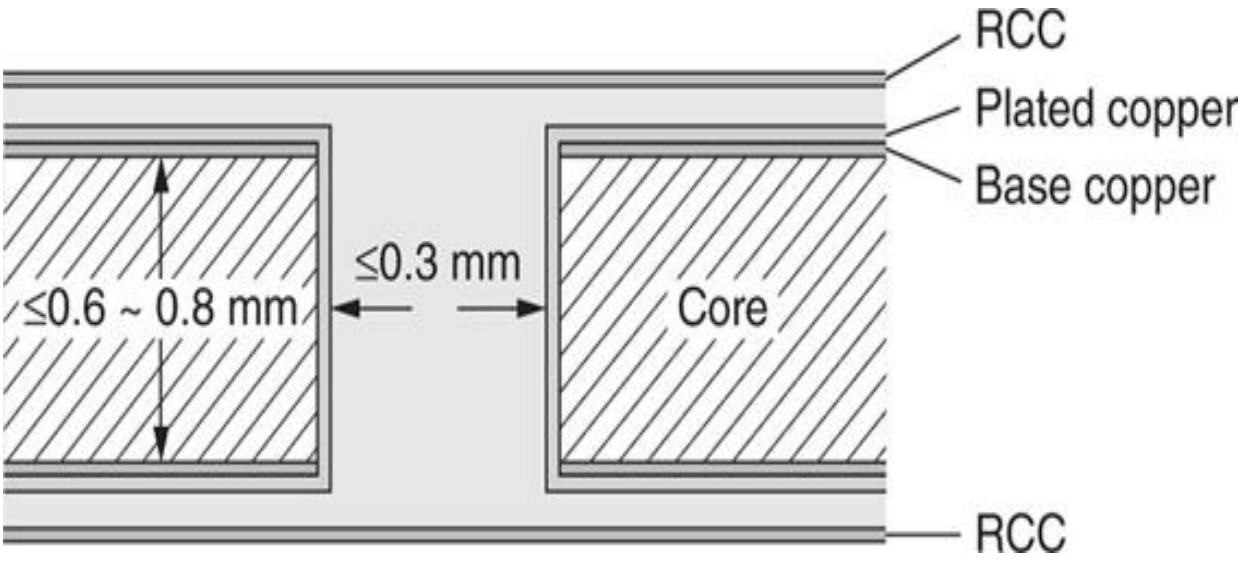

FIGURE 25.15 Conditions under which the through hole can be filled with resin by RCC lamination.

When the diameter/thickness conditions are not met, it is necessary to fill the holes using a separate process. A screening process does this from one side of the panel with polyester screen with an oversized hole pattern. After hole filling and curing the resin completely, the fabricator removes excess resin using a belt sander (#600 to #800) or a ceramic brush. Figure 25.16 illustrates the process. This is a tricky but necessary operation for microvia board makers, particularly for photovia processing.

FIGURE 25.16 Hole filling and surface scrubbing.

Hole filling is costly but yields a few advantages over simultaneous hole filling by lamination of RCC or prepreg. The edge of the plated holes is well protected; therefore, forming finer annular rings on the base core by tenting is easier. There is no concavity problem over the hole that can cause difficulties in later processes.

25.5.3.2.2 Dual-Cure (UV+ Thermal) Epoxy Resin. The main purpose for using a dual-cure epoxy resin is the stability of the B-cured material and the ease with which it can be removed by grinding during planarization. A homogeneous, semicured state can be reached because the liquid environment within the UV exposure system helps to control the temperature and stabilize the intensity of UV light. Furthermore, because the temperature of the liquid environment is kept low, the expansion of air bubbles that may have been trapped in the fill material at room temperature is prevented.

In formulating epoxy resin via-fill ink, one must consider the adhesion between the fill material and the copper plating in the hole barrel. Normally it may seem suitable to use a material that does not include an acrylic component. However, some suppliers have found it more beneficial to add an acrylic component because of its resistance to moisture absorption. They determined that it would be preferable to improve the ink's adhesion to copper by pretreatment with a black oxide or chemical etching process. This is similar to the approach taken by many dielectric suppliers.

25.5.3.2.3 Photoimageable Dielectrics. An advantage of a dielectric being photoimageable is that unwanted material is washed off during development, thus eliminating the planarization step. Typically, one screen pass is sufficient to fill or plug vias, but two passes can also be used to maximize hole filling. Standard screen-printing equipment is needed

with a bed-of-nails or dimple plate to maximize air release out of the plugged holes. If a squeegee is being used, single-sided application is recommended. Two coats are recommended to minimize the effects of material. Cores as small or smaller than 0.030 in (0.76 mm) require a secondary coating application.

25.5.3.2.4 Conductive Paste. In addition to the previous advantages of via filling stated earlier, conductive via fills also dissipate heat, increase electrical conductivity in the hole, and allow a via-in-pad design option (Fig. 25.17). The latter advantage is another way to recover real estate.

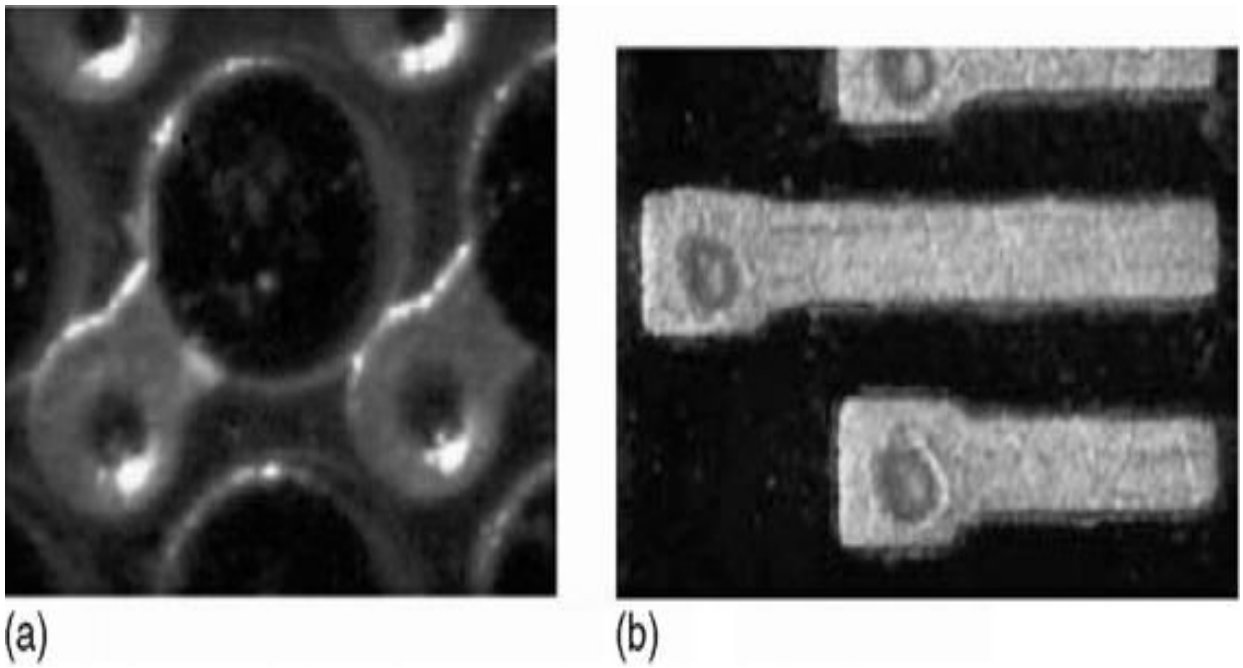

FIGURE 25.17 A via-in-pad option with conductive via fill: (*a*) traditional "dog-bone" design; (*b*) via-in-pad design. (*Courtesy of DuPont*.)

One example is a screen-printable paste made of silver, copper, and epoxy. The optimum mix of metal particle shapes and sizes bonded together with epoxy resin produces essentially zero shrinkage. In general, the plated or unplated through hole is filled with paste using a stencil-printing process. After drying and curing, the plugged through holes are planarized and plated to make them solderable. Some

typical design rules are an aspect ratio of 1:1 to 6:1 with vacuum assist, a via size of 6 to 25 mil (152 to 635 µm), and a core thickness of 6 to 85 mil (152 to 2159 µm). The product is extremely reliable during assembly.

25.5.3.2.5 Single-Cure (Thermal) Resin. Typically, thermally cured resins exhibit good adhesion strength to copper. Unfortunately, the rate of heat dissipation throughout the filled core material is unstable, making it difficult to achieve a reliable semicured state prior to planarization.

As a result, a rapid and unpredictable rise in temperature is likely to occur; as such, it is imperative to fill the holes completely, leaving no voids, if this type of material is to be used.

25.5.3.2.6 Solder Mask Ink. Using this type of material, it is relatively easy to fill the hole. However, the presence of volatile elements (solvents) and the degree of shrinkage during curing have a significant effect on the stability of the manufacturing process. In the case of small diameter through holes, the solvent residue may remain in craters or dishes at the mouth of the hole opening. Furthermore, the copper adhesion strength of these materials is typically lower than that of other hole fill materials.

25.5.3.2.7 Resin-Coated Foil (RCF). Similar to the potential problems faced with photoimageable dielectrics, there is a divergence between the material characteristics required for hole filling and the characteristics that are desirable for an innerlayer dielectric-copper material. Nonetheless, it is likely that the RCF foil materials will prove to be acceptable for filling vias in the limited range of specific applications that exhibit a low-aspect ratio between hole diameter and core thickness.

Liquid dielectric resin is coated more or less the same way as in photovia. However, there is a fundamental difference between photovia and laser via dielectric. In laser via

processing, the resin is fully cured before laser drilling (microvia formation). This is a big advantage over photovia materials since the resin movement after hole formation is much more stable than in the case of photovia processing in which resin is fully cured after holes are formed. This resin (hole) movement makes pattern-imaging registration difficult for photovia processing.

25.6 HDI MANUFACTURING PROCESSES

This section discusses processes that employ non-drilling via-hole formation techniques. Through-via drilling is possible below 0.20 mm (0.008 in), but cost and practicality discourage this. Below 0.20 mm (0.008 in), laser and other via-formation processes are more cost-effective. Each of the five major via-hole formation processes used for printed circuits is discussed in the following sections.

- Photovia
- Plasma via
- Laser via
- Solid (paste) via
- Insulation displacement via

The manufacturing process for each microvia technology begins with a base core, which may be a simple double-sided board carrying power and ground planes or a multilayer board carrying some signal pattern in addition to power and ground planes. The core usually has plated through holes (PTHs). These PTHs become BVHs. Such a core is often called an *active core*.

25.6.1 Photovia Process

Prior to dielectric material coating by any of the methods described previously, the copper surface of the base core must be treated by an adhesion promotion process to ensure good adhesion of dielectric material to the copper surface. Today, very few manufacturers use oxide treatment for this purpose. The most popular adhesion promotion treatment is a special etching process offered by many suppliers of chemicals. This step is common to all microvia processes.

Dielectric resin is semicured after coating to eliminate tackiness, and then the hole pattern is exposed by photoexposure processing. The usual photodeveloping process creates microvia holes and the dielectric is fully cured, typically at 160°C for about 1 hour. Then, the panel goes through a permanganate etching process to remove any residual resin at the bottom of the hole and simultaneously create microporous surfaces that act as an anchor and ensure desirable peel strength after copper plating.

The level of peel strength is controversial. Minimum peel strength required for chip package substrates is about 600 g/cm^2, but motherboard users, particularly cell phone makers, demand a minimum of 1.0 kg/m^2 or more in order for cell phone handsets to withstand drop tests. Laser via materials usually yield stronger peel strength because of fillers that can be added to dielectric resin. When etched, these fillers generate a superior microporous surface structure needed for strong peel strength.

After permanganate etching, the panel is catalyzed and metallized in an electroless copper bath and panel-plated galvanically to desired thickness. Some photovia process practitioners roughen the resin surface mechanically by brushing or liquid horning prior to catalyzing. Then, the conductor pattern is formed by dry-film tenting and etching. Some manufacturers prefer to use the pattern-plating

method for this purpose. Very few microvia board manufacturers use direct metallization methods for metallizing holes prior to galvanic plating. Several Japanese manufacturers use electroless copper all the way to the desired thickness in panel plating and use a positive electrodeposited (ED) system to achieve fine lines and very small annular rings. One important step in microvia hole board fabrication when resin is the dielectric choice, whether the process is photovia or laser via, is the removal of residual catalysts (normally palladium) entrapped in a microporous surface that can cause migration. The process used in this step is normally a trade secret.

Photovia processing is now used primarily to fabricate semiconductor chip package sub- strates because a large number of holes can be formed in one photoexposure and development step. However, as mentioned previously, photovia processing suffers more from material shrinkage than laser via processing after full cure, and hole locations tend to move randomly, which makes subsequent registration for patterning difficult. Because of this problem, photovia users limit the size of the panel to be much smaller than the usual panel size prevalent in motherboard fabrication to about 400 × 400 mm. Small hole formation is also difficult with the photovia process. As a result, even makers of package substrates are now resorting more to laser via processes as the laser-drilling speed is being improved. Photovia process users engaged in mass production are found only in Japan today. All photodielectric processes have certain characteristics in general. Table 25.11 lists the typical processing factors. A standard photovia process sequence is described in Fig. 25.18*a*.

25.6.2 Plasma Via Process

Plasma via processing was developed by a Swiss PWB maker, Dyconex. Products made with the plasma via process are called DYCOstrate.

There are many variations to the plasma via process, one of which is illustrated in Fig. 25.18*b*. Today, it is mainly used to fabricate sophisticated flex and flex-rigid wiring boards in small quantities.

First, an opening or window is made through copper foil by a normal etching process. When plasma etching is applied through this window, the shape of holes tends to be like a bowl (as shown in Fig. 25.28*b*), which is not suitable for reliable plating (although new plasma- etching equipment claims to have solved this problem).[7,8] Another problem is related to how the microvia hole is formed. The copper edge of the window hangs out over the hole, which results in poor reliability after panel plating. Therefore, to ensure reliable plated holes, a secondary etching is necessary to remove this copper overhang. One good thing results from this secondary etching, however. Since surface copper is thinned, formation of finer conductors is made easier. Nevertheless, by the time the panel is ready for plating for subsequent conductor pattern formation, it takes several times longer than other processes in a mass-production environment.

Plasma via processing is effective for forming through holes on flexible materials since holes are formed by plasma etching from both sides of the film and the bowl effect is minimized.

Plasma via etching evolved from the traditional process of plasma desmearing of through holes. Different gas,

magnetrons, and equipment fixturing are employed by current plasma via-etching equipment. The plasma is generated in a partial vacuum filled with a mixture of oxygen, nitrogen, and chlorofluoro (CF4) gasses. Microwave magnetrons create the plasma field and special low-frequency kilowave units help provide rapid etching of organics.

25.6.3 Laser Via Process

Laser via processing is by far the most popular microvia hole formation process. But it is not the fastest via formation process. In Fig. 25.19, the chemical etching of small vias is the fastest, with an estimated rate of 40,000 to 50,000 vias per second. This is also true of plasma via formation and photovia formation. These are all *mass-via-formation* processes. Laser drilling is one of the oldest microvia generation techniques.[9] The wavelengths for laser energy are in the infrared and ultraviolet region. Figure 25.20 shows the five major wavelengths used in current laser drills. The absorption curves of many organic dielectrics epoxy, polyimide, matte copper, and glass fibers are shown in Fig. 25.21. Laser drilling requires programming the beam fluence size and energy. High-fluence beams can cut metal and glass, whereas low-fluence beams cleanly remove organics but leave metals undamaged. A beam spot size as small as approximately 20 microns (<1 mil) is used for high-fluence beams and about 100 microns (4 mil) to 350 microns (14 mil) for low-fluence beams.[10,11]

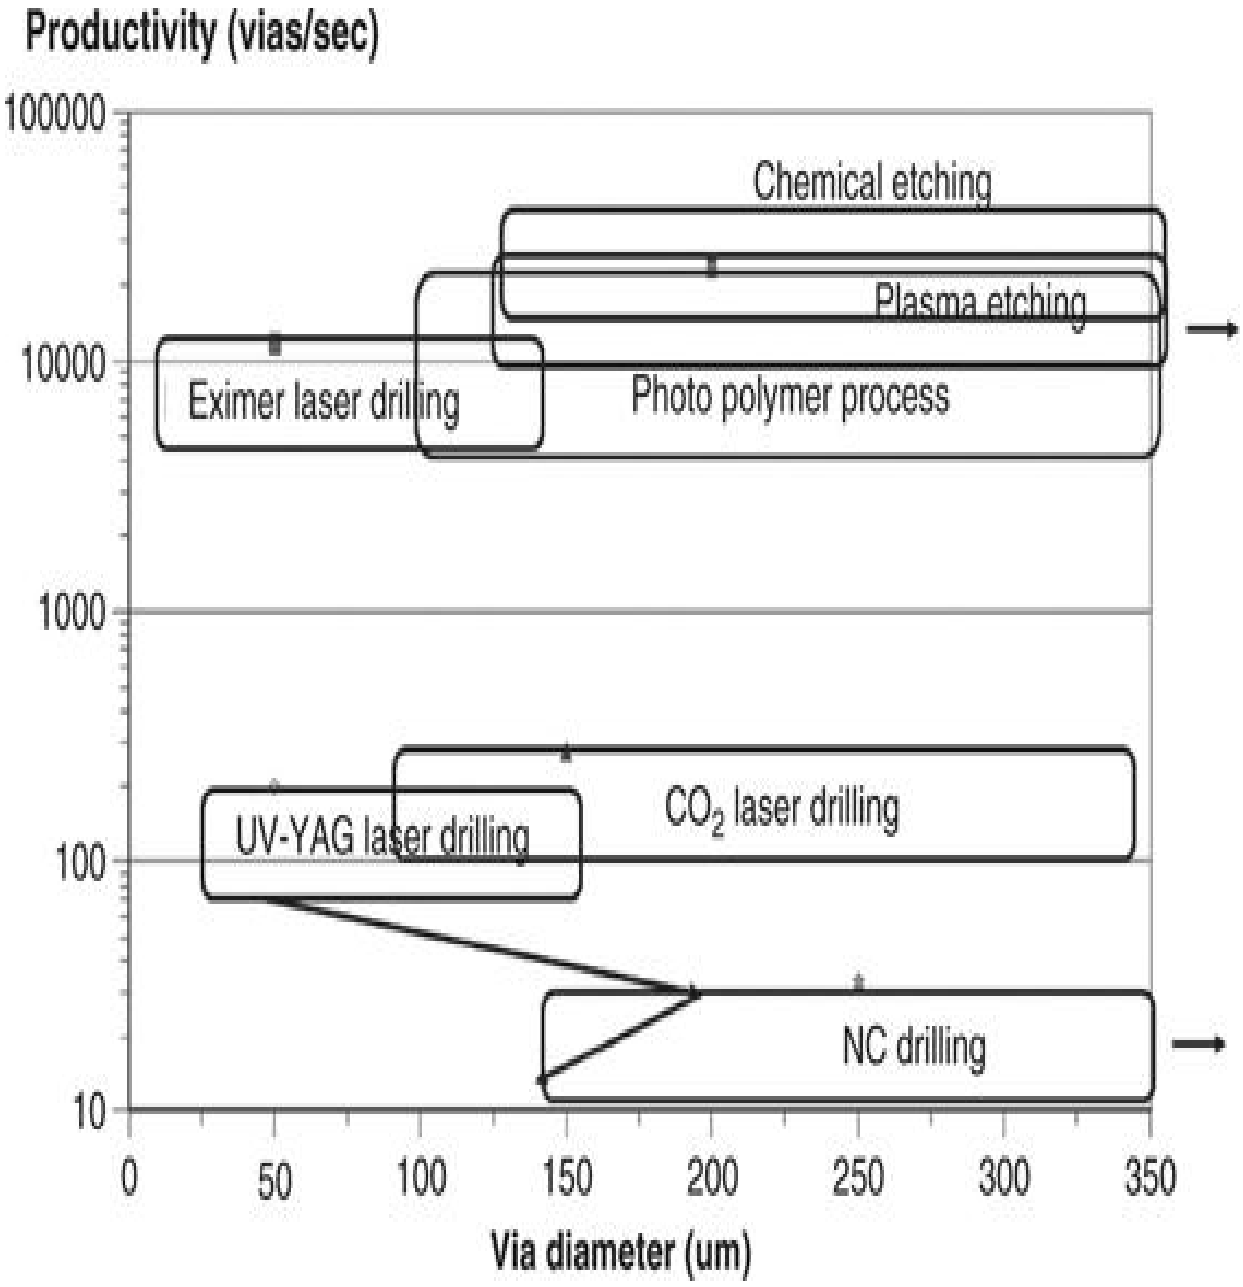

FIGURE 25.19 The various rates of via formation based on diameter and method of via ablation, from chemical, plasma, photo and laser techniques.

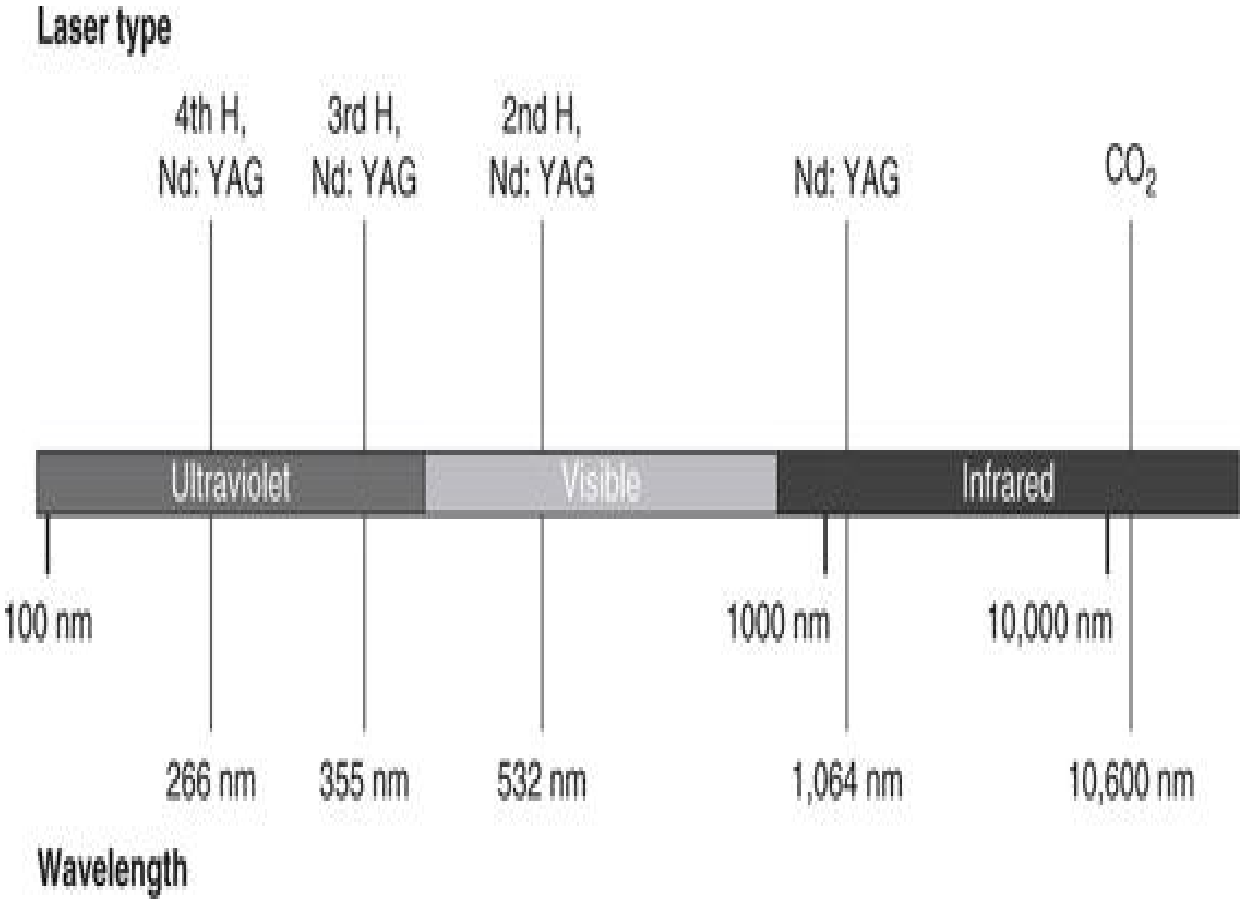

FIGURE 25.20 The wavelengths used by laser via drilling from infrared to ultraviolet region, including the harmonics of Nd:YAG lasers.

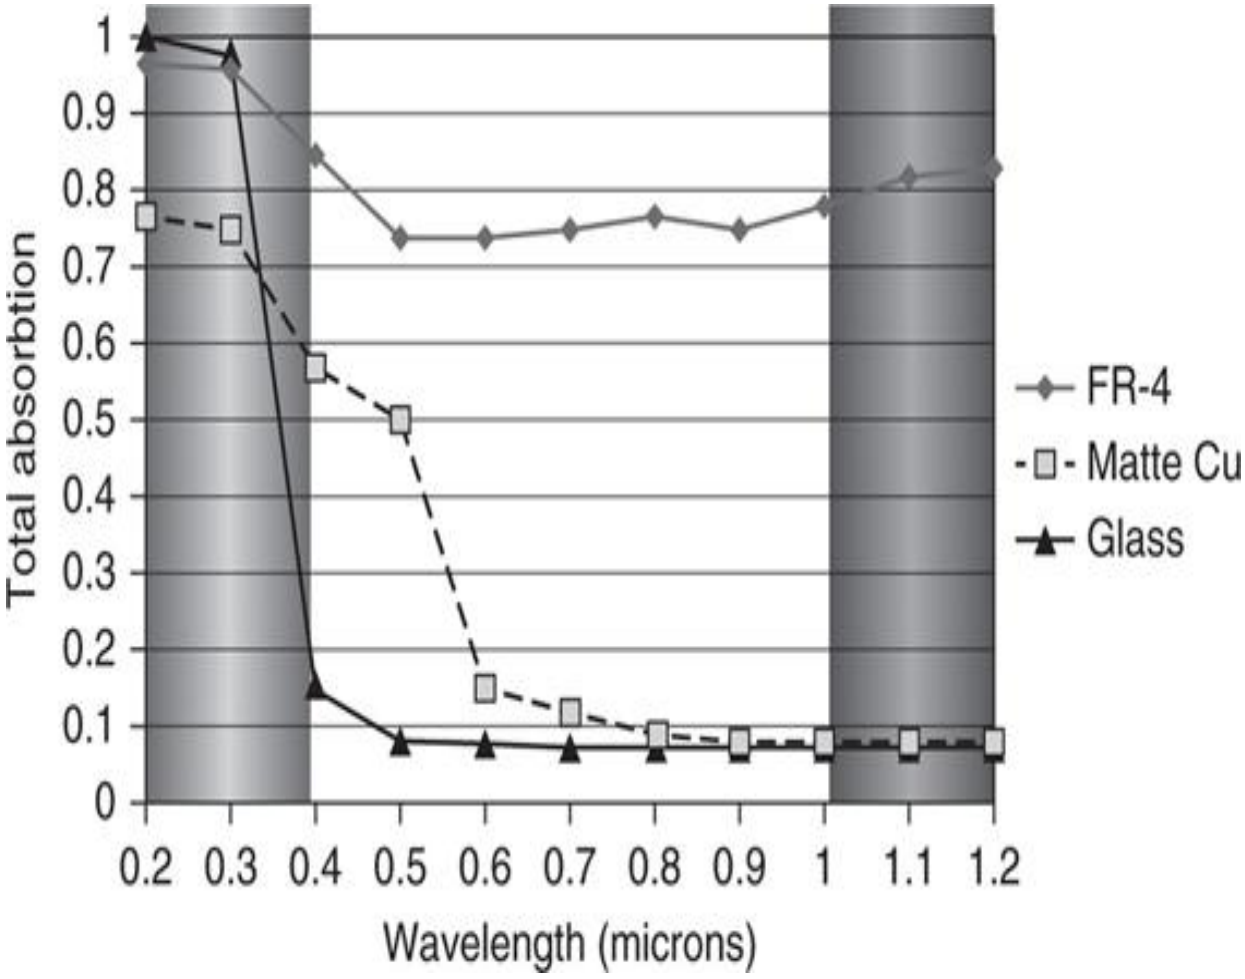

FIGURE 25.21 The absorption wavelength of different materials respond to different wavelength of laser energy. Epoxy, copper and glass of laminate are ablated by the UV wavelength but only the resin is ablated by the CO_2 wavelengths.

However, there are many variations. For the purpose of drilling microvia holes, there are four laser systems: UV/Yag laser, CO_2 laser, Yag/CO_2, and CO_2/CO_2 combinations. Then there are three dielectric materials: RCC, resin only (dry-film or liquid resin), and reinforced prepreg. Therefore, the number of ways to make microvia holes by laser systems is driven by the permutation of four laser systems and these three dielectric materials.

There are several factors to observe in laser via processing: position accuracy of lased holes (microvia holes), uneven diameters of holes, dimensional change of the panel

after curing dielectric, dimensional change of the panel due to temperature and humidity variations, alignment accuracy of the photoexposure machine, unstable nature of negative artwork, and so on. These should be carefully monitored and are important for all microvia hole processes.

25.6.3.1 UV/Yag Laser. A Yag laser can penetrate copper; therefore, it is not necessary to pre-etch the window when the choice of dielectric is RCC or a copper-foil/prepreg combination. Positioning accuracy in relation to the capture pad is good, but there are weaknesses associated with the Yag laser. The speed of drilling (ablation) is slower than the CO_2 laser, particularly when a hole diameter is equal to or larger than 125 µm, because the laser beam is very small. Therefore, it is necessary to do trepanning (spiral drilling pattern), which results in longer drilling time. Another weakness is the Yag laser's sensitivity to the thickness of dielectric material. If the thickness of the RCC's resin is not even, the Yag laser beam, the power of which is adjusted to remove the thicker part of the resin, may damage the capture pad. If adjusted to the thinner part, it may not reach the capture pad.

Although the Yag laser can penetrate copper and glass-reinforced prepreg, the situation is worse in this material than with RCC. The laser power must be adjusted to penetrate through the crossover part of woven glass. Then, when the laser beam hits the part of prepreg where there is now a glass bundle (opening), the beam can really damage the capture pad. To avoid this problem, the operator must reduce the laser power and apply laser ablation for a longer duration, which increases drilling time considerably. Depending on the construction of the dielectric layer through which the Yag laser beam must penetrate, the drilling speed must be adjusted to about 3 to 50 holes per second when glass-reinforced dielectric is used.

When the dielectric is RCC, the speed of the currently available UV/Yag laser is somewhere around 100 to 300 holes per second.

When the dielectric is resin without copper foil, a CO_2 laser is the best since a CO_2 laser can offer much faster drilling speed (a single-head CO_2 laser can drill as many as 25,000 holes per minute, including overhead such as loading a panel onto the drilling table and registering the panel).

The best feature of the UV/Yag laser drilling machine is its ability to drill a very small hole (down to 20 to 30 μm, whereas the smallest hole a CO_2 laser can drill is 50 μm in a mass-production environment) and its superior position accuracy through RCC.

For higher-speed drilling, even Yag laser users are now etching copper foil down to 6 to 9 μm, the process more frequently seen in CO_2 drilling.

25.6.3.2 CO_2 and Twin CO_2. A CO_2 laser beam cannot penetrate copper foil unless the foil is very thin, less than 5 μm, and the surface is treated to be dark to absorb the CO_2 laser beam (this process is called CO_2 laser direct drilling and will be treated later).

When the surface is resin only, a single-headed CO_2 laser machine can drill holes at the rate of 20,000 to 25,000 per minute depending on hole density and distribution. The drilling speed continues to increase. The denser the hole, the faster the drilling speed because time lost by table motion is minimized. A dual-head CO_2 machine can boost drilling productivity by about 70 percent compared to a single-head machine.

Manufacturers of dielectric resins mix fillers in the resins to enhance peel strength. Some fillers can slow down the drilling speed of a CO_2 laser beam (beam absorption is weaker in this case). For example, when the required

dielectric thickness is 60 µm, resin is coated twice, which is a frequent practice to produce a thick coating. The first coating is made with resin without filler (40 µm), and the second coating (20 µm) is resin with filler. Since the laser beam goes through a thin layer of filled resin, the speed degradation is minimized.

The most desirable shape of drilled microvia holes is tapered, which is accomplished by pulse drilling. Normally, two to three pulses are used. When three pulses are applied on the same spot continuously, the capture pad may be overheated and excessive epoxy smear may result. Therefore, when three pulses are to be applied, the entire panel is drilled first by two pulses and then the third pulse is once again applied to all holes. This way, the quality of the holes is ensured, although it takes longer to drill.

When the choice of dielectric is RCC, the opening or window must be formed first on copper foil, as in the case of plasma via. Prior to window formation, an etching process thins the surface copper, usually down to 6 to 7. This process is sometimes called *half-etching*.

Half-etching yields a few benefits. Window formation is made easier, and formation of fine-line conductors is also made easier. H_2O_2/H_2SO_4 etchant is often used for this purpose for even thickness. As mentioned previously, this half-etching procedure is also becoming common for Yag laser users.

There are two variations to CO_2 laser drilling through a window opening. One is called *conformal* and the other *semiconformal* (see Fig. 25.18*c*).

In the conformal method, a laser beam with a diameter larger than the window opening is used. Straight ablation of dielectric results in a bowl-shaped hole, as in the case of plasma via. Therefore, improved systems use laser beam diameters slightly larger than the window opening, and beams are pulsed to minimize the bowl effect.

In the semiconformal method, a laser beam with a diameter slightly smaller than the window opening is used. This results in a slight step when plated afterward, as shown in Fig. 25.18*c*. To minimize this step, half-etching is important in semiconformal drilling.

Some manufacturers using CO_2 drilling etch down copper completely after RCC lamination. The dielectric surface below copper is already microporous, which generates good adhesion except prior to the RCC stage. Therefore, some special treatment is applied to the resin surface, such as electrolessly plated nickel layer, prior to copper plating, but such treatment is kept secret. The RCC approach suffers from misregistration of window opening to capture pad when the surface and capture pad diameter becomes less than 250 μm, which causes serious defects (see Fig. 25.22). Laser via process practitioners have several solutions to this problem. They can use liquid resin or resort to a Yag or Yag/CO_2 laser. Since a Yag laser can break through copper foil, the beam can be directed to the capture pad position accurately. Another choice is to use laser direct imaging (LDI) for window etching in order to benefit from the speed of the CO_2 laser.

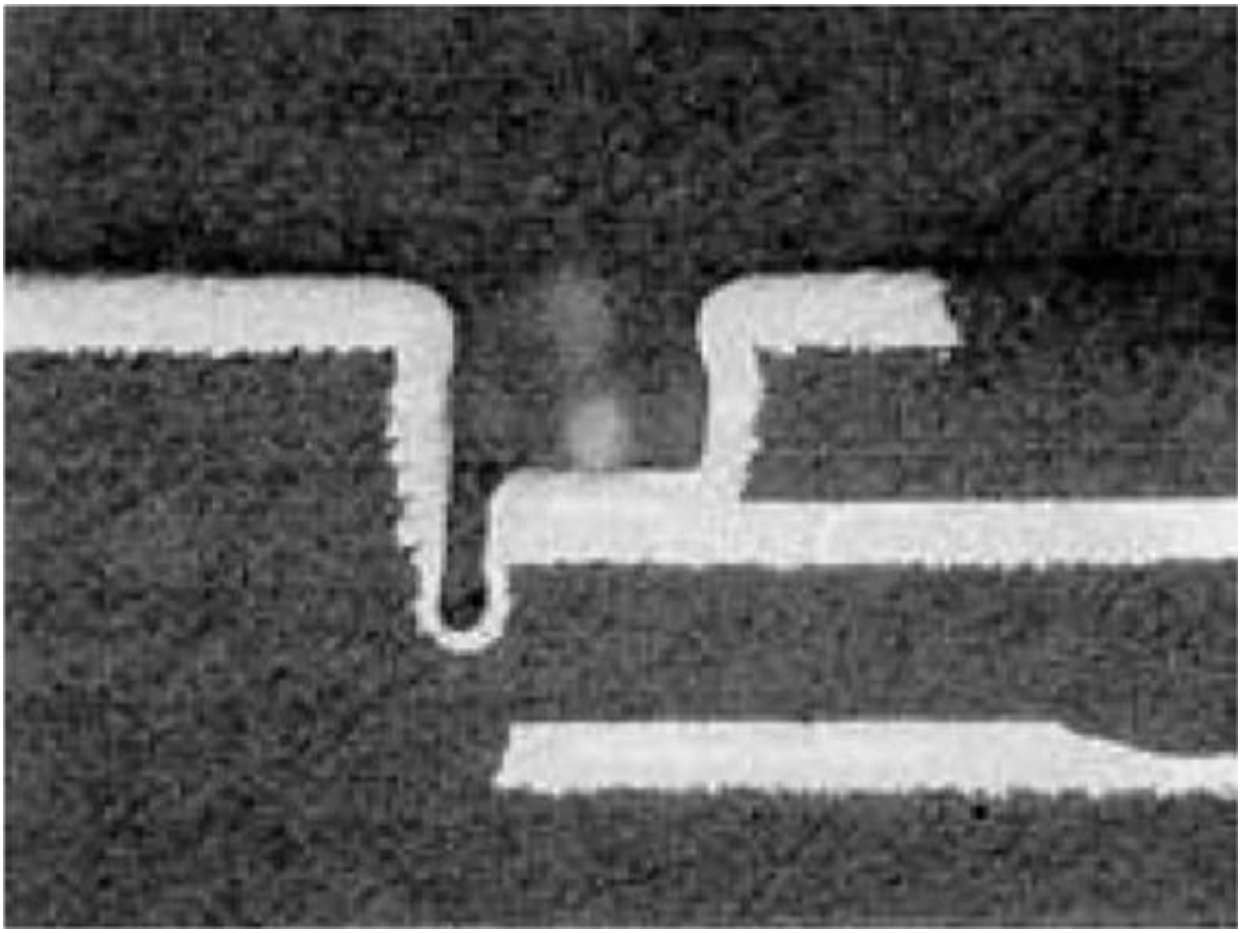

FIGURE 25.22 Misregistration of laser hole to capture pad. (*Courtesy of Ibiden*.)

Another solution is to use CO_2 laser direct drilling. The advantage of using RCC is the pre-established peel strength. Manufacturers go through delicate steps to establish the appropriate peel strength when using liquid resin. The degree of resin cure, permanganate etching, control, and regeneration of the permanganate solution affects the resultant peel strength as well as cost.

In this laser direct drilling method, copper foil is etched down to about 5 μm and its surface goes through oxide treatments such as black oxide or other methods, typically as alternatives to oxide treatment, which is normally an etching process. The copper thickness is further reduced by 1 μm, and the surface color becomes dark, allowing the CO_2 beam to penetrate.

Alternatively, ultrathin copper RCC may be used. Carrier foil, usually copper foil of 70 µm thickness (2 oz), is coated with a very thin layer (10 to 20 µm) of current conductive release film, and a thin foil of 3 to 5 µm is plated. After such RCC is laminated to the core, the carrier film is peeled off and the surface condition is the same as etched-down copper. Drilling speed in this direct CO_2 laser drilling method is degraded by 30 to 40 percent compared to that of straight resin drilling, but the registration to the capture pad is ensured.

25.6.3.3 Yag/CO_2. This combination is particularly useful for a copper/prepreg structure. The Yag laser offers good position accuracy and cuts through copper, but it tends to leave glass fibers sticking out in the hole after prepreg drilling. And as mentioned before, it is sensitive to dielectric thickness variation. The CO_2 laser beam cuts through glass fiber more cleanly than the Yag. In this combination laser drilling, the power of the Yag laser beam is adjusted to cut through copper and remove a portion of glass fiber and leaves the finishing to the CO_2 laser. The speed of drilling is governed by the speed of the Yag laser and is therefore slower than a pure CO_2 laser. However, this is the preferred laser-drilling machine for fabricating infrastructure types of PWBs, such as ones used for servers, network routers, and base stations that typically have copper/prepreg surface structures. The size of the panels used to fabricate such boards is usually large; therefore, the positioning accuracy of the Yag laser is preferred. Microvia hole boards used by the automotive industry also have this copper/prepreg structure.

The speed of drilling by a Yag/CO_2 machine is much slower than that of a CO_2 laser. However, the number of microvia holes to be drilled for infrastructure boards is normally one magnitude less than that seen in cell phone applications, in which the number of microvia holes can reach as many as

650,000 to 700,000 per m^2 Furthermore, the price of infrastructure boards is much more than that of mass-produced cellular phone motherboards. Therefore, slower speed of drilling, which means higher drilling cost, does not affect the total cost of manufacturing.

Residual glass fibers in the hole that can affect reliability may be removed chemically or mechanically. Mechanical removal is preferred. Blasting with aluminum oxide (about 20 µm diameter particles) is commonly used to remove glass fibers and smears as well. An excimer laser is also used to remove smears in the hole by a sweeping motion through the copper opening. In both cases, it takes about 30 seconds to desmear one side of the panel.

25.6.4 Dry Metallization (Conductive Inks, Conductive Paste, and Insulation Displacement)

Three types of dry metallization are covered: conductive ink, conductive paste, and insulation displacement. Conductive ink describes a single-layer dielectric with microvias formed by photoimaging, laser, or insulation displacement. A conductive paste is used to fill the microvias and act as the conductive path between layers. Surface metallization may be accomplished either by laminating copper foil onto the dielectric surface or by chemical deposition. This process is shown in Fig. 25.18*d*.

Insulation displacement is a unique process in that the silver conductive paste is screened on copper foil and cured. The conductive paste forms a “pointed” via that penetrates conventional prepregs during lamination and adheres to the copper foil on the reverse side, forming a via. Figure 25.18*e* shows this via formation process.

Standard activities concentrate on the use of photoimaging and screen printing while overcoming the limitations and expense associated with processes such as plating and etching. The concept is built on the use of a photoimageable dielectric to produce both vias and circuit channels that are then filled with a conductive ink. These approaches eliminate the need for a separate dielectric and clad-metal layer that requires either etching or a combination of plating and etching to produce a circuit. They also eliminate the resist deposition and stripping previously required to define that circuit. The conductive ink technique of metallization virtually eliminates the generation of metal waste streams.

Conventional multilayer printed wiring boards must be subjected to drilling and through- hole plating to create interconnections. These holes represent inefficient use of PWB area. In addition, to connect the printed wiring with part connection lands, some through holes must be provided in areas other than where the lands are located.

CHAPTER 26

ADVANCED HIGH-DENSITY INTERCONNECTION TECHNOLOGIES

Happy T. Holden

Co-Editor-in-Chief, Printed Circuits Handbook, *and PCB Technologist, Zeeland, Michigan*

26.1 INTRODUCTION

Since the introduction of HDI in the mid-1980s [HP-Finstrate, Siemens's MicroWiring, and IBM's Surface Laminar Circuit (SLC) technology; see Figs. 22.1, 22.2, and 22.3 in the 6th edition of this book], many variations of making high-density interconnect (HDI) wiring boards have been developed and implemented for mass production. However, if one technology is to be judged in terms of volume produced and picked as a winner, laser-drilling technology is the one. Other methods are still used by a number of printed wiring board (PWB) manufacturers, but on a much smaller scale.

The purpose of this chapter is to examine a variety of HDI fabrication processes as seen in Fig. 26.1. However, a

greater emphasis will be placed on the laser-drilling process (hereinafter *laservia*) since it is the most popular process today and it seems its popularity will grow in the future. It must be understood that interconnect via hole (IVH) formation is just one element of fabricating HDI wiring boards. The other two important factors are the various dielectric materials and the methods of metallization. Fabrication of HDI wiring boards with microvia holes involves many new processes not common to conventional board fabrication. Therefore, additional emphasis will be placed upon these new fabrication processes that are common to other microvia technologies.

FIGURE 26.1 The HDI technologies in use today are made up of three factors: the dielectric materials, the methods of IVH formation, and the method of metallization of those z axis via connections. In recent years up until now, 21 different HDI processes have been used.

Additional advanced HDI applications will be introduced in the form of *embedded optical waveguides*, a next generation use of printed circuits.

26.2 DEFINITIONS OF HDI PROCESS FACTORS

The 21 different HDI processes shown in Fig. 26.1 have three basic fabrication factors in their process makeup:

1. Dielectric materials
2. IVH formation
3. Methods of metallization

26.2.1 Dielectric Materials

Eight different general dielectric materials have been used in the current or past HDI processes. IPC slash sheets such as IPC-4101B and IPC-4104 cover many of these, but many are not yet specified by IPC standards. The materials are

1. Photosensitive liquid dielectrics
2. Photosensitive dry-film dielectrics
3. Polyimide flexible film
4. Thermally cured dry films
5. Thermally cured liquid dielectrics
6. Resin-coated copper (RCC) foil
7. Conventional FR-4 cores and prepregs
8. Thermoplastics

26.2.2 Interconnect via Hole Formation

Seven different methods of forming the IVHs have been used in current or past HDI processes. Laser drilling is the most prominent, but the other six come into use also. The methods are as follows:

1. Photo processes to define vias in photodielectrics
2. Various laser-drilling methods, including UV-Yag, UV-Eximer, and CO_2
3. Mechanical drilling
4. Plasma drilling
5. Screen printing of via pastes
6. Photo and etch of solid vias
7. Toolfoil

26.2.3 Method of Metallization

Four different methods of metallizing the IVHs have been used in the current or past HDI processes. The methods are as follows:

1. Fully additive electroless copper
2. Conventional electroless and electroplating copper
3. Conductive pastes
4. Fabricating solid metal vias

26.3 HDI FABRICATION PROCESSES

The three basic and original HDI processes are laser drilling laminate (Finstrate) and flexible materials (microwiring), photo dielectrics with SLC and plasma-etching polyimide

(Dycostrate). These and the other 18 HDI processes have been integrated into standard printed circuit manufacturing flows. There is no standard way to organize these processes, but the method of IVH formulation is the most unique characteristic of each process and will be used for this purpose.

26.3.1 Photo-Via Technologies[1,2]

26.3.1.1 IBSS-AAP10 System. The Interpenetrating Polymer Network Build-Up Structure System (IBSS) is a new photodielectric. This photoimageable dielectric (PID) is a proprietary photodielectric developed by Ibiden of Japan. It complements Ibiden's older epoxy type of photo-redistribution layer technology, IP-10.

26.3.1.1.1 Structure. IBSS is specifically formulated for integrated circuit and flip-chip packages and has a high T_g and flexibility. The bismalene-triazine (BT) core also provides high-temperature resistance.

26.3.1.1.2 Manufacturing Process. IBSS is a liquid system applied by roller coater to a rigid core, typically BT. The coating is cured and photodeveloping creates the vias. The IBSS requires an aggressive swell-and-etch because of the higher-temperature nature of the photodielectric (PD). The metallization is fully additive copper, also proprietary to Ibiden.

The imaging for additive metalization uses a permanent dry-film photoresist. For additional layers of dielectric, an adhesion promoter is applied to the surface copper.

26.3.1.2 Surface Laminar Circuits. SLC technology was the first of the PID microvia, build-up technologies to reach the interconnect market in high volume. Development of SLC technology began during the late 1980s at IBM (Yasu,

Japan), and the first product was introduced in 1990.[1] The first flip-chip, direct-chip-attach (FC/DCA) product employing SLC technology was shipped from Yasu in 1992, and in 1995 IBM Endicott, New York, shipped its first printed wiring boards that utilized SLC technology.[2] Used by many original equipment manufacturers (OEMs) in Japan, the SLC process provided the high-density interconnect technology for Sony's first digital Camcorder, the DCR-PC7, seen in Fig. 26.2. This eight-layer build-up structure had two SLC layers on each side of a four-layer core. The assembly density of this was over 612 pins per sq. in due to the wall-to-wall 0.5 mm pitch chip scale package (CSP) used.[3]

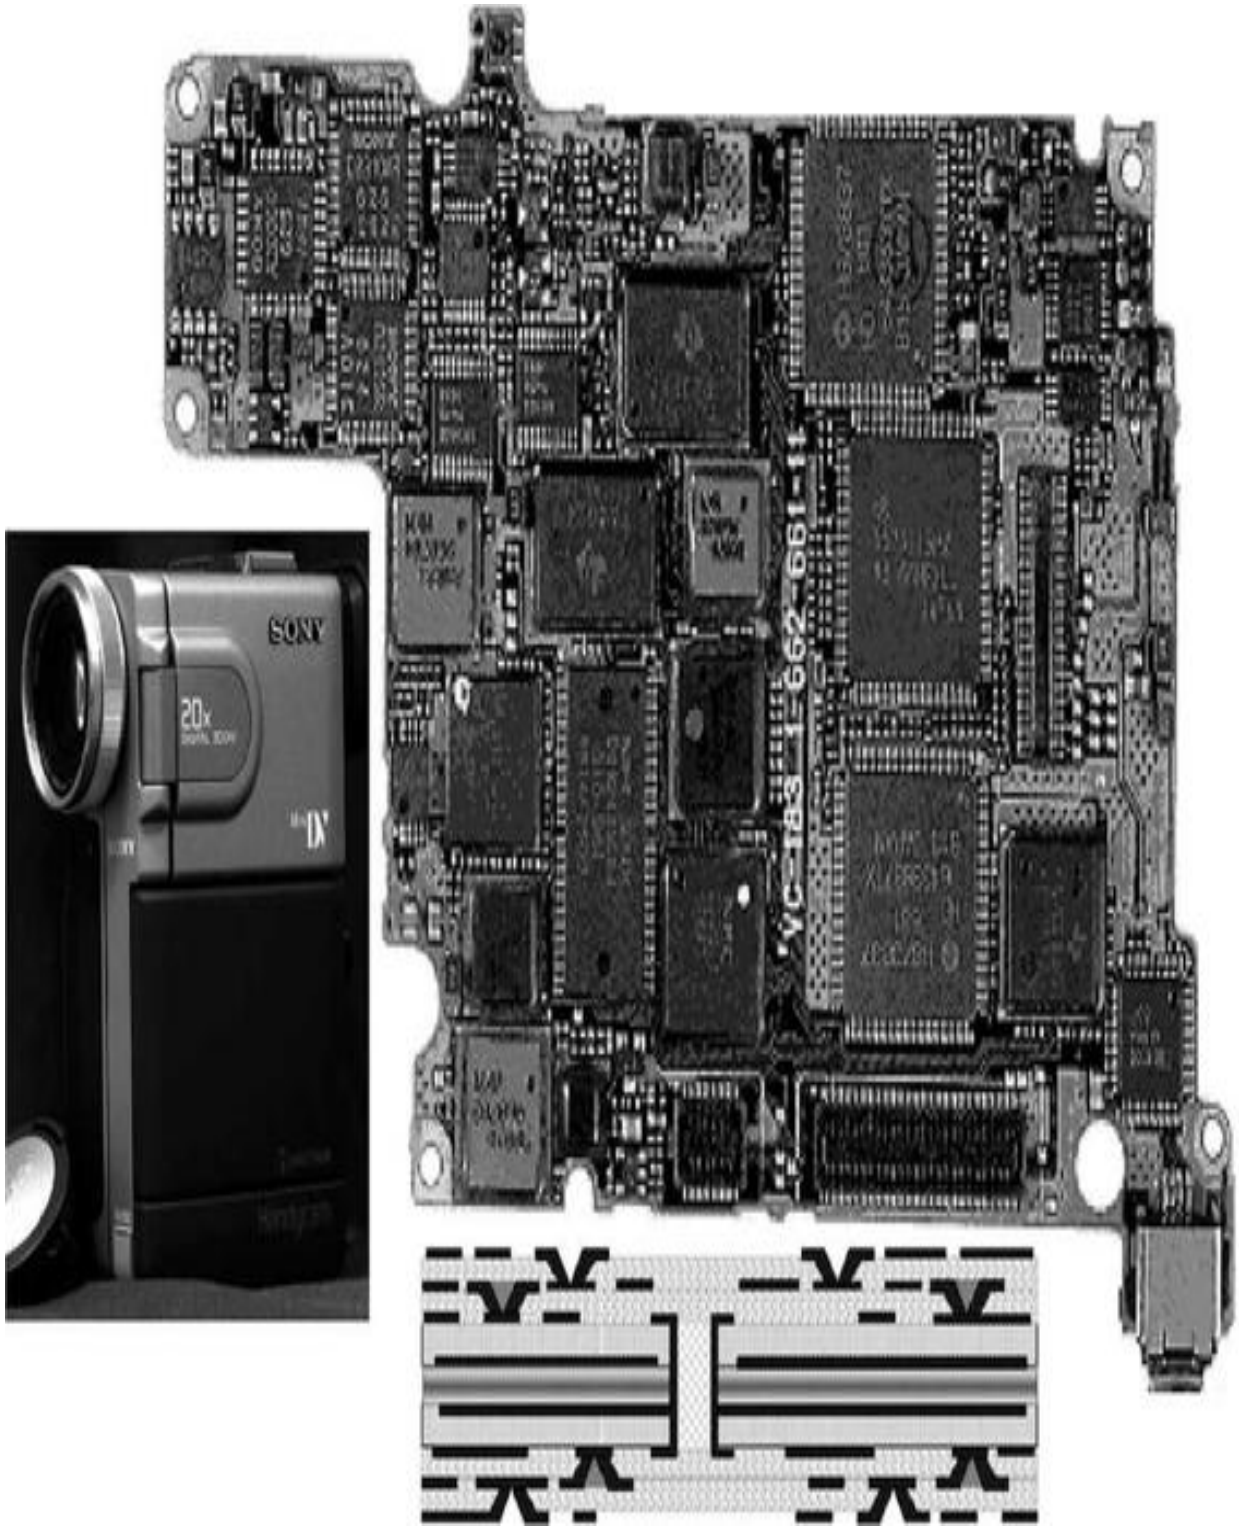

FIGURE 26.2 The Sony DCR-PC7 digital camcorder utilized the SLC process for the 2+4+2 build-up structure and 0.5 mm CSPs to achieve over 600 connections (pins) per sq. in.

The most suitable photosensitive dielectric was the photoimageable solder masks, due to their proven compatibility with printed circuit assembly processes, ability to withstand exposure to service environments, and possession of the necessary via-imaging characteristics. SLC technology was originally developed and implemented with a liquid PID solder mask applied by curtain coating. In 1995, it was also qualified with a dry-film PID with virtually identical electrical properties. The dry-film version did not require the extensive surface grinding processes that the liquid PID process required.

PID technology is based on photoimageable polymeric systems to form blind microvias in dielectric material between layers of circuitry. The use of PIDs allows all microvias on a panel to be formed simultaneously, with no incremental-per-via cost. Its use is particularly advantageous on applications with high densities of vias (e.g., more than 50,000 on an 18 × 24 in panel).

26.3.1.2.1 Liquid versus Dry PID. A typical flowchart of the PID technology fabrication process, including options for multiple build-up layers and a multilayer core, is shown in Fig. 26.5. At this level in the process, PID technology is the same whether a liquid or dry-film PID is used.

Liquid and dry-film PIDs do provide slightly different via wall profiles. The liquid PID has tapered via walls, whereas the dry-film PID has essentially vertical via walls. The tapered via walls provide good plating coverage on the via walls and base. Vertical walls allow for a smaller via top opening, and correspondingly smaller capture land for a given via bottom diameter.[4,5]

26.3.1.2.2 Tools. The use of a liquid PID requires two unique pieces of equipment: a coater of some variety, either curtain, slot, roller coater or screen printer (with associated drying ovens), and a leveling tool (surface sander). A leveling tool is required to planarize the surface of the cured liquid

PID to accommodate fine-line photolithography on the surface. Liquid PID provides a conformal coating over underlying circuit features, producing nonuniform planarity. The leveling operation also removes a lip of exposed PID that overhangs the via openings in these processes. Many liquid PIDs have a self-leveling characteristic and do not require any other leveling.

The use of a dry-film PID requires only one unique piece of equipment: a vacuum laminator. Vacuum laminators are common at printed circuit fabrication shops; in addition, the capital to obtain one is significantly less than for a curtain or slot coater. The dry-film PID has excellent planarization and does not require a leveling process due to the film's low solvent content, low shrinkage, and vacuum lamination process.[6,7]

PID technologies were originally conceived as an alternative to multilayer lamination as a way to make multilayer PWBs. PID technology builds up each surface signal layer on top of the previous layers in a sequential fashion. The base under all of the outer build-up layers is a conventional double-sided or multilayer circuit board containing voltage, ground planes, and even signal layers. Mechanically drilled and plated holes are used only in the core layers, to make connections to the backside of the laminate base and accommodate mounting pinned components. There is greater wiring density to use plated through holes (PTHs), which extend only through the base printed circuit structure and not through the build-up layers, especially when two or more build-up layers are used. Figure 26.3 provides additional details of the SLC manufacturing process of multilayer printed circuit boards.[8,9]

FIGURE 26.3 The manufacturing flows for the two major SLC manufacturing processes.

26.3.1.3 DV Mult-PID. DV Mult-PID is from NEC. This structure uses a PID primarily as an integrated circuit (IC) substrate and for high-density electronic products. It is capable of three build-up layers per side. The use of a dry-film PID requires only one unique piece of equipment: a vacuum laminator. Vacuum laminators are common at printed circuit fabrication shops; in addition, they cost much less than a curtain or slot coater. The dry-film PID has excellent planarization, does not require a leveling process due to the film's low solvent content, low shrinkage, and vacuum lamination. The modified structure of DV Multi-AD uses laminates and RCC for the build-up layers and fully additive electroless plating.

26.3.2 Laser Via Technologies[3–5,3–6,7–10]

Circled processes 3, 4, and 5, as well as squared 3 through 10 in Fig. 26.1, utilize a laser drill via generation technique. This process was first used in the late 1970s to drill small holes in G-10 laminate for buried vias in mainframe computer boards by IBM for its 3081 system and by Burroughs. (Attempts to find pictures of these products proved unfruitful.) The Hewlett Packard laser-drilled Finstrate family of boards, first produced in 1983, is shown in Chap. 22 of the previous edition. Siemens' laser-drilled microwiring was produced since 1987.

26.3.2.1 High-Density Interconnect (HDI). The HDI process developed by General Electric and now owned by Lockheed Martin is the one most similar to IC processes. This process is what is called a "chips first," as the assembly is

done before the substrate is completed and the IC bonding is direct to the substrate. It does not use flip-chip or wire bonding, but can utilize unmodified chips directly. A number of build-up layers and very fine geometry are possible. There are obvious advantages in making multichip modules and in using standard chips. The materials and bonding technologies have proven to be very reliable and suitable for military applications. The disadvantage is the maximum panel that can be sputtered. Future use of PVD/CVD metallization may make this process more cost-effective.

26.3.2.1.1 Structure. The circuit structure of HDI consists essentially of common conventional flex circuits or more advanced microvia flex structures. These are purchased for this process. The polyimide film is usually 25- or 50-micron adhesiveness. The laser ablates away the polyimide to produce blind and through vias. The through vias are stopped by the aluminum bonding pads of the integrated circuits. By doing this, integrated circuits designed for wire bonding can be directly attached.

26.3.2.1.2 Manufacturing Process. The process starts with a finished single-sided, double-sided, or multilayer polyimide flex circuit. An adhesive is applied to the flex circuit. All the ICs and components are bonded to the polyimide film layer pair flex circuitry and cured. The assembly is turned over and a laser drills down through the flex circuitry to make blind and through vias including opening up the bonding pads on the IC chip. Gold, underbump metallurgy, or C4 bumps are not required. The panel goes through tungsten sputtering to metalize the vias and seed the top layer. Circuit pattern can be applied, plated, and then etched to complete the circuit.[10,11]

26.3.2.2 Meiko-BU. Meiko Circuits of Japan takes a photoresist and coats it onto a stainless steel panel. This starts the process to produce high-density interconnect structures (HDIS) in a remarkable way. The advantages of

this process is that surface geometries are not determined by etching or full additive metallization, the vias are under the surface lands, and the circuits are all flush with the dielectric, permitting the elimination of solder masks. On the negative side, this is a more expensive process that involves carriers.

26.3.2.2.1 Structure. Figure 26.11 shows the structure of Meiko's build-up circuits. These are called carrier-formed because a stainless steel carrier serves as the base for the photodielectric even though they are laser-drilled to form the vias. The resulting structure is similar to other HDIs. The core is still a rigid board and the build-up layers are PID.

26.3.2.2.2 Manufacturing Process. The manufacturing process starts by taking a photoresist and coating it onto a stainless steel panel. The surface pattern is exposed and developed in the photoresist. First gold is plated, then nickel, and finally copper is plated on the panel. When the resist is stripped, the PID is applied over the entire panel and via holes are laser-drilled in the dielectric. Once metalized and plated, photoresists can define the circuitry by etching. The process can be repeated until the circuitry is complete or it can be laminated to FR-4 materials as rigidizers.[12,13]

26.3.2.3 CLLAVIS. The CLLAVIS build-up technology is marketed by CMK of Japan. This laser-drilled microvia technology is the most common of HDI processes. The construction is based on a filled buried vias in the multilayer core, as well as the optional filled microvias that can be stacked. This structure is also available with the simpler, unfilled staggered microvias.

26.3.2.4 SSP. The SSP technology was developed by Ibiden of Japan. It used standard FR-4, copper plating, and laser drilling. The additional step is the application of a thin adhesive to each finished single-sided, pump-plated core. The process sequence is as follows:

1. Start with single-sided copper-clad laminate.
2. Laser drill from the noncopper side.
3. Desmear laser holes and run through the electroless copper process.
4. Plate up bumps on the clad side.
5. Image and circuitize the copper side.
6. Apply a thin adhesive to the unclad side.

Repeat steps 1 to 6 for the remaining cores of the multilayer:

7. Lay up the finished cores with copper foil.
8. Vacuum laminate the finished layers.
9. Image and circuitize the outer layers
10. Coat the solder mask and finish.

26.3.2.5 FACT-EV. FACT-EV (Fujikiko Advanced Chemical Technology-Etched Via Post) is from Fujikiko of Japan. As with the SSP process, the via is a solid-plated copper post. In this case, the process uses standard dry-film photoresist to define the posts and a thin-liquid dielectric to coat the plated posts. Unlike SSP, however, the process is sequential and each two sets of layers are processed on the prior layers.

26.3.2.6 PPBU. The PPBU (Prepreg Build-Up), from CMK, is a standard sequential lamination process using laser-drilled vias similar to the CLLAVIS process.

26.3.2.7 Solid Conductive Via Fill. The next group of HDI technologies all utilize metal-particle pastes or a solid sheet of metal to form the via connections. Table 26.1 presents these alternatives to copper plating for forming IVH connections.

TABLE 26.1 Alternative HDI Technologies

Fabricator	Trade Name	IVH Process	Metallization
Dyconex	DYCOre	Copper etching	Etched copper bumps
Ormet	OrmeLink	Laser, plasma, or photodielectric	Cu/Sn organo-metallic
Matsushita Comp.	ALIVH	Laser	Copper particles in epoxy
Toshiba	Bbit	Insulation displacement	Silver/epoxy paste
Parelec	PARMOD	Drill, laser, or photodielectric	Metallo-organic decomposition, Cu or Ag
Namics	Unimec	Punch, drill	Silver, palladium, and copper particle pastes
North Corp.	NMBI NMTI (Neo-Manhattan)	Image and etch	Etched copper bump
Denso	PALUP	Laser	Cu organo-metallic
Ibiden	SSP	Laser	Plated copper bumps
Fujikiko	Fact-Ev	Photoprocessing	Plated copper posts

26.3.2.8 OrmeLink. CTS's colamination process and Ormet's transient liquid phase sintering (TLPS) process (OrmaLink) are similar to the ALIVH process conductive paste in that it is a via paste copper-tin organometallic matrix that sinters into a solid metallurgical via.

CTS's process is called ViaPly. Past users, in addition to Sheldahl (now Multek), included Litronics, now called Allied-Signal Substrates, in Costa Mesa, California. Up to four layer pairs have been connected (eight metal layers) using OrmeLink.

26.3.2.8.1 Structure. The Ormet structure is made up of polyimide or FR-4 layer pairs. Different materials can be mixed if a rigid core or heat spreader is required. The conductive paste is a TLPS ink of copper-tin. The structure is shown in Fig. 26.4. Figure 26.5 shows the cross-sections of two finished circuits with lasered-via polyimide layer pairs, with TLPS solid metallurgical vias connecting the layer pairs and FR-4 innerlayer cores with buried TLPS vias.

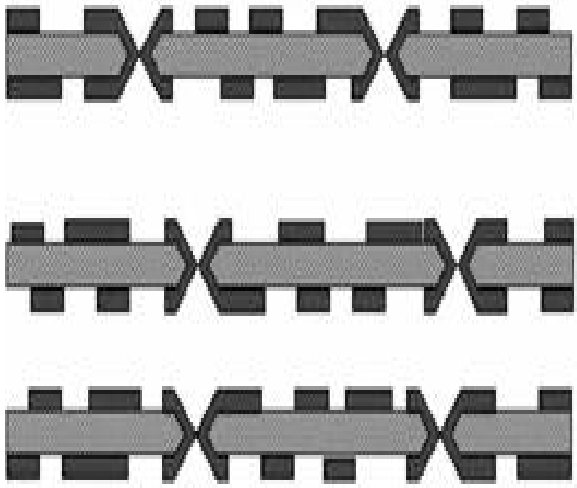
FIGURE 26.5 Examples of TLPS cross-sections of three layer pairs with lasered-vias filled with TLPS paste vias and buried vias for FR-4 innerlayers.

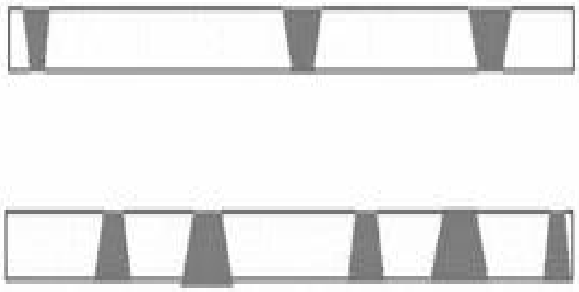
26.3.2.8.2 Manufacturing Process. The manufacturing process is shown in Fig. 26.6. The microvias are lasered or punched in the polymide adhesive and then filled with the TLPS paste. The structure can now take layer pairs from any other HDIS process (such as Sheldahl's) and turn them into a multilayer structure through sintering. The conductive pastes have to be sintered in a condensing vapor of fluorocarbon at 215°C for 2 min. The structure is then postcured by baking for 40 min. at 175°C. Table 26.2 details the process.

1. Acquire layer-pairs

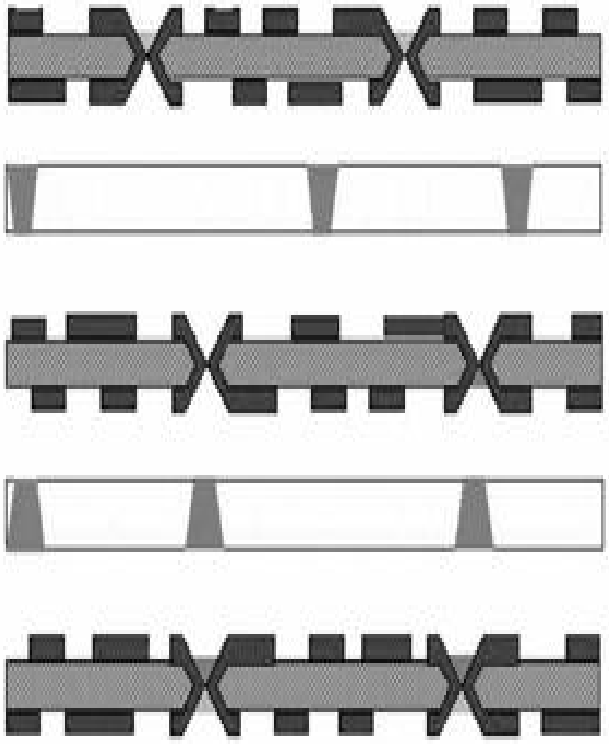


2. Generate vias in adhesive

3. Fill adhesive with TLPS metal paste



4. Lamination with paste filled adhesive



5. Sinter TLPS paste & Coat solder mask

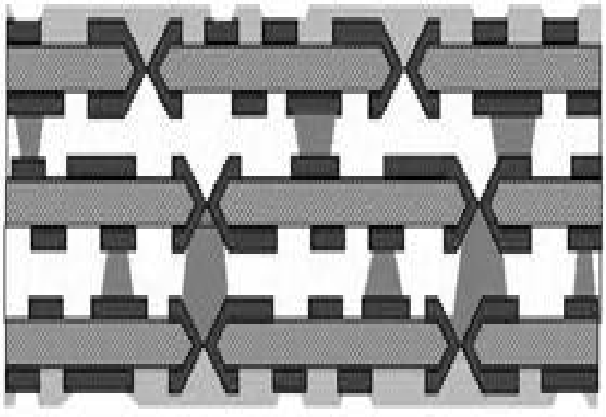


FIGURE 26.6 The OrmaLink multilayer substrate fabrication process.

TABLE 26.2 Properties and Curing Processes for the Ormet Type of TLPS Conductive Pastes

Property	Curing Process
Ormet 2005 series ink	Specification and processing parameter
Electrical conductivity	Bulk 4.0×10^{-3} Ω-cm Sheet resistance 10.0×10^{-3} Ω/sq. in
Adhesion (Tensile Pull) on Various Materials	
FR-4 (T_g = 125°C)	1300 psi (minimum)
Copper	2921 psi (average)
Printability	With 230 stainless steel wire mesh and emulsion thickness of 7.5 µm Sintered thickness 28–38 µm 200 µm traces on 400 µm pitch
Cure cycle	30 min drying at 85°C 2 min vapor cure at 215°C 40 min postcure at 175°C

26.3.2.9 ALIVH. The ALIVH (Any Layer Interstitial Via Hole) process has been in development for many years by Matsushita Components of Osaka, Japan. The novel process eliminates additive metallization and plating, but defines all features by subtractive etching of the copper foil. The build-up process is not sequential, though; it uses layer pairs and aramid-epoxy prepreg with copper-paste vias that can be laminated at one time into a three-dimensional structure. CMK (the second largest PCB maker in the world) and other Japanese firms have licensed the process. Six to 10 layers have been laminated in this way.

26.3.2.9.1 Structure. Figure 26.7 shows the structure and cross-sections for an ALIVH product. The PCB consists of laser-produced blind vias. The core material is an epoxy-aramid laminate. The man-made aramid filaments are ideal to be cut with a CO_2 or UV laser. If the DuPont Kevlar filaments are added, then the resulting material will have a very low coefficient of thermal expansion (CTE). This is useful for mounting ceramic packages and for direct attachment of flip-chip integrated circuits. The structure can be as simple as a two-sided PCB or as complex as a many-layered PCB. The vias consist of a copper-epoxy paste that connects the top and bottom copper foil. If used as a prepreg layer without copper, the vias connect the various ALIVH layer pairs into a multilayer structure. This is not a sequential build-up process, but rather a parallel build-up process.

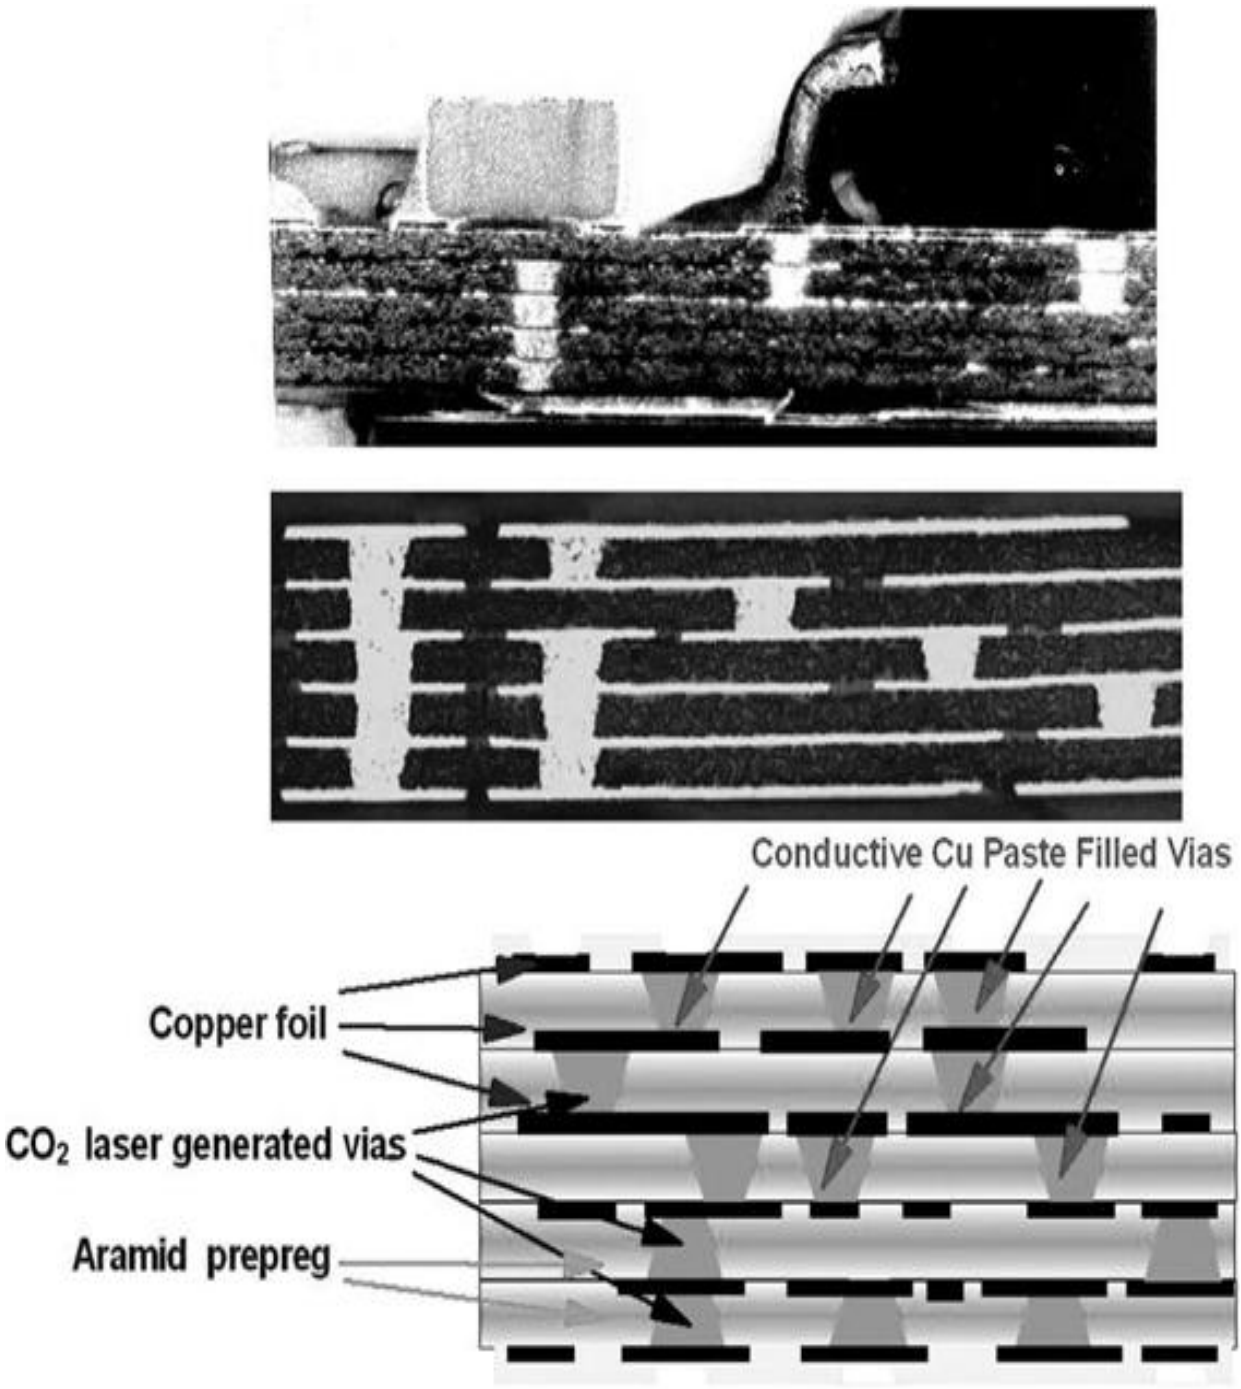

FIGURE 26.7 The parallel-bonded solid via structure of the ALIVH multilayer with cross-sections of examples.

26.3.2.9.2 Manufacturing Process. The ALIVH process is shown in Fig. 26.8. The process starts with an epoxy-aramid B-stage prepreg. The laser cutting of holes can proceed very rapidly. The material is then printed with a conductive paste

of copper and epoxy to fill these holes. Copper foil is applied and the structure is laminated to attach the foil and cure the prepreg and conductive pastes that serve as vias. The sheet of material is imaged and etched to provide the various circuits. Registration is less critical because the vias are now under the surface lands. Several of these two-sided layer pairs can be produced, inspected, and tested. The two-sided structures can then have additional single layers of B-stage/conductive paste layers with foil laminated to one or both sides, or the B-stage/conductive paste layer can be used to attach a number of layer pairs in one parallel lamination. The outside is imaged, etched, and completed as a normal PCB.

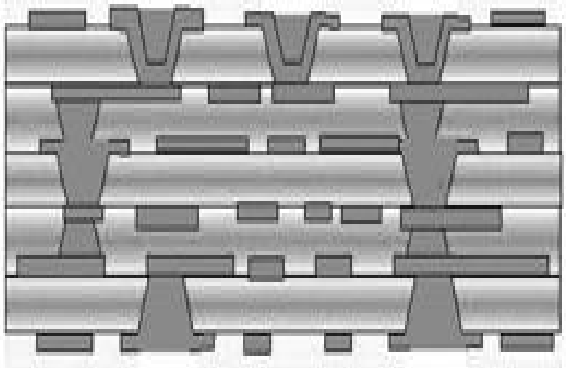

FIGURE 26.8 The ALIVH manufacturing sequence for a multilayer substrate.

An advanced manufacturing process results in a product known as ALIVH-FB. This product has a fine-line, tight via structure suitable for wire-bonding and flip-chip substrates, as shown in Fig. 26.9. The manufacturing process for each microvia technology begins with a base core, which may be a simple double-sided board carrying power and ground planes or a multilayer board carrying some signal pattern in addition to power and ground planes. The core usually has PTHs, which become blind via holes (BVHs). Such a core is often called an *active core*.

FIGURE 26.9 The ALIVH-FB manufacturing process for a multilayer substrate. (*Illustration Courtesy of CircuiTree*.)

In fabricating a base core with a pattern, manufacturers usually panel-plate the core panel and create the pattern through a dry-film tenting process. Some makers seem to prefer pattern plating, however. The choice depends on the fabricator's familiarity with these processes. After the pattern is formed, dielectric material is laminated over the core (in the case of prepreg, with copper foil) and the holes can be filled with resins, depending on the plated hole diameter and the thickness of the core. It is generally agreed that when the diameter of plated holes is equal to or less than 0.3 mm and the core thickness is equal to 0.6 mm or less, these holes can be filled effectively by the lamination process (although the resin thickness of 80 µm is preferred in the case of RCC).

When the diameter and thickness conditions are not met, it is necessary to fill the holes by a separate process. A screening process does this from one side of the panel with a polyester screen that has an oversized hole pattern. After filling the holes the resin is cured completely.

26.3.2.10 MSF. Shinko of Japan developed the MSF HDI technology. It utilizes laser-drilled RCC materials and vias filled with a conductive paste. After testing, these are laminated into the parallel build-up structure.

26.3.2.11 PALAP. PALAP (Patterned Prepreg Layup Process) is a process that was developed by a consortium consisting of the Japanese firms Denso, Wako Corporation, Airex, Kyosha, Noda Screen, and O.K. Print. Originally, the process started with copper-clad laminates (CCL), but now utilizes thermoplastics like PEEK resins (polyether-ether ketone) or a new plastic called PAL-CLAD. PAL-CLAD is characterized by the electrical properties and heat resistance

of BIAC, a recyclable thermoplastic resin film produced by Japan Gore-Tex, Inc.

The single-lamination process compares favorably to conventional PCB processing, where lamination, curing, and wiring patterning are repeated layer after layer. PALUP boards can be multilayered by pressing together all thermoplastic resin layers, each having wiring patterns. This significantly improves quality, lowers costs, and shortens delivery times. PALAP boards also offer high-interconnecting reliability by adopting metallic paste for filling vias, and have excellent high-frequency properties due to a low dielectric constant.

PALAP boards also give due consideration to the environment, one of the major issues requiring action in the area of electronics products, including those used in information technology and automobiles. Because PALAP boards use thermoplastic resin as their base material, they enable material recycling in which only the resin is separated and reused.

26.3.2.12 VIL. The VIL (Victor Interconnected Layers) HDI technology was developed by Victor of Japan. It utilizes FR-4 prepreg materials that are laser-drilled and sequentially laminated after the vias are filled with a conductive paste.

26.3.3 Mechanical Drill-Via Technologies

Hitachi HITAVIA is an example of the mechanical drill-via technologies available.

26.3.3.1 HITAVIA. The Hitachi HITAVIA technology is the only HDI process developed for use with conventional mechanical drilling. It utilizes RCC or prepreg materials that are mechanically drilled and sequentially laminated after the

vias are filled with a conventional electroless copper and copper plating. The typical manufacturing sequence for this HDI technology is similar to that of previously described HDI processes such as CLLAVIS and PPBU.

26.3.4 Plasma-Via Technologies

Plasma-via technologies include DYCOstrate, plasma micromilling, and plasma-etched redistribution layers (PERL).

26.3.4.1 DYCOstrate. Starting in 1989, Dr. Walter Schmidt of Contraves in Switzerland developed the plasma-etching process for microvias. Evolving from the traditional plasma desmear process, the plasma etcher for vias was jointly developed by Dyconex (successor to Contraves) and Technic Plasma of Germany. Dyconex trademarked and patented its via-generation process as DYCOstrate. Hewlett Packard licensed the technology in 1993 and developed it for mass, low-cost production. The low-cost production process of Hewlett Packard is called PERL (for plasma-etched redistribution layers).

DYCOstrate, along with SLC and Finstrate, is among the most enduring production processes for microvias generation. The DYCOstrate process was first employed for high-reliability military, aerospace, medical, and IC packaging starting in 1991. Since that time, Dyconex has used the process to produce hundreds of different printed boards both in polyimide film and with the new laminates called FR-4 RCC. This Dyconex called DYCOstrate-C.

26.3.4.1.1 Structure. Figure 26.10 shows the structure of DYCOstrate. The core material can be polyimide film with plasma-etched holes, drilled epoxy fiberglass, or other plasma-etchable materials such as liquid crystal polymers. Multiple layers can be built up to increase density with the resulting buried and blind vias, but two-sided DYCOstrate

structures are also used in products because of the very high density that 0.075 mm through holes allow.

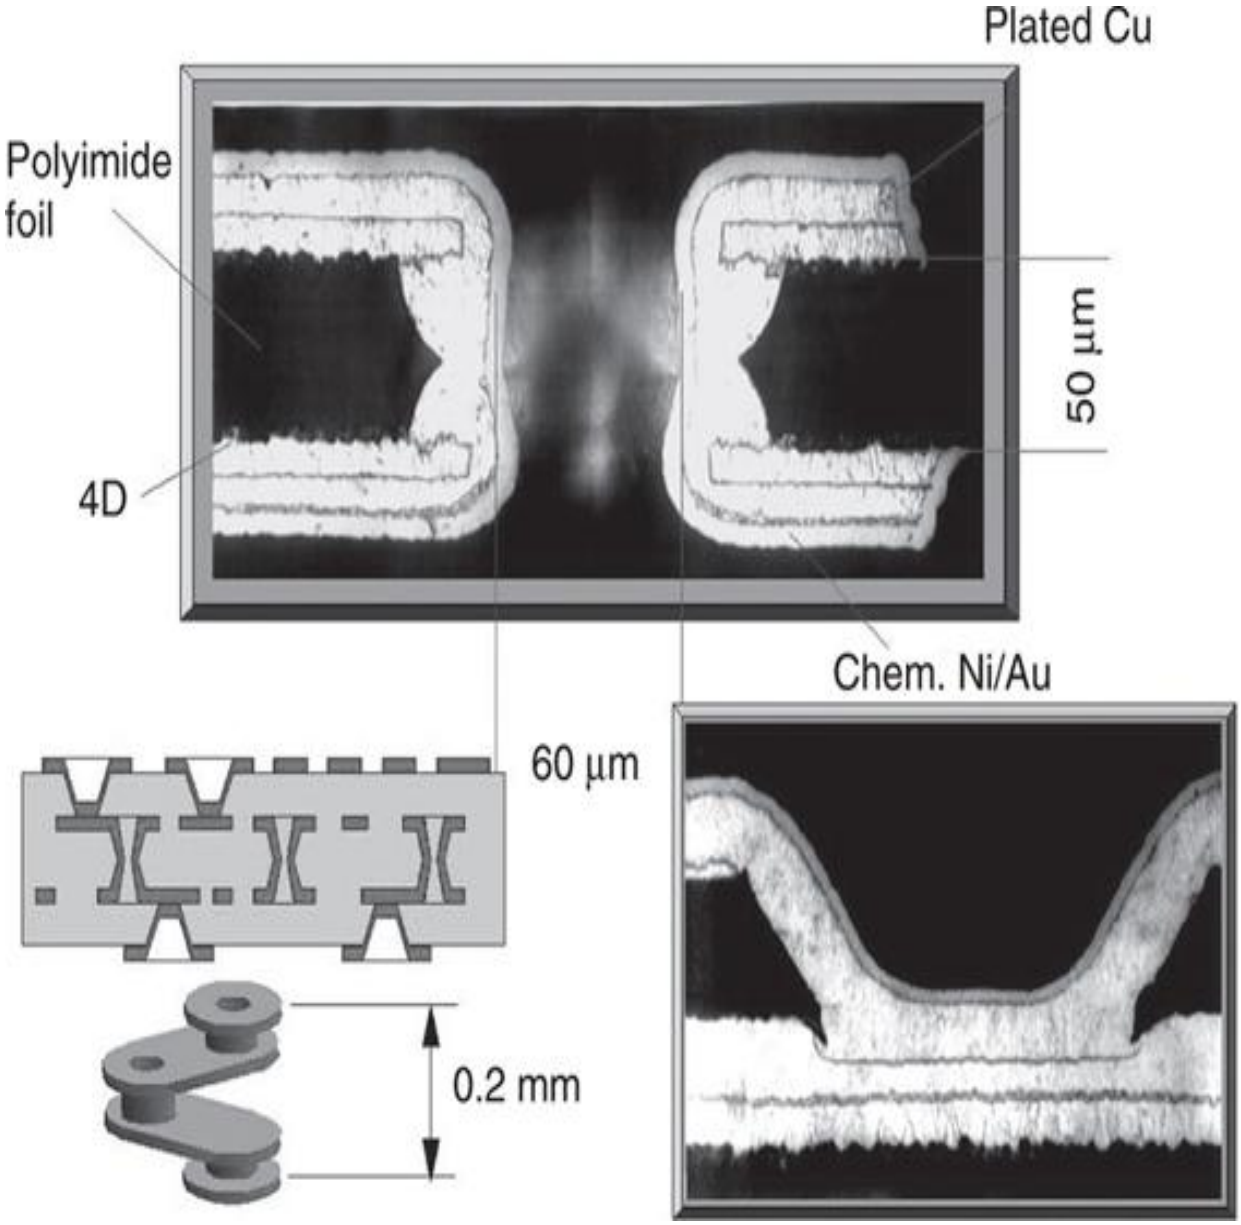

FIGURE 26.10 The DYCOstrate multilayer structure and cross-sections of through and blind vias.

26.3.4.1.2 Manufacturing Process. The manufacturing process for a DYCOstrate substrate utilizes common printed circuit board techniques. Only the via-generation process is different. To produce a plasma-etched via hole,

manufacturers use two or three process steps that replace the conventional mechanical drilling-debur-desmear steps:

1. Define photographically the location and geometry of the via holes.
2. Etch an opening in the copper foil that will serve as the resist mask.
3. For blind vias, reduce the copper-foil thickness to eliminate the copper overhang.

Figure 26.10 shows microsections of a plated through hole and a blind via in polyimide film. The plasma-etch procedure is basically an isotropic process, as indicated by the undercut seen on the through hole; considering the actual dimensions, however, this undercut is too small to cause any plating problems.

When the etching depth is increased, as in the case of a blind via, the resulting undercut is generally too big to allow reliable plating. To overcome this problem, the manufacturer can reduce copper use by etching the copper foil, eliminating the copper overhang, and providing a thinner copper foil for fine-line resolution.

Figure 26.12a shows two common products made with the Dycostrate process [a four-layer flex-multilayer chip-on-board (COB) for a hearing aid] and the PERL process (a six-layer FR-4 COB for a networking module).

The manufacturing process for a DYCOstrate substrate with a standard four-layer build-up is shown in Fig. 26.11. Starting with a prefabricated double-sided DYCOstrate foil, the manufacturer bonds two single-sided copper clad foils to the center-core foil using standard lamination techniques of mass-lam-like process. The resulting four-layer structure is then processed and structured analog to the two-layer foil, producing blind vias instead of through holes.

FIGURE 26.11 The DYCOstrate multilayer manufacturing sequence for a four-layer substrate.

Further refinements in magnetrons for IC manufacturing provide the opportunity for finer plasma-etched vias. Additionally, Dyconex has demonstrated landless vias to be simple and reliable, offering much higher densities at lower cost and simplifying fabrication registration.

26.3.4.2 Plasma Micromilling. The drilling of simple holes is not the only process in which plasma etching is used. Plasma can be also be used to sculpture the surface of the substrate or to fabricate slots, grooves, stepped windows, and more. Even angled vias or tubular systems can be formed. This is useful since cavities can be formed for wire bonding or recessed mounting of components. A simple definition of the periphery outline by artwork can provide extremely accurate final fabrication, or windows in the final etch step can define areas that will flex.

26.3.4.3 Plasma-Etched Redistribution Layers. The plasma-etched redistribution layer (PERL) process was developed by Hewlett Packard to produce microblind and buried vias using the DYCOstrate plasma via process. The materials used are the FR-4 epoxy-coated copper foils (RCC) to replace epoxy-glass prepregs in normal multilayer production. These are copper foils coated with a B-stage epoxy or dual C-stage/B-stage epoxy films.

26.3.4.3.1 Structure. The structure of DYCOstrate PERL is shown in Fig. 26.11. The core material can be standard FR-4 multilayer innerlayers or a through-hole-plated two-sided or multilayer board. Multiple layers can be built up to increase density with the resulting buried and blind vias. Current production ranges from 4 layers to 12 layers with various buried board and buried via constructions. As with DYCOstrate, many materials are plasma-etchable and the resin butter-coated copper foils come in many thicknesses

and resin types, such as BT, cyanate ester, and polyphenelene-ether (PPE).

26.3.4.3.2 Manufacturing Process. The manufacturing process for a DYCOstrate PERL substrate utilizes common printed circuit board techniques. Only the via-generation process is different. To produce a plasma-etched via hole requires only two or three process steps that replace the conventional mechanical drilling-debur-desmear steps:

1. Define photographically the location and geometry of the via holes.
2. Etch an opening in the copper foil that will serve as the resist mask.
3. For blind vias, reduce the copper-foil thickness to eliminate the copper overhang.

The manufacturing process for a DYCOstrate PERL substrate with a standard four-layer build-up starts with FR-4 innerlayers or a prefabricated double-sided or multilayer board. Two single-sided copper foils with resin coatings are bonded to the center-core foil using standard lamination techniques. This structure could also be procured through standard masslam channels. The resulting four-layer structure is then processed and structured analog to the two-layer DYCOstrate foil, producing blind vias. Through holes can be added or they can be in the preexisting buried board.

26.3.5 Screen-Printed Via Technologies[11]

Toshiba's new Buried Bump Interconnect Technology is a new screen-printed via process.

26.3.5.1 Buried Bump Interconnect Technology (BBIT). Toshiba has developed a new process referred to as

BBIT (Buried Bump Interconnection Technology). With this process, a conductive paste is employed to replace via drilling, additive metallization, and via plating. The process has the advantage that hole-producing equipment is not required. Instead, a screened silver-epoxy paste is cured to be pointed like a thumbtack. This paste displaces the glass and epoxy during lamination to connect to the copper on the opposite side of the prepreg. The mass via-generation techniques, the simplification of metallization, and the fact that no drilling equipment is required make this new technique potentially very inexpensive. Currently, the design rules and features are for consumer products, but future uses are for simple plastic ball grid arrays (PBGAs).

26.3.5.1.1 Structure. The BBIT structure appears similar to that of other PCBs employing conductive paste vias. As shown in Fig. 26.12b, the structure is similar to ALIVH. The difference is that the BBIT structure uses standard FR-4 materials and a novel way to produce a via.

FIGURE 26.12 (*a*) DYCOstrate and PERL multilayer examples; (*b*) structure of the BBIT substrate.

26.3.5.1.2 Manufacturing Process. A silver ink is screened on copper foil in the locations where vias are required. This copper is used in the manufacture of standard FR-4 laminate. The silver paste thumbtack-like obstruction forces itself through the glass cloth during lamination to connect itself to the copper foil on the other side of the laminate and to cure the prepreg. The sheet of material is imaged and etched to provide the various circuits. Registration is less critical because the vias are now under the surface lands. Several of these two-sided layer pairs can be produced, inspected, and tested. The two-sided structures can then have additional single layers of B-stage/conductive paste layers with foil laminated to one or both sides, or the B-stage/conductive paste layer can be used to attach a number of layer pairs in one parallel lamination. The outside is imaged, etched, and completed as a normal PCB. This process is seen in Fig. 26.13.

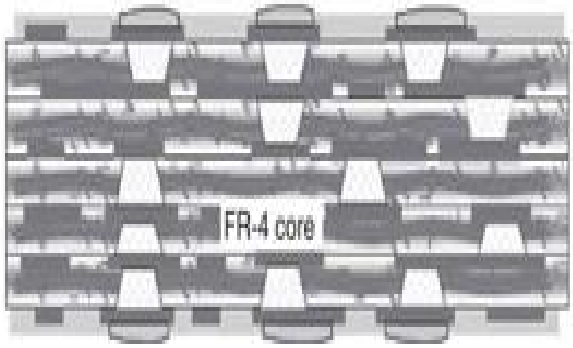

FIGURE 26.13 The manufacturing process for BBIT boards.

A newer BBIT process has been defined to manufacture wire-bonding and flip-chip substrates. In this BBIT process (shown in Fig. 26.14), the prepreg is laser-drilled so that smaller cream Ag solder can be used to bond to the copper.

FIGURE 26.14 The manufacturing process for the fine-pitch BBIT substrates.

26.3.6 Photo-Defined/Etched-Via Technologies

Neo-Manhattan Bump Interconnect is an example of the photo-defined and etched-via technologies available.

26.3.6.1 Neo-Manhattan Bump Interconnect (NMBI). The NMBI technology is one of the newest of the Japanese HDI technologies. It might be considered a "third-generation" HDI technology after technologies as ALIVH is considered a second-generation HDI technology. NMBI was pioneered by North Corporation of Japan.

26.3.6.1.1 Structure. Figure 26.15 shows the structure of an NMBI substrate. Also in this figure is a scanning electron microscope (SEM) of the etched-metal bumps that make up NMBI's via interconnects.

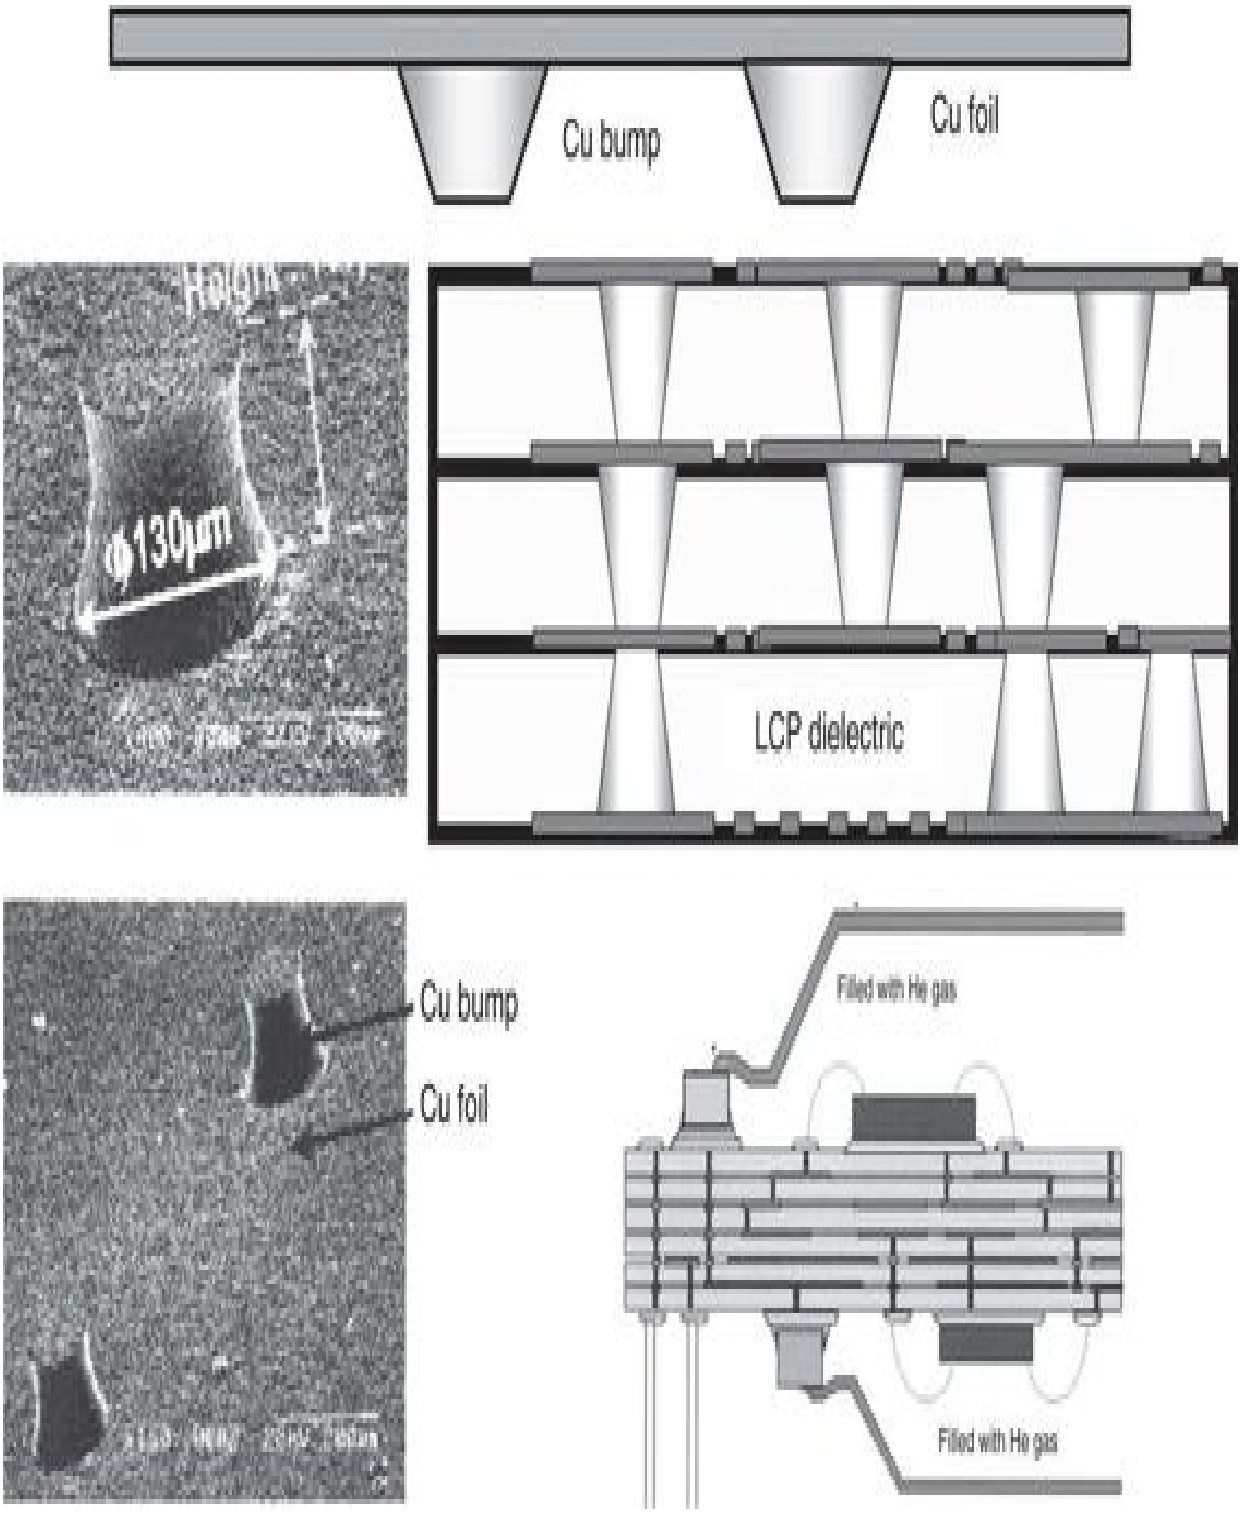

FIGURE 26.15 The neo-Manhattan bump interconnect structure.

26.3.6.1.2 Manufacturing Process. The manufacturing process for NMBI is unusual in that it does not drill the via

connections. Instead, a new material is employed that consists of two different coppers (one thicker than the other) that are bonded together. The thicker copper is imaged and etched to form the interconnect vias. This structure is then filled with a film or liquid dielectric. It is bonded to copper foil and both are cured. These copper foils are then imaged and etched to circuitize the layer pair. The layer pairs can be tested and later be stacked with uncured NMBI structures to form the final multilayer. Like the second-generation ALIVH HDI structure, an NMBI structure allows the connection of any layer to any other layer. This manufacturing process is shown in Fig. 26.16.

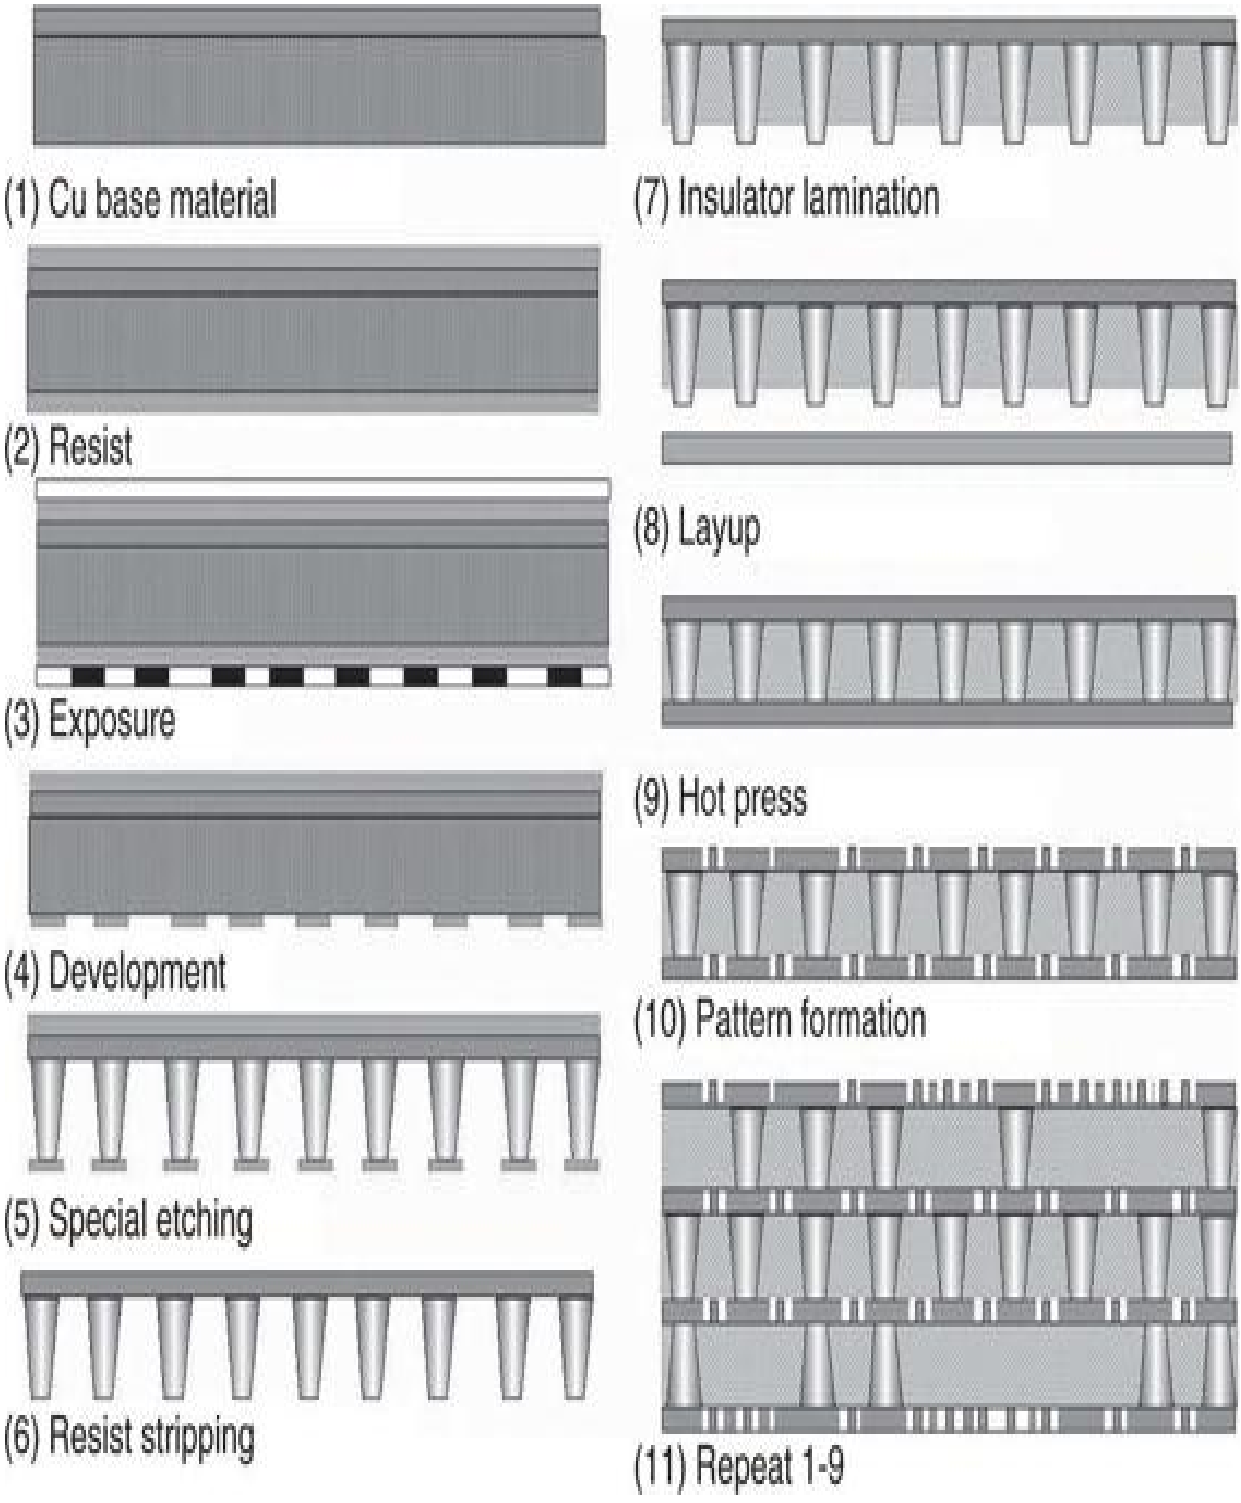

FIGURE 26.16 The manufacturing process for the NMBI substrates.

26.3.7 ToolFoil Technologies

Imprinted circuits are an example of a ToolFoil technology.

26.3.7.1 Imprinted Circuits. Imprint pattering is a similar technique used to manufacture compact discs (CDs). No photoresist, registration, or conventional techniques are employed.

Every substrate is a copy of the mold (or ToolFoil, in this case), and each can be done in sequence to make a build-up substrate. The unique characteristic of CDs and DVDs is the millions of 0.5 micron pits or vias. A typical CD includes over 3 km of these. The simple manufacturing process and perfect reproduction of the master tool creates inexpensive and accurate substrates. The patented process is a lab process; actual complexity is still under evaluation.

26.3.7.1.1 Structure. Figure 26.17 shows a diagram of the imprinted circuit structure, whereas Fig. 26.18 shows SEMs of an imprint-patterned circuit. The unique characteristic of this structure is that all features are embedded in the substrate. The critical dielectric is the part that is imprinted or molded. A long fiber molding compound, such as that used on components' overmolding, is best suited for this task. Such a compound can be used with or without an FR-4 backing. The cross section of an imprint circuit shows the features similar to a CD or DVD, that is, the various impressions. All are metallized but the vias are deeper. This allows the vias to contact the next layer of imprinted circuits.

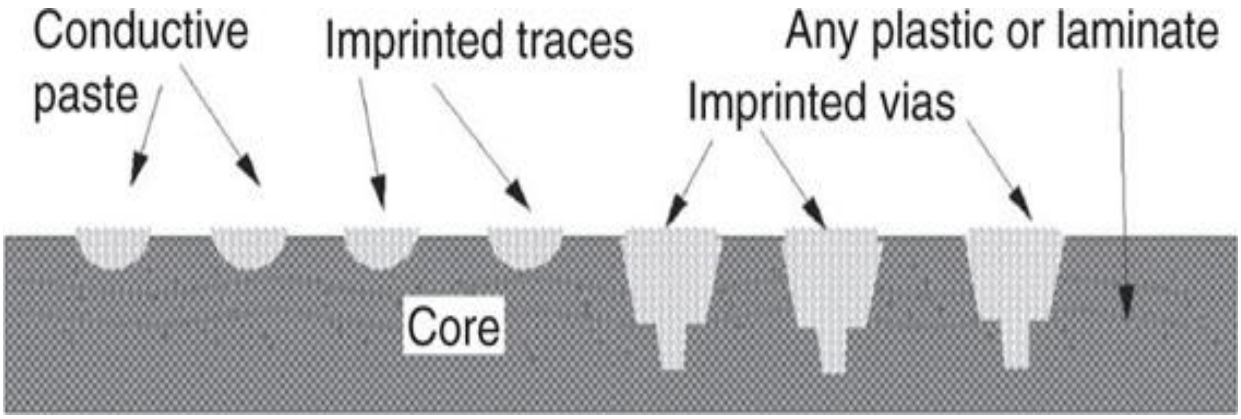

FIGURE 26.17 A simplified diagram of the imprinted printed circuit structure.

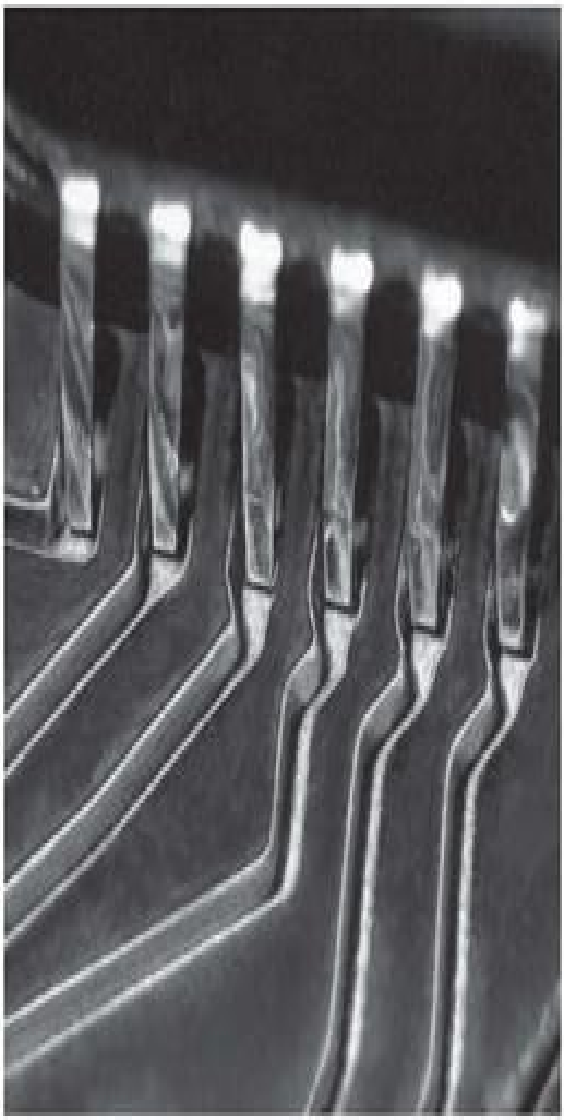
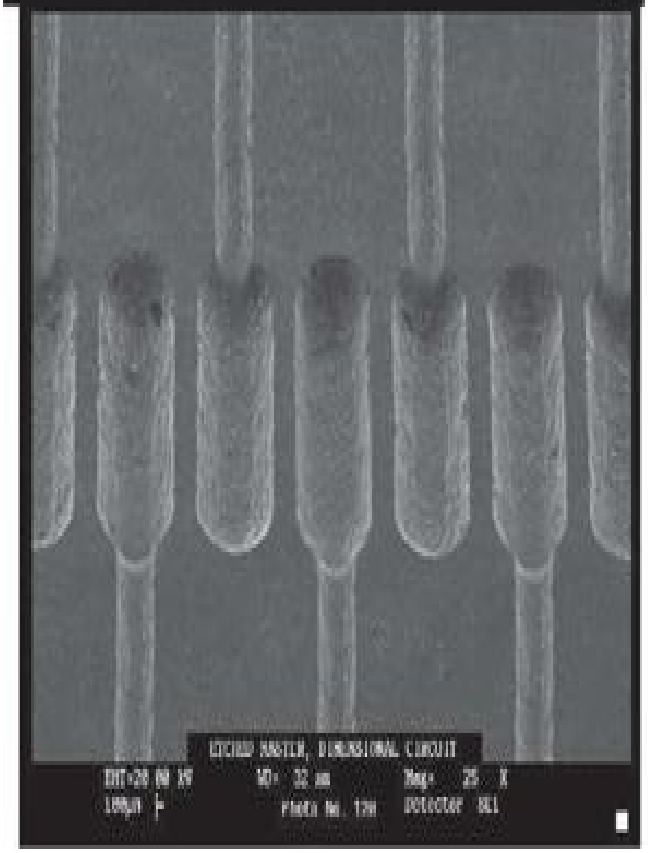
30 mil pitch SMT without the solder paste





25 mil pitch SMT lands with 4 mil traces

FIGURE 26.18 Various views of SEMs of imprinted circuit liquids and traces. (*Courtesy of Dimensional Circuits*.)

26.3.7.1.2 Manufacturing Process. A master of the substrate is machined in copper by a UV laser or by photochemical machining. The vias are deep, and the circuits and pads are shallow. Since only one master tool, called a ToolFoil, is required, time can be taken to make sure the master is perfect. With a laser, it is possible to have perfect registration of lands to via holes or even landless vias. This master is electroformed with nickel and back-filled to make a master tool. A sample ToolFoil is shown in Fig. 26.19.

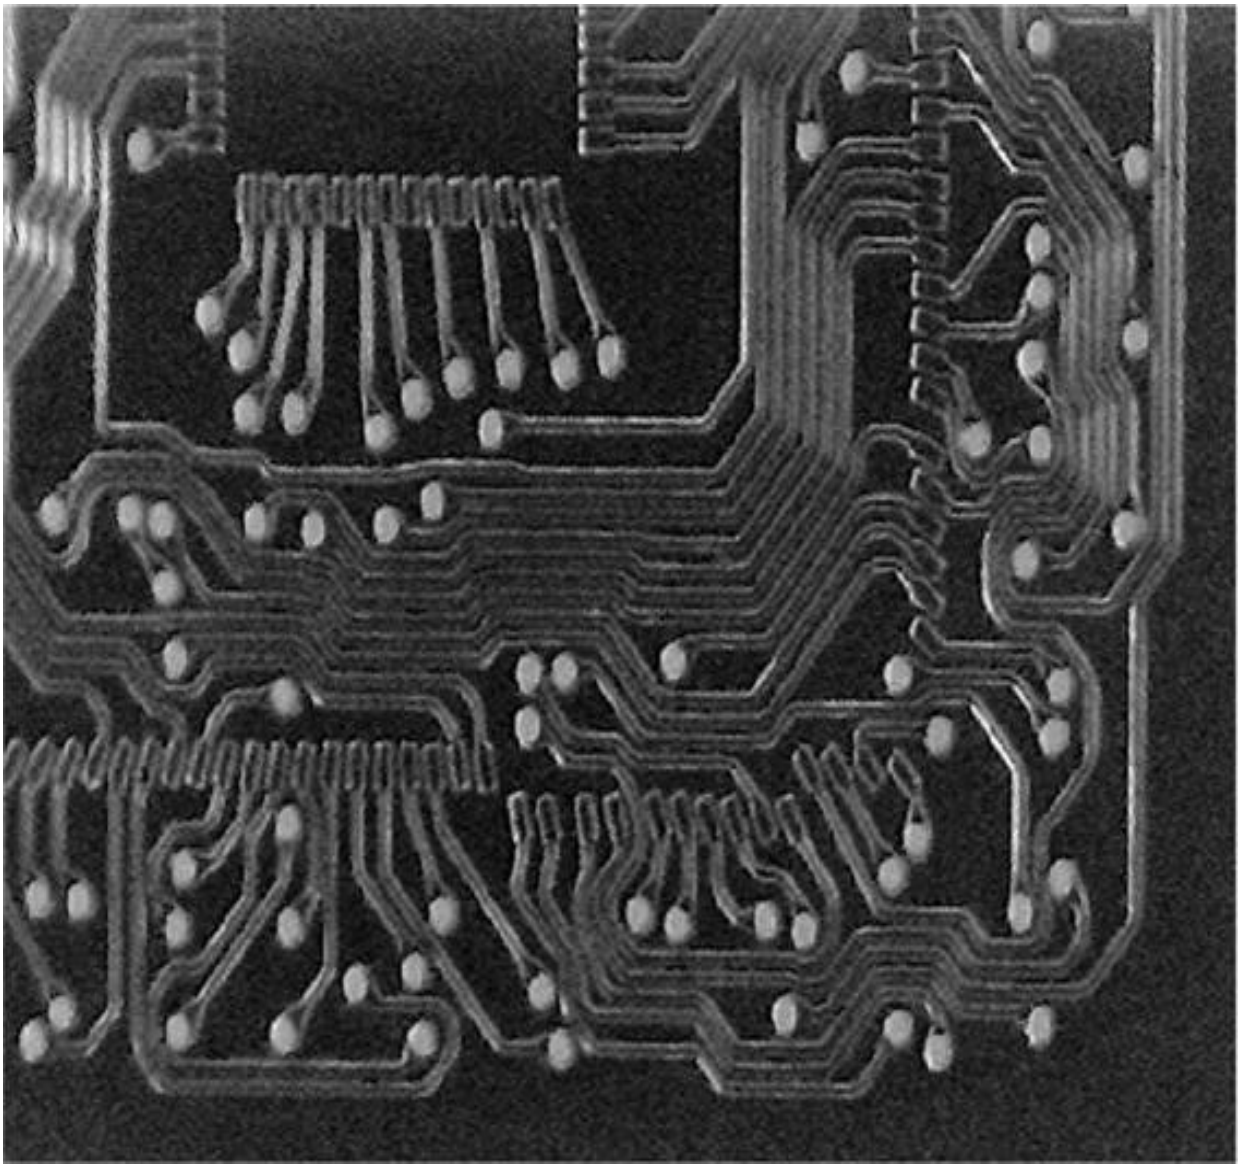


FIGURE 26.19 Example of a ToolFoil for imprinting. (*Courtesy of Dimensional Circuits*.)

For production, the mold is filled with a thermoset or thermoplastic resin and then cured. The substrate is additive or semi-additive metallized, and plated thicker with copper. The recesses are filled with an etch resist, and the surface resist is removed to expose the copper surface by polishing or by using an abrasive agent. The exposed copper is etched away and the etch resist is dissolved. The entire manufacturing process does not employ photoresists,

exposure, or registration. Because of this, the yield is expected to be very high.

26.4 NEXT-GENERATION HDI PROCESSES

HDI and microvias provide a big boost in density due to miniaturization. These technologies will continue to evolve and become smaller, following integrated circuit cell geometries. So the next revolution will be in optical wiring. Currently, optical networking ties together continents and cities, providing the backbone of modern worldwide networking. The fiercely competitive market is what technology will provide “the last mile” on connectivity? Optical wiring is competing for that market.

26.4.1 Embedded Optical Waveguides

Although electrical signals can be multiplexed on a single 100 micron wire or trace, many individual laser wavelengths can each carry many multiplexed signals on a single 100 micron wide waveguide. This results in a 10,000× increase in information handling while not being influenced by magnetic and electrical fields such as electronic signals. These optical conduits can now be mass produced on a printed circuits as polymer optical waveguides, as shown in Fig. 26.20 [12]. Much like when the industry transitioned from single-point soldering by individual wires to printed circuits, single-point fiber-optical cabling can now have low-cost printed waveguides.

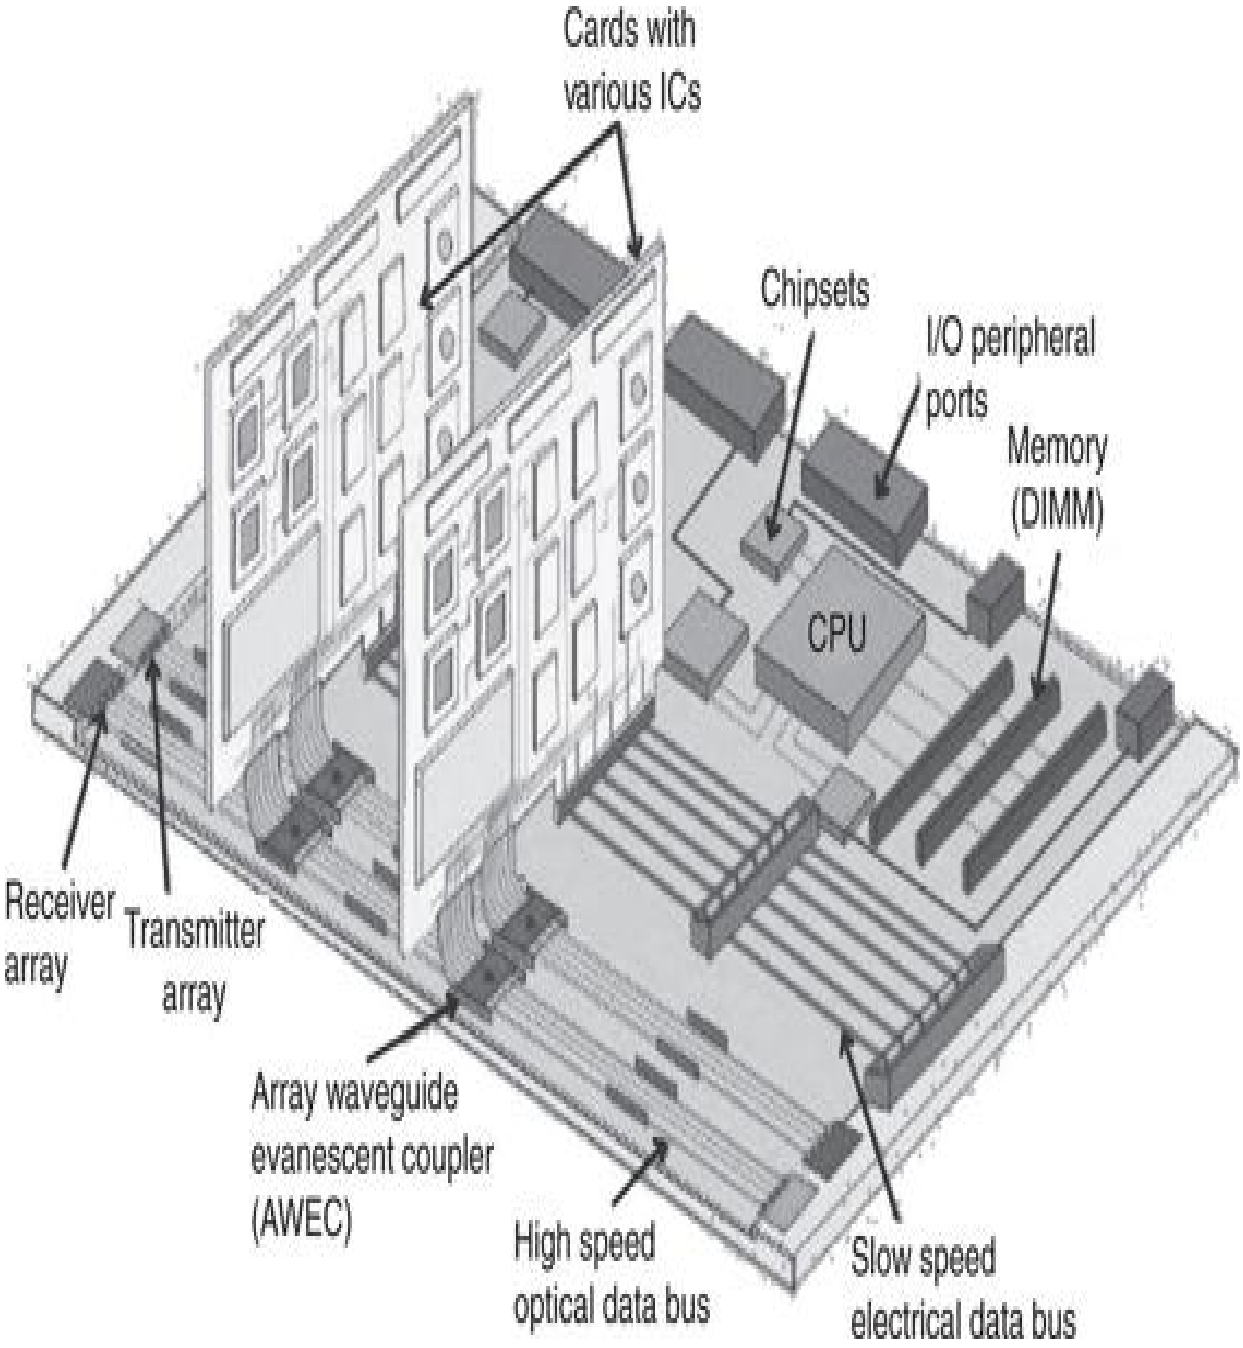

FIGURE 26.20 Board-to-board optical and electrical interconnections. (*Source: 3M.*)

Optical interconnections have major advantages over electrical signals: individual optical cables are 10× smaller than comparable high-speed shielded cables; optical bussing is 20× smaller than comparable electrical bussing; optical connectors are 7× smaller than electrical controlled

impedance cables while being 20 to 40 percent faster; and embedded optical waveguides are 8× smaller than differential striplines in PCBs. While optical bussing has many advantages, it will coexist with electrical bussing for the future as seen in Fig. 26.20.

26.4.1.1 Structures. The optical waveguide structures are shown in Fig. 26.21.[13,14,15] The transmitter package provides the multiplexed laser signal sources, through vertical cavity surface emitting laser (VCSEL) arrays into mirrors at the optical polymer waveguide level. At the receiver package, mirrors direct the laser signal up into photodiode arrays.

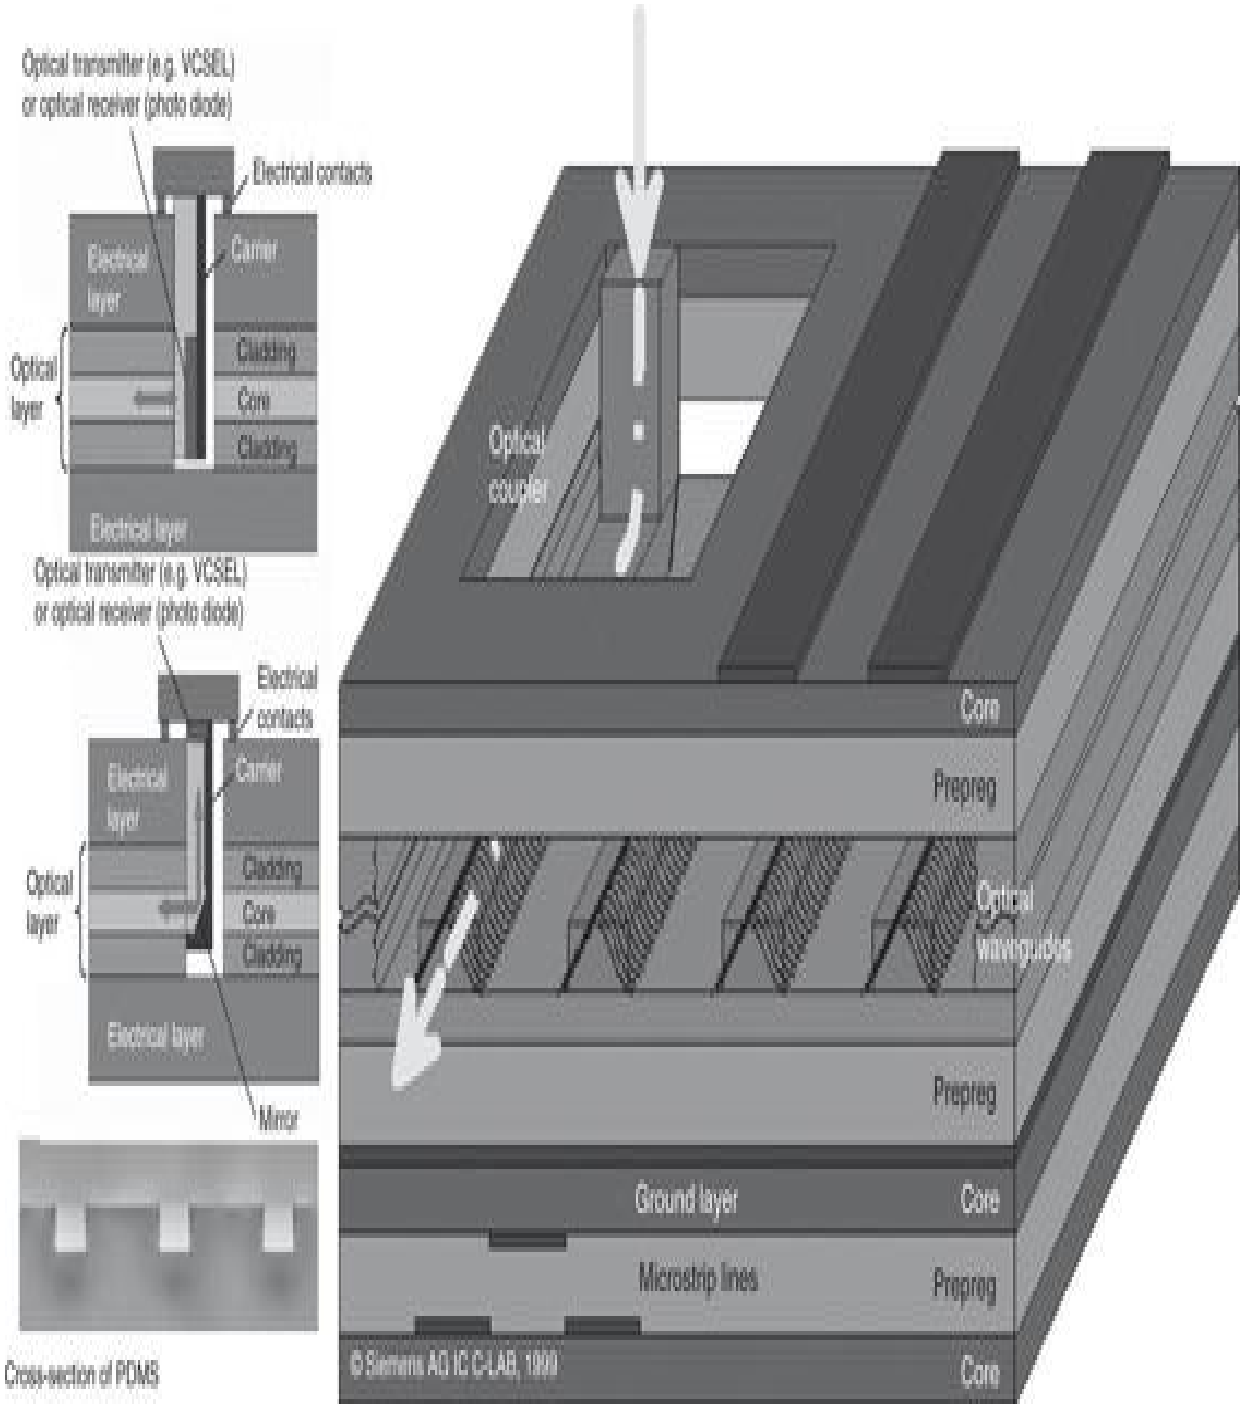

FIGURE 26.21 Structure of a printed optical waveguide. (*Courtesy of Siemens C-Lab*.)

26.4.1.2 Components. Figure 26.22[16] shows what the transmitter and receiver BGA packages will look like,

whereas Fig. 26.23[17] shows what the micro-mirrors, VCSEL, and photoreceptor sensors may look like.

Rx: 20 mm SQ., 134 pin @1.27 mm

FIGURE 26.23 NTT chip-to-chip optical interconnection, Tx and Rx. (*Courtesy of NTT-Lab*.)

26.4.1.3 Optical Waveguide Materials. The optical materials being considered for integrated waveguides are currently polymers. Polymers have a number of advantages:

- *Stability*. Such materials offer high thermal stability and long-term photostability. Bellcore Telecordia compliance (i.e., 1209, 1221) tested for less than 600 hr. at 85°C/85 relative humidity (RH), solder temperature >230°C, and degradation temperature >350°C.
- *Well established*. A huge body of data has been gathered over the last 100 years on polymers including all the popular photoresists.
- *Useful*. Polymers have unique properties (such as bend radius, modulators, and index tuning) that you cannot get anywhere else. These properties include unique processing options [photolithographic, reactive ion etching (RIE), direct laser writing, molding, and printing].

They also have a number of disadvantages:

- *Unstable*. Many have low thermal stability (POF below 80°C) with photodegration (laser dyes < days) and are sensitive to delamination, moisture, and chemicals.
- *Unknown*. New materials require new processes, equipment, and experience.
- *Useless*. Some polymers have losses of POF of 20 dB/km, whereas optical glass is <0.1 dB/km. The packaging cost of polymers is 80 percent of the cost in devices.

Candidate materials are acrylates, halogenated acrylates, cyclobutenes, polyimides, and polysiloxane. Table 26.3 lists many of the most popular materials. The optical losses of the polymers (dB/cm) are in the lower wavelengths near 840 nm.

TABLE 26.3 Polymers for Optical Waveguides and Candidate Materials

			Waveguide Optical Losses (dB/cm)		
Manufacturer	Polymer Type	Patterning Techniques	840 nm	1300 nm	1550 nm
Allied Signal	Halogenated Acrylate	Lithography, RIE	0.01	0.03	0.07
	Acrylate	Laser	0.02	0.2	0.5

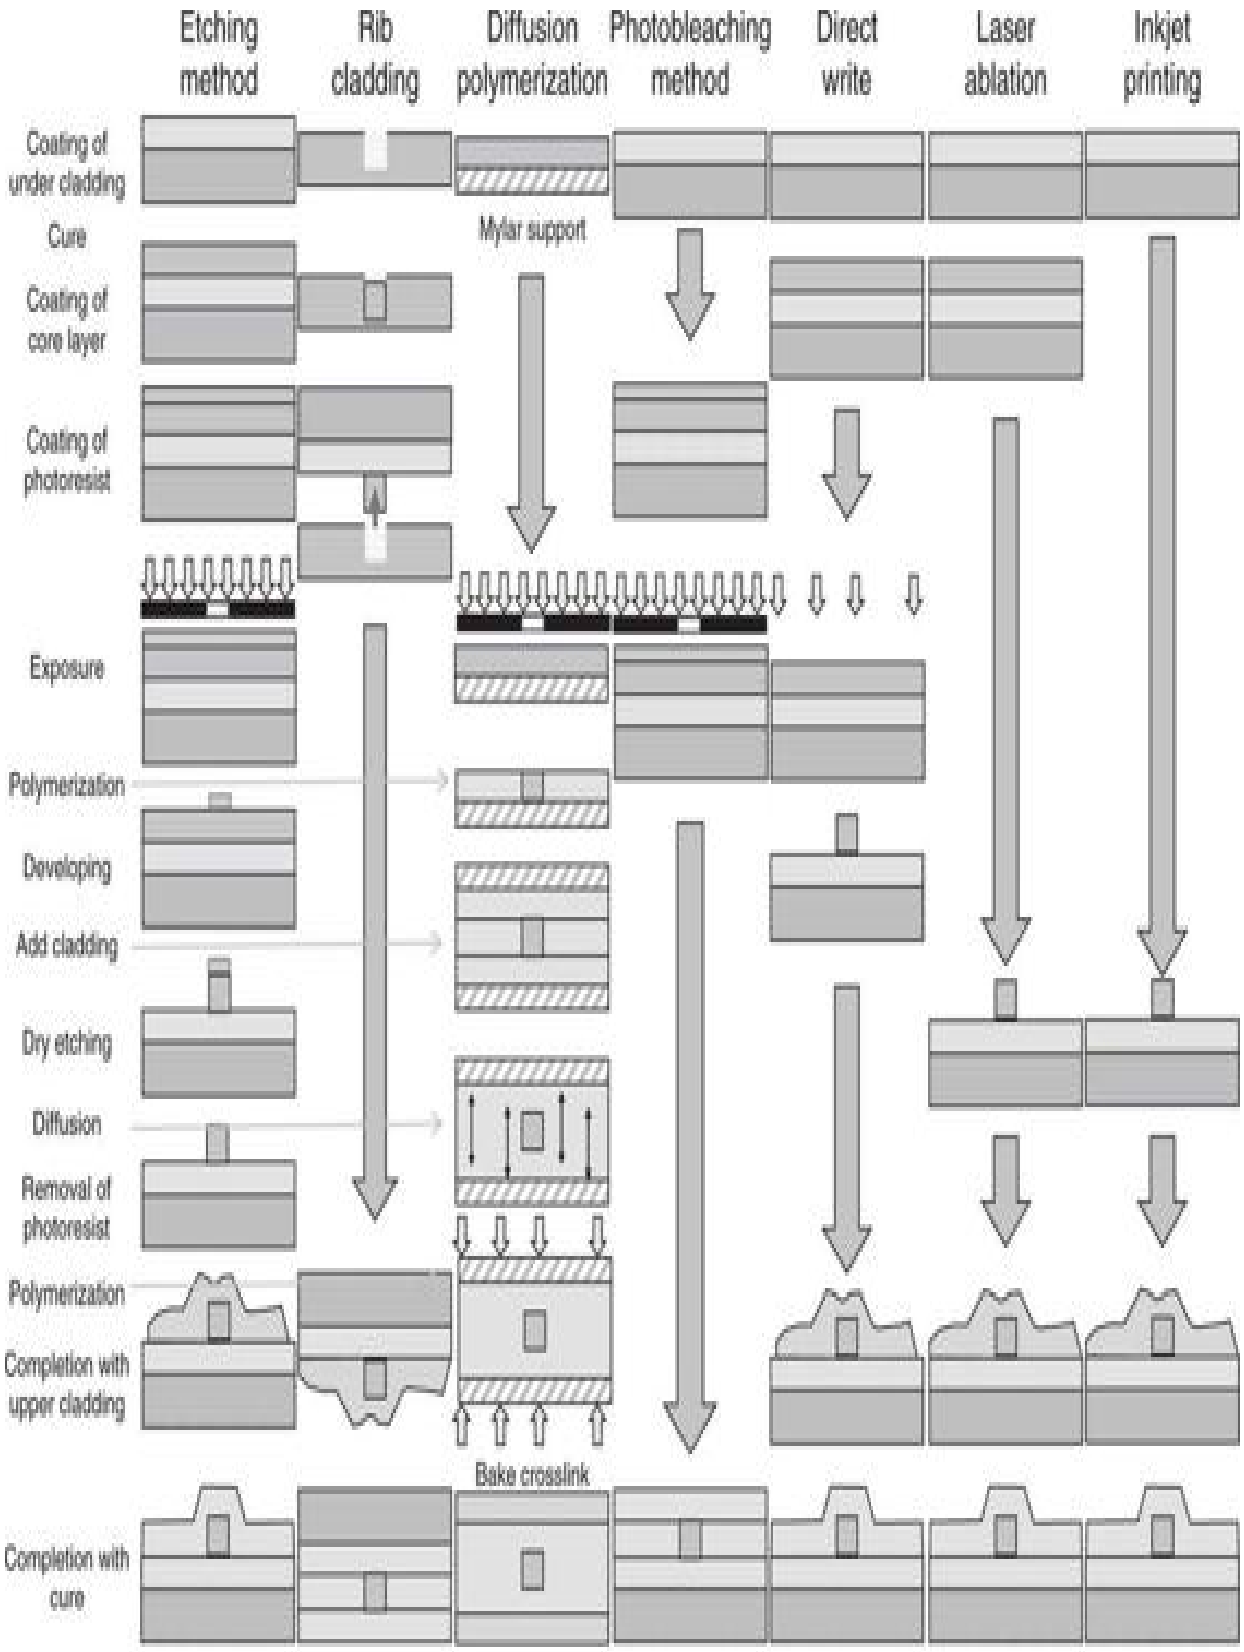
26.4.1.4 Manufacturing Process. The manufacturing process for polymer optical waveguides is much like using a liquid photoresist. Roller coating or meniscus coating of the liquid polymer is all that is required to apply the optical polymer on a standard multilayer innerlayer. After drying, the optical polymer is exposed through standard photo masks and developed. After a final curing, they are laminated into standard multilayers with prepregs. Figure 26.24 shows the seven fabrication techniques experimented on. These are then fabricated into a standard multilayer, as seen in Fig. 26.25.[18]



Process for defining polymer optical waveguides

FIGURE 26.24 Seven processes for defining polymer optical waveguides.

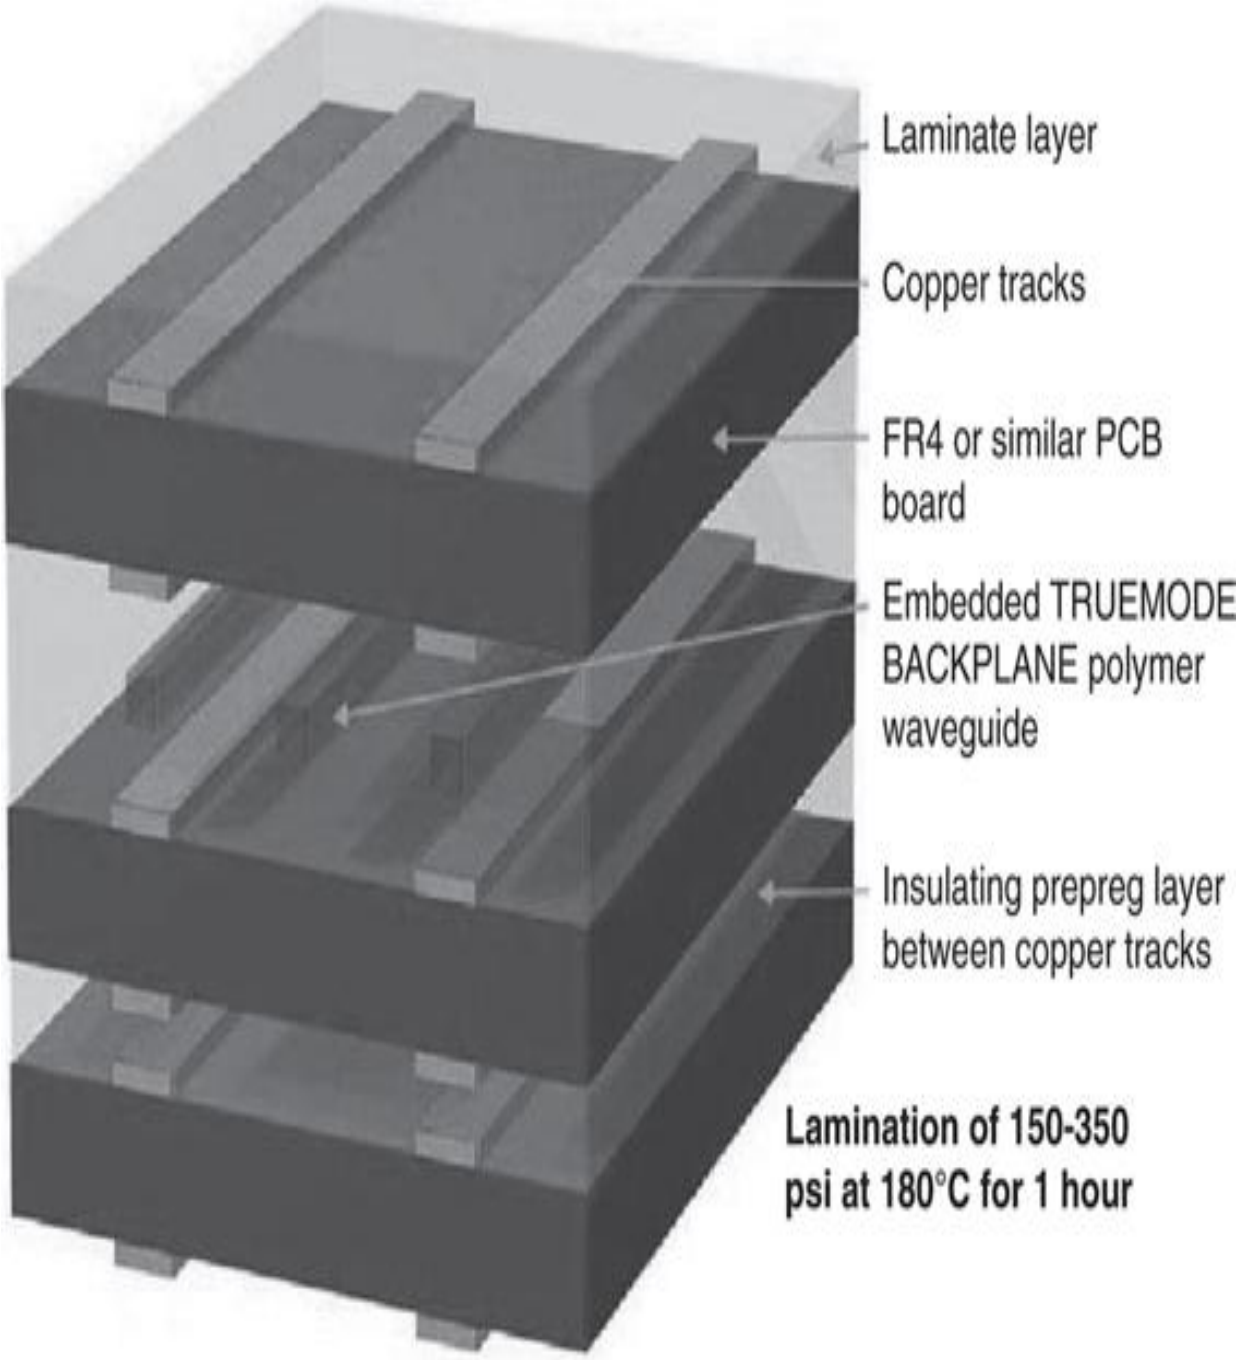


FIGURE 26.25 Optical waveguide stack-up in a conventional multilayer prior to lamination. (*Courtesy of Terahertz Corporation*.)

26.4.2 Current Research Globally Into Optical Waveguides in PCBs

Current optical waveguide research is being conducted all over the globe, with three programs of special note:

- EU's Electrical/Optical Circuit Board (EOBC) and OptoSys
- UK's Optical PCB (OPCB)
- US/DARPA/IBM Terabus Optocard

EOBC: This work is part of the German projects 'Electrical/Optical Circuit Board' and 'OptoSys,' which are supported by the German government's Department of Education and Research (BMBF) under grants 16SV802/6 and 01BP801/01. (Dortmund, Ulm and the Fraunhafer Institute for Applied Solid-State-Physics in Freiburg are participating on a suborder basis.)[19, 20, 21]

The progress in Germany is typical of that in the United Kingdom and United States, moving from the laboratory at universities to industrial companies building prototypes and the infrastructure. The EOCB (Electrical Optical Circuit Board) typified by C-Lab of Siemens in the last update is now replaced by commercial firms like VarioOptics AG of Villingen, Switzerland (spin-off of Varioprint AG of Heiden, Switzerland), and tested/qualified by Microtec GmbH laboratorie. Microtec tested and reported on the EOCB performance along with failure mechanisms and failure predictions. This provided new information for standards and pre-qualification actions.

OPCB: In the UK, a large team of university and industrial companies collaborated under EPSRC's leMRC, and OPCB: University College London, (UCL) Instigator, Principal Investigator and Technical Project Leader; the School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh; and the Wolfson School of Mechanical and Manufacturing Engineering, Loughborough University—

together with eight companies: Xyratex Technology (Project Manager and manufacturer of petabyte data storage systems), BAE Systems (global aerospace, security and defense company), Renishaw, Dow Corning USA (polymer supplier), Exxelis (polymer supplier), Stevenage Circuits Ltd. (PCB manufacturer), Cadence Design Systems (PCB layout software supplier) and National Physical Laboratory (national standards laboratory).[22, 23]

TERABUS: IBM Research and Agilent Corp. have invested heavily in the past 5 years in optical printed circuit board technology and connectors based on multimode polymer waveguides. This is now referred to as Optocard. This research was partially funded by the U.S. government as the Terabus Program.[24, 25, 26] IBM believes this technology will be needed to provide the bandwidth for future server generations (clouds), allowing highly integrated electrical-optical links of waveguides, flex and fiber between systems, modules, boards and chips. Their 2015 Project Milestone is seen in Fig. 26.26, the Anatomy of an Optomodule.

FABRICATION

CHAPTER 27

CAM TOOLING FOR FAB AND ASSEMBLY

Happy T. Holden

Co-Editor-in-Chief, Printed Circuits Handbook, *and PCB Technologist, Zeeland, Michigan*

27.1 INTRODUCTION

The manufacturing of printed circuit boards (PCBs) and assemblies (PCAs) begins with the soft-tooling process. This process is the transformation of customer computer-aided design (CAD) data and specifications into the necessary tools required for manufacturing the bare PCB and populating the assembly. The typical tools required for manufacturing PCBs include artwork for photoprinting of inner conductive layers, outer conductive layers, and solder mask patterns. Artwork is also created for screen-printing patterns for nomenclature and via-plugging layers. Additional tools required include drill and routing numerical controlled (NC) programs, electrical testing netlists and fixtures, and CAD reference soft-tools.

The tooling process for assembly requires assembly drawings, bills of materials (BOM), and schematic or logic diagrams, and includes the solder-paste stencil design,

assembly array layout, and the resulting computer numeric control (CNC) programs for component placement, in-circuit test program creations, and possibly the creation of a functional test program. Many of these procedures will be covered in subsequent chapters in the Part 8 of this handbook (assembly).

During the tooling process, the customer part numbers are analyzed to determine the compatibility of the design features with the manufacturing process capabilities. Additionally, attempts to optimize the manufacturing of the product at the lowest cost are a primary goal. However, the majority of the costs have been defined before the design is transmitted to the manufacturing site by the PCB designer. An early investment in time by the PCB design team and the manufacturing tooling team can result in the most significant savings in overall product cost.

This chapter describes the PCB tooling process, as defined in Fig. 27.1, including the transfer of information, design reviews, optimization of materials, definition of BOM and routings, tool creation, and additional processes that are required.

27.2 MANUFACTURING INFORMATION

The tooling process begins with the receipt of information from the customer. Unfortunately, although the time required to send information to the manufacturer has decreased to minutes or hours from day(s), a significant issue with the provision of packages to manufacturers is the completeness of the information provided. The Institute for Interconnecting and Packaging Electronic Circuits (IPC) has a new document, IPC-2610, that defines a complete documentation package, including the following:

- IPC-2611, “Generic Requirements for Electronic Product Documentation”
- IPC-2612, “Sectional Requirements for Electronic Diagramming Documentation (Schematic and Logic Descriptions)”
- IPC-2613, “Sectional Requirements for Assembly Documentation (Electronic Printed Board and Module Assembly Descriptions)”
- IPC-2614, “Sectional Requirements for Board Fabrication Documentation (Printed Circuit Board Description Including Embedded Passives)”
- IPC-2615, “Sectional Requirements for Dimensions and Tolerances”
- IPC-2616, “Sectional Requirements for Electrical and Mechanical Part Descriptions (Specification and Source Control Part Descriptions)”
- IPC-2617, “Sectional Requirements for Discrete Wiring Documentation (Wire Harness, Point to Point and Flexible Cable Descriptions)”

- IPC-2618, “Sectional Requirements for Bill of Material Documentation (Complete Listing of Parts, Materials, and Procurement Documents)”

Timely tooling of a part number depends on having the correct information. All features required to exist on the PCB must be defined for the manufacturer. The information is defined via design data, drawings, and textual information. Automated data are encouraged whenever possible.

27.2.1 Required Information

The information and common data formats required to permit the tooling of the PCB include the following (details are found in Sec. 5.2.1 and 5.3):

- Part number information
- Fabrication drawing
- Drill drawing
- Subpanel drawing
- Manufacturing notes
  - Board details: The type, size, and shape of the printed board, bow and twist allowances, overall board thickness requirements including tolerances, tooling hole information, special markings, and specific manufacturing processes and tolerances.
  - *Materials:* Type class and grade of materials, including color if applicable. Plating and coating material(s), type, thickness, and tolerances. Solder mask and marking inks type, minimum thickness, and permanency.
  - *Conductors:* Shape and arrangement of both conductors and nonconductor patterns, thickness, dimensions, and tolerances, including conductor width and spacing allowances.

- *Acceptability:* Location of quality conformance coupons or circuitry, control documents for acceptability, X-OUTs accepted and assembly-panel concerns.
- *Format:* Common formats for drawings are Adobe PDF, HP-GL, HP-GL-II, and Post- Script.
- Artwork data
- Aperture list files
- Drill data
- Drill tool files
- Special requirements information
- Netlist data

27.3 DESIGN ANALYSIS AND REVIEW

Design analysis and review is a refinement of the initial design review performed earlier but is the first step in the CAM (soft-tooling) process. This step focuses on the actual design data submitted for fabrication and assembly. The design analysis and review step consists of the following tasks:

- Design rule checking
- Manufacturability analysis
- Single-image edits
- DFM enhancements
- Panelization
- Fabrication parameters extraction

These tasks provide the final checking of the PCB design requirements against the capabilities of the PCB manufacturer and preparation of the design for manufacturing.

Most fabrication problems occur or are discovered during the initial tooling (CAM) phase. The following are among the causes of such problems:

- Poorly documented designs
- Improperly formatted drill files
- Use of 274-D Gerber with separate aperture tables
- Lack of proper clearance on solder mask openings
- Inadequate drill-to-copper clearance
- Misaligned layers
- Inadequate manufacturing clearances
- Lack of an IPC-D-356 netlist
- Use of positive plane layers instead of negative ones
- Minimal communication between the designer and the fabricator

The best advice for these problems is to fix them during the design phase. Consider the following precautions and considerations:

- Try not to use 274-D with separate aperture tables.
- Because there are no standards for aperture tables, the fabricator must do extra work to accommodate the tables, with increased opportunity for error.
- Use 274-X whenever possible. The apertures are embedded and files are easier for the fabricator to work with. This provides better support for special aperture shapes.
- Better yet, if possible, use “intelligent” formats like GenCAM, DirectCAM, or ODB++. These formats should enable the fabricator to better understand your design. Also, such formats have the netlist information embedded.
- Design rules can be embedded in some formats.

27.4 THE CAM-TOOLING PROCESS

27.4.1 Design Rule Checking

Design systems lay out circuits to defined rules; however, these systems may fail to adhere to these rules, because of either system failure or manual intervention. The purpose of reviewing the data package, in addition to reviewing the documented design constraints, is to confirm that the product can be produced at the manufacturing site and to the expected manufacturing yields. The analysis of the data describing the circuitry of the PCB to the manufacturing facility's production capabilities is critical to the success of the product.

Table 27.1 defines typical design rule checking that is performed, the reasons for checking, and the method of checking.

TABLE 27.1 Design Rule Checking

DRC Item	Purpose of Checking	Method of Checking
Drill layer duplicate coordinates	Duplicate drill holes consume manufacturing capacity and may result in broken drill bits.	Most PCB CAM systems have an explicit check for this problem, provided a given radius of tolerance.
Minimum drill hole-to- hole spacing	Drill holes too close together may result in broken material between the holes.	Most PCB CAM systems have an explicit feature spacing check.
NPTH-to-board edge minimum spacing	Drill holes too close to the board edge may result in broken material at the board edge.	Merge the routing profile onto a copy of the NPTH layer and execute a spacing check of the pad to trace (the route layer would appear as a trace).
Missing drill holes	Missing holes may result in nonfunctional designs or products that cannot be used due to missing mounting or tooling holes.	Check the pad registration against a circuit reference layer, and verify pads without PTH holes.
Extra drill holes	Extra drill holes could result in nonfunctional designs due to cutting of traces or shorts (if the holes become plated).	Check the pad registration against a circuit reference layer, and verify PTH holes without pads.
Board edge-to-board edge minimum spacing	Routing cuts leaving minimal material may result in fractured or broken material between routing.	Check the feature spacing of the routing layer as a design layer, without considering electrical connectivity.
Copper-to-board edge minimum spacing	Tolerances of the routing operation may result in copper exposed at the edges of the product.	Check the feature spacing of the routing layer as a design layer against the circuitry layer.
Minimum annular ring	Most customer specifications define the minimum acceptable annular ring on PCB products. Annular ring is dependent on the design and the registration tolerances of the manufacturing processes.	Most PCB CAM systems have an explicit annular ring check.

Minimum pad-to-pad spacing	In addition to feature spacing and potential shorts, pad spacing affects the capability to test products electrically.	Most PCB CAM systems have an explicit feature-to-feature spacing check.
Minimum pad-to-track spacing	Feature spacing below manufacturing capabilities could result in shorts and poor product yields.	Most PCB CAM systems have an explicit feature-to-feature spacing check.
Minimum track-to-track spacing	Feature spacing below manufacturing capabilities could result in shorts and poor product yields.	Most PCB CAM systems have an explicit feature-to-feature spacing check.
Copper-to-NPTH minimum spacing	NPTH locations too close together may prevent proper tenting of holes and require secondary drilling operations. NPTH too close together may result in damaged features (e.g., cut traces).	Check the feature minimum spacing against a copy of the design layer merged with the NPTH layers.
Minimum line width	Line widths below manufacturing capabilities could result in poor product yields.	Some PCB CAM systems have an explicit check for this problem; others may require review of the apertures used and highlighting of the apertures for visual inspection.
Track termination without pad	Although this may be the design's intent, missing pads may be the result of poor design information or loading failures. These problems can result in nonfunctional designs.	Most PCB CAM systems have an explicit check for this problem.
Padstack alignment	Misaligned padstacks may result in unpredictable annular ring results, incorrect compensations of registration, and product scrap.	Most PCB CAM systems have an explicit pad registration check.
Minimum solder mask pad clearance	Solder mask pad clearances below manufacturing capabilities could result in solder mask on the pads and poor product yields.	Check the solder mask layer (as a circuit layer) against the circuitry layer using an annular ring check.

Minimum solder mask edge-to-feature spacing	Solder mask edge to feature spacing below manufacturing capabilities could result in exposed features and poor product yields.	Check the feature minimum spacing against a copy of the design layer merged with the solder mask layer.
Minimum solder mask annular ring for NPTH	NPTH solder mask clearances may need to be larger to prevent ghosting of the solder mask from light diffraction through the product mask.	Check the solder mask layer (as a circuit layer) against the NPTH layer, and verify that there are no matches of the NPTH to the solder mask layer.
Solder-mask-to-board edge minimum clearance	PCB edge clearances may need to be larger to prevent ghosting of the solder mask from light diffraction through the product.	Check the feature minimum spacing against a negative copy of the solder mask layer merged with the routing layer.
Solder mask minimum web	Solder mask webs below manufacturing capabilities could result in solder mask breakdown and poor product yields. This problem could result in a PCB assembler with solder bridging defects.	Use minimum feature-to-feature spacing on the solder mask layer.
Plane-to-board-edge minimum clearance	Spacing below the tolerances of the routing operation may result in exposure of copper at the edges of the product.	Check the feature spacing of the routing layer as a design layer against the plane.
Minimum plane layer annular ring	An annular ring below manufacturing registration and tolerance capabilities could result in open connections and poor product yields.	Most PCB CAM systems have an explicit annular ring check.
Minimum plane layer clearance	Plane clearances below manufacturing registration and tolerance capabilities could result in shorts and poor product yields	Most PCB CAM systems have an explicit annular ring check.

Plane-to-plane isolation	Plane layer isolation typically results from either incorrect designs or interpretation of aperture lists; the result is a nonfunctional product.	Most PCB CAM systems have an explicit layer-to-layer isolation check.
Nomenclature-to-NPTH minimum spacing	Nomenclature spacing below manufacturing capabilities may result in nomenclature in the hole, due to misregistration or bleeding of the nomenclature ink.	Check the feature minimum spacing against a copy of the nomenclature layer merged with the NPTH layers.
Nomenclature-to-solder mask minimum spacing	Nomenclature spacing below manufacturing capabilities may result in nomenclature on product features, due to misregistration or bleeding of the nomenclature ink.	Check the feature minimum spacing against a copy of the nomenclature layer merged with each solder mask layer.
Nomenclature-to-feature minimum spacing	Nomenclature spacing below manufacturing capabilities may result in nomenclature on product features, due to misregistration, bleeding of the nomenclature ink, or skipping of the screen over features, resulting in illegible markings.	Check the feature minimum spacing against a copy of the design layer merged with the nomenclature layer.
Nomenclature minimum feature sizes	Nomenclature sizes below manufacturing capabilities could result in illegible nomenclature and poor product yields.	Some PCB CAM systems have an explicit check for minimum line width; others may require review of the apertures used and highlighting of the apertures for visual inspection

27.4.2 Manufacturability Review

The design rule checking results are reviewed against the PCB manufacturing capability matrix, with dispositions being made

to the acceptability of violations. The PCB customer may be contacted regarding design violations, to correct and retransmit the design or to permit design changes to be performed by the PCB manufacturer.

Additionally, the factors reviewed during the initial design review are revisited to confirm the results based on design actuals. If differences are noted, product yields and/or cost predictions may need to be altered. During this step of tooling, several concerns are uppermost in the fabricator's mind: Does the board meet the intent of the design? Can it be built? Will it function as planned? Does it pass a master rule set? Can it be improved, that is, be made cheaper or better? Is there component interconnectivity? Does the IPC-D-356 netlist show any shorted nets or broken nets? Were any multiple plane ties not happening? Did a design work-around fool the system—or allow intentional errors to slip through?

27.4.2.1 Bare-Board Analysis. Several physical artwork problems are not discovered by design rule checking and are not strictly speaking the result of design rule violations. Nonetheless, these problems can affect the manufacturability of a board and its yield. Table 27.2 describes some of these issues.

TABLE 27.2 Physical Artwork Issues

Physical Artwork Issue	Description of Issue	Illustration
Acid traps (photo-resist slivers)	Small pieces of photo-resist that have minimum adhesion and can break off, resulting in plating or redeposits	Figure 27.2*a*
Pin holes	Small openings in planes or pours that can result in loss of adhesion	Figure 27.2*b*
Copper slivers	Small features that may lose adhesion and break off	Figure. 27.2*c*
Starved/isolated thermals	Copper legs for thermals that are cut off from the rest of the plane	Figure 27.2*d*
Soldermask(S/M) slivers (web)	Small S/M features too tiny to image and adhere properly	Figure 27.2*e*
S/M to trace spacing	Small spacings that create S/M slivers	Figure 27.2*f*
S/M coverage	Features left open that could result in solder bridging	Figure 27.2*g*
Solder bridging	Small gaps between soldered features without S/M that could bridge solder	Figure 27.2*h*
Legend on pads	Silkscreen or legend on surface mount technology (SMT) lands	Figure 27.2*i*

Figure 27.2 shows examples of many of these problems. Most modern CAM-tooling systems can correct these manufacturability issues. Thus the manufacturing notes on the fabrication drawings should acknowledge this and allow for the fabricator to implement corrections. Other, less frequent, artwork errors discovered include

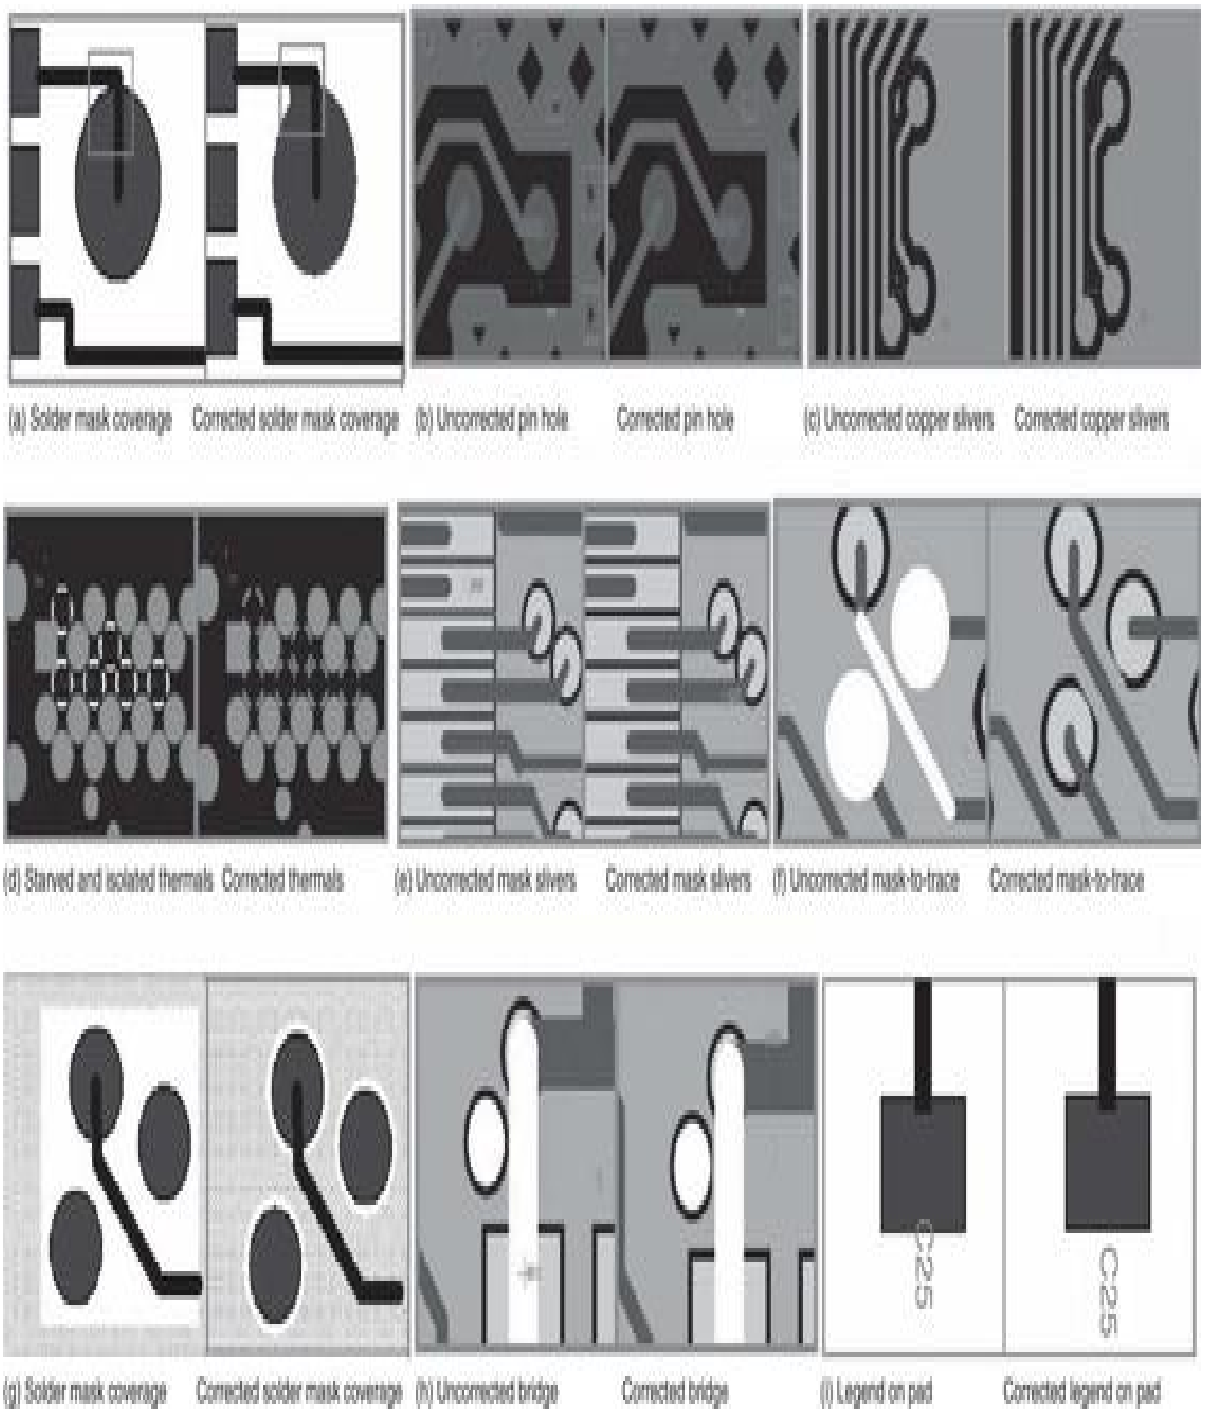

FIGURE 27.2 Typical producibility problems created in design (physical artwork).

- Signal integrity and performance issues
- Verification of last-minute changes [life savers and engineering change orders (ECO)]
- “Made in XX” and revision controls

27.4.2.2 Printed Circuit Assembly. In a similar situation, assembly tooling requires the checks and analysis of supplied BOM, machine files, and artwork for the assembly process. These actions are specifically designed to locate potential manufacturability problems during board assembly and to collect design statistical data for quoting, planning, and allocating resources. Each action covers a specific aspect of board assembly, including component location, fiducial coverage, and testability issues. These include but are not limited to the following:

Fiducial analysis: SMT component placement needs to align the machine to the individual board. By analyzing global and fine-pitch fiducials, you can identify and correct potential problems. Table 27.3, col. A, shows the checklist of a typical analysis.

TABLE 27.3 Checklist of Various Assembly and Test Analyses That Need to Be Performed in Tooling

A. Fiducial Analysis	B. Component Analysis	C. Padstack Analysis	D.Testpoint Analysis	E.Solder Paste Analysis
Global fiducial summary	Comp. max height	Toeprint to toeprint	Toeprint testpoints	Solder paste not on SMD pad
Local fiducial summary	Comp. pitch	Extra solder mask web	Via testpoints	SMD pad without solder paste
Non uniform local fiducial	Comp. rotation	No solder mask web	Other testpoints	Solder paste outside copper
Fiducial to copper	Comp. length Min	Special toeprints	Testpoint to rout	Solder paste not exposed by solder mask
Fiducial to hole	Comp. length max	Via to via center	Testpoint to NPTH	Solder paste to solder mask
Close fiducials	Comp. Spacing	Via to via edge	Testpoint to testpoint	Toe distance min (rect. pins)
Far fiducials	Comp. to toeprint	Via in SMD	Testpoint to toeprint	Heel distance min (rect. pins)
Fiducial to like pad	Rout spacing	Via to toeprint	Testpoint to capped via	Left Distance min (rect. pins)
Fiducial close to rout	Carrier wall spacing	No thieving pad	Testpoint wrong shape	Right distance min (rect. pins)

Fiducial far from rout	PTH to carrier wall	Toeprint to plane	Testpoint to THMT toeprint	Toe distance max (rect. pins)
Fiducial to background	NPTH to carrier wall	Toeprint annular ring	Testpoint to tooling hole	Heel distance max (rect. pins)
Fiducial to solder mask	Via to carrier wall	Toeprint SM clearance	Testpoint to uncapped via	Left distance max (rect. pins)
Fiducial to solder paste	Label to component	Toeprint to rout	Testpoint to exposed copper	Right distance max (rect. pins)
Fiducials to silk screen	Assembled board thickness	Hole in SMD	Testpoint to unexposed copper	Pin area/pad area min
Fiducial to conveyed edge	Comp. touch silkscreen	Flow solder orientation	Testpoint under component	Large pin area/pad area min
Component center fiducial	Component to conveyed edge	Gold fingers to capped via	Testpoint to component	Pin area/pad area max
Component covers fiducial	SMT component to conveyed edge	Gold fingers to thru TP	Testpoint to component angle	Large pin area/pad area max
Component local fiducial	Other side area keepout	Gold fingers to surface TP	Testpoint to solder mask	Pin width/pad pitch
Component global fiducial	Other Side pins keepout	Gold Fingers to uncapped via	Capped testpoint vias	Pin Pitch/pad pitch
Course-pitch component global fiducial	Comp. to gold fingers	Shadowing of inline components	Nets with one testpoint	Direct connection to plane
Fine-pitch component global fiducial	Component to tooling hole	Shadowing of staggered components	Nets without testpoints	No clearance in plane

Component analysis: SMT components can have a multitude of missing, incorrect, or incomplete characteristics or properties. Component analysis looks for these potential problems, such as one component extending under another component. Table 27.3, col. B, provides a typical checklist for such an analysis.

Padstack analysis: SMT components have critical toeprints (TPs) and need to be checked with respect to vias, planes, solder mask, fabrication edges, and gold fingers. Table 27.3, col. C, shows a checklist for a typical analysis.

Testpoint analysis: SMT components need to be tested by in-circuit test (ICT). These analysis check testpoints to vias, surface features, tooling holes, and electrical nets. See Table 27.3, col. D, for a typical checklist for testpoint analysis.

Solder paste analysis: SMT components have to be soldered correctly. This is the second most important aspect of assembly, just behind placing the right part in the right place. Many checks are necessary to ensure manufacturability, as seen in Table 27.3, col. E.

The benefits of performing a comprehensive and thorough assembly analysis include the following:

- Estimation of cost can be derived from the results of the analysis.
- Manufacturing defects can be identified and corrected prior to construction on the assembly line.
- Such analysis can help detect potential problems so that any necessary reworking can be implemented early in the design process. Each analysis category is governed by a set of engineering reference file (ERF) values, usually unique to each production facility, thereby supporting full job portability between different assembly sites.
- The design rule checking results are reviewed against the PCB or assembly manufacturing capability matrix, with dispositions being made to the acceptability of violations.

The PCB and assembly customer may be contacted regarding design violations; the designer may need to send corrected designs or to allow design changes to be performed by the PCB manufacturer or assembler.

- Additionally, the factors reviewed during the initial design review are revisited to confirm the results based on design actuals. If differences are noted, product yields and/or cost predictions may need to be altered.
- When issues are addressed during the fabrication or assembly stage, the design database may not get updated to reflect vital changes, thus compromising the integrity of the design. If the design is respun in the future, this issue might be overlooked, resulting in scrap, or worse, faulty boards.

27.4.3 Single-Image Edits

Almost all designs include information that must be removed before they can be manufactured. Most of these items of information are used as references during the PCB layout phase to assist the designer in understanding the available real estate. However, these references must be removed or modified in order to manufacture the board to design intent. Among these typical items are the following:

Item	Impact if not removed/modified
NPTH pads on outerlayers	Plated holes
Routing crop marks	Copper at board edge
Direct contact plane markings of drilled holes	Open circuits
Clip nomenclature with solder mask data	Nomenclature on pads or in holes
Scaling and compensation	Finished traces or geometries that are the wrong size

27.4.4 DFM Enhancements

The manufacturability of the PCB can be improved through design enhancements. Many of the enhancements can be performed on CAD systems (or through specialized post-CAD software); other enhancements can be performed at the manufacturing site.

Ideally, all design enhancements would be performed at the design site to maintain the consistency of products from multiple manufacturers; however, some of the DFM enhancements can impact the CAD system's capability to provide further design changes. Specifically, the optimization of track-to-feature spacing could result in blocked routing channels, preventing an autorouter from performing. The following are typical DFM enhancements (see Fig. 27.3):

Item	Result from enhancement
Copper balancing	The balancing of copper on the surface of the design will improve the distribution of plating (in the pattern-plating process), preventing areas of overplating due to the isolation of features. This improvement enables the manufacturer to control the plated hole diameters to tolerances and reduce plating heights, which impact solder mask coverage. (See Fig. 27.3*a*.)
Teardropping	As annular rings decrease due to tighter design specifications, the probability of defects occurring due to registration/annular ring failures increases. The addition of teardropping increases the pad-to-trace junction size, improving the reliability of the connection and improving product yields. (See Fig. 27.3*b*.)
Removal of nonfunctional pads on innerlayers	Innerlayer shorts result from several factors, among them the proximity of circuitry to other circuitry.

	The occurrence of shorts can be correlated to the running length of the circuitry versus the running length at some minimum spacing between circuitry (at the process capability of the operation). Reducing the total distance at minimum spacing will reduce the probability of shorts, resulting in improved yields. (See Fig. 27.3*c*.)
Optimization of track-to-feature spacing	As described in the nonfunctional pads discussion, the occurrence of shorts can be correlated to the running length of the circuitry versus the running length at some minimum spacing between circuitry (at the process capability of the operation). Reducing the total distance at minimum spacing will reduce the probability of shorts, resulting in improved yields. (See Fig. 27.3*d*.)
Track width optimization	The occurrence of opens can be correlated to the running length of the circuitry versus the running length at minimum track width (at the process capability of the operation). Reducing the total distance at minimum track width will reduce the probability of opens, resulting in improved yields. (See Fig. 27.3*e*.)

(e)

FIGURE 27.3 Typical producibility problems created in design.

27.4.5 Panelization

In the panelization process, the PCB single images are placed in the locations defined in the panelization definition step of the initial design review. In addition, the following features may be added to the panel for manufacturing:

Item	Purpose
Customer coupons	These coupons are provided to the customers for their inspection of the PCB product. These coupons are typically treated as separate PCB single images.
Internal coupons	During the manufacturing process, destructive testing may be required to confirm product quality. These coupons are typically treated as separate PCB single images.
Tooling holes	Holes used for registration of manufacturing panels to artwork, drilling, or routing operations are added to the panel borders.
Outerlayer thieving patterns	Plating thieving patterns are sometimes needed to balance the platable area across the panel.
Innerlayer venting patterns	The addition of copper to innerlayers outside the PCB single image provides more consistency in the lamination process.
Textual markings	Operator aides may be provided outside the PCB single image to improve manufacturing quality.

27.4.6 Fabrication and Assembly Parameter Extraction

Additional manufacturing information must be extracted or calculated from the design file before fabrication or assembly can begin. This information is loaded and stored in several files and databases used to run various fabrication and assembly equipment. In addition to requiring the basic tooling steps already defined, most PCB manufacturing sites also require the designer to provide the following information:

- Raw materials shearing and labeling instructions
- Copper foil thicknesses and etch rates
- Automatic optical inspection files
- Lamination lay-up BOM and order/stack height
- Lamination press cycles, heat input, and pressure settings
- Drill-file location and revision levels
- Plating area calculations and current density settings
- Copper foil thicknesses and etch rates
- Router-file location and revision levels
- Electrical test programs
- Quality control procedures and coupon disposition
- Final packing and shipping instructions

27.4.6.1 AOI Files. The CAD reference files, if required, are generally created at the PCB manufacturing site. These files prepare automated optical inspection (AOI) systems with data that confirm that manufactured pieces match, within tolerances, the PCB design.

27.4.6.2 Lamination Parameters. Each multilayer stack-up and material may require specific lamination processes. Modern multilayer presses have microprocessor-controlled time, temperature, and pressure. These parameters require selection in the tooling process.

27.4.6.3 Drill Files. Drill files and the respective drill bit tools must be archived and available for download to the appropriate drilling machine when production needs them. Drill

bit preparation precedes the actual drilling operation in order to create the drill cassette.

27.4.6.4 Plating Coefficients. Plating requires specific direct currents (DC) to be applied to this part. The current density of the appropriate plating bath is multiplied by the plated area on each production rack. After the first actual run, direct measurement of the plated metals is used to adjust the plated area to achieve the correct thicknesses.

27.4.6.5 Routing Files. Router files and the respective router cutting tools have to be archived and available for download to the appropriate routing machine when production needs them. Router tool preparation precedes the actual routing or secondary drilling operation in order to create the final fabrication cassette.

27.4.6.6 Electrical Test Programs and Fixture Creation. An electrical test netlist file may be either created internally from the artwork or prepared from a supplied IPC-D-356 file. This test file has to be compared to the netlist extracted from the artwork supplied. Any difference must be resolved before the actual electrical test file is finalized. In addition, the electrical test fixture must be constructed or sent to an outside contractor to prepare.

27.4.6.7 CAD to Assembly Processes. The assembly tooling operations include CAD interfacing to component data and BOM. These operations include the generation of manufacturing documentation (see Fig. 27.4) and assembly engineering for component machine management, program optimization, and line balancing (see Fig. 27.5).

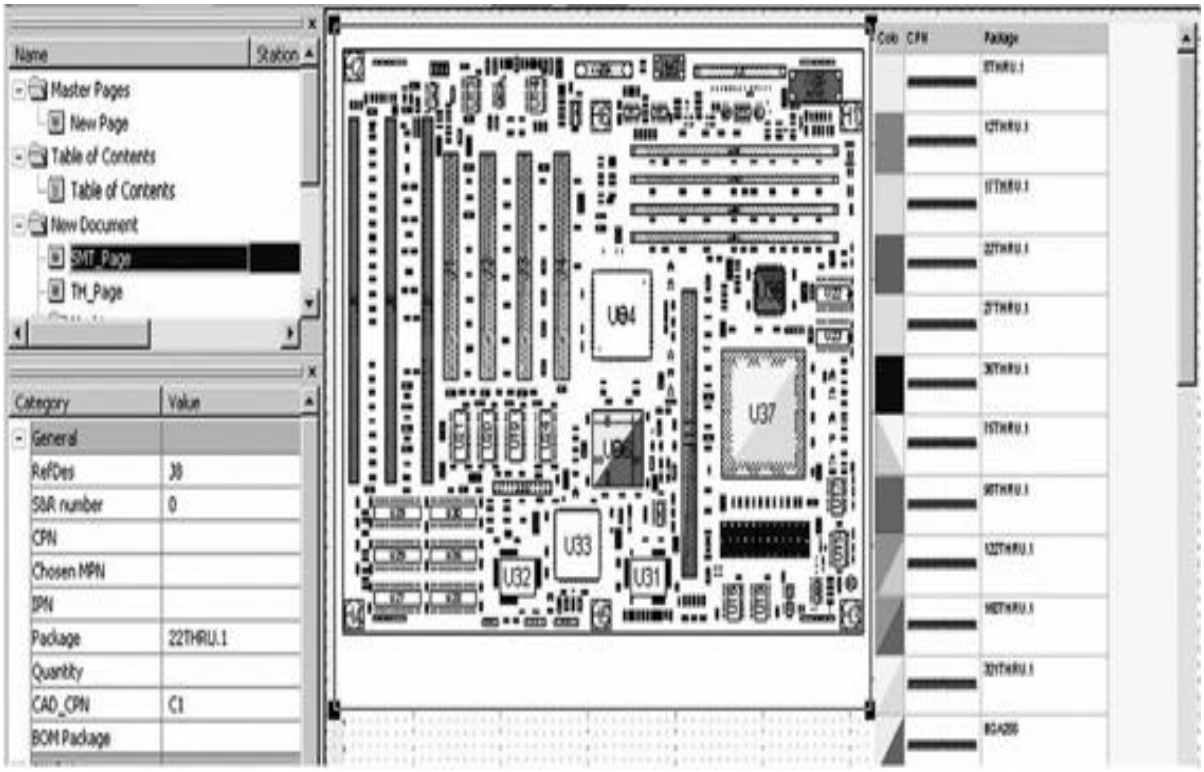

FIGURE 27.4 Assembly manufacturing documentation and instructions creation.

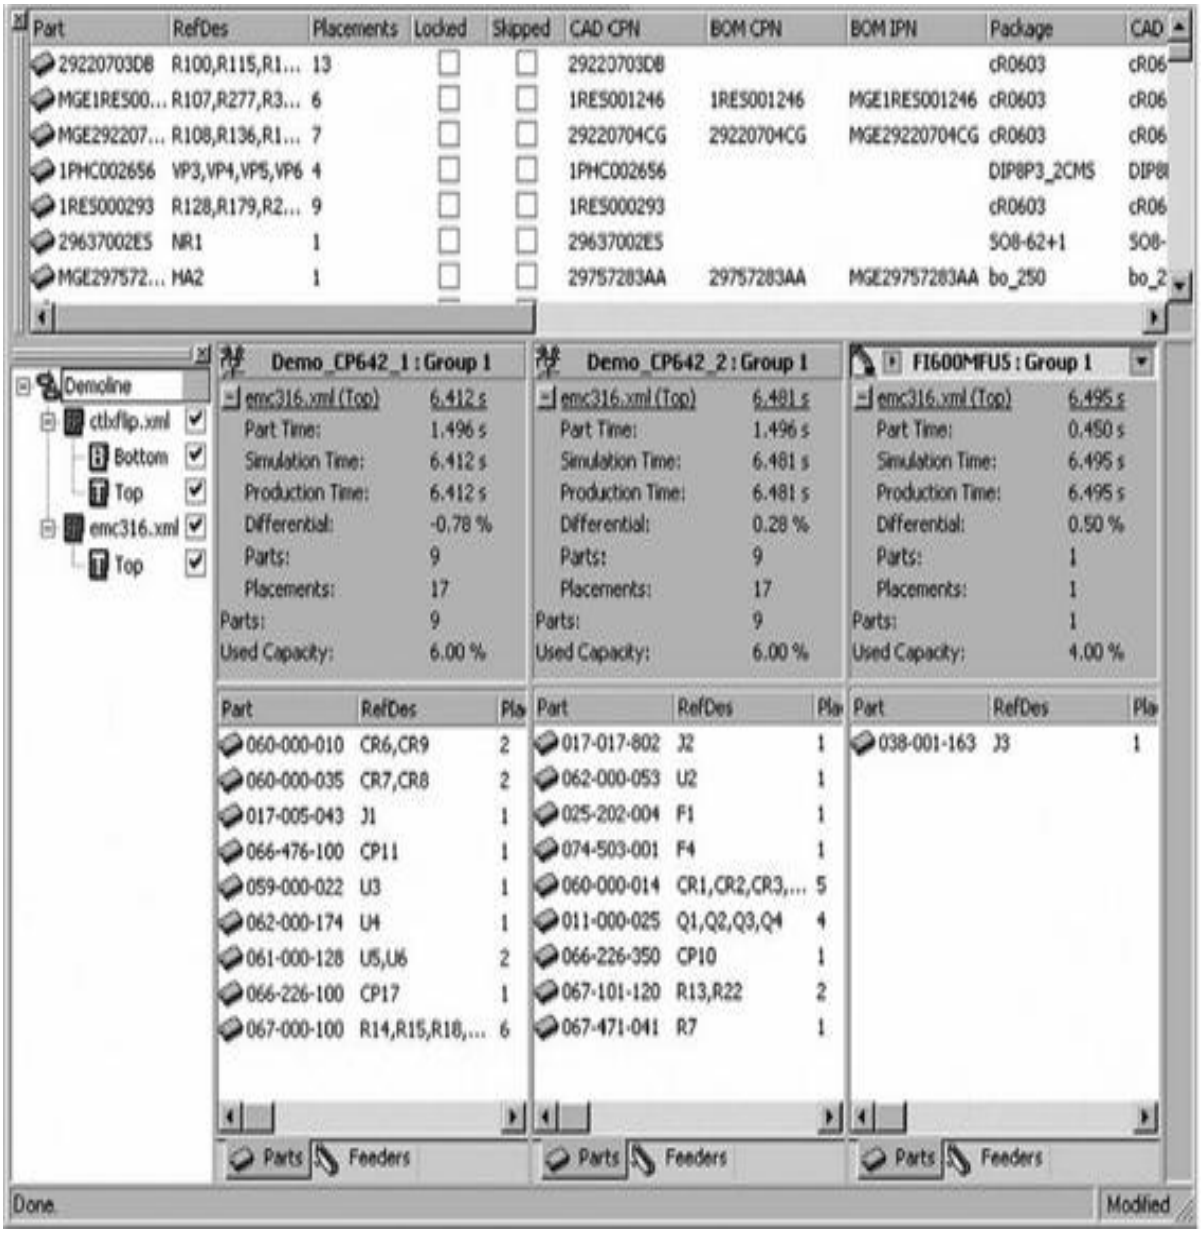

FIGURE 27.5 An assembly BOM control optimizing mixed vendors lines with line balancing.

27.5 ADDITIONAL PROCESSES

Because of variations in the PCB manufacturing process, additional CAM-tooling operations may be required. Variations in manufacturing that may call for additional tooling include the following:

- Rivet lamination versus pin lamination
- Laser drilling
- Multiple panel sizes
- Very large lamination presses (48 × 48 in)
- A very high degree of automation

New processes or PCB product features that may require additional tooling processes include the following:

- Embedded passives
- Embedded waveguides

Embedded passives and embedded waveguides are complicated to implement in production. Alignment and overlap are critical. Proper scaling for the particular embedded materials is especially important, depending on whether the materials are additive or subtractive. Figure 27.6 shows some of the critical tooling dimensions.

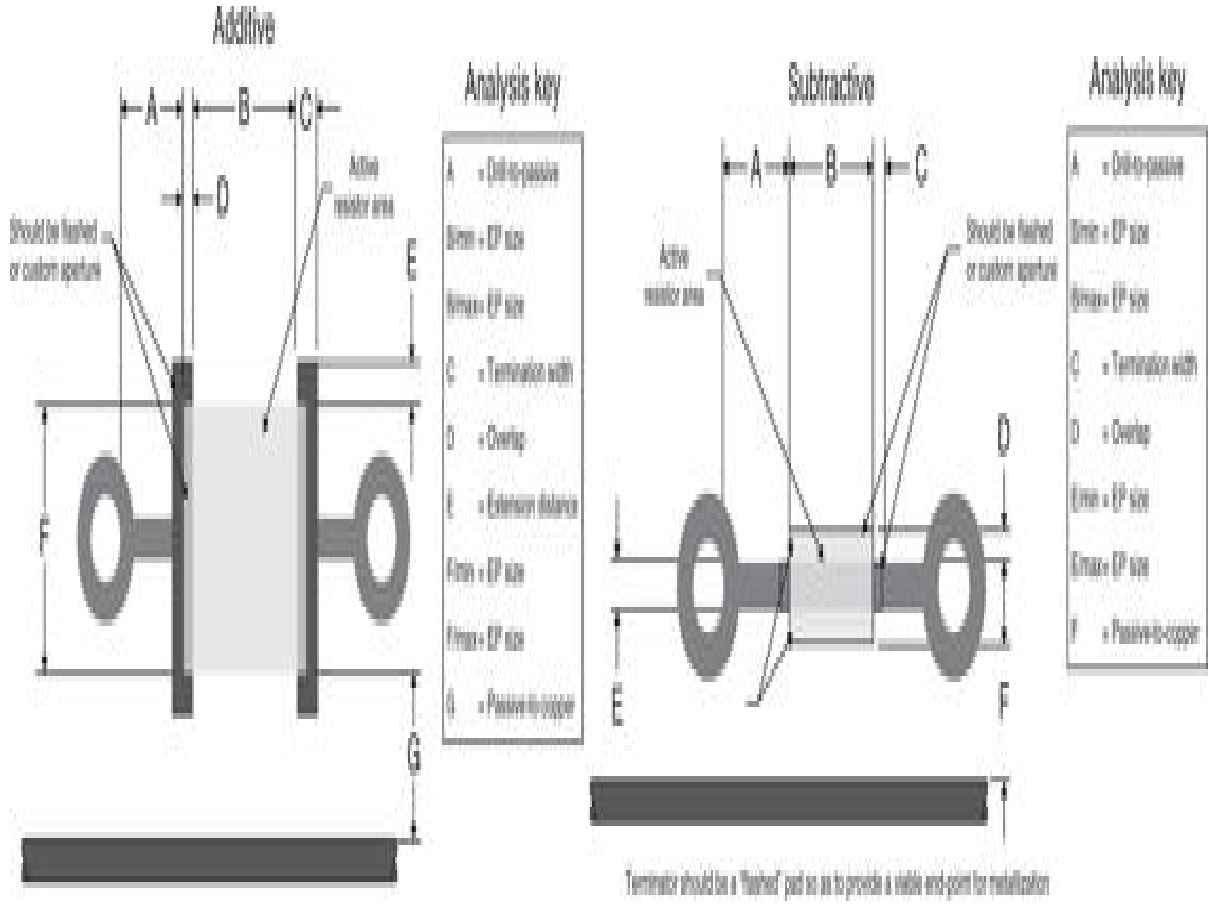

FIGURE 27.6 Critical tooling data for embedded passives.

An important step in all the processes already defined is the necessity for proper information management. Archival of PCB customer-supplied information and the files generated from the tooling process are critical for disaster recovery. Archiving systems available on the market also provide for centralized data management and distribution of the information to the various departments within an organization.

27.5.1 Macros

Macros (or scripts, as they are sometimes called) are used to automate tooling operations. Most modern CAM systems come with the facility to create, edit, debug, and exercise macros. One example of a macro was shown in Sec. 5.5.6.1 and in figure 5.27. This macro automatically scans all the CAM

information (artwork and NC files) and reports minimum, maximum, and critical geometries.

27.5.2 Design-to-Fab and Assembly Automation

Although a vast number of sophisticated CAD and CAM software packages are available today, experienced operators are still needed to exercise this software. During the era of captive printed circuit manufacturing by original equipment manufacturers (OEMs), internally developed software tools were created that actually automated the entire CAM tooling process. This level of automation was made possible through the development of software that automatically created drill, rout, fabrication, and panel drawings and manufacturing notes from the CAD database. In doing all this, the software captured in a digital header file all the pertinent information on the drawings. The header file could then automatically supply macros that would complete all the tooling. Although this software was never extended to the commercial market, today new automatic blueprint creation software is available that works off of the CAD database.

27.6 ACKNOWLEDGMENTS

I would like to thank Jeff Miller, WISE Software Solutions (www.wssi.com); DownStream Technologies (www.downstreamtech.com); and Julian Coates of Valor, Inc. (www.valor.com) for their invaluable contributions to this chapter.

CHAPTER 28

DRILLING PROCESSES[a]

Matthias Stickel
KSG Leiterplatten GmbH, Gornsdorf, Germany

28.1 INTRODUCTION

The purpose of through-hole drilling printed circuit boards (PCBs) is twofold: (1) to produce an opening through the board that will permit a subsequent process to form an electrical connection between top, bottom, and internal conductor pathways, and (2) to permit through-the-board component mounting with structural integrity and precision of location.

The quality of a hole drilled through a PCB is measured by its ability to interface with the following processes: plating, soldering, and forming a highly reliable, nondegrading electrical and mechanical connection.

As with any process, the elements of the drilling process are as follows:

- Materials
- Machines

- Methods
- Workers

When workers are properly trained and educated so that they possess a sound understanding of the other three elements, it is possible to drill holes meeting the aforementioned requirements with high productivity, consistency, and yield. The goals of this chapter are as follows:

- Understanding the drilling process thoroughly
- Recognizing what might go wrong
- Locating where problems could occur
- Detecting whether problems do occur
- Finding root causes of problems
- Correcting undesirable conditions
- Striving for zero discrepancies
- Making improvement a team effort

28.2 MATERIALS

Materials that affect the drilling process are as follows and as shown in the fishbone diagram of Fig. 28.1.

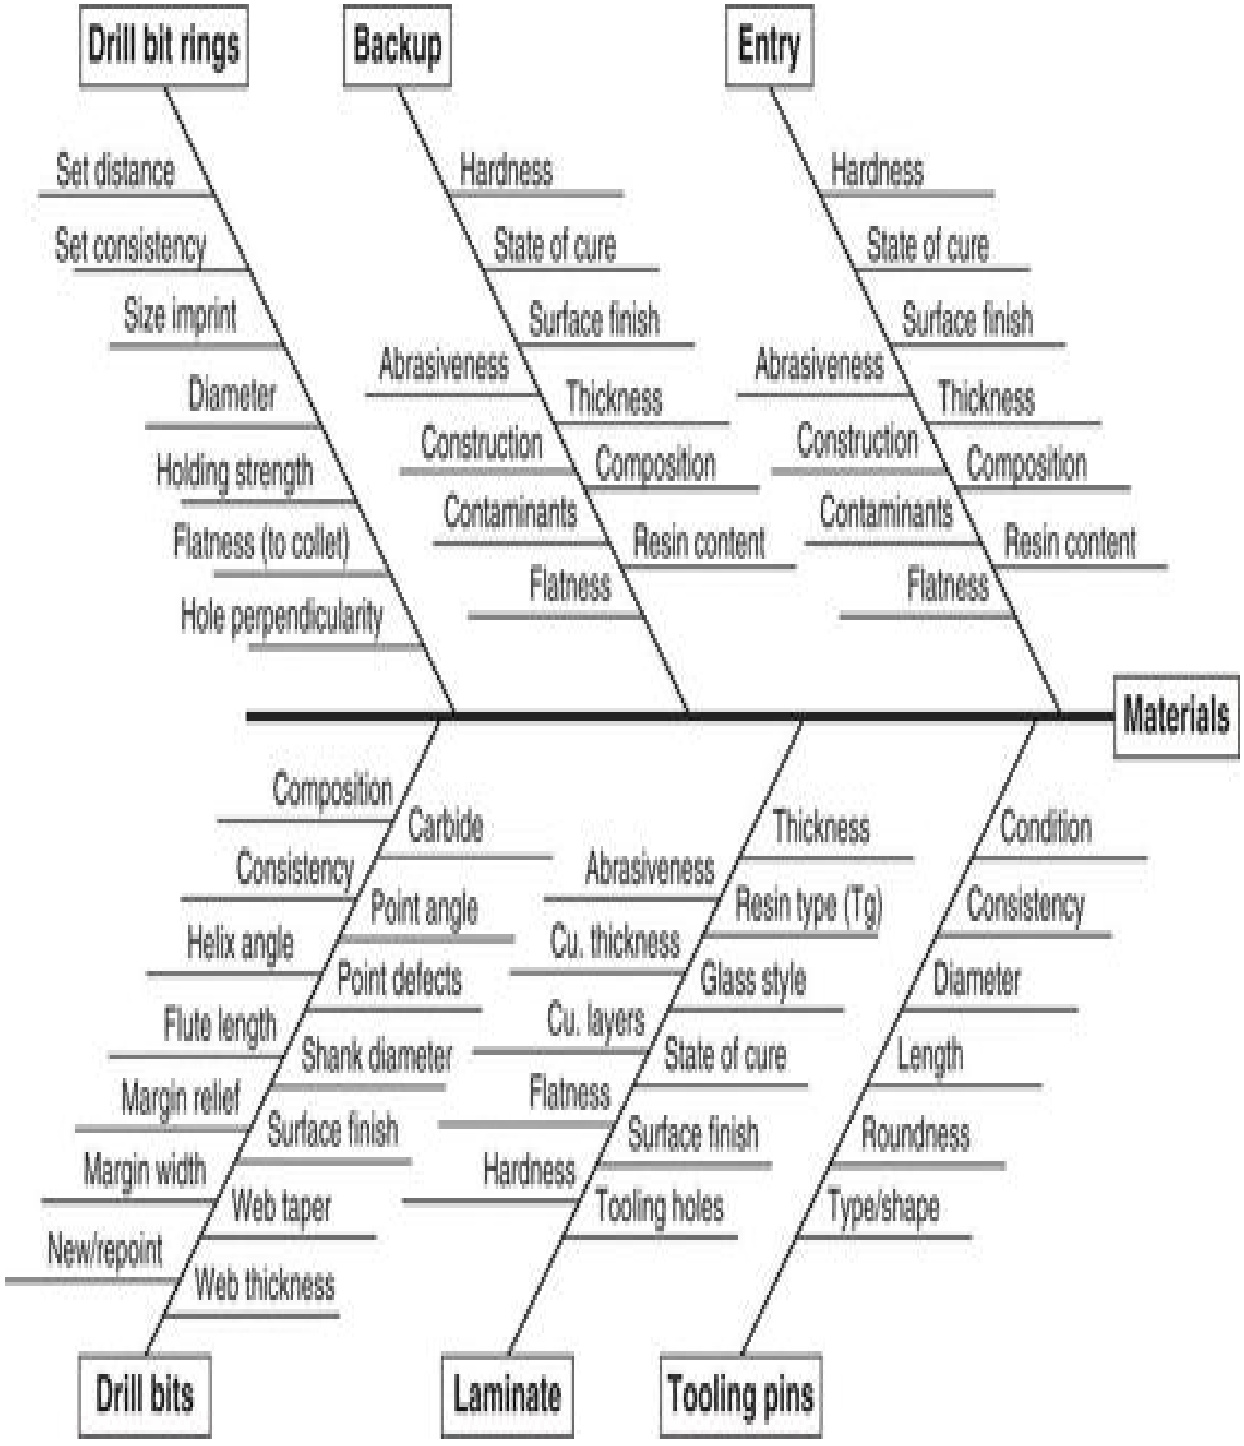

FIGURE 28.1 Materials used in the drilling process, with major variables and special considerations identified.

- Laminate material
- Drill bits

- Drill bit rings
- Entry material
- Backup material
- Tooling pins

28.2.1 Laminate Material

A typical circuit board laminate panel consists of three basic components:

1. Supporting fibers
2. Resin
3. Copper layers

The laminate substrate material is constructed of supporting fibers (most commonly a glass fiber weave) and a resin (most commonly an epoxy compound). Finished board thickness may range from 0.010 to 0.300 in or thicker, with the most common panel thickness ranging around $^{1}/_{16}$ (0.0625 in).

28.2.1.1 Supporting Fibers. Generally, the larger the glass fibers in the weave, the lower the cost of the base material. However, larger fibers are less desirable from a drilling point of view because they are more likely to cause the drill bit to deflect, resulting in decreased hole registration accuracy. In addition, larger fibers adversely affect drilled hole wall quality because they create larger (drilling) voids, defined as tear-out of supporting fibers. In simple terms: the larger the glass fibers, the larger the chunks torn out during drilling and thus the greater the hole wall roughness.

28.2.1.2 Resin. A common resin system is FR-4 epoxy. However, general drilling considerations (see Fig. 28.1) are the same for all resin systems. The glass transition (Tg)

rating of a material is defined as the temperature at which fully cured resin starts to soften. The Tg of “standard FR-4” is typically around 130°C, of “middle Tg FR-4” is around 150°C and of “high Tg FR-4” is around 170°C. Some materials include inorganic fillers resulting in a lowered z-axis expansion rate and making the material more stable under increased thermal environments like “lead-free assembly”. The compromise of a higher-Tg product which includes fillers is that the material is more brittle and more abrasive to the drill, resulting in increased tool wear and hole wall roughness. This increased abrasiveness to the drill bit may be offset by reducing the surface speed to reduce the spindle speed, resulting in less frictional heat being generated. Lowering drilling heat reduces drill wear.

28.2.1.3 Copper Layers. Outer and inner copper layers may be of various thicknesses, the most common being what is referred to as ½ oz and 1 oz copper. One ounce copper equates to a thickness of approximately 1.4 mils (0.0014 in). The more copper layers within a laminate, the more balanced the panel from a drilling point of view, meaning reduced occurrences or extents of drilled hole defects such as voids (torn-out fiber bundles). However, in order to compensate for a greater number of copper layers, the chip load (advance per revolution) that determines the infeed rate usually needs to be adjusted to control nail-heading. Increasing the chip load reduces the amount of nail-heading. In addition, more copper layers wear the drill bit at a faster rate and may require lowering the maximum hit count per drill bit.

28.2.2 Drill Bits

28.2.2.1 Materials. Drill bits are made of tungsten carbide because its wear resistance (and relatively low cost)

make it the most ideal material for cutting the very abrasive circuit board laminate materials. The binding agent for the tungsten carbide (>90 percent by weight) is cobalt (6 to 8 percent by weight). Other elements that can be added are titanium carbide, tantalum carbide, or other carbides (1 to 2 percent by weight). The carbides are categorized by their grain size into “ultrafine: (>0.5 μm), “extra-fine” (>0.05 to 0.09 μm) and “fine” (1 to 1.5 μm) with the smaller the diameter the smaller the selected grain size. The compromise of this very hard (carbide) material is that it is also brittle and subject to damage in the form of chips if not handled carefully and correctly.

28.2.2.2 Handling and Inspection. When handling drill bits, do not permit the bits to come in contact with one another and be careful not to touch them to the sides of the tool pods. Modern drilling machines utilize drill cassettes to reduce time per load by eliminating manual tool changes. These cassettes may accommodate 120 or more drill bits and reduce drill bit handling damage. If drill bits are measured to verify diameter using a contact-type measuring device (such as a contact micrometer), take the measurement away from the point to prevent chipping of the cutting corners. Following diameter measurement, inspect the drill bit for damage using a microscope. After use, again use care when removing drill bits from the tool pods or cassettes and remember, if they are intended for repointing, to use the same careful handling practices as when they were new.

28.2.2.3 Geometric Attributes. The geometry of a drill bit very much affects the way it behaves during drilling. (See Fig. 28.2 for attribute nomenclatures.) The land is the area remaining after fluting. In order to reduce the amount of land that creates friction with the hole wall (thus generating heat), drill bits are margin relieved. The amount of land

remaining in contact with the hole wall during drilling is referred to as the margin. The wider the margin, the greater the friction area and the higher the drilling temperature, resulting in higher extents of heat-related hole quality defects such as resin smear and plowing (defined as furrows in the resin).

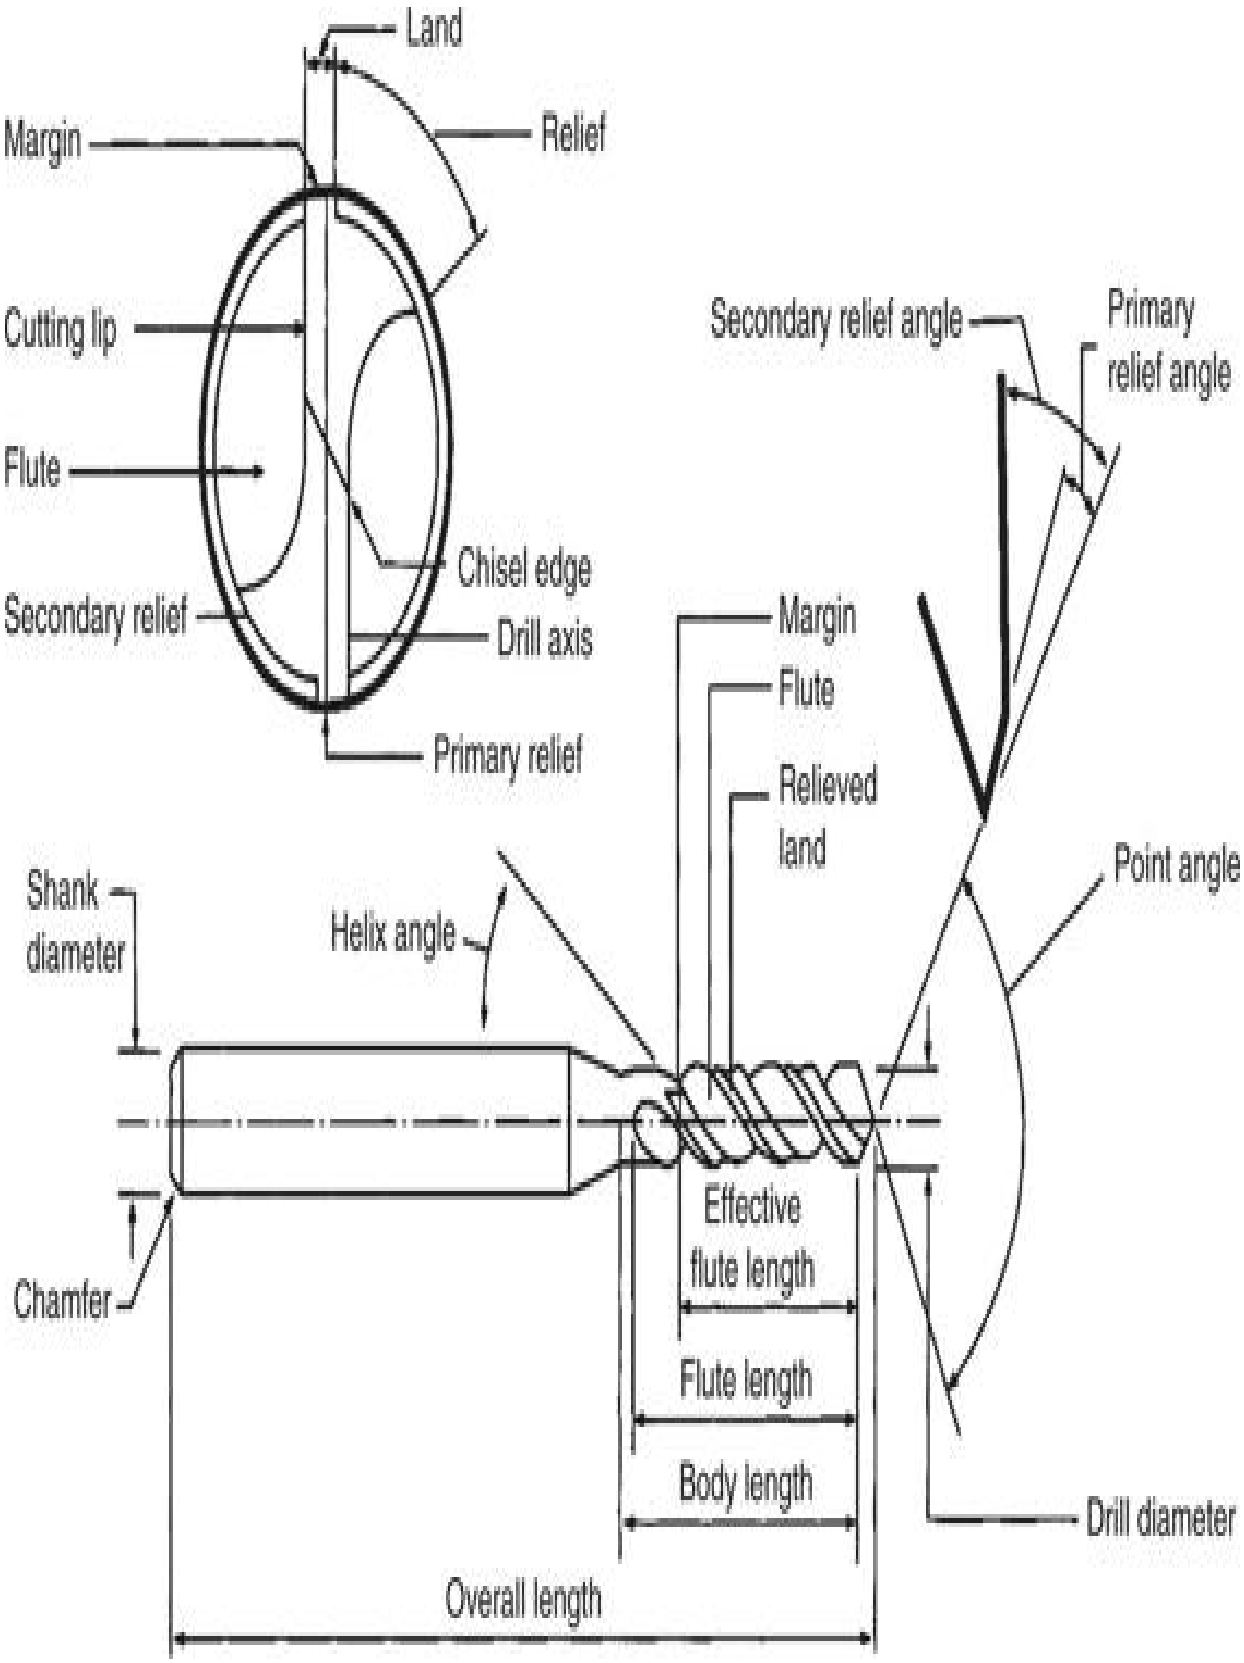

FIGURE 28.2 Drill bit geometry.

The result of increasing the land mass and the web is a smaller flute area. Less flute space implies reduced amounts of available area to remove drilling debris, which again raises the drilling temperature. It is important to understand that some drill designs that are meant to increase strength (particularly in smaller-diameter drill bits, with the intent to reduce breakage) may include what are referred to as partial margin reliefs (see Fig. 28.3). What this means is that when the drill bit is viewed from the point, a relieved margin is seen. However, viewing this type of design drill bit from the side reveals that the relief extends only part of the way, typically about one-fifth of the total flute length. The major drawback of this particular design is that it increases drilling temperatures (documented to be as much as 25 percent or more), resulting in increased heat-related drilled hole defects (such as smear) and drill breakage due to packed margins.

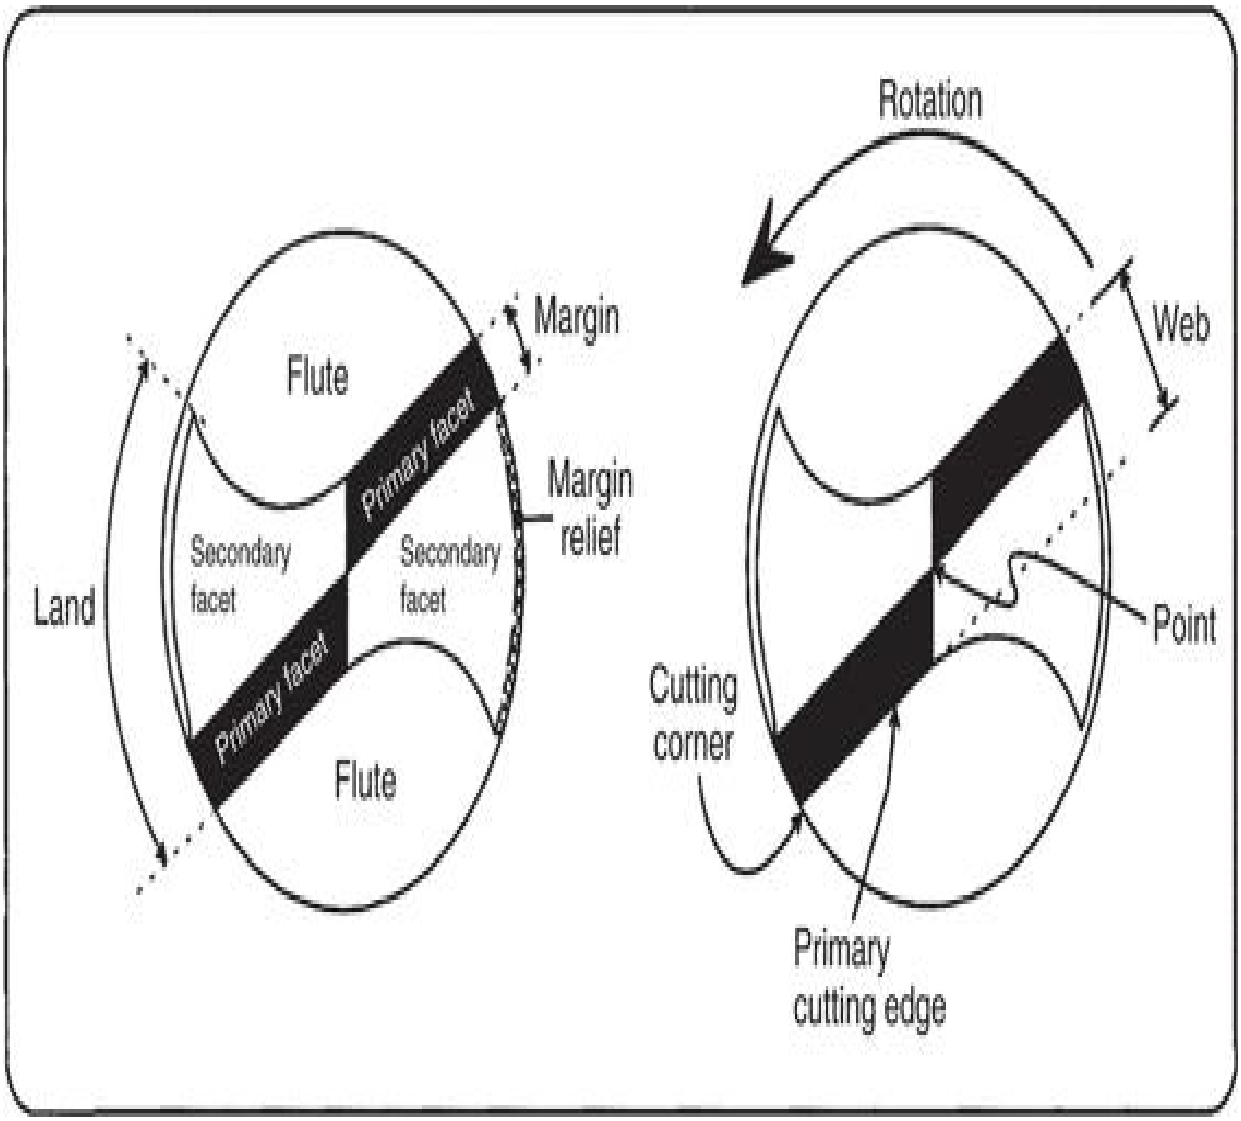

FIGURE 28.3 Drill tip attribute nomenclatures.

28.2.2.4 Flute Length. Minimum flute length must equal total drilled depth (total laminate thickness + entry thickness + backup penetration depth) plus at least 0.050 in of unused drill flute remaining above the stack at the bottom of the drill stroke to allow debris to be removed by the vacuum system. If debris cannot be removed from the drill flutes during and between drill strokes, the results are extensive hole quality defects and drill breakage.

28.2.2.5 New Drill Bits. It is not necessary to inspect incoming orders of drill bits 100 percent. A procedure proved to be effective is to inspect drill bits according to an acceptable quality level (AQL) method (such as MIL-STD-105). This type of sampling plan allows the user to determine the percentage of drill bits that are inspected to judge an entire lot of drill bits to a predetermined quality level. Using this method, finding a defined quantity of drill bits that do not meet the specification is cause to return all received drill bits to the vendor; if the selected quantity of inspected drill bits meets specification, the entire lot of drill bits is accepted. Inspection criteria might include point geometry defects (refer to Fig. 28.4), damage (chips), diameter (drill and shank), and flute length, as well as correct ring set distance and size imprint (matching both the actual diameter and that labeled on the box).

28.2.2.6 Repointed Drill Bits. Drill bits are typically repointed for reasons of economics. The cost of repointing a tool may be as low as 15 percent of the cost of a new tool. The number of times a drill is repointed varies anywhere from 1 to as many as 10 times or more and typically depends on the drill diameter. The smaller the drill, the fewer times it is normally repointed. The reason is that smaller-diameter holes are more critical and require better hole quality.

There are two methods used to repoint tools:

1. The first is to specify a certain number of times the tool is to be repointed before being discarded. This number typically varies between one to three for smaller-diameter tools depending on hole quality experienced after repointing.
2. The second is to specify a minimum overall length of the tool at which it is discarded. Minimum overall length is determined by calculation based on minimum remaining flute length required to drill the required total drilling depth. This method does not allow determination of how many times a drill is actually repointed because stock removal during each regrind may vary from 0.002 to 0.005 in or more.

Repointed drill bits cannot be expected to perform as well as new drill bits because only the points are refurbished to a quality that may be as good as a new drill bit while the rest of the drill bit, including the critical margin, is not. The condition of the margin is very important because it is the part of the drill bit that finishes the hole wall. A rough margin results in a rough hole wall surface. When inspecting repointed drill bits, examine the sides of the drills for margin damage and/or fused or packed drilling debris remaining

from previous use. These drill bits contaminate holes from the very first one drilled and may cause run-out due to an imbalanced condition of the drill bit resulting from the buildup. Drill bits must be repointed to the same point geometry specifications as those that apply to new drill bits. Point inspection criteria, therefore, is the same for repointed drill bits as for new drill bits.

28.2.3 Drill Bit Rings

Drill bit rings are set to a common distance from the point to the back of the ring, thereby allowing a controlled drilling depth on machines lacking other options for applications requiring this. The quality of these rings is as critical as the consistency of drill bit attributes because they can equally affect drill bit performance. Rings that fit loosely on the drill shank have been known to move during tool changes, resulting in insufficient drilling depth. Rings that fit too tightly may crack. Rings that have protruding material (“flash”) on the inside diameter may cause improper seating of the drill bit in the collet (of the spindle) or may prevent the drill bit from being properly inserted into the tool pod or cassette, resulting in destructive tool change problems.

Rings have specific color codes assigned to each size and are commonly imprinted with size, diameter, and design or series number. Rings may be either machined or mold-injected. While machined rings are superior because of their consistency and quality, their cost is prohibitive for many drill bit manufacturers. Some of the drawbacks of mold-injected rings that must be monitored are inside diameter, affecting how well the ring fits on the drill shank, and remaining flash.

28.2.4 Entry Material

28.2.4.1 Purpose. The purpose of the entry material is fivefold:

- Centers the drill
- Prevents drill breakage
- Prevents copper burrs
- Avoids contamination of the hole or drill bit
- Prevents pressure foot marks

28.2.4.2 Types. There are many different available types (constructions) of materials used as entry material for PCB drilling, although few are specifically designed and engineered for this purpose. Engineered products are designed to improve hole registration accuracy and reduce drill breakage. The performance qualifications of the most popular materials are discussed in the next section.

Commonly available entry materials, listed in order of performance quality with respect to the five characteristics listed in the preceding section, are

- Aluminum-clad cellulose core composite
- Solid aluminum (various alloys and thicknesses)
- Solid or melamine-clad phenolic
- Aluminum-clad phenolic

28.2.4.3 Performance. The right entry material will improve drilled hole registration and lower the risk of drill bit breakage by minimizing drill deflection upon contact with the stack. In order for the entry material to function properly, it must be flat and free of pits, dents, and scratches. Warped or twisted material will result in increased extents of entry burrs and drill bit breakage. Surface imperfections and materials that are too hard contribute to drill deflection, resulting in decreased hole registration accuracy and breakage of small-diameter drills.

Phenolic materials or phenolic composites (i.e., aluminum-clad phenolic) often warp and under most drilling conditions contaminate the hole wall, which results in problems with adherence of the plating because desmearing chemicals are not designed to remove phenolic resin. Solid aluminum materials of the correct composition and hardness that are not of an excessive thickness, yet are not too thin, may work satisfactorily with larger-diameter drill bits. However, drilling with solid aluminum materials (0.008 in and thicker) may increase the risk of breakage of smaller-diameter drills. Aluminum-clad cellulose core materials provide a hard surface to prevent burrs yet minimize drill deflection and breakage associated with solid aluminum.

28.2.5 Backup Material

28.2.5.1 Purpose. The purpose of backup material is defined by the following criteria. An ideal backup material will

- Provide a safe medium for drill stroke termination
- Prevent copper burrs
- Not contaminate the hole or drill bit
- Minimize drilling temperatures
- Improve hole quality

28.2.5.2 Types. Numerous materials are available that are sold as backup material. Few of the materials used as backup materials are actually specifically engineered for circuit board drilling. Many of the popular backup products are composites with a variety of surface coatings or skins bonded to several different core materials. Available backup products include the following:

- Epoxy-paper-clad, wood-core composite utilizing a bonding agent with lubricating properties
- Aluminum-clad, wood-core composite
- Epoxy-paper-clad, wood-core composite
- Melamine-clad, wood-core composite
- Urethane-clad, wood-core composite
- Solid phenolic
- Aluminum-clad phenolic composite
- Plain wood
- Hardboard

28.2.5.3 Performance. Desired qualities in a backup material are minimal thickness variations, flatness (no bow, warp, or twist), no abrasives or contaminants, a smooth surface, low cutting energy (minimizing drilling temperatures), and a surface hardness that supports the laminate copper surface (to prevent burrs) yet does not cause damage or extensive wear to the drill bit.

Backup materials with lubricating properties have been proven to significantly reduce drilling temperatures by as much as 50 percent or more, often resulting in temperatures below the T_g of the laminate product being drilled. This advantage greatly reduces hole wall defects such as roughness, smear, and nail-heading and often allows increased drill stack heights and/or greatly increased drill bit maximum hit counts. The importance of these benefits is significant reduction in drilling cost per hole and improved productivity and yield.

Remember that drilled backup debris exits the stacks by passing through the holes in the laminate material and that therefore contamination (from the backup material) is of great concern. Materials containing phenolic, or composed of solid phenolic, are not suitable for circuit board drilling. Phenolic materials or phenolic composites (i.e., aluminum-

clad phenolic) often warp and under most drilling conditions contaminate the hole wall, which results in problems with adherence of the plating because desmearing chemicals are not designed to remove phenolic resin. Hardboard types of materials cannot be maintained to thickness variation tolerances acceptable for circuit board drilling and are a source for a great variety of contaminants (e.g., oils crystallized on the surface for hardening purposes).

28.2.6 Tooling Pins

Seldom is any due attention given to the tooling pins. They come in many shapes and sizes and their cost, with respect to how much they add to the cost of fabricating a circuit board, is insignificant. Yet, quite often, tooling pins are found to be damaged or deformed (e.g., “mushroomed” from being hammered into the stack) or do not fit snugly. Tooling pins that do not hold the stack tightly in place or that allow the stack to move create a large variety of problems from burrs and other hole defects to poor registration or drill bit breakage. These unnecessary problems may be prevented by simply replacing tooling pins when they start to show signs of wear or damage. Use tooling pins that are hardened to minimize wear and deformation, and (ideally) $^{3}/_{16}$ in. in diameter. Pins that are less than $^{3}/_{16}$ in. in diameter (i.e., ⅛ in) do not hold the stack firmly in place during drilling and may result in stack movement.

28.3 MACHINES

Machine variables that affect the drilling process are as follows and as shown in the fishbone diagram of Fig. 28.5.

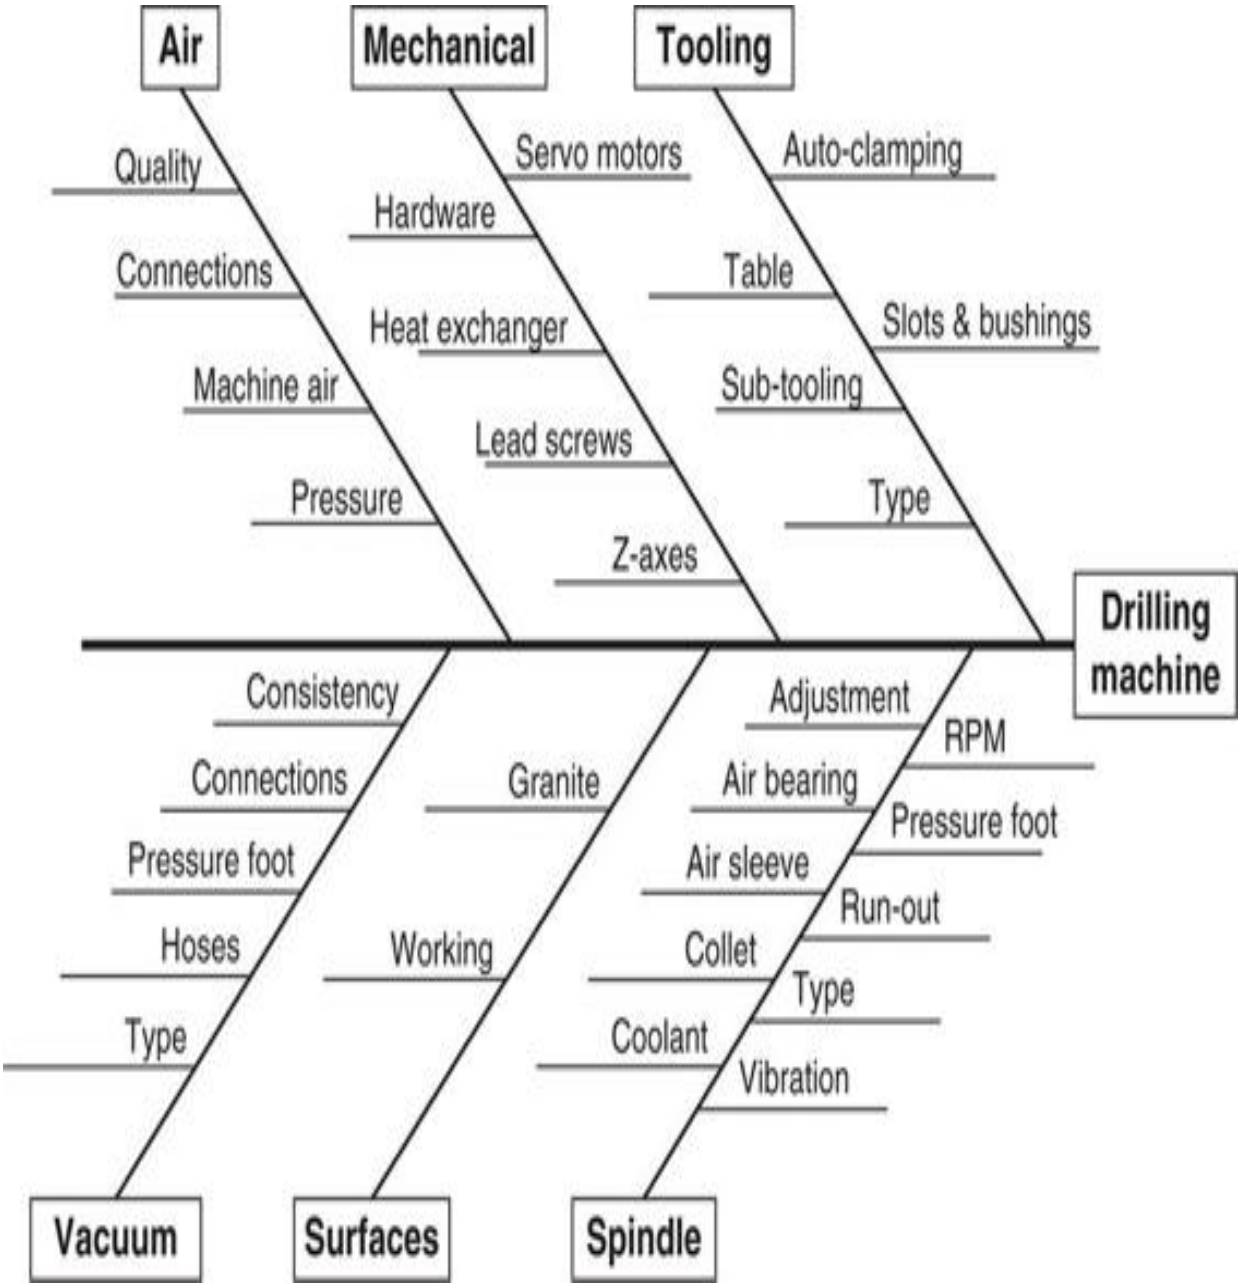

FIGURE 28.5 Drilling machine elements, with major issues and special considerations identified.

28.3.1 Air

28.3.1.1 Quality. Maintaining high levels of air quality is important. Air supplied to the machine and the spindle assemblies needs to be clean and dry. This is accomplished

by filters that remove dirt and moisture from the air. In areas where the relative humidity is high, or when using air-bearing-type spindles, an inline air drying and filtering system may be necessary to control air moisture levels and dirt. Moist air causes corrosion of air surfaces (such as the spindle sleeve and other spindle components operating on air) and reduces the life of these components, resulting in increased repair costs. Dirty air affects operation of components relying on air by clogging the channels that supply the air (e.g., to the spindle sleeves and table air shoes). In addition, dirt serves as an abrasive that causes faster wear of machine components, resulting in reduced life cycles between repairs, again increasing downtime and repair costs. Cleaning the machine air filters and purging air compressors and lines on a routine basis may minimize problems resulting from dirt or moisture.

28.3.1.2 Connections and Pressure. Check connections, gauges, hoses, and switches for leaks and wear. Air hoses connected to the pressure foot pistons often crack near the piston connector; by simply bending the hoses in these areas it can be determined whether they are leaking. Other locations that commonly have poor connections and air leaks are the collet air connector on top of the spindle and the air manifold on the side of the spindle sleeve housing that supplies air to the collet and the spindle sleeve. Sufficient air pressure to both the collet and the spindle sleeve is critical and must be maintained adequately for proper operation. The tool table is designed to ride on a bearing of air supplied through the table air shoes. Verify proper operation of the air shoes by slightly rotating them back and forth; the shoes should move freely. If the shoes do not move with ease or do not move at all, the most likely reason is that the air channels are blocked due to trapped drilling debris, meaning the shoes need to be cleaned or replaced. Check the pressure foot air gauges for the correct

air pressure; equal pressure must be supplied to each of the spindle stations. Insufficient or unequal air pressure results in burrs and increases the possibility of drill bit breakage.

28.3.2 Vacuum

Effective vacuum is absolutely essential because it greatly affects the resulting drilled hole quality. Heat (drilling temperature) seen by the hole walls depends on how effectively hot drilling chips are removed. Excessive temperature due to inefficient removal of drilling debris causes heat-related hole defects such as smearing and plowing, increases the opportunity for plugged holes, and is a major contributor to drill wear. Check hoses for proper connections, wear, and restrictions and examine the inside of the pressure foot for holes worn inside the connector attaching the vacuum hose.

28.3.3 Tooling

28.3.3.1 Bushings and Slots. Maintain tight tolerances on tool table bushings and slots and replace bushings that are sunken below the tool table surfaces or are worn. Bushings and slots that do not hold tooling pins snugly and allow stack movement during the drill stroke cause burrs, registration problems, and drill breakage.

28.3.3.2 Subtooling. Avoid subtooling plates that overlap across individual tool table stations and fasten the plates securely to the base plates with no separation or gaps. Ensure the subtooling is not warped, does not vary significantly in thickness, and has no surface protrusions (such as broken drill bits) to allow stacks to lay flat and to minimize variation in drill bit penetration depth into the backup material. If your subtooling is other than metal,

watch for potential shrinkage or expansion problems indicated by difficulties in fitting the pinned stacks to the existing pinning holes in the plates. If this problem occurs, the results are the same as those caused by bushings and slots that allow stack movement.

28.3.4 Spindles

Spindle assemblies are one of the single most important components of the drilling machine. Proper operation is essential and requires maintenance (e.g., collet and collet seat cleaning) and verification on a regular basis.

28.3.4.1 Collet Maintenance. For mechanical (ball) bearing spindles, cleaning of the collet and the collet seat (inside the spindle) needs to be performed a minimum of once per shift; dirty collets increase drill run-out. When processing certain laminate materials that create greater amounts of drilling dust, and depending on your vacuum system efficiency, a higher cleaning frequency may be necessary to maintain acceptable levels of drill run-out. It is recommended that after cleaning the collets be returned to the same spindle from which they were removed because collets tend to adjust to the respective collet seats. For air-bearing spindles, most manufacturers recommend cleaning the collets only when the run-out measures excessive.

28.3.4.2 Run-Out Measurement. Drill/collet concentricity, or total indicated run-out (TIR), is a measure that indicates how true the assembly rotates. It can be determined while the spindle is running at various speeds (rpm), which is referred to as a dynamic form of measurement. Another method is performed while the spindle is not running and is called a static measurement. Static TIR is determined by rotating a ⅛-in (0.1250-in)-diameter pin installed into the collet by hand while reading

movement on a dial indicator placed against the pin at a distance of approximately 0.800 in (simulating the distance of the drill point) from the collet nose (refer to Fig. 28.6). Of course, the pin used to measure TIR must itself be concentric.

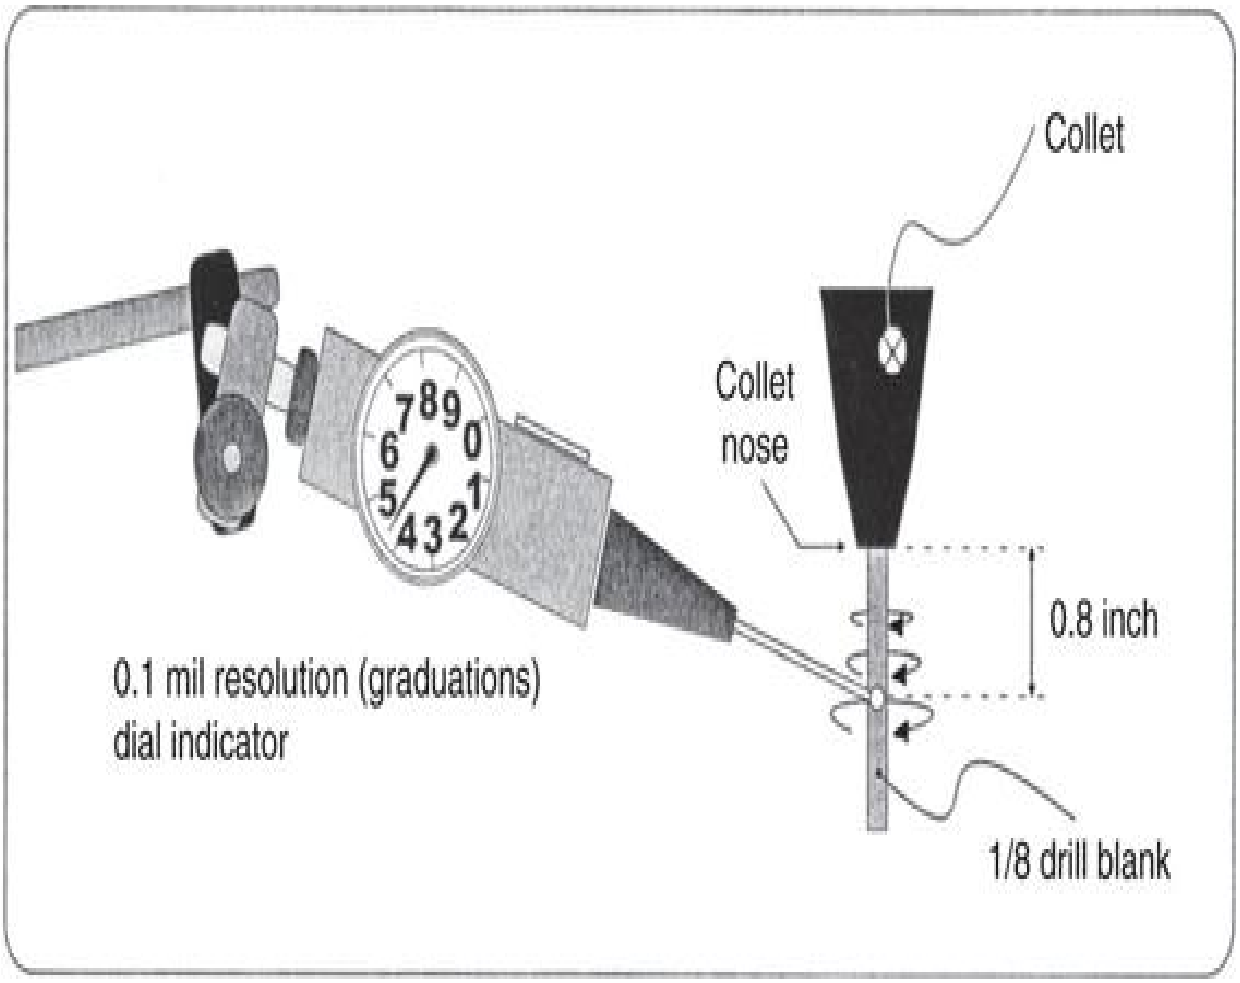

FIGURE 28.6 TIR measurement (static).

Maximum acceptable TIR for drills greater than 0.0200 in. in diameter is 0.5 mil (0.0005 in). When using drills 0.0200 in or less in diameter, the maximum TIR needs to be maintained within 0.2 mil (0.0002 in) to prevent drill breakage. If excessive TIR is noted, it is wise to replace the pin and again measure the run-out. Drill bit blanks make ideal pins for measuring TIR and may be acquired from drill

bit suppliers. Excessive spindle run-out results in drill breakage, causes burrs and other drilled hole defects, and adversely affects hole registration accuracy. Excessive TIR may often be corrected by simply cleaning the collet and the collet seat or by replacing a worn collet. Measure the run-out of spindles of each machine at a minimum frequency of once per week.

28.3.4.3 Spindle Speed. Maintaining correctly adjusted spindle speed is important because spindles running at speeds other than those displayed on the monitor imply that drill bits are rotating at surface speeds other than those that are desired. When actual rpm is higher than the displayed rpm, it implies higher surface speeds (refer to Sec. 28.4), and vice versa. Higher surface speeds cause greater frictional drill heat, resulting in faster drill wear and greater extents of heat-related hole defects such as smearing and plowing. Noncontact-type tachometers able to measure up to 150,000 rpm or more are available for around $300 (a lot less than the cost of rebuilding just one spindle) and allow measurement of actual spindle rpm in a matter of minutes. Verifying spindle speeds once every 6 months is usually sufficient.

28.3.4.4 Pressure Foot. The pressure foot insert lead distance to the point of the drill bit is set at approximately 0.050 in to give the pressure foot sufficient time to hold the stack flat before the drill bit contacts and enters the stack. If the lead distance is significantly less than the specified distance or if the drill bit point protrudes from the pressure foot, drill bits will break. To ensure the pressure foot assemblies function properly, check pressure foot inserts for wear or damage daily and verify that the pistons and guide rods are not bent and move smoothly.

28.3.4.5 Adjustment. When adjusting the physical *z*-axis height of the spindle, for instance to accommodate a thicker subtooling plate, care must be taken to also adjust the pressure foot so its height remains identical relative to the spindle. The pressure foot adjustment is independent from the spindle and, if not performed correctly, may result in a gap between the bottom of the spindle casing and the top of the pressure foot window. This gap is noticed only while the spindle is engaged and will draw most of the vacuum air, effectively cutting off the vacuum from the pressure foot insert, resulting in a great variety of hole defects and drill bit breakage. If a gap is present, it is usually accompanied by great amounts of drilling debris spewed across the stacks and drilling machine.

28.3.5 Mechanical Factors

28.3.5.1 Heat (Coolant) Exchanger. Drill motor temperatures are reduced by exchanging a fluid through the spindles. The fluid is processed through a heat exchanger that works much like a car radiator. As with a car, it is important to maintain the recommended coolant mixture, proper fill level, and flow rate indicated by the flowmeter. Check the operation of the fan and minimize coolant flow restriction (due to algae buildup) by cleaning filters regularly. Algae growth is promoted through exposure to ultraviolet light and may be controlled by using black hoses instead of clear ones in addition to adding growth inhibitors to the coolant mixture.

28.3.5.2 Hardware. Although simple to perform, checking mechanical connections for loose or worn parts (i.e., causing travel slop of pressure foot assembly movement) is often neglected. It may be accomplished by

observing the machine while it is running or checking by hand while the machine is idle.

28.3.5.3 Lead Screws and Servos. The environment and cleanliness of the drill room determine how often lead screws need to be cleaned and lubricated to ensure smooth operation and minimize wear. Most machine manufacturers recommend performing this type of maintenance every 6 months. When lubricating the lead screws, only a light coat of the appropriate grease needs to be applied. Excessive amounts of grease on the lead screws defeat the purpose, as this causes more dirt to be attracted, resulting in faster wear. Constant searching for programmed *x*-*y* locations indicates problems with the servo motors or lead screws. If this occurs, the displayed *x* or *y* (actual) location displayed on the controller will change continuously while the machine is stopped.

28.3.5.4 z-Axis Stroke. Because machines may have as many as six mechanical connections in the *z* axis, travel slop during the drill stroke or retraction may occur, causing chip loads to vary during the stroke, which results in burrs and other hole defects and drill breakage. Check connections by hand for slop while the machine is idle and observe and listen for improper operation while the machine is running.

28.3.6 Surfaces

A clean drilling room decreases repair costs and the possibility of improper operation of the drilling machines. Wipe surfaces clean using a lint-free cloth or use a vacuum to remove debris.

Never use compressed air to clean the drilling machine because debris will be blown into areas that need to be kept clean (e.g., lead screws).

28.3.6.1 Granite. Granite provides a stable platform that absorbs unwanted vibration. It also offers a smooth and level surface to support the movement of the table. Keep granite surfaces clean to prevent tool table air shoes from becoming clogged and to minimize collection of dirt on the lead screws.

28.3.6.2 Working Surfaces. Maintain clean working surfaces, such as the tool table, to minimize the possibility of dirt particles getting trapped between the stacked laminate, entry, and backup panels, causing stack separation that may result in burrs and possible drill bit breakage.

28.4 METHODS

Drilling parameter variables that affect the drilling process are as follows and as shown in the fishbone diagram of Fig. 28.7.

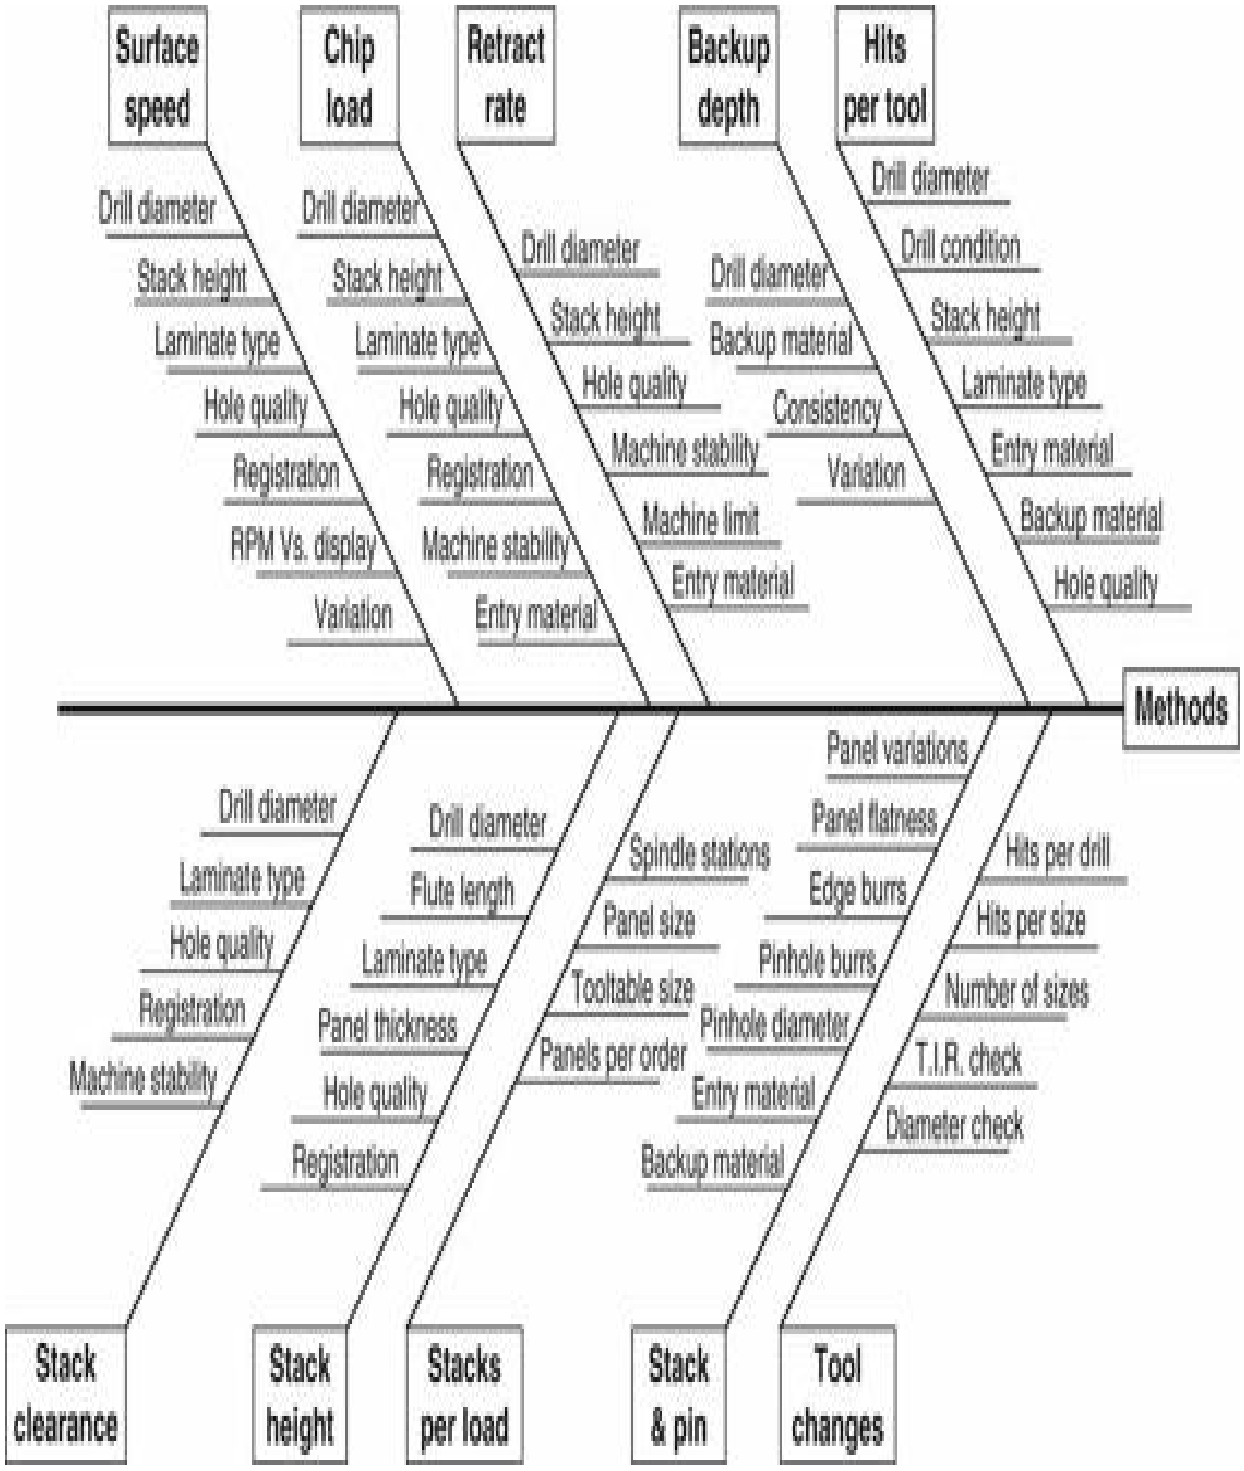

FIGURE 28.7 Methods used in the drilling process, with major variables and special considerations identified.

28.4.1 Surface Speed and Spindle Speed

As holes are getting smaller, higher spindle speeds are required to achieve the desired surface speed that determines throughput. However, higher surface speeds result in higher drilling temperatures that may increase heat-related hole defects such as smearing and plowing.

28.4.1.1 Definition. Surface speed is a measure of how much distance is covered by the drill's diameter while it is rotated by the spindle and is expressed in surface feet per minute (sfm). It is used to calculate spindle speed (rpm) for a given drill diameter. The formula to calculate spindle speed using the desired surface speed is shown in Eq. (28.1).

$$\text{spindle speed (rpm)} = \frac{\text{sfm} \times 12}{\pi \times \text{diam.}} \tag{28.1}$$

$$\text{where diam.} = \text{drill diameter (in)}$$

$$\pi = 3.1415$$

$$\text{cutting speed} = \pi \times \text{d}/1000 \times \text{spindle speed}$$

28.4.1.2 Effects. The higher the surface speed, the higher the spindle speed, and subsequently the higher the frictional heat that is generated, translating into greater extents of heat-related hole defects and drill wear. Conversely, lower surface speeds imply lower spindle speeds and less frictional heat. When more abrasive materials (e.g., materials with higher T_g such as multifunctional FR-4, polyimide, or cyanate ester) are processed or drilled stack height is increased, drilling temperatures increase. To offset the resulting increase in temperature under such conditions or when excessive extents of heat-related hole defects are

apparent, decrease the surface speed to lower the spindle speed.

28.4.2 Chip Load and Infeed Rate

28.4.2.1 Definition. Chip load is defined as advance per revolution and is usually expressed in mils [1 mil equals $^{1}/_{1000}$ of an inch (0.001 in)]. It implies the distance the drill travels during the drill stroke per each full revolution of the drill bit. Chip load is used to calculate the infeed rate in inches per minute (ipm).

$$\text{infeed rate (ipm)} = \text{chip load (mils/revolution)} \times \text{rpm} \qquad (28.2)$$

28.4.2.2 Effects. Higher chip loads result in greater throughput. However, chip load and infeed rate affect hole registration accuracy, drill breakage, burrs, and mechanical types of drilled hole defects such as voids (tear-out of the supporting fibers) and nail-heading. Faster infeed rates translate into higher (top laminate) entry burrs, lower extents of nail-heading defects and (bottom laminate) exit burrs, increased occurrences of drill bit breakage, and higher extents of drilling voids. Lower infeed rates result in exactly the opposite but lower throughput.

28.4.3 Retract Rate

28.4.3.1 Definition. Retract rate is the speed at which the drill bit exits the stack following the drill stroke and is expressed in inches per minute (ipm). Machine default (maximum) settings vary between manufacturers and may range anywhere from 500 to 1000 ipm.

28.4.3.2 Effects. Higher retract rates imply lower processing times per load. While the maximum retract rate

setting may be fine for larger-diameter drill bits, when using drill bits in the diameter range of 0.0250 in (size #72) to 0.0135 in (size #80), retract rates may have to be reduced to 500 ipm or lower to prevent drill breakage. When drilling with sizes smaller than 0.0135 in. in diameter, retract rates may have to be reduced even further. The maximum retract rate that may be used with any given drill diameter without causing drill breakage greatly depends on the stability and vacuum system efficiency of the drilling machine as well as the drilled stack height, laminate construction and thickness, type of entry material, use of proper stacking and pinning procedures, and the design characteristics of the drill bit such as flute length, web thickness, and web taper.

28.4.4 Z Compensation/Individual Z/Point Length

28.4.4.1 Definition. The z compensation or “individual z” refers to geometric aspects at the tip of a drill bit. It describes the length of the tip which varies with the point angle and the drill bit diameter (see Figs. 28.8 and 28.9).

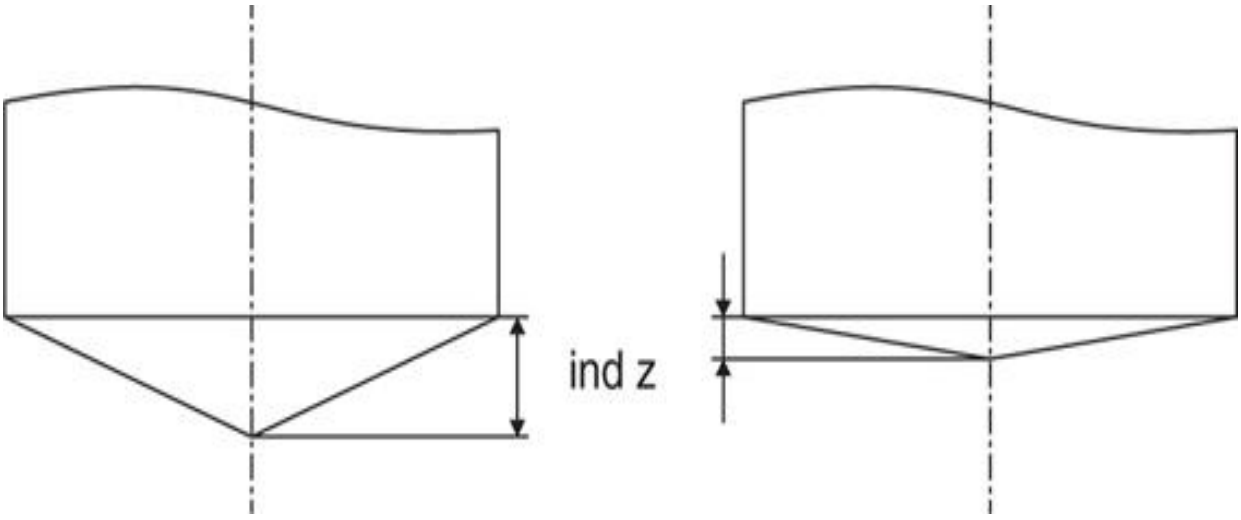

FIGURE 28.8 Individual z on bits with different point angles.

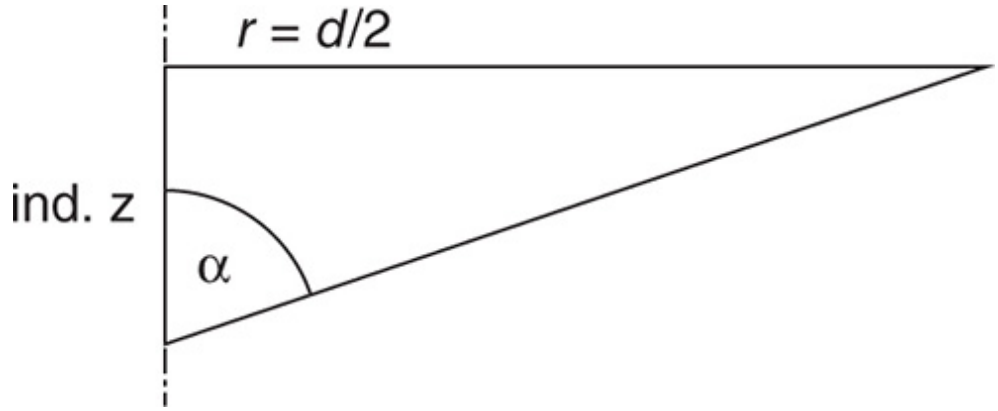

FIGURE 28.9 Geometrical aspects of the individual z.

28.4.4.2 Effects. The z compensation has an influence on the drilling depth. This is why it needs to considered in the drilling depth into the backup material ("backup penetration") and for any "depth controlled" drilling operations (blind vias, back drilling). As it depends on the drill bit diameter and the point angle, it is typically part of the parameter file.

$$\tan a = r/\text{ind. z} \qquad r = \text{radius [mm]}, d = \text{diameter [mm]}, a = \text{point angle/2 [°]}$$

$$\text{ind. z} = r/\tan \alpha$$

$$\text{ind. z} = d/2 \times \tan \alpha$$

28.4.5 Backup Penetration Depth

28.4.5.1 Definition. Backup depth is the distance a drill bit penetrates the backup material at the bottom of the drill stroke. The minimum backup penetration depth setting varies depending on drill diameter and is determined by calculating the drill bit point length (see Fig. 28.10) and adding approximately 0.010 in. As a rule of thumb, backup penetration depth may be set to a distance equal to the drill diameter or 0.040 in, whichever is less.

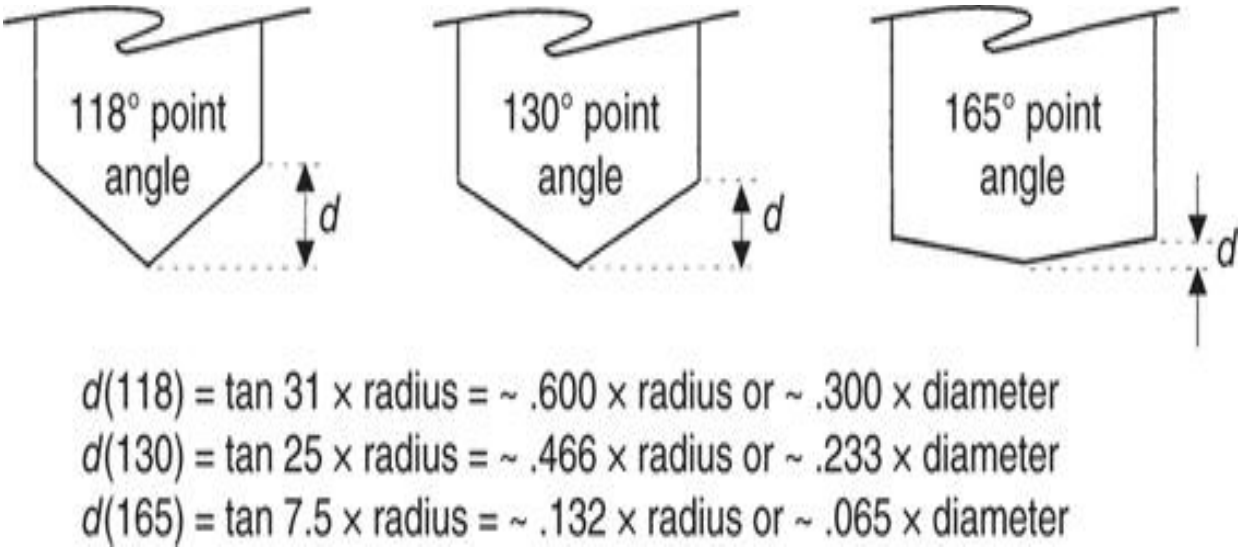

FIGURE 28.10 Point length calculation.

28.4.5.2 Effects. Excessive backup penetration depth increases drill wear and the occurrence of breakage of small-diameter drill bits, adversely affects hole quality, and increases process time per load. Insufficient backup penetration depth results in incompletely drilled holes. This implies that thickness variations of the backup material are very important, meaning that minimal variations are a much desired characteristic of the backup and need to be considered when choosing a material suitable for your application.

28.4.6 Hits per Tool

28.4.6.1 Definition. The maximum hits per tool specified for any given drill size implies the number of drill strokes a drill bit is used for until its expected effective life is expired. Maximum hit count per tool is product and process specific and is affected by laminate material construction, panel thickness, drilled stack height, surface speed, and the type of entry and backup material used. Additionally are there different quality specification levels that can be

applied. Therefore no specific number of hits per tool can be arbitrarily specified.

28.4.6.2 Effects. Excessive drill wear caused by excessive maximum hit count increases drilled hole defects and may prevent proper repointing. Conservative maximum hit counts greatly impact drilling cost per hole and increase time per load because of increased numbers of tool changes.

28.4.6.3 Parameter Example.

Diameter [mm]	Speed/RPM [rev/min]	Cutting-Speed [m/min]	In-Feed [m/min]	Chip-Load [mm/rev]	Retract-Rate [m/min]	Ind-z [mm]	Hit Count [#hits]
0,10	125000	39	0,8	0,006	2	0,030	500
0,15	125000	59	1,3	0,010	3	0,045	600
0,20	125000	79	1,8	0,014	4	0,060	800
0,25	125000	98	2,4	0,019	5	0,065	1000
0,30	125000	118	2,9	0,023	6	0,070	1200
0,35	125000	137	3,2	0,026	7	0,082	1300
0,40	119000	150	3,5	0,029	8	0,093	1500
....	....	....	....	....	....	....	....
2,20	22000	152	2	0,091	25	0,513	1000
2,30	21000	152	1,9	0,090	25	0,536	1000
2,40	20000	151	1,8	0,090	25	0,560	1000
2,50	20000	157	1,8	0,090	25	0,583	1000
....	....	....	....	....	....	....	....
3,10	20000	195	1,8	0,090	25	0,723	800
3,175	20000	199	1,8	0,090	25	0,740	800
3,20	20000	201	0,9	0,045	25	0,211	500
3,30	20000	207	0,9	0,045	25	0,217	500
....	....	....	....	....	....	....	....

The example in Fig. 28.10 shows selected diameters to highlight some general items in a parameter table:

- The maximum spindle speed is 1,250,000 rpm. This max rpm is already required at a drilling diameter of 0.35 mm,

resulting in a cutting speed of 137 m/min and with that deviating from the targeted 150 m/min for this and smaller diameters. If a spindle with a max rpm of 160,000 was used, the targeted cutting speed of 150 m/min would be achieved until 0.3 mm.

- The minimum spindle speed is 20,000 rpm. This min rpm is already reached at a drilling diameter of 2.4 mm, resulting in a cutting speed deviation from the targeted 150 m/min for bigger diameters.
- The fact that for diameters bigger than the shank diameter (3.175 mm) the point angle changes from 130 to 165° (also visible on the individual z), requires a reduced infeed.
- The inconsistency of the cutting speed in the diameter range 2.2 to 2.4 mm is due to the fact that the rpm's are rounded (up or down) to thousands.

28.4.7 Stack Clearance Height

28.4.7.1 Definition. Stack clearance height is the distance between the point of the drill and the surface of the stack at the top of the drill stroke. Maintain a minimum stack clearance distance of ⅛ in (0.125 in), which implies a space between the bottom of the pressure foot and the top of the stack of 0.075 in, assuming the pressure foot lead distance to the point of the drill is correctly set at 0.050 in. Stack clearance may be adjusted for each load by simply sliding a 0.075-in shim between the pressure foot and the stack and adjusting the upper limit until the pressure foot touches the shim.

28.4.7.2 Effects. The less the stack clearance distance between the drill point and the top of the stack, the shorter the drill stroke and therefore the shorter the processing time per load. Increasing the stack clearance distance allows

more time between drill strokes and gives the tool table more time to settle, which may improve hole registration accuracy and prevent small-diameter drill bit breakage. In addition, the greater the time between drill strokes, the more likely drilling debris will be removed from the drill flutes and, consequently, the lower the drilling temperatures, which results in reduced occurrences of drill breakage and lower extents of drilled hole quality defects. On some machine controls can different heights be defined. This is done based on the location of the hole (to avoid damage of the spindle, when passing alignment pins). With that can the retraction height be very small for economic drilling and only selectively be increased to avoid damage.

28.4.8 Drilled Stack Height

Material construction (panel thickness, number of copper layers, laminate type, etc.), drill bit diameter, and flute length, as well as hole quality and registration accuracy requirements, all are factors that need to be considered when deciding on appropriate drilled stack heights. A greater number of panels in the drilled stack means higher drilling temperatures, accelerated drill wear, and greater drill deflection, affecting the resulting hole quality and registration accuracy. When using smaller-diameter drill bits, stack heights need to be reduced to prevent drill breakage and to accommodate the shorter flute lengths. As a rule of thumb, the maximum total drilled depth (number of panels × panel thickness + entry thickness + backup penetration depth) that can safely be handled by the drill bit without breakage is approximately 17 times its diameter. When the stack height is determined, an additional “safety” in the flute length should be considered to allow debris removal during and in between the strokes (see Fig. 28.11).

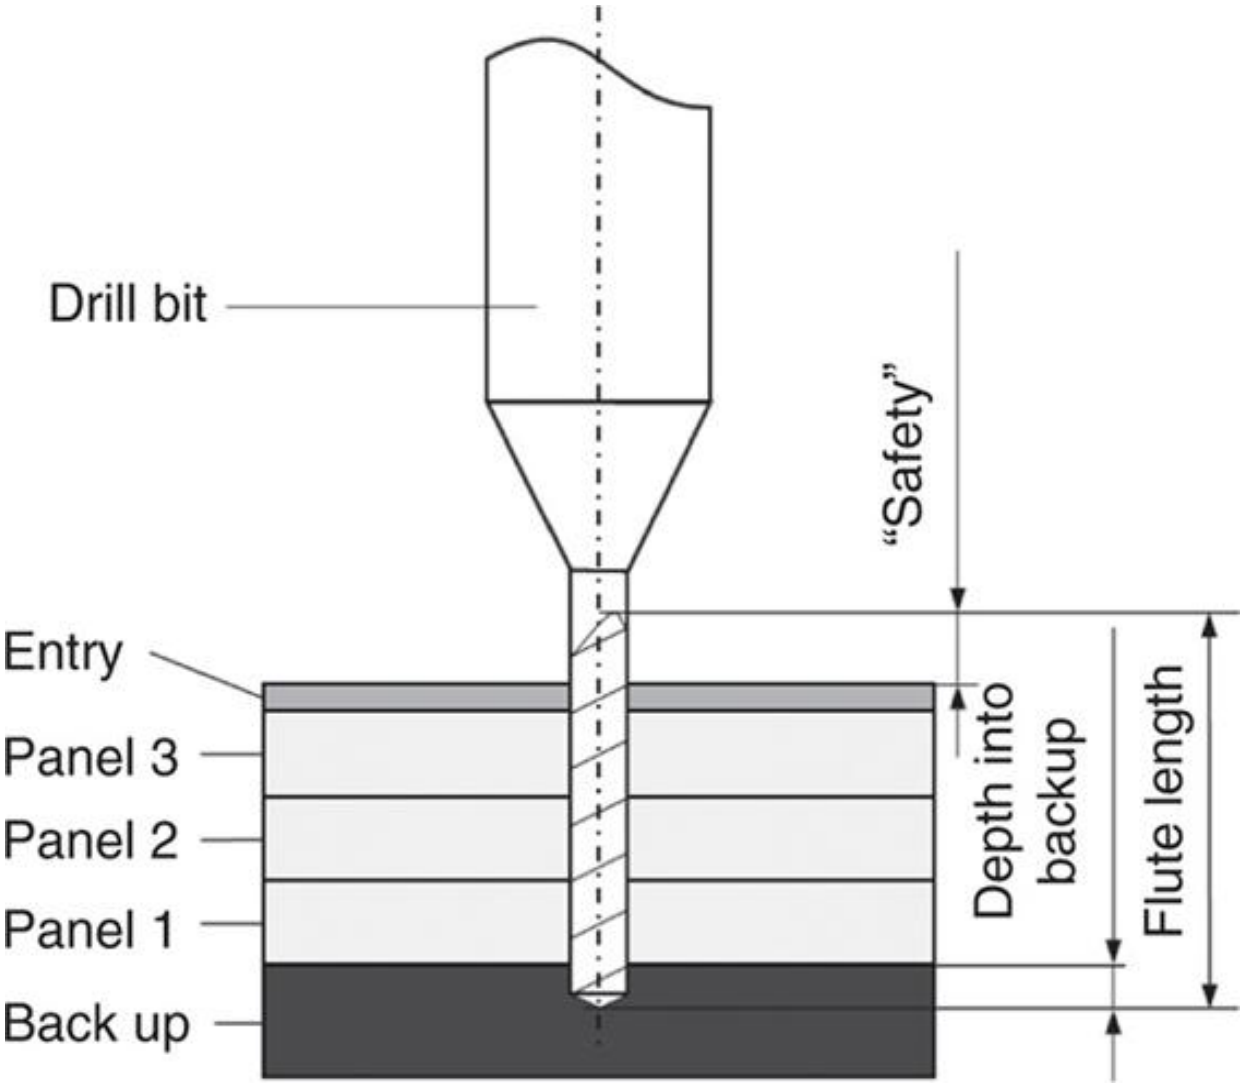

FIGURE 28.11 Drill stack.

28.4.9 Stacking and Pinning

***28.4.9.1 Building the Stack*.** Inspect all laminate panels and the entry and backup materials for surface damage and remove burrs from the panel edges as well as from the pinning holes. Even though the registration tooling holes on the laminate material may not be used to pin the stacked panels together, it is important to remove any resin buildup remaining around these holes after lamination (a common occurrence). Burrs and raised surface areas do not permit

the panels to lay flat, causing gaps resulting in drilled hole registration problems, burrs, hole quality defects, and drill breakage. Reject entry and backup materials with excessive nicks, scratches, and other surface defects as well as those that are warped or twisted.

28.4.9.2 Pinning Procedures. Wipe the surfaces of all laminate panels and the backup material using a lint-free cloth to remove any debris before stacking the panels (allowing intimate contact between the stacked panels). Verify that the pinning holes and pin insertion are perpendicular to the stack and avoid using pins that are damaged or deformed.

28.4.9.3 Installation. Before placing the pinned stacks onto the drilling machine tool table, inspect the surface for burrs or broken drill bits protruding from the table that may prevent the stacks from lying flat. Do not continue if the pin bushings of the tool table are sunken or worn to the point that they do not hold the stack firmly in place. Loose or sunken tooling pin bushings cause movement of the stack during drilling and result in a variety of hole defects, registration problems, and drill breakage, yet are simple to replace at a minimum cost. After stacks are put in place, again wipe the surface of the top laminate material as well as the entry material. Place the entry material on top of the stack and tape it in place. The entry material size should be such that it clears the pins and does not extend beyond the stack edges. Pinning the entry material to the stack is not recommended because it tends to constrict the movement of the material, causing separation between it and the stack and resulting in entry burrs and possible drill breakage.

28.4.10 Backdrilling

29.4.10.1 Definition. Back drilling is an additional blind via drilling step to improve the electrical signal of the circuits at high frequencies, by removing that part of the copper barrel which is irrelevant for the electrical functionality. The fact that this blind via drilling step initially was performed from the bottom side or back side of the board gave this operation the name. Meanwhile it's misleading as back drilling is also performed from the top or front side.

28.4.10.2 Effects. For example (see Fig. 28.12), a product with 10 layers of copper with areas on which the signal travels in the hole only from layer 1 to layer 4. In this case is the barrel between layer 5 to 10 electrically irrelevant or unused and basically only required to achieve the minimum thickness of plated copper in the hole (as the aspect ratio for such a blind via is too high). If this part of the barrel is not removed, reflections and interactions with pulled back copper layers (parasitic capacitances) distort the signal causing losses at high frequencies. The challenge for this drilling step is to come as close as possible to the layer carrying the signal (in the example layer 4), but without violating it. This layer is also referred to as "must-not-cut-layer" in specifications. The distance of the remaining copper barrel to the "must-not-cut-layer" is called "stub." Even though the machine drilling capability in the *z* axis is within a couple of µm is it required to consider several product and process tolerances of the PCB increasing the stub in cases where all tolerances add up. Typically also a minimum drilling depth is specified in relation to a copper layer. This layer is called the "must-cut-layer."

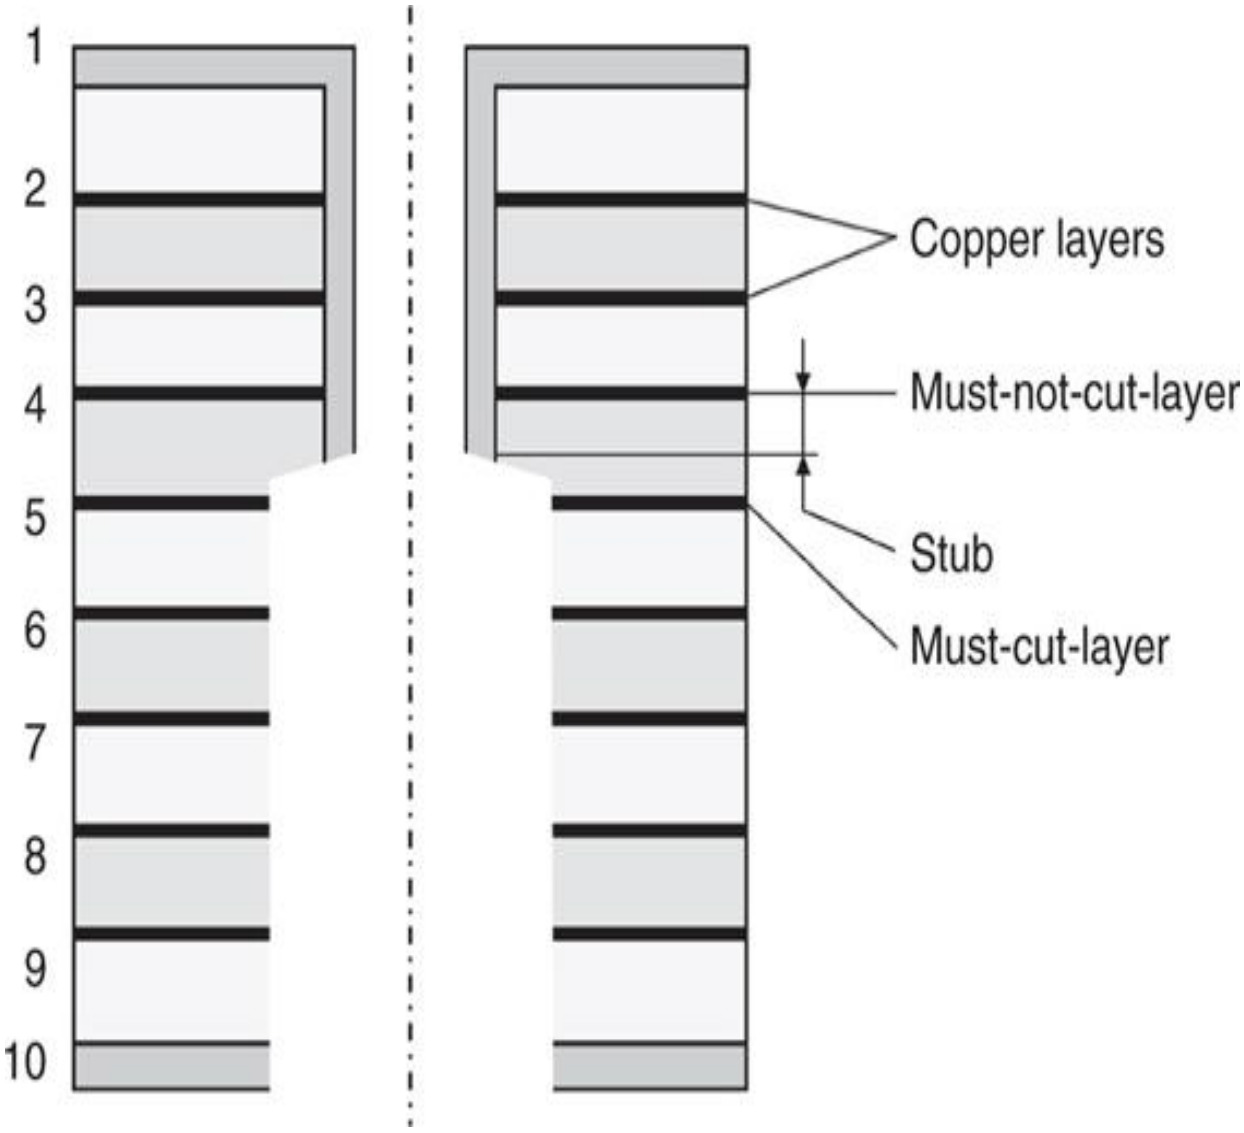

FIGURE 28.12 Back drilling from layer 10 to layer 4 (must-not-cut).

28.5 HOLE QUALITY

28.5.1 Definition of Terms

The terms in Tables 28.1 and 28.2 are commonly used to describe drilled hole defects observed on copper and substrate surfaces. It is important to be able to identify these defects specifically rather than in general terms. Using a general term such as *roughness* may imply voids or plowing.

While voids are a mechanical type of defect, plowing is a heat-related type of defect. Therefore, excessive voids would lead one to examine the chip load (infeed rate) used; plowing would lead one to look at surface speed (spindle speed).

TABLE 28.1 Copper Defects

Defect	Definition	Type
Burr	Ridge left on external surface	Mechanical
Debris	Drilling residues	Mechanical
Delamination	Separation of the copper from the substrate	Mechanical/heat-related
Nail-heading	Burr on internal copper layer	Mechanical/heat-related
Smearing	Thermomechanically bonded resin deposit	Heat-related

TABLE 28.2 Substrate Defects

Defect	Definition	Type
Debris pack	Drilling residues packed into voids	Mechanical
Delamination	Separation of the substrate layers	Mechanical/heat-related
Loose fibers	Unsupported fibers in the hole wall	Mechanical
Plowing	Furrows in the resin	Heat-related
Smear	Thermomechanically bonded resin deposit	Heat-related
Voids	Cavities due to torn-out supporting fibers	Mechanical

28.5.2 Examples of Drilled Hole Defects

Examples of typical drilled hole wall defects are shown in Figs. 28.13 and 28.14.

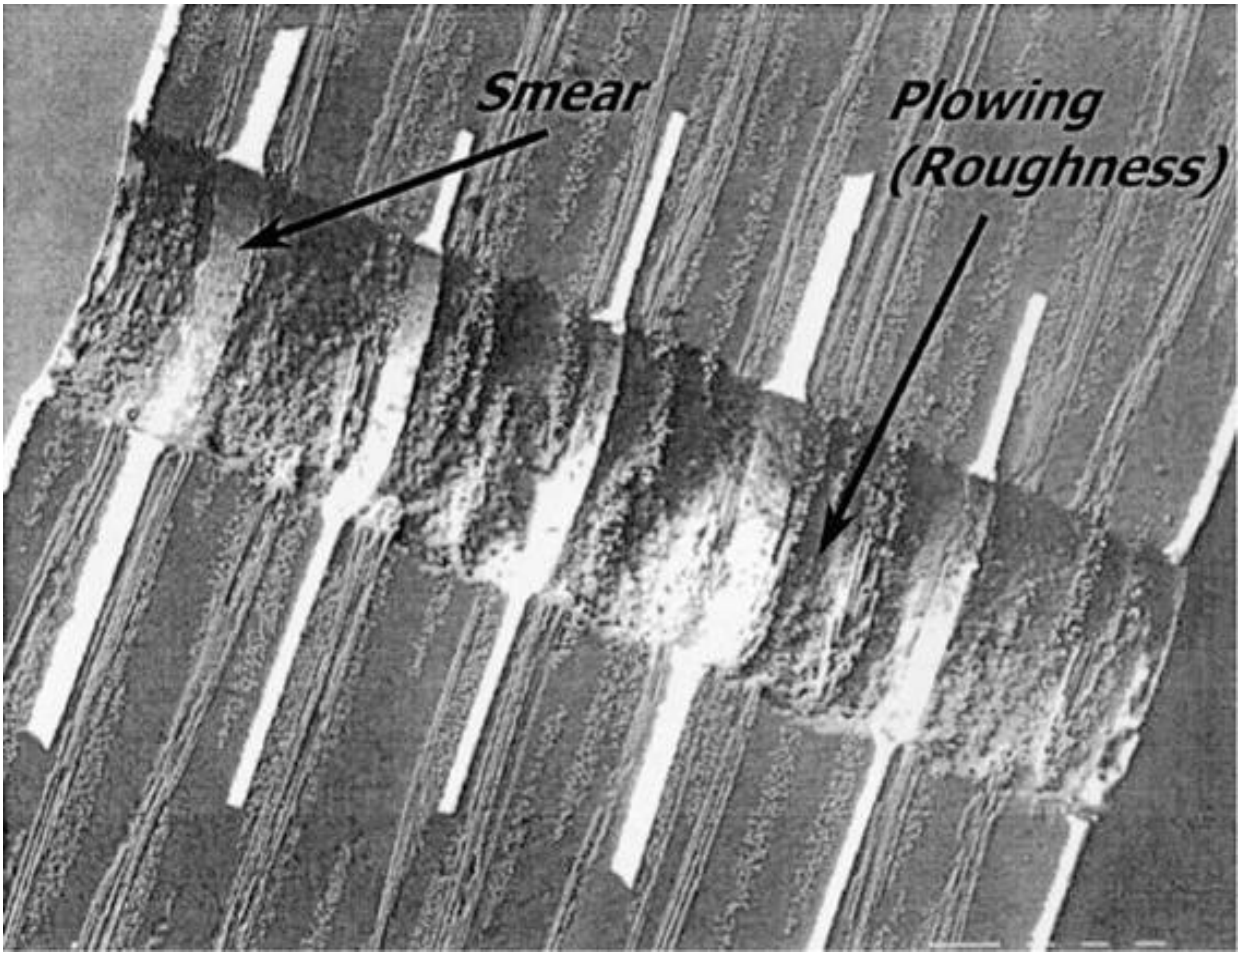

FIGURE 28.13 Cross-section of drilled hole showing.

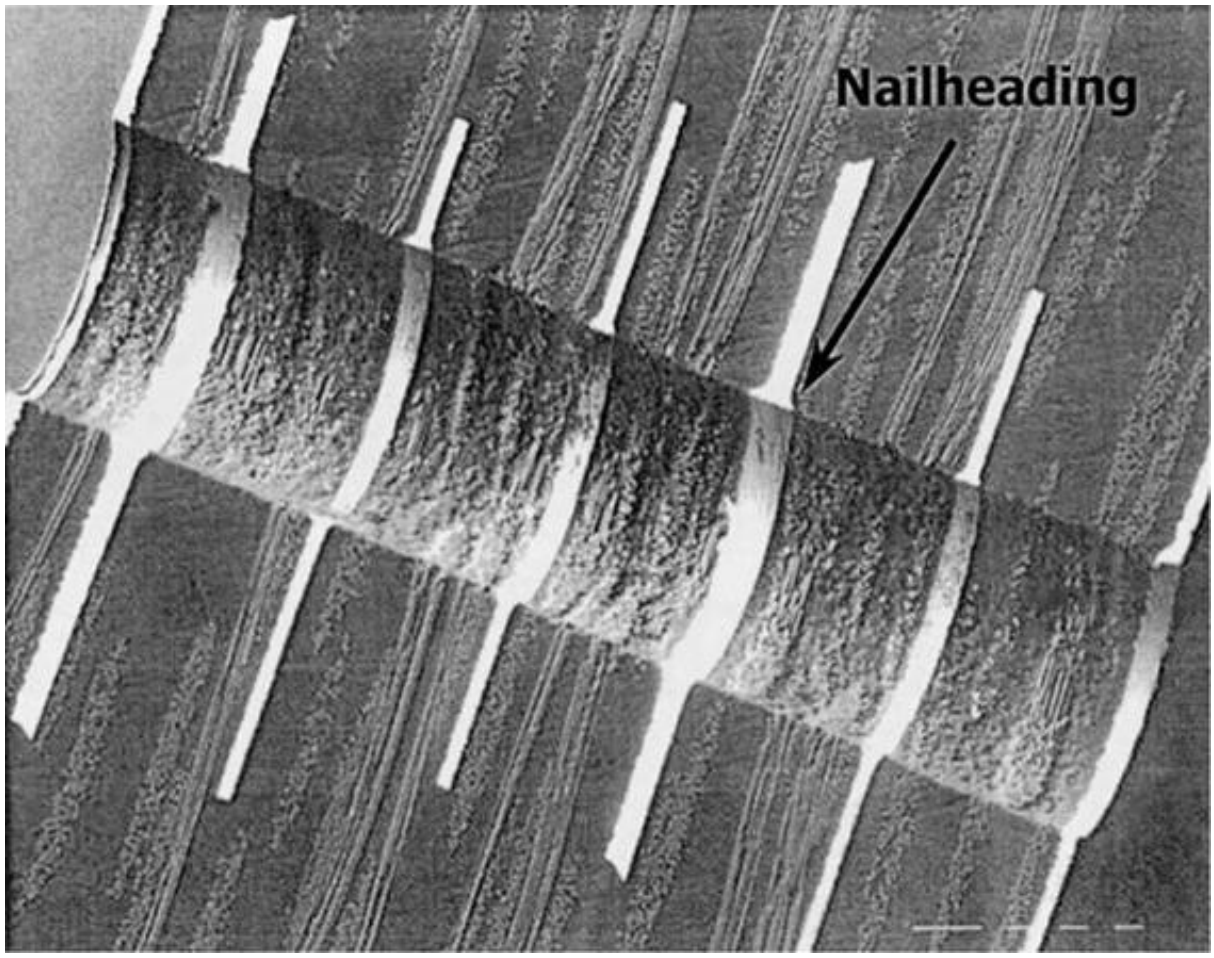

FIGURE 28.14 Cross-section of drilled hole show examples of smearing and plowing of nail-heading.

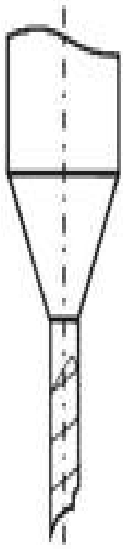
28.6 TROUBLESHOOTING

Drill bit breakage/ broken drill bits



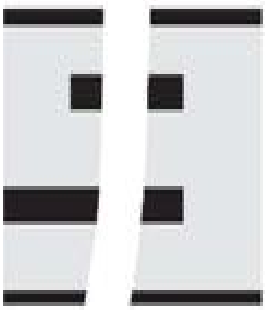
Insufficient flute length:
- Stack too high/flute length too short
- Drilling depth into backup too deep

Wrong drilling parameters/cutting pressure too high:
- Spindle speed/cutting speed too low
- Infeed rate too high
- Retract rate too high

Pressure foot:
- Pressure too low
- Wrong timing between pressure foot and vacuum (down too late/up too early)

Excessive wear:
- Hit count too high
- Damaged/chipped edges
- Spindle run out (tolerance too high)

Drill wander/drill bit deflection



Poor entry material quality
- Inclusions
- Scratches
- Burr on pressure foot => indentions/scratches

Excessive wear:
- Hit count too high
- Damaged/chipped edges

Flute length too long

Spindle run out (tolerance too high)

Debris between entry material and top panel

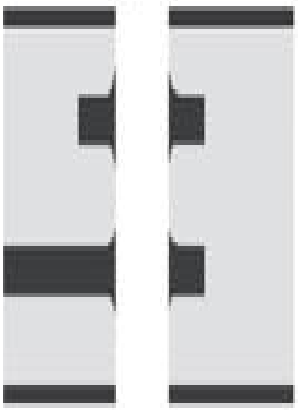
Pressure foot
- Pressure too low
- Wrong timing between vacuum and pressure foot (down too late/up too early)

Misregistration[1]

Alignment system:

- Alignment holes offset, holes too big
- Pins: improper insertion, pins too small
- Improper clamping system

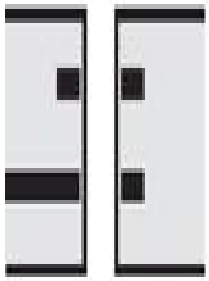
Nail heading



Excessive wear:

- Hit count too high
- Damaged/chipped edges
- Drilling depth into backup too deep
- Spindle speed too high

Smear



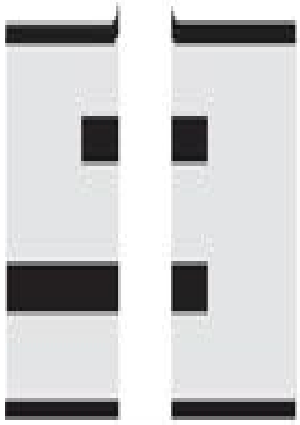
Excessive heat generation:

- Spindle/cutting speed too high
- Infeed too low
- Chip load too low

Material/prepregs not properly cured

(Inefficient desmearing process; depending on if the smear is detected prior or after the desmearing process.)

Burr (entry side)



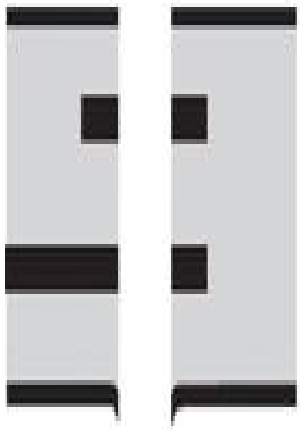
Excessive infeed rate or retract rate

No entry material or entry material too soft

Pressure foot:

- Pressure too low
- Defect

Burr (exit side)



Excessive infeed rate or retract rate

Excessive wear:

- Hit count too high
- Damaged/chipped edges

Warped panels

Pressure of pressure foot too low

Backup material:

- Too soft
- Off contact: debris between panels and backup

Bird nesting 	Chip load too low: • Infeed too low • Spindle speed/cutting speed too high No chip breakers tools (for big diameters) No step drilling/pulse drilling for "high copper" products
Hole wall roughness 	Excessive wear: • Hit count too high • Damaged/chipped edges Chip load too high: • Spindle speed/cutting speed too low • Infeed too high
Haloing (delaminations/cracks in resin on exit side)	See burr on exit side No contact between exit side and backup material, e.g., when drilling after etching or at "routing"/cut out process step

[1]Detected at the drilling department; at AOI are additional influences like misregistration of the imaging process and "overetching" reducing the annular ring and making any drill wonder/deflection or misalignment appear worse than it actually is.

28.7 POSTDRILLING INSPECTION

A wealth of information is available by simply examining the materials from the drilled stack and the drill bits. For instance, inspecting the drill bits will allow one to determine if wear occurs at consistent rates (for drills of same diameter) or will reveal whether hit count maximums are excessive and the type of drilled hole wall defects to expect. Bonded debris and/or extensive wear to the drill corners imply high drilling temperatures (resulting in greater extents of defects such as smearing and plowing) or materials that are not fully cured and point to a problem with the materials (laminate, entry, or backup) or may suggest an excessive surface speed.

Extensive primary cutting edge wear indicates abrasive materials and may require lowering stack heights, reducing hit counts, or replacing entry or backup materials.

Burrs on the surfaces within the stack mean that there is a problem with the way panels are assembled and pinned or may be the result of warped panels. Entry or exit burrs on the outer laminates should cause one to question the entry and backup materials or the infeed rate.

The point of a postdrilling inspection process is that if one takes the time on a regular basis, to examine materials and drill bits after drilling, many drilling problems would be solved before they get out of hand.

28.8 DRILLING COST PER HOLE

Material and processing costs, as well as the resulting total drilling cost, may be determined by using an analysis matrix such as a cost model specifically designed for this purpose and generated with the use of a computer spreadsheet

program. The advantage of using a spreadsheet is that it allows changes to be made in, for instance, specific material prices and processing times or parameters, and allows instantaneous viewing of the resulting effects on the total drilling costs, the cost per panel, and the average cost per hole. Knowing the cost per hole is important because it allows comparing different jobs or processing situations. Following is a step-by-step description of how to construct a drilling cost analysis matrix such as the one shown in Fig. 28.15. The Table demonstrates the different aspects that need to be considered and is just an example in which the actual numbers have to be entered.

TABLE A Machine Time

a	b	c	d	e	f	g	h	i	j	k
Drill bit size	Number of holes per panel	Number of drilled panels	Total number of drilled holes	Panels per drilled stack	Total number of drilled hits	Total number of drilled stacks	Stacks per machine load	Number of machine loads	Drill time per load (h)	Total machine time
0.0135	7,000	120	840,000	2	420,000	60	4	15.0	1.12	16.80
0.0160	5,000	120	600,000	2	300,000	60	4	15.0	0.80	12.00
0.0225	3,125	120	375,000	2	187,500	60	4	15.0	0.48	7.20
0.0350	1,500	120	180,000	2	90,000	60	4	15.0	0.19	2.85
0.0520	800	120	96,000	2	48,000	60	4	15.0	0.10	1.50
0.0700	250	120	30,000	2	15,000	60	4	15.0	0.04	0.60
	17,675		2,121,000						2.73	40.95

TABLE B Drill Bits

l	m	n	o	p	q	r	s	t	u	v
Drill bit size	Cost per new tool	Cost per repoint	Number of repoints per tool	Total cost per drill bit life	Number of uses per drill bit life	Average cost per drill bit use	Total number of drilled hits	Number of hits per drill bit use	Total number of drill bit uses	Total drill bit cost
0.0135	$1.25	$0.25	2	$1.75	3	$0.58	420,000	1,000	420.0	$245.00
0.0160	$1.20	$0.25	2	$1.70	3	$0.57	300,000	1,000	300.0	$170.00
0.0225	$1.15	$0.25	3	$1.90	4	$0.48	187,500	1,250	150.0	$71.25
0.0350	$1.15	$0.25	3	$1.90	4	$0.48	90,000	1,500	60.0	$28.50
0.0520	$1.15	$0.25	4	$2.15	5	$0.43	48,000	2,000	28.0	$10.32
0.0700	$1.30	$0.25	4	$2.30	5	$0.46	15,000	2,500	6.0	$2.76
										$527.83

TABLE C Entry and Backup Material

	w	x	y	z	aa
Material type	Cost per ft^2	Stack size ft^2	Cost per stack*	Total number of drilled stacks	Total material cost
Entry material	$0.53	3.00	$1.59	60	$95.40
Backup material	$0.65	3.00	$0.98	60	$58.50
					$153.90

* Backup material = cost/2 (uses per panel)

TABLE D Labor and Burden

	ab	ac
	Cost per hour	Cost total
Labor	$15.00	$614.25
Burden	$10.00	$409.50
		$1,023.75

TABLE E Total Costs

Cost variable	Cost per panel	Total cost	% of total
Drill bits	$4.40	$527.83	30.9%
Entry material	$0.80	$95.40	5.6%
Backup material	$0.49	$58.50	3.4%
Labor	$5.12	$614.25	36.0%
Burden	$3.41	$409.50	28.0%
Total drilling cost	$14.21	$1,705.48	100.0%

TABLE F Drilling Costs

Drilling cost per panel	$14.21
Average cost per 1000 holes	$0.804

FIGURE 28.15 Drilling cost analysis matrix. (*Courtesy of LCOA Technical Center.*)

28.8.1 Machine Time

Table A in the drilling cost analysis matrix is used to calculate the total time that is required to complete the job. First, the different drill sizes (a) and their respective total drilled holes per panel (b) as well as the total number of panels (c) to be drilled are determined and entered in the spreadsheet; this allows the spreadsheet to calculate the total number of holes for each size to complete the job (d).

Second, using the appropriate drilled stack height (e), the total number of drilled stacks (g) and the total number of drilled hits per drill size (f) can be calculated. The total number of drilled hits (drill strokes) is the total number of drilled holes per panel (b) divided by the number of panels per drilled stack (e).

Third, the number of total drilled stacks (g) is divided by the number of stations per machine [stacks per load (h)] to calculate the number of machine loads (i).

Fourth, the total drill time per load required per drill size (j) is entered to calculate the total machine time for each drill size (k).

Fifth, the total times of each of the drill sizes are simply added up to arrive at the total time required to finish the job.

An option is to enter the total drill time per load instead of entering the time for each of the drill sizes and multiplying the total drill time per load by the number of machine loads to determine total machine time.

28.8.2 Drill Bits

The cost of the drill bits needed to complete the job may be determined after the average cost per drill bit use has been

calculated. To find the average cost per drill bit use, the typical number of repoints for the particular size (*o*) is multiplied by the cost of each repointing (*n*). The resulting cost, added to the new drill bit price (*m*), is the cost per drill bit life (*p*). By dividing the cost per life by the number of uses (*q*) per life (the number of times the bit is repointed + 1), you arrive at the average cost per drill bit use (*r*). Next, by dividing the total number of hits per drill size (*s*) by the number of maximum hits per drill bit use (*t*), the number of required drill bit uses (*u*) for each size may be determined. Then calculate the total cost per drill bit size (*v*) by multiplying the number of uses (*u*) by the average cost per use (*r*). The sum of the total costs of each of the drill bit sizes (*v*) brings you to the total cost of drill bits needed for the job. This cost, of course, is true only with the assumption of no drill bit breakage.

28.8.3 Entry and Backup Materials

Entry and backup material cost per stack (*y*) is determined by multiplying the stack size [square foot per panel (*x*)] by the cost per square foot. Remember to divide the backup cost by 2 since each backup panel may be used twice. Total material cost (*aa*) is calculated by multiplying cost per stack (*y*) by total number of drilled stacks (*z*).

28.8.4 Burden and Labor

Using typical burden and labor rates per hour (ab), these values are multiplied by the number of hours to complete the job (determined in Table A) in order to calculate the total burden and labor costs (ac).

28.8.5 Total Drilling Cost and Cost per Hole

After entering the required data in Tables A through D of Fig. 28.15, the total drilling cost and the cost distribution (see Table E) as well as the drilling cost per panel and the cost per hole (see Table F) can be calculated. Because the cost per hole typically ranges around 1/10 of a cent, a more accurate and easier way to comprehend this value is by showing the average cost per 1000 holes, as is done in the cost model.

28.9 ACKNOWLEDGMENT

Portions of this chapter were taken from Chap. 24, “Drilling Processes,” written by Hans Vandervelde, Laminating Company of America, for Clyde F. Coombs, Jr. (ed.), *Printed Circuits Handbook*, 6th ed. (McGraw-Hill, New York, 2008).

[a] Significant portions of this chapter are based on “Drilling Processes,” by Hans Vandervelde, Chap. 24 in *Printed Circuits Handbook*, 6th ed. (McGraw-Hill, New York, 2008).

29.1 INTRODUCTION

As circuit density continues to increase along with the demand for higher and higher accuracy in hole location, the drilling machines and the environment in which the machines operate must be tightly controlled to achieve success in the drilling operation.

High-density interconnect (HDI) has been defined as referring to holes with diameters of 0.006 in or less. HDI holes were generally expected to be made by nonmechanical means, such as lasers, plasma, or photoimaging. However, most holes continue to be created by mechanical means, and as the hole size approaches or in some cases decreases to less than 0.004 in, special challenges face the mechanical drilling process. With the density increase, innerlayer registration is of utmost importance. Artwork generation and fabrication processes can introduce layer shift. This shift is

particularly troublesome in high-layer-count printed circuit boards (PCBs). This chapter addresses these issues of small-hole drilling as well as laser drilling.

In this chapter, holes created by traditional mechanical drilling methods are referred to as “drilled,” and the process is referred to as “drilling.” Holes created by laser, plasma, or photoimaging are not really drilled, even though the term is often used to describe them. When this chapter references nonmechanical via-hole creation processes, these are referred to by their specific type.

29.2 FACTORS AFFECTING HIGH-DENSITY DRILLING

PCB technology requires holes as small as 0.002 in (0.05 mm) to be drilled with extremely high accuracy, particularly when drilling dense hole patterns. The processes and machines used to drill these holes now constitute a highly developed science.

As the drilling process approaches these HDI dimensions, numerous factors become increasingly critical, such as:

- Hole location
- Predrilling process issues
- Drill room temperature/relative humidity
- Vacuum
- Drill bit condition
- Dynamic spindle run-out
- Backup and entry material (type and thickness)
- Maximum spindle speed
- Depth control

29.3 LASER VERSUS MECHANICAL

Although it is somewhat subjective, the decision to drill with mechanical or laser systems can be influenced by the following considerations:

- *Aspect ratio determination:* If the via to be formed is more than 0.016 in (6.3 mm) deep, it is better to use a mechanical drilling process.
- *Material type:* Materials that tend to have excess smearing that clogs the flutes in a mechanical system are usually better on a hybrid laser system.
- *Size of holes:* If the hole to be drilled is larger than 0.012 in, then use a mechanical system for speed and hole wall quality.

29.3.1 Other Advantages and Benefits to Use Lasers for the Via Formation

- Very fast [>500 holes/s (up to 1000 holes/s) compared to 200 holes/min for the mechanical process]
- No “safety” required, reducing the dielectric thickness under the landing pad; while for mechanical blind vias, thickness variations have to be considered with an increased drilling depth, which requires also a greater distance under the target layer, can the parameters for CO_2 lasers be set in a way to mitigate these variations (with extra energy) because the landing copper will not be damaged, due to the fact that copper reflects certain wavelengths to a great extend
- Easy alignment to the landing IL copper on the laser machine/in the same operation

- Ability to form dual-diameter holes (“telescope vias”) when going through multiple layers

29.3.2 Lasers for PCB Processing

Several types of lasers can be used to fabricate PCBs (solid state and gas), including:

- Infrared (IR) (CO_2) lasers (9.4 to 10.6 µm)
- Ultraviolet (UV) lasers for PCB (solid-state)
  - Nd:YAG (Neodymium-doped Yttrium-Aluminum-Garnet)
  - Yb:YAG (Ytterbium-doped Yttrium-Aluminum-Garnet)
  - Nd:YVO_4 (Neodymium-doped Yttrium-Vanadate)
  - Nd:YLF (Neodymium-doped Yttrium-Lithium-Fluoride)

In solid-state lasers is the beam delivery from the source to the working optics done with optical waveguides or with mirrors. The (fundamental) wavelength is typically in a range of 1030 to 1070 nm.

See Fig. 29.1 for diagram of laser wavelengths by type.

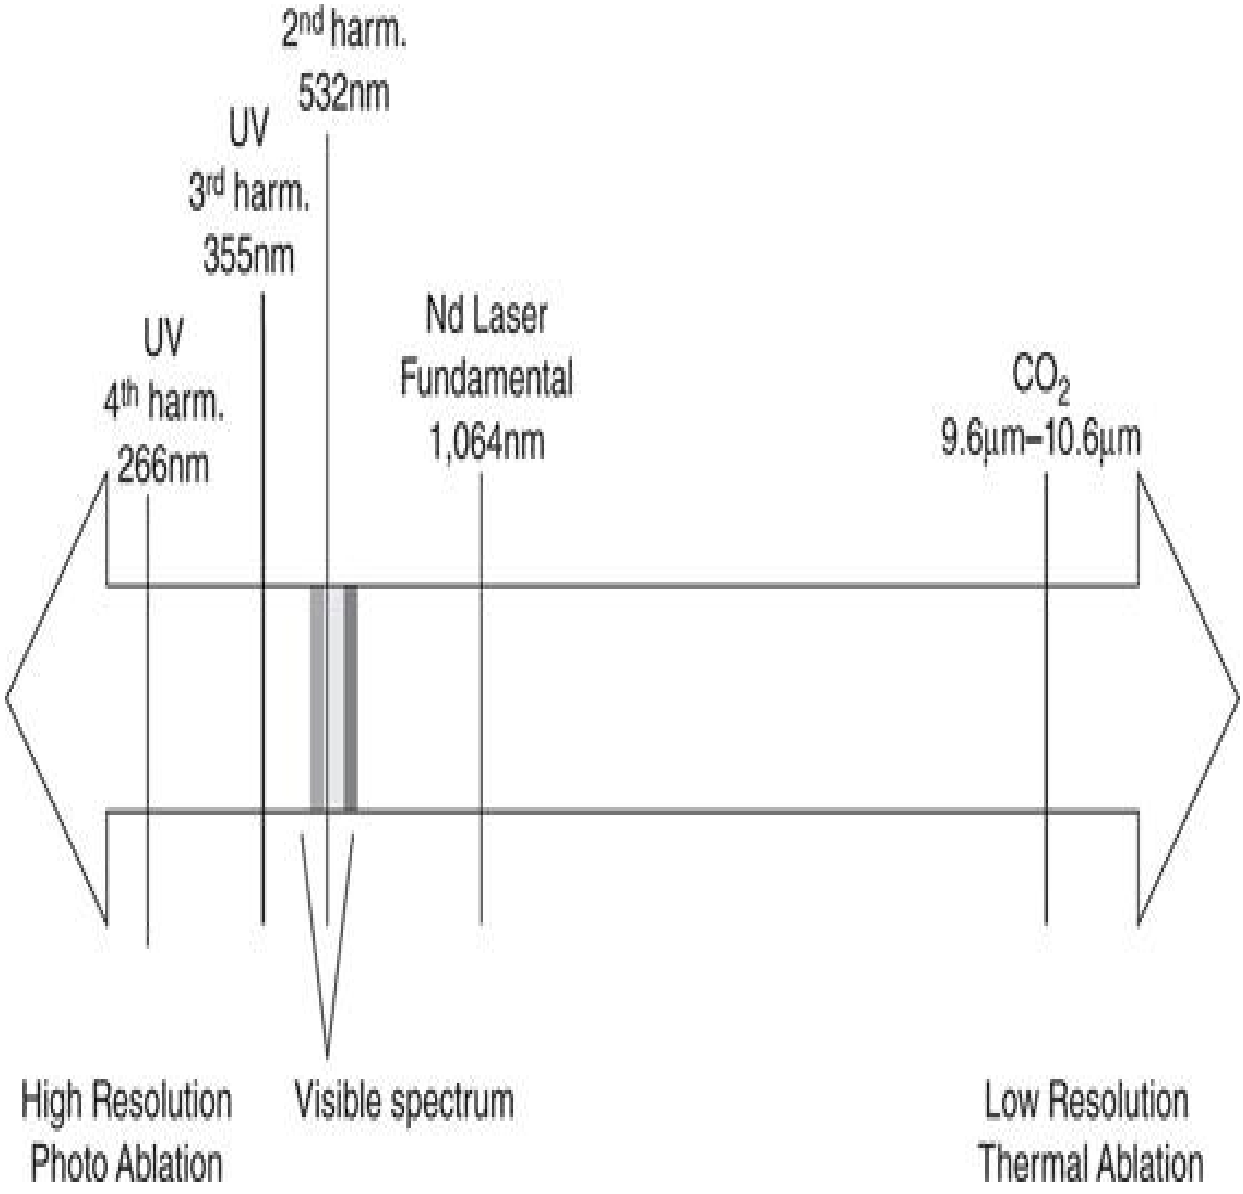

FIGURE 29.1 Laser wavelength by type.

29.3.3 Beam Delivery

Laser source outputs a collimated beam. Turning mirrors (see Fig. 29.2) guide the beam to the scanners. The attenuator is used to control UV beam power. Scanners move the beam on the worktable. The lens focuses the beam to the worktable.

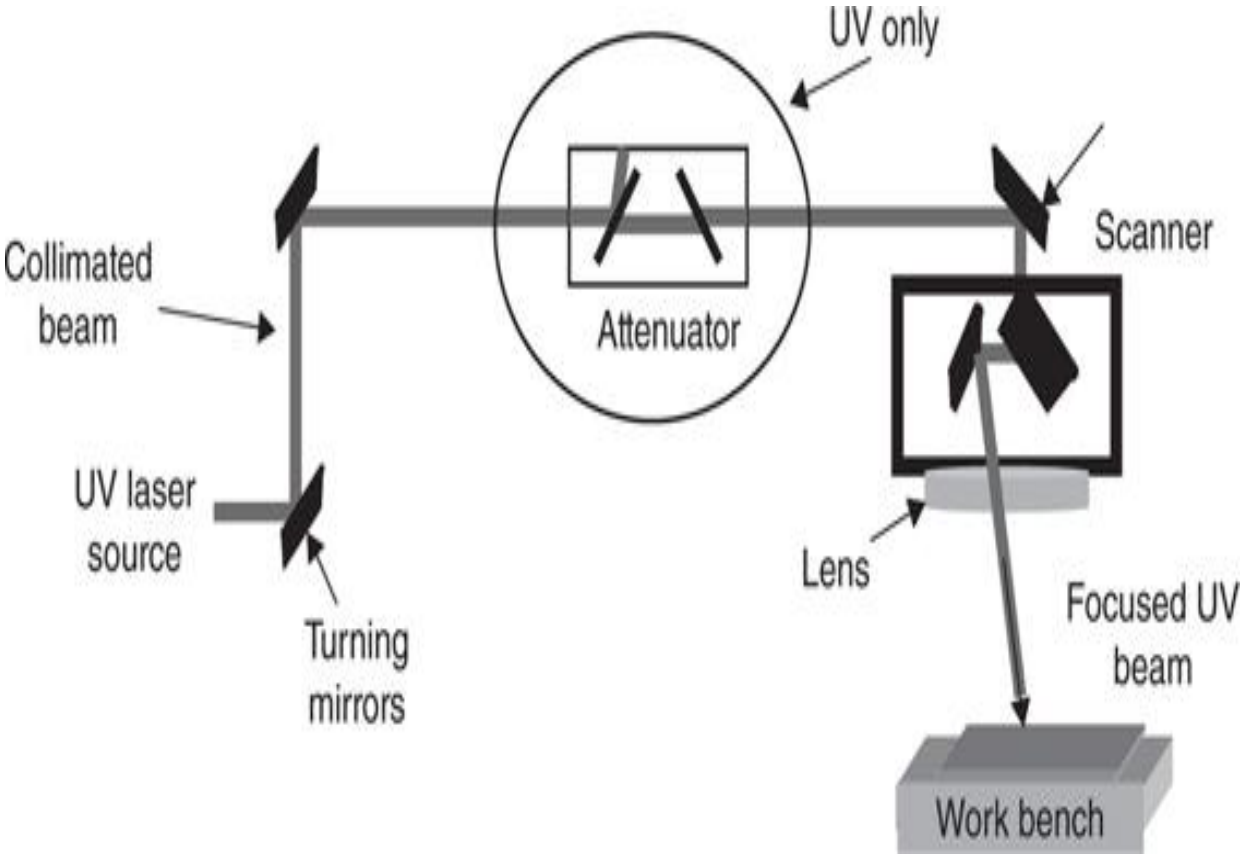

FIGURE 29.2 Laser beam delivery.

29.3.4 IR (CO_2) Drilling

IR drilling requires the following:

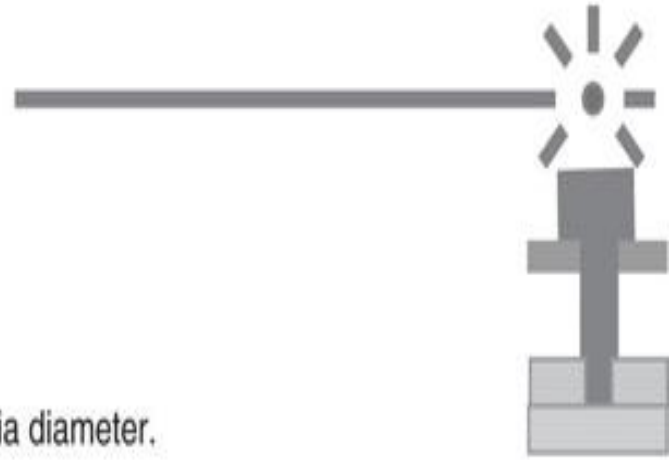
- *Thermal ablation*: This ablation requires heating, melting, and vaporizing. CO_2 IR wavelengths are reflected by copper.
- *Large focus diameter:* The focus should be ~200 mm.
- *Larger beam size*: The beam is adjustable through defocusing or apertures.
- *Percussion drilling:* Each pulse removes a portion of dielectric material.
- *High dielectric removal rate:* Scanner speed limits throughput.

- *Postprocess clean:* A desmear process is required.

See Fig. 29.3 for an overview of the CO_2 process.

Conformal mask processing

A mask of holes made by drilling, etching, or laser-ablating the top layer of copper. CO_2 is used for dielectric removal and a high ablation rate.



Direct dielectric drilling

No copper layer is required.
The mask in the laser beam defines the via diameter.

Via formation with CO_2 only

The copper layer is etched and oxidized.
CO_2 is used for copper and dielectric.

FIGURE 29.3 CO_2 process overview.

29.3.5 UV Drilling

UV drilling requires the following:

- *Photo ablation:* This process breaks molecular bonds. Minimal heat damage is inflicted on the surrounding area.
- *Precise cutting:* The small focus diameter should be ~20 mm.
- *Percussion drilling:* The hole diameter must be the same as the focus diameter.
- *Trepanned drilling:* The hole diameter must be greater than the focus diameter.

UV light is absorbed well by most PCB materials, but each material absorbs at a different rate.

29.3.6 Creating Board Elements with Lasers

Vias are created by having the laser beam make concentric circles or spiraled cuts. Laser pulse trains can be used to create vias or lines. Hole desmear can also be done by laser.

29.3.7 UV Lasers

29.3.7.1 Yitrium-Aluminum-Garnet

- The output pulse is ~120 ns.
- Yitrium-Aluminum-Garnet (YAG) was first used for laser PCB drilling.
- It provides high-pulse energy.

29.3.7.2 Yitrium-Vanadate

- Yitrium-Vanadate's (YVO_4) output pulse is ~20 ns.
- Its repetition rate is ~100 kHz.
- Currently YVO_4 is most commonly used for PCB drilling.

29.3.7.3 Yitrium-Lithium-Fluoride

- The output pulse is ~50 ns.
- Yitrium-Lithium-Fluoride (YFL) is more efficient, providing five times the absorption coefficient of YAG at the pump wavelength.

29.3.8 Hybrid Lasers (UV and CO_2)

Figure 29.4 shows a flow of the use of hybrid lasers for via formation. This hybrid is the combined use of CO_2 and UV laser technology.

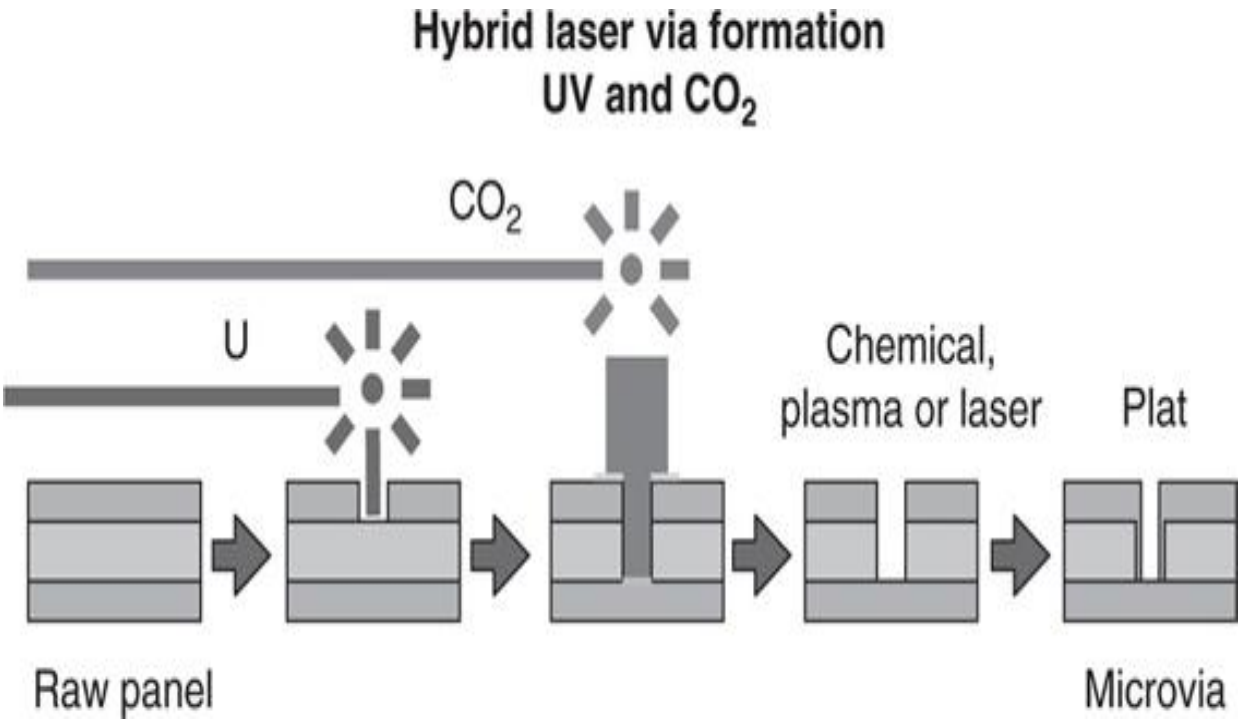


FIGURE 29.4 Hybrid laser via formation using UV and CO_2 lasers.

29.4 FACTORS AFFECTING HIGH-DENSITY MECHANICAL DRILLING

The following are factors to be considered regarding mechanical drilling.

29.4.1 Positioning/Hole Location

The positioning system for conventional drilling machines consists of *x, y*, and *z* axes. The *x* and *y* axes refer to the position of the circuit board under the drill spindle, and the *z* axis to the plunging and retracting motions that allow the drill spindle to feed the drill bit into the substrate material. Machine accuracy is defined by the machine's ability to position the table under the spindles to the desired programmed *x* and *y* values. All process variables, such as tool design, stack height, feeds and speeds, and tooling methods, must be eliminated to evaluate machine accuracy.

The stability of the machine is critical when microdrilling dense drill patterns. When the drilling system is designed, stability is one of the most important factors taken into consideration. The foundation or base of the machine is usually constructed of granite or similar material. Granite is typically used because of its mass and low coefficient of thermal expansion (CTE) to temperature fluctuation. The upper structure of the machine is designed with a high natural frequency, which allows the structure to stabilize quickly, reducing the time the machine must pause before making a rapid movement to the next hole location.

Vibration caused by forces such as punch presses, drilling machines operating in close proximity, or any other type of

equipment capable of causing severe vibration can have a detrimental effect on HDI drilling, such as drill bit breakage and hole mislocation. Each drilling machine should be isolated from these forces as thoroughly as possible. The ideal solution is to have each drill machine placed on its own isolated pad made of reinforced concrete. This setup serves to isolate the drill machine from a large percentage of the vibration transmitted through the shop floor.

29.4.2 Drill Room Temperature and Relative Humidity

All materials have coefficients that, because of the precision required, are critically important to the operation of drilling machines. Temperature has a profound impact on the accuracy of the drilling machines. With changes in ambient temperature, the materials used to build the machines may expand or contract, changing the position of the drilled hole in the PCB.

Keeping a consistent room temperature is essential for maintaining accurate positioning of the machine. A stable temperature throughout the PCB process assists in decreasing the amount of potential growth and contraction of the substrate materials. The drill room should be kept at a constant temperature and humidity, typically 72 ± 2°F (22 ± 1.1°C) and 45 to 60 percent humidity.

29.4.3 Vacuum

Sufficient vacuum flow is imperative when drilling high-aspect-ratio holes in tightly drilled grids. The vacuum system serves two main purposes:

1. To extract debris from the drilling surface

2. To keep the tool cool by removing the debris, thus decreasing the amount of friction in the hole wall

Insufficient vacuum flow leads to hole wall quality problems such as gouging, nail heading, and excessive smearing

There are numerous applications such as high-aspect-ratio drilling that require an increased amount of vacuum pressure to remove debris sufficiently, and the equipment manufacturer can provide specific guidelines for special situations. Increasing the *z*-stroke distance between the pressure foot insert and the top of the drilled stack also assists in cooling the drill bit.

29.4.4 Drill Bit

Drill bits (called *tools*) are critical in the drilling process. A wide variety of tools are available and your tool vendor can be very helpful with selecting feeds and speeds. Be sure to try several vendors to find the best tools for your particular process.

29.4.5 Drill Bit Condition

The condition of the used drill bit is a key indicator of the control and capability of the drilling process and provides an indication of the condition of the drilled hole wall. A wealth of process information can be extracted from the used drill bit. Examining drills before the repointing process can be a warning indicator of drilling problems in a real-time mode soon after the process has been affected.

Drill machine operators and drill bit resharpeners should regularly evaluate the condition of used drill bits and report the findings to the process engineers. The areas of greatest concern when evaluating the condition of used drill bits are

- Excessive margin wear
- Large amounts of burned substrate material attached to the relief areas
- Chips in the primary cutting edges of the tools

When tracked over time, this information can help alert the engineering team of any sudden changes in the drilling process. Although the used drill bit condition information is subjective, with properly trained personnel it can serve as a key indicator of the level of hole wall quality.

29.4.6 Dynamic Spindle Run-Out

The spindle houses the collet, which holds the drill bit that produces the hole in the PCB. Modern spindles are capable of running at a wide range of rpm (15,000 to 300,000) with a power rating near one horsepower (1 hp). Due to the accuracy required when drilling with small drill bits, the drill bit must run true in the spindle. Excessive spindle run-out causes the drill bit to rotate eccentrically, which leads to inaccurate hole location, drill bit breakage, and hole wall quality problems.

The spindle run-out must not exceed 0.002 in (0.005 mm) total indicated run-out (TIR) in a static situation. This trueness is achieved by using electrically powered spindles that rotate by the means of air bearings rather than mechanical ball bearings.

Other factors, such as poor collet condition and adjustment, can also lead to excessive run-out. Frequent collet cleaning and adjustment are necessary to ensure accurate mechanical hole location. Some modern drill machines are equipped with a tool metrology gauge (TMG). This feature measures the run-out for each drill bit during the tool change process, and if the run-out value measures over the predefined range, the tool is rejected. TMGs can help

increase productivity and quality by identifying potential problems before they occur.

29.4.7 Spindle Speed

As via holes get smaller and smaller, maintaining an adequate cutting speed is essential, particularly with chip loads exceeding 0.001 in per revolution. Increased spindle speed also allows for higher productivity because it corresponds to maintaining consistent chip load values while increasing *z*-axis feed rates. Spindle speed settings control the rotation of the drill bit during the drilling cycle. Measured in revolutions per minute, speed impacts hole wall quality as well as the condition of the drill bit's cutting edge. Excessive spindle speeds can result in premature wear on the cutting edges of the drill bit and may clog the margin relief area of the tool with burnt substrate (see Table 29.1). Spindle speeds are dependent on the process and the application. The maximum spindle speed capability is a factor when microdrilling, particularly when the desired surface foot per minute (sfm) values are above 300. Note the maximum achievable sfm for the microdrilling diameter range when utilizing the 180,000 rpm parameters for FR-4 material listed in Table 29.1. When the maximum allowable spindle speed is increased to 180,000 rpm, the 300 sfm value can be achieved when microdrilling, as shown in Table 29.1. As the table indicates, the upper spindle speed range accommodates microdiameter drill bits. Table 29.2 shows spindle parameters for FR-4 materials at various spindle speeds.

TABLE 29.1 Spindle Parameters for FR-4 Materials at 180,000 rpm

Spindle Speed 180,000 rpm Desired Cutting Speed: 500 sfm				
Tool Size (inch)	Infeed Rate (in/min)	Spindle speed (rpm)	Chip Load	sfm
.0071	077	180,000	.00043	334

.0145	137	131,700	.00104	500

TABLE 29.2 Spindle Parameters for FR-4 Materials at Various Spindle Speeds

Spindle Speed 125,000 rpm Desired Cutting Speed: 500 sfm				
Tool Size (inch)	Infeed Rate (in/min)	Spindle Speed (rpm)	Chip Load	sfm
.0071	054	125,000.0	.00043	232
.0080	065	125,000.0	.00052	262
.0100	090	125,000.0	.00072	327
.0120	105	125,000.0	.00084	393
.0145	130	125,000.0	.00104	474

29.4.8 Chip Load

Chip load is calculated by dividing the feed rate by the spindle speed. The term identifies the amount of penetration the drill bit completes per revolution. As commonly used, the chip load accurately describes the proper cutting action needed to drill certain applications successfully.

29.4.9 Surface Speed

The surface speed in sfm is described as the distance that the drill bit's outermost cutting edge travels in 1 min. Cutting speed is frequently used in the metal-cutting industry, and the meaning is the same in the PCB drilling process. Particular substrate materials drill and fabricate favorably at certain cutting speeds. Cutting speed should remain consistent throughout the drill range (except when limited by spindle speed capability). For general guidelines, see Table 29.3.

TABLE 29.3 General Guidelines for Cutting Speed

Cutting Speed, sfm	Material Type
200	Plastics, acrylics, soft materials
300	Teflon, Kapton
400	Polyimide, cyanate ester, BT epoxy, high-T_g laminates
500	FR-4, tetrafunctional, multifunctional multilayers
600	FR-4, difunctional rigid, double-sided

29.4.10 Retraction Rate

The *z*-axis return stroke can be programmed as well. This rate, known as *retraction*, should be set to the value that will minimize the time that the drill bit spends inside the drilled hole. The *z*-axis stability and drill bit diameter often influence the optimum retract values. An unstable or worn *z* axis can lead to poor depth control, poor hole wall quality, and high levels of drill bit breakage. Another advantage of high retraction rates is the speed of the drill stroke.

Increasing production in this case through faster drill stroking is a high priority for the PCB manufacturer. Machine technology allows the user to set retraction rates upward to 1400 in/min (35,560 mm/min).

29.5 DEPTH-CONTROLLED DRILLING METHODS

There are three common methods of depth control used in the drilling process:

- Manual through-hole drilling
- Machine depth-controlled drilling
- Controlled-penetration drilling

29.5.1 Manual Through-Hole Drilling

Manual through-hole drilling utilizes a down limit value to determine the bottom of the *z*-axis stroke. This method does not utilize the top of the stack or the top of the backing material as a reference point. Careful consideration should be given when a down limit is set. The operator needs to ensure that the drill bit is penetrating all the way through the

stack of laminated panels. Shallow penetration or incomplete holes can result in drilling scrap. Excessively deep penetration leads to increased drill bit cutting edge wear, excess debris to be removed, higher drilling temperatures, and drill bit breakage. The down limit should be set at a value that enables the drill bit to clear the point and also avoids drilling too deeply into the backing material.

29.5.2 Machine Depth-Controlled Drilling

Depth-controlled drilling utilizes the top of the drilled stack as its reference point. Before this depth-control method can be utilized mechanically, the machine needs to know what the distance is from the pressure foot insert to the tip of the drill bit.

To determine this distance, the manufacturer performs a TMG check using standard measuring devices. Once this distance is established, any negative (−) values entered into the depth box will cause the *z* axis to stop at the desired depth measured from the top of the stack.

29.5.3 Controlled-Penetration Drilling

Controlled-penetration drilling is utilized for drilling applications where the depth is referenced from the top of the backing material. This mode of depth control is not affected by stack height. The specified depth value or *z*-axis offset is treated as the desired amount of penetration relative to the top of the backing material. For the machine to be run in mode 3 depth control, a process called *mapping* must be performed prior to drilling any panels. During the

mapping cycle, the machine touches down on the surface of the backing in 2-in increments.

At each touchdown point, the thickness value of the backing is recorded. Once the mapping procedure is complete, the *z*-axis zero is established. Any negative values entered into the offset box represent the drill depth into the backing material. Controlling the penetration of the drill bit into the backing material assists in decreasing heat generation, improving hole wall quality by limiting the amount of debris, and decreasing drill bit breakage due to excessive depth.

29.6 CONTROLLED DEPTH VIA DRILLING

29.6.1 Blind Vias

29.6.1.1 Definition. Blind Vias are mechanically drilled holes which are not drilled all the way through the PCB, but only partially from one side (top or bot) to a specific innerlayer. It must be considered that the aspect ratio (ratio of the drilling diameter to the drilling depth) must be within the capability of the metallization processes. Another critical factor is that a minimum distance to the next (conductive) innerlayer under the target layer must be available to allow processing tolerances.

29.6.1.2 Effects. There are several approaches to realize blind vias:

The precision of “referencing to the table” relies on the knowledge of the location of the drill tip. This approach is mainly selected on machines using drill bits with rings, as the rings on the drill bit are set to a defined location and

with that help to reduce the tolerance given when the drill bit is picked up and set in the collet.

“Depth-controlled drilling with mechanical contact” utilizes the top of the drilled stack as its reference point. Before this depth-control method can be utilized mechanically, the machine needs to know what the distance is from the pressure foot insert to the tip of the drill bit. To determine this distance, the manufacturer performs a TMG check using standard measuring devices. Once this distance is established, any negative (−) values entered into the depth box will cause the *z* axis to stop at the desired depth measured from the top of the stack.

“Depth-controlled drilling with electrical contact” utilizes the “electrical broken drill bit detection” in which the surface of the PCB is detected with the help of an electrical signal generated when the drill bit touches the surface. A secondary measurement system is started, enabling a relative movement to the “new zero.” Especially with the introduction of linear *z* stages are very small tolerances in relation to the surface achievable, also on machines with multiple stations.

Controlled-penetration drilling is utilized for drilling applications where the depth is referenced from the top of the backing material. This mode of depth control is not affected by stack height. The specified depth value or *z*-axis offset is treated as the desired amount of penetration relative to the top of the backing material. For the machine to be run in mode 3 depth control, a process called mapping must be performed prior to drilling any panels. During the mapping cycle, the machine touches down on the surface of the backing in predefined increments. At each touchdown point, the thickness value of the backing is recorded. Once the mapping procedure is complete, the *z*-axis zero is established. Any negative values entered into the offset box represent the drill depth into the backing

material. Controlling the penetration of the drill bit into the backing material assists in decreasing heat generation, improving hole wall quality by limiting the amount of debris, and decreasing drill bit breakage due to excessive depth.

29.6.2 Peck Drilling

29.6.2.1 Definition. Peck-drilling refers to a drilling operation simulating the movement of a woodpecker, in which the hole is not drilled entirely in one step, but incrementally. The drill bit is retracted completely in between the increments, removing material in each step. This option is comparable to the generation of multiple blind vias with different levels of depth in the same location. The depth of each increment can be chosen individually, so that product or stack up specific aspects like copper weights can be considered.

29.6.2.2 Effects. The advantages of peck drilling are as follows:

- Decreased drill bit breakage
- Lower aspect-ratio values
- Improved positional accuracy/reduced deflection
- Decreased bottom-panel burring

There are different approaches for the selection of the size of the increments: linear (all the same size), progressive (getting bigger with each increment) or declining (getting smaller with each increment). Quite common is to set a small first increment, acting like predrilling and centering the drill bit for the next steps, with a total number of 3 to 5 increments. Peck drilling is typically applied when the construction of the PCB leads to an increased amount of

broken drill bits. A negative aspect (on top of longer cycle time) is that the multiple passes of drill bit on the same location of a via can lead to temperature related problems like excessive smear. The primary accomplishment of peck drilling is the decrease in effective aspect ratio value. Whereas aspect ratio is defined as the thickness of the board divided by the hole diameter, effective aspect ratio is defined as the total *z* stroke divided by the smallest drill bit diameter. For example, if the total *z* stroke equals 0.209 in (the total thickness of the board) and the smallest diameter is 0.025 in, the aspect ratio and the effective aspect ratio would have the same value of 8.36. By taking a total *z* stroke of 0.209 in and dividing it into four pecks, the aspect ratio is decreased from 8.36 to 2.08. In general terms, an aspect ratio scale of 1 through 15 is commonly used, 1 being conservative and 15 being on the aggressive side of the scale. See Fig. 29.5.

FIGURE 29.5 An example of through-hole peck drilling, showing a stack of three boards with entry and backup material creating a stack height of 0.285 in and a total *z*-axis drill stroke of 0.206 in. The effective aspect ratio of 15.3 is reduced to 3.8 per peck when four pecks are made to complete the hole.

If the *z* stroke is reduced, the drill bit has less debris to extract per revolution, decreasing the chances of clogged flutes, which can cause the drill bit to seize in the hole and break.

Hole location improvement Another benefit of peck drilling is an improvement in hole location. Once a drill bit is deflected, it will continue at that deflection angle as it drills through the stack. Essentially, hole location is worse at the exit point than at the entrance point, particularly when drilling through thick panels with small-diameter tools (high aspect-ratio drilling). Peck drilling can assist in achieving better hole location by lessening the effects of deflection by dividing up the total drill stroke, therefore decreasing the effective aspect ratio value.

Bottom-panel burring Peck drilling can assist in decreasing the amount of bottom-panel burring by reducing the drilling temperatures resulting from drilling thick panels with small drill bits. Plowing, voids, and debris pack are reduced by peck drilling due to the decrease in the amount of debris the tool must extract per *z*-axis stroke.

Drill bit cooling when peck drilling, each individual stroke increment returns to the upper limit value.

The disadvantages of peck drilling are as follows:

- Increased nail heading
- Increased smearing
- Hole wall roughness
- Increased cycle times

Peck drilling increases the overall cycle time due to the greater number of *z* strokes necessary to complete one drilled hole. Nail-heading values tend to be worse for peck drilling due to the certainty that some copper pads will make contact with the drill bit several times as opposed to making only one contact when using a single drill stroke. Hole wall smearing can also be a problem when peck drilling. The increase in heat caused by drilling the same hole several times can cause the substrate material to become heated to its melting point, which can lead to deposits of resin along the hole wall. A similar effect on hole wall roughness.

Methods for reducing the negative effects on the hole wall caused by peck drilling include the following: Increasing the feed rate decreases the amount of time the drill bit spends in the hole. Minimizing the number of pecks also decreases heat generation and reduces overall drilling cycle time. The design of the tool has a major effect on hole wall quality when peck drilling. To decrease heat generation in the hole wall, the manufacturer must reduce the amount of friction caused by the drill bit making contact with the hole wall. To accomplish this reduced friction, the manufacturer can use an undercut tool design, sometimes referred to as a headed drill bit. The undercut tool design decreases the amount of contact by reducing the diameter of the tool, which creates a larger clearance area, consequently decreasing the amount of flute making contact with the hole wall. The undercut tool design reduces the amount of nail heading and smearing caused by peck drilling.

29.6.3 Slot Drilling

29.6.3.1 Definition. Slots can be realized on drilling machines without routing spindles or routing options, by placing multiple holes in the same area forming the final shape of a slot.

29.6.3.2 Effects. There are two ways to “slot drill.” The first one is setting one hole in a predefined overlapping distance to the next one. This method is predominantly used for small slots (<2 to 3× tool diameter). For larger slots an alternating method is used. The first holes are the two holes defining the slot width and are comparable to entry and the exit hole on a routing operation. From then on are holes always placed in between two holes (dividing the hole-to-hole distance by two). The advantage is that the drill bit always enters solid material (as long as possible) improving the precision by reducing the chance for deflections.

29.6.4 Predrilling

29.6.4.1 Definition. Pre drilling is an additional drilling step before the “main” drilling operation is performed and is typically applied for bigger diameters.

29.6.4.2 Effects. As the cutting conditions generally get worse going from the going along the primary cutting edge from the outside towards the center of the drill bit tip, in combination with the inability to have sufficient space to remove all material due to the remaining land or core of the drill bit, an additional drilling step upfront is made for diameters being equal or greater 0.157 in or 4.0 mm. This “predrilling” step removes a first volume of material and also centers the main drill bit. The size of this primary drill is chosen to be 15 to 35 percent of the main diameter.

“Predrilling” can also be applied for high aspect ratio holes for small diameters. In this case is the reduced diameter optional. The intention is more to use a drill bit with a very short flute length being more stable and having a smaller hole-to-hole tolerance and to perform a blind via centering the drill bit in the “main run.”

29.6.5 Pulse Drilling

29.6.5.1 Definition. Pulse drilling, also called step-drilling, is an incremental drilling step (like peck drilling), without retracting the drill bit out of the hole in between the drilling steps, but only pausing for a short period of time or number of revolutions, before continuing the stroke.

29.6.5.2 Effects. Especially on big diameters or counter sink holes is there a high risk for a continuous chip getting caught around the shank especially on high aspect ratio holes or heavy copper applications. This phenomena, also called “bird nesting” due to the visual similarity, is especially critical when operating with “contact drilling” as this chip can contact the surface of the stack before the drill bit, initiating the relative drilling operation “too early,” leading to a wrong depth or even missing holes. As an alternative to sole pausing in between the increments is the drill sometimes retracted to a very small extend. This is why some machine controls don’t differentiate between “peck drilling” and “step drilling” as they basically only differ by the amount the drill is retracted.

29.7 INNERLAYER REGISTRATION OF MULTILAYER BOARDS

Innerlayers of multilayer boards can shift during fabrication processes and create poor layer-to-layer alignment. During the artwork exposure or fabrication of the multilayer boards, the position of the copper shifts relative to the nominal stacked position. This can create breakout or missing of the copper pads when drilling the interconnection holes.

Two methods of inspecting the innerlayers of multilayer panels exist. One that has been used for several years is x-

ray. This technology has progressed significantly and is widely used.

29.7.1 X-Ray

X-ray technology is used to inspect the innerlayers of multilayer PCBs and to verify that the drill pads are located properly. Innerlayer shift is identified easily in an x-ray image, and a simple technique can be used to measure the misalignment accurately. In developing the PCB artwork, a set of stacked pads are located in the coupon area. These are inspected and a “bestfit” centering is calculated.

X-ray inspection also is used to determine movement of each individual layer. In this case, a locating pad with a corresponding layer pad is on each individual layer. The system can measure the distance from the locating to layer pad and determine movement of each layer due to the location of the layer pads. PCBs can be inspected after tooling holes are drilled to verify that they are in the proper locations. In addition, x-ray inspection can be performed after final drilling to verify that the holes are centered within the pads.

29.8 LASER DRILLING

The laser drilling operation can be split into data preparation, alignment, drilling (types), via formation, tool types.

29.8.1 Data Preparation

Similar to the conventional mechanical drilling operation, contain the data packages of a printed circuit boards the coordinates or locations of the laser vias and the diameter

information. As there are multiple methods or ways to generate the holes, there are several things that need to be defined in advance to enable the laser operation comparable to the selection of the drill bit geometry and the parameters. These parameters need to be set for different copper thicknesses, glass styles and resin (including the fillers) systems. But prior the parameter or tool definition, is the selection of the laser system and laser source.

29.8.2 Alignment

Before the laser operation can be started is it required to align the laser to the PCB. Usually is the laser operation immediately before or after the mechanical drilling process, avoiding an extra cleaning or desmearing operation. The alignment can be done:

1. To x-ray drilled holes (which are typically generated in relation to all inner layers)
2. To conventionally drilled holes
3. To the next inner layers

or to combinations of the three.

To enable an alignment to the inner layers is an additional process step called “skiving” required. In this process is all material above the target/landing layer removed with the laser in a square shape, clearing up alignment features (crosses, circles, …), to which the camera alignment can be done.

29.8.3 UV-Drilling

The most common lasers for UV drilling in PCB applications are the ND:YAG lasers. The generated (fundamental) wavelength is 1064 µm. However, for most systems is the

generated frequency doubled or tripled with optical elements (special crystals) leading to a harmonic of the fundamental frequency and with that to a shorter wavelength. The 2nd harmonic of Nd:YAG has a wavelength of 532 nm and the 3rd harmonic of 355 nm.

Configurations of conventional, pulsed, UV laser applications are average powers of 6 to 28 W, max. Repetition Rates of 40 to 300 kHz and pulse durations of 20 to 120 ns. The main parameters that can be set are for the via formation are: Drill type (spiral, trepan, punch, …), bite size, velocity, repetition rate, effective spot size, inner diameter, revolutions, radial pitch, entry angle (see also Sec. 29.6).

29.8.4 IR-Drilling

The most common lasers used for IR-drilling are CO_2 lasers. There are systems with different wavelengths available which are in the range of 9,400 to 10,600 nm or 9,4–10,6 µm.

Configurations of conventional, pulsed, CO_2/IR-laser applications for PCBs are average powers of 6 to 250 W, max. Repetition rates of 2 to 300 kHz and pulse durations of 1 to 100 ms. The main parameters for pulsed IR-drilling in addition to the diameter are: pulse period, pulse width, Z-focus offset.

The beam delivery from the resonator to the working area is done with mirrors.

29.8.5 Combination of UV—and IR-Drilling

To combine the advantages of UV drilling and IR drilling are systems with two different laser sources available. So that it

is possible to open the copper with the UV laser and remove the dielectric with the IR laser without additional alignment or setup times.

29.8.6 Short Pulse and Ultrashort Pulse Lasers

In addition to the wavelength which generally determines the type of ablation, is the “impact time” of the emission another important figure. For the laser drilling of blind vias are mainly “pulse lasers” used in which the light is emitted in portions or pulses. The length of the pulse is described in the duration in which the light is emitted.

For “short pulse lasers” is this time in the range of nano (10^{-9}) seconds. The energy impact causes a temperature exchange between electrons and between atoms. The material heats up until it exceeds the melting point and finally vaporizes.

“Ultrashort pulse lasers” have an even shorter pulse length in the range of pico (10^{-12}) seconds or even femto (10^{-15}) seconds. The material vaporizes directly without spreading much heat to the surrounding material. This is how carbonation of micro vias can be be minimized or even totally avoided.[3]

Configurations of conventional Ultra short pulse lasers are average powers of 6 to 50 W, max. Repetition rates of 400 to 1000 kHz and pulse durations of 0.3 to 20 ps.

29.9 LASER VIA FORMATION

The generation of laser (blind) vias is typically done in two steps to be most efficient and to assure a reliable process. In a first step is the surface copper removed and the via

“opened.” In the second step is the dielectric material removed all the way down to the landing copper. Both steps can be achieved in different ways (see Table 29.4).

TABLE 29.4 Steps for the Formation of a Blind Via with a Laser

Step#	Removal of	Laser Drilling Type 1	Laser Drilling Type 2	Alternatives
1	Copper	UV-drilling	Oxidation of copper + IR-drilling	Imaging + etching of Cu
2	Dielectric	UV-drilling	IR-drilling	Mechanical drilling

Removing the copper with a conventional imaging process (dry film lamination, exposure, Develop-Etch-Strip) is typically only practiced when there’s only an IR-Laser and no UV-laser available and the “work around” of oxidizing the copper to increase the absorption of the IR does not fulfill the quality requirements.

In case the “opening” of the via in step 1 is done with UV-drilling, some dielectric will be removed in addition to the copper. In the second step it’s necessary to adjust for UV-drilling the energy in such a way that the landing copper is not removed excessively. A minor removal of the outer diameter on the landing pad as indicated in Fig. 29.6 is quite common as the quality of cutting the glass in the dielectric needs to be compromised with the penetration of the landing Cu.

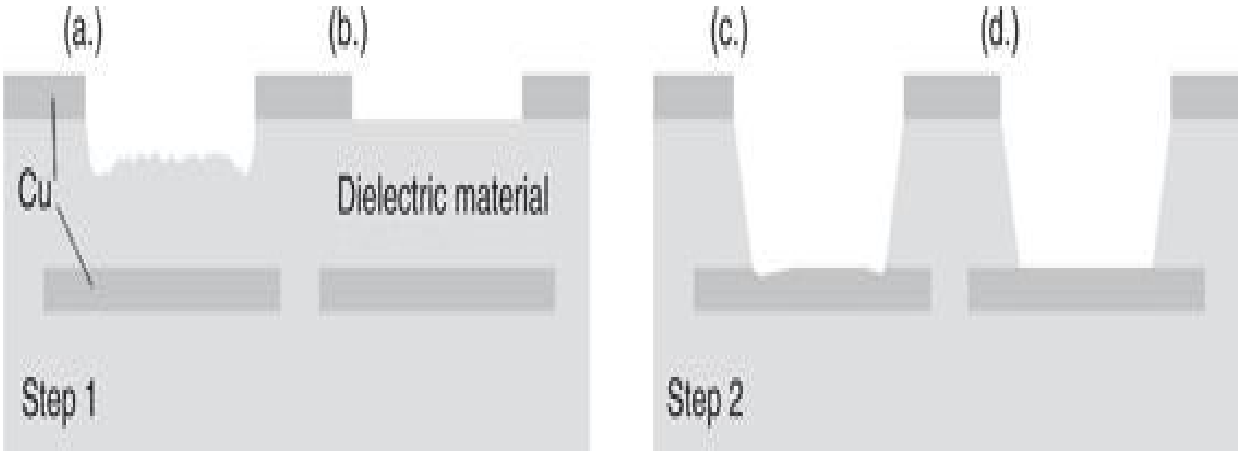

FIGURE 29.6 Removing the surface Cu with UV: (*a*) or etching (*b*). Removing the dielectric with UV, (*c*) or IR (*d*).

29.10 LASER TOOL TYPES

The two steps of generating the laser blind vias need to be set and adjusted for each diameter and material construction. For step one is the main driver the copper thickness. For step two are the key differentiators the type and amount of glass weave and the type and amount of filler elements in the dielectric. It’s possible to predefine different settings of the via formation with the selection and adjustment of different tool types.

29.10.1 Punching and Percussion Drilling

In this process is the materials removed with short pulses. In case of one single pulse this is called “single-shot” operation. In case of multiple pulses on the same location this process is called “percussion drilling” or “burst drilling.”

29.10.2 Trepan/Trepanning

This process describes a percussion mode, while moving the beam along a circular profile at a constant velocity. The distance from one pulse to the next is also called “bite size”. Some machine controls start at the center, going radially to the outer diameter, making the circular movement including some overlap and going back to the center. Others start with a center or pilot hole generated in percussion mode; this hole is then enlarged in a series of increasingly larger circles.

29.10.3 Spiraling

This process describes a percussion mode, while moving the beam from the center of a hole in a spiral path to the circumference. This spiral can be rotated and repeated, for example, to achieve the target depth of a blind via.

29.10.4 Helical Drilling

This process is used to generate through holes and describes percussion drilling in multiple circles of the same diameter at constant velocity. The laser starts removing material on the outside diameter (without starting from the center) in circles leading to a downward spiral. Once the laser has pierced through the material, additional revolutions help to improve the exit side of the hole.

29.10.5 Profile

This process describes a percussion mode, while moving the beam along a defined path at constant velocity to generate or cut any shape.

29.11 ACKNOWLEDGMENT

Portions of this chapter were taken from Chap. 24, “Drilling Processes,” written by Hans Vandervelde, Laminating Company of America, for Clyde F. Coombs, Jr. (ed.), *Printed Circuits Handbook*, 6th ed. (McGraw-Hill, New York, 2008).

CHAPTER 30

IMAGING AND AUTOMATED OPTICAL INSPECTION

Gareth Parry
Draig Technologies Inc., Stouffville, Ontario, Canada

30.1 INTRODUCTION

Imaging is the process that patterns the metal conductor to form the circuit. This process involves a multistep integration of imaging materials, imaging equipment, and processing conditions with the metallization process to reproduce the master pattern on a substrate. Large features (200 µm and greater) can be very economically formed by screen printing. Feature sizes smaller than 200 µm, however, are formed using a photolithographic process, which is the main discussion of this chapter. As circuit densities have increased over the years, the imaging process has continually evolved to enable commercial production of finer features. This need for high-density interconnect (HDI) is driving the industry to feature sizes of 10 µm or lower. Imaging equipment and materials have been developed to meet this challenge.

To achieve a reproducible high-yield/low-cost imaging process for a given feature size, various factors must be carefully balanced. This chapter outlines the chemistry and equ ipment options for the photolithographic imaging process, highlighting trade-offs that must be considered so that process engineers, designers, and procurers of printed wiring boards (PWBs) and HDI structures have an overview of the process considerations that can enable a manufacturable product.

Printing is an alternate process for imaging. Screen printing is used to print resist on foil and silver inks on polyester. Ink jet printing has been used to pattern resist, legend, and silver conductors. A number of ink jet systems have been introduced that prints a UV-curable resists or a catalyst layer to electroless plate copper at thicknesses of 0.05 to 5 μm.[1] Significant development work is underway on organic transistors patterned by ink jet and other printing methods. These PCB ink jet techniques are covered later in this chapter.

The photolithographic process sequence for imaging is given in Fig. 30.1. Basically the process involves applying a light-sensitive polymeric material (photoresist) onto the substrate of interest, exposing this photoresist to light with the desired pattern, and developing the exposed pattern. This developed pattern is used for either subtractive (etching) or additive (plating) metal pattern transfer. Details of these metallization processes are given in subsequent chapters. After metallization, the photoresist is stripped from the surface and the panel is ready for further processing.

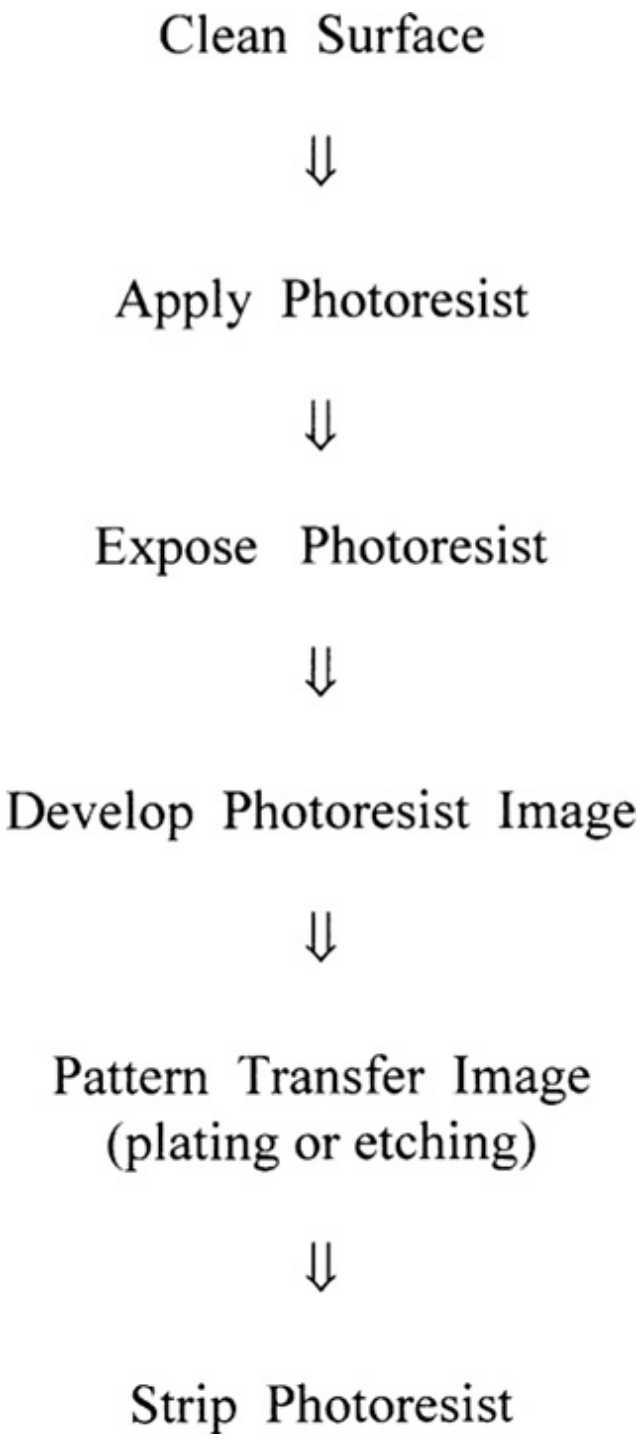

FIGURE 30.1 The photolithographic process sequence.

30.2 PHOTOSENSITIVE MATERIALS

The photosensitive polymeric systems used as photoresists in the interconnect industry are either liquids or dry films formed from a liquid solution. Dry-film photoresists are the industry standard, but liquid photoresists have become widely used, particularly for fine-feature circuits. Liquid resists come in both positive and negative acting, in neutral and electrolytic acting. Both types of photoresist can be used for a variety of processing requirements.

30.2.1 Positive- and Negative-Acting Systems

Photoresists may function in a photographic sense in either a positive or negative tone. The difference, illustrated in Fig. 30.2, is a result of the specific chemical reactions that occur on exposure to light. For the common negative-acting systems, exposure initiates cross-linking between one or more of the components in the polymeric matrix, reducing the photoresist's solubility in the developing solution. The exposed regions remain after development of the image. For positive-acting photoresists, the chemistry is often the novalac resin-based materials utilized by the semiconductor industry. Upon exposure, an acid-catalyzed reaction occurs that increases the solubility of the photoresist in the developer solution. In this case, it is these exposed regions that are removed in the developer solution.

Photographic tone can have an effect on product yield caused by contamination between the phototool with the master image and the photoresist. For a negative-acting photoresist, contamination blocks the light and prevents cross-linking, leading to a mousebite (partial reduction in line width) or an open circuit in the conductor after etching. For a positive-acting photoresist, contamination blocks the light and prevents the acid-catalyzed solubilization, leaving excess metal and a possible short after etching, assuming the resist is utilized in a print and etch process. Since circuit patterns often have a greater area of spaces than lines, there is a lower probability of a contaminant causing an actual defect with the positive-acting photoresist. Defect can be short or open, depending if print and etch or plate and etch. However, negative-acting photoresists are the most widely used since many other factors impact yield and contamination must be minimized in any photolithographic process.

30.2.2 Decision Factors

The large variety of commercially available photoresists makes it a challenge to determine which one is likely to perform best for a given application. Key technical and economic factors that must be considered are summarized in Fig. 30.3. The primary consideration is the end use of the pattern.

Key Considerations in Photoresist Selection

Metallization Process

- Etching
  - –Acid
  - –Akaline
- Plating
  - –Copper
  - –Tin
  - –Tin/Lead
  - –Gold
  - –Nickel
  - –Full-Build Electroless Copper

Imaging Process
- Standard UV
- LDI
- DDI

Panel Design
- Substrate Topography
- Required Copper Thickness
- Number and Size of Holes
- Minimum Feature Sizes

Economic Factors
- Compatibility with Existing Application and Exposure Equipment
- New Capital Equipment Investment Required
- Productivity
- Process Latitude for High Yield
- Material Cost

FIGURE 30.3 Criteria for selection of photoresist materials.

The photoresist must be chemically compatible with the subsequent pattern transfer steps (i.e., can withstand the chemical environment such as the solution pH) for it to function as an accurate mask for pattern transfer.

The nature of the substrate itself in terms of topography and surface features must also be considered. Is the photoresist required to cover or tent plated through holes or tooling features, and must it conform to existing circuitry? This consideration will dictate if dry-film or liquid photoresists are appropriate and, in some instances, the required tone.

The required product feature dimensions are equally important. They are usually specified in terms of line width and spacing with a given allowable variation. Since these product specifications are for the final conductor features, the impact of photoresist processing on the critical dimensions must be established. Each photoresist has an inherent contrast (i.e., the rate of change of solubility on exposure to light). This contrast, combined with the resist thickness, phototool, light source used for exposure, and developing conditions, determines the finest feature that can be imaged. For photoresists used in the PWB industry, the minimum line width achievable in production is usually 10 to 25 μm greater than the photoresist thickness. Novel process sequences have demonstrated it is possible to overcome this traditional barrier.[2]

The adhesion of the photoresist is another key attribute. The chosen photoresist must have good adhesion to the underlying substrate during pattern transfer but must also be able to release cleanly from the substrate during stripping.

Key consideration that can effect resist selection is UV versus laser direct imaging (LDI).

30.3 DRY-FILM RESISTS

Dry-film photoresists are generally used for pattern formation prior to both plating and etching.

These films have a three-layer structure, with the photosensitive material sandwiched between a polyester coversheet and a polyethylene separator sheet (see Fig. 30.4). The photoresist thickness is typically 25 to 50 μm, but thinner and thicker films are used for special applications. The photoresist is applied to the PWB substrate using lamination: The polyethylene separator is removed, and the photoresist flows under the heat and pressure from the laminating rolls to adhere to the substrate. The polyester coversheet performs several key functions. It protects the photoresist during handling, prevents sticking to the phototool during contact printing, and acts as an oxygen barrier during exposure. The optical properties of this polyester coversheet are important, especially for producing features less than 100 μm.

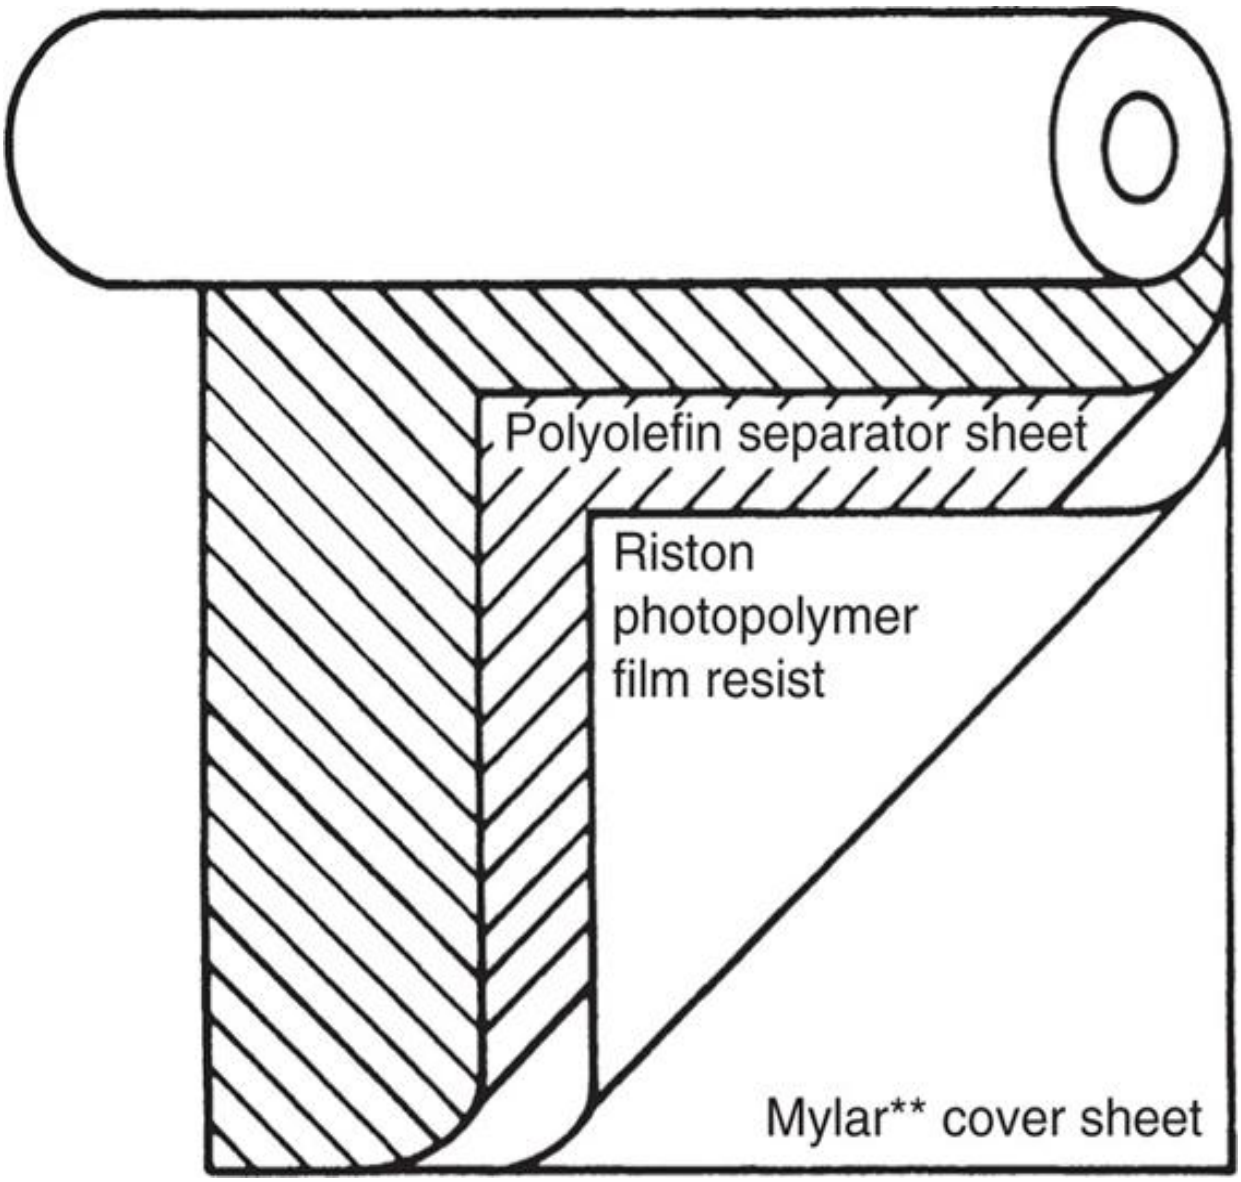

FIGURE 30.4 Dry-film photoresist components. (*Reprinted with permission of DuPont Electronics, DuPont Technical Literature*.)

Dry-film manufacturers have increased the optical clarity and reduced the thickness of the polyester sheet to achieve the required image quality. Thin dry films of 25 μm thickness and less generally use this high-quality coversheet.

The chemical and mechanical properties of dry-film photoresists have been tailored to withstand various plating solutions and acid or ammoniacal-etching solutions. They

can be grouped in terms of the processing chemistry used to develop the image:

- *Aqueous-developable:* This group is the industry standard.
- *Semiaqueous-developable:* These are used in special applications.
- *Solvent-developable:* This is the original system (see Table 30.1). Since solvent development used chlorinated hydrocarbons, use of the solvent-developable photoresists has generally been abandoned.

TABLE 30.1 Summary for Dry-Film Photoresist Types and Chemistries

Photoresist Type	Develop Solution	Strip Solution	Application
Aqueous-processable	Sodium/potassium carbonate	Sodium/potassium hydroxide	Acidic solution: etching, plating Limited alkaline solutions: alkaline etch
Semiaqueous-processable	Sodium tetraborate/ Butyl cellosolve	Ethanolamine or Butyl carbitol/Butyl cellosolve	Alkaline solutions: etching, precious metal plating
Solvent-processable	(Methyl chloroform) Alternate to CFCs	(Methylene chloride) Alternate to CFCs	Strong alkaline: full-build electroless Cu plating

30.3.1 Chemical Composition Overview

Dry-film photoresists vary in their exact chemical compositions, but all contain the following components[3]:

- Polymer backbone
- Photoactive compound
- Monomer
- Dye
- Additives: The polymer backbone sets the fundamental solubility and chemical resistance of the system.

On exposure, the photoactive compound absorbs light of the appropriate wavelength and subsequently reacts with the monomer to alter the solubility of the film in exposed areas. The dye changes color on exposure to provide a visible latent image of the master pattern in the film, referred to as the printout image. Although the printout image decreases the efficiency of the desired photoreaction by consuming a portion of the exposed photoactive compound, it has proven to be a valuable manufacturing aid and is used in almost all dry-film photoresists.

Additives include adhesion promoters, flexibilizers, and other compounds that can improve a desirable property. All the ingredients function together to provide the process latitude needed for the photoresist’s specific range of applications.

30.3.2 Aqueous-Processable Dry Films

The majority of materials used are based on an acrylic polymer with various forms of photoreaction initiation. The initiator’s absorption is designed to coincide with the major emission wave- length of the mercury arc lamps in the ultraviolet region of the spectrum at 365 nm.

Many are based on the use of Michler’s ketone and its subsequent sensitization of a triplet state promoted radical chain polymerization. This also explains the material’s

sensitivity to oxygen, an efficient triplet quencher. These materials are also very efficient at converting light energy into a chemical reaction due to the radical chain reactions; absorption of one photon of light results in many cross-links in the polymer matrix. Usual exposure doses measured as the irradiance from 330 to 405 nm to cross-link these materials functionally vary from 25 to 90 mJ/cm^2 depending on the exact chemistry used and the thickness of the materials, which compares favorably to positive-acting materials used for optical lithography in semiconductor integrated circuit (IC) production, where doses of 200 to 500 mJ/cm^2 are common.

The images in these materials are developed in alkaline solutions of 1 percent or less by weight of sodium or potassium carbonate. The complete removal of the photoresist after pattern transfer is accomplished in 1M or greater solutions of sodium or potassium hydroxide at elevated temperatures, often with an antitarnishing additive to limit oxidation of the copper. Thus, in general, these materials exhibit excellent stability in acidic solution, but they do have varying stability to more strongly acid and alkaline solutions. In fact, there are three subclasses of materials: for acid etching of copper, for acid plating of copper, and for alkaline (ammoniacal usual) etching of copper. Increased acid stability is required for use in acid copper plating, in which the pHs of the solutions often are below 1. For ammoniacal copper etching at pH 8 to 9, increased alkaline stability is required. This latter capability illustrates the flexibility in tailoring these materials to their end use since these materials are imaged using similar alkaline chemicals: develop at pH 10.3 and strip at pH 13. Often these alkaline-stable materials are developed at high temperatures.

In the past, several photoresists were formulated for exposure at a visible wavelength, 450 nm, using specialized exposure equipment—visible lasers or magnified projection

printing. Laser direct imaging (LDI) based on the Ar^+ laser output clustered around 360 nm has been commercialized and is becoming more popular for fine line processing and complex designs that require enhanced registration protocols. Direct digital imaging (DDI) is now also being used, based on Texas Instrument's proprietary DLP™ technology of digital micromirror devices (DMD). Conventional photoresists can be exposed on LDI and DDI equipment, but higher photospeed has been key to the productivity and economics of LDI/DDI.

Photoresists requiring only 10 mJ/cm^2 are commercially available for the major applications. In general, these high-speed photoresist processes are similar to conventional ones, but improvements include photospeed, sensitivity to yellow safelights, and postlamination hold.[4]

Novel aqueous-developable photoresists have been formulated to process in dilute acidic media. A dry film based on electrophoretic depositable (ED) materials was shown to have excellent stability in strong alkaline solutions, potentially useful for etching polyimides or for full-build electroless copper plating.[5]

30.3.3 Semiaqueous- and Solvent-Developable Dry Films

Semiaqueous-developable photoresists are used when increased resistance to chemical attack is required, such as the highly alkaline solutions used in polyimide etching or gold and precious metal plating applications. Their composition is similar to the aqueous-developable photoresists, but the polymer backbone is less alkaline-soluble. This increased chemical stability provides accurate image transfer by maintaining the integrity of the surface and sidewalls and minimizing underplating. Semiaqueous-

developer chemistry is slightly alkaline (sodium tetraborate) and contains an organic assist, typically butyl cellosolve. Process control for this mixture is more complicated than that used for aqueous development.

Solvent-developable dry-film photoresists were the first to be commercially produced. Since they are the only materials that can withstand the harsh conditions in some chemical processing sequences, they still have some interest. They are based on methyl methacrylate polymers and a Michler's ketone initiation system similar to that used for aqueous-developable photoresists. Although they can have very high contrast, they are prone to scumming, leaving residue in the spaces between exposed photoresist features after development. Slight etching of the underlying substrate is often required to have a clean image-transfer step, especially for pattern-plating applications. Traditionally these materials were developed in trichloroethane and stripped in methylene chloride. However, as the hazards associated with chlorinated hydrocarbons were recognized, use of these solvents has been practically eliminated. This has forced the use of alternative develop and strip chemistries for solvent development.[6]

30.4 LIQUID PHOTORESISTS

Liquid photoresists come in a variety of chemistries.[7] Many are simply coatable forms of the dry-film materials. They have been used primarily for patterning innerlayers and are applied to the substrate by roller, spray, curtain, or electrostatic coating techniques. These methods are discussed later in the chapter (with equipment). Applied thickness is typically 6 to 15 µm, giving superior resolution compared to dry-film resists that are generally thicker. Since resolution is approximated by the thickness, they have the

ability to resolve features less than 25 µm. Conformation of liquid photoresist to the copper substrate is generally very good, and it is possible to achieve high yield at 50 µm features and less.[8] However, cleanliness of the substrate and the coating and drying operation is critical. Liquid photoresists are dried to allow for hard contact with the phototool during exposure, maximizing resolution. If soft or off contact is used, resolution and yield decrease, especially for features 100 µm or less. For the majority of liquid photoresists, the developing and stripping conditions are similar to those for aqueous-developable dry films: mild alkaline sodium carbonate and strong alkaline sodium hydroxide. Exceptions are positive-acting novolac-based photoresists, thermal photoresists,[9] and negative-acting acid-developable photoresists.

30.4.1 Negative-Acting Liquid Photoresists

The chemistry of the typical materials is similar to that of the aqueous-developable dry films. They depend on a radical chain reaction to promote cross-linking in the acrylic polymer. Their sensitivities differ depending on the initiator system chosen. Materials are available with minimal solvent content, and a few are diluted with water.[10,11] This reduces the emissions from coating and drying that must be contained and treated.

Acid-developable photoresists mentioned in the dry-film aqueous section can also be formulated as electrophoretic-depositable liquids. These materials have high contrast, good resolution, and chemical stability in strongly alkaline solutions since they are developed in aqueous acid solutions.

30.4.2 Positive-Acting Liquid Photoresists

The other alternative is a positive tone novolac resin-based system that finds its application most usually in the semiconductor industry for imaging integrated circuits. It has excellent resolution and chemical stability in acid and a large number of basic solutions (precious metal plating). The chemistry involves the conversion of a base-insoluble diazonaphthoquinone to the base-soluble indene acid. Thus, this photo-driven conversion alters the solubility of the base material in alkaline solutions, allowing for image formation (see Fig. 30.5).

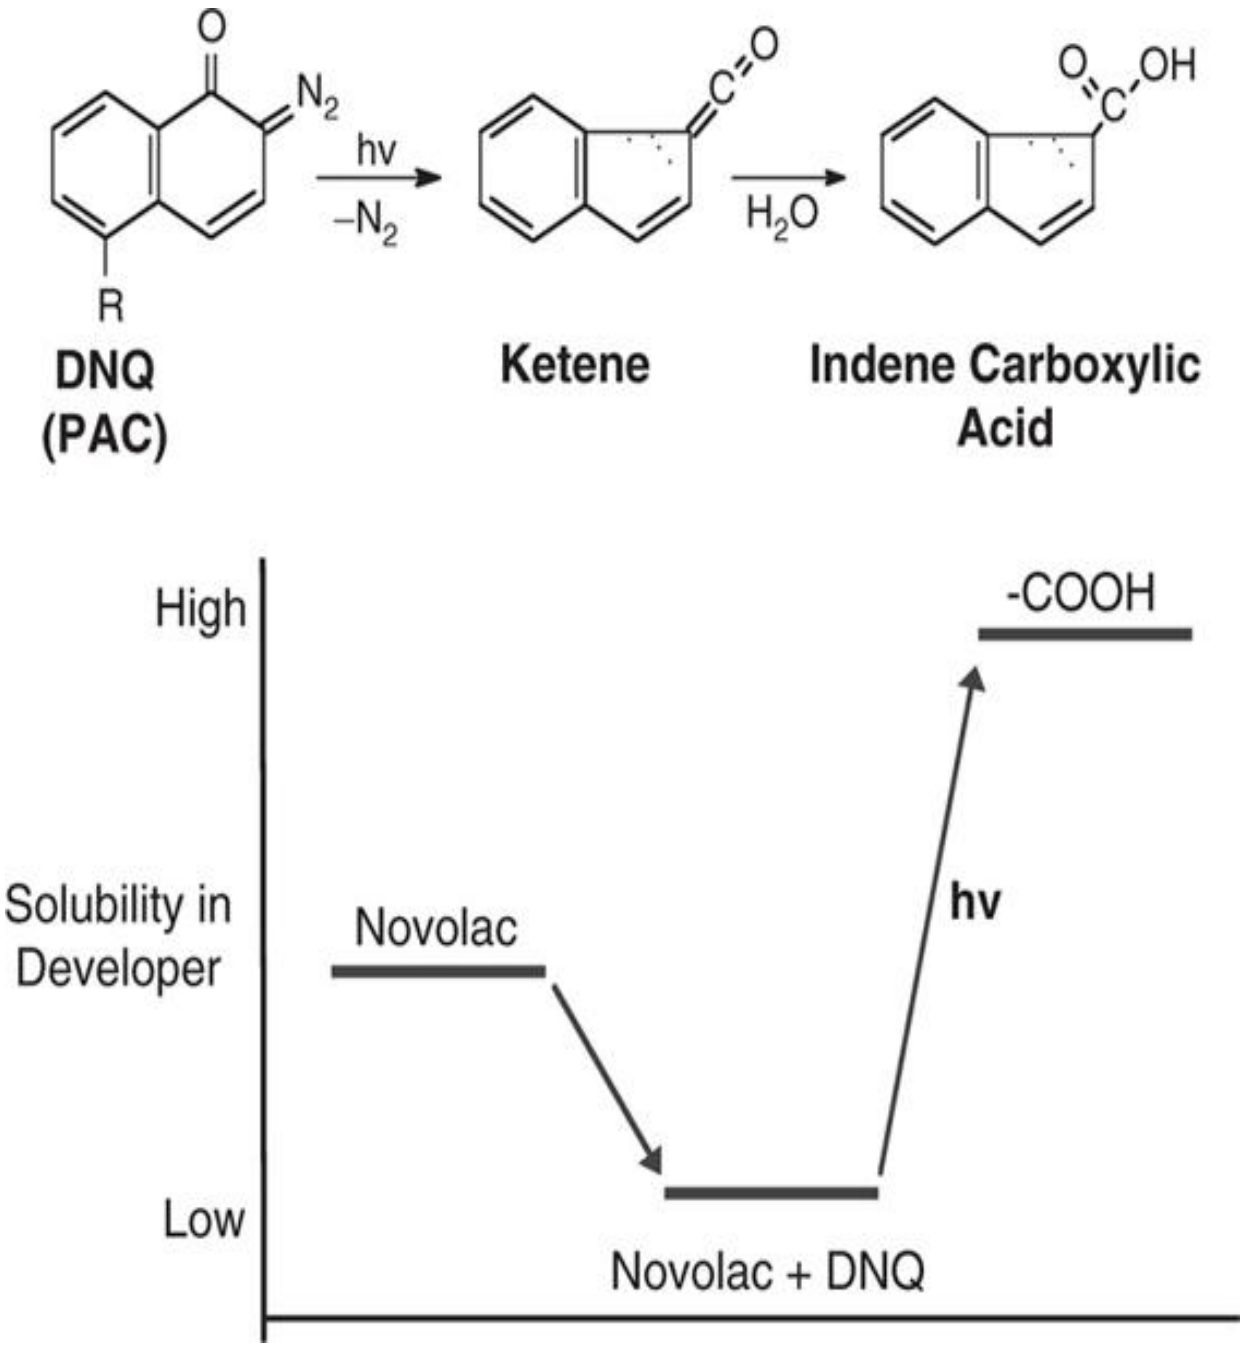

FIGURE 30.5 Chemistry mechanism of positive-acting liquid photoresists.

30.5 ELECTROPHORETIC DEPOSITABLE PHOTORESISTS

Electrophoretic depositable (ED) photoresists[12,13] were introduced in the late 1980s with expectations of broad adoption by the interconnect industry. The early materials were modifications of those used for coating automobiles and appliances. These fast-coating processes provide a defect-free film of high durability on conductive substrates and are well suited to large-volume production. Anodically and cathodically deposited materials that are both positive and negative acting have been introduced but have achieved limited market penetration in the interconnect industry. Advances in dry-film photoresists and liquid photoresists reduced the interest in implementing a new photoresist process. (A detailed discussion of electrophoretic depositable photoresists is included in Sec. 17.1.6 of the fourth edition of this handbook.)

30.6 RESIST PROCESSING

Imaging is a sequential process, and the various steps are very interdependent. Equipment and processing conditions play a large role in the image quality, yield, and productivity that can be achieved. The choice among the numerous options for each step depends on the type of substrate to be imaged, the feature sizes to be produced, the existing equipment, the type of photoresist, and the productivity and economics of the production line. Alternatives for each process step are described and compared.

30.6.1 Cleanliness Considerations

Cleanliness is an issue throughout the entire photolithography process, including yellow room contamination level (cleanliness class), solution filtration, equipment cleanliness class, and product handling. Its

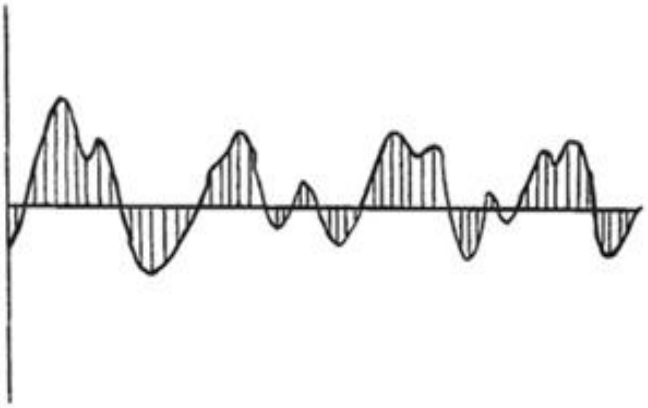
importance increases as feature size decreases. The level of cleanliness needed to give acceptable yield for the finest features must be established and maintained.

Sticky rollers, either as free-standing equipment or as handheld items, are one type of equipment used to remove contamination from flat surfaces, either panels or equipment.

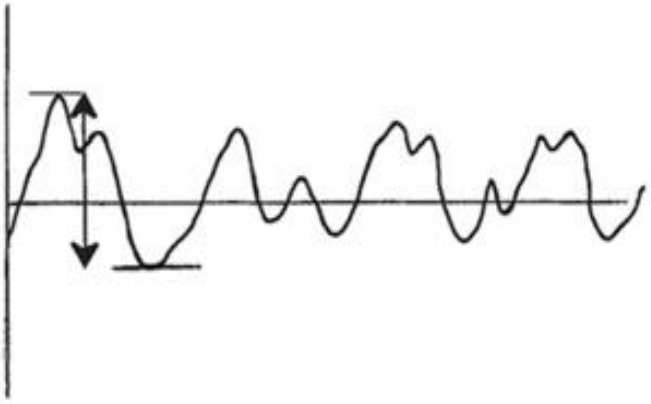
30.6.2 Surface Preparation

Good adhesion between the photoresist and the substrate is essential for the remainder of the process to be successful. All laminates arrive at the imaging area, dirty, and the exact process sequence for surface preparation is chosen based on the nature of the contamination. Epoxy dust generated during trimming and processing of the laminate is removed by mechanical cleaning. The copper surface is either foil or foil with electroless or electroplated copper. Foil typically has an antitarnishing agent of chromium and zinc that must be removed for reproducible imaging results. During cleaning, the texture or surface roughness of the copper is altered, promoting mechanical adhesion between the copper and the photoresist. The extent of this texturing is measured by the usual parameters for surface roughness, the height and spacing of the topography measured by profilometry (see Fig. 30.6).

R_a Arithmetic mean of all departures from the mean line



R_{max} Maximum peak to valley height within sampling area



R_m Mean spacing between peak measured at the mean line

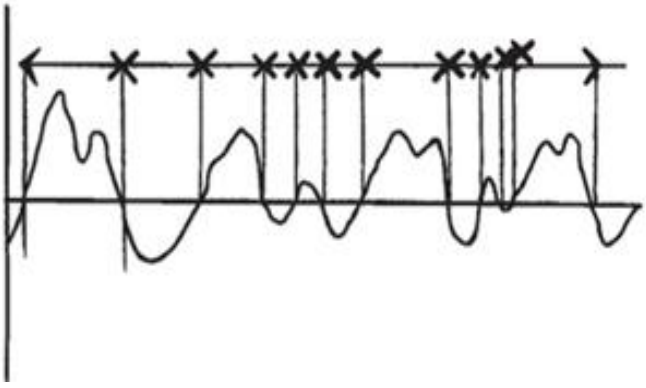


FIGURE 30.6 Surface roughness parameters.

Chemical cleanliness can be determined in a variety of ways. Wetting is often tested using a *water break test* or

more analytically in terms of contact angle, with a low value being desirable.

In addition, analytical techniques (Auger and x-ray photoelectron spectroscopies) can be used to evaluate the chemical composition of the surface (see Table 30.2).[14]

TABLE 30.2 Copper Surface Chemical Composition as Measured by X-Ray Photoelectron Spectroscopy (XPS)

Sample	% Cu	% O	% C	% N	% Zn	% Cr
Initial		46	24		16	12
Preclean 1	12	19	68			
Preclean 2	6	10	70	14		

30.6.2.1 Mechanical Cleaning. Most mechanical cleaning equipment physically abrades the copper surface using a pumice or aluminum oxide slurry either directly (scrubbing or vapor blasting) or impregnated into brushes. Scrubbing provides an even final surface texture, whereas brushing creates grooves (see Fig. 30.7). The copper thickness must be sufficient to provide the desired final conductor height after cleaning. Mechanical cleaning is more difficult for very thin flexible panel and should only be used on cores>0.020 in. (0.52mm)due to registration issues caused by mechanical distortion of the cores.

FIGURE 30.7 Comparison of the pumice cleaned (*a*) and mechanically abraded copper surfaces (*b*), 1200×. (*Reprinted with permission of D. P. Seraphim, R. C. Lasky, and C-Y Li*, Principles of Electronic Packaging, *McGraw-Hill, 1989, p. 383*.)

The texture of the mechanically cleaned surface affects the adhesion between the photoresist and the copper. The resist should conform to the topography, and thus, the extent and type of texture must be tailored to the type of photoresist. If

the gouges are too deep, a dry film applied with traditional lamination will have difficulty conforming to the surface and create defects: near or full opens after etching, and underplating or shorts after pattern plating. Thus, the cleaning process, photoresist type, and application method must be matched to image at high yields.

Conveyorized equipment is used that passes the panels through the brushes or slurry and then to rinse chambers before exiting through a dryer section. If rinsing is insufficient, residual pumice can remain on the copper surface. Maintaining proper functioning of the mechanical parts that contact the product is essential since brushes and slurry deteriorate with use. Equipment designs that isolate the abrasive from the majority of the tool are more durable. Conveyorized equipment that utilize brushes can distort thin panels and cause registration concerns of the build-up circuitry.

30.6.2.2 Chemical Cleaning. Chemical cleaning includes a variety of solutions since the solubility of contaminants can be quite different (see Table 30.3). Grease and fingerprints require a soap solution or solvent to dissolve them. Antitarnish treatment removal and copper roughening is done with mild etchants for the copper, such as ammonium persulfate, sodium persulfate, or peroxide/sulfuric acid. Depending on the oxidation level and the amount of antitarnish treatment, there is often an induction time for copper removal. Solutions used can be common chemicals or proprietary mixtures in which surfactants and other additives have been included. Alternatively, the oxide and antitarnish treatment can be removed initially, followed by a surface roughening. In this case, the oxide removal is accomplished with mild acidic cleaning solutions such as sulfuric acid spray followed by adhesion promoter.

TABLE 30.3 Cleaning Solutions Used to Remove Various Contaminants

Cleaning Technique	Process Chemistry	Contaminant Removed
Abrasion	Pumice, Aloxide	All
Plasma	CF_4/O_2, O_2/H_2O	Organic
Chemical solutions (aqueous etchants)	H_2SO_4, HCl, etc.	Inorganic
Chemical solutions (nonaqueous)	Alcohols, etc.	Organic
Thermal	N_2	H_2O

Source: Adapted from *Introduction to Microlithography,* 1st ed., L. F. Thompson and M. J. Bowden, American Chemical Society Symposium Series 219, Washington, D.C., 1983, p. 184.

The selection of the cleaning solution also depends on the copper thickness. Thin “seed” layers used for electrolytic pattern plating can tolerate very little etching, and extremely dilute solutions or dry methods are used. Thus, chemical adhesion can be more important than mechanical.[15] Selection of the proper process chemicals and sequence depends on the overall conductor formation process and the photoresist to be used.

Chemical cleaning sequences are often contained in conveyorized spray equipment with rinsing between each step. Batch processing in a tank system is also used, with a hoist for basket movement between solutions. Uniformity of the etching of panels within a basket must be measured, but is generally quite good and reproducible as long as the immersion time is short and the bath’s chemical composition is consistent.

Reverse treated foil (RTF) or drum side treated foil (DSTF) have a textured copper tooth topography designed for resist

adhesion. Further chemical roughening can effectively smooth out the copper surface. As such, no chemical etching is required on RTF/DSTF copper. A mild cleaner may be utilized to remove grease and fingerprints, and antitarnish coating. Several manufacturers find acceptable yields by not pre-cleaning RTF/DSTF foil and go straight into the resist application process.

30.6.2.3 Electrolytic Cleaning. A unique inline conveyorized tool built by a equipment supplier uses electrolytic cleaning.[16,17] The antitarnish is removed electrolytically along with oils and fingerprints in a uniform process with very little copper removal. The surface texture is then altered by microetching and passivated prior to dry-film photoresist lamination or other coatings.

30.6.3 Photoresist Application

The technique used to apply the photoresist to the substrate depends on the type of photoresist selected. The various techniques used with dry-film and liquid photoresists are discussed. For any of these techniques, the cleanliness of the operation—both the equipment and the room—and the handling of the product are critically important, especially for high density. It is also advisable to minimize handling at this stage by using automated inline equipment for the preclean step and automatic loading and unloading.

30.6.3.1 Dry-Film Hot Roll Lamination. In this process, both temperature and pressure are used to laminate the dry-film photoresist to the panels. After stripping off the polyethylene separator sheet, the photoresist is contacted to the substrate in a nip between two heated rolls. Heat reduces the viscosity of the photoresist and pressure causes

it to flow, conforming to the irregularities of the copper surface.

The weave of the laminate affects the topography of the substrate and how much flow is required to achieve good conformation, an essential condition for high yield. Dry-film photoresists are tailored to have rheology that maximizes flow during lamination while preventing flow in the roll prior to lamination, which could cause edge fusion. Panels are often heated with heated rolls and infrared heaters prior to lamination to improve photoresist conformation. The key process parameters affecting conformation are laminator speed, laminating roll temperature, and rigidity of the rolls with respect to the core material and rubber durometer. Typical rubber durometer is 40 to 50 on the Shore A hardness scale. Durometers of 55 to 65 can be used where extra conformance of the resist to the panel surface is required. For aqueous-developable materials, wet lamination has proven to be effective in improving conformation and yield for innerlayers. By using a water-alcohol mixture, wet lamination can also be applied to tent and etch inner via holes to minimize the land diameter.[18]

Both automatic and manual tools are available for film lamination (see Fig. 30.8). With manual tools, the panel is placed in the nip and pulled through by the rotation of the rollers.

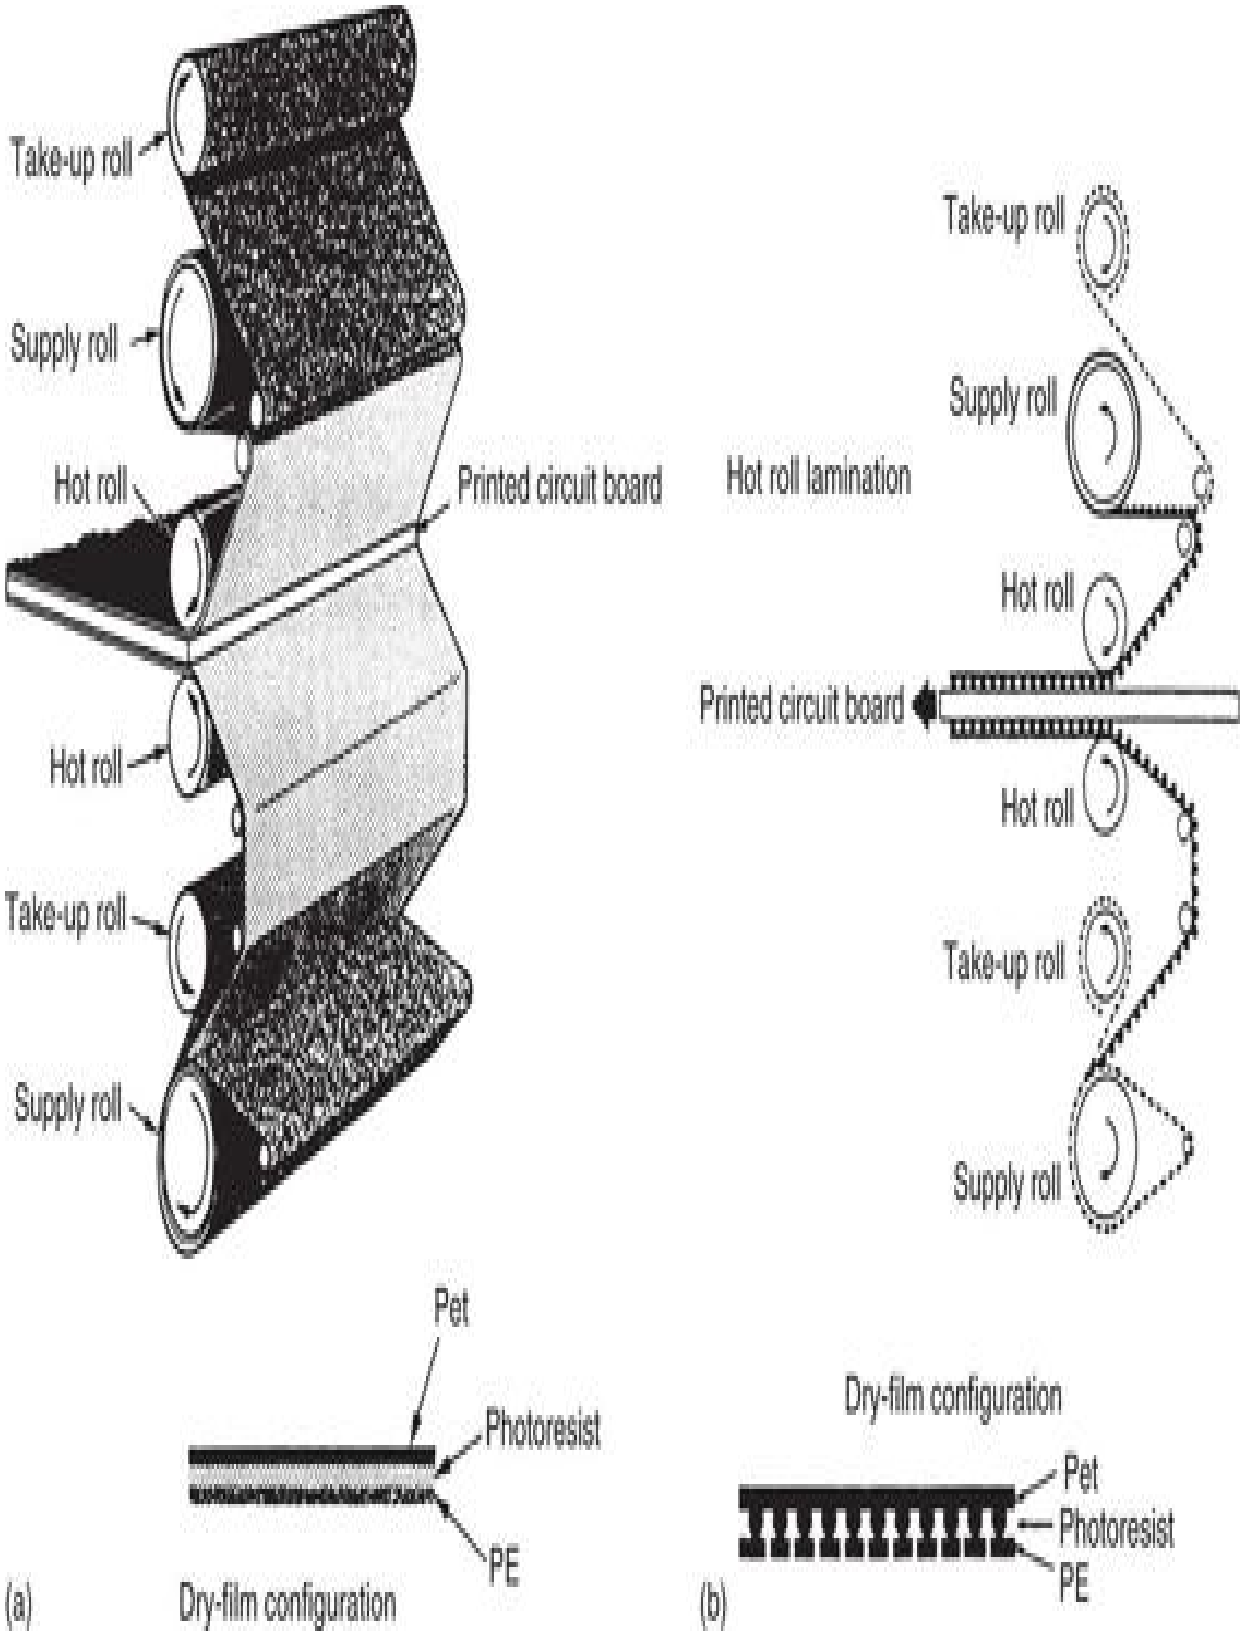

FIGURE 30.8 Configuration of a hot roll laminator: (*a*) three-dimensional schematic, (*b*) two-dimensional schematic. (*Reprinted with permission of E.S.W.*

Kong, Polymers for High Technology, *ACS Symposium Series 346, Washington, D.C., 1987, p. 280*.)

The continuous film of photoresist must be trimmed for each panel on at least two sides. This technique is labor-intensive and extremely dirty due to the chips of resist generated by trimming. However, it is useful for very thin materials and nonstandard-size panels in small lot sizes.

With automatic equipment, the basics are the same but the panel enters from an automatic loader or a conveyorized preclean tool directly into and through the dry-film laminator.

This is a relatively clean operation with little handling of the panels since the photoresist is automatically trimmed to the appropriate size and placed 1 to 4 mm within the board edge. Equipment is available to convey even very thin panels. Panels are often heated, wetted (wet lamination), or cleaned before the actual lamination.

30.6.3.2 Dry-Film Vacuum Lamination. This method is similar to hot roll lamination but the temperature and pressure used to adhere the photoresist to the substrate is applied by a heated vacuum platen instead of laminating rolls. Vacuum lamination is useful for products with tall or closely spaced features that make it difficult for the photoresist to conform. The vacuum removes the air that would be trapped and pulls the photoresist into tight spaces, providing conformal coverage. This equipment is also used for material that will deform nonuniformly under the pressure of laminating rolls, such as thin unreinforced polyimides. With vacuum lamination, the pressure is evenly distributed over the panel, improving dimensional stability control.

30.6.3.3 Liquid Coating. A great variety of methods are used to apply liquid photoresist to panels. Roller, spray, electrostatic, and electrophoretic coating provide double-sided application and are well suited to high-volume manufacturing. Curtain coating is single-sided, requiring

either two passes of the panel through the equipment with slight drying between coatings or an inline equipment layout with two coating and drying units. This causes a difference in the solvent content of the two sides. Screen-coating equipment is available for either single-side or double-side coating. In all instances, the cleanliness of the surroundings, equipment, and solutions is essential for high-yield processing. Most equipment is designed to minimize material consumption by collecting and filtering excess liquid so it can be recycled to the feed tank.

30.6.3.4 Roller Coating. This method places liquid photoresist on the board by transferring the liquid from one set of rollers to another (see Fig. 30.9). The exact number, physical configuration, and surface of the rollers vary, as well as how the material is metered. Often, gravure roller coating is used. Grooves or crosshatches in the rollers that contact the panel determine the amount of liquid deposited on the substrate and are set with a measured overlap or interference so that the board is squeezed between the rollers.19 Photoresist viscosity also influences the coating thickness applied. Improvements in panel handling and in confining the solution to the center of the panel allow for simultaneous two-sided “postage stamp” coverage similar to that obtained with dry-film photoresists, leaving the tooling and location holes clear of material. In commercial systems, the coater is conveyorized, with panels entering a clean oven immediately after coating. The throughput of these systems can be as high as 240 panels per hour.

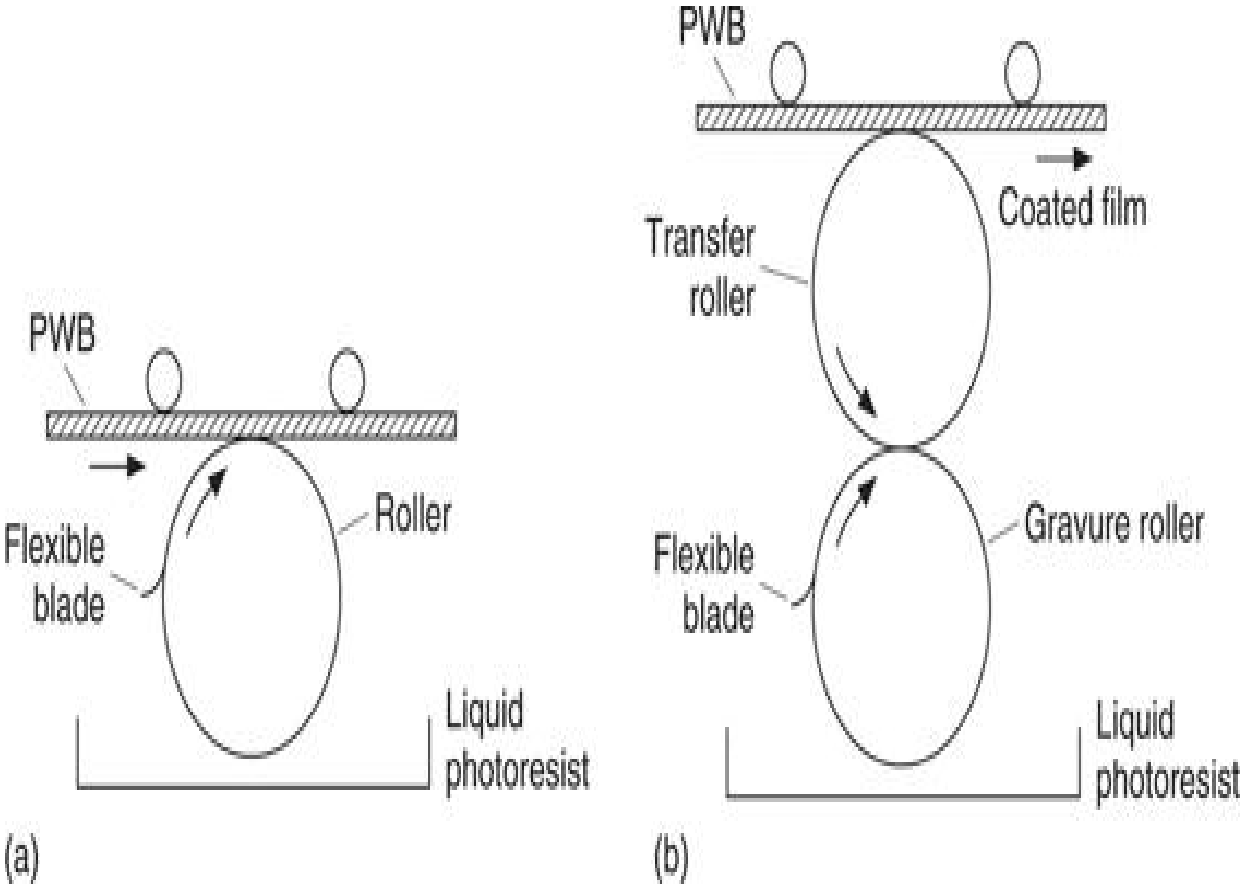

FIGURE 30.9 Configuration of a roll coater: (*a*) direct coating, (*b*) indirect coating.

30.6.3.5 Spray Coating. Although very thin and uniform coatings are possible with this method, its use in resist imaging has been limited due to concerns about waste caused by overspray.

The spray head traverses a larger area than the substrate to be coated, and the amount of liquid photoresist that becomes overspray can be significant. Exact characteristics of the coating in terms of thickness and topographical coverage depend on spray-head configuration, nozzle backpressure, droplet size, and conveyor speed.[20]

30.6.3.6 Electrostatic Coating. This method is similar to spray coating except that the rotation spray head is charged and the panel is grounded. Since the atomized

photoresist is attracted to the substrate, there is less material waste than with spray coating.[21] Electrostatic coating is used for solder mask since it provides good coverage of conductor sidewalls. However, its use with photoresist is limited to innerlayers. It is unsuitable for outerlayers because it deposits a thicker coating on the rim of a plated through hole while leaving its interior uncoated.

30.6.3.7 Electrophoretic Coating. This method requires materials specially formulated for anodic or cathodic deposition. The equipment schematic in Fig. 30.10 illustrates the process sequence: preclean, coat, permeate rinse, rinse, and dry.[22] Panels are placed in the photoresist solution wet or are often sprayed with solution to ensure wetting, especially if the parts have blind or through vias. Voltage is applied, and within 20 s to 3 min an insulating film forms.

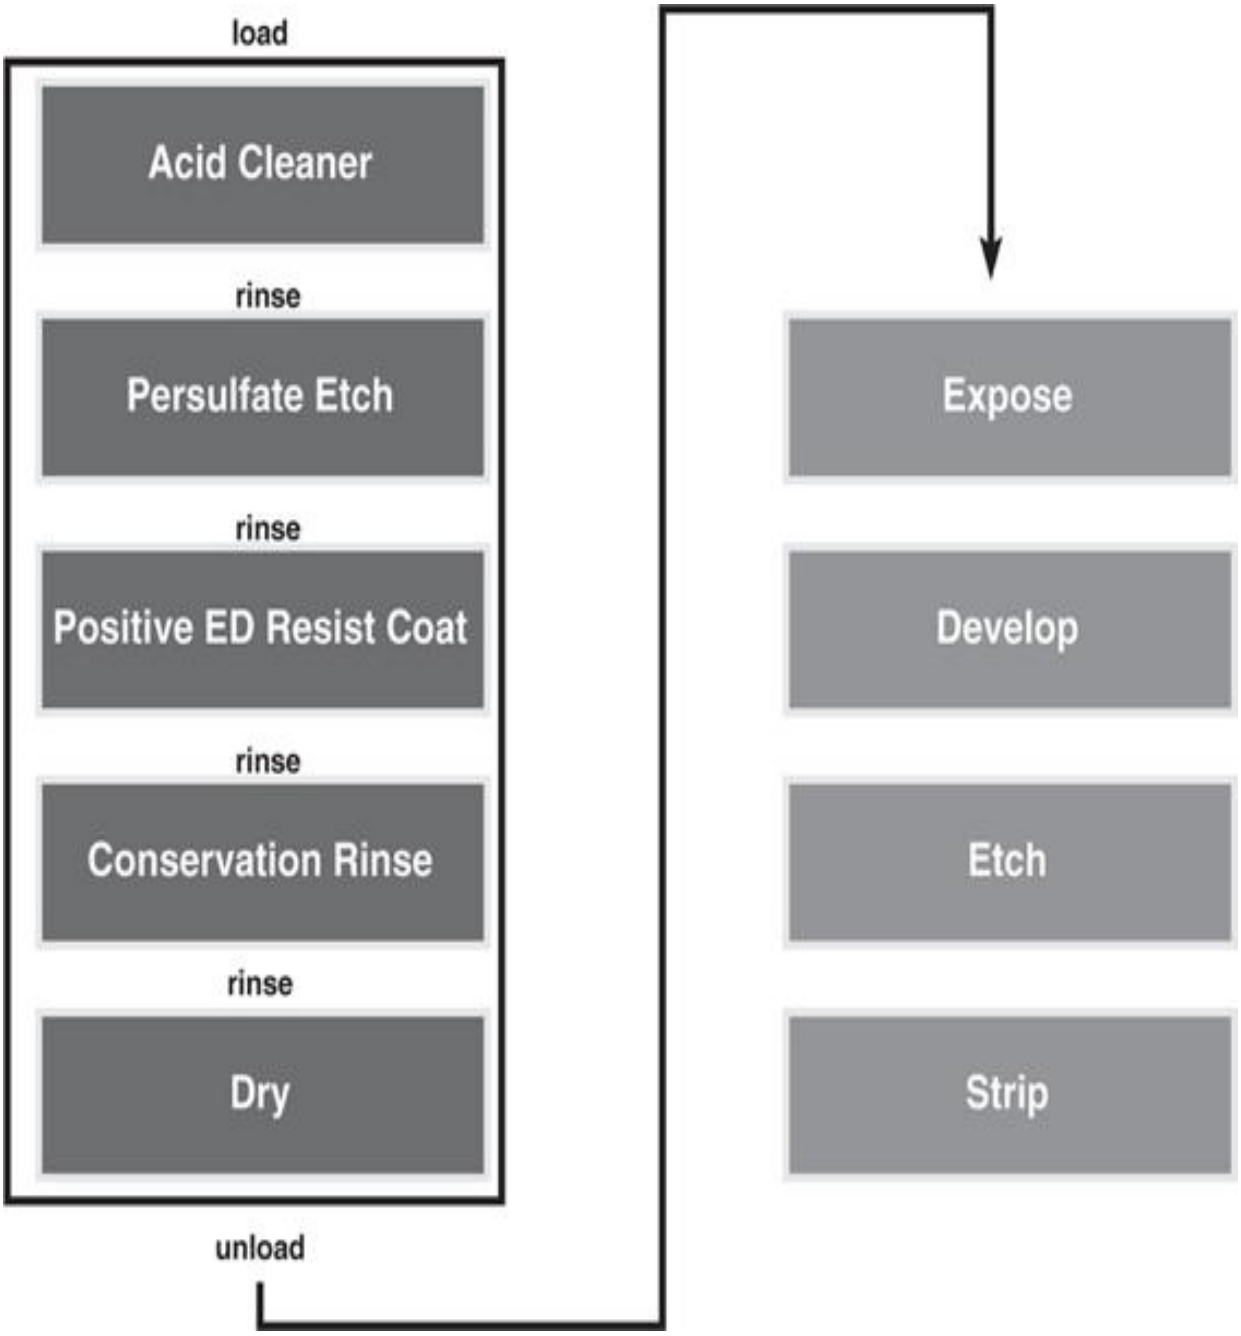

FIGURE 30.10 Configuration of an electrophoretic photoresist coater. *(Reprinted with permission of J. Dubrava et al., "Development of a Novel Positive-Working Electrodeposited Photo Resist Process for the Production of High Density PWB Outerlayers," presentation at the IPC Conference, San Diego, California, Spring 1995.)*

Rinsing removes loosely bound material that is returned to the plating cell after ultrafiltration to separate the

photoresist and the counterion. This aids in maintaining the ionic balance.

After a final water rinse, the panel is dried to remove water and consolidate the film. The film is now tack-free and can be imaged.

The chemical composition of the photoresist determines whether the equipment components are made from polyvinyl chloride (PVC), polypropylene, or polyethylene. Electrodes are made of stainless steel and encased in an ion-selective membrane that is flushed to prevent the build-up of counterion migrating there during deposition. The permeate and ultrafiltration unit is important for long-term stability of the coating solution. The coating unit is often enclosed in a clean environment to reduce the amount of particles found in solution or resting on the panel as the process proceeds.

30.6.3.8 Curtain Coating. This method is commonly used to coat liquid solder mask materials. The panel is conveyed at high speed through a vertically falling curtain of the liquid photoresist. The coating width can be adjusted so that the edges are not covered. Temperature and viscosity are controlled for reproducible coatings, and coating thickness is determined by the conveyor speed and the solution flow rate.[23] Material in the curtain is returned to the sump and reused, giving very efficient material utilization. This method is one-sided, and the first-side photoresist coating must be partially dried before coating the reverse side. Due to the extra handling required to coat one side at a time and the inability to convey very thin panels through the curtain at high velocity, this method has seen only limited use with photoresist.

30.6.3.9 Screen Coating. Another common method for coating solder mask with either a pattern or flood coverage is screen coating. The screen mesh size and the liquid solution viscosity set the wet coating thickness. The screen

is placed above the panel to be coated, and the material is forced through the openings in the screen onto the panel surface, where it forms a film.

Equipment is available for either single-side or double-side coating. With single-sided screen printers, special standoff are used on the screen bed to allow the panel to be flipped and coated on the reverse side. Without these standoffs the coating must be partially dried before the reverse side is coated. This causes a difference in the solvent content between the two sides that would result in nonuniformity for very precise lithography. In addition, the sequential nature of the coating allows debris and contaminants to be embedded into the first coating. Double-sided screen printers eliminate a drying step and minimize panel handling. The advantages of screen coating are that the equipment is relatively inexpensive to purchase and operate, “postage stamp” (small embedded areas) coating is possible, and waste is minimized.

30.6.4 Expose

Expose is the actual imaging step, reproducing the master pattern in the photoresist. The relief image is created after subsequent development. The expose process elements are phototool generation, registration of the phototool to the panel, and exposure through the phototool by the light source. Light-source alternatives include contact printing, either collimated or uncollimated; proximity printing; projection printing; and direct digital imaging (DDI) and laser direct imaging (LDI). The noncontact methods separate the phototool from the substrate, reducing yield losses caused by contamination between the phototool and photoresist. With laser direct imaging (LDI) and DDI, there is no phototool and the design data file of the master pattern drives the laser beam or quartz/LEDs to expose the photoresist.

Phototools are generated on either film or glass substrates, depending on the feature sizes that are being patterned and the durability required. The panel is either mechanically aligned, with pins holding the phototool with respect to the product, or optically aligned, with alignment features dictating the movement of the phototool and product. The alignment requirements are interrelated to those achieved at composite lamination and drilling. The registration scheme is contained within the exposure equipment.

30.6.4.1 Conventional Imaging

30.6.4.1.1 Artwork Generation. Polyester and glass are the substrates used for phototools. They differ in optical properties, dimensional stability, and durability. Silver halide on polyester is used to create first-generation phototools on a laser plotter. This image is often contact printed onto diazo on polyester to make the copies used in production. Optical absorbance of the different phototool materials versus wavelength is plotted in Fig. 30.11.

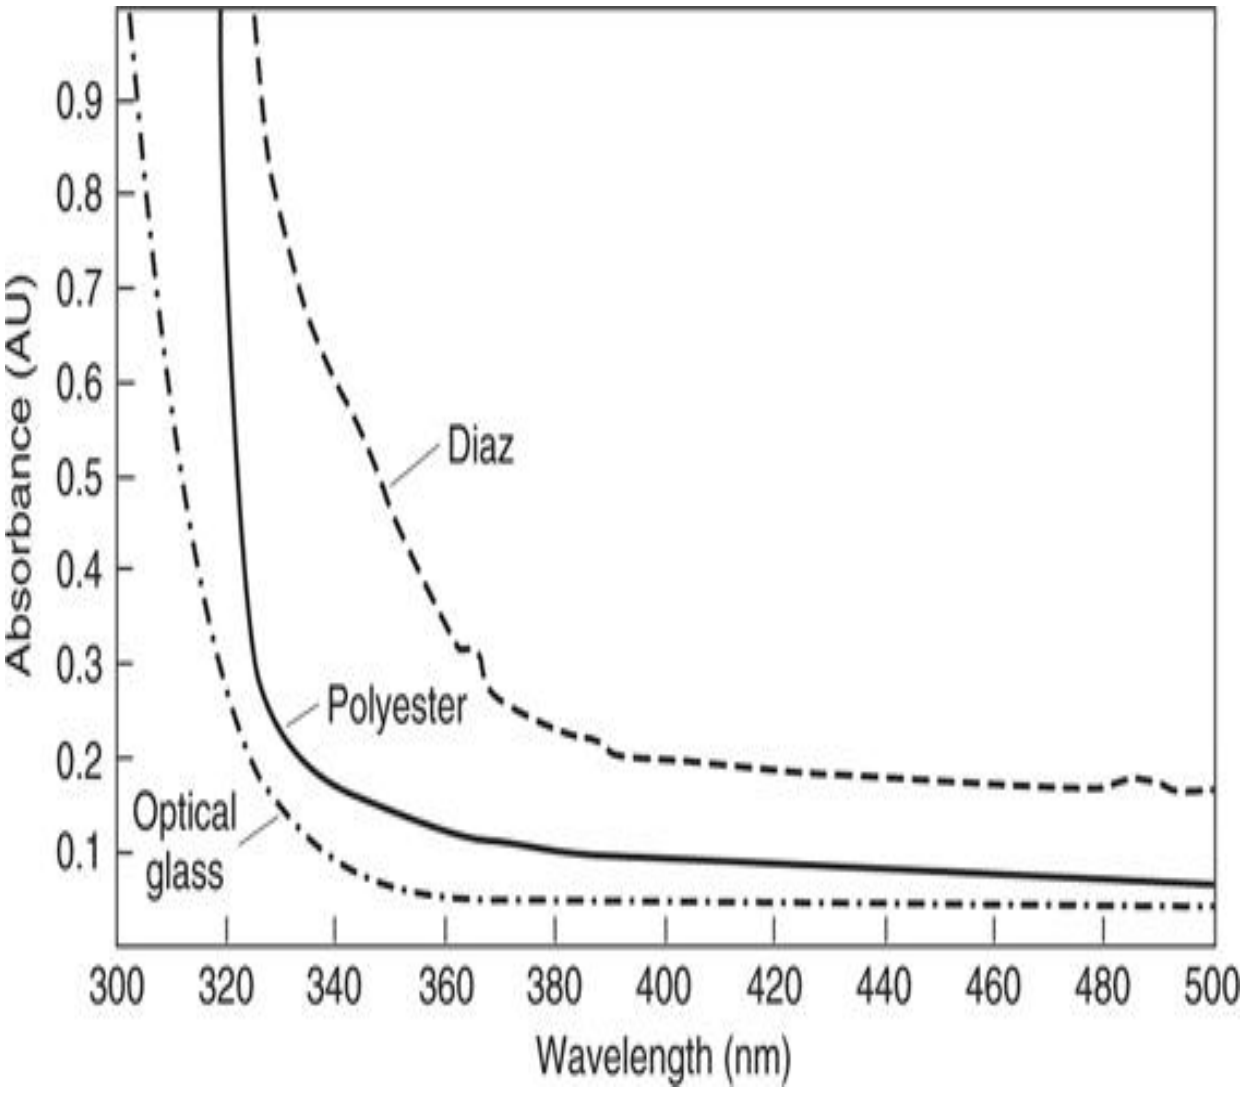

FIGURE 30.11 Optical absorbance of common phototool materials in the spectral region of PWB photoresist exposure.

Diazo phototools are the least expensive, and glass is the most expensive. Although the less-expensive materials have poorer transmission, this property is generally not limiting, except for applications requiring high intensity. Table 30.4 illustrates the impact on exposure time. Edge definition is a major difference among the options, as shown in Fig. 30.12. The photos illustrate that chromium on glass gives the sharpest edge definition. Edge definition is also affected by the pixel size of the phototool plotter and the spot's addressability (see the section on LDI). For applications that

use a low-contrast photoresist and poor light collimation, these differences are not measurable on the printed photoresist image or in the patterned conductor. However, for high-density imaging, edge definition is important, as is the dimensional stability of the phototool.

TABLE 30.4 Comparison of the Optical Transmission of Various Phototool Materials

Property	Diazo	Polyester	Glass
Absorbance at 365 nm	0.271	0.107	0.047
Transmission at 365 nm	54%	54%	90%
% increase in exposure time vs. glass	40	13	0

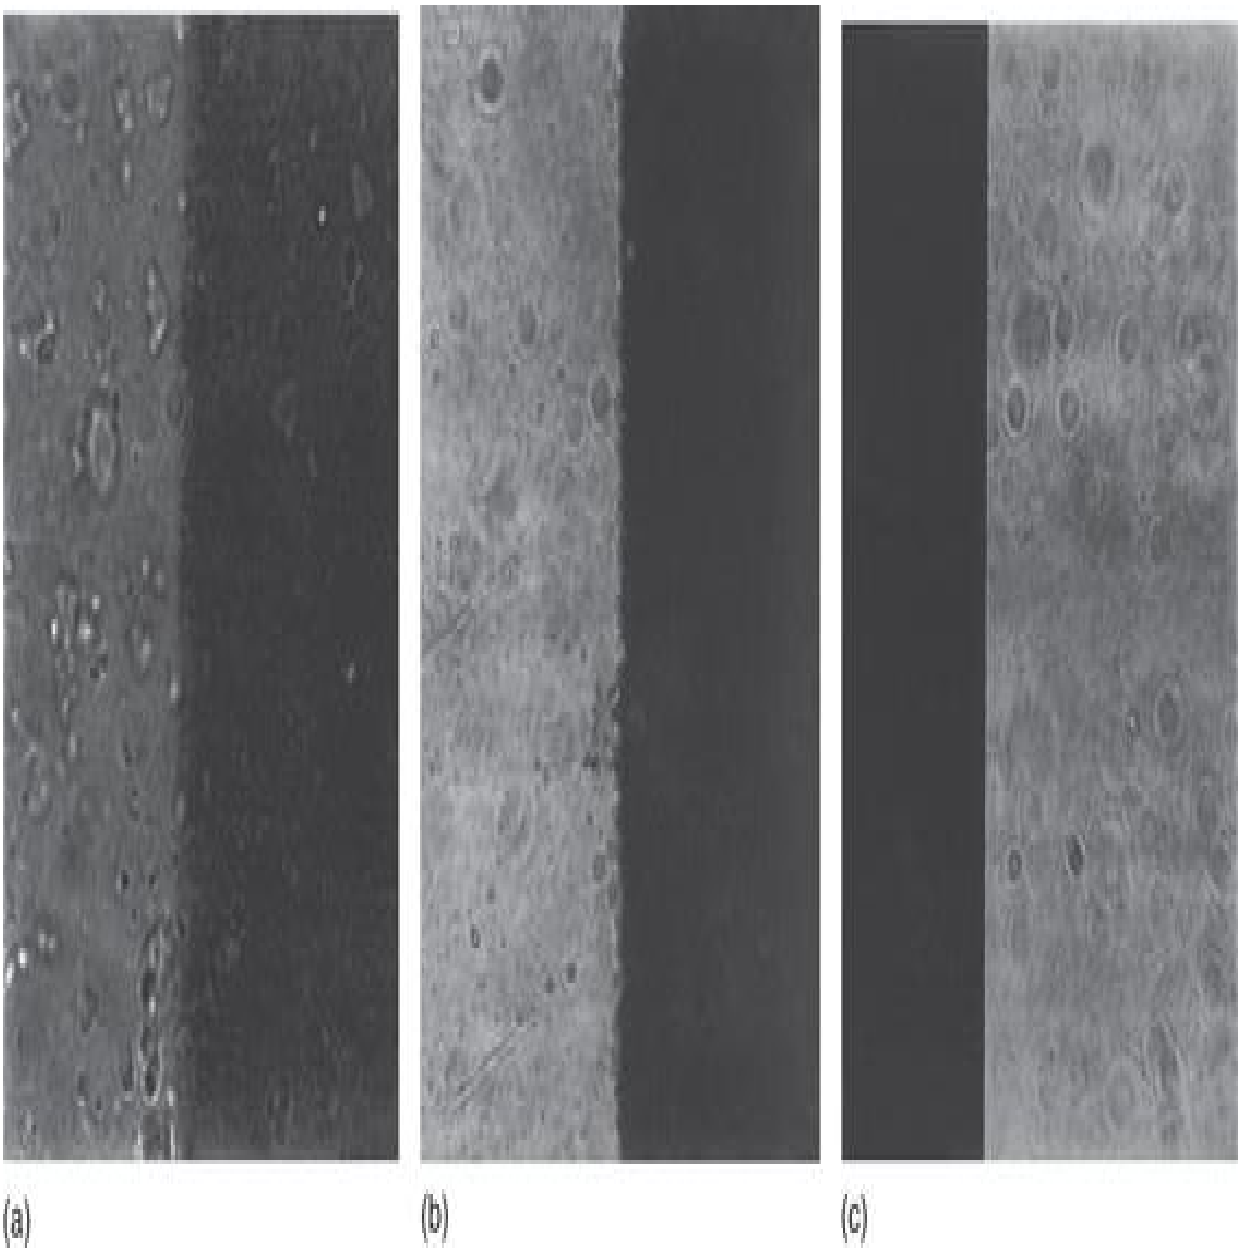

FIGURE 30.12 Optical micrograph of the image edge of common phototool materials, 1600×: (*a*) diazo on polyester, (*b*) silver on polyester, (*c*) Cr on glass.

Film dimensions change more rapidly with temperature than glass and are also affected by humidity. Careful control of both temperature and humidity is required throughout the life of a phototool (see Table 30.5).

TABLE 30.5 Dimensional Stability of Phototool Substrate Materials with Respect to Temperature and Relative Humidity

Substrate	Expansion Coefficient, ppm/°C	Expansion Coefficient, %RH/°C
Soda lime glass	9.2	0
Low-expansion glass	3.7	0
Pyrex	3.2	0
Quartz	0.5	0
Polyester	18	9

The durability of the phototool is also important, especially for use in a manual contact printer. Damage depends on phototool handling, the exposure tool, the cleanliness level of the operation, and the surface of the product being contacted. Commonly, glass artwork is usable for 100 to 400 contacts with repair, while film artwork is usable for 20 to 50. For large numbers of the same part, number cost per contact may actually be lower with glass artwork, while for prototype parts, film artwork is ideal. However, the majority of production panels are exposed with film artwork. High-density applications such as chip scale packaging and multichip modules using laminate (MCM-L) may require glass artwork. The requirements of the product determine the type of phototool that should be used.

30.6.4.1.2 Registration. The image is placed on the panel with respect to a point of reference so that the image is well aligned to previous and future features. In multilayer construction, the innerlayer images are aligned front to back for successful lamination and drilling of the plated through holes (PTHs). The outerlayer image is then aligned to the

drilled holes. The same considerations are relevant for single-layer boards. Thus, accurate alignment is clearly part of the imaging process and also depends on knowledge and control of the dimensional stability of the product. The image must be scaled to match the dimension of the board at the exposure step; for multilayer structures with several photolithographic steps, a series of dimensional measurements are required prior to product manufacture.

Mechanical registration entails the use of fixed pins or other mechanical devices to hold the phototool and the panel in place during exposure. The actual configuration of the pins and their shape varies. Both two- and three-point systems are used. The three-point systems well define the center location since they are located at the extremes of the area to be patterned.

The shapes of the pins are either round or elongated with one flat side. In the latter case, the flat side defines the edge, while round pins center within the hole in the panel and phototool.

Film artwork alignment holes are punched with respect to the product pattern by plotting alignment targets as part of the product pattern and optically aligning and punching a slot or hole. The edges of the punched feature wear, and registration will deteriorate with use. For glass artwork, the glass is drilled at the alignment locations and a bushing is placed at the center of the hole. The pin is then inserted through the bushings in top and bottom artwork and through the panel. With use, the bushings do move and must be reset for maximum reproducibility.

LDI and DDI systems print a target on the reverse side of the undrilled panels to allow for front to back registration. For drilled panels, with multiple drill operations, a complex target is drilled to allow the LDI registration system to consider all the drill files. Some DDI systems can memorize the locations of *ALL* the holes (front and back) and can

manipulate the artwork in real time to have “perfect” registration.

30.6.4.1.3 Exposure Control and Measurement. The role of exposure is to change chemically the photoresist and its solubility in the developer solution. The appropriate energy dose is determined experimentally by measuring the combination of dose and development that is needed to produce features with straight sidewalls. The photoresist is coated on an optically clear substrate and exposed from the backside. Contrast curves, plots of the log of the exposure dose versus the thickness of the film remaining, are used to identify the functional cure point—for example, the dose that loses thickness less than 10 percent (see Fig. 30.13).

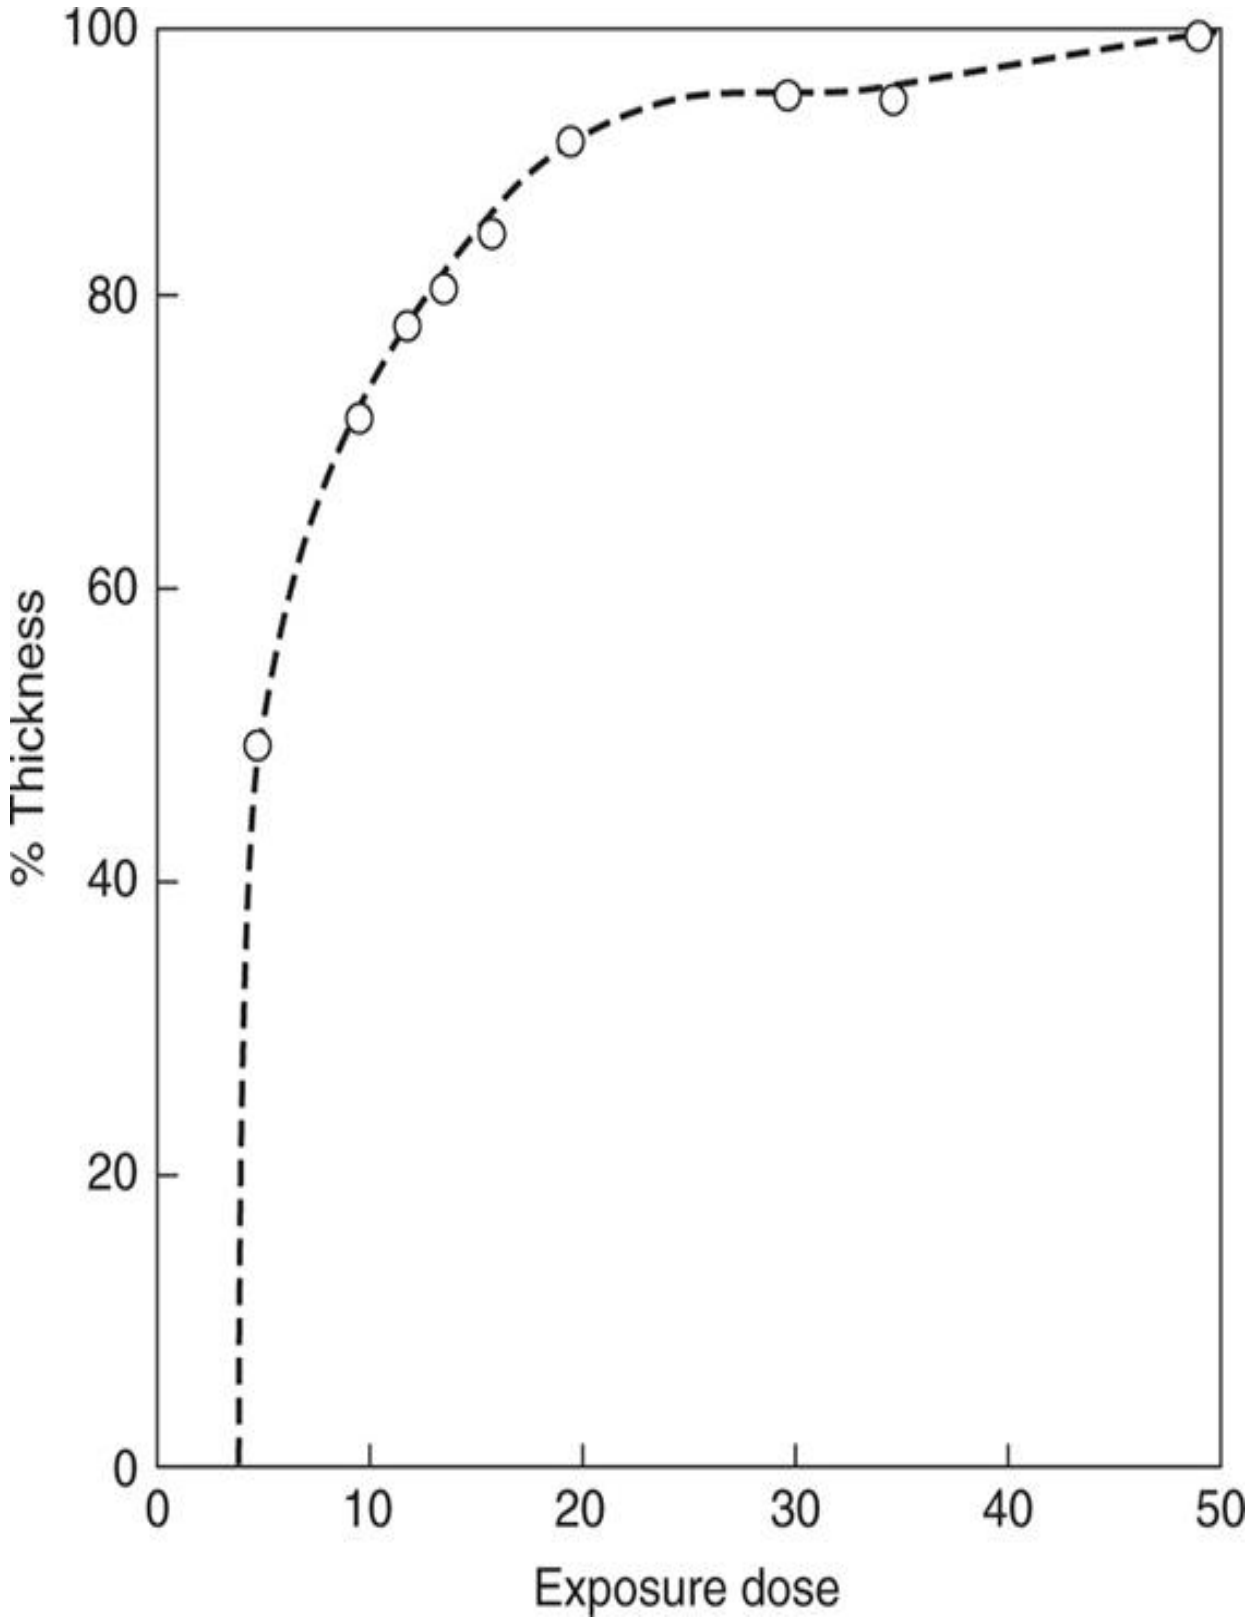

FIGURE 30.13 Contrast curve for a negative-acting dry-film photoresist, percent film thickness remaining versus exposure dose (mJ/cm^2).

Exposure in the region of stability ensures that the base of the material has reacted. Step wedges, film strips with a series of neutral density filters, are also used to determine appropriate exposure doses. The dose is varied to obtain photoresist residue on the area with the manufacturer's recommended step value. This technique depends on appropriate and consistent developer conditions.

Step wedges are often used to control the expose or expose-and-develop processes.

The energy incident on the photoresist is the product of the lamp intensity and the time of exposure:

$$\text{Energy} = \text{intensity} \times \text{time} \tag{30.1}$$

Thus, the exposure dose can either be measured directly by using an integrating radiometer or indirectly by measuring exposure time and light intensity with a radiometer. The radiometer response must be matched to the spectral output of the light used so that representative measurements are made (see Fig. 30.14). Most exposure equipment provides the option of using either direct energy or time measurement. With a stable light source, both approaches are equally reproducible.

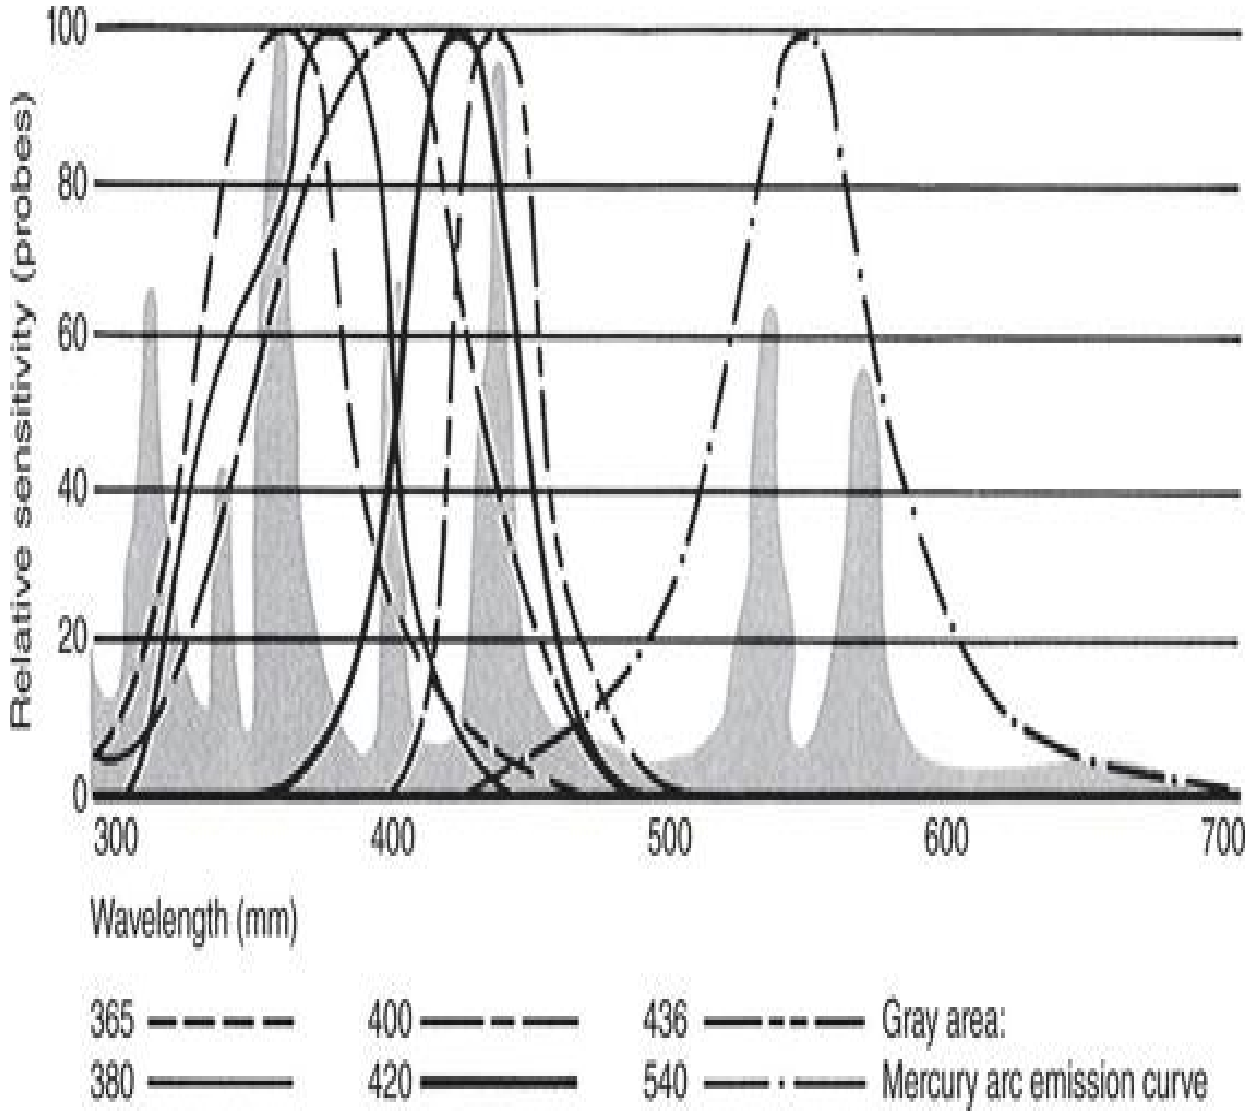

FIGURE 30.14 Output of Hg/Xe light source and radiometers. (*Reprinted with permission of Optical Associates, Inc., Milpitas, California, Technical Literature*.)

30.6.4.1.4 Contact Exposure Tools. This equipment places the phototool and the panel in direct contact and draws a vacuum between the pieces for hard contact. A range of light wavelengths is used, often from a mercury or mercury/xenon light source, which is stable and has a high intensity output at ultraviolet and visible (UV/Vs) wavelengths (see Fig. 30.14). The light is distributed over the area to be exposed by placing the board at a distance from the source, either noncollimated or collimated by the use of optical elements, as shown in Fig. 30.15. Collimation refers

to the angle of incidence of the light onto the photoresist, and it is critically important for fine-line images. Defining fine spaces is the challenge for both additive and subtractive conductor formation, and exposure under the opaque areas cannot be tolerated. The lamp intensity for noncollimated sources is greater, and therefore less time is required to expose the panel. Process throughput is noticeably enhanced for photoresists requiring a large dose.

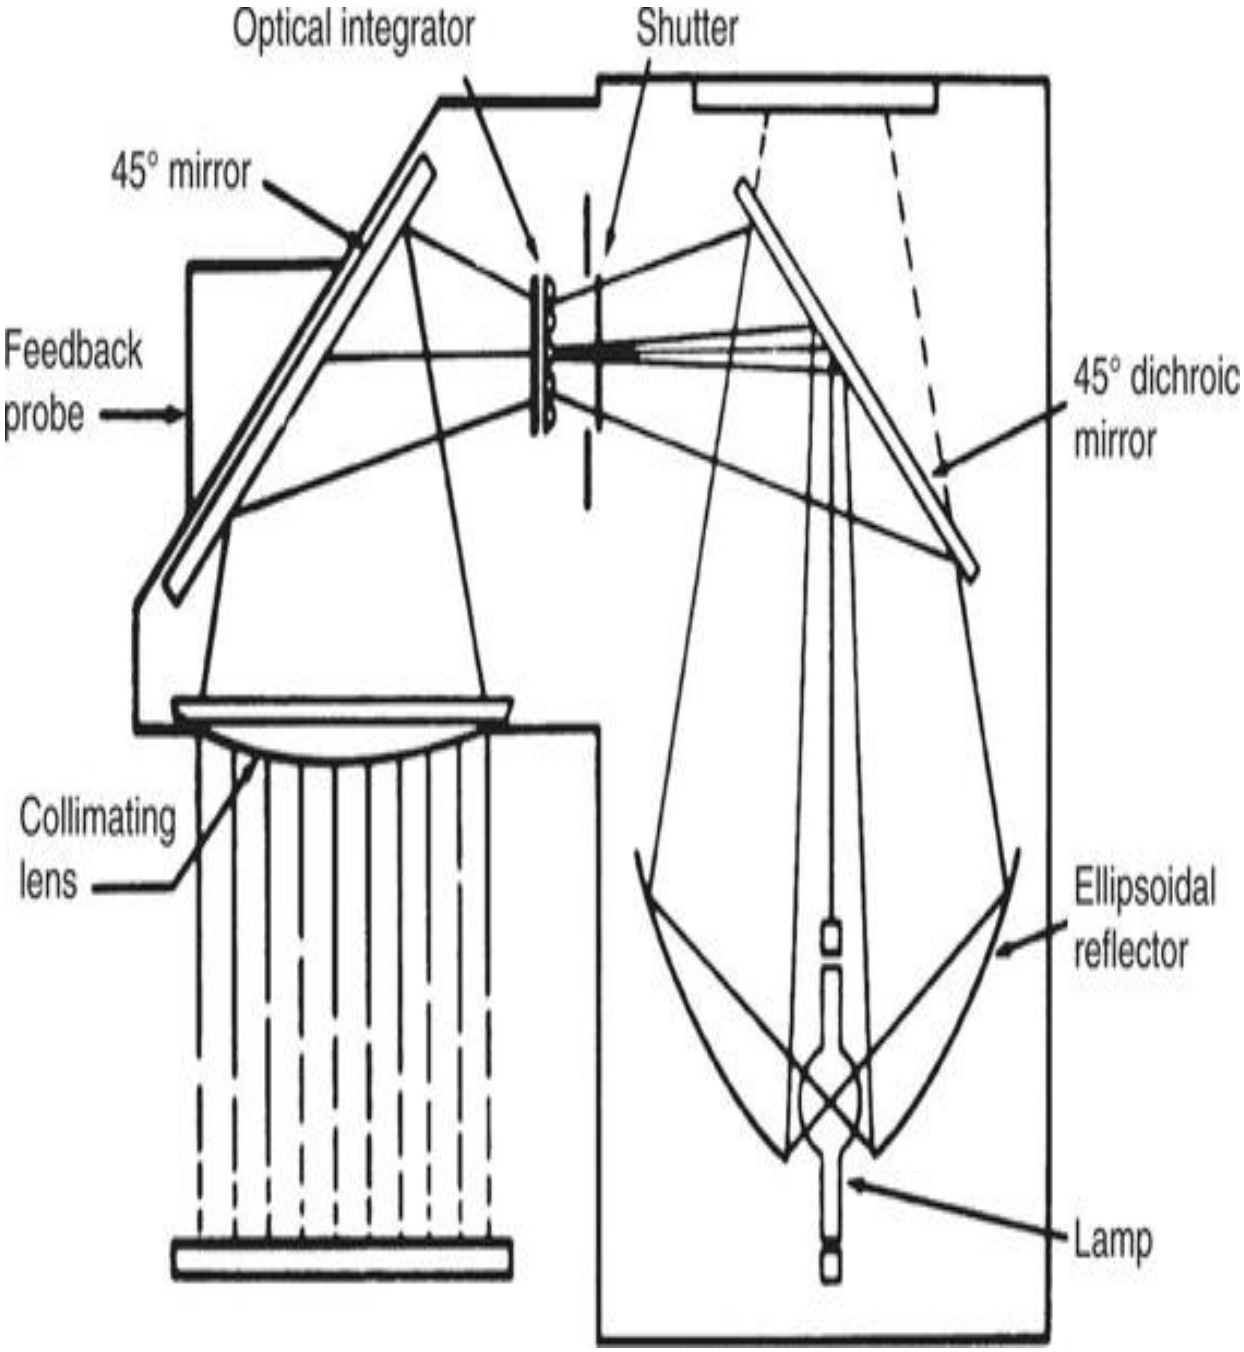

FIGURE 30.15 Configuration of lamp and optics for a collimated contact printer. A noncollimated source is identical except for the collimation lens in the lower left. (*Reprinted with permission of Optical Associates, Inc., Milpitas, California, Technical Literature*.)

In addition to collimation, good contact between the phototool and the panel is the most important factor to control in fine-line formation. Any gap will allow exposure

under the opaque, resulting in poor linewidth control and reduced resolution. The sensitivity to off-contact exposure varies among photoresists, and newer resists are formulated with increased off-contact latitude.[24] Since the lamp's spectral output degrades over time, the lamp must be routinely replaced to maintain a stable photoprocess. The exact frequency for replacement depends on the line and space definition required, but the lamp life is typically 1000 h.

Failure to replace a lamp can result in it exploding and damaging the optical elements in the exposure unit, which is far more costly than routine maintenance.

30.6.4.1.5 Noncontact Exposure Equipment. Semiconductor imaging demonstrated the yield limitations in using contact-exposure equipment. Noncontact methods had to be developed to achieve acceptable conductor yield as critical dimensions decreased to 0.18 µm and below.

The PWB industry is following this evolution, driven by the increased demand for products with fine features of 25 µm and less. Semiconductor tool concepts cannot be used directly due to important differences between IC and PWB products, namely the physical size of the substrate and features to be imaged and the flatness of the substrate. The key to noncontact methods is the use of appropriate optics for clear image placement in the photoresist (Fig. 30.16), even if the image transfer function has degraded. For PWB applications, this includes the depth of focus to allow for panel warpage and the resolving power, given the contrast of the resist. The following approaches address these concerns and are viable alternatives to contact printing.

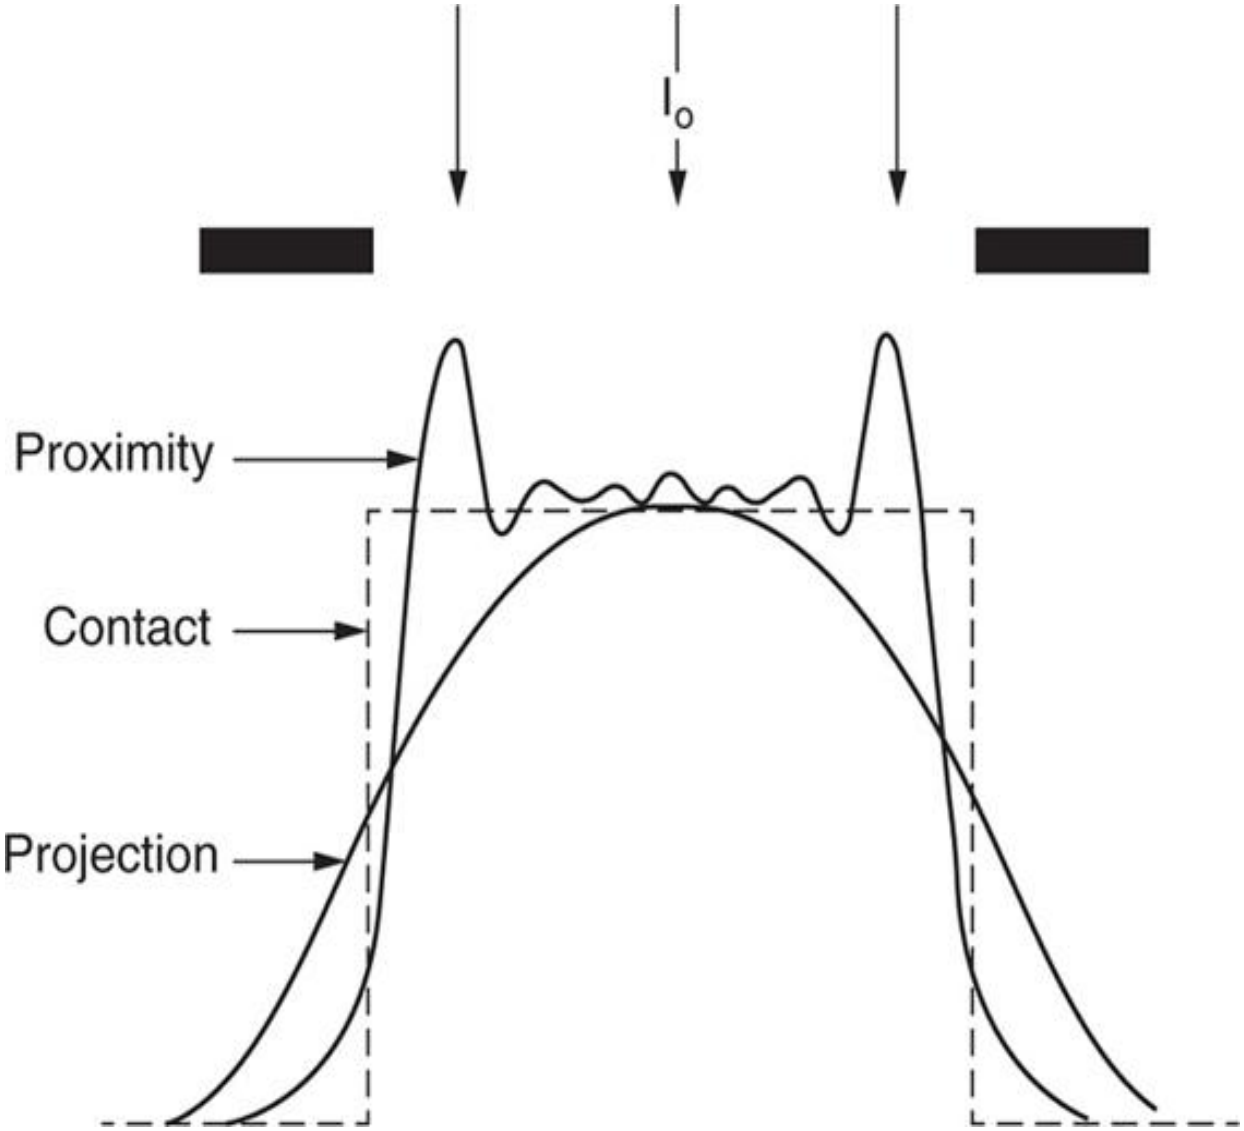

FIGURE 30.16 Image transfer for contact, proximity, and projection printing.

30.6.4.1.6 Proximity Printing. This is the oldest method for off-contact printing and requires no modification to the equipment optics. The phototool is held out of contact from 125 to 500 µm. The image in the photoresist suffers since the distance between the phototool and the part allows exposure under the opaque area and imaging of debris on the phototool. Nevertheless, resolution as fine as 75 µm has been reported for proximity printing with thin coatings of liquid resist.[25]

30.6.4.1.7 Projection Printing. Three approaches are possible for this technique: scanning, stitching, and magnified projection printing. Scanning and stitching evolved from semiconductor and MCM-D thin-film technology, where smaller, flatter substrates are used. They require movement of the phototool and/or the substrate during exposure. Magnified projection imaging is unique to the PWB application and has no moving optical components. A schematic of all three systems is given in Fig. 30.17.

(c)

FIGURE 30.17 Configuration for projection imaging equipment: (*a*) scanning, (*b*) stitching, and (*c*) magnified.

- The scanning printer requires the synchronized movement of the part and the phototool during exposure. Precise alignment of the two pieces must be maintained during the motion. Periodic adjustment for flatness is usually required since this equipment has a small depth of focus. For typical PWB formats, a large phototool is needed, requiring expensive glass phototools for their flatness, rigidity, and sharp line definition. This exposure technique has demonstrated high resolution over a large, relatively flat area using a high-contrast resist.[26] Few PWB applications exist, but the technique is useful for flat panel display manufacture.
- Stitcher projection printers are step-and-repeat tools that use a repeating image or "stitch" together several images. The artwork generation and management in the equipment are complicated, which has hampered these printers widespread use for large panels. The usual active area size as defined by the optics is approximately 6 × 6 in. Thus, for a standard 18 × 24 in panel, 12 artwork changes are required to expose one side. These systems have very high resolving capability and large depth of focus. Again, glass artwork is used, but these smaller plates are easier to generate and use than in a scanning projection printer.
- The magnified projection imaging concept was first demonstrated in the late 1980s with the SeriFLASH exposure tool, utilizing 436 nm illumination and a 5 × 5-in liquid crystal display as the phototool. The image was magnified six times to expose an 18 × 24-in panel, but demonstrated photoresist definition was limited to 125 μm since the liquid crystal features were one-sixth of the final conductor width. The equipment was subsequently modified for 365 nm exposure with a glass phototool to

improve resolution. Fifty-µm line and 63 µm space resolution has been demonstrated.[27] The exposure time required is similar to that of contact exposure equipment. With optimized optics, this may become a high-resolution tool that utilizes conventional photoresist and phototools.

30.6.4.2 Laser Direct Imaging. The LDI method of exposure provides the ultimate in flexibility for customized pattern compensation factors and for engineering changes to the product design since it does not require a phototool. Systems introduced in the 1980s used an Ar^+ laser with visible optics, requiring specialized photoresists that were sensitive to visible light. Improved Ar^+ systems relied on the UV wavelengths, making it compatible with conventional photoresists. However, high-speed photoresists were needed to achieve the productivity for high-volume production. Concerns about the lifetime (3000 to 5000 h) and power consumption (60 to 80 kW) of gas lasers led to development of solid-state laser systems at various wavelengths.[28,29,30] The initial solid-state laser systems used 355 nm with a polygon mirror to scan the panel. LDI systems have used digital mirror devices (DMD) instead of polygon mirrors and image at a wavelength of 405 nm. Filters are used to block 355 nm light, extending the lifetime of the DMD device. Due to the small size of the individual mirrors, about 1.5 µm, DMD technology provides better resolution than an 8000 dpi polygon mirror system. However, the area coverage is smaller and several DMDs working in parallel are needed to expose a PWB panel. Systems have also been introduced that use no photoresist at all, laser ablating either tin for use as an etch resist or physical vapor deposition (PVD) copper on polyimide for use as a plating base.[31,32] In addition to varying in laser type and wavelength, specific equipment designs differ in optics, either single- or multiple-beam operation; platen design; single- or double-side exposure; pixel shape; and spot size and resolution.

Multiple-beam operation increases exposure productivity, a key requirement for economic feasibility in large-volume manufacturing. Target production rates for the various systems ranged from 60 to 180 panels per hour (18 × 24 in with 50 μm features). Initially, LDI systems have been used primarily for prototype and small-lot, quick-turn production of high-density boards. For these applications, savings are achieved due to artwork elimination and reduced setup time. For volume production of medium- to high-technology boards, it is possible to achieve an economic return through yield savings and the ability to produce designs that had not been technically or economically possible with conventional imaging.[33] LDI technology makes it possible to scale the electronic data and compensate for dimensional changes in sequential build-up (SBU) structures. Although the UV systems can expose conventional photoresist, use of high-speed photoresist is needed to maximize tool throughput. Most LDI systems use a flatbed platen design and can image both innerlayers and outerlayers.

Systems with an external drum architecture, similar in design to laser photo plotters, are limited to innerlayers because the panel must have sufficient flexibility to conform to the drum (Fig. 30.18). The pixel shape can be either square or gaussian. Square pixels are made up of many point sources of light and can theoretically achieve perfect stitching. However, in real systems there is intensity variation due to mechanical vibration and edge rounding. Gaussian pixels use a single-point source and may have less intensity variation. Due to the diffraction-limited nature of light, greater depth of focus can be achieved.[34] Figure 30.19 illustrates that imaging with a smaller laser spot size gives steeper aerial image sidewalls, increasing process latitude.[35] In addition to spot size, addressability of the beam is important in determining the system resolution, as shown in Fig. 30.20.

In selecting an LDI system, you must consider both the capital cost and operating cost. However, the critical factor is that the equipment combined with the photoresist material is capable of achieving both the resolution needed for the product mix and the productivity needed for the production volume. Photoresists for LDI are available that are compatible with the various metallization processes.[36]

30.6.4.3 Direct Digital Imaging. Very fine line imaging (<10 µm lines/spaces) has the growing need for

- High through-put using conventional photoresists
- "True position" imaging of small features over large formats
- Improved layer-to-layer registration
- Incremental-expandable image resolution and size
- The "scaling" of an image, i.e., changing the image dimensions and/or shifting the image for best-fit registration to a shifted or distorted reference image, on group or individual board basis
- Lower cost of ownership for an direct imaging system

These needs are now met through improved capabilities of the direct digital imager, with longer life and lower power consumption of conventional or "improved" UV lamps, LEDs or lasers and compatible with the vast majority of photoresists for primary imaging as well as soldermasks with reasonable photospeed.

Some attempts to introduce UV- LDI exposure machines (Etec DigiRite 2000, Automa-Tech DI2700, Barco Gemini) were abandoned but others are still being actively sold by Pentax' DI-2080, Hitachi DE-F, ORC, Fuji Film INPREX and notably Orbotech's solid state Paragon™-Xpress9 imager. The DDI units come from Maskless Technologies, Dainippon Screen Mercurex LI-9500, KIWO Screen Setter and Hitachi DE-S and DE-H series.

A typical DDI unit using high-pressure mercury UV light (as seen in Fig. 30.21) will have typical characteristics of

- Minimum feature size: 15 µm L&S
- Edge roughness (line width variation): ±1 µm
- Position accuracy (repeatability): ±1.0 µm
- Side-to-side registration: ±10 µm (3 sigma)
- Exposure time: 20 s for 530 × 650 mm
- Source wavelength: 350 to 425 nm (i-line to h-line)
- Source life: >3 years
- Other features: auto scaling/auto numbering/automatic loader + unloader

In their various configurations, they can be customized for (1) high output (up to 5000 panels per day), (2) fine-pitch (down to 8 µm L/S), or (3) combination of fine L/S and high-output (20 mm L/S and 2 panels per minute).

30.6.5 Develop

In this process step, the solubility difference between the exposed and unexposed areas of the photoresist creates a relief image of the master pattern. The panel is immersed in an appropriate solvent, and the process conditions are adjusted to control the clearing time for dissolving the unexposed areas for negative photoresists or exposed areas for positive ones. Total dwell time is set to approximately double the time to clear, commonly called a 50 percent breakpoint. Solution concentration, temperature, and agitation are key variables. The resulting photoresist images should be distinct, with vertical sidewalls. Failure to achieve this indicates that one of the previous steps requires adjustment. For images larger than the phototool dimension, the cause is either incomplete development, overexposure, or poor contact during exposure. For images that are smaller

than expected, either the exposure dose is too low or development is too aggressive. Distorted images can be caused by problems with preclean, application, or exposure. The common equipment for developing is spray conveyorized, either horizontally or vertically.

Additives are used in the developer solution to prevent foaming. The solution is filtered to remove resist particles and either replenished with fresh solution to maintain a consistent dissolved resist content and solution concentration or operated continuously for a certain amount of product and then replaced. Waste-developer solution is treated (aqueous and semiaqueous) or distilled and reused (solvent). Rinsing is important in stopping the dissolution and, for aqueous photoresists, water with a high-mineral content often improves the resist image and the conductor yield. Tank systems can also be used with photoresists that have a wide-process latitude. Ultrasonic agitation was formerly used to aid in the dissolution.

There are additional steps that improve the resist removal in the line channels and the conductor formation yield. Plasma treatment has been used effectively to improve product yield, especially with respect to shorts in a print-and-etch process. In addition, for some aqueous-developable dry films, a heat treatment after exposure has improved the space definition, and spaces equal to or smaller than the resist height have been resolved. Thus, these process steps ensure that tight resolution requirements can be met.

30.6.6 Strip

After the pattern transfer has been completed, the photoresist is removed from the substrate using equipment similar to that used for development. The stripping solution swells and dissolves the photoresist, stripping it either in sheets or as small particles. The equipment design must

effectively remove and separate the skins. Brushes and ultrasonic agitation are added to aid in the resist removal. As with developing, filtration is important to keep the spray nozzles clean and keep fresh solution reaching the panel. For stripper chemistries that oxidize the copper, an antitarnishing agent is often added either to the stripping solution or as part of the rinsing.

30.7 DESIGN FOR MANUFACTURING

As design features are continually reduced to produce higher-density interconnects, tighter control of every step in the conductor formation process is required to achieve high yield. The maximum possible yield with an etching or plating process depends on the conductor dimensions such as the conductor pitch in terms of line and space, the conductor thickness, and the size and shape of the capture pads around plated through-holes (PTH) and vias.

30.7.1 Process Sequence: Etching versus Plating Considerations

For a specific circuit design, there is often a question of the appropriate process sequence. Although the capabilities of imaging and the pattern transfer step dictate the overall limitations, the decision depends on the unique capabilities of the manufacturing line to be used. Some general considerations can clarify the true issues for most production situations.

Photoresist patterning has different constraints for etching and plating. For etching, a thin photoresist is desirable to maximize the etchants' attack in the channel developed in the photoresist. Resolution does not limit the process, since

very small spaces can be resolved in either liquid or thin dry-film photoresists. The etching process itself is key to conductor formation.

Etching the copper from the channel becomes increasingly difficult as feature size is reduced, particularly for thicker metal layers. Therefore, the key criteria defining the capabilities of the print-and-etch process is the minimum space cleared, constrained by the final conductor height and the etchant chemistry and equipment.

For pattern plating, the photoresist thickness must be greater than or equal to the maximum final plated thickness of the copper on the base copper, and it must be possible to develop a photoresist channel equal to the final conductor width. As conductor thickness increases, it becomes more challenging to produce channels with a higher aspect ratio. Since photoresist resolution is on the order of its thickness, it would be difficult to resolve smaller than a 38 µm photoresist channel for 25 µm thick plating, irrespective of the final conductor spacing. Thus, the challenge for pattern plating is to resolve and develop fine channels in thicker photoresist materials and then ensure that the plating solution wets the bottom of the narrow photoresist channels.

Thus, in choosing the conductor formation process, the thickness of the conductor and the linewidth and spacing are the key parameters. A generalized relationship between them is found in Fig. 30.23. It is important that this type of plot is known for the production area before the process sequence is determined.

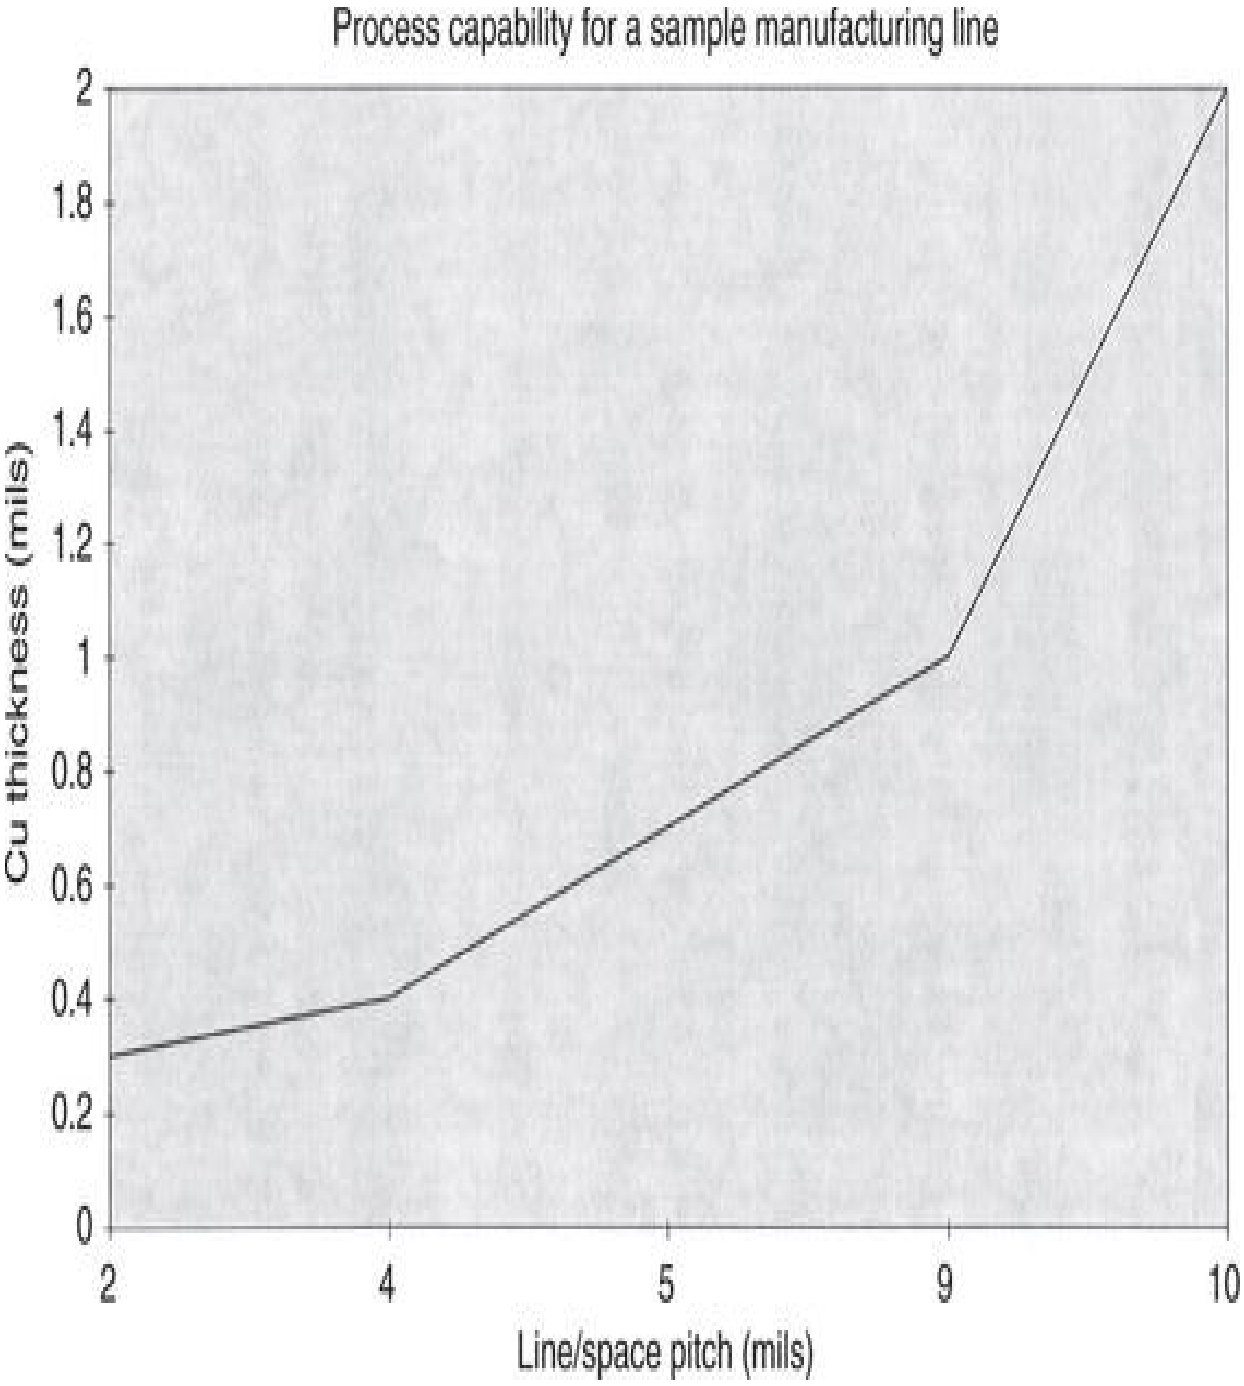

FIGURE 30.23 Sample plot of manufacturing line process capability to aid in processing sequence decisions.

30.7.2 Line and Space Division for a Fixed Pitch

It is common for product designs to have a fixed pitch, whether it refers to the I/Os for direct chip or packaging attachment or to the spacing between PTHs. This space is often divided equally between conductors and spacing. For etching or pattern-plating processes, avoiding their respective resolution limitations can increase the pattern transfer yield.

In etching, the etchant undercuts the photoresist and an etch factor is used to obtain straighter sidewalls and improved linewidth control. If lines and spaces are equally allocated in the circuit design, then the photoresist must resolve a smaller space than a line. This is difficult for fine features, except for very thin photoresists. For fine pitch, having a larger space than line will give higher yield. For pattern plating, the spacing in the photoresist is the limiting factor. After pattern transfer, this will become the line. In this instance, equal line and space is more acceptable, but based on the photoresist concerns, a wider final line than space is preferred. At the same time, it is desirable to increase the spacing for reduced incidence of line shorting, which translates to a wider “line” in the photoresist. The former is usually more important. Therefore, for both processes there is preferably balance between linewidth and spacing.

30.7.3 PTH Capture Pad Size and Shape for Optimum Line Formation

Just as the conductor line and spacing can be optimized, the PTH capture pad shape and size can also be altered to increase the yield. The absolute dimension of the feature is dictated by the placement accuracy of the drilling process and the overall dimensional stability of the product. The feature is sized to ensure that the PTH and conductor are connected. There are varying specifications as to the extent of capture that is required.

Feature dimensions above the line would be processed with pattern plating, and those below the line with print and etch.

Depending on the direction and magnitude of the dimensional stability and the drill wander and accuracy, the shape required to capture the PTH can be changed. This would reduce the size of this feature in at least one direction. In consequence, the spacing between the line and pad increases. Since this location is a change to the nominal line-to-line spacing, the narrowing of the channel results in shorting between the features in both a print-and-etch process and additive processes. In the former case, it is more difficult to clear the space, and in the latter, the narrower resist width is often underplated. Thus, when possible, an elongated pad will benefit the final conductor yield.

30.8 INKJET IMAGING

An *inkjet printer* is a type of computer printer that creates a digital image by propelling droplets of ink onto paper, films or in our application, printed circuit laminate. Inkjet printers are the most commonly used type of printer and range from small inexpensive consumer models to very large professional machines that can cost up to thousands of dollars. Direct printing of the resist, legend or solder mask can save many processing steps in fabrication.

Thermal-inkjet heads use a thin-film resistor to heat and “volatilize” a “portion” of the ink to produce a bubble that will drive the ink out through its nozzle. The figure below (Fig. 30.24) shows this process, as compared to the piezo effect. Piezo printheads are made by Xaar, Trident, Seiko-Epson, Kyocera, Konica-Minolta, Dimatrix, and Ricoh.

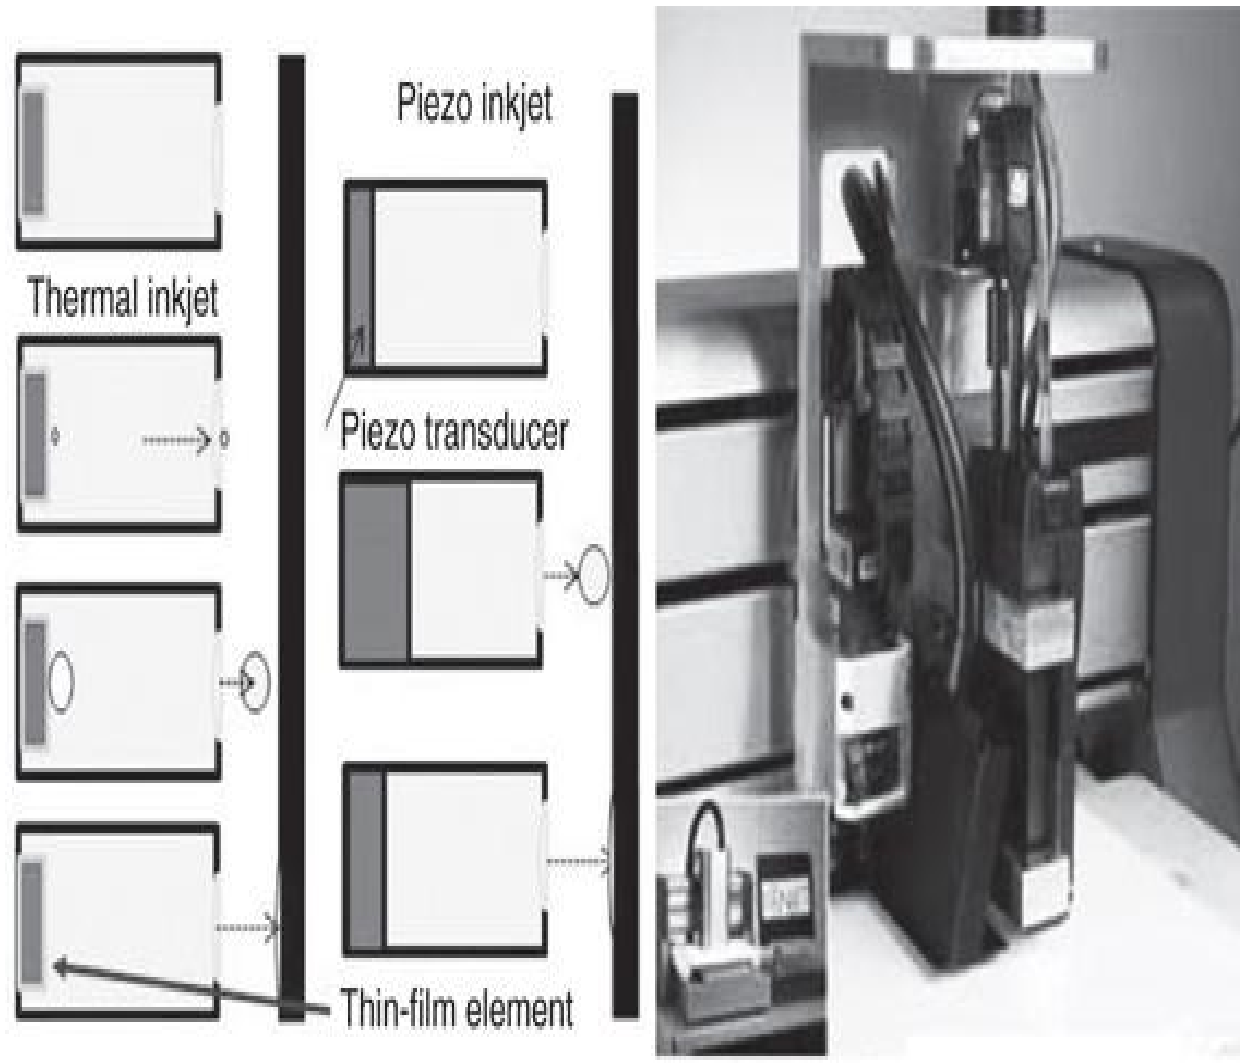

FIGURE 30.24 Thermal and piezo inkjet printing elements. Typical large format inkjet printers for legend, solder mask, print-and-etch innerlayers or plating resist.

Inkjet printers, especially models produced by Dimatix (now part of Fujifilm), JetXpert, Xennia Technology and Pixdro, are in common use in many labs around the world for developing alternative deposition methods that reduce consumption of expensive, rare, or problematic materials. These printers have been used in the printing of polymer, macromolecular, quantum dot, metallic nanoparticles, carbon nanotubes, human proteins, etc.

The emerging ink jet material deposition market also uses inkjet technologies, typically printheads using piezoelectric

crystals, to deposit materials directly on substrates. Dimatix, Orbotech, OCE, and MicroCraft utilize the MEMS and Piezo printheads for printing legend, soldermask and etch-resist ink for PCB and FPC. From single print heads to up to five 128-jets, 1 or 10-picoliter MEMS-based printheads and up to five different fluids for sequential production printing. Using a large 500 × 500 mm printable area with positional accuracy and repeatability of ±5 µm and ±1 µm, respectively. They can print with 1.5 mm depth-of-focus (DOF) for uniform printing over thick traces. Most printers are equipped with a drop watcher, fiducial camera, heated vacuum platen, ink drying either by UV or infrared, automated printhead maintenance and cleaning, PC, monitor and easy to use software.

30.9 AUTOMATIC OPTICAL INSPECTION

After imaging of any nature, comes inspection. Automatic optical inspection (AOI) replaces manual inspection and has become essential for high-density printed circuits fabrication and SMT assembly. For a bare PCB board AOI inspection may detect these features:

- Line width violations
- Spacing violation
- Excess copper
- Missing pad, i.e., a feature that should be on the board is missing
- Slivers
- Thin resist or scumming
- Trace shorts and dust/debris
- Cuts

- Hole breakage, i.e., a drilled hole (via) is outside of its *landing pad*

After a board scan, the defects report may be either rule based (e.g., no lines on the board should be smaller than 150 μm) or CAD based, in which the board is locally compared with the intended design via its artwork.

AOI inspection is much more reliable and repeatable than manual visual inspection and is used extensively in printed circuit fabrication world-wide. Units can have multiple illumination sources, including laser and multiple optical detection sensors, along with multiple-scan techniques to make false detection a rarity. A majority of the AOI units in production come from Israel, Japan, USA, and S. Korea. China is hoping to produce units in the future.

For SMT assembly, smaller circuit board designs are driving up the demand for AOI versus in-circuit test. Figure 30.25 shows a typical bare PCB scanning unit and a “repair and verification” unit.

FIGURE 30.25 A typical automatic optical inspection station for bare printed circuits with a “repair and verification” station interconnected by its CAM

network.

CHAPTER 31

MULTILAYER MATERIALS AND PROCESSING

C. D. (Don) Dupriest

Lockheed Martin Missiles and Fire Control, Dallas, Texas

Happy T. Holden

Co-Editor-in-Chief, Printed Circuits Handbook, *and PCB Technologist, Zeeland, Michigan*

31.1 INTRODUCTION

Printed circuit board (PCB) structures and processes continue to be driven by device miniaturization, functional densification, and speed. The choice of components, actives and passives, and connectors are primary determinants of layer count and layer options, such as copper foil weights. Reductions in chip voltages are matched by an increase in current demand; this in turn causes increases in the number and thickness of the plane layers. More device leads combined with decreasing pitch increases the number of vias and interconnecting layers, while miniaturization and weight

reduction at the product level forces reduction in the physical package for the product.

New structures or advancements on existing structures are then needed to make these interconnections. These structures—such as blind and buried vias, multi-lamination (sublaminations), and build-up technologies—directly impact multilayer processing. Deeper blind vias and buried vias have caused a major increase in the demand for reliable via filling materials and methods. Relatively new materials, equipment, and processes have and are being developed to address this need. A new section in this chapter, “Filled Via Processing and Sequential Lamination,” addresses filled vias internal to the PCB.

Ever increasing frequencies continue to shift demand to materials with lower attenuation and propagation delay. To guarantee the electrical performance requirements of this product type and to benefit from the increased raw material and processing costs, the industry is specifying each element in the construction more so than in the past, and with less latitude. For instance, requirements for post-pressed thickness tolerance on a prepreg fill section, or surface roughness of the treatment side of the copper foil, or percent resin of the prepreg or core are much more likely to find their way onto fabrication prints.

Globalization of sourcing for PCBs continues to have a major impact on the physical design or the fabrication processes for the PCB construction. Mass lamination techniques have scaled to higher layer counts, and alternate tooling methods and panelization approaches have contributed to increases in material utilization and throughput. These technologies increase production volumes and reduce costs and are discussed in this chapter in Secs. 31.4.4 and 31.4.6.

The continued challenge to the physical PCB is coming from regulatory bodies and consumers who demand products that are less damaging to the environment.

Materials developed to meet these demands are known colloquially as either lead-free or RoHS-compliant (i.e., in accordance with the Restriction of the Use of Certain Hazardous Substances in Electrical and Electronic Equipment Directive). This chapter will not deal at length in the specific requirements of this directive, but will address the major impacts to the PCB materials and subsequent processing (see Secs. 31.5.5 and 31.6.2).

Lead-free joints, which have no appreciable lead content (for what "appreciable" means in this context, refer to the appropriate directive; see also Chap. 13 reflow at temperatures 30 to 40°C higher than the melt point of eutectic solder. These temperature increases have necessitated the development of newer resins or blends, different curing agents, and fillers to provide a laminate system that can survive and remain reliable after these elevated heat excursions. The changes to the laminates themselves are covered elsewhere in more detail (see Chaps. 9 through 15), but those properties directly applicable to the performance of the PCB are discussed in this chapter in Sec. 31.2.2.

In some market segments, particularly the consumer market, "green" technology is an important product differentiator or even a market requirement.

31.1.1 Relevant Specifications, Standards, and Test Methods

Industry standards groups such as the IPC have defined properties requirements and performance specifications to facilitate the choice of laminates. Design standards are available to inform the material selection process to achieve a desirable form, fit, or function. Standardized property tests have been developed to provide a common method to test

for property values and to interpret results. Some of the most commonly used are

- IPC-2221, “Generic Standard on Printed Board Design”
- IPC-4101, “Specification for Base Materials for Rigid and Multilayer Printed Boards”
- IPC-4104, “Specification for High Density Interconnect (HDI) and Microvia Materials”
- IPC-4652, “Metal Foil for Printed Wiring Applications”
- IPC-TM-650, “Test Methods Manual”

Table 31.1 lists some laminate tests covered in IPC-TM-650.

31.2 MULTILAYER CONSTRUCTION TYPES

The construction of the rigid multilayer ML-PWB can take on many variations. To help categorize the various constructions, the IPC has developed industry PWB design specifications, defining them by class and type. Grouping the ML-PWB into categories facilitates the ability of designers and fabricators to communicate using a common format.

31.2.1 IPC Classifications

IPC classifications specify generic PCB design and rigid organic printed board structure.

31.2.1.1 IPC-2221: Generic Standard on Printed Board Design. There are many ML-PWB structures. This section discusses the methods and materials for the basic and several of the advanced structures. The IPC has two comprehensive standards for the design of rigid printed circuits, IPC-2222 and IPC-2226. The classification system within these standards for the ML-PWB by structure is shown. The distinction between the two is the focus on microvias in the later standard.

31.2.1.2 IPC-2222: Rigid Organic Printed Board Structure Design. This standard covers products with conventional feature sizes:

- *Type 3:* Multilayer board without blind or buried vias (see Fig. 31.1).

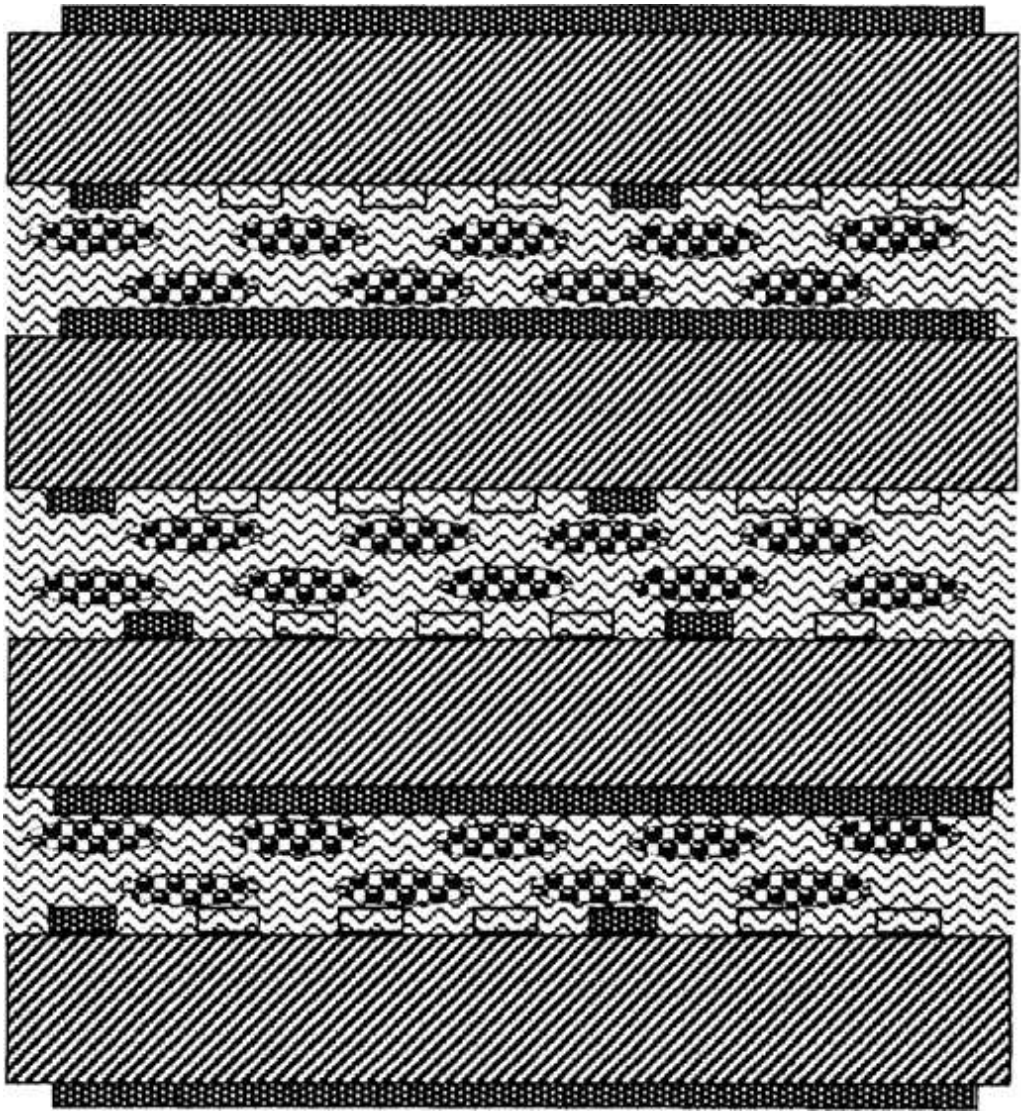

FIGURE 31.1 Type 3 (eight-layer ML-PWB) multilayer board without blind or buried vias.

- *Type 4:* Multilayer board with blind and/or buried vias (buried is shown in Fig. 31.2).

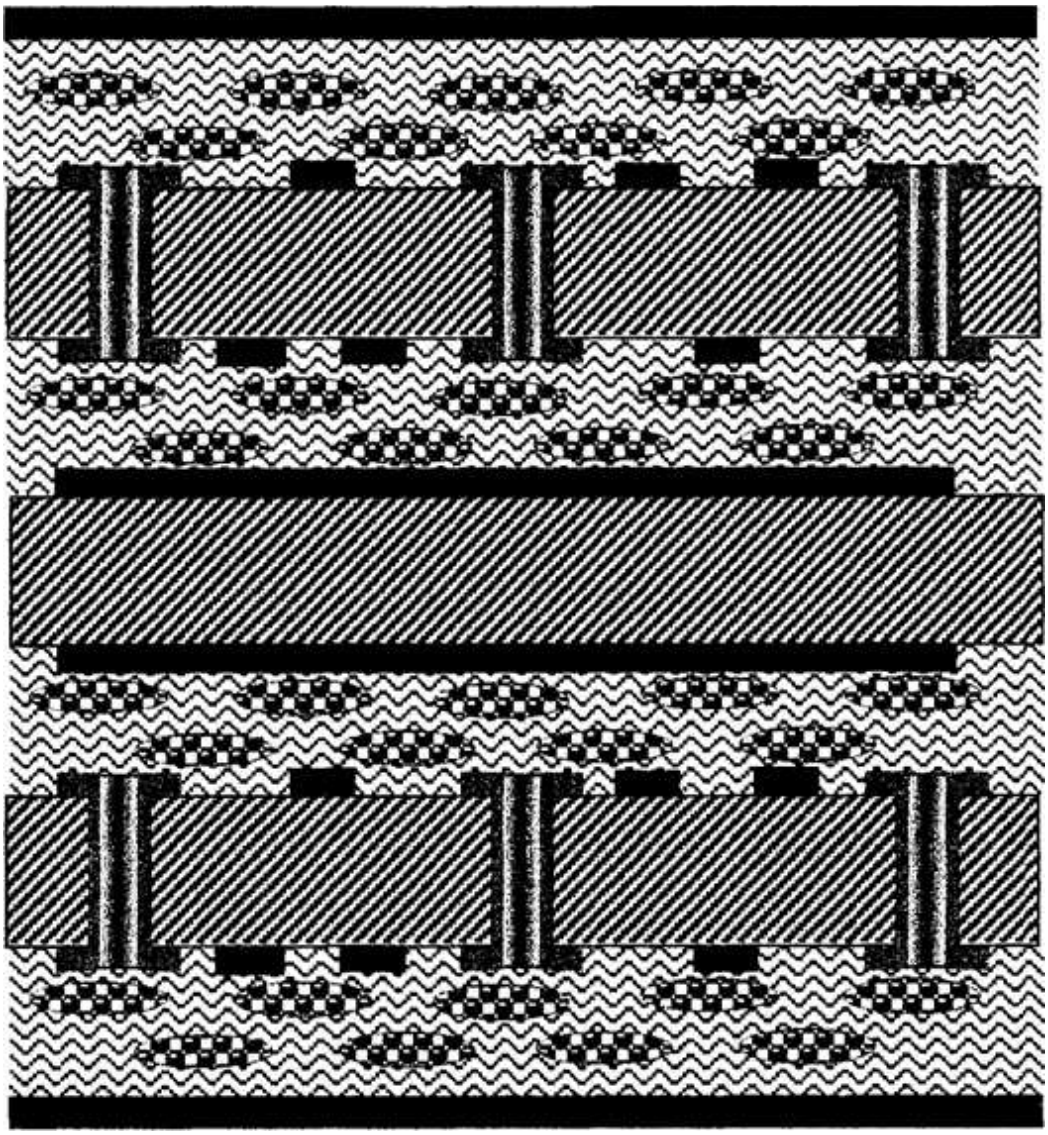

FIGURE 31.2 Type 4 (eight-layer-B/V MLPWB) multilayer board with buried vias.

31.2.1.3 IPC-2226: Design Standard for High-Density Interconnect (HDI) Printed Boards. This covers products with high-density feature sizes:

- *Type I:* 1[C]0 or 1[C]1 has through vias connecting the outerlayers (see Fig. 31.3).

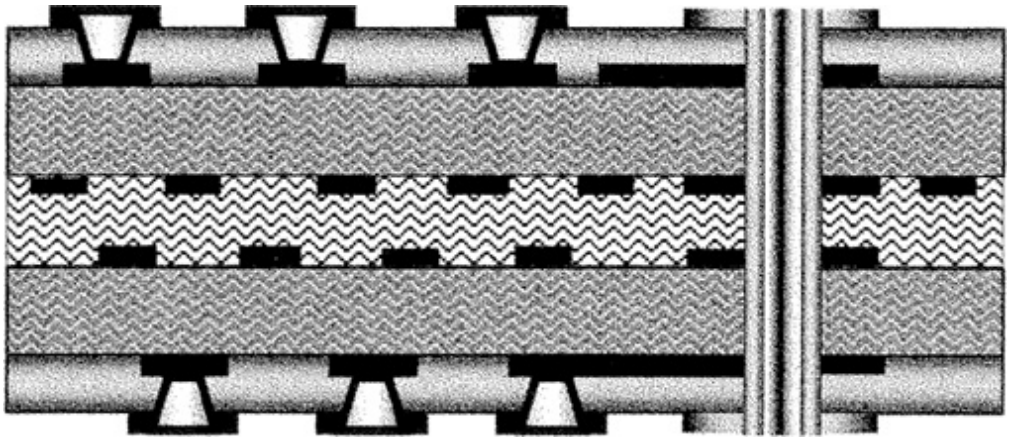

FIGURE 31.3 Type I (six-layer HDI MLPWB) high-density multilayer board with blind vias from top and bottom layers and through vias connecting the outerlayers.

- *Type II:* 1[C]0 or 1[C]1 has buried vias in the core and may have through vias connecting the outerlayers (see Fig. 31.4).

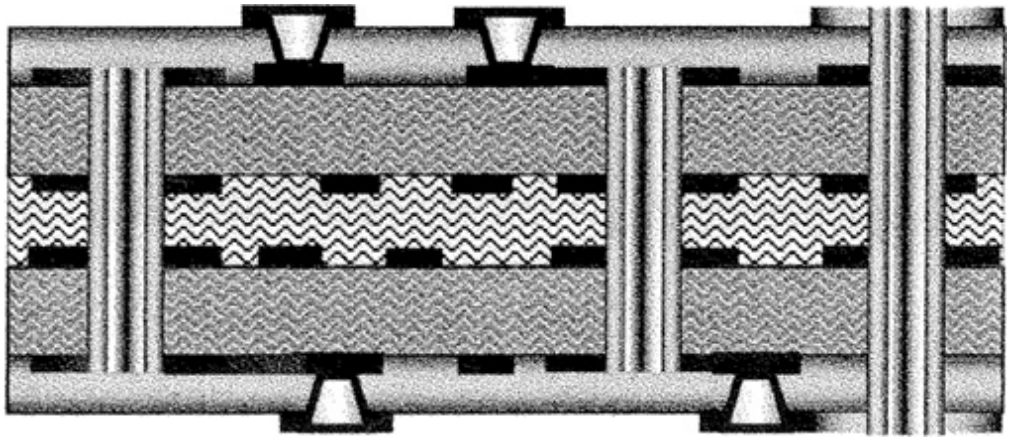

FIGURE 31.4 Type II (six-layer HDI MLPWB) high-density multilayer board with vias as well as buried vias in the core and through-vias connecting the outerlayers.

- *Type III:* >2[C]>0 may have buried vias in the core and may have through vias connecting the outerlayers (see Fig. 31.5).

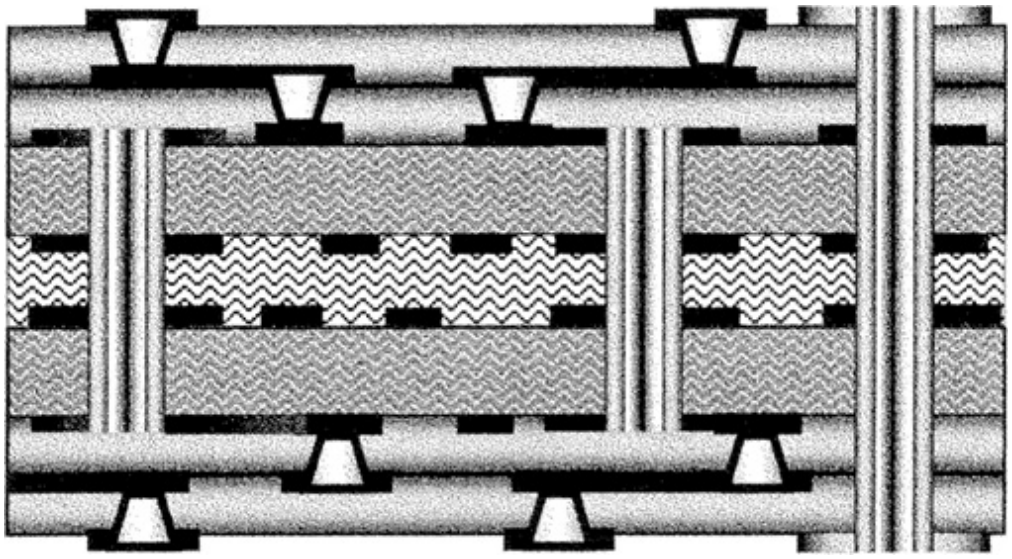

FIGURE 31.5 Type III (eight-layer HDI MLPWB) high-density multilayer board with blind vias as well as buried vias in the core and through vias connecting the outerlayers.

31.2.2 Basic Type 3 ML-PWB Stack-Ups

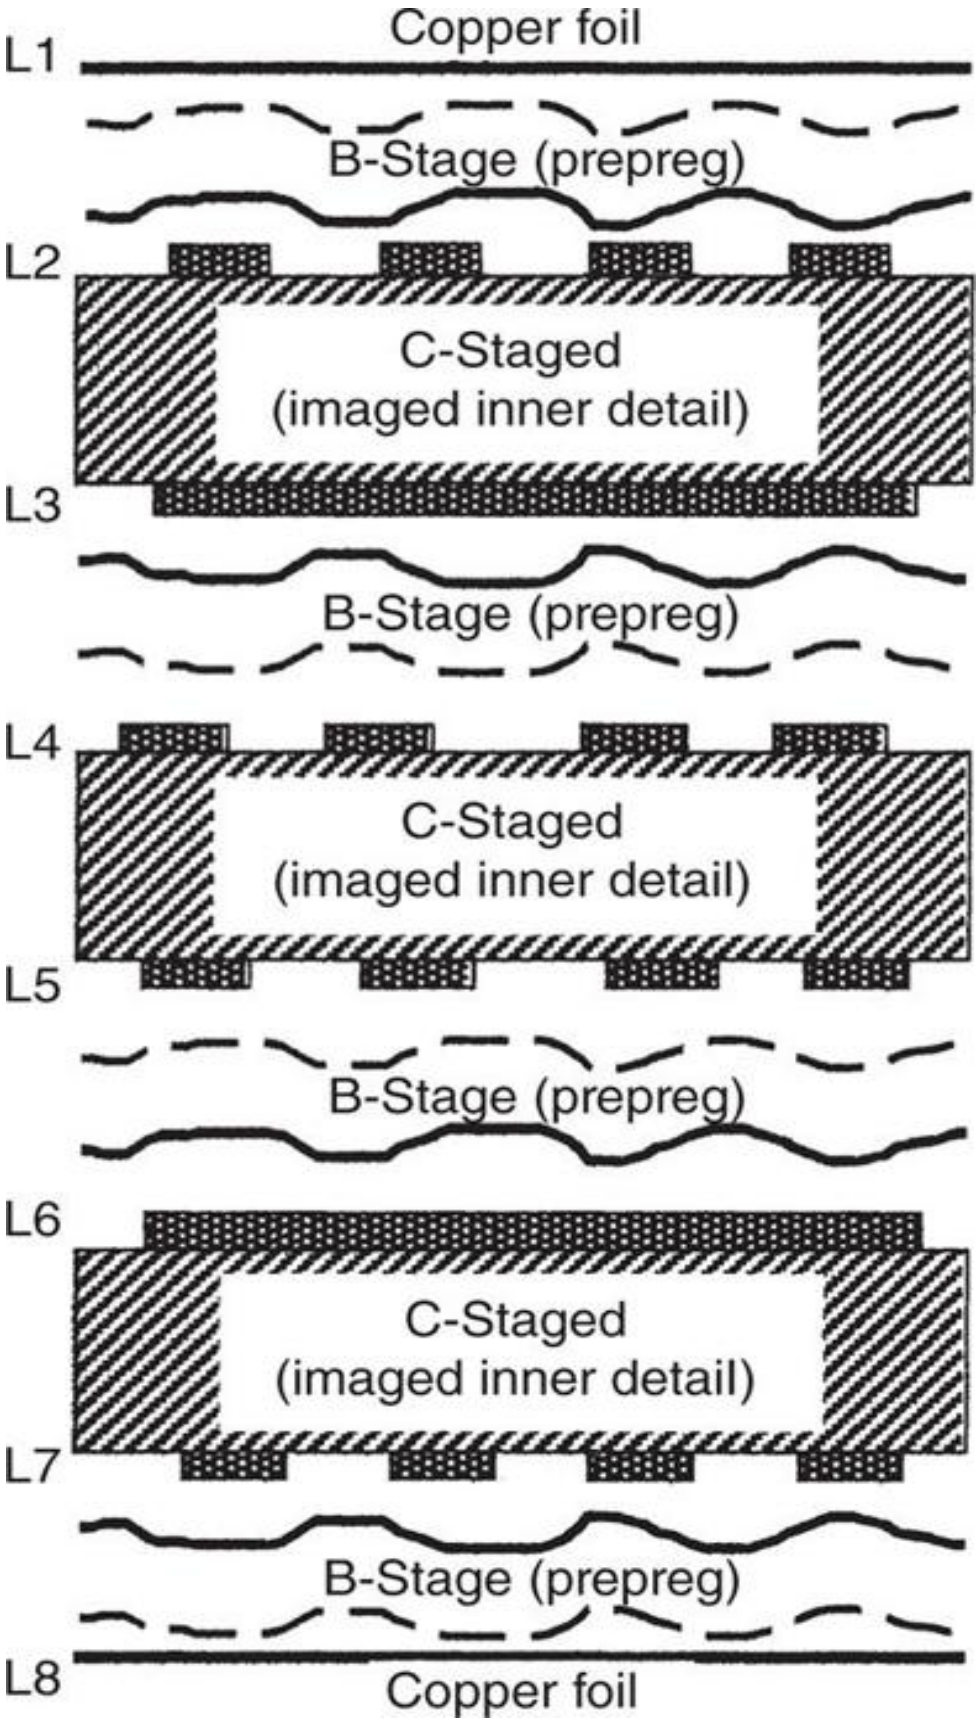
The type 3 construction can be said to be the most basic of PWB multilayer technologies. An ML-PWB is fabricated by the bonding (laminating) of copper-clad details consisting of imaged and etched laminates (typically double-sided). The bonding medium, known as prepreg, is a B-staged (partially cured) reinforced resin. The imaged details consist of C-staged (fully cured) laminate. These material components are arranged by layering according to the design documentation. This layering method in fabrication, known as the stack-up, follows the layer numbering order of the design. The stack-up formation method is often loosely defined in the design documentation; therefore, a good understanding of the lamination options is necessary. The lamination options described in this discussion refer to methods used to form the outerlayers and to form layer pairs. The material resin system should be defined on the

design documentation. Refer to IPC-2221/2222 for minimum suggested design documentation requirements.

The basic ML-PWB stack-up can be constructed with two options to produce the outerlayers and to form layer pairs. A third option that employs single-sided “capped” clads is rarely used and is not discussed. Often, in the case of designs having an odd number of layers, a combination of these methods is employed. The following three-layer stack-up methods are discussed:

- *Foil outerlayer construction (foil outer):* In this stack-up, the outerlayers are formed by using a sheet of copper foil per side.
- *Clad outerlayer construction (clad outer):* A clad detail provides the copper for the outerlayer.
- *Odd-layer construction:* This stack-up method balances a construction consisting of an odd number of layers.

31.2.2.1 Foil Outer Stack-Up. A board produced with copper foil outers is fabricated from one or more patterned innerlayer details and two copper sheets. The copper sheets form the outerlayers of the fabricated ML-PWB. This stack-up is the least expensive way to fabricate an ML-PWB and is by far the most popular design option. Figure 31.6 shows a typical stack-up for a foil outer board consisting of eight layers.



Copper foil

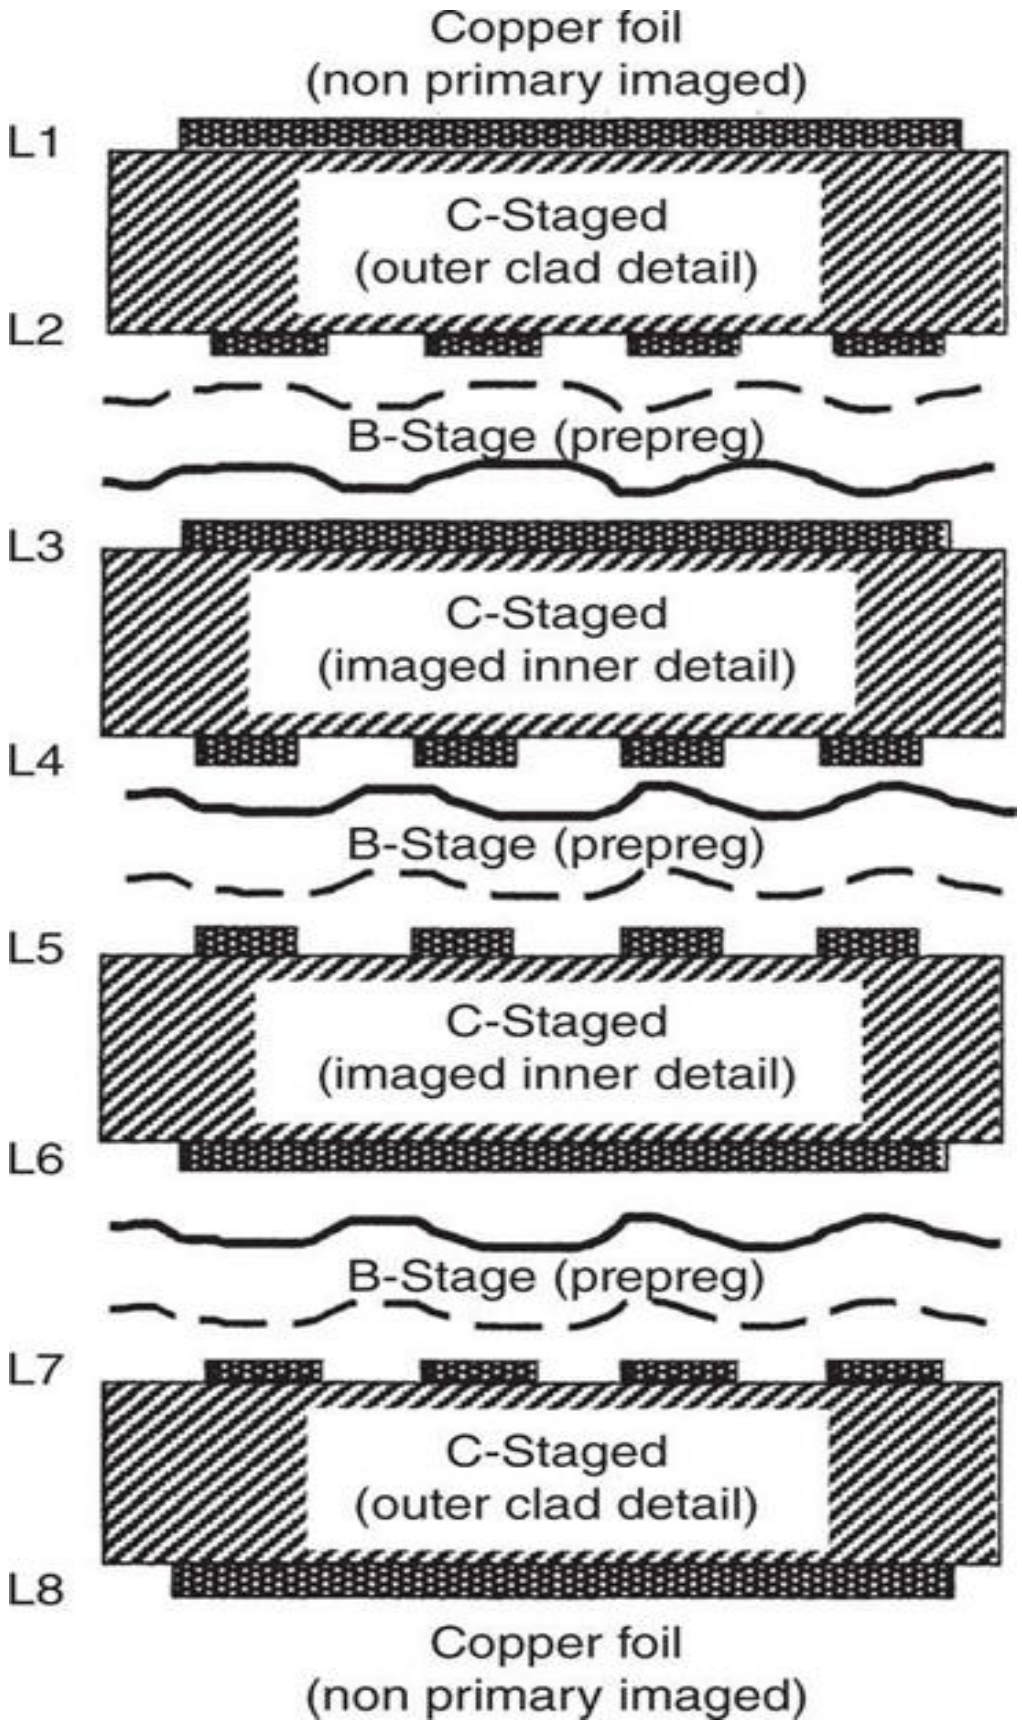
FIGURE 31.6 Foil outer stack-up (eight-layer ML-PWB), a typical stack-up for a foil board.

The stack-up shown contains three imaged clad details bonded with two sheets of prepreg at each opening and having two sheets of copper foil on the outside. When possible, the higher resin content prepreg ply should face the signal layer side. This is especially important when the signal is a heavyweight copper (2 oz or more). The copper layers, numbered from L1 to L8, begin with the top foil layer (typically called the primary side). In the design pictured, the layers L2, L4, L5, and L7 represent signal layers. Layers L3 and L6 represent power/ground layers. When the final imaged patterned is produced, it can provide another signal layer pair or a set of ground layers, or a "pads-only" pattern to support vias and component holes, as well as the device footprints of the electrical components and their associated fan-out patterns. Some of the advantages of this bonding method are

- *Lower raw material cost:* Loose sheet copper foil and prepreg sheets are more economical than clad laminate.
- *Lower consumable material cost:* The reduction in imaging resist and chemistry results in a cost savings.
- *Lower labor cost:* The reductions in material handling and in the processes of imaging and pre-lamination result in less total labor.

31.2.2.2 Clad Outer Stack-Up. Figure 31.7 depicts the same eight-layer design as Fig. 31.6, except the outerlayers are formed with a clad laminate. This stack-up arrangement requires four clad details, as compared to only three for the foil-stacked board shown in Fig. 31.6. This makes the clad outer board more expensive than the more commonly used foil outer construction.



Copper foil
(non primary imaged)

FIGURE 31.7 Clad outer stack-up (eight-layer ML-PWB) multilayer board design with the outerlayers formed with a clad laminate.

However, the clad outer design has one less B-stage opening and no loose individual copper foil. In addition, the clad outer boards are patterned on only one side prior to lamination. These factors partially offset the higher cost of this design. In Fig. 31.7, notice how the layer pairs have changed position placement. Layers L3 and L6 are now paired with a signal layer, which may be advantageous for controlling the dielectric thickness. Some of the advantages of using the clad outer bonding method include:

- *Improved surface topography:* When surface flatness is critical, the clad outer construction provides a smoother surface. When a signal layer of heavyweight copper is the first layer down, it is possible for weave texture imprinting to occur. This topography condition, sometimes referred to as “telegraphing,” can sometimes imprint the circuit pattern when using a foil build-up.
- *Improved handling:* Depending on the layer pairing, sometimes additional copper can be retained, as in a case where a signal-to-signal imaged detail can be avoided. This is mostly the case when the layer pair details are being produced on very thin core laminate.
- *Improved dielectric thickness control:* Sometimes, it is necessary to control the thickness at a specific layer pair tightly. This could be due to high-voltage considerations or to aid in the precision spacing of a signal plane to a ground plane where controlled impedance is necessary. This is possible because the C-staged (fully cured) clad laminate typically has an improved thickness tolerance.

The chief disadvantage with a clad outer layer design is in the potential for lower yield. This is because the external copper foil must be protected by the image mask during all the internal layer image, etch, strip, and oxide processing

steps; then the mask must be removed at a later point in the process so that the external details can be fabricated. The potential exists to scratch the photomask during all the handling steps, which will result in shorts or opens (depending at which point in the process the scratch occurs).

31.2.2.3 Odd-Layer Stack-Up. Sometimes, due to signal routing or the need to have a greater dielectric space, an odd-layer circuit is formed. Similar in characteristics to the clad stack-up, the odd-layer construction technique employs a nonimaged single-sided clad laminate. Material can be procured with a single side, but a warning is associated with its use due to a lack of bondability. When this material is manufactured at the laminator supplier with only copper on one side, a release sheet is used against the noncopper side. The release sheet produces a slick, smooth surface. The non-copper surface thus requires an aggressive surface preparation to promote bondability. One alternative to gain the same benefit of the single-sided clad is to etch the copper off one side of a double-sided clad. The etched side becomes the bond surface, which has greater adhesion due to the copper tooth imprint left behind. See Fig. 31.8 for an example of a balanced odd-layer construction.

FIGURE 31.8 Odd-layer clad stack-up (five-layer ML-PWB), an example of a balanced odd-layer construction.

Some of the uses of the single-sided odd-layer stack-up are

- *Odd-layer construction option:* The single-sided construction technique allows an opportunity to supply a layer for circuit designs having an odd layer count.
- *Odd-layer core balance:* One of the problems associated with a build-up of odd-layer circuits is the ability to maintain a balanced construction of the cores. Depending on the overall design thickness and layer count, this can become a major concern to reduce warping. Figure 31.8 depicts an example of an odd-layer stack-up with three equal core thicknesses.

31.2.3 Sequential Laminations

When a design includes buried and/or blind vias, it typically requires a set of sequential lamination and plating cycles. These technologies are defined in the industry design standard IPC-2221/2222 and are known as Type 4 ML-PWBs. These build types, when employing industry standard feature sizes, are mature in the industry. Complementing technologies, employing use of sequential processes for ML-PWB designs containing microvias less than 0.15 mm, are considered as build-up technologies. The terminology of build-up technologies encompasses many design stack-up variations; they can take on many forms and employ a multitude of methods. The build-up technologies defined in IPC-2315 and IPC-2221/2226 include categories named Type I, II, III, IV, V, and VI. The advanced build-up technologies use the materials found in IPC-4104. These include materials for layer forming, dielectric insulation, and interconnectivity. Included are photoimageable and non-photo-imageable materials (liquid, paste, or dry-film nonreinforced dielectric);

adhesive-coated dielectrics (reinforced and nonreinforced); and conductive foils and paste (coated and non-coated, photoimageable). For a detailed discussion of these processes, see Chaps. 25 and 26. This discussion will limit itself to addressing processes for standard technology Type 4 and advanced technology build-up Types I, II, and III, which can be manufactured with conventional processes.

31.2.3.1 The Buried Via Stack-Up. To avoid hopelessly complex routing, each signal net is generally routed using only one pair of layers with what is called *Manhattan geometry*. This means that diagonal routing is avoided and all signal lines run in a horizontal or a vertical direction. To avoid blockage and side-to-side cross-talk problems, horizontal lines are run on one layer and vertical lines on the other. This means that, in addition to a via at each end of the net (I/O via), most nets need one or two additional vias (routing vias) to change direction from horizontal to vertical. Figure 31.9 shows an example of Manhattan geometry.

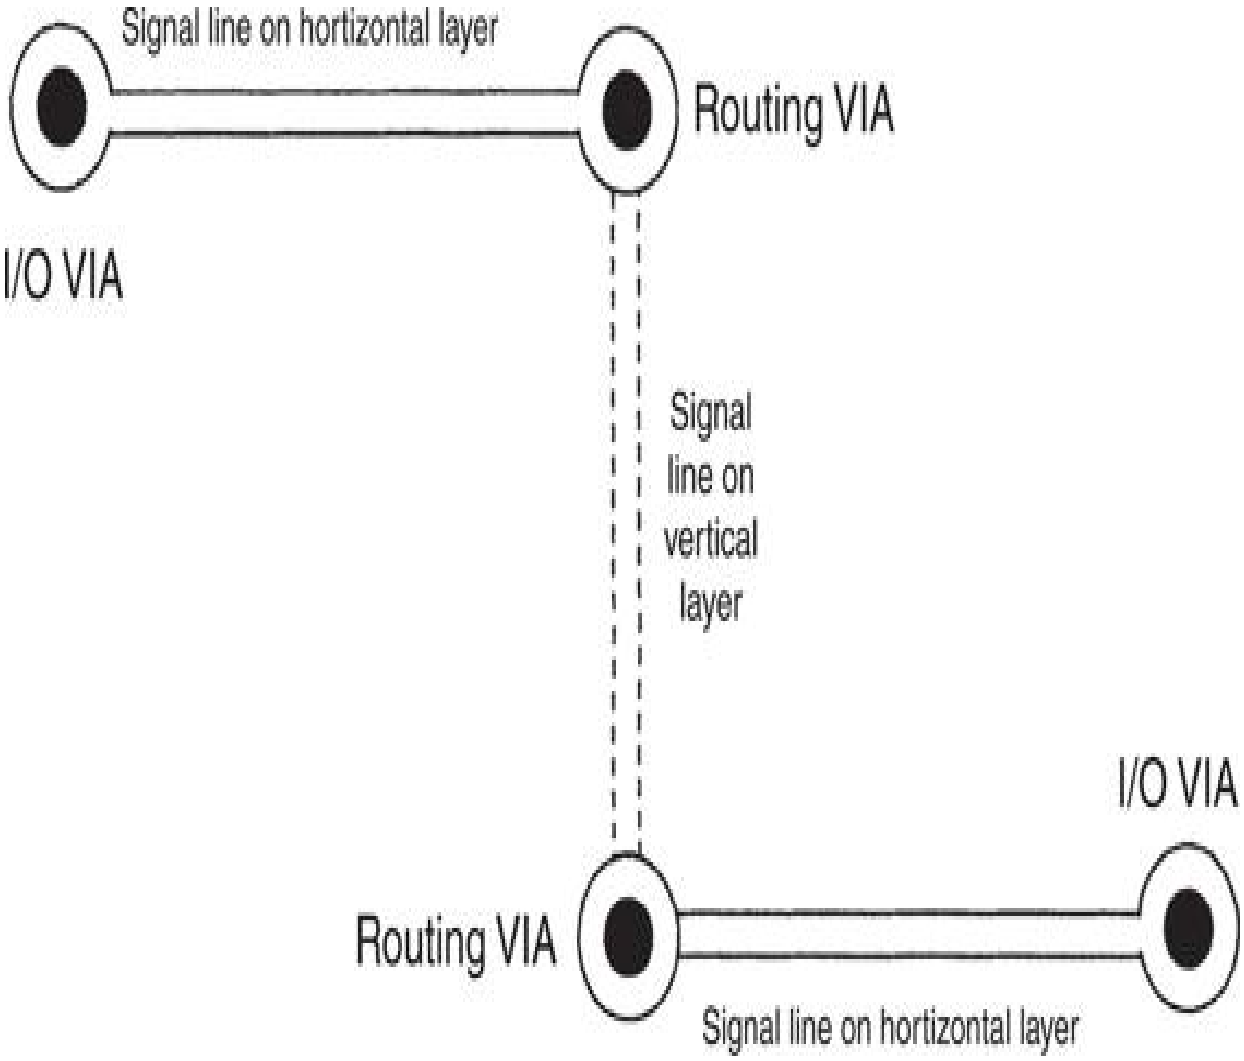

FIGURE 31.9 An example of a net routing using Manhattan geometry.

The net shown in Fig. 31.9 has two I/O vias and two routing vias. The I/O vias connect the signal lines to the board surface, where the net connects to an input or output point of an active circuit. The routing vias are used to change directions from horizontal to vertical. With through-hole vias, the routing vias pass through all layers, consuming valuable routing space. A high-layer-count board with many signal layer pairs can run out of via sites. In this case, additional layers will not improve routing completion and the board is said to be via-starved. One solution to a via-starved board is to use buried vias. The buried via connects two adjacent signal layers and provides routing vias without affecting

routing on other layers. Figure 31.10 shows an eight-layer board with two buried via layers.

FIGURE 31.10 Type 4 (eight-layer B/V ML-PWB), an eight-layer board with two buried via layers.

Buried vias do not pass through the board, so they do not congest the routing on other layers. In addition, the same via site can be used simultaneously on different layer pairs. Since buried vias are drilled and plated in the thin laminate prior to lamination, they can be very small and positioned very accurately, saving additional routing space. In some applications, buried vias are placed where needed with no reference to a predetermined grid. This gridless routing approach gives very high computer-aided design (CAD) autoroute completion.

To benefit from buried vias, signal layer pairs must be routed on opposite sides of the same C-stage component. In Fig. 31.10, L4 and L5 are not buried via candidates. In Fig. 31.7, no signal layers can benefit from buried vias. The design shown in Fig. 31.10 is able to use buried vias on two layer pairs because a power/ground layer pair separates them. In nonburied via designs, it is best to use one power/ground plane between each signal layer pair. This gives cross-talk isolation and impedance reference. A buried via design uses a second redundant layer to force the next signal layer pair onto the same imaged detail. In other words, for a high-layer-count design to use buried vias on all signal layer pairs, power/ground plane pairs must be inserted between each signal layer pair. This increases the number of layers in the board and increases cost. Another disadvantage of buried vias is the cost associated with the extra drilling and plating operations.

31.2.3.2 The Blind Via Stack-Up. Another via option is the blind via, which connects the surface layer to one or more internal layers but does not go through the board to the opposite outside layer. Figure 31.11 shows an example of an eight-layer ML-PWB with both blind and buried vias. The design shown in Fig. 31.11 contains buried vias connecting

L5 and L6. Blind vias connect layers L1 and L2. The buried vias can be fabricated in layer details as described earlier or can be fabricated by blind drilling. Blind vias may become very important in very dense double-sided surface-mount designs that have interference between I/O vias from opposite sides on the board. If this is particularly troublesome, a via-in-pad (VIP) approach or dog-bone escape pattern is used. The VIP approach places a blind hole directly in the device I/O pad and typically plated shut (filled). The dog-bone approach places a blind hole in an adjacent pad next to the solderable land. A second application for buried vias is to ensure complete side-to-side electrical isolation.

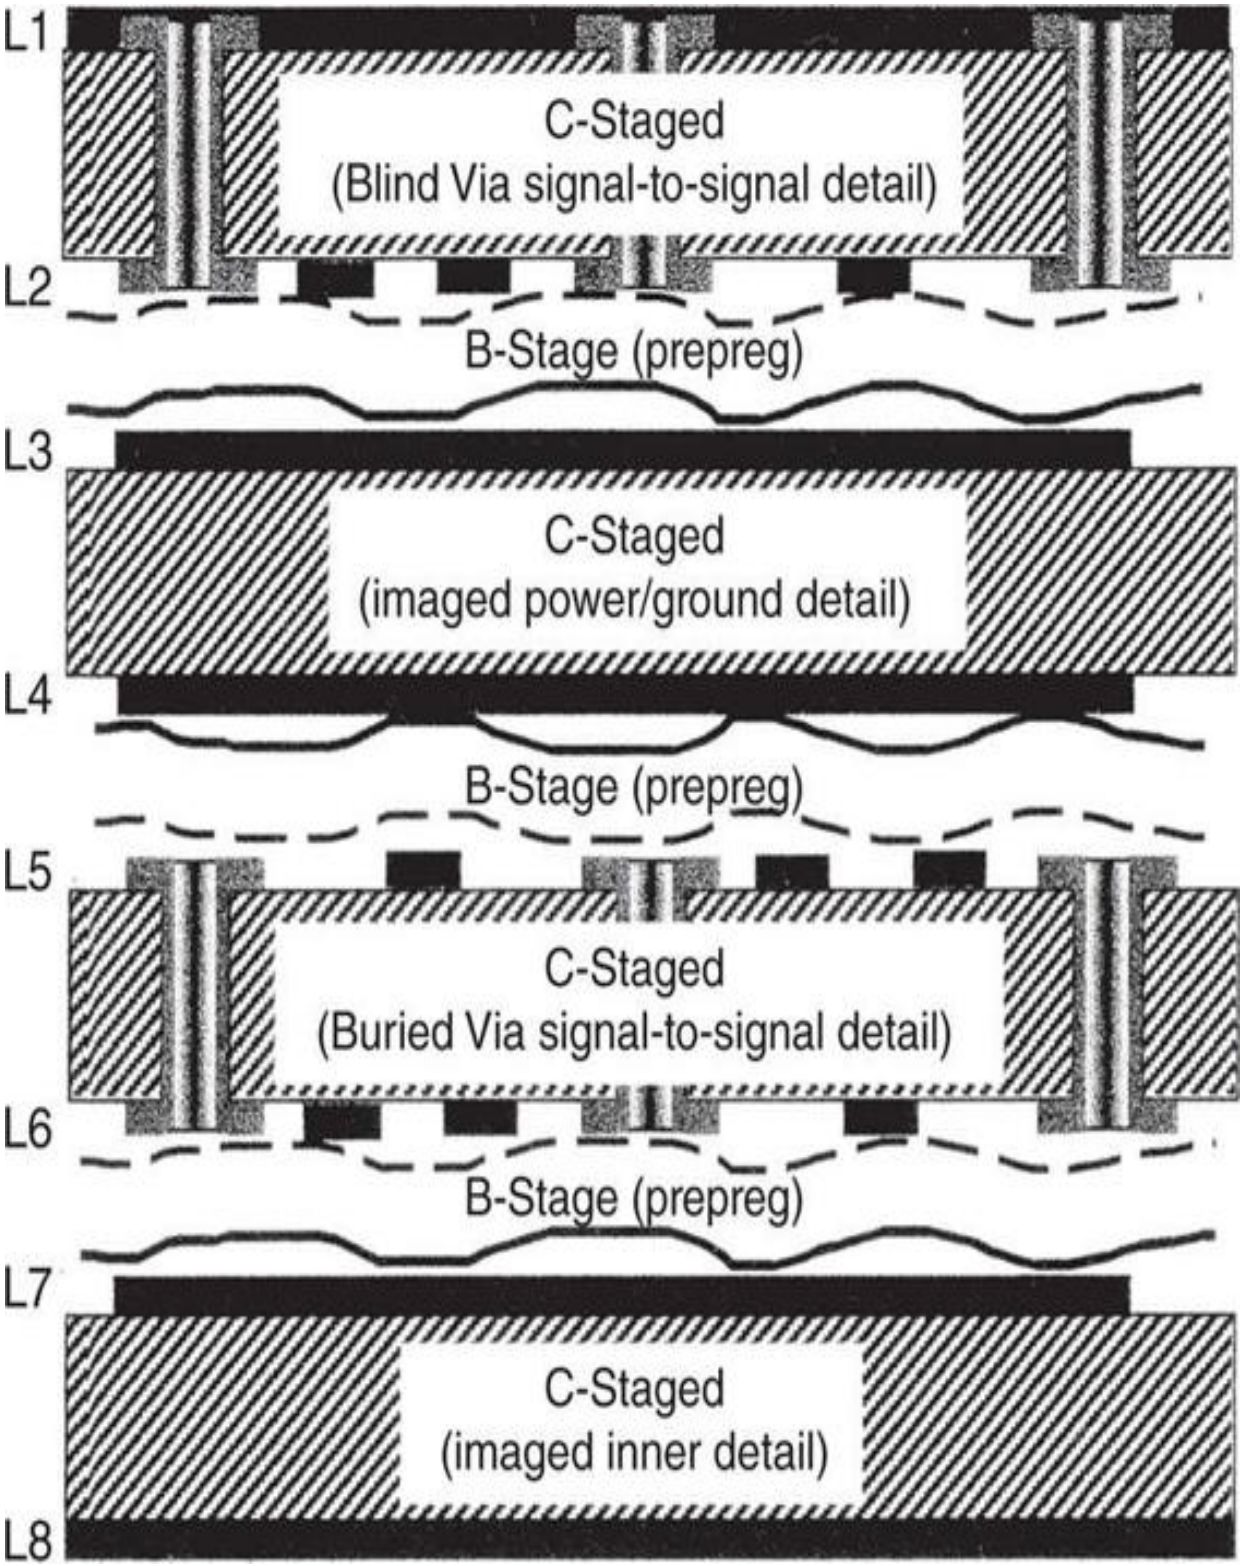

FIGURE 31.11 Type 4 (eight-layer blind and buried via ML-PWB). The design contains buried vias connecting L5 and L6. Blind vias connect layers L1 and L2.

This is particularly important in wireless designs where the RF circuits must be shielded from other circuits. Through vias allow RF electric fields to escape from a shielded region. A blind via eliminates this problem and allows RF functions to be combined with logic and control functions on the same board.

The ultimate use of blind vias is effectively to convert a dense double-sided surface-mount design to a pair of less-dense single-sided surface-mount designs. To see how this is possible, visualize an ML-PWB with fine-pitch SMDs on both sides as two separate boards with some level of side-to-side interconnection. If the board is manufactured as two separate subassemblies, the I/O connections on one side will not interfere with the I/O connections on the opposite side. For example, consider a 16-layer board fabricated as two 8-layer subassemblies. The subassemblies are laminated, drilled, plated, and patterned like a standard ML-PWB, with the exception that the sides that will become the board exterior are blanket-metallized. After patterning, the two subassemblies are laminated together and then processed as a standard ML-PWB. This process is another form of sequential lamination. The only through holes required in this design are the relatively few that provide side-to-side interconnection. Since each via site is used twice, a 100-mil grid may replace a 50-mil grid, providing a significant increase in innerlayer routing resources. This type of ML-PWB structure is very costly and has mostly been replaced with the routing features of the high-density design.

31.2.3.3 The High-Density Stack-Up. The buried via stack-up design came about for a solution to gain signal routability when CAD routing solutions were pressed to the limit. Early on, Type 4 designs were considered specialty products and utilized standard-feature-size characteristics. With the advent of more sophisticated CAD routing tools, it became possible to autoroute with greater efficiency,

sometimes avoiding the necessity and cost of buried vias. Soon high-I/O, full array components created new interconnectivity demands. Today buried via sections defined as cores in IPC-2221/2226 are used for the central starting point of manufacture, and then build-up layers are applied to complete the design as an HDI structure. As noted earlier, the common discriminator that separates the high-density design from a conventional Type 4 is mainly the feature size. For example, the HDI Type II, as shown in Fig. 31.4, uses a conventionally processed ML-PWB Type 3 board as the core (L2 to L5) and the PTHs become buried after the high-density features of L1 and L6 are added. Microvias are used to form a connection to L2 and L5; then through holes are formed to tie L1 through L6. The microvias and holes are now metallized in one cycle. The build-up layers in the example use thin dielectrics to provide a close proximity to the adjacent layer. This is required to accommodate the microvia connection and maintain producibility for metallization.

Figures 31.12 to 31.14 show a comparison of the HDI build-ups for Types I, II, and III. In each case, complexity is added by building add-on layers sequentially. The build-up layers are typically for signal routing and contain low copper weight. Dielectric-coated (nonreinforced) microfoils (as thin as 9 to 12 µm) are employed to provide a low-profile thickness after copper plating. This is needed to facilitate the image of fine-line widths typically associated with HDI. These styles of circuits offer some economy through use of a variety of dielectrics. The use and style of construction type must be matched with the product's expected application environment and operating life. Often the need for CTE match of area array components compels the application of a nonwoven aramid layer at the surface. The resin system selection should be based on the expected CTE mismatch concerns, such as when a ceramic device is surface-mounted to the assembly. Thermal cycling of power on and off can cause earlier failure when a large mismatch is present.

FIGURE 31.12 Type I (six-layer HDI stack-up) shows one example of how to stack up an ML-PWB with HDI features.

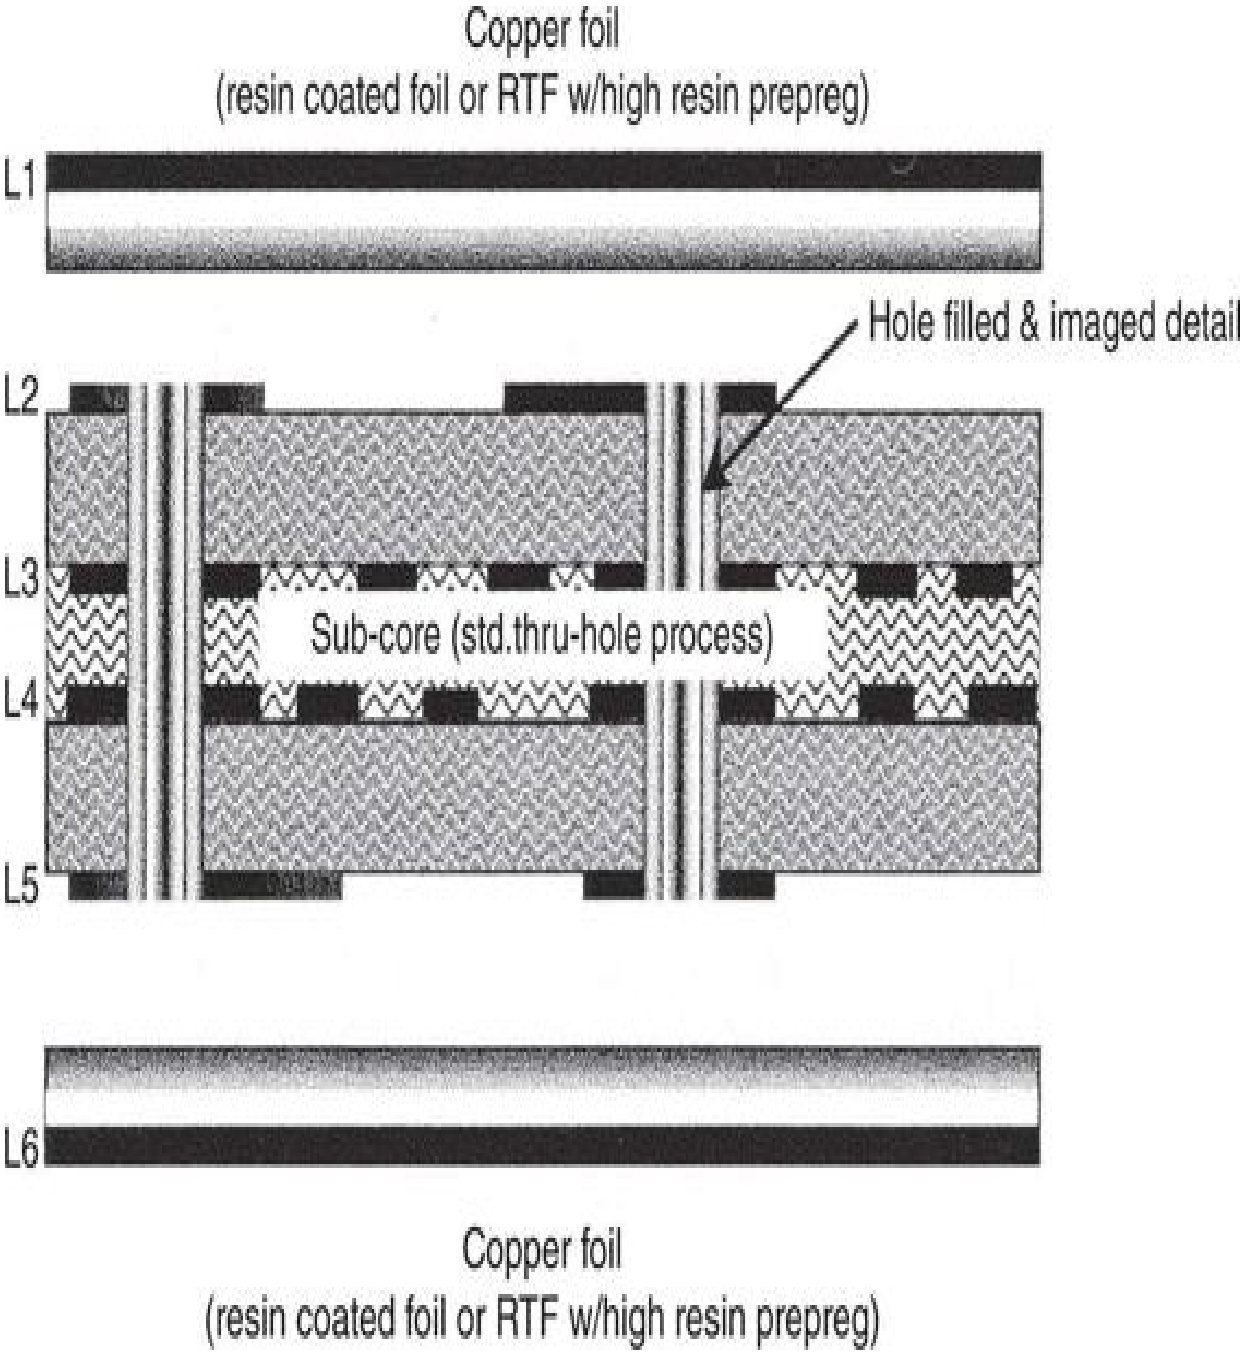

FIGURE 31.13 Type II six-layer stack-up having at its core a four-layer board with through holes, which later become buried.

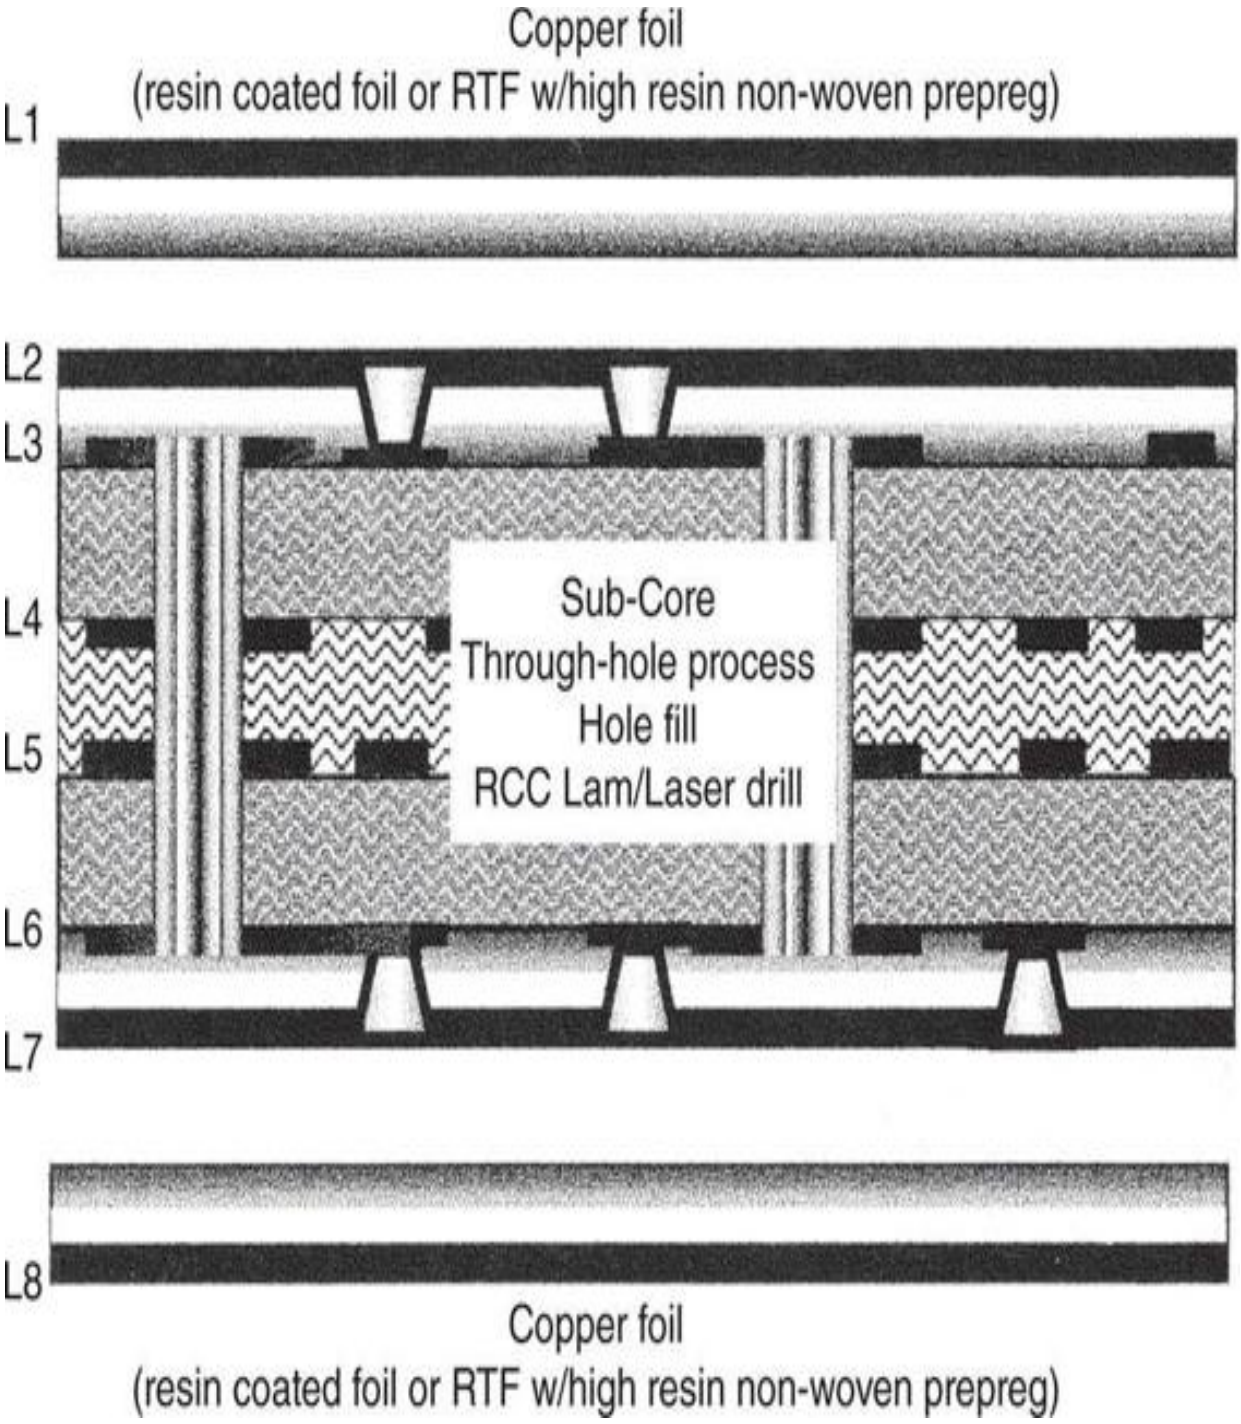

FIGURE 31.14 Diagram showing how an HDI Type III (eight-layer HDI stack-up) might be produced employing conventional lamination techniques.

Manufacturing capability becomes critical when targeting HDI features. The IPC-9151 Process Capability, Quality, and Relative Reliability (PCQR2) Benchmark Test Standard and

Database has taken the responsibility of developing industry standards to assist in benchmarking and quantifying capability limits. Manufacturing features such as imaging, etching, hole formation, plating, and lamination registration are all strained and must be optimized. Other processes that are equally challenged are the end-product continuity testing to access the high-density features.

31.2.3.3.1 HDI Type I Stack-Up. Figure 31.12 shows one example of how to stack up an ML-PWB with HDI features. The economies of this design are obvious because it requires only one lamination cycle. The density push in this level of HDI focuses on imaging and microvia routing. By routing at a high circuit density, the surface area of the board is better utilized. The outerlayers are typically formed with a low height dielectric. When utilizing conventional lamination, this is usually a resin-coated foil or a microfoil bonded with a high-flow nonwoven aramid prepreg. Special nonwoven series of aramid fiber laminates have been developed to yield an equivalent dielectric thickness of 1.9 mil.

Special handling is required for the microfoils, which are usually 9 to 12 μ m thick. To facilitate handling, a sacrificial carrier foil is sometimes cohered to the microfoil externally for added stiffness. After lamination, one option is to process the microvias through laser drilling and conventional through-hole drilling. Sometimes a clad outer construction may be best, depending on the laser technology chosen. For example, infrared (IR) (CO_2) laser ablation using an etched mask (small etched openings the size of the via) in the outer copper can be performed at primary print. This process helps reduce possible misregistration error. One metallization cycle is required to tie in all vias electrically. This reduces costs compared to sequential cycles. (See Chap. 29.)

31.2.3.3.2 HDI Type II Stack-Up. Density demands, when not met by the single lamination approach of Type I, must then address the use of sequential processing when

employing standard ML-PWB techniques. The Type II stack-up shown in Fig. 31.13 has at its core a four-layer board with through holes, which later become buried.

31.2.3.3.3 HDI Type III Stack-Up. The use of a Type III structure may be employed when routing densities are greatly pressed. At this point of complexity and above, alternative HDI approaches should be investigated because of the extra cost associated with performing repetitive cycles with conventional ML-PWB processes. Alternatives to lamination provide build-up of the dielectric and conductive layering through other means. These should be discussed with the manufacturer prior to selection. It is important to remember that the manufacturing method related to fabrication can have a great impact on the design rules chosen at CAD layout. Figure 31.14 represents how an HDI Type III might be produced employing conventional lamination techniques. Here, the core substrate is a four-layer ML-PWB detail similar to the Type II starting construction discussed earlier. Processing for the first pair of build-up layers follows the processing analogy of the Type II structure. Here, as in other foil laminated build-ups, the starting copper thickness should be kept to a minimum. Plating uniformity becomes critical when attempting to image/etch high-density features. After L2 and L7 have been defined, the final copper layer pair (L1 and L8) is laminated. At this final build-up, since no through holes are present, the flow of the resin-coated foil or prepreg should be sufficient to fill the microvias and flush the circuits. Once the additional layer is laminated, another level of microvias may be produced.

31.2.4 Filled-Via Processing and Sequential Laminations

The requirement to fill vias is driven most often by routing density. When high-density-area array components are utilized, the quantity of vias per square inch greatly increases in the local area under the device. Buried vias or blind vias are frequently the solutions to through-via starvation.

Buried vias, unless otherwise prefilled, will fill with resin during final lamination. The volume of resin necessary to fill the buried vias is dependent on the diameter, length, and total quantity. Buried vias might straddle a single core, or might interconnect several cores and dielectric separations in a sublamination section. If there is insufficient resin in the prepreg to fill the buried vias, those vias can starve bonding resin from the local area where they are concentrated. To prevent the prepreg resin from entering the buried hole, the fabricator often is required to prefill the vias prior to a build-up lamination with a resin or paste formulation. Other design constructions require blind vias that are planar and within the land pattern at the surface mount attachment locations. These VIP structures free up real estate on the component attachment surfaces and provide enhanced signal integrity at high frequencies. Prefilling internal buried vias or blind VIPs with a hole-fill resin can provide a more robust interconnect structure, improved lamination integrity, and a planar surface in the case of the blind vias.

31.2.4.1 Fill Materials. Since the fill material is an additional fabrication material that becomes a part of the design construction, procurement documentation is required to specify a fill material type and thereby implement the via fill process. The selection and documentation of the fill material require the same consideration as the base laminate preference. This is especially critical when targeting a lead-free-compatible process. Currently, an industry-based material specification for via fill material does not exist. Therefore, specific fill-material brands may be named on the

drawing, or some other form of user/supplier agreement must be established. The fabricator has preferences for the type of material used for via fill. Just as suppliers often have preferences for a specific solder mask brand, they also often prefer to use of a specific via fill material around which they have developed their principal processes. Supplier preferences can be driven by specific via fill material characteristics, such as accessibility, equipment compatibility, process supportability, plateability, and/or shelf/pot life. This may complicate source selection, or it might influence the use of a dedicated service center for the hole-fill process. The fabricator may not always know the reliability of its preferred material for a given via structure or end-use environment.

Determining the properties of the various fill materials may be difficult for the user. Obtaining properties from the material suppliers' data sheets may be possible for some properties, whereas others are more difficult to obtain; for example, many manufacturers' data sheets omit the modulus. Table 31.2 provides a cross-reference for some of the more common material types with properties available. Additional properties and performance data may also be found at the specific manufacturer Web page.

TABLE 31.2 Common Via Fill Manufacturers and Material Properties

Mgf. (Link)	Type	Material[2] (part number)	Pencil Hardness	Color & Plateability	Thermal conductivity (W/m/K)	T_g °C	CTE under T_g (ppm)	CTE over T_g (ppm)
Peters	Nonconductive (ceramic filler)	PP 2795	9H	White and light gray[1]	N/A	140	40	150
Peters	Nonconductive (ceramic filler)	PP 2794[1]	N/A	White[1]	N/A	115	40	105

Taiyo	Nonconductive	TCHP-200 DB4 (2 part)	8H	Green[1]	N/A	130	24	78
DuPont	Conductive	CB-100 Copper /Silver	4H	Silver[2]	3.5	115	35	47
Tatsuta	Conductive	AE 3030 Copper/Silver[3]	N/A	Silver[2]	7.8	171	40	86
Taiyo	Conductive	SCHP-7901 Silver	4H	Silver[2]	6.7	110	45	120

Notes: Some via fill materials are not typically compatible with permanganate chemical processing. Confirm with the specific supplier before using. The denotation of N/A indicates that the data were not readily available.

[1]Compatible with Plasma desmear, requires electroless followed by electrolytic processing.

[2]Compatible with Plasma desmear, conventional electroless recommended but may be use direct electrolytic processing.

[3]Capability with a lead-free profile should be verified; typically the higher T_g materials with a lower ppm above T_g will be more compatible.

31.2.4.2 Concerns and Common Defects. Concerns associated with filled-via structures have mostly been eliminated with process maturity today yet potential impact on reliability still exist. Some concerns include plating

adhesion, air entrapment (voids) created during the filling operation, CTE mismatch with the bulk resin, and the risk of overplanarization to remove excess resin. Entrapped voids are suspected to have an effect on hole wall integrity due to outgassing; CTE expansion mismatch could have an adverse interaction with the material and copper CTE properties. Overplanarization can grind down the plated hole wall knee, weakening the interconnect at the barrel plate. This is commonly called a reduction in wrap copper. A lack of wrap copper will leave a butt joint at the interconnect that is vulnerable to pad rotation (lift) knee crack. Reliability data within the industry for these structures suggest higher risk exist when wrap plating is less than 5 um (0.0002 inches). Some performance criteria for the via fill method has been quantified in industry standards today. To specify the most cost-effective via fill method with confidence, the designer must know the method's compatibility with the assembly process and targeted mission criteria. Qualification testing to the end-use environment with a preproduction build is recommended.

Designers need to be aware of potential processing issues associated with specifying via fill. Although the risks are well known, the manufacturing issues are often still difficult to detect from standard coupon analysis. Construction integrity weaknesses often are not found until latent defects occur or become revealed by aggressive thermal stress screening. Figure 31.15 is an example of a design employing conductive via fill within two via structures (blind and through holes) sharing a common surface layer. It should be noted conductive fill materials are very costly and difficult to process. This example is free of plating interconnect defects; the buried structures are fabricated without an internal cap plate; the voids in the conductive fill are typical for this type of material. Figure 31.16 is a nonconductive fill with a close-up view of a micrograph illustrating the plating integrity and surface planarization that has maintained the wrap copper

requirement. In this example, the full plating requirement was deposited without a separate button plate cycle. The wrap copper demarcation is noted and no separation has occurred at the cap plate. Some common failure mechanisms, which illustrate the risk associated with fill technology, are shown in Fig. 31.17. Here, micrographs show a via fill with a lack of plating adhesion and wrap copper, allowing interconnect separation.

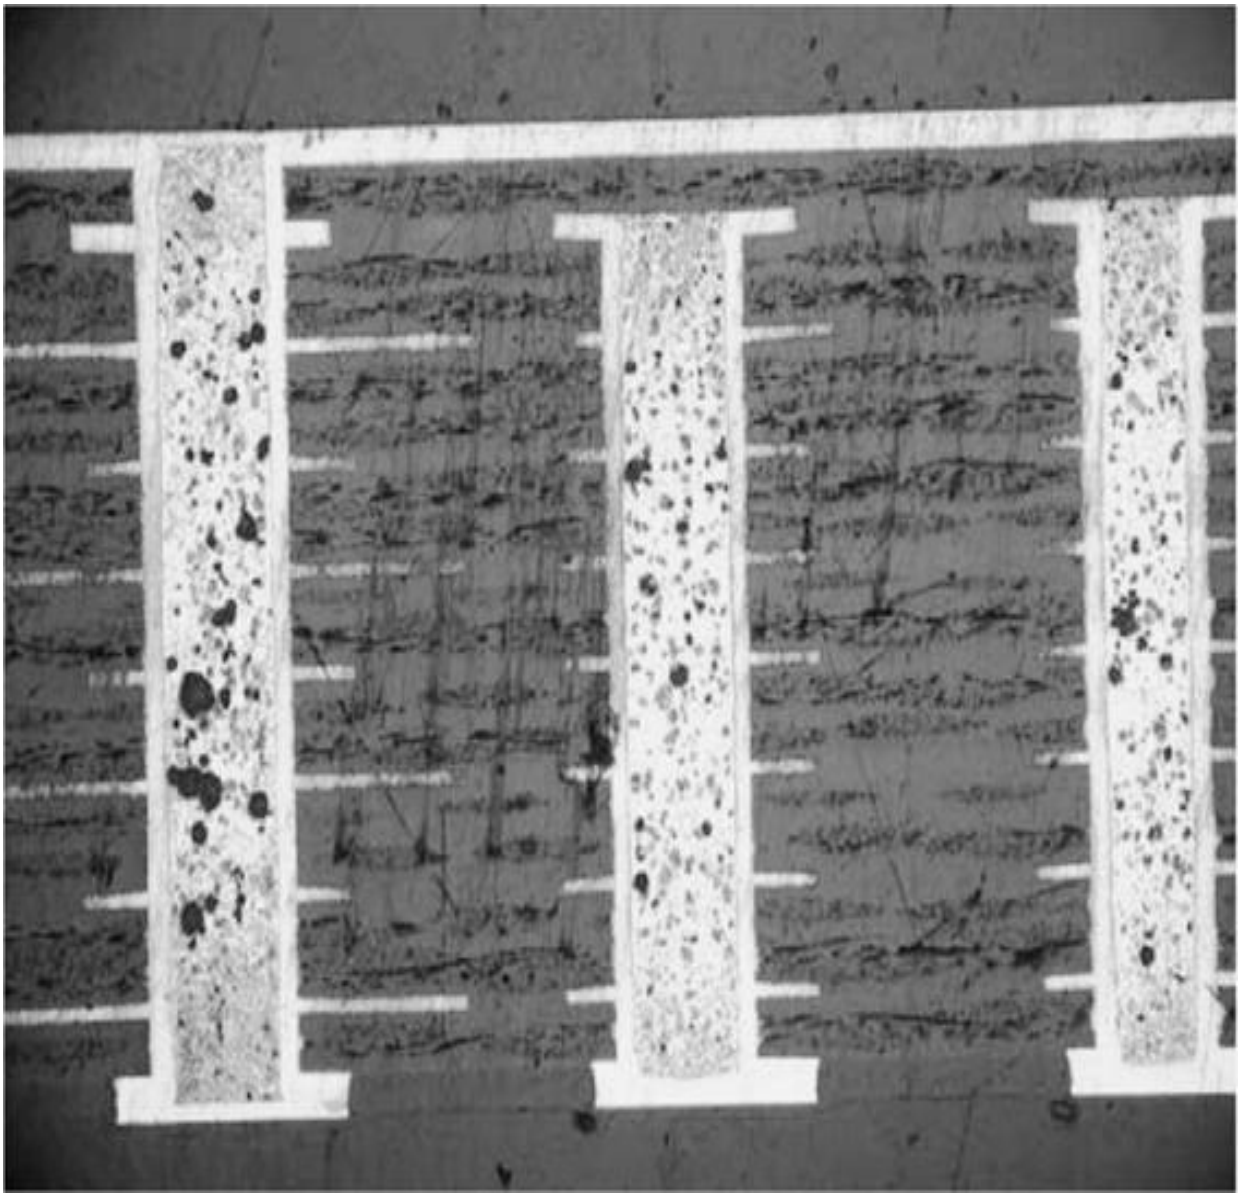

FIGURE 31.15 Micrograph of conductive via fill.

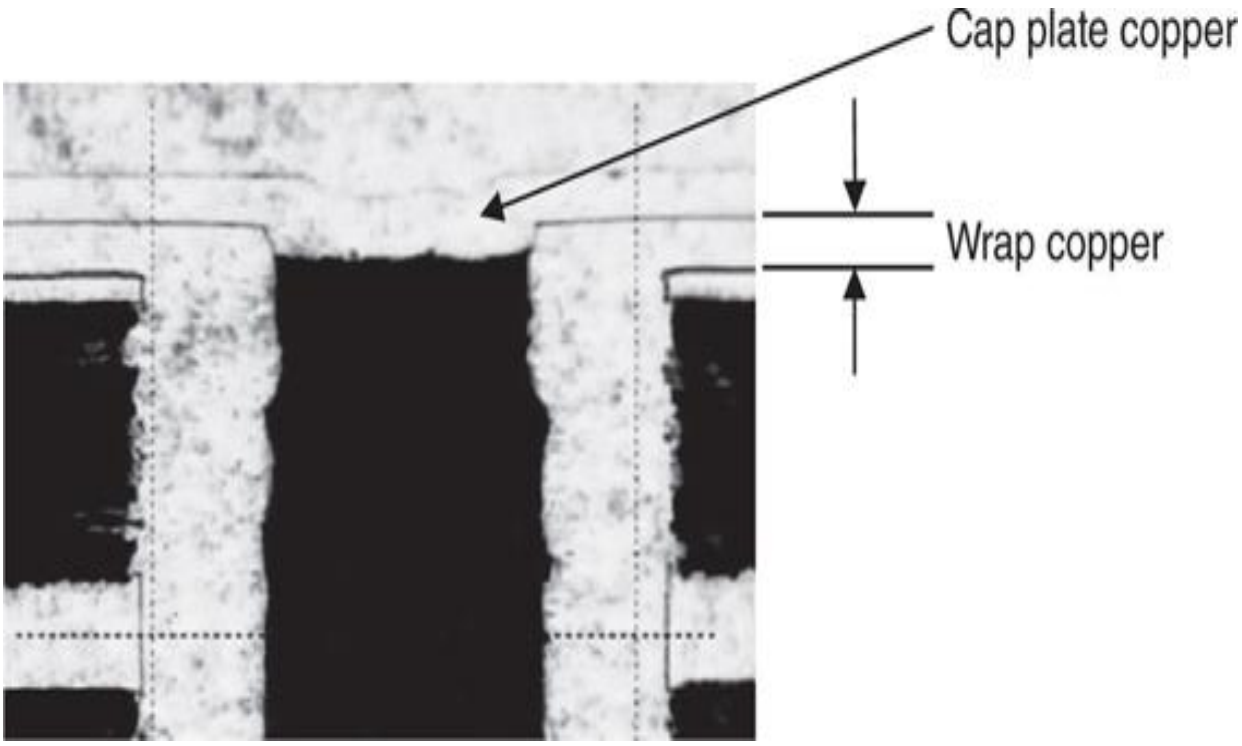

FIGURE 31.16 Micrograph of a nonconductive via fill with good plating features.

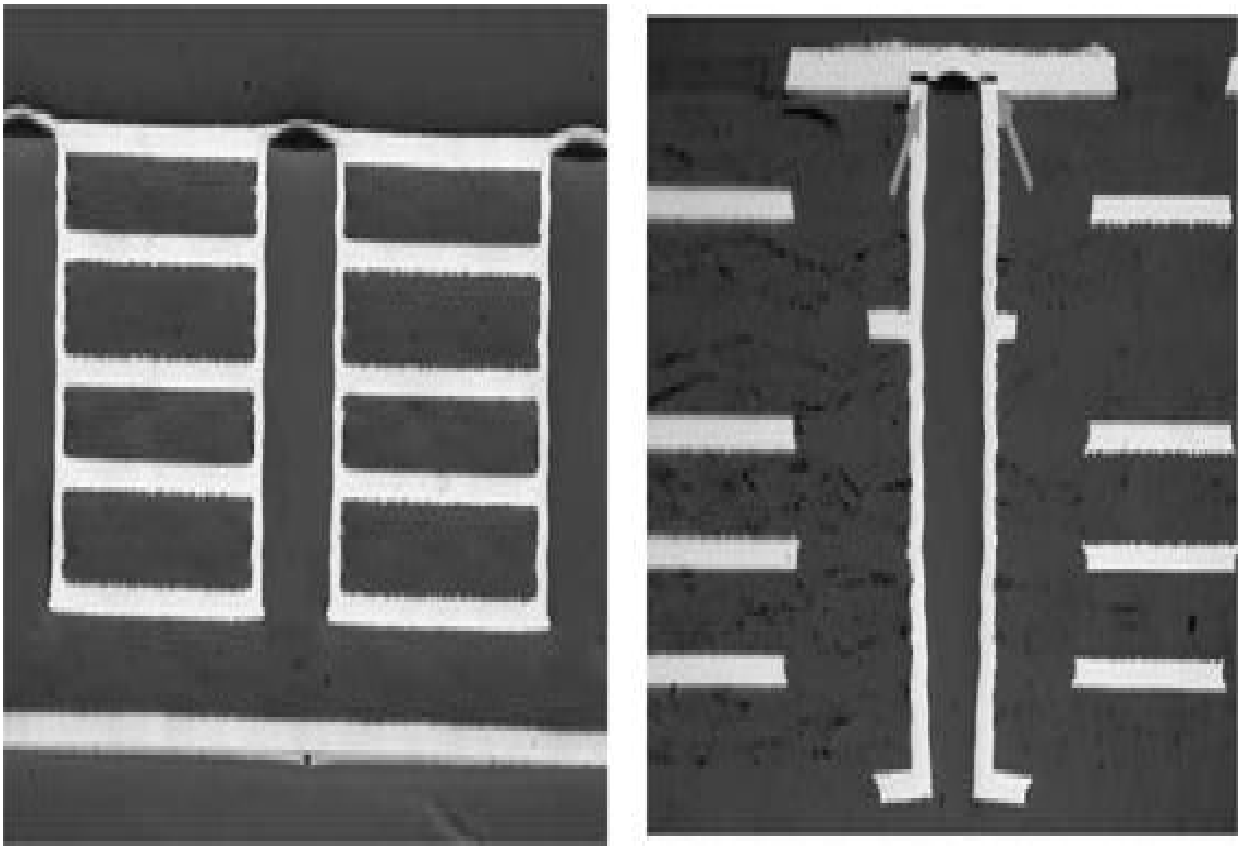

FIGURE 31.17 Micrograph of a nonconductive via fill with defective features.

31.2.4.3 Via Fill Processing and Flow. A via fill process flowchart can be used to communicate the modified steps of a typical manufacturing flow. Two process maps are shown to illustrate two typical process flow variables of a plated-cap versus non-plated-cap via fill process. Reliability testing to segregate the performance of via fill materials with the cap-plate and non-cap-plate features in the selected application should be performed prior to selecting this design feature.

When a plated-over via is required, plateability of the fill material should be a chief consideration. Fabricators should screen for this compatibility across the various via fill materials within their plating process to determine the integrity of the metalization. The flowcharts illustrate the fabrication methods employing a panel plate scheme. The flow could also be modified for a pattern plate methodology.

The two process flows are illustrated in Figs. 31.18 and 31.19. The key via fill process steps are highlighted for clarity.

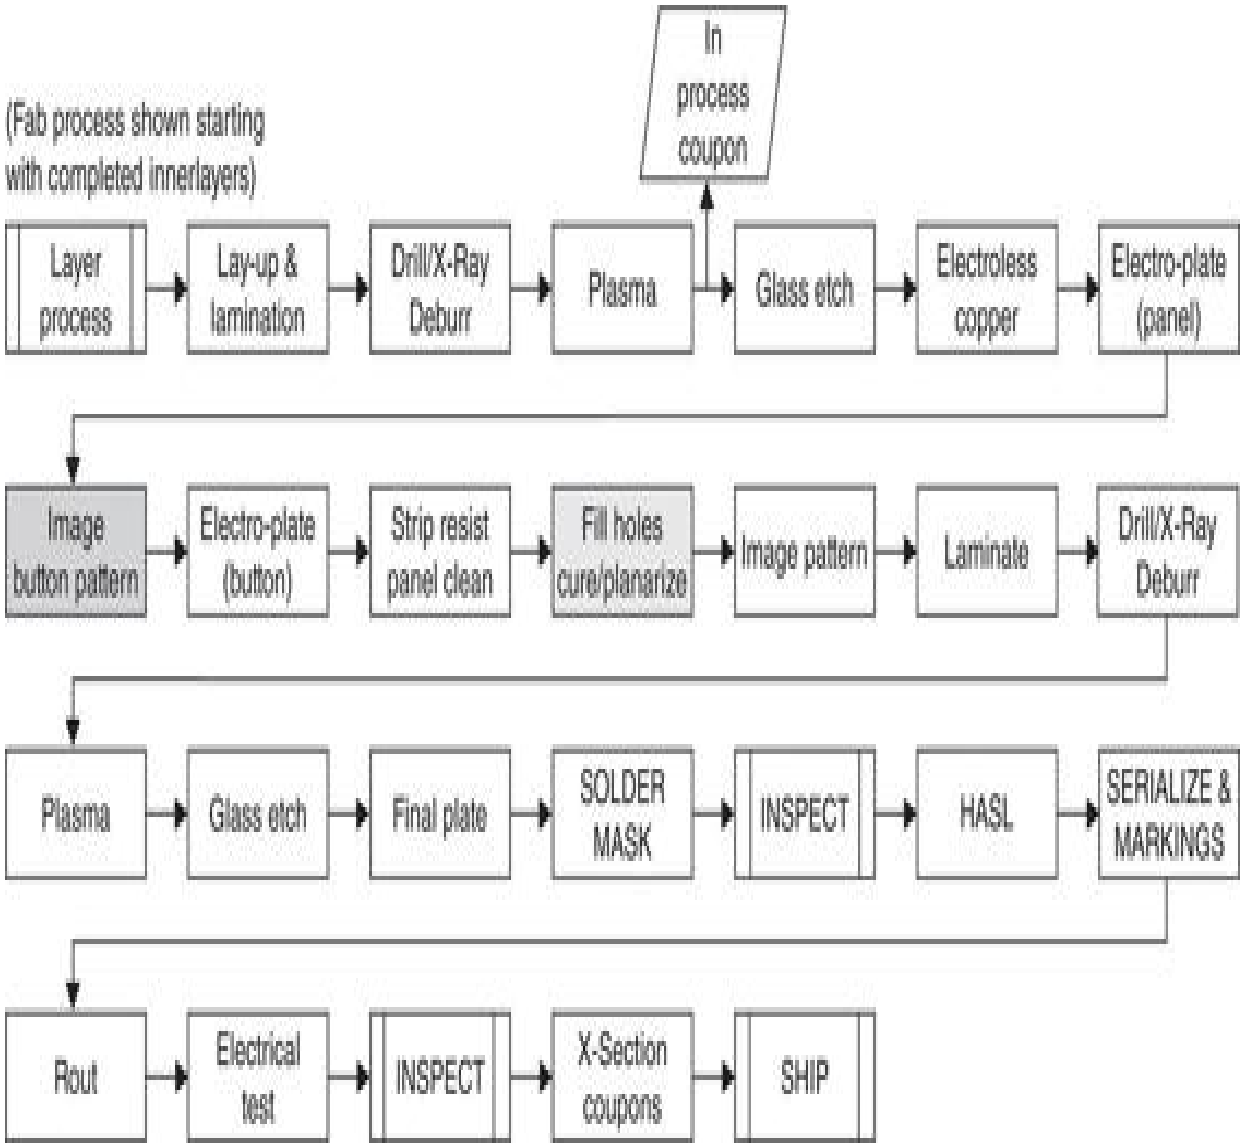

FIGURE 31.18 Via fill flow in a noncap plate process (panel plate/button plate).

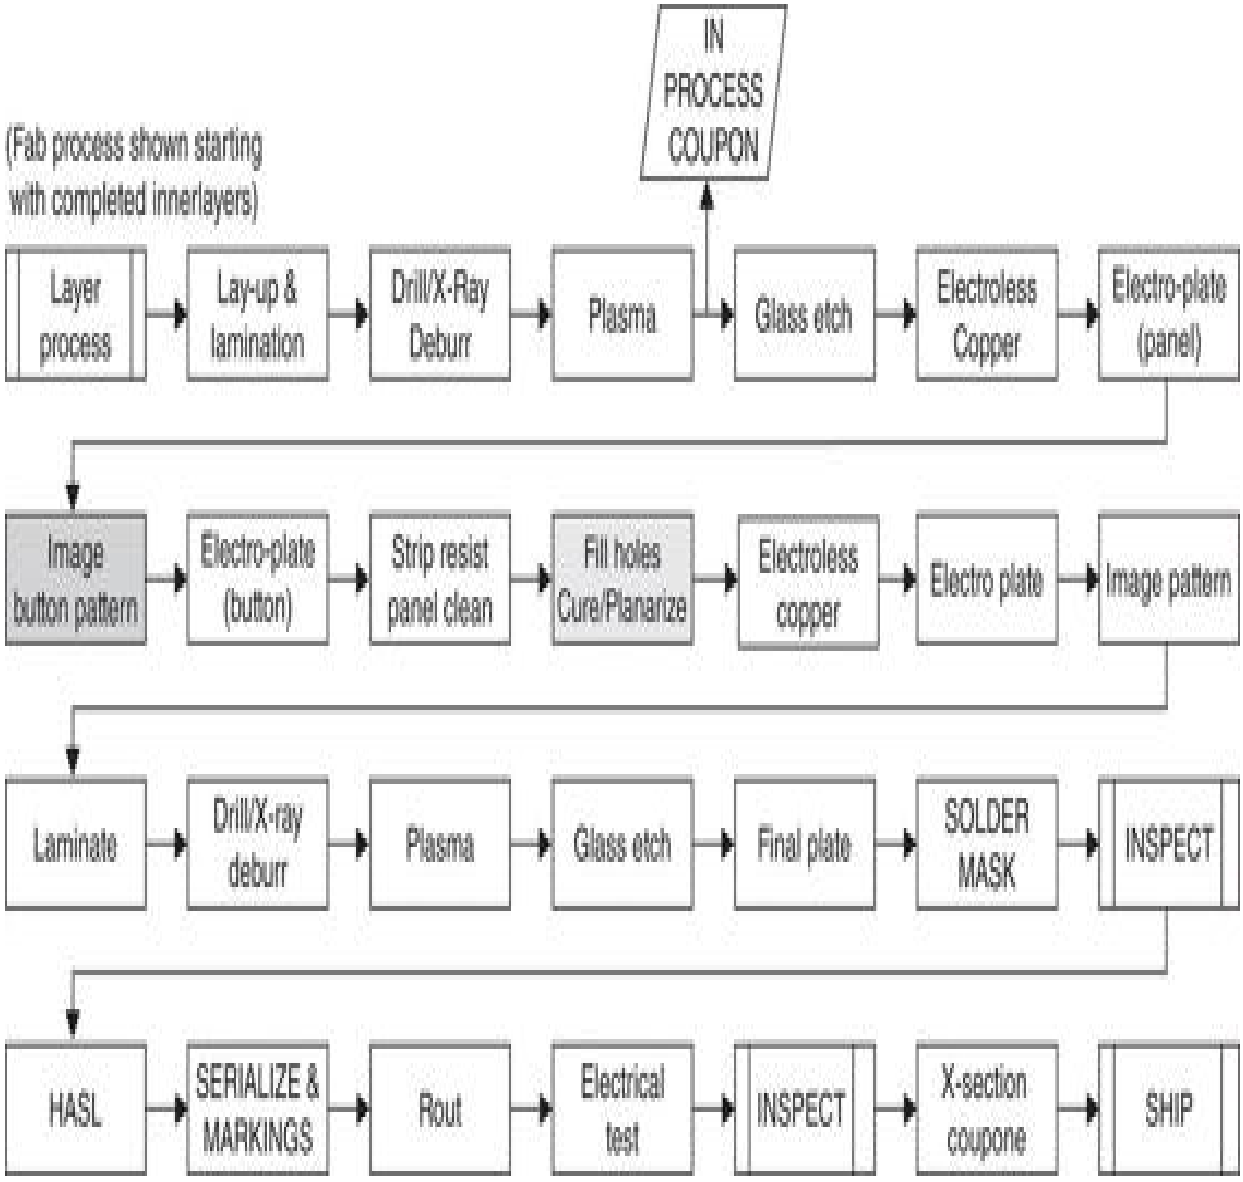

FIGURE 31.19 Via fill flow in a cap-plate process (button plate/panel plate).

31.2.4.3.1 Pre-Via-Fill Processing (Plating Variables). The plateability of via fill material is an important feature to understand due to industry trends that have shown that plated caps may be problematic in some design constructions. Outgassing of the fill material may separate the metallization during sequential lamination or thermal stress. Poor adhesion can also contribute to a separation but typically can be screened with standard tape testing. Figure 31.20 illustrates a cap-plated buried structure

and a micrograph showing a cap-plated via with separation occurring.

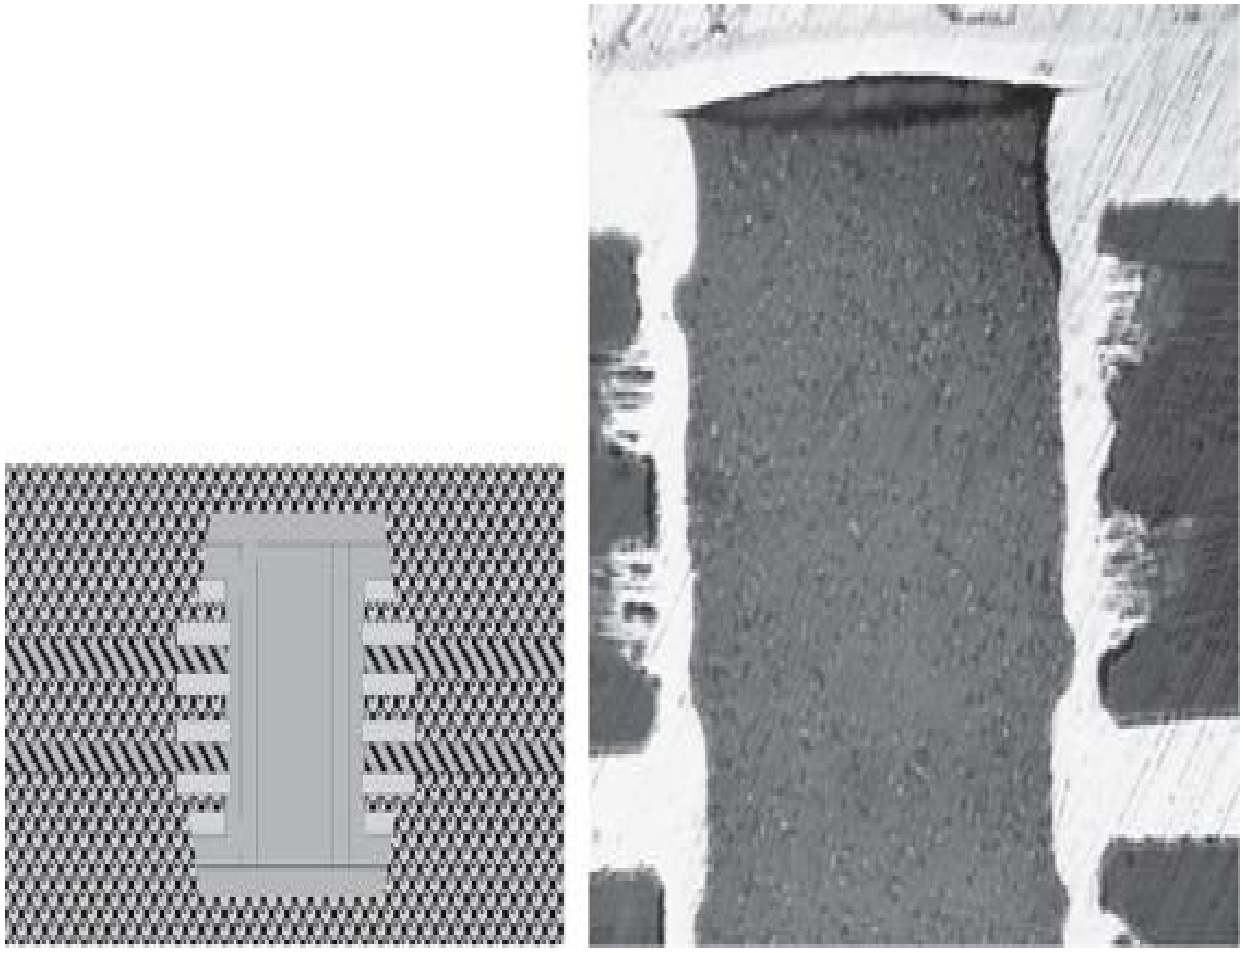

FIGURE 31.20 Cap-plated filled structure.

When the main design attribute is to limit resin from flowing into holes at sequential, lamination, the plating over the filled structure may not be required. Here, the filled panel after planarization can be staged for lamination. Figure 31.21 illustrates a non-cap-plated buried structure, and the micrograph shows a non-cap-plated via with lamination separation occurring.

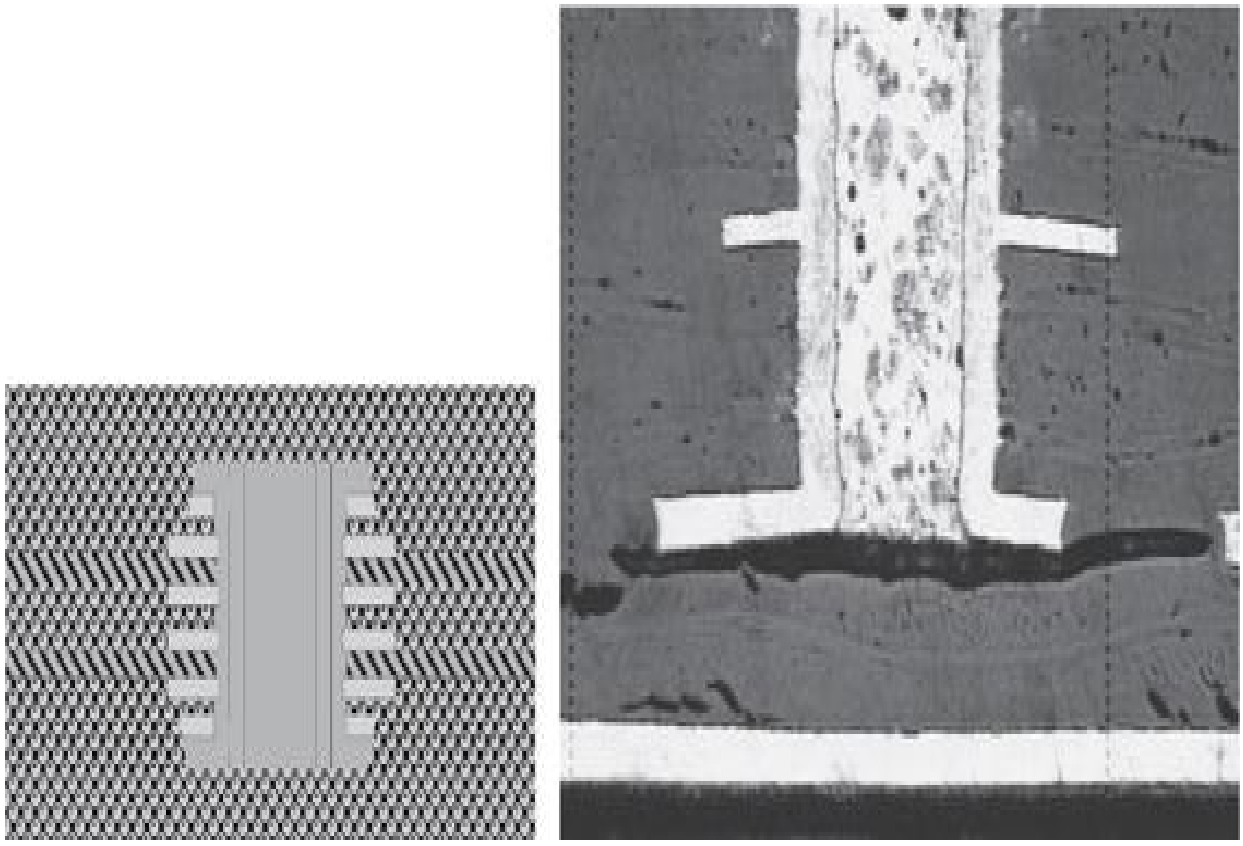

FIGURE 31.21 Noncap-plated filled structure.

Each of these techniques requires the fabricator to understand the fill material compatibility with their base laminate system and plating processes. Typically, process compatibility can be screened with a simple solder-float thermal stress analysis and cross section.

Prior to plating, the fabricator must understand the ability of the fill material to accept the electrolytic process. Some via fill materials have been reported to not be compatible with permanganate chemistry commonly found in electroless copper lines. Some cases of early failure of the via fill cap-plating integrity have been traced to this process. Elimination of the programming step to process the board through permanganate will avoid this incompatibility. Plasma desmear is the generally recommended preplating preparation step. Some resin chemistries that are loaded with ceramic are susceptible to excessive surface

roughening if the plasma is too aggressive as is typical in a full etchback cycle. This becomes problematic when secondary nonfilled plated vias are required and are processed with a full etchback cycle. In this instance, it is best to choose a nonceramic filled material or modify the drill sequence so they are protected. Typically, the conductive fill materials may be electroplated directly, omitting the electroless process. If the final surface plate has secondary drilled holes that require metallization, all features may be exposed to the electroless process anyway. If directly plating the material, the fabricator should characterize the material to confirm peel strength because some cases of plating separation have been traced to poor adhesion in direct plate applications. Therefore, when choosing a via fill material, it is best to develop a process map of the required via structure processing and understand the process sequence of when drilling, filling, and plating occur.

Figure 31.22 illustrates a typical manufacturing process targeting plating allowances for the successive plating steps prior to via filling. The first plating step establishes the minimum wrap plating requirement, and deposit thickness should be adjusted for the procurement specification and the balance of final plating. Here the substrate has a panel plate followed by a button plate. One advantage of the button plate is that it serves as a visual guide for the planarization removal process. Acting as a gauge, the button, when completely sanded off, indicates any additional sanding can be assumed to reduce the wrap plating.

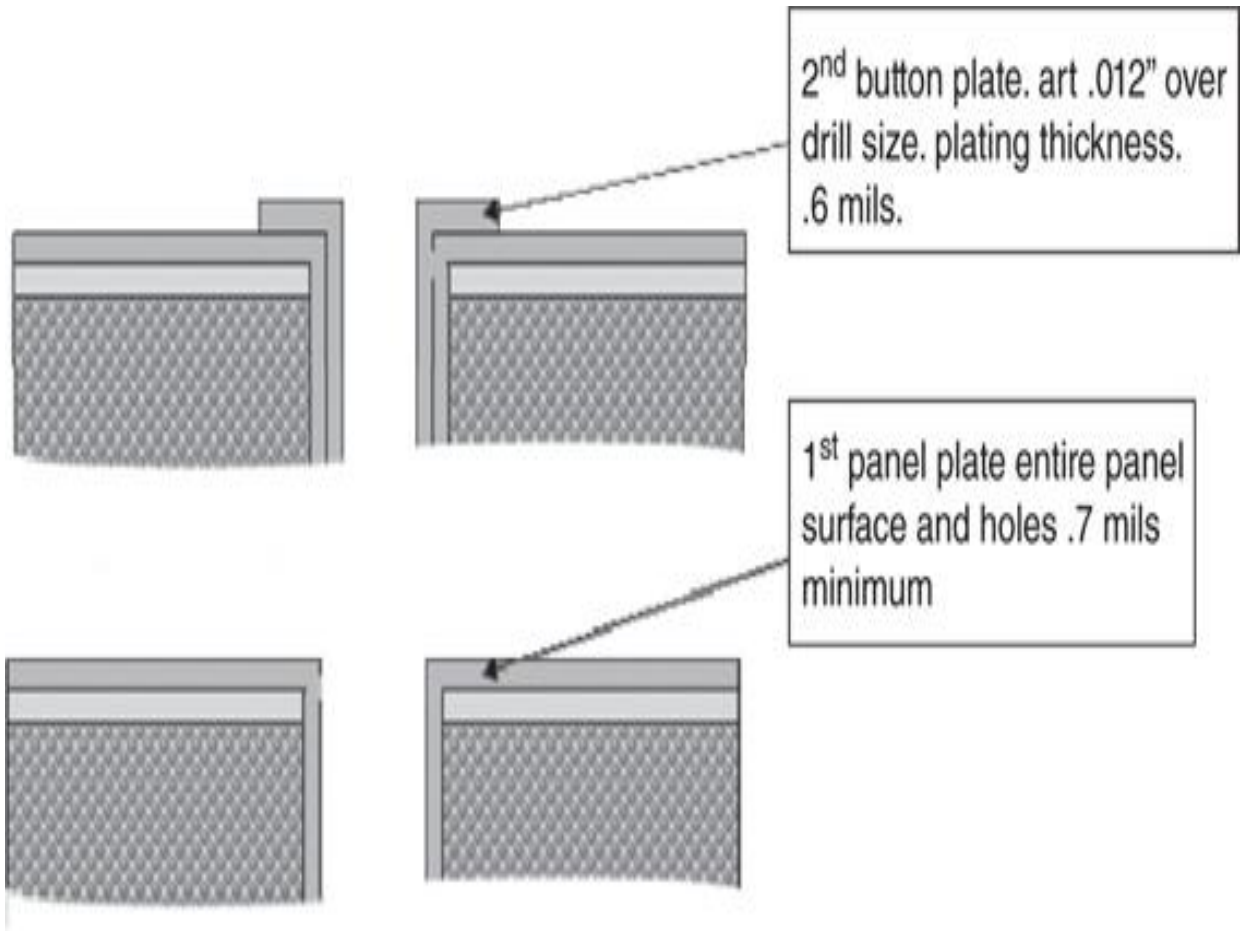

FIGURE 31.22 Pre-hole-fill plating.

31.2.4.3.2 Hole-Fill Process. Once the prefill-plating process is complete, the next major step is the actual hole-fill process. The fill materials can be divided into two major categories: conductive and nonconductive. A generic hole-fill process flow is shown in Fig. 31.23. The specific equipment and technique can vary by the material type used. The method chosen to apply the material in the holes can be influenced by many variables such as material cost, pot life, viscosity, equipment resources, and the quantity of panels to be processed. Some hole-fill materials lend themselves to a variety of fill methods. Some of the common hole-fill application methods are noted in the flowchart in Fig. 31.23. Application guideline parameters should be followed as noted in the respective material supplier data sheets. Via-

hole filling may be considered a mature process since process sensitivity has been reduced with advent of equipment designed to perform the process. Each application methods each have advantages and disadvantages associated with the technique employed.

PWB via fill application
(Generic flow)

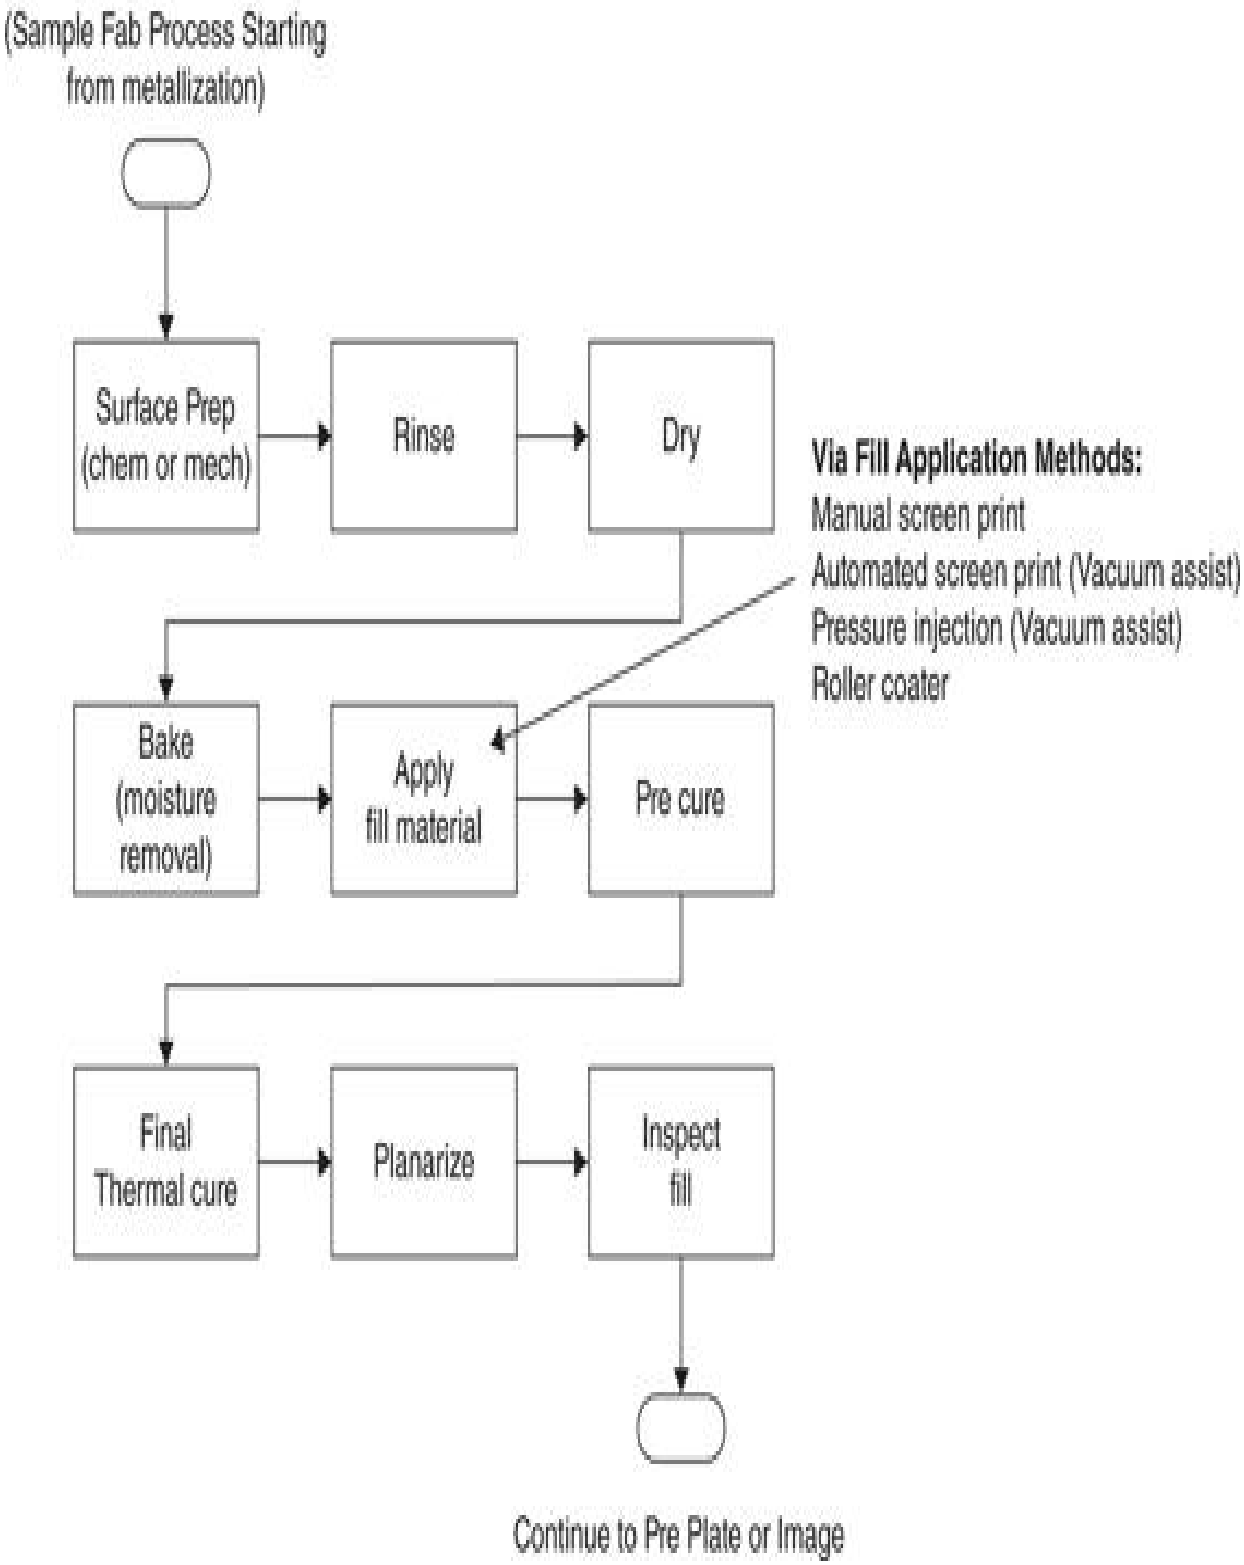

FIGURE 31.23 Generic via fill application flow.

Manual methods can be problematic. Such as when a fabricator uses screen printing, with a mask sized just over the hole size keeps excess material from being applied to the surface. Screen printing with a dot mask using a back side receiving template with open holes sized just over the plated hole diameter yields a domed fill bump. These bumps can act as a visual indicator similar to a button plate pad to indicate when the planarization is flush to the surface. Other methods include roller coating modified to squeegee excess material off the surface of the panel. Fewer problems exist with commercially available equipment designed specifically to apply fill material. One such machine uses a pressure-assisted injection method to force material into the holes under a vacuum. The principal advantage of this technique is the ability to reduce the opportunity for void entrapment.

Figure 31.24 illustrates an example of how the filled structure forms with successive steps for a non-cap-plated fill process. Note in this example how the surface button plating is mostly removed at the planarization step. Process development should be performed to target the optimum plating build-up method in regard to the process control of available planarization equipment. This means that whatever plating method is employed, both the deposit thickness across the panel and the net removal of deposit thickness as a result of planarization must be understood. Simple eddy current measurements of multiple locations across the panel are recommended prior to and after planarization sanding passes.

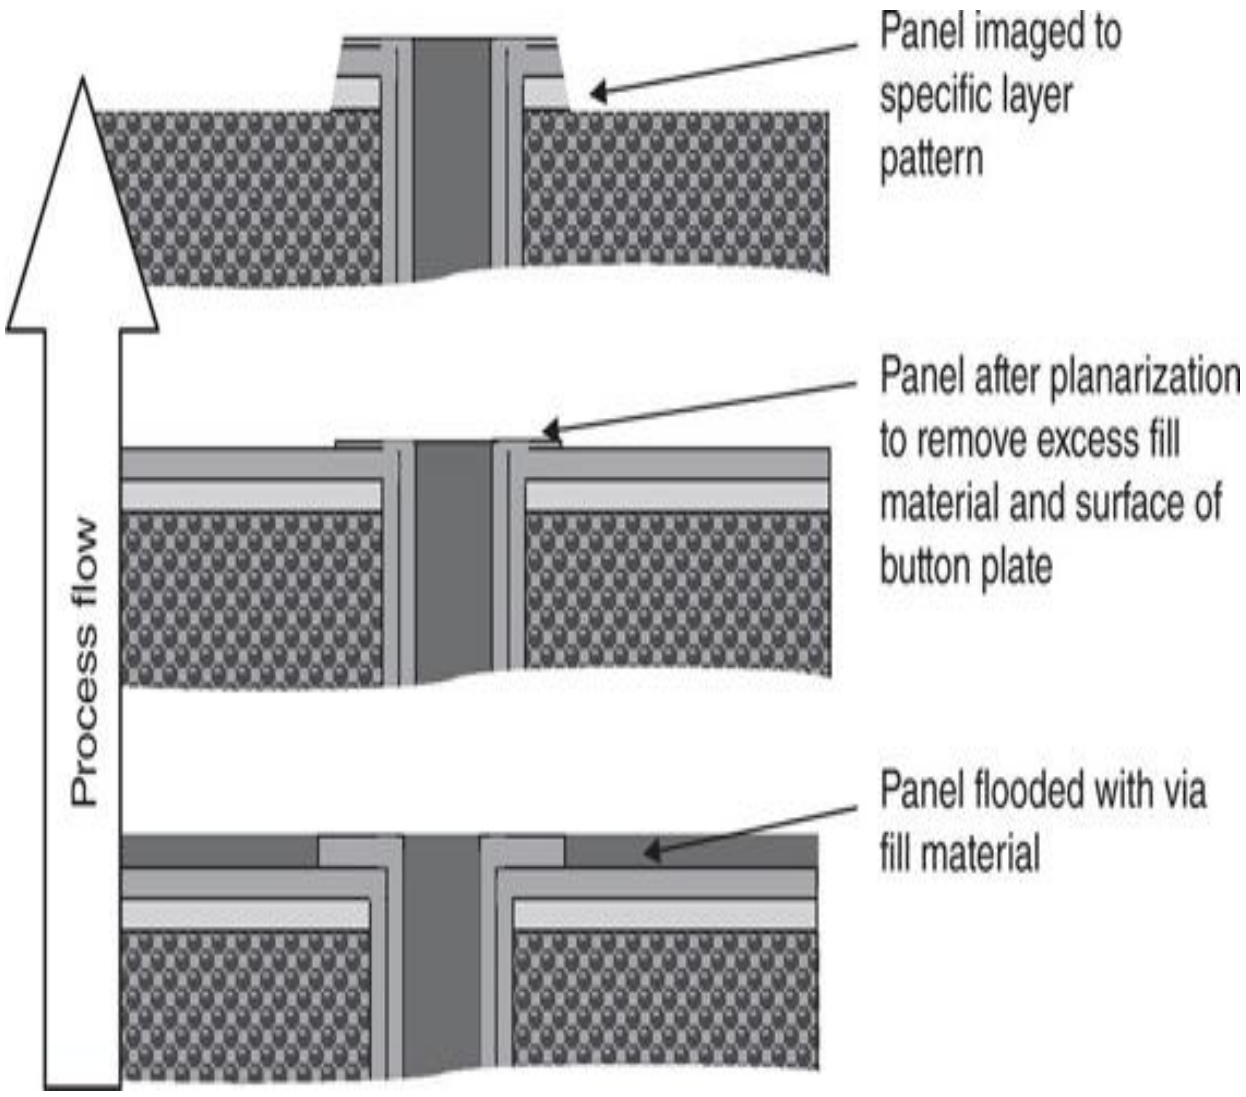

FIGURE 31.24 Non-cap-plated fill and planarization.

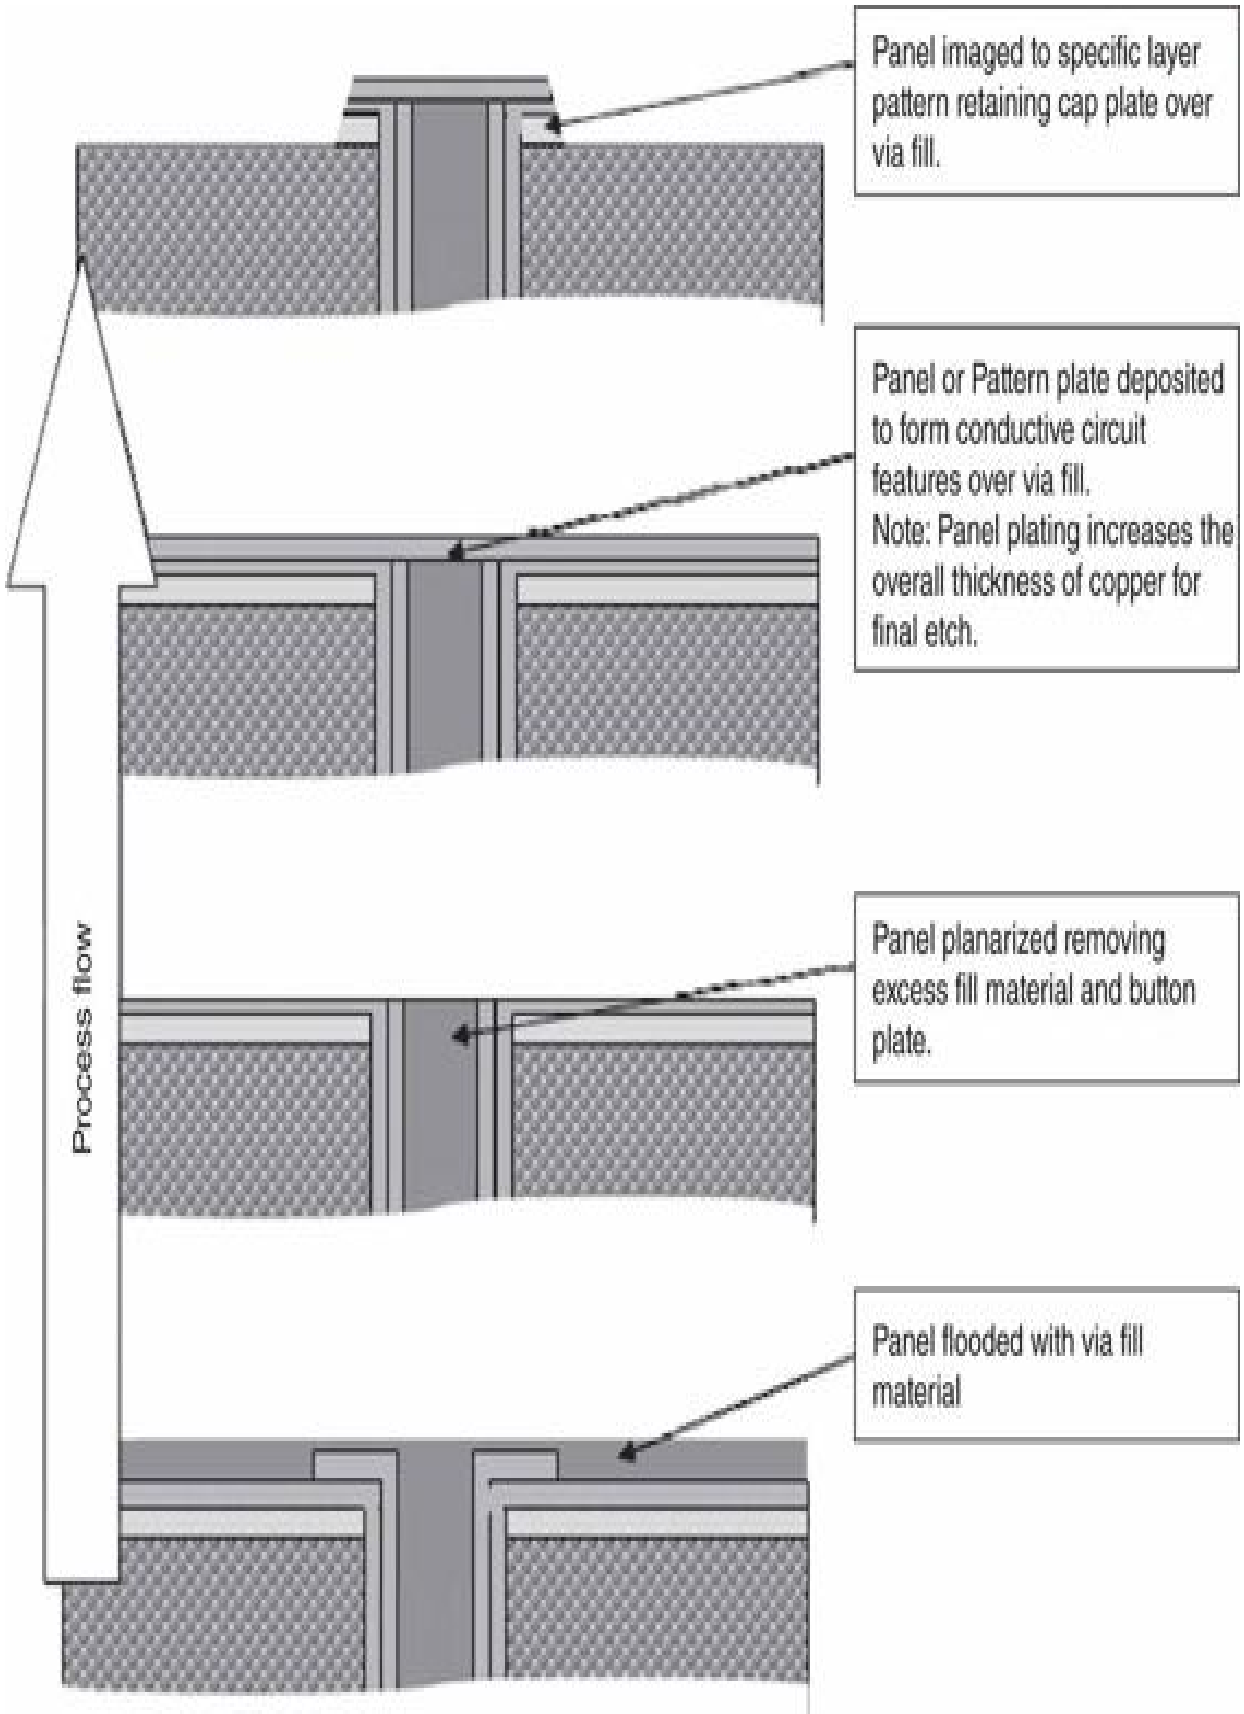
Once the planarization is complete, the panels are ready for imaging and etching to allow typical process flow, depending on construction type. The plating method chosen should take into account the surface pattern and construction level of difficulty. Multiple plating cycles are often required if multiple filled structures occur on the same surface plane. Excessive copper plating complicates the imaging, so the starting foil thickness should be kept to a minimum. Figure 31.25 illustrates how the fill method forms from use of a method employing cap plating over the fill material. It should be noted how the copper thickness

requiring etch can quickly build up, making pattern definition difficult.



Panel imaged to specific layer pattern retaining cap plate over via fill.

31.2.4.3.3 Specifications. The industry has released a design guideline document outlining via protection classifications, including the hole fill as described in this chapter. The IPC-4761, “Design Guide for Protection of Printed Board Via Structures,” has established via-protection techniques, creating specific types identified as Types I through VII. IPC-4761 contains many combinations of techniques where an added material is utilized to plug, tent, cover, or fill a via structure. Many of the techniques established are used in Class 1 and 2 hardware or where circuit card assembly consideration is the primary focus. Many of the 4761 via-protection types are of lower cost and lesser complexity than are those used for hole fills. The designer is encouraged to consult the application guide included in Table 5-1 of IPC 4761 to narrow the selection prior to layout and specifying a method. The via fills described in this chapter fall under the Type V and VII classifications. These types are maturely developed performance-based requirements for use in Class 3 hardware.

IPC-6012 and other IPC-6010 series specifications control minimum wrap copper. The specification limit remains at 127um (0.0005-inch) minimum wrap as verified by cross-section for Class 3 product. This is considered a conservative value resulting from the nonuniformity of the process. Correlation data is difficult and costly to verify coupons on the panel perimeter match that of the actual product. Maintaining uniformity of the planarization across the entire panel is difficult, so a conservative value at cross section was established to ensure that the part maintains wrap copper. The reliability data gathered support this value due to the additional manufacturing risk that can occur from the added fabrication steps. However, some data collected in MRB (Material Review Board) action and assessment indicate that

wrap copper as low as 0.0002 in is acceptable for some end-use environments; i.e., Class 2. Revisions of IPC 6012 continue to review the wrap requirement as the industry matures in regard to controlling the planarization process and additional reliability data become available. Additionally, some suppliers today have proprietary processes developed to lower risk associated with reduced wrap plating.

31.2.4.4 Via Fill Summary and Additional Considerations. The manufacturing of reliably filled vias should not be underestimated. Considerable process development is required to optimize the interaction of maintaining plating wrap to lower the risk associated with via fill planarization. The nature of reported failures due to compromised interconnect integrity have ranged from infant mortality at assembly to latent field failures. These failure mechanisms are very difficult to screen with standard performance verification methods. Even postassembly environmental stress screening (ESS) may not exercise sufficient stress levels to screen out marginal product effectively. This has directed some users to specify thermal shock temperature cycling at the bare-board production lot level for acceptance testing. This level of lot acceptance becomes more critical for lead-free assembly thermal stress environments, requiring the user to be more cognizant of the fill material selection.

A number of commercially available material choices exist with a wide variety of physical properties. Matching a material to a design type is necessary prior to specifying it on a drawing. Industry dialogue indicates the desire eventually to establish a material performance specification for fill materials similar to the IPC SM 840 for solder mask. The absence of a material specification requires the user to specify the brand(s) of acceptable fill materials through a user/supplier agreement. The process of specifying a hole-fill material can add cost to the PWB manufacturing process.

The process labor cost is relatively flat to apply a material with automated equipment application methods; the most significant cost variable being the material type. Some of the silver-filled conductive materials are roughly twice the cost of nonconductive materials. The process time and material cost can be roughly estimated at $25 to $50 per panel not including setup fees or minimum lot charges.

The impact to reliability is judged to be weighted more toward the suppliers' ability to successfully process the panels without degrading plated interconnects rather than the fill material type. This is followed by the ability of the manufacturer to metallize a specific fill material. The greatest number of failures reported in industry have historically been related to the planarization process. To this end, commercially available planarization equipment is now common place in the marketplace. Even with automatic planarization equipment, careful consideration should be given when specifying via fill for designs with heavy-weight copper or rigid flex constructions. Any construction that lends itself to circuit pattern imprint at the surface will have difficulty in the planarization process. Panel thickness at via structures can often be several mils thicker than open circuit areas. This change in height is not easily recognized and is problematic for producing a uniform sanding surface. Additionally, some softer materials or non-glass-reinforced materials may not be able to be planarized without distortion or gouging.

With more designs migrating to higher-density layout schemes via fill is common. The process of via fill has matured for Class 3 hardware as well. Many end users who learned difficult lessons quickly introduced their user-defined specifications for hole fill. User- defined specifications often do not lend themselves to producible limits, so consideration for via fill should be part of the DFM dialogue during the design layout cycle. The user and supplier must work closely

together to understand the impact of specifying hole fill for each design construction method employed.

31.3 ML-PWB PROCESSING AND FLOWS

31.3.1 Process Flowcharts

Attempting to visualize the process flow of the manufacture of multilayer printed wiring products can be overwhelming. One way to help picture the multiple paths a board travels is through the use of flowcharts. The flowchart in Fig. 31.26*a* is a typical process flow for the beginning innerlayer process identified as 1 through 4. Figure 31.26*b* is a typical finish board flow process after lamination and drill. Three additional diagrams are provided in Fig. 31.27 that represent possible sequential flows for HDI products. They are identified as processes 5, and 6 referring to how the different HDI types might flow. It should be noted that alternative flows and methods are possible in HDI. This discussion is limited to mostly conventional processing. Major aspects of these processes are discussed in detail in the following sections.

FIGURE 31.27 Diagrams representing possible sequential flows for HDI products. They are identified as processes 5, 6, and 7, referring to how the different HDI types mentioned in the text might flow.

31.3.2 Innerlayer Materials

The multilayer process begins with the accumulation of the innerlayer clad dielectric laminate.

31.3.2.1 Documentation and Specifications. The ML-PWB design documentation should specify the specific material system to be used in the fabrication. Typically materials are identified by IPC-4101 callout or slash sheet designation, for example, IPC-4101/24. Copper weights as well will be specified within the drawing documentation. The specification IPC-4562, "Metal Foil for Printed Wiring Applications," provides reference to the various weights of copper foils along with an applications use guide. The common terminology refers to foils less than oz/ft^2 as a metric thickness of micrometers.

31.3.2.2 Copper Foil. High-current applications use heavier (thicker) copper of 2 oz or above. With copper weights above 3 oz, processing difficulty is increased. High-density circuit designs that have low voltage and that are mainly concerned with passing signals may use thinner copper weight foils, such as 18 µm or less. When sequentially processing clads as buried via pairs, the fabricator must use thin starting foil to promote line definition and image integrity and, where necessary, impedance-controlled tracks. Copper foil is fabricated in an electroplating process on a rotating drum that produces a coarse-grained columnar copper. The economy of the foil process always yields copper at the minimum thickness tolerance. Due to the speed of the foil process, often a course grain structure can yield poor elongation. Elongation

is a property of major importance in reducing trace fracturing. Standard copper foils typically fail at elongations around 3 percent. IPC-4562/3 high-temperature elongation (HTE) provides a slight, but important, improvement in elongation from 5 to 8 percent. High-ductility electrodeposited foil, called HD-Type E (IPC-4562/2), is specified to withstand an elongation of 10 percent minimum. Foil vendors also sell special fine- grain-structure, annealed, or wrought foils. The foils with higher elongation are advertised to have superior etch performance for fine-line densities.

Standard foils have a rough surface called *tooth* on one side (drum side out) and a smooth or shiny surface on the opposite side (drum side). The rough side, treated with an adhesion promoter, is laminated against the C-stage dielectric to ensure good adhesion. Since the shiny side of the copper has poor adhesion characteristics, the ML-PWB fabricator must include adhesion promotion steps prior to resist lamination and prior to final board lamination. Double-treated copper foil has an adhesion promoter applied to both sides and is attractive in high-volume applications. Although double-treated foil requires no further adhesion promoting treatments, it has several process disadvantages to overcome:

- Cleanliness and material handling sensitivity is more critical.
- The cost often offsets the savings from the eliminated processes.
- It is somewhat fragile, so it is difficult to rework.
- Complete resist development is difficult, leading to a high incidence of shorts.
- It is not compatible with the plating processes used to make buried and blind vias.

Another foil type offered by laminate suppliers, reverse-treated foil (RTF), offers an advantage for producing fine lines. The RTF copper has adhesion promoter applied to both sides and is classified by 4562 as code R (reverse-treated bond enhancement [cathode side] stain-proofing on both sides). This approach provides advantages to imaging fine lines. When the copper tooth is reversed, the fabricator can improve line definition by allowing the etch chemistry process to stop sooner at the surface of the laminate.

31.3.3 ML-PWB Tooling

The tooling system employed for ML-PWB fabrication is one of the most critical aspects of the process and requires much forethought. The investment in tooling is significant and not easily changed. Planning is required to determine the degree of flexibility that is needed in a tooling system based on the types of ML-PWBs that will be produced in that facility. The ML-PWB tooling system can be broken down into four aspects: the panel size scheme, the front-end tooling, the method of generating tooling holes, and the hard tooling (plates).

31.3.3.1 Panel Size Scheme. The first decision is to choose from essentially three broad approaches to panel size: full sheet, or mass-lamination; standard panel sizes based on cuts from a full sheet; or customized (flexible) panel sizes based on cuts from a full sheet. Any particular facility may also employ more than one approach.

31.3.3.1.1 Mass-Lamination. Sheet sizes can be 24 × 48 in; 36 × 48 in; 48 × 52 in; 1.5 × 2 m; or other similar large formats. This approach is well suited to medium or mainstream technology requirements in lines and spaces, and hole-to-pad ratio. It works best with larger sized PWBs since too many small PWBs leave too much blank space

between the circuits, wasting the principal advantage of full-sheet lamination. Typically, the copper foils are standard weights. The cores are 0.004 in (1.0 mm) or thicker, although some mass laminators are capable at 0.002 in (0.05 mm); and the lamination is a single-resin system, not a mixed dielectric build. The most common construction is from epoxy resin, since most of the enhanced electrical or thermomechanical resin systems are not available in large sheet sizes.

31.3.3.1.2 Standardized Size Cut Panels. This approach is dominant in high-end technology PCBs. Some very common panel sizes are 18 × 24 in and 20 or 21 × 27 in. The facility strives to have the fewest number of standardized panels that will accommodate the majority of the MLB sizes typical of their customer base. Tooling is then either fully fixed or modular based on those panel sizes, but other new panel sizes are not possible without new hard tooling and die. Having four to eight panel sizes is common. These sizes are based on full yield cuts from the laminator's full sheets; for example, the laminator might offer a 36 × 48 or 42 × 54-in sheet and the fabricator orders (or cuts from full sheets) 14 × 18, 12 × 24, 18 × 24, and 21 × 27-in panels. This system standardizes tooling into the fewest number of different sizes of hard tooling (e.g., caul plates and separator plates; see Sec. 31.5.1.1). This approach is also best suited to advanced feature sizes, where limiting the panel size to just over the MLB size has the advantage of reducing some degrees of difficulty such as the registration requirement over a larger area. Fixed panel sizes work well for mixed dielectric builds and sequential laminations. Very large cut panel sizes such as 24 × 36 in, approaching mass lamination size, are uncommon but available in very high-volume or backplane fabrication specialty facilities.

31.3.3.1.3 Custom-Cut Panels. Asian fabricators have pioneered flexible custom-cut panel sizes to maximize material utilization further and so reduce costs. The

difference between standard and flexible cut panels is that standard-cut panels have a limited number of predetermined sizes and consequent hard-tooling configurations, while the flexible cut panels afford a continuous range of size because the tooling isn't fixed but highly configurable. Flexible cut panels are often paired with riveting instead of pinning to hold the details, prepreg, and foil together for lamination. Many Asian facilities will offer both approaches, selecting the best suited to the job at hand.

31.3.3.2 Front-End Tooling. The first aspect of the ML-PWB tooling is commonly called front-end tooling or simply computer-automated manufacturing (CAM) tooling. (Current data transfer XML schema is migrating to IPC-2581 to replace Gerber.) The front end is where manufacturing personnel using a CAM software package generate all phototools or output directly to Laser Direct Imaging (LDI), the associated computer numerical control (CNC) electronic files (used by equipment such as drillers and routers), the construction stack-up, and the part manufacturing instructions, or "work order," also called the "traveler." The CAM station mirrors the tooling method chosen for the shop and the job's work order. The CAM software overlays the tooling pattern on each circuit layer to produce the master pattern alignment. The master artwork pattern is then photo-plotted to reproduce the artwork film tools for the imaging operations. Several important manufacturing functions fall within the bounds of the front-end tooling responsibility.

31.3.3.2.1 Design Rule Check (DRC). Design rule check (DRC) is where the electronic design data are analyzed against a specific set of fabrication rules, a virtual simulation of the design for manufacturing (DFM). The capabilities and attributes of these rules are based on sound, industry-proven values that match the technology targeted for construction. The default values embedded into the CAM are input by the manufacturer as technology files. These files should reflect

the capability of the fabricator’s equipment and processes in light of how they are utilized against the ML-PWB type being produced.

31.3.3.2.2 Panelization. To gain economies in the manufacturing process, the individual board design is stepped and repeated within the artwork tooling. Panelization is the term used to describe this method. Here the elemental goal is to yield as many parts on one process panel as possible. The CAM software allows manipulation of the single design pattern to place or nest multiples within the confines of the chosen panel dimensions.

31.3.3.2.3 Artwork Generation (Photo-Plotting). Once the design has been formatted into the desired panelization, it is ready to be made into a working phototool or LDI data format. The CAM data are output to a server that converts the data into a language recognizable by the plotting/LDI equipment. The plotter exposes the circuit pattern on the film tool or direct writes it to the resist coated panel. Typically, the film tool is polyester-based with a silver emulsion and is exposed by means of a laser or fiber-optic light source. The resolution of the light source directly affects the ability to image the technology type. Note that when the technology type approaches the feature size of HDI, the use of an alternative approach to phototooling are commonly employed. This is known as laser direct imaging, and, as the name implies, the image is directly exposed onto the production innerlayer, thereby eliminating the use of a phototool.

31.3.3.2.4 CNC Drilling Routing Tools. The machine communication method commonly employed in the automation of the drilling and routing process is output from the CAM tooling as CNC programs (from the earliest computer numerical control machines, as differentiated from manual or template positioning systems). The front-end tooling software facilitates the organization and optimization of the CNC routine. The routine must match the flow of the

technology process steps being produced. When sequential processing is required, the drilling routing data must be broken out into separate routines. When the technology type involves HDI features that require laser drilling, specific tooling accommodations have to be considered to match the discipline of the laser equipment—for example, the use of special imaged fiducial targets or a special etched dot mask aligned to the drill locations.

31.3.3.2.5 Automatic Optical Inspection. Another aspect of the tooling set is the data configuration to support the automated optical inspection (AOI) process. AOI is considered part of the detailed inspection process. When the AOI equipment supports what is known as CAD reference, the original design data are now output as a configured file to compare the imaged circuit layer to the original designed circuit (see Chap. 53 for a complete discussion of inspection).

31.3.3.2.6 Electrical Testing. The final aspect of the tooling set is preparation of the electrical design data to support an electrical testing routine. The purpose of the electrical testing within the ML-PWB production process is to verify the integrity of circuit continuity. The electrical data required for the test must be extracted from the circuit pattern unless a separate net list is provided that contains the connectivity. The standard data format for electrical testing is IPC-356.

Electrical testers can take on many forms, but are generally divided into two major categories, the bed-of-nails and the flying probe. Tooling for a bed-of-nails tester consists of outputting data to manufacture a fixture to accommodate the pins, which make contact with the circuit nets. When a flying probe tester is employed, the net data are fed into the machine, which uses its own software to configure the routine to probe continuity and perform isolation. (See IPC-9252 for standard industry test parameters)

The chosen method of test tooling requires an examination of the economics based on the volume and technology of the ML-PWB. For small prototype lots required in short cycle times, flying probe may be more suitable than bed-of-nails testing. Although the throughput of a flying probe unit is less than that of a bed-of-nails tester, the flying probe does not require expensive, and time consuming to construct, fixtures. When the technology type involves HDI features, the only alternative is to use a flying probe due to the limitation of the grid spacing in a bed-of-nails tester. High-density test requirements continue to drive flying probe technology. (See Chaps. 39 to 42 for a complete discussion of electrical testing.)

31.3.4 Tooling Hole Formation

The shape, size, and location of tooling holes or slots are dependent on the investment tooling system determined by manufacturing engineering for a given facility, and there a variety of methods to form them. The tooling holes range in size and shape from 0.125 to 0.250-in diameter to a slotted hole of 0.187 × 0.250 in. The common methods used to produce the mechanical alignment in innerlayers are punch and die or drilling, but the point in the process where they are formed can vary depending on the total tooling scheme. New tooling schemes are coming to the marketplace that eliminate dependence on tooling holes described below. This new method inductively bonds layers together prior to lamination eliminating the tooling pins/holes.

31.3.4.1 Prepunch. The oldest method, fixed punch and die set are used to generate tooling holes/slots prior to imaging/etching. To avoid having to cut away the photoresist material over the tooling hole, fabricators sometimes perform the punching after resist lamination. In this case,

cleanliness has to be significantly refined. If a cut sheet resist laminator is used, it can be adjusted so the resist falls inside the boundary of the tooling locations. The punching occurs in a hydraulic punch press, where alignment is ensured by means of an edge stop on two axes of the panel to square the alignment. The die set penetrates the laminate in one stroke, punching all holes at one time while holding the material flat. Material is punched one piece at a time, yet high throughput can be achieved by this method. Punching of multiple laminates at once is not recommended because the quality and size of the tooling hole/slot are affected. Additionally, thicker laminates (greater than 0.032 in) require the punch and die set to have a slightly larger tolerance to accommodate the spring-back of the hole within the composite material. Overall, the prepunch method is very accurate and repeatable. Materials with a high degree of movement (low-dimensional stability) are at a significant disadvantage in this method due to the drift of the tooling location after innerlayer processing.

31.3.4.2 Post-Etch Punch. A more popular method uses an optically aligned punch to generate holes/slots after imaging/etching. The fully processed innerlayers are edge-aligned into the punch; a pair of video cameras locates on a diagonal pair of printed fiducials; a servo-system aligns the panel, minimizing alignment errors due to panel distortion; and tooling holes are punched. This process punches an optimized set of tooling holes/slots in the layer just prior to lamination. Post-etch punch can be automated so it has high productivity, but it is slower than a simple punch and die. However, the productivity gain achieved by printing without tooling reduces some of the productivity loss from using post-etch punch.

31.3.4.3 Drilled Tooling. When processing follows the process sequence 3 and 4 described earlier, tooling locations

may be drilled by X-Ray location of buried fiducials. This allows the tooling locations to be formed prior to the via-drill cycle. This accommodates the effects of final registration accuracy by optimizing for scaling of the pattern. i Scaling helps minimize the dimensional effect that processing has on the true positions of the holes. Alternatively, extra sets of tooling holes may be produced just for the imaging process, followed by a post-etch punch operation to optimize the lamination registration.

31.3.5 Tooling System

There are numerous rationales for innerlayer tooling schemes, and this has resulted in a wide assortment of tooling systems being used across fabricators. Over the years, many tooling systems have evolved, ranging from full-perimeter distribution of holes to as few as four holes located on the midaxis. One low-cost tooling system comprises use of rivets in a flexible layout scheme. The tooling system comprises a substantial investment and therefore merits considerable engineering conceptual judgment. Many shops become trapped with poorly conceived tooling schemes that are difficult to migrate from due to the cost of converting earlier designs. Therefore, careful analysis should be given to the product mix and technology types to be manufactured prior to choosing a scheme.

The primary purpose of the tooling system in ML-PWB manufacturing is to facilitate layer-to-layer alignment during the lamination cycle while maintaining a positional reference for subsequent processing. The tooling hole arrangement is mirrored within the front-end tooling routines mentioned earlier. The master alignment of each part keys off the tooling scheme. The primary tooling locations may be used at all process steps or sometimes used to introduce secondary reference holes.

Figure 31.28 shows three different tooling schemes. Figure 31.28*a* shows a system known as four-slot tooling. This is an excellent system, because the use of four slots allows for growth and shrinkage of the layers during processing. The four slots may be used for printing, inspecting, and lamination, or, if post-etch punch is used, they are used for inspection and lamination only. Figure 31.28*b* shows a system known as four-slot/four-hole. This is common in a pre-punched system where the slots are used for image printing and the extra holes are engaged at lamination. Alternatively, punched slots can be used for innerlayer image and lamination, while post-lamination holes are drilled for plated holes' drilling and outerlayer imaging. In this method, targets imaged in the details under the outerlayers are exposed by controlled depth boring; a camera then locates the targets and a spindle drills the locating holes for the secondary operations. Figure 31.28*c* shows a tooling system with a full perimeter of holes placed. This style would be considered overdetermined. It has a disadvantage at lamination because imaged panels typically have to be stretched over the alignment pins. A fourth tooling system not shown uses low-profile rivets to align layers. The rivets can be arranged outside the pattern area and do not penetrate into the caul plate. Rivet height is chosen based on the appropriate panel thickness. Alternative to rivets a newer process inductively bonds layers together in place of rivets.

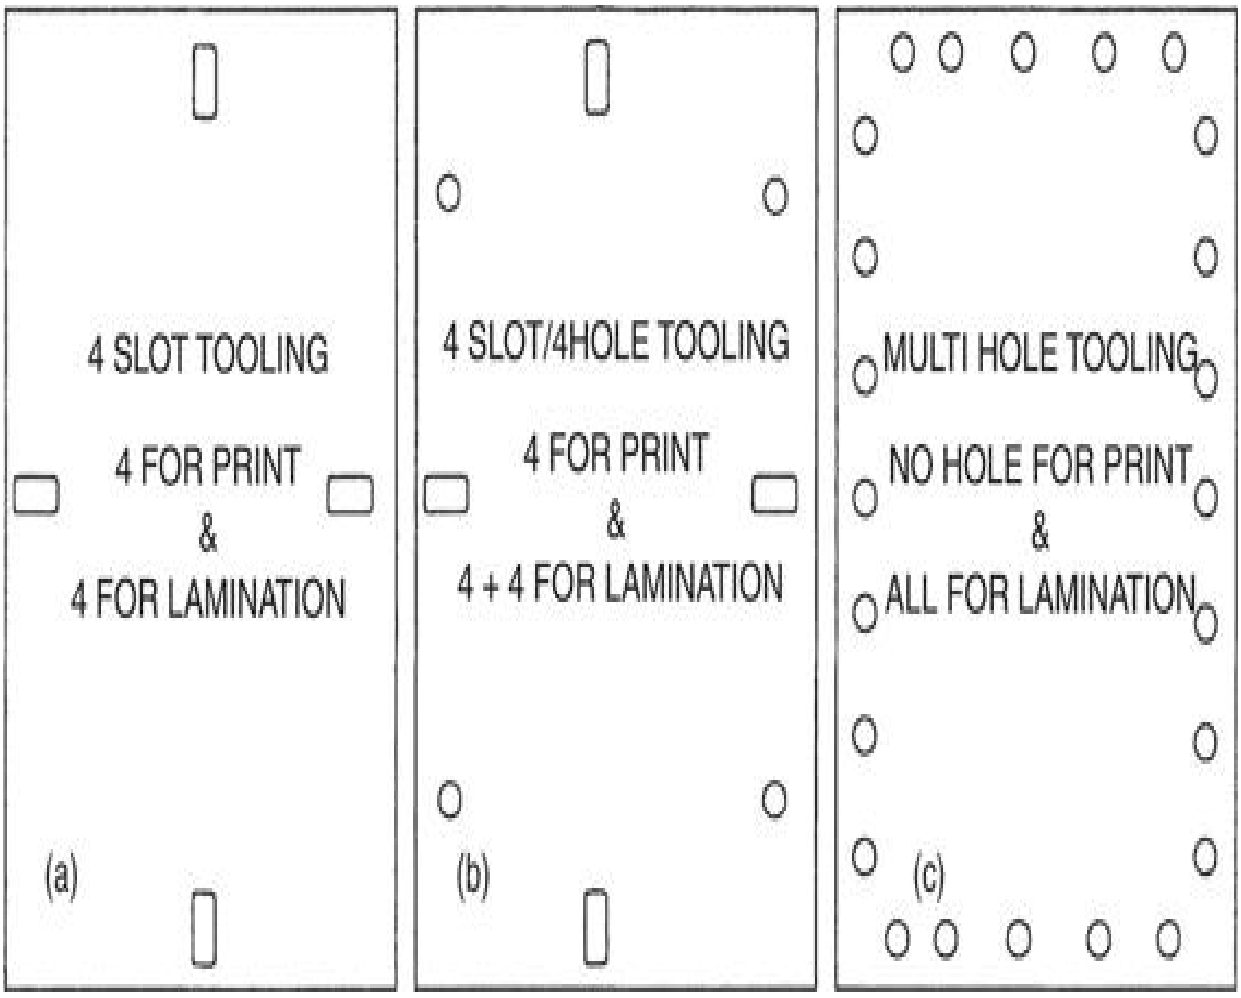

FIGURE 31.28 Three different tooling schemes: (*a*) four-slot tooling, (*b*) four-slot/four-hole; (*c*) a tooling system with a full perimeter of holes placed.

31.4 LAMINATION PROCESS

The lamination process is an essential step in the fabrication of an ML-PWB. The process is also one of the longest cycle time operations. Therefore, when the process method calls for repeat cycles, or what is called sequential laminations, it can be a significant cost driver. (*Note:* Sequential lamination is often paired with distinct, separate drill and plate processes for the subcore that further ratchets up pricing, as they are also time-intensive operations.) The lamination

process involves two distinct yet linked operations: lay-up and laminating.

31.4.1 Lay-Up and Materials

Lay-up occurs in a clean and controlled room environment. The level of environmental control depends on the circuit feature technology being fabricated. The lay-up process for standard multilayer processing is relatively forgiving. However, working with material that is hygroscopic will require additional measures. The innerlayer details require a bake cycle (typically 105 to 110°C for 1 h minimum) to remove moisture. A reduced bake cycle duration is indicated when certain oxide reduction chemistries are employed. Once layers are readied for lay-up, they should be processed as soon as possible. Should extended hold times become necessary, storage in a nitrogen-purged dry box is recommended.

The lay-up operation is often referred to as “building up a book.” The operation follows a guide, often referred to as a stack-up sheet. The guide sheet, which depicts the engineering design of the ML-PWB, is highly recommended to minimize error. The written and illustrated guide to the book build-up process is made a part of the job planning/traveler. Due to the complexity of some products, the operator follows this guide in a recipe-type manner to perform the systematic construction. The lay-up may consist of some four or more PWB material components or other subassemblies. The lay-up operation produces a large assembly when complete that consists of the tooling plates, consumable press materials, and the ML-PWB detail. Refer to Figs. 31.29 and 31.30 for illustrations of the following.

FIGURE 31.29 Typical ML-PWB stack-up for hydraulic lamination.

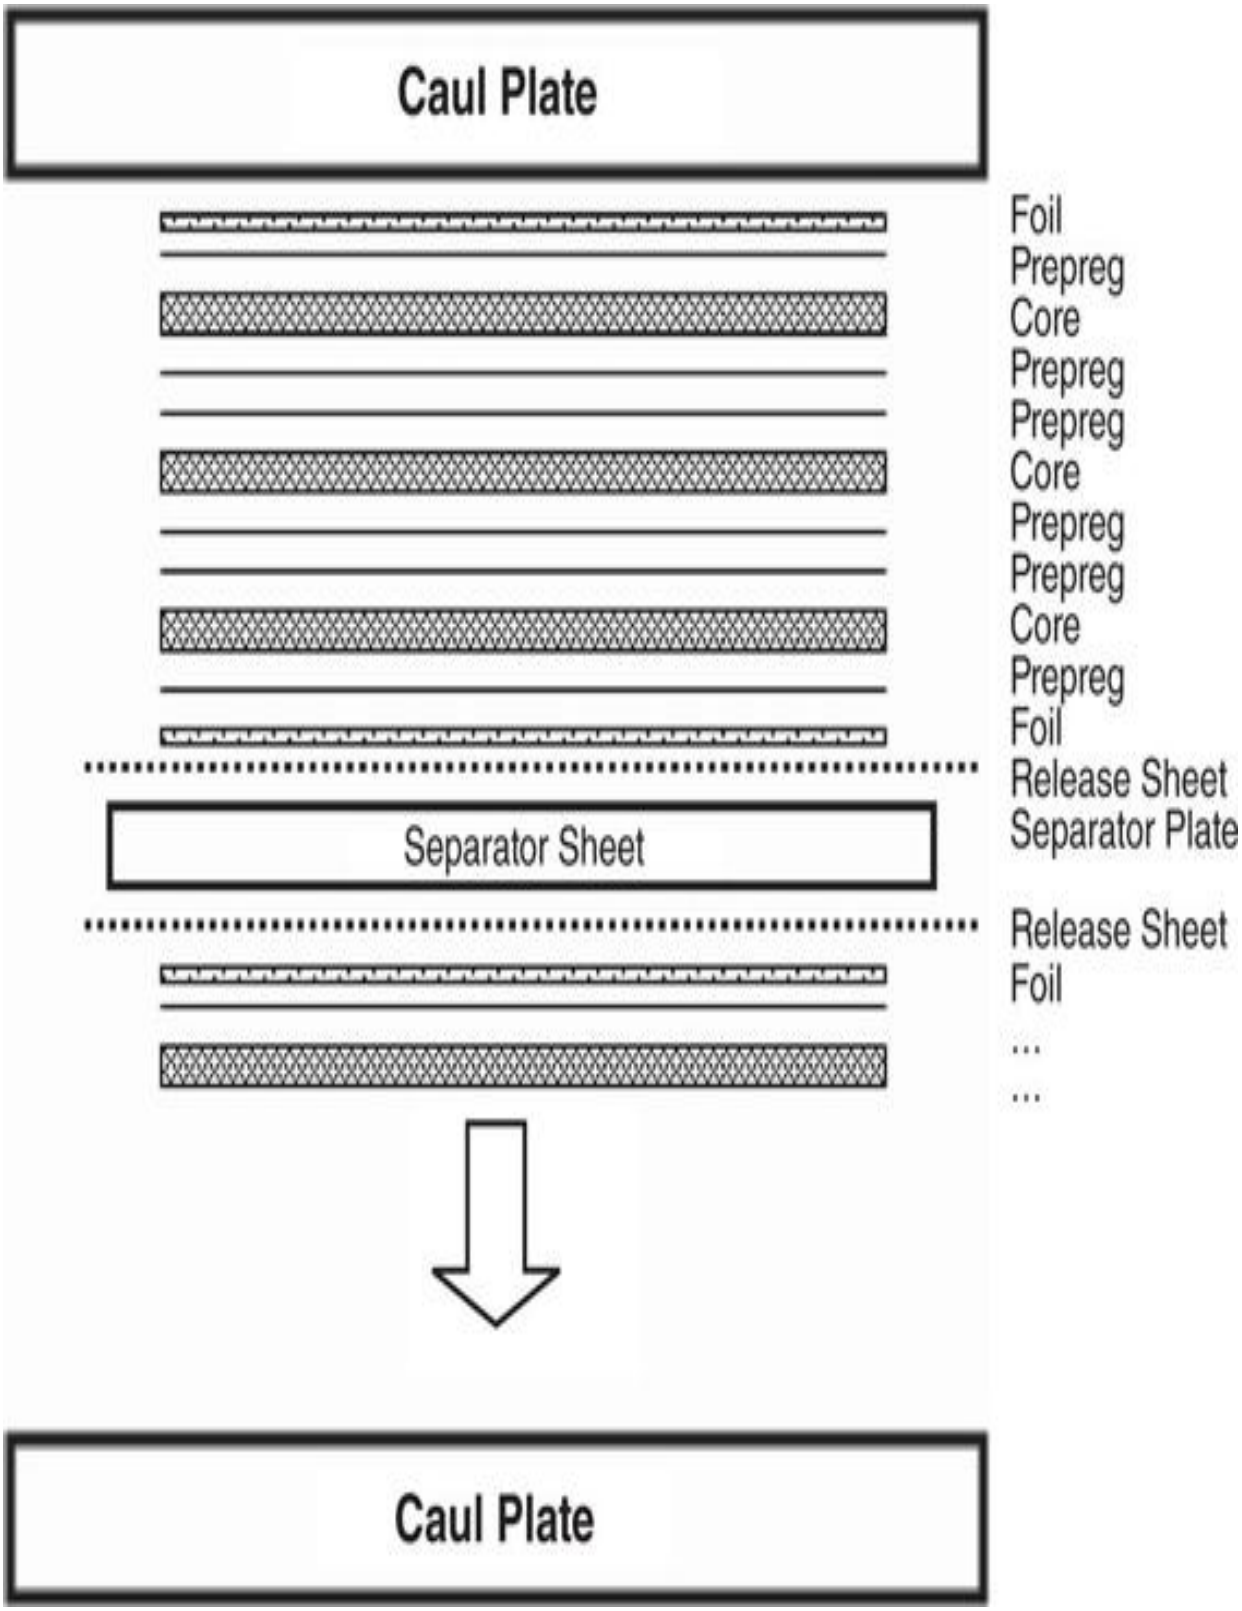

FIGURE 31.30 Press stack-up using release sheets and a separator plate.

31.4.1.1 Tooling Plates. The outermost item in the stack is termed a caul plate or carrier plate. These are thick, oversized metal plates, generally made of ⅜ in (9.525 mm/0.375 in) thick steel. The 4130 alloy of steel is often chosen due to its precision machining capability for placement of the holing holes. Sometimes a hardened aluminum alloy is chosen, but is not highly recommended due to its high in-plane expansion. The purpose of the caul plate is to provide a stable base to transport the ML-PWB stack.

31.4.1.2 Separator Plates. The multilayer boards in the stack are isolated from each other by metal separator plates. The separator plates provide a mold surface for the laminated ML-PWB. It is extremely important that the separator plates be clean and free of debris. Both aluminum and steel separator plates are used. Separator plates should be cleaned regularly. The surface finish of the plates becomes very critical when laminating against microfoils that will be printed with fine lines. The most common type of steel is one of the 400 series stainless steels that have a very durable surface. Hardened 300 series steels are also occasionally used. Separator plate thicknesses range from as thin as 0.015 in to as thick as 0.062 in. The thicker plates are more rigid and resist the tendency of internal layer features to print through from one ML-PWB to another. Thin aluminum plates have the advantage of being disposable, eliminating the need for cleaning.

31.4.1.3 Consumable Press Materials. The purposes of consumable press materials placed between the tooling plate and the top layer are to ensure that pressure is applied uniformly and to provide thermal lagging to correct heat rise. The purposes of consumable release sheets placed in contact with the foils are to protect the outerlayer foils,

keeping them resin-free, and to allow easy separation of the foil from the separator sheet.

Among the materials used to provide for pressure and temperature uniformity are multiple sheets of Kraft paper, silicone rubber pads, expanded mat paper, and composite board. Kraft paper and composite board have the advantage of low cost, but produce an odor that some press operators find objectionable. Silicone rubber pads have the advantage of being reusable, but are limited by the number of heat cycles they can withstand. Silicone rubber pads, when close to the end of their life, go through reversion and leach out silicone oil, which can become a source of contamination. They also have limited success in controlling edge voids. Excellent results are reported with expanded paper mat products that are commercially available. Mat paper press pad materials come in different thicknesses. Some are even produced with a sandwich layer of release material cohered. Other products exist that flow and thus act as a stop for resin during lamination of subcores with predrilled blind vias.

Some form of release material is required against the outer foil surface of the ML-PWB. The release material acts as a nonstick slip sheet to keep the copper surface smooth, minimize the plate cleanup, and catch the resin run-out. Figure 31.30 shows the location of the release sheets. Alternatively, oversized foil can be used to catch the resin run-out. Or, a product called C-A-C (for copper-aluminum-copper) is used that consists of two sheets of foil laminated to either side of an aluminum carrier sheet. In this configuration, the one sheet of C-A-C is between two PCBs with the bottom copper foil over prepreg to form the top side of the bottom PCB, and the top copper foil under prepreg to form the bottom side of the top PCB. Figure 31.31 shows the location of the C-A-C sheet. The aluminum serves to replace the steel or aluminum separator plates and has the added benefits of reducing the stack height (which can sometimes translate to increased productivity by enabling another board

to be made in the “book”) and providing excellent protection to the surface of the outerlayer foils. Since they are not handled as foils but as a more rigid composite, there is no propensity to wrinkle, and since they are covered for the entire book-building operation, they are not subject to scratching or having errant debris introduction cause a pit during lamination. Finally, when the book is broken down, the aluminum between the ML-PWBs is easily separated from the foils, leaving the distinct ML-PWBs. The aluminum itself is sometimes sent to the drilling department to be used as an entry material, and then sent to reclamation.

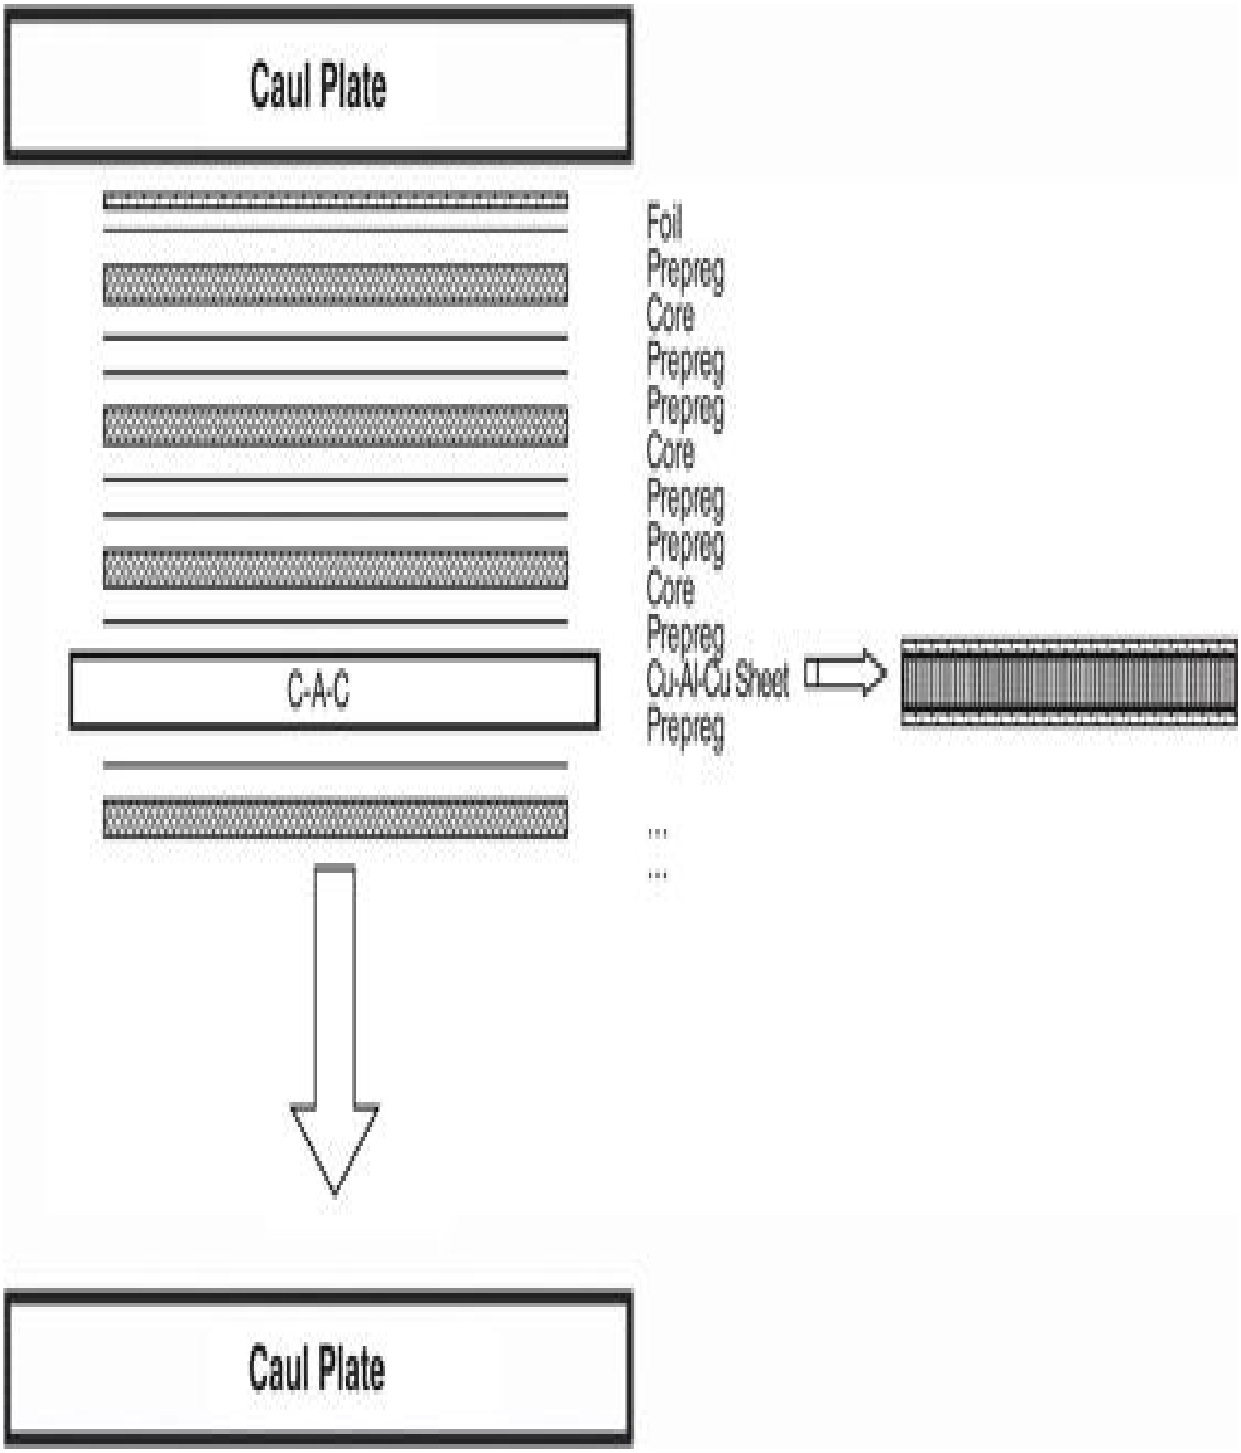

FIGURE 31.31 Press stack-up using one sheet of C-A-C to replace two sheets of foil, two release sheets, and one separator plate.

31.4.2 Lamination Stack-Up

The lamination process is key to building a reliable ML-PWB. In the lamination process, the board is subjected to heat and pressure that melts the B stage (bonding sheets) and causes it to flow. This encapsulates the circuits and fills any buried vias. The B stage then cures, establishing a good mechanical bond to the inner detail layers. A variety of materials can be utilized in standard laminating press cycles. (Refer to Sec. 31.3.5 for a detailed discussion of the materials and prefill process.) A typical ML-PWB stack-up is shown in Fig. 31.30. For productivity reasons, multiple stack heights are repeated within each opening of the press. The various components and their placement within the book are shown.

A standard lamination uses tooling pins that go from caul plate to caul plate, passing through each board and all of the separator sheets. Since the CTE of stainless steel roughly matches the in-plane CTE of a multilayer board, a tight fit to the pin is possible. Aluminum has a much higher CTE, so if aluminum is used, a loose fit to the tooling pin is required. Some fabricators use as few as four tooling pins. Others may use 20 or more. In addition to easy stacking, the four-slotted pin system minimizes problems arising from material growth and shrinkage in an overdetermined tooling system. On the other hand, users of systems with a large number of pins believe that firmly anchoring the ML-PWB to stainless steel obtains better dimensional stability.

31.4.3 Lamination Breakdown

Once the ML-PWB is fully cured and then cooled to room temperature per the manufacturer’s guidelines, the book is taken apart; this process is called “breakdown.” This is usually a manual process which consists of de-pinning the book, then separating the individual ML-PWBs from each other at the separator sheets or C-A-C boundary as shown in Fig. 31.31. The panels are sent to an automatic thickness

checker to ensure compliance with requirements, then on to an edge-finishing machine. The edge finisher removes the rough cured prepreg from the edges (called “ooze out”) and any copper foil overhang by routing the four sides to reduce imaging defects. The machine will then bevel and polish the edges so that they are not sharp and there are no protruding glass fibers or copper slivers. The finishing process might also include a bore to remove surface epoxy from around the tooling holes or slots.

31.4.4 Lamination Process Methods

31.4.4.1 Standard Hydraulic Lamination. A standard hydraulic press generally has a top or bottom ram and several floating platens that create multiple press openings. Typical presses have four to eight openings. The output of the press is based on the stack height in each opening. Low-layer-count designs can yield as many as 96 panels per press cycle based on a stack height of 12 by 8 openings. High-layer-count and thick laminated boards have the stack height reduced to ensure uniform heat rate from the outside to innermost stack. Steam, hot oil, or electrical resistance heaters may heat hydraulic-style presses. The steam and hot oil presses have the advantage of a fast heating rate, but the temperature of the heating fluid limits their maximum temperature. For steam, this is generally below the lamination temperature needed for high-temperature materials. If a steam press must be used, polyimide, PPO, and cyanate esters can be oven-baked to complete their cure. However, the thermal plastic adhesive layers used with Teflon are not compatible with a steam press.

31.4.4.2 Vacuum-Assisted Hydraulic Lamination. Many hydraulic presses use a vacuum to eliminate volatiles. Users of vacuum presses report a

reduction of edge voiding and the ability to laminate at a lower pressure. Almost all hydraulic presses sold since 1990 are equipped with a vacuum chamber. In a typical process, the ML-PWB caul plate is loaded onto a carrier sheet, where a spring-loaded rail holds it off the press platen and limits the heat transfer to the ML-PWB stack. Next, the vacuum chamber is closed and a vacuum is drawn and held. A typical vacuum cycle may be from 15 to 60 min, depending on the nature of the materials being laminated. This gives the vacuum time to pull air, moisture, and other volatiles out of the ML-PWB stack. At the completion of this prevacuum process, the press is closed, compressing the spring-loaded rails and establishing good thermal contact with the press platens.

31.4.4.3 Autoclave. The autoclave is a popular tool in the composites industry and has found limited use by board fabricators. The autoclave is a sealed cylindrical chamber that subjects the ML-PWB stack to a high-pressure heated gas. The ML-PWB stack is sealed in a vacuum bag, and the hydrostatic pressure from the gas produces the force necessary for lamination. In principle, the autoclave is an excellent machine for producing a void-free lamination. Since the pressure is hydrostatic, it eliminates the problem of low pressure at the panel edge. This results in void-free panel borders and increases the usable area on a panel. In practice, an autoclave requires a long prevacuum cycle and has a slow heatup rate. It is also vulnerable to problems with vacuum bag failures. The result is that autoclaves have not found broad acceptance among rigid board manufacturers.

31.4.4.4 Direct Current or Continuous Foil Manufacturing. The continuous foil method of lamination is covered in Chapter/Section 9.7.4.

31.4.5 Critical Lamination Variables

Since hydraulic presses are by far the most common type of press, the following discussion focuses on that process. The quality of the ML-PWB lamination is affected by both the pressure ramp and the temperature ramp. There are almost as many unique cycles (also known as press recipes) as there are fabricators. However, in general the lamination cycle can be divided into four regions: B-stage melt; B-stage flow; B-stage cure; and cooldown. Figure 31.32 shows a typical lamination cycle with these critical variables identified.

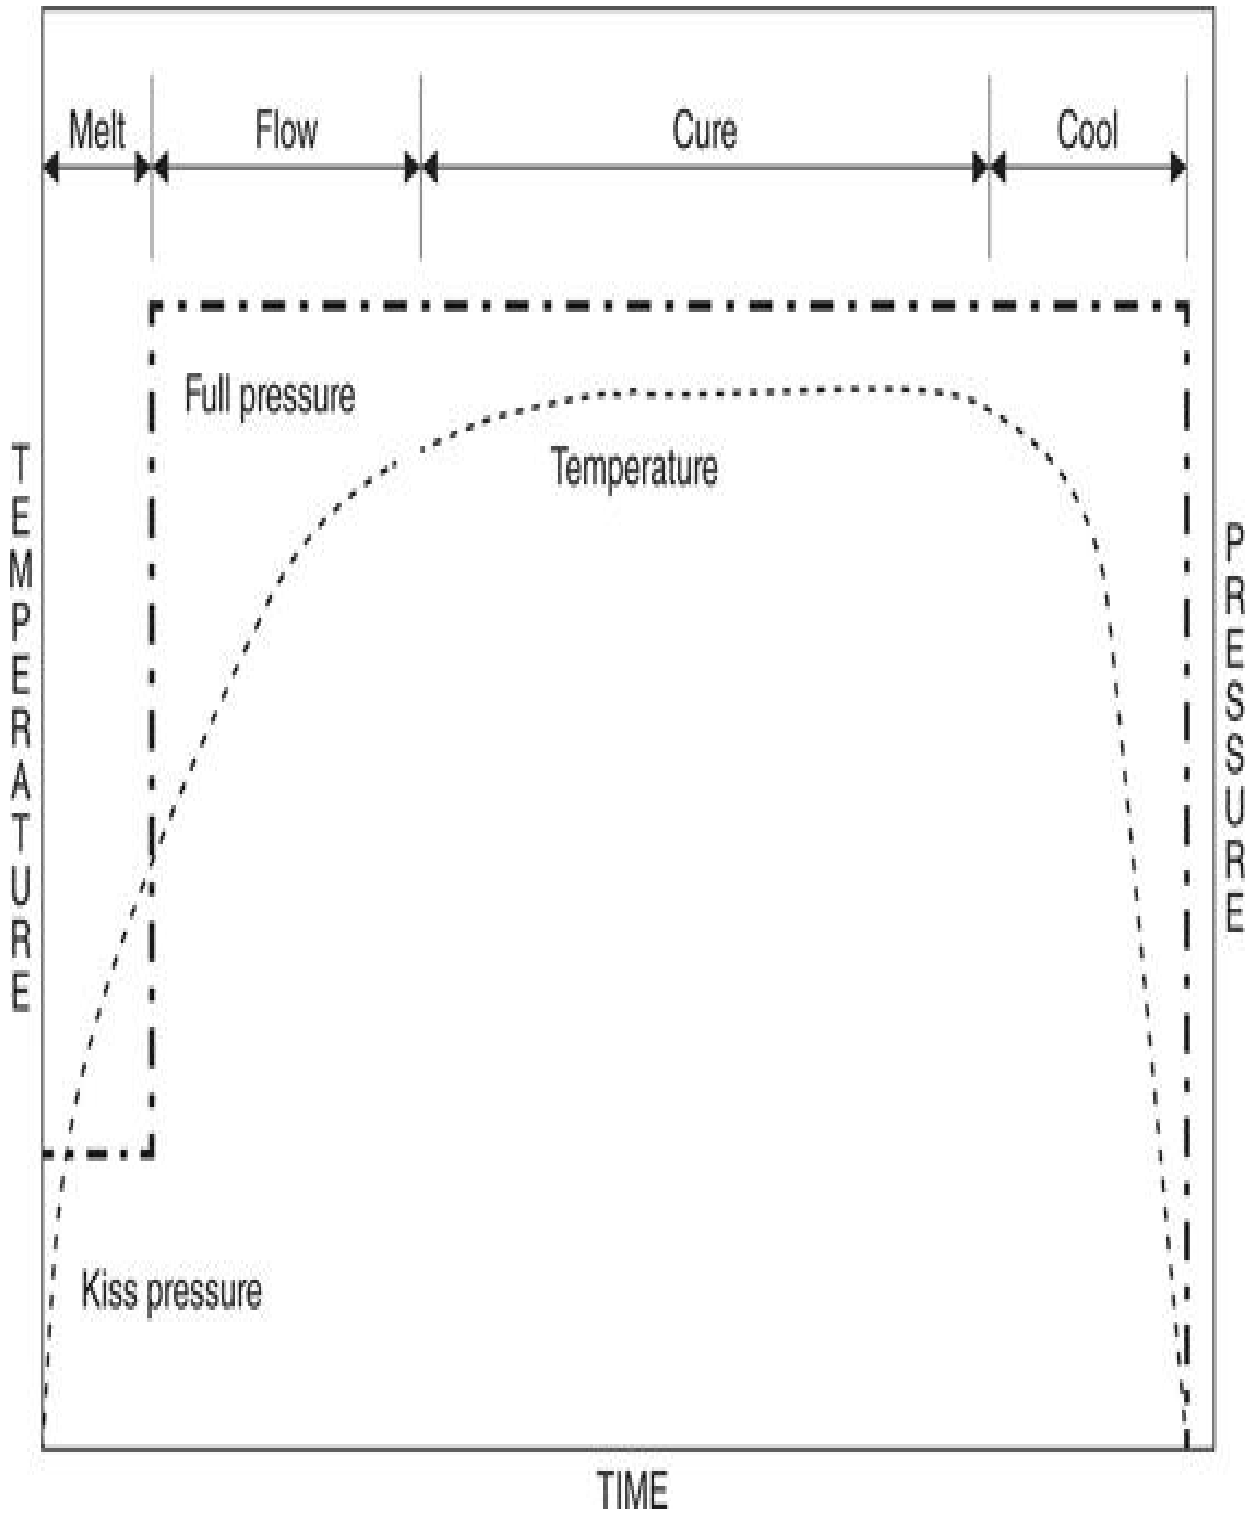

FIGURE 31.32 Typical temperature and pressure cycle for hydraulic lamination.

31.4.5.1 B-Stage Melt. During the melt cycle, the B stage is solid and the pressure should be low. Excessive

pressure during this portion of the cycle will damage the glass cloth and exaggerate problems with image print-through, also known as “telegraphing.” Most press cycles start with a low pressure known as a kiss pressure. The kiss pressure is high enough to ensure good thermal contact without damaging the ML-PWB. The length of the kiss cycle depends on the heating rates and the cure kinetics of the B stage. In a hot press cycle, the ML-PWB stack is loaded into a preheated press, and the heating rate may approach 20°C/min. In a hot press, the kiss cycle should be limited to a few minutes, or the B stage will begin to cure before flow is complete. At the opposite extreme, the press is loaded cold, and the heating rate is determined by the heating ramp of the press. For a slow heating rate of 5°C/min., a kiss cycle of 15 min. is appropriate. Consult the Technical Data Sheet for specific prepreg rise time flow characteristics.

Some LFAC laminates, however, have process guidelines where a best practice is to have a kiss cycle with 0 psi with a slow heat rise on the order of not more than 15°C/min until approximately a 90°C internal temperature. This step is held for 30 to 40 min to drive out moisture before pressure is applied and the flow stage initiates.

31.4.5.2 B-Stage Flow. The second portion of the cycle begins when the B stage liquefies, but before its viscosity begins to rise due to curing. In this region of the cycle, the liquid B-stage flows and encapsulates the circuitry. As long as the internal features are surrounded by liquid B stage, print-through is not an issue. The key to good results is to select a pressure that will allow reproducible resin flow but that does not squeeze out all available resin before the progressing cure stops the flow. Once again, the exact pressure depends on the temperature cycle, the B-stage viscosity characteristics, and the B-stage cure kinetics. For a fast-curing B stage and a fast temperature ramp, pressures as high as 600 psi may be needed to ensure complete circuit

encapsulation. On the other hand, with a slow ramp and a long B-stage working time, high pressures give excessive flow and best results are obtained at 200 psi. Improper melt staging can result in “footballing,” a term used to describe a panel whose center is significantly thicker than its outside. To determine proper melt, it is recommended to install a thermocouple in the center stack edge to chart the actual heat rise through the flow.

A typical dicy-cured FR-4 multifunctional epoxy has a flow range, called the critical range, at the temperatures between 70 and 130°C. HF and LFAC laminates have a critical range typically between 80 and 140°C. During the critical range, the heat rate input and pressure are critical variables. A typical dicy-cured FR-4 press recipe would be 4 to 8°C/min rise at 200 to 300 psi pressure. HF and LFAC laminates’ recipes are usually lower in the rate of rise and higher in pressure, such as 2 to 4°C /min and 225 to 360 psi pressure.

Table 31.3 shows some press recipes from the processing guidelines posted on the laminators’ webpages. This table is intended to illustrate that moving from standard FR-4 to other HF or LFAC laminates will require the development of new press recipes.

TABLE 31.3 Press Recipes for Selected Materials

	T_g °C, DSC	Rise, °C/min	Critical Range, °C	Pressure, psi	Cure Time, min/temp (°C)
Standard dicycured FR-4	175	4–7	70–130	200–300	60/182
Nondicy FR-4 laminate	155	2–4	80–140	275–360	90/193
HF laminate	160	2.3–5.6	>100	380	90/200
LFAC laminate A	185	4.4–7	70–130	200–300	75/185
LFAC laminate B	190	2.3–5.6	83–139	225–325	75/193
LFAC laminate C	210	2–4	80–140	275–360	90/193
LFAC laminate D	190	2–4.5	80–135	200–300	120/200
LFAC laminate E	215	2	80–135	300	120/200
Polyimide	250	2–4	80–138	225–275	200/218

31.4.5.3 B-Stage Cure. In the third part of the cycle, flow has stopped and the resin cure is proceeding. The temperature is held at its maximum value to minimize the time to obtain full cure. For a typical epoxy system, this usually is approximately 180°C for 60 min LFAC laminates, however, tend to require longer and hotter cure stages: up to 200°C internal temperature for 120 min, and longer for thicker boards. Some materials, such as polyimide, require a significantly higher cure temperature for even longer.

31.4.5.4 Cooldown. The last part of the cycle is the cooldown cycle. In Fig. 31.32, it is suggested that the pressure is released after some cooling has occurred, but before the stack reaches room temperature. In many modern systems, the ML-PWB stack is transferred hot to a low-pressure cooling press. It is important to control the cooling rate to minimize warpage. It is generally desirable to cool through T_g in a stress-free state without any significant

thermal gradients present. A properly designed cooling press will meet these conditions.

31.4.6 Critical B-Stage Variables

During a typical lamination cycle, the B stage undergoes several significant changes. At the beginning of the cycle, the B stage is a solid with a low cross-link density and a melt temperature near 90°C. As the temperature rises, the B stage melts and becomes a high-viscosity liquid. As the press heats further, the viscosity of the liquid drops. When the B stage begins to cure, viscosity reaches a minimum and begins to rise. The region around the viscosity minimum is called the region of maximum flow. The wider this region and the lower the minimum viscosity, the more flow occurs. Figure 31.33 shows a schematic viscosity curve for a typical cure cycle. In a high-flow B stage, the initial cure level is low. This results in a longer time at temperature before the B-stage viscosity rises due to cure. This is often described as a long gel time. In terms of Fig. 31.33, a high-flow B stage has a low minimum viscosity and a wide region of maximum flow. A low-flow B stage has a higher degree of initial cure and may include flow restrictors to increase the minimum viscosity. High-flow B stages are useful in presses with a high-heating rate where the resin may begin to cure before flow is complete. They give excessive flow if used in a press cycle with a very slow heating rate.

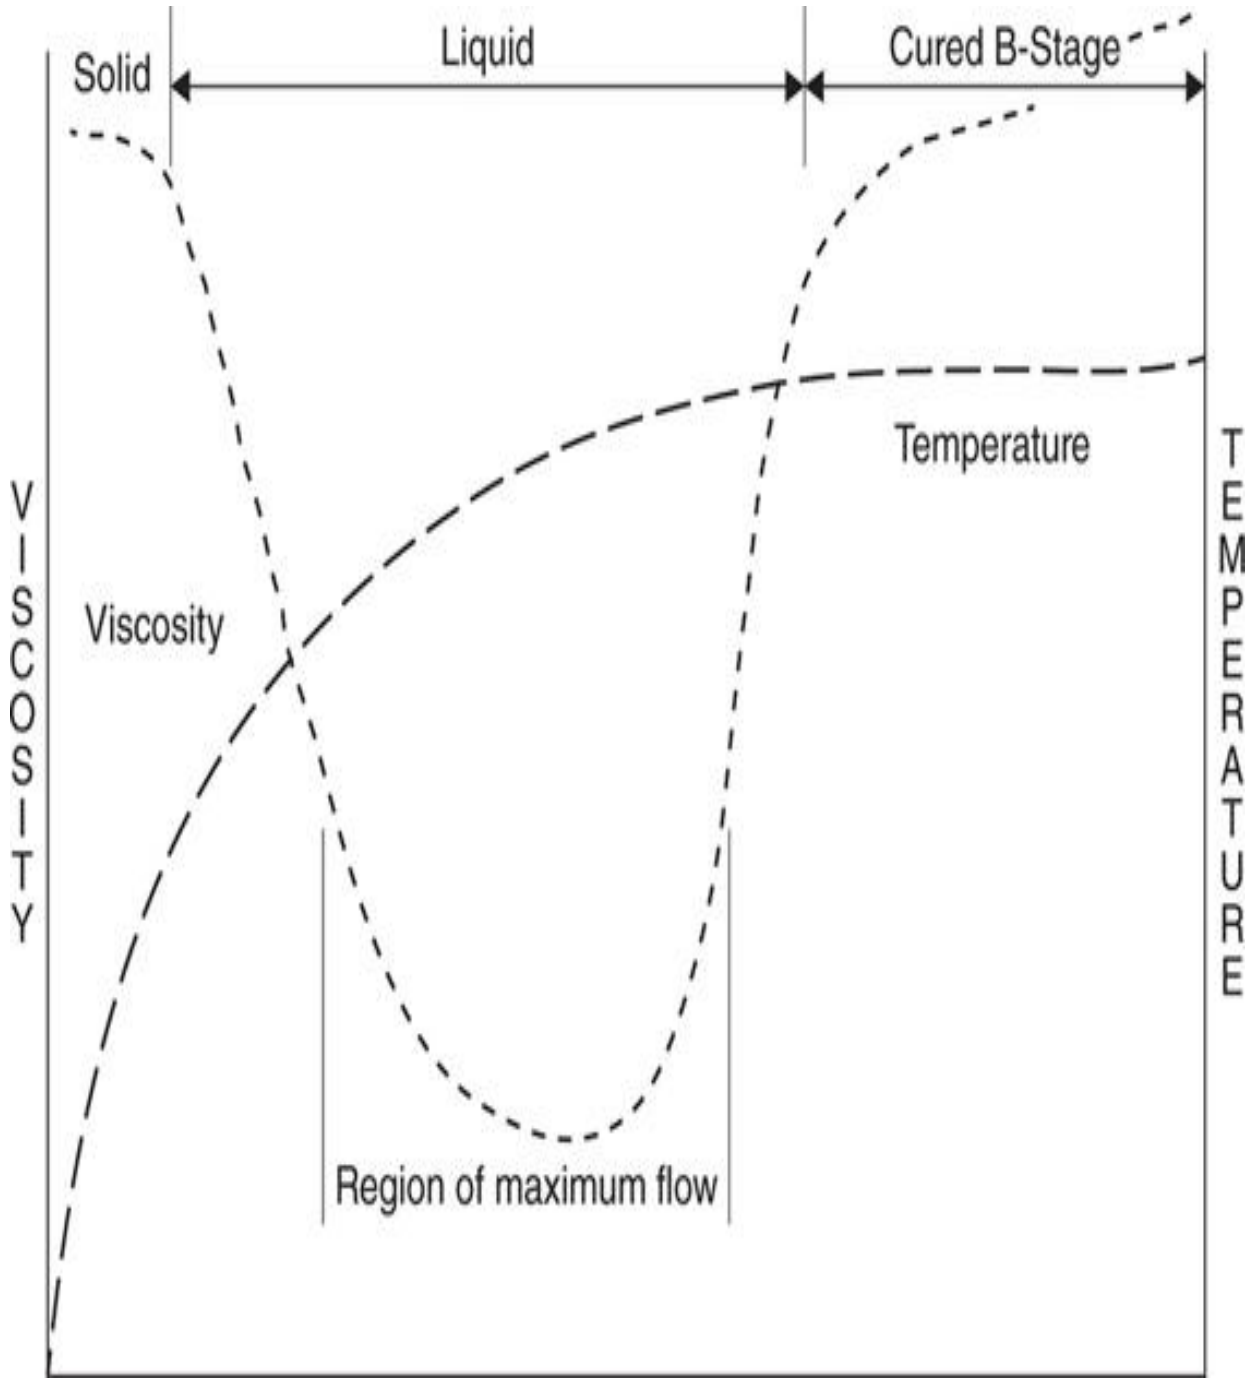

FIGURE 31.33 Typical viscosity curve for B stage during lamination.

31.4.7 Single-Ply versus Multiple-Ply B-Stage Fill Considerations

For dielectric separations that could be filled by either one “thick” ply of B stage—for instance, style 7628—or by two thinner plies of B stage—for instance, style 1080—the fabricator and engineer need to determine which approach is best on a product-by-product basis. Building ML-PCBs with single-ply B-stage fill is common for HDI and has the following advantages:

- Costs are reduced significantly when sheets of prepreg are eliminated—the main advantage.
- *Z*-axis expansion is easier to control since there is usually less resin with a thicker style.
- Overall thickness has less variation since there are fewer elements in the construction.
- Single-ply fill allows for overall thickness reduction when two plies of any style are replaced by one ply of the same style or thinner.

Building with two plies is usually either preferred or required with the following conditions:

- The separation to be filled is between two planes generating a large voltage bias and additional dielectric separation is required to minimize the potential of dielectric withstanding breakdown.
- The separation to be filled is between two layers having thicker (70 µm) copper foil. In this case, there is frequently insufficient resin in a single ply to encapsulate the features and prevent air bubbles in etched-out regions.

31.5 LAMINATION PROCESS CONTROL AND TROUBLESHOOTING

A good lamination cycle produces a flat ML-PWB that is free of moisture or voids and has a fully cured substrate. All layers must be well registered. The ML-PWB must be free of warp and the thickness must be within the specification. Any controlled impedance layers must have the correct pressed dielectric separations above and below the signal layer. Each of these requirements puts special demands on the lamination process. To assist in setting control measures, the following process indicators (see Table 31.4) should be monitored with a Statistical Process Control (SPC) method.

TABLE 31.4 Process Variables and Limits

Process Indicator	Specification Limit	Gauge Type or Method
Thickness control	Per engineering drawing or internal spec requirement	Over-arm micrometer
Heat rise °C/min through melt	Per resin system requirement	Chart recorder
Cure	T_g of resin system	TMA
Post cure	Dwell time/temp per resin system requirement	Chart recorder
Registration	Per engineering drawing or internal spec requirement	Appropriate coupons or x-ray inspection equipment
Dielectric separation	Per engineering drawing	Cross-section

31.5.1 Common Problems

31.5.1.1 Voids and Moisture. Substrate voids are a serious problem in many lamination processes. One source of these problems is moisture. B stage is very hygroscopic and must be stored in a low-humidity environment to

preclude serious void problems. C-stage components also have a tendency to absorb water, and many fabricators use a bake to dry layers prior to lamination. However, for a fast innerlayer line with a good dryer in the oxide line, an innerlayer bake may not be necessary. Voids generally cluster in the low-pressure regions near the edge of the panel. This effect is minimized by the use of vacuum lamination. Increasing the lamination pressure can also reduce voids. However, the use of high pressures with high-flow materials can result in excessive flow, which leads to other substrate flaws such as resin starvation.

31.5.1.2 Blisters and Delamination. Blisters and delamination are also caused by trapped volatiles that collect in the low-pressure regions associated with print-through. If a board has wide copper borders on every layer, blisters are often found in the lower-pressure circuit areas adjacent to the borders. The best solution to this problem is to avoid areas of heavy copper adjacent to low-density circuit areas by replacing solid borders with a dot or stripe pattern. Also, the glass style and resin content of the prepreg should be matched to the weight of copper thickness adjacent to the prepreg.

31.5.1.3 Under Cure. The requirement of full cure is relatively easy to obtain if proper cure time and temperature are used. One measure of the cure level is T_g. Periodic measurements of T_g are an excellent check for material and process consistency. Another way to check cure is to make two consecutive measurements of T_g: If the epoxy is only partially cured, it will continue to cure during the first measurement and a higher T_g will be detected on the second measurement. A shift in T_g of more than 5°C is an indication of under cure. This measurement is typically performed on a

TMA. Figure 31.34 shows an example of an epoxy TMA run; note that the second TMA run has a delta of 3°C.

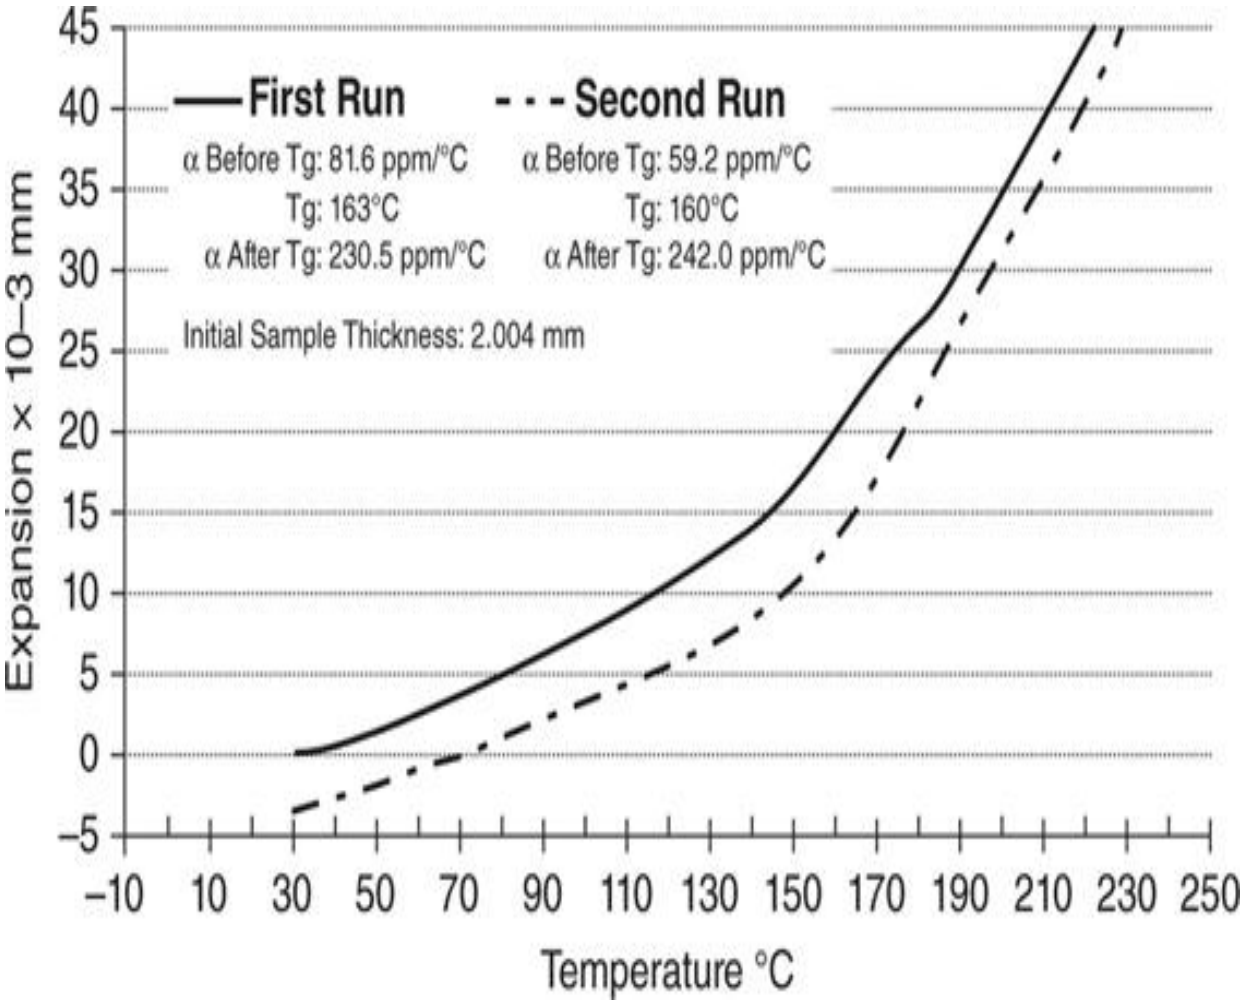

FIGURE 31.34 TMA analysis of epoxy with woven fiberglass. (*Courtesy of Microtek Labs, Anaheim, CA*.)

31.5.1.4 Post-Lamination Bake. Many fabricators bake the ML-PWB at 150°C for up to 4 h after lamination. One purpose of this baking is to ensure a complete cure. Although a bake will advance the cure, it is unnecessary if a proper lamination cycle is used (although polyimide is an exception; check the recommended processing guidelines). As discussed earlier, this can be verified by T_g

measurements. However, additional baking beyond full cure degrades the material and reduces T_g.

A second purpose of the bake is to reduce the warpage often seen in the outer boards of a stack-up. Although a post-lamination bake will flatten the boards, it is more of a repair than a root solution. If the panels are cured in the press in a way that ensures they go through T_g in an isothermal stress-free state, warpage should not occur. The warpage seen in the outer boards of a stack is generally a symptom of nonuniform cooling.

The third purpose of a bake is to relax internal stress and improve registration. Internal stresses are a symptom of an overdetermined tooling system. If such a system is used, a bake may improve registration. If the more popular four-pin system is used, a bake is unnecessary. Always confirm the need of a post cure with the recommendations of the material supplier.

31.5.2 Special Consideration for Nondicy, Nonbromine, and LFAC Laminates

For decades, the majority of PCBs have been built with epoxy resins, dicy-cured, and with bromine flame retardant. The industry has developed around this paradigm. Drills and drilling, chemistry, lamination, and circuit card assembly are all well understood with reference to standard FR-4. Although there are fabricators with processes developed to manufacture PCBs using laminates other than standard FR-4, this knowledgebase is not distributed industrywide. Especially problematic is the intersection of requirements for HF and/or LFAC with high thermal resistance and improved electrical characteristics, such as low attenuation in the material. Many laminators recognized that the heart of their

product line would need to be revamped from the entry-level cost-conscious material all the way through to the highest performance material. This was a large undertaking, requiring many different trials to find the right ingredients, in the right combinations, with the desired properties, especially the response to the new elevated reflow temperatures. As is frequently the case, there are trade-offs. For instance, reducing CTE by increasing filler is desirable to a point; the increase of filler increases the dielectric constant and loss tangent properties of the material, making it less suitable for high-speed digital products. The line-up from the bottom to the top of the performance ladder, with and without bromine, capable of withstanding high-temperature reflow, isn’t complete in all cases.

The major processes that need to be developed and optimized specifically for nonstandard FR-4 laminates are innerlayer adhesion promotion, lamination, drilling, and hole wall preparation. The fabricator must work closely with its laminate and chemistry providers to develop the specific process parameters that will work with their lamination equipment and chemistries.

Early problems have been delamination (both adhesive and cohesive failures), voiding, and hole wall pull-away. Some of these quality problems can be discovered prior to shipment by cross-section analyses, but some do not manifest until after high-temperature reflow. Since laminators test laminates rather than finished PCBs, and fabrication and design features both effect the final product, a cautious fabricator will test completed PCB parts for quality and reliability, simulating the intended assembly soldering profile. Accordingly, submitting an actual final ML-PWB to multiple cycles through a production reflow oven with a lead-free soldering profile can be advantageous. After reflow exposure, the parts are visually inspected for blisters, then cross sections are taken at both high and low hole density areas to look for internal delamination or laminate cracks,

voiding, and hole wall pull-away. Figures 31.35 through 31.38 show examples of these defects.

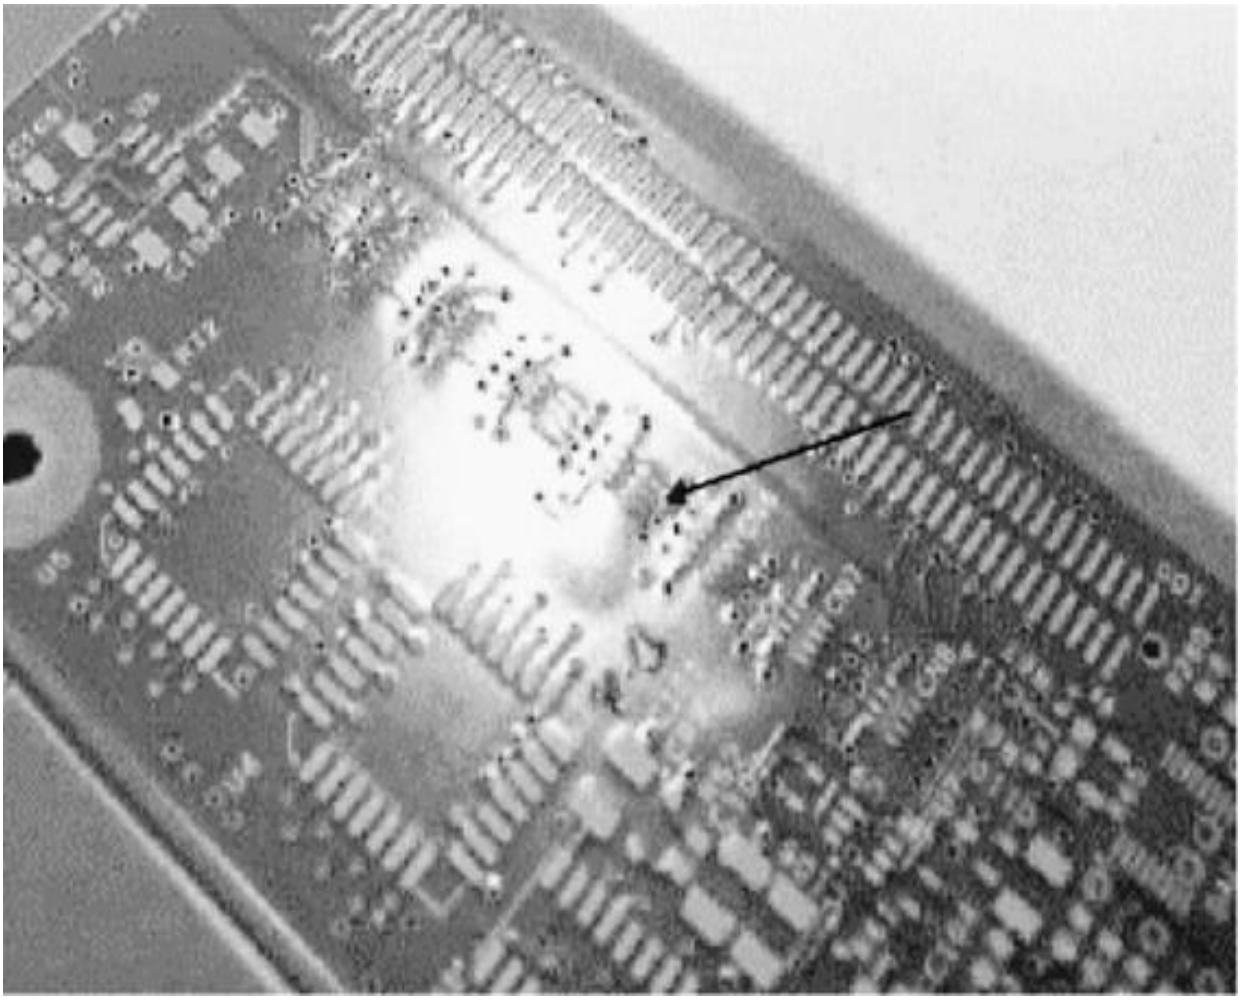

FIGURE 31.35 Blistering.

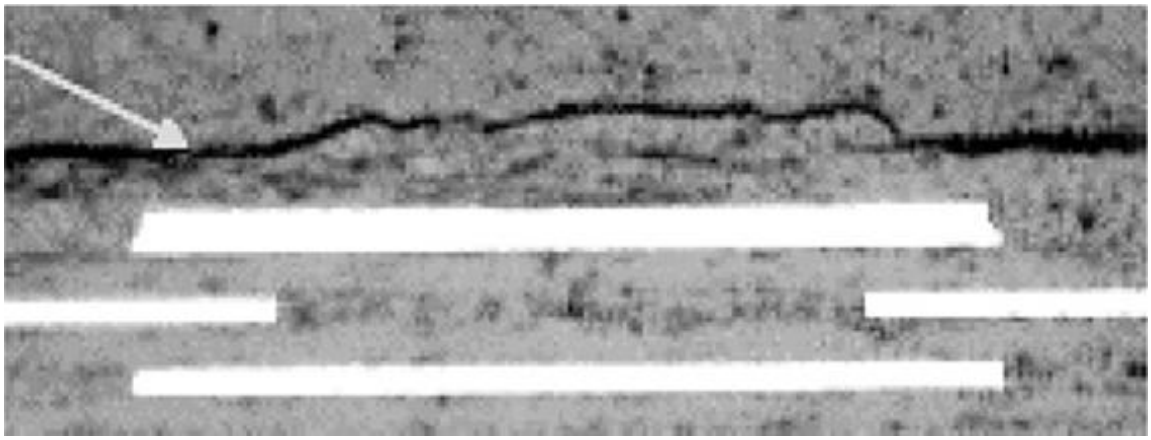

FIGURE 31.36 Laminate crack.

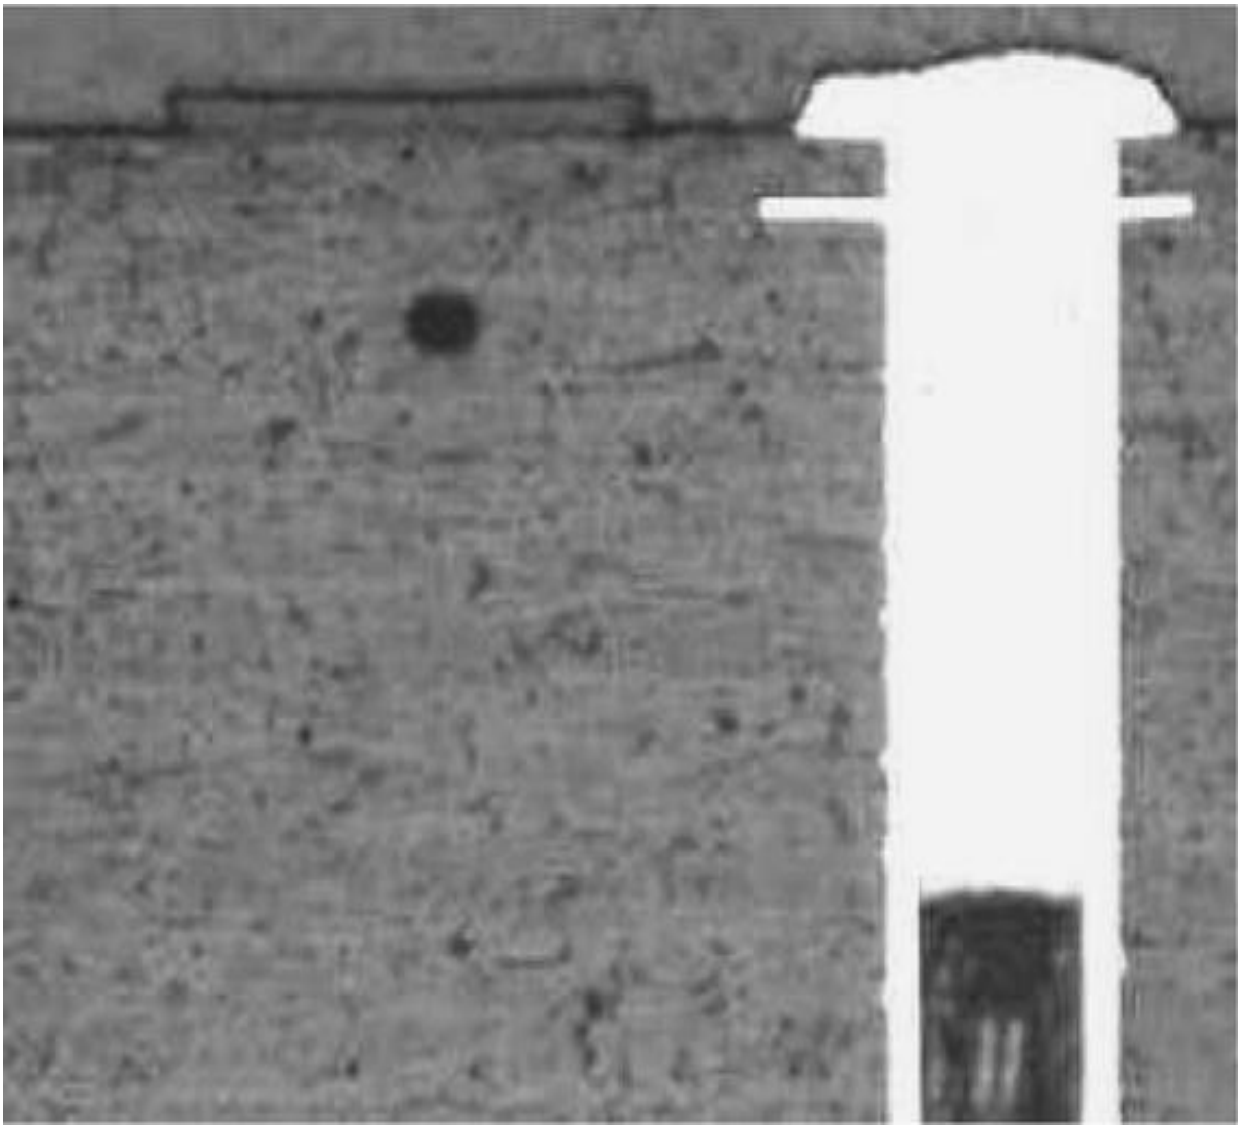

FIGURE 31.37 Void.

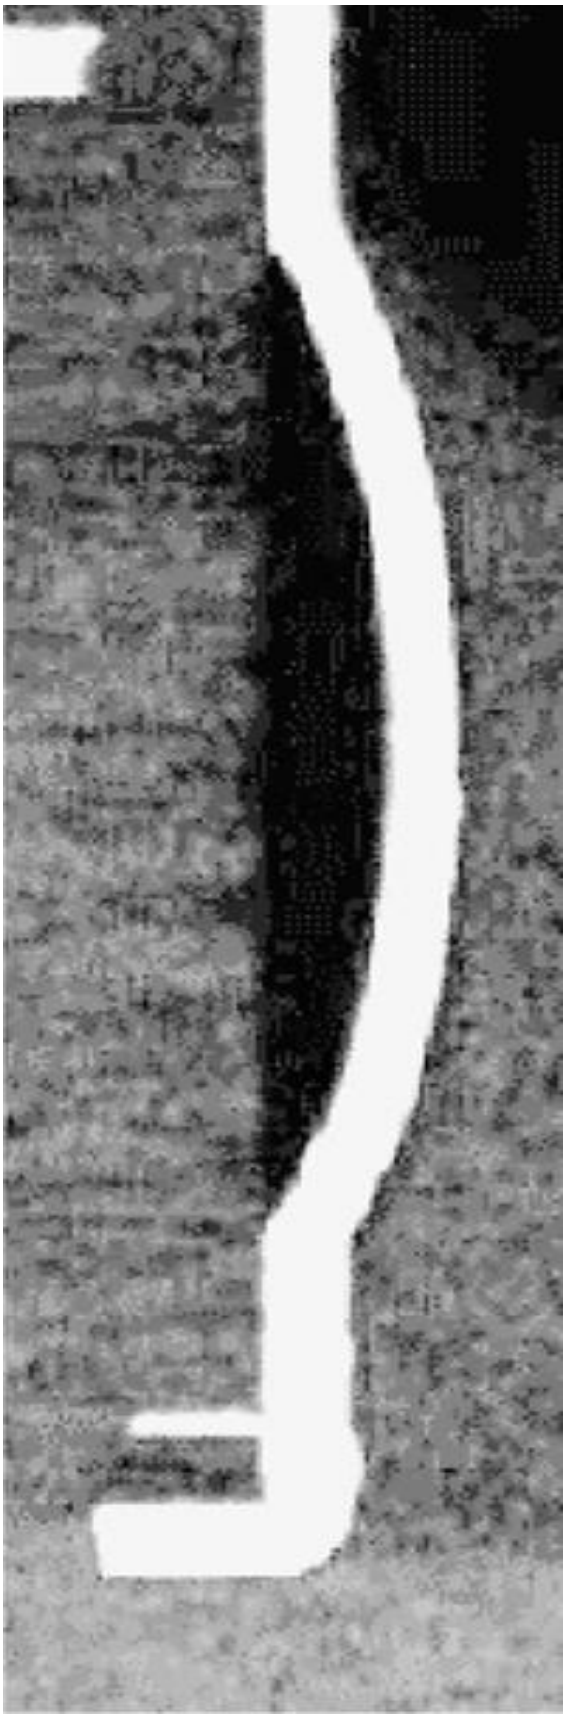

FIGURE 31.38 Hole wall pull-away.

31.6 LAMINATION OVERVIEW

The standard hydraulic vacuum press cycle is flexible and has very high output. Through the use of multiple openings and stacked lamination, high productivity is obtainable. Hydraulic lamination works effectively with all modern materials systems.

ML-PWB fabricators use many different laminate systems, press cycles, and B-stage formulations. The most significant differences among press cycles are in the heating rate, cure temperature, and cure time. At one extreme, the ML-PWBs are loaded into a cold press. This gives a very slow heating rate, and a B stage with a low flow is needed to avoid excessive flow. This material works well at low pressures, minimizing print-through and innerlayer distortion. A vacuum cycle is recommended to minimize voiding in low-pressure regions near the panel edge. The other extreme is a hot-loaded press with a very fast temperature rise. This cycle needs a high-flow material a high pressure to complete the resin flow cycle before the onset of cure. Although a vacuum is less important with this cycle, it will minimize edge voids. Some materials require a moisture drive-off prior to heat using a 0 psi low temperature hold.

Some fabricators use bakes both before and after lamination. The bake before lamination is designed to ensure moisture removal from cores after the application of the adhesion promotion chemistry; follow the recommendations of the laminate manufacturer carefully. The bake is also needed if innerlayers are stored at high humidity prior to lamination, or as a standard process for hygroscopic materials such as some of the LFAC laminates or polyimide. Other fabricators use a bake after lamination to complete the

cure, reduce warp, and relieve stress. Although a post bake will achieve these goals, it is usually unnecessary in a controlled lamination process. In the case of high-temperature materials such as polyimide, cyanate ester, and PPO, a post bake is a useful way to achieve a full cure in a process where the maximum press temperature is limited.

31.7 ML-PWB SUMMARY

The printed wiring board manufacturing industry continues to be challenged with a high rate of change. Today's global market and added environmental considerations are driving investments and innovation in research and development of integrated components (e.g., laminates), subcomponents (e.g., resins and glass), and process consumables (e.g., oxide chemistry) for PCB fabrication. The manufacturing flow has only a backbone of standard methodologies, with many optional branches and staging through some process sequences multiple times (as in sequential lamination and HDI technologies). PCB fabrication has become much more complex, interactions between processes and components are compounded, and the user requirements are more formidable. A successful implementation of any of the high-density constructs or high-temperature-resistant materials should always be complemented with sound statistical process verification and testing appropriate to the end use.

CHAPTER 32

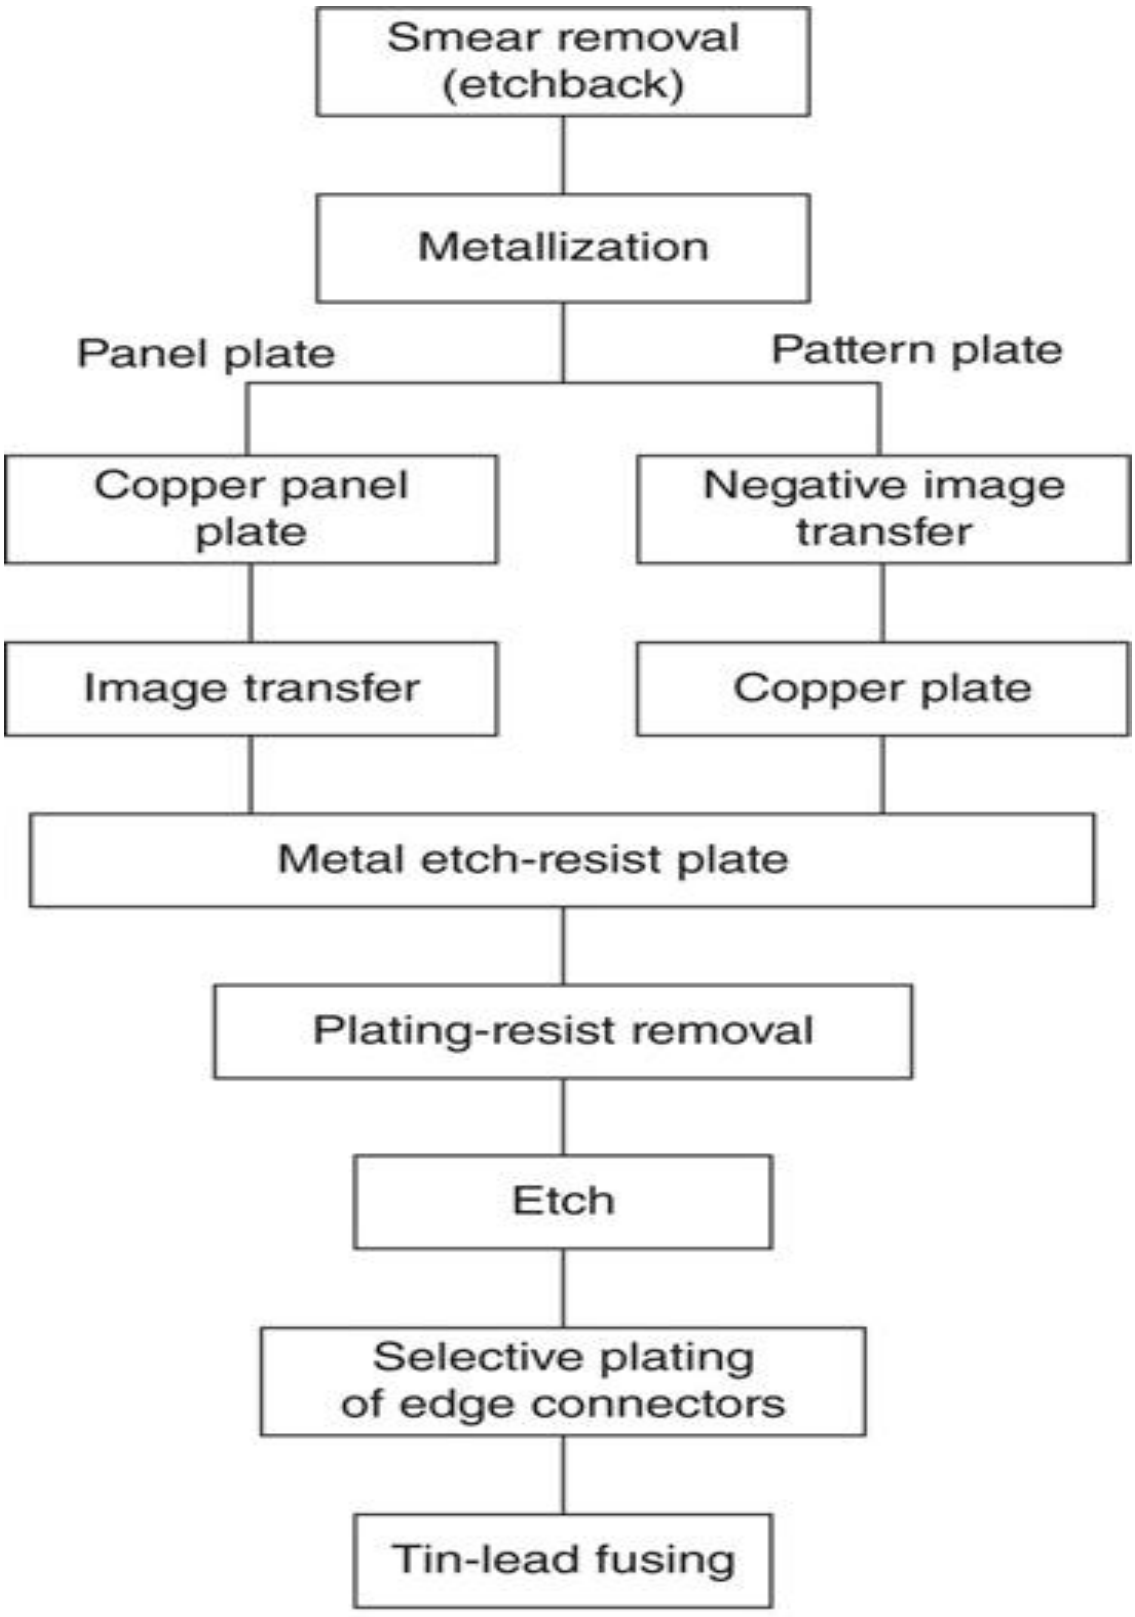
PREPARING BOARDS FOR PLATING

Michael Carano

Technologist and Chemical Consultant, Maple Plain, Minnesota

32.1 INTRODUCTION

A major part of manufacturing printed circuit boards (PCBs) involves *wet process* chemistry. The plating aspects of wet chemistry include deposition of metals by electroless (metallization) and electrolytic (electroplating) processes. Topics to be described here are multilayer processing, electroless copper, direct metallization, electroplating of copper and resist metals, nickel and gold for edge connector (tips), tin-lead fusing, and alternative coatings. Specific operating conditions, process controls, and problems in each area will be reviewed in detail. The effects of plating on image transfer, strip, and etching are also described in this chapter. See the printed circuit plating flowchart in Fig. 32.1.



Direct metallization technology (DMT)

FIGURE 32.1 Printed wiring board plating flowchart.

Two driving forces have had major influence on plating practices: the precise technical requirements of electronic products and the demands of environmental and safety compliance.

Recent technical achievements in plating are evident in the capability to produce complex, high-resolution multilayer boards. These boards show narrow lines (3 to 6 mils), small holes (12 mils), surface-mount density, and high reliability. In plating, such precision has been made possible by the use of improved automatic, computer-controlled plating machines, instrumental techniques for analysis of organic and metallic additives, and the availability of controllable chemical processes. Military-specification-quality boards are produced when the procedures given here are closely followed.

32.2 PROCESS DECISIONS

Process and equipment needs dictate the physical aspect of the facility and the character of the process, and vice versa. Some important items to consider are the following.

32.2.1 Facility Considerations

1. *Multilayer and two-sided product mix:* Lamination presses and innerlayer processes are required.
2. *Circuit complexity:* Dry film, photoimageable resist, and a clean room are needed.
3. *Level of reliability (application of product):* Extra controls and testing are required.
4. *Volume output:* Equipment sizing and building space are needed.

5. *Use of automatic versus manual line:* Productivity, consistency, and a workforce are required.
6. *Wastewater treatment system:* Water and process control capability must be available.[1]
7. *Environmental and personnel safety; compliance with laws*.
8. *Costs*.

32.2.2 Process Considerations

1. *Material:* The principal printed board material discussed will be NEMA grade FR-4 or G-10, that is, epoxy fiberglass clad with 1.2-, 1-, or 2-oz copper. Other materials will be briefly mentioned because they can significantly alter plating and related processes.
2. *Standard:* Plated through hole (PTH) is the current standard of the industry. The following purposes, objectives, and requirements apply to both multilayer and two-sided boards:
   a. *Purposes:* Circuit density; double-sided circuitry
   b. *Objectives:* Side-to-side electrical connection; ease of component attachment; high reliability
   c. *Requirements:* Complete coverage; even thickness; a hole-to-surface ratio of 0.001 in minimum; no cracks; no voids, nodules, or inclusions; no pull-away; no epoxy smear; minor resin recession; optimum metallurgical structure; M/L compatibility
3. *Image transfer:* Photoimageable, dry film, or screening of plating resists will depend on board complexity, volume, and labor skills.
4. *Electroless copper:* The type chosen will depend on the method of image transfer as well as on the need for panel plating. These processes are readily automated. The largest percentage (estimates are as high as 95 percent)

of PCB manufacturers worldwide rely on the electroless copper method for hole metallization.

5. *Direct metallization technology (DMT):* Some of the remaining PCB manufacturers have eliminated the electroless copper step and converted to DMT.

Developed in the 1980s, DMT methods produce a conductive surface on the nonconductive through-hole surfaces (see Chap. 30 for a detailed discussion). Electroless copper baths contain formaldehyde and chelators. In addition, the baths use large volumes of water, are difficult to control, and make it difficult to treat waste. DMT claims include increased productivity, ease of control, and lower hazardous material involvement. Because of these characteristics, DMT will probably gain significant acceptance as a primary hole metallization method.[2] Acceptance of the DMT process has been delayed by the high cost of conveyorized equipment and chemicals.

DMT primary technologies include:

- Palladium
- Carbon-graphite
- Conductive polymer
- Other methods (see Chap. 30 for further information)
- *Electroplating processes:* Deposit requirements are as follows:
  - Electrical conductivity
  - Mechanical strength
  - Ductility and elongation
  - Solderability
  - Tarnish and corrosion resistance
  - Etchant resistance
  - Compliance with military specification (mil-spec)

Details emphasizing operation, control, and mil-spec plating practices are given elsewhere. Metal-plated structures of completed PC boards are as follows:

- Copper/tin-lead alloy
- Copper/tin (SMOBC)
- Copper/tin-nickel (nickel)/tin-lead
- Copper/nickel/tin-nickel/silver

- *Strip, etching, and tin-lead fusing:* Methods required by these steps are determined by the preceding processes and by the need for automation.

32.3 PROCESS FEEDWATER

32.3.1 Water Supply

PCB fabrication and electronic processes require process feedwater with low levels of impurities. Large volumes of raw water must be readily available, either of suitable quality or treatable at reasonable cost. New facilities must consider water at an early stage of the site selection and planning process. Zero discharge, although a desirable goal, is very costly and difficult to achieve.

32.3.2 Water Quality

Highly variable mineral content causes board rejects and equipment downtime, as well as reduced bath life, burdened waste treatment, and difficult rinse water recovery. Many water supplies contain high levels of dissolved ionic minerals and possible colloidals that can cause rejects in board production. Some of these impurities are calcium, silica, magnesium, iron, and chloride. Typical problems caused by these impurities are copper oxidation, residues in the PTH,

copper-copper peelers, staining, roughness, and ionic contamination. Problems in the equipment include water- and spray-line clogging, corrosion, and breakdown. The best plating practices suggest good-quality water for high yields. The need for water low in total dissolved solids (TDS), calcium hardness, and conductivity is well known. Good water eliminates the concern that the water supply may be responsible for rejects. Although water quality is not well defined for plating and PC board manufacturing, for general usage, some guidelines can be assigned as follows. Where high-purity water is required, see Sec. 32.3.3. Typical quantities are

TDS:	4 to 20 ppm
Conductivity:	8 to 30 μS/cm
Specific resistance:	0.12 to 0.03 M
Carbonate hardness ($CaCO_3$):	3 to 15 ppm

Somewhat higher values are acceptable for less-critical processes and rinses.

32.3.3 Water Purification

Two processes widely used for water purification are reverse osmosis and ion exchange. In the reverse osmosis technique, raw water under pressure (1.4 to 4.2 MPa or 200 to 600 lb/in^2) is forced through a semipermeable membrane. The membrane has a controlled porosity that allows rejection of dissolved salts, organic matter, and particulate matter, while allowing the passage of water through the membrane. When pure water and a saline solution are on opposite sides of a semipermeable membrane, pure water diffuses through the membrane and dilutes the saline water on the other side

(osmosis). The effective driving force of the saline solution is called its *osmotic pressure*. In contrast, if pressure is exerted on the saline solution, the osmosis process can be reversed. This is called the *reverse osmosis* (RO) process, and involves applying pressure to the saline solution in excess of its osmotic pressure. Fresh water permeates the membrane and collects on the opposite side, where it is drawn off as product.

Reverse osmosis removes 90 to 98 percent of dissolved minerals and 100 percent of organics with molecular weights over 200, as shown in Table 32.1.

TABLE 32.1 Purified Water Supply Values
Typical in/out RO values

TDS, ppm	SiO_2, ppm	Conductivity, µS	Hardness-$CaCO_3$, ppm
170/4	30/1	130/8	24/1
240/7	45/2	200/14	35/2
300/10	60/2	250/20	45/3

A small quantity of dissolved substances also facilitates deionized (DI) water production, wastewater treatment, and process rinse water recovery, since it makes recycling less costly and more feasible. An RO system will result in lower costs for DI water preparation and for process water recycling. The setup for recycling requires additional equipment for polymer addition, filtration, and activated carbon treatment.

DI water purification is used when high-purity water is required, for example, in bath makeups, rinses before plating steps, and final rinses necessary to maintain low ionic residues on board surfaces. Mil-spec PC boards must pass

the MIL-P-28809 test for ionic cleanliness. This is done by final rinsing in DI water. Deionized water is made by the ion exchange technique. This involves passing water containing dissolved ionics through a bed of solid organic resins. These convert the ionic water contents to H^+ and OH^-. Deionized water systems are more practical when using feedwater low in ionic and organic content. Other requirements are as follows:

- pH: 6.5–8.0
- Total organic carbon: 2.0 ppm
- Turbidity: 1.0 NTU
- Chloride: 2.0 ppm

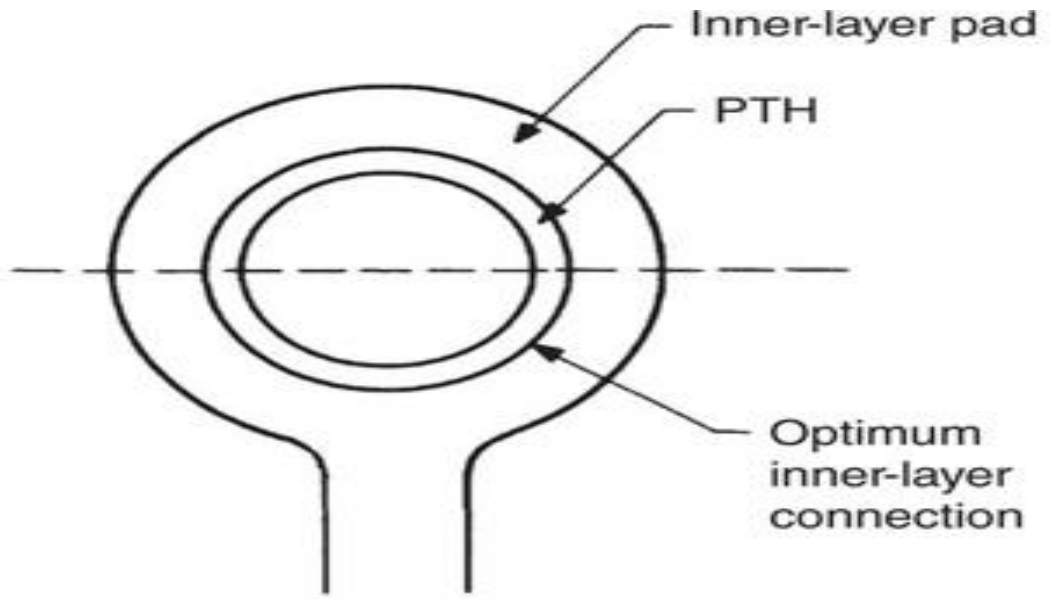
32.4 MULTILAYER PTH PREPROCESSING

Two-sided PCBs are usually processed by first drilling and deburring, then metallizing the through hole. Multilayers require treatment prior to any metallization process. Resin smear must be removed from the innerlayers, and texturing of the epoxy surface enhances hole wall adhesion. The preprocessing can be categorized as either smear removal or etchback.

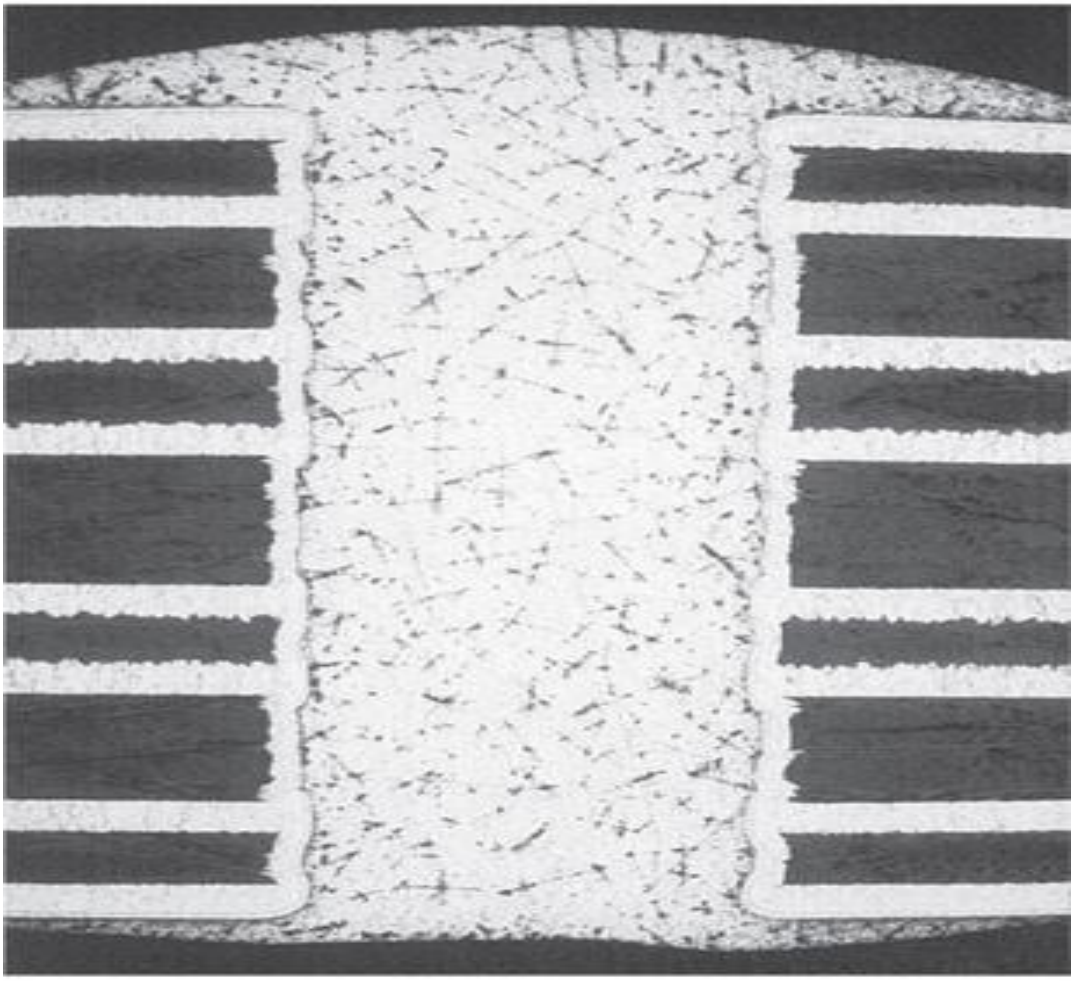
Fresh solution replenishment is crucial for effectively attacking smear and achieving uniformity through the holes. Circulation pumps and 90°C work piece movement are required to prevent temperature stratification of the heated baths as well as assist in forcing fresh chemistry through the holes. Higher aspect-ratio holes may require vibration to dislodge air bubbles from the holes and enhance uniformity of attack (see Chap. 29).

32.4.1 Smear Removal

High-speed drilling machines are used to drill holes into the PWB dielectric. During the drilling operation, sufficient heat is generated, causing the epoxy to melt. As the drill is withdrawn, the melted epoxy smears across and coats the innerlayer copper surfaces, causing a condition commonly known as *drill smear* (see Figs. 32.2 to 32.6).



(a)



(b)

FIGURE 32.2 PTH vertical and horizontal cross-sections illustrating optimum innerlayer connection and smear removal.

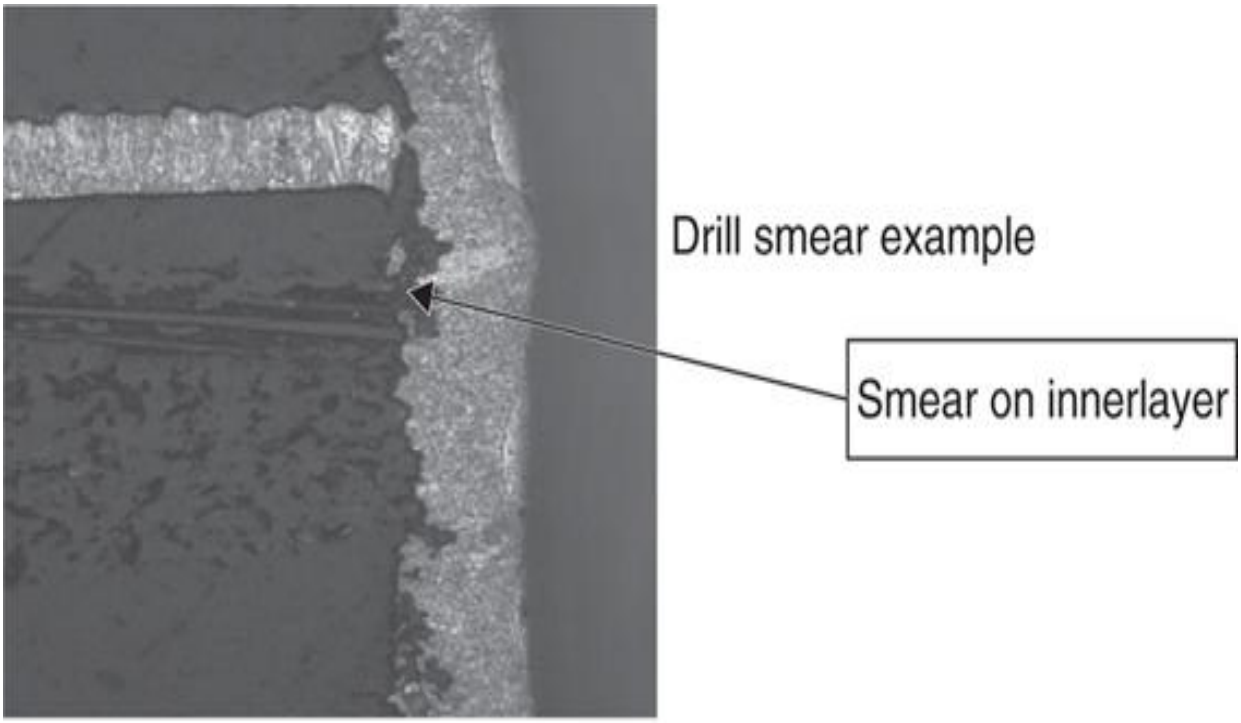


FIGURE 32.3 Drill smear example (note smear on the innerlayer).

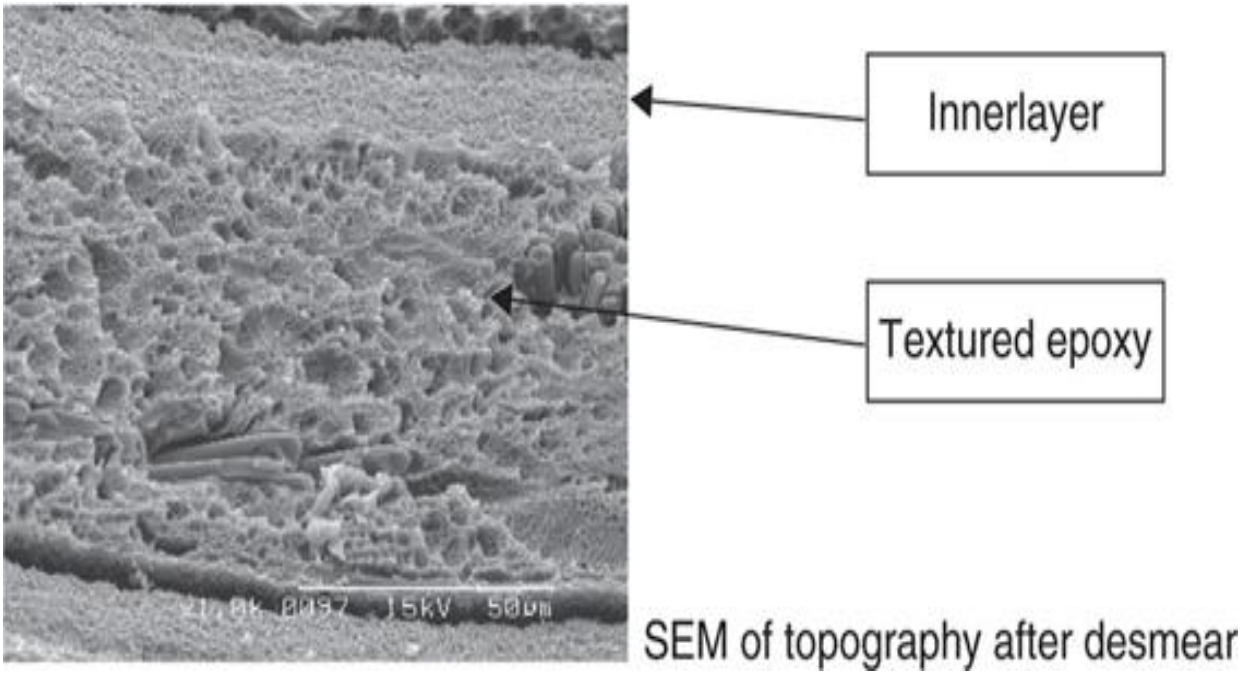

FIGURE 32.4 Scanning electron microscope (SEM) view of topography after desmear.

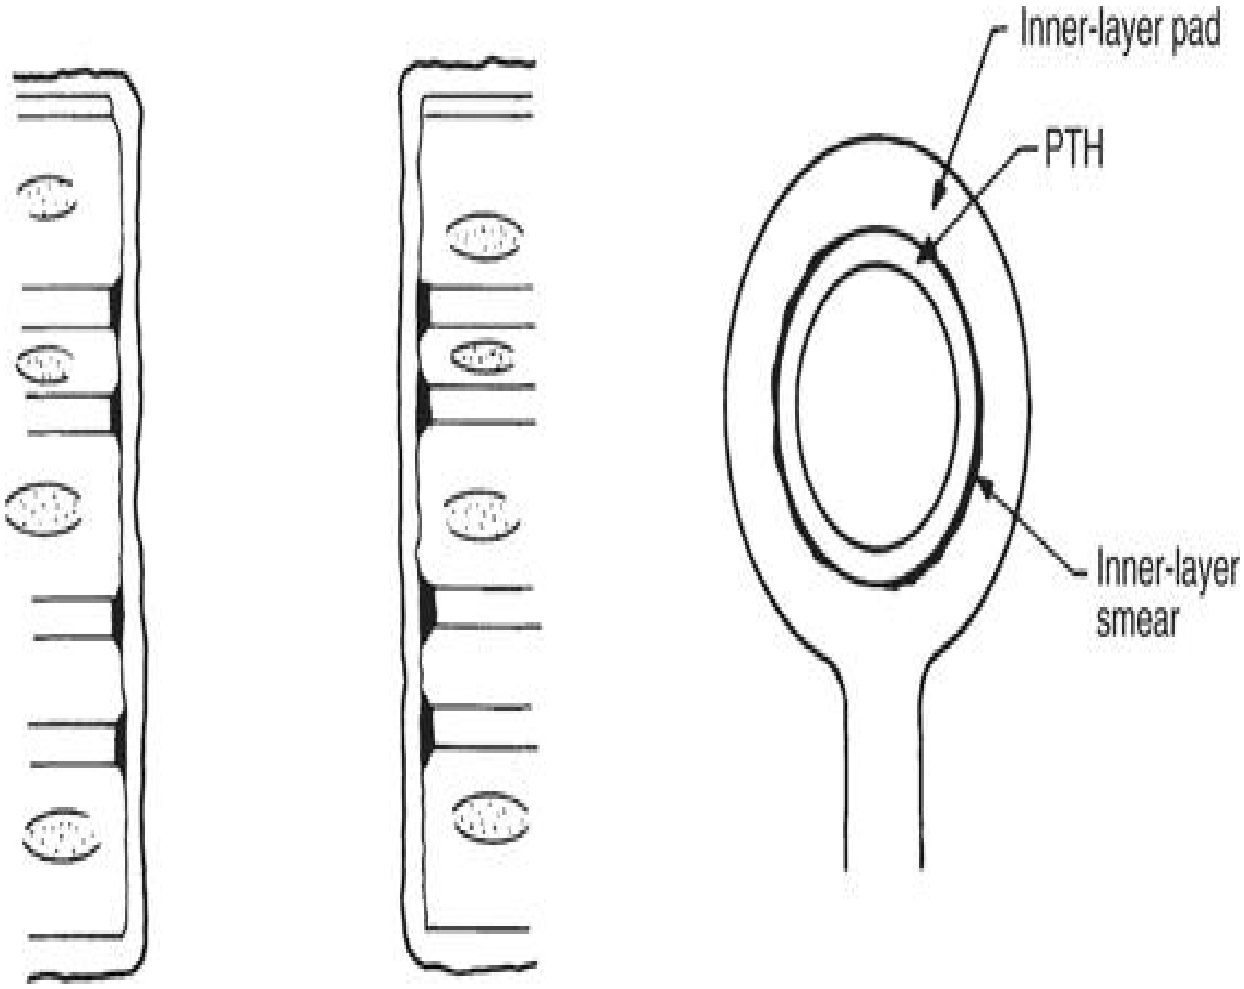

FIGURE 32.5 PTH vertical and horizontal cross-sections illustrating innerlayer smear.

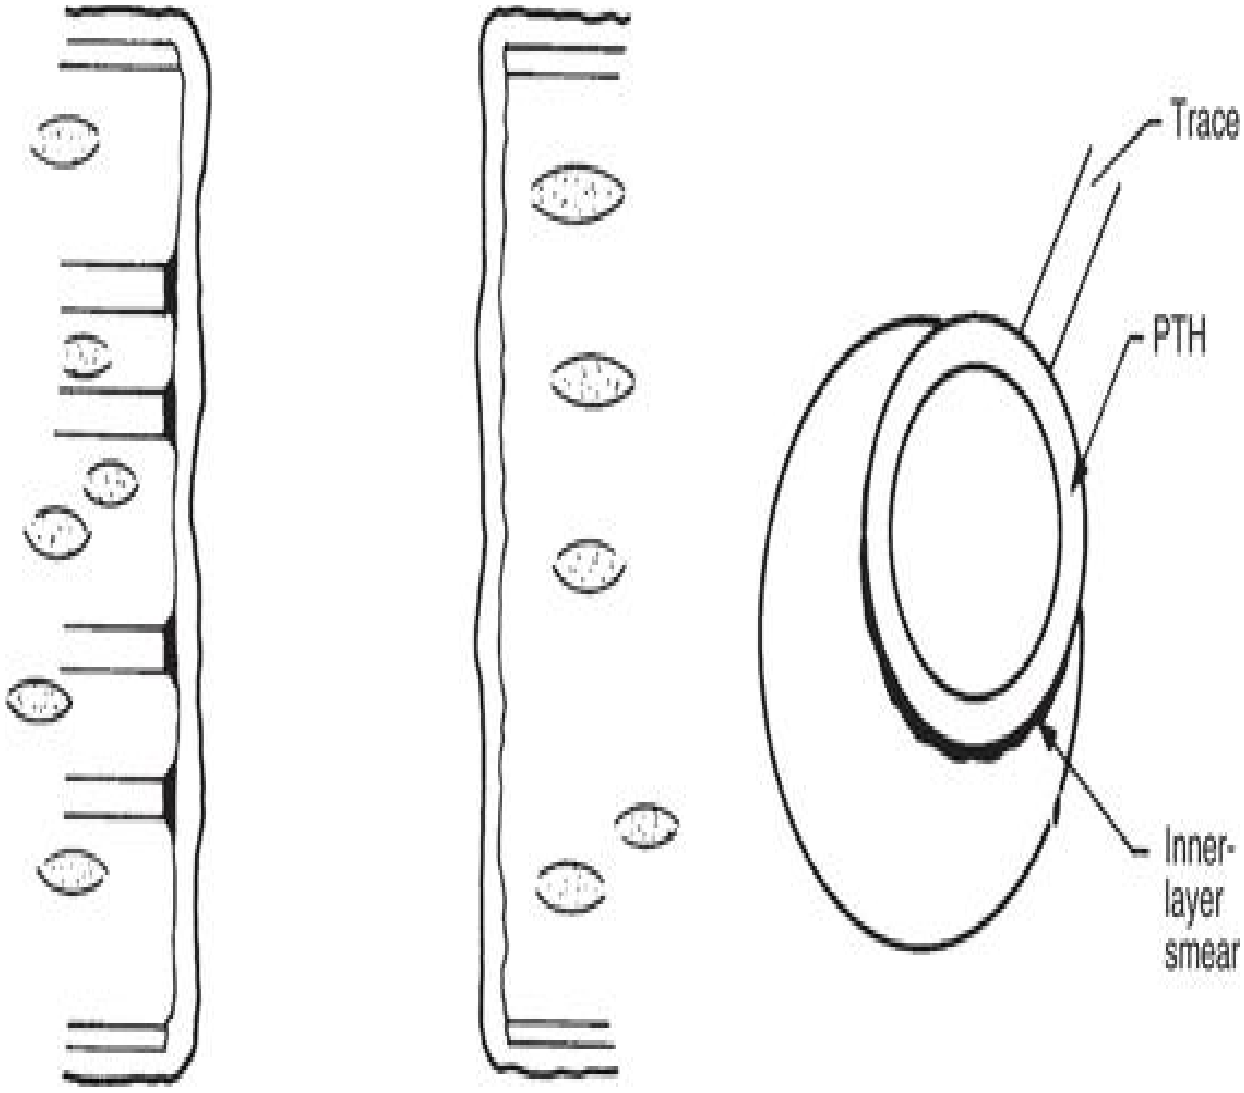

FIGURE 32.6 PTH vertical and horizontal cross-sections illustrating innerlayer smear and misregistration.

32.4.2 Etchback

Etchback refers to the aggressive removal of the epoxy and glass that results in the protrusion of the innerlayer copper. When two surfaces of the innerlayer are exposed, it is referred as two-point connection, and when three surfaces of the innerlayer are exposed, it is referred as three-point connection. Physically, the innerlayer copper will protrude from the drilled-hole three-point connection for copper

bonding, which is required on some mil-spec boards (see Fig. 32.7).

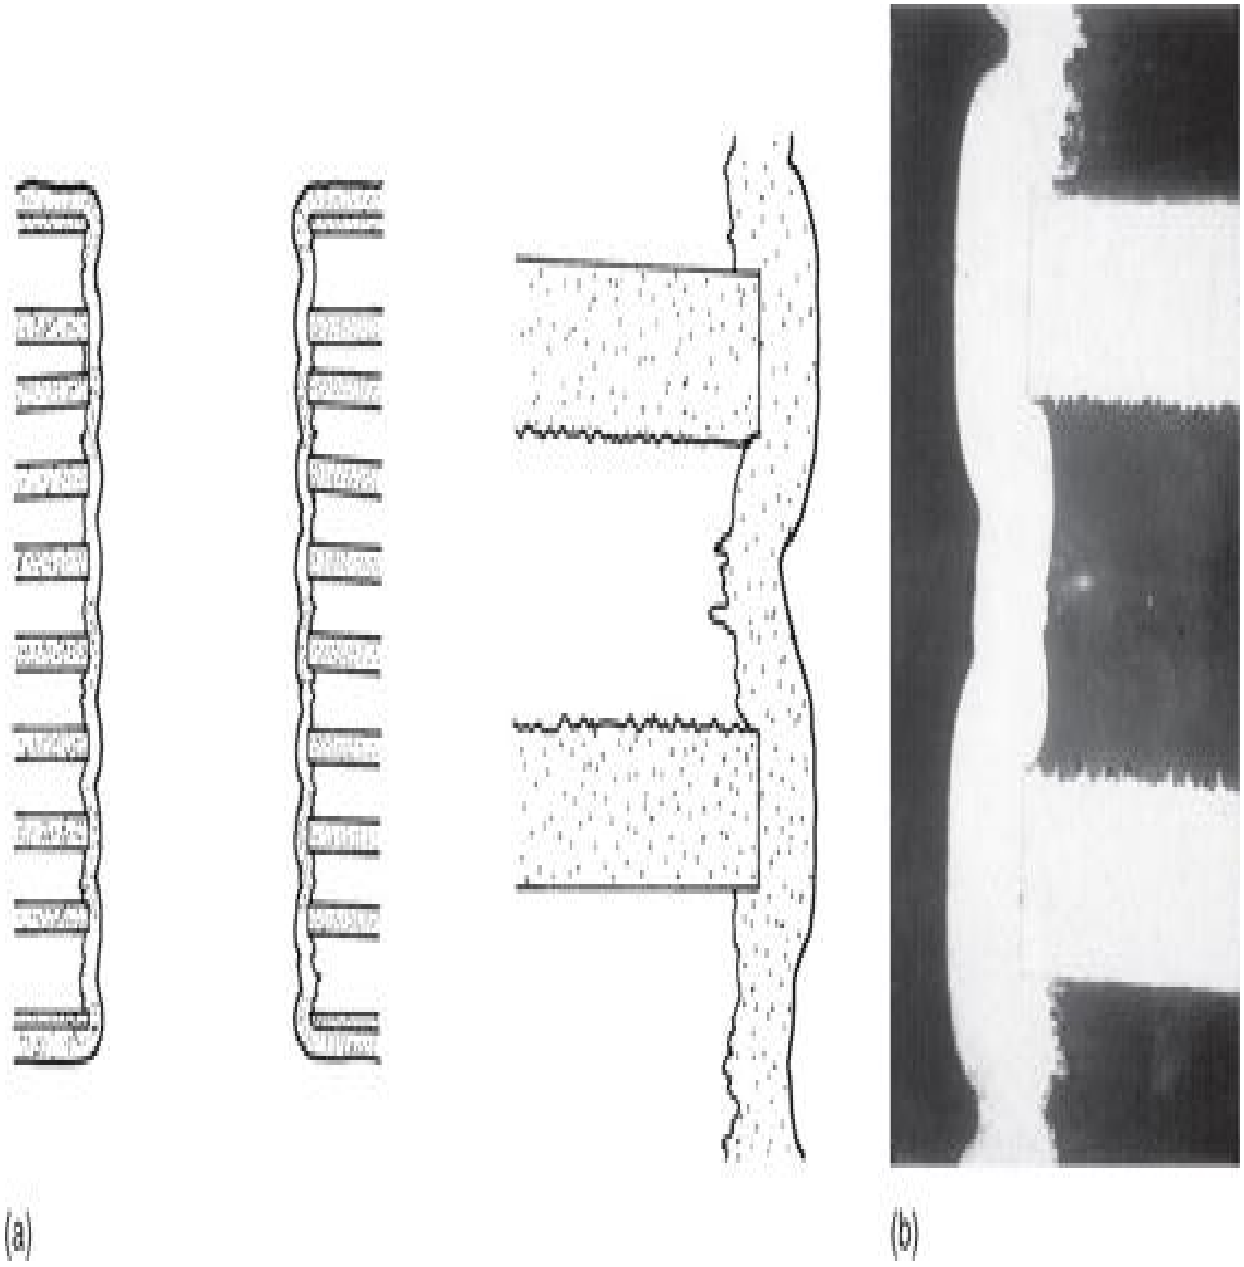

FIGURE 32.7 PTH vertical cross-section illustrating optimum connection and etchback: (*a*) shows a drawing of expected cross section; (*b*) shows an actual cross section with expected results.

32.4.3 Smear Removal/Etchback Methods

The four methods commonly used utilize hole wall epoxy or dielectric oxidation, neutralization-reduction, and glass etching. Three of the four common methods employ technology that oxidizes resin or dielectric, followed by a neutralization-reduction step. The fourth method—sulfuric acid—solvates or dissolves resin or dielectric. All methods remove smear, but the resultant surface of the epoxy affects hole wall pull-away and adhesion.

32.4.3.1 Sulfuric Acid. This process has been used extensively for many years because of its ease of operation and reliability of results. Disadvantages are lack of control, inability to attack certain resin systems, and the inability to create significant topography resulting in poor hole wall adhesion. Operator safety is crucial since concentrated sulfuric must be used. However, due to the significant changes and improvements in resin systems these last several years, sulfuric acid as a desmear method has fallen out of favor.

32.4.3.2 Chromic Acid. Chromic acid is a more controllable method that imparts some topography for enhanced hole wall adhesion and has a longer bath life. However, insufficient neutralization of the Cr^{+6} leads to copper voids. The line cost of using chromic acid is appealing. However, the Restriction of Hazardous Substances (RoHS) and waste treatment regulations of chromic acid add substantial costs that make this method a nonviable option. Etchback is possible by double processing.

32.4.3.3 Permanganate. Permanganate is the most widely used and preferred method in the industry. This easy-to-control process incorporates electrolytic regeneration,

which adds to consistency and increases bath lives. Permanganate effectively removes drill smear from most materials and imparts some texturing to the resin that increases hole wall adhesion.[3] See Fig. 32.3 for an example of hole wall topography after etchback. Problems result from lack of chemical control or inconsistent cure of the multilayer package.

Permanganate is also used as a second step in conjunction with the other methods to enhance hole quality.[4]

32.4.3.4 Plasma. Plasma utilizes electrical current to generate a plasma from fluorocarbon gases. This plasma oxidizes the epoxy resin and removes drill smear. Longer cycles or double cycling will generate etchback. Plasma works on any material and is especially effective when processing polytetrafluoroethylene (PTFE)-based dielectrics. This process has few steps and does not require the use of large quantities of chemicals. Disadvantages of plasma are nonuniformity of the treatment across the batch and across the panel. The texture generated on the epoxy is minimal, and an ash is commonly left behind that leads to poorer hole wall adhesion. A secondary cleanup, such as permanganate, is commonly used after plasma to remove the ash. The cost of the equipment and its maintenance is high. Controls must be provided to prevent air pollution.

32.4.4 Process Outline: Smear Removal and Etchback

The four common methods for smear removal and etchback are given in Table 32.2. Combinations of these methods are also in use because of added reliability they offer to both process and product.

TABLE 32.2 Smear Removal and Etchback Processes*

Sulfuric Acid	Chromic Acid
Rack panels	Rack panels
Sulfuric acid, 96%	Chromic acid 20-s dwell, 15-s drain, 3 min, 140°F room temperature
Neutralizer 8 min, 125°F	Reducer 3 min, room temperature
Ammonium bifluoride 3 min, room temperature	Ammonium bifluoride 3 min, room temperature
Unrack panels	Unrack panels
High-pressure hole cleaning	High-pressure hole cleaning
Release to electroless copper/DM	Release to electroless copper/DM
Permanganate	**Plasma Etch**
Solvent conditioner 90°F, 5 min	Plasma Oxyget, CF_4, 30 min
Alkaline permanganate 170°F, 10 min	Glass etch (optional)
Neutralizer-120°F, 5 min	High-pressure hole cleaning
Glass etch, 4 min, room temperature	Release to electroless copper/DM
High-pressure hole cleaning (optional)	
Release to electroless copper/DM	

*Water rinses after each step are not shown.

Polyimide and polyimide-acrylic systems are processed in chromic acid or plasma. Teflon, and R T Duroid materials are treated (before operations) in sodium-naphthalene mixtures to yield void-free, high-bond-strength copper in the PTH. The introduction of lead-free material and halogen-free material has challenged the desmear processes. The new materials

are more chemically resistant, and thus more aggressive desmear cycles are required to remove any smear. These more chemically resistant resin systems are more difficult to texture. Alternative solvents, higher temperatures, and cycle optimization may be required to process these newer materials effectively.

32.5 ELECTROLESS COPPER[5–10]

32.5.1 Purpose

This second series of chemical steps (after smear removal) is used to make panel side-to-side and innerlayer connections by metallizing with copper. The process steps required include racking, cleaning, copper microetching, and hole and surface catalyzing with palladium and electroless copper. Typical steps are as follows:

1. *Cleaner-conditioner:* Alkaline cleaning is used to remove soils and condition holes.
2. *Microetch:* This slow acid etching is used for removal of copper surface pretreatments, oxidation, and presentation of uniformly active copper. Persulfates and sulfuric acid hydrogen peroxide solutions are commonly used.
3. *Sulfuric acid:* This acid removes persulfate residues.
4. *Predip:* This process maintains the balance of the next step.
5. *Catalyst (activator):* Neutral or acid solutions of palladium and tin are used to deposit a thin layer of the catalytic metal on the nonconductive surfaces. Some palladium is unintentionally absorbed onto the foil surface and innerlayers.
6. *Accelerator (postactivator):* This process removes colloidal tin on board surfaces and holes or change the

charge of the palladium tin colloid.

7. *Electroless copper:* This alkaline-chelated copper-reducing solution deposits thin copper in the holes (20 to 100 µin) and surfaces.
8. *Antitarnish:* This neutral solution prevents oxidation of active copper surfaces by forming a copper conversion coating.

32.5.2 Mechanism

Equations (32.1) and (32.2) illustrate the process.

$$Pd^{+2} + Sn^{+2} \rightarrow Pd + Sn^{+4} \qquad (32.1)$$

$$CuSO_4 + 2HCHO + 4NaOH \xrightarrow{Pd} Cu + 2HCO_2Na + H_2 + 2H_2O + Na_2SO_4 \qquad (32.2)$$

However, Eq. (32.2) is an old two-step catalyzation sequence that is no longer in use in the industry.

32.5.3 Electroless Copper Processes

New materials and increased reliability criteria have precipitated a newer generation of electroless copper baths. Lead-free assembly forces the PWB to undergo higher thermal excursions, thus increasing the stress on the plated through holes. Proprietary additives (which are not listed in Table 32.3) affect the integrity of the electroless copper-plated deposit. Selection from the several types available depends on the type of image transfer desired. Operation and control of three bath types and the function of constituents are given in Tables 32.3 and 32.4. The problems encountered with this system are as follows:

TABLE 32.3 Electroless Copper Processes
Operation and control

	Low Deposition	Medium Deposition	Heavy Deposition
Copper	3 g/L	2.8 g/L	2.0 g/L
HCHO	6–9 g/L	3.5 g/L	3.3 g/L
NaOH	6–9 g/L	10–11 g/L	8 g/L
Temperature	65–85°F	115 ± 5°F	115 ± 5°F
Air agitation	Mild	Mild/moderate	Moderate
Filtration	Periodic	Continuous	Continuous
Tank design	Static	Overflow, separate sump	Overflow, separate sump
Heater	Teflon	Teflon	Teflon
Panel loading	0.25–1.5 ft^2/gal	0.1–2.0 ft^2/gal	0.1–2.0 ft^2/gal
Replenish mode	Manual	Manual or continuous	Automatic
Idle time, control	70–85%	Turn off heat	Turn off heat
Deposition time	20 min	20 min	20–30 min
Thickness	20 µin	40–60 µin	60–100 µin

TABLE 32.4 Electroless Copper
Function of constituents

Constituent		Function
Copper salt	$CuSO_4 \cdot 5\,H_2O$	Supplies copper
Reducing agent	HCHO	$Cu^{+2} + 2e \rightarrow Cu^0$
Complexer	EDTA, tartrates, Rochelle salts	Holds Cu^{+2} in solution at high pH; controls rate
pH controller	NaOH	Controls pH (rate) 11.5–12.5 optimum for HCHO reduction
Additives	NaCN, metals, S, N, CN organics	Stabilize, brighten, speed rate, strengthen

1. *Uncoppered holes or voids:* Voided holes appear as black or dark color in the holes. Corrective actions: Ensure that the process is functioning correctly by verifying the times, temperatures and concentrations of all preceding process tanks, including the desmear process as specified. The electroless copper bath components should be verified as well as the dwell time. Low loading factor, low temperature, or high air agitation lead to low bath activity and poor plating characteristics. Voids may also be caused by an overaggressive electrolytic preclean line.
2. *Hole wall pull-away:* This is the separation of the copper pulling away from the dielectric. The defect is usually detected during the cross-sectioning inspection. If the hole wall pull-away is severe, large blisters can be seen in the hole with the naked eye. Hole wall pull-away can be caused by insufficient texturing of the epoxy dielectric during the desmear process, overconditioning, overcatalyzation, or insufficient acceleration. The electroless copper bath may become overactive and plate a stressed deposit. Ensuring that the process is functioning as specified with regard to dwell times, chemical concentrations, and bath temperature are the corrective actions.

3. *Bath decomposition:* This is rapid plating out of the copper. Common causes are bath imbalance, overloading, overheating, lack of use, tank wall initiation, by-product build-up and contamination.
4. *Electroless copper–to-copper-clad bond failure:* Copper-to-copper adhesion failures can occur on the surface or on the innerlayers. Surface copper adhesion failures arise from unclean copper. Dry-film and/or developing residues, overconditioning, insufficient rinsing, insufficient microetch, and overcatalyization are common causes. Innerlayer copper-to-copper adhesion failures, commonly referred as ICD, may be due to all the items mentioned. Further causes may be related to the electroless copper bath itself. A stressed deposit due to high bath activity or decomposition has poor integrity and may fail under reliability testing. Specific additives in supplier formulations may contribute to ICDs as well.
5. *Staining:* Copper oxidation is due to moisture or contamination on the copper surface. Corrective action involves dipping boards in antitarnish or hard rinsing in DI water.

32.5.4 Process Outline

This outline presents the typical steps in an electroless copper process:

1. Rack
2. Clean and condition
3. Water rinse
4. Surface copper etch (microtech)
5. Water rinse
6. Sulfuric acid (optional)
7. Water rinse

8. Preactivator
9. Activator (catalyst)
10. Water rinse
11. Postactivator (accelerator)
12. Water rinse
13. Electroless copper
14. Rinse
15. Sulfuric acid or antitarnish
16. Rinse
17. Scrub (optional)
18. Rinse
19. Copper flash plate (optional)
20. Dry
21. Release to image transfer

CHAPTER 33
ELECTROPLATING

George Milad
Uyemura International Corporation, Southington, Connecticut

33.1 INTRODUCTION

The reality in printed circuit board (PCB) evolution is that the parts are continuing to increase in degree of difficulty and complexity. A new genre of high-density interconnect (HDI) boards is making the transition from leading edge to mainstream. These boards are characterized by a combination of complex features that include buried and blind vias, high-aspect ratio plating, small-hole plating, and fine lines and spaces side by side with ground plane areas of different sizes.

The industry, however, still has a need to produce simpler products, such as single-sided and double-sided boards; these are still in demand. Multilayer boards with lower layer counts (four to eight) fall in this category also.

This chapter focuses on different aspects of electroplating. Emphasis will be on acid copper. Acid copper electroplating is the process that forms the traces and the through-hole

connectivity that conveys the signal from end to end of the final device. Tin, tin-lead, nickel, and gold electroplating will also be covered.

33.2 ELECTROPLATING BASICS

Electroplating is the production of adherent deposition of conductive surfaces by the passage of electric current through a conductive metal-bearing solution. The rate of plating depends on current and time and is expressed by Faraday's law [Eq. (33.1)]:

$$W = (ItA)/(n\mathrm{F}) \tag{33.1}$$

where W = metal, grams
I = current, amperes
t = time, seconds
A = atomic weight of the metal
n = number of electrons involved in metal ion reduction
F = Faraday's constant (96,485 C/mol)

Plating occurs at the cathode (the negative electrode). Accordingly, deposition thickness is determined by the time and the current that is impressed on the surface being plated; for example, by using the preceding formula, one can readily calculate the weight of the deposited metal. The weight can then be converted to a specific thickness over a known area. To plate 1.0 mil of copper, one would need 17.8 amperes per square foot (ASF) or 1.88 amperes per decimeter (ASD) for 1 h (60 min). The rate of deposition of the most common metals is shown in Table 33.1.

TABLE 33.1 Rate of Deposition of the Most Common Metals Grams

Metal	Grams Deposited per amph	Amp. h. per sq.ft to Deposit 0.001 in	Amp. h. per sq.dm. to Deposit 25 µm
Copper	1.186	17.8	1.88
Tin	2.214	7.8	0.82
Lead	3.865	6.9	0.73
Nickel	1.095	19.0	2.00
Gold	7.348	6.2	0.65

Table 33.2 shows the properties of common electrodeposits.

TABLE 33.2 Properties of Electrodeposits

Property	Cu	Ni	Au	SnPb	Sn
Melting point, °F	1980	2600	1945	361	450
CTE X 10^{-6}/°F	9.4	8.0	8.2	12.2	12.8
Conductivity, %IACS	101	25	73	11.9	15.6
Electrical resistivity, µΩ/cm	1.67	6.8	2.19	14.5	11.1
Thermal conductivity, CGS°C	0.97	0.25	0.71	0.12	0.15

33.3 ACID COPPER ELECTROPLATING

Acid copper plating for PCB application must meet two challenges:

1. Thickness distribution/uniformity of the plated copper
2. Physical/metallurgical properties of the deposit

33.3.1 Thickness Distribution

The biggest challenge facing copper electroplating is the thickness uniformity of the deposit on the different features of the PCB. This is becoming more critical as demands for speed and impedance control continue to increase. On the surface, patterns have extremes of isolated small traces and pads as well as ground plane areas, the isolated traces are of low resistivity and attract more current than the ground plane areas; giving rise to big differences in plating thickness. The through hole offers its own challenges, particularly holes with a high aspect ratio (hole diameter to board thickness ratio). The knee of the hole is a sharp edge that attracts more current and tends to over-plate (dog bone effect) while the middle of the hole may lag behind in thickness.

33.3.1.1 Panel and Pattern Plating. Surface copper can be plated uniformly if the pattern is eliminated as in the case of “panel plating.” With panel plate the surface and the thru hole are plated first. The pattern definition is achieved by subsequent imaging and etching. Here the definition of fine traces is going to be as good as the imaging and the etching capabilities of the manufacturing site. Panel plating is wasteful as a large area of the panel is etched away. It also becomes challenging when the pattern involves small lines and traces, the etching process has to clear the trenches between the traces. In contrast “pattern plate” plates less copper and only etches the laminate copper (Fig. 33.1).

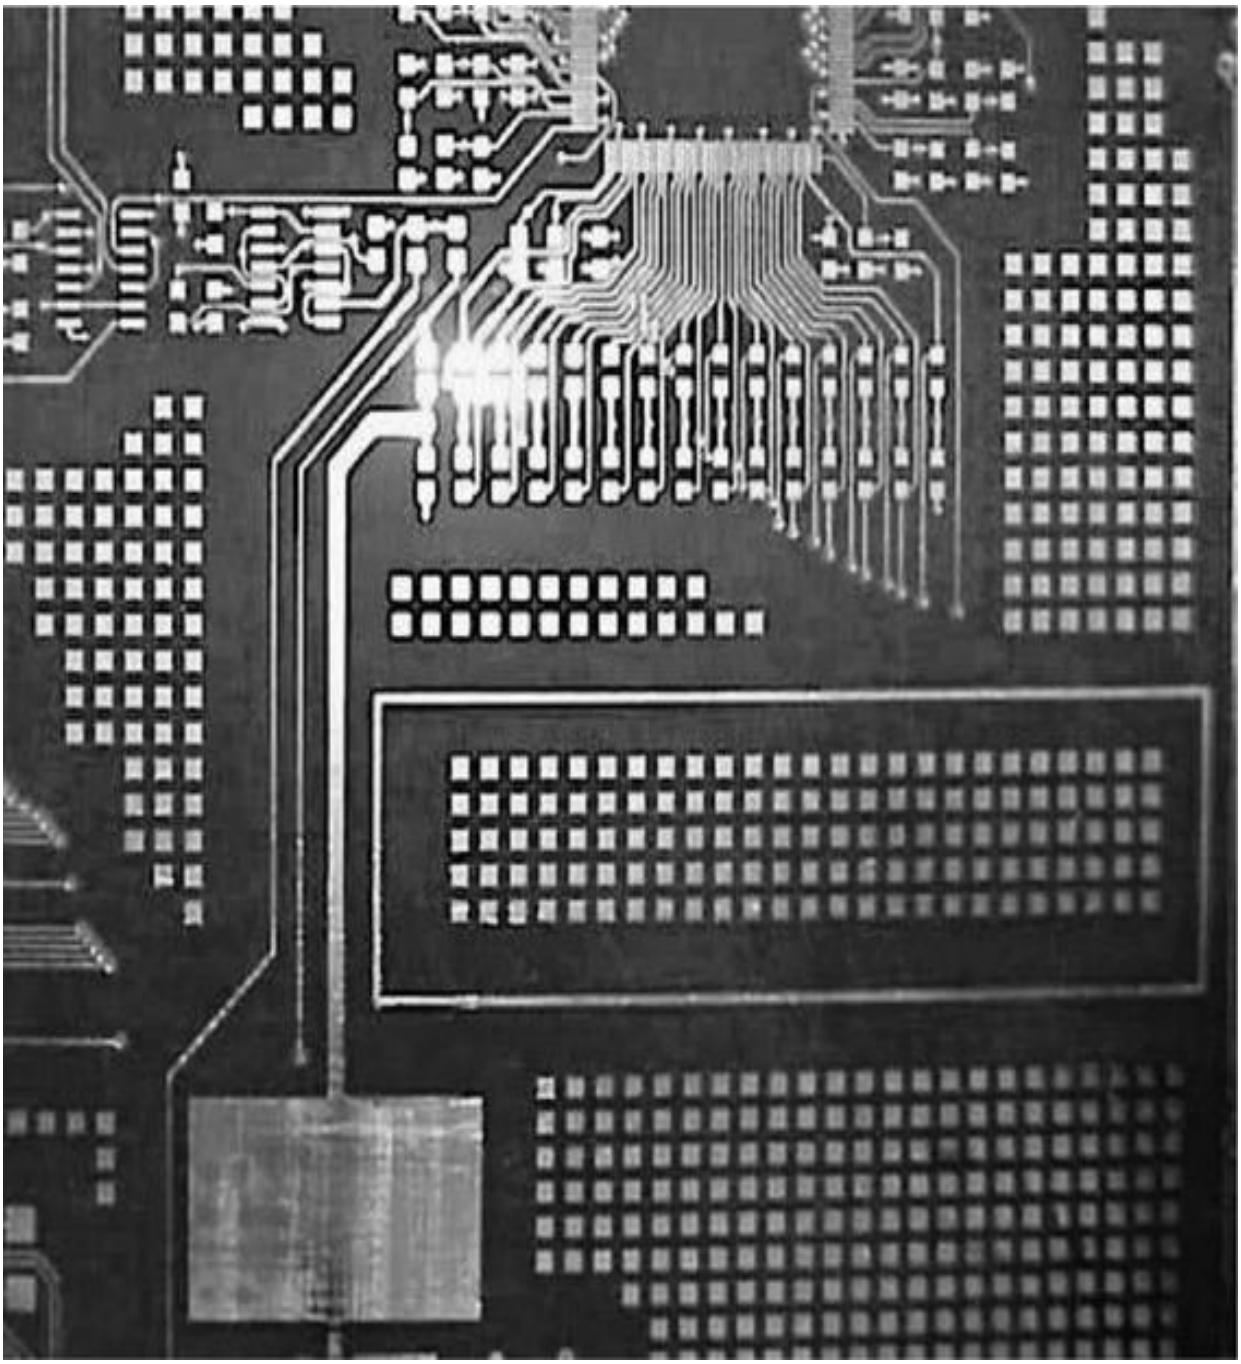

FIGURE 33.1 Example of isolated traces versus ground plane areas.

33.3.1.2 Throwing Power. High aspect thru holes will over plate the knee of the hole and depending on the throwing power (TP; the ratio of the plated thickness in the middle of the hole compared with the thickness at the entrance of the hole) of the plating solution will plate less in

the middle of the hole. The throwing power of the bath is a function of the aspect ratio; meaning the thickness of the plated copper in the middle of the hole may be equal to the thickness on the surface (100 percent TP) for a 3:1 aspect ratio hole and may be only 1/3 of the thickness on the surface (33 percent TP) for a 15:1 aspect ratio hole. In the latter case to achieve a thickness of 1.0 mil in the middle of the hole would result in plating 3.0 mils on the surface (Fig. 33.2).

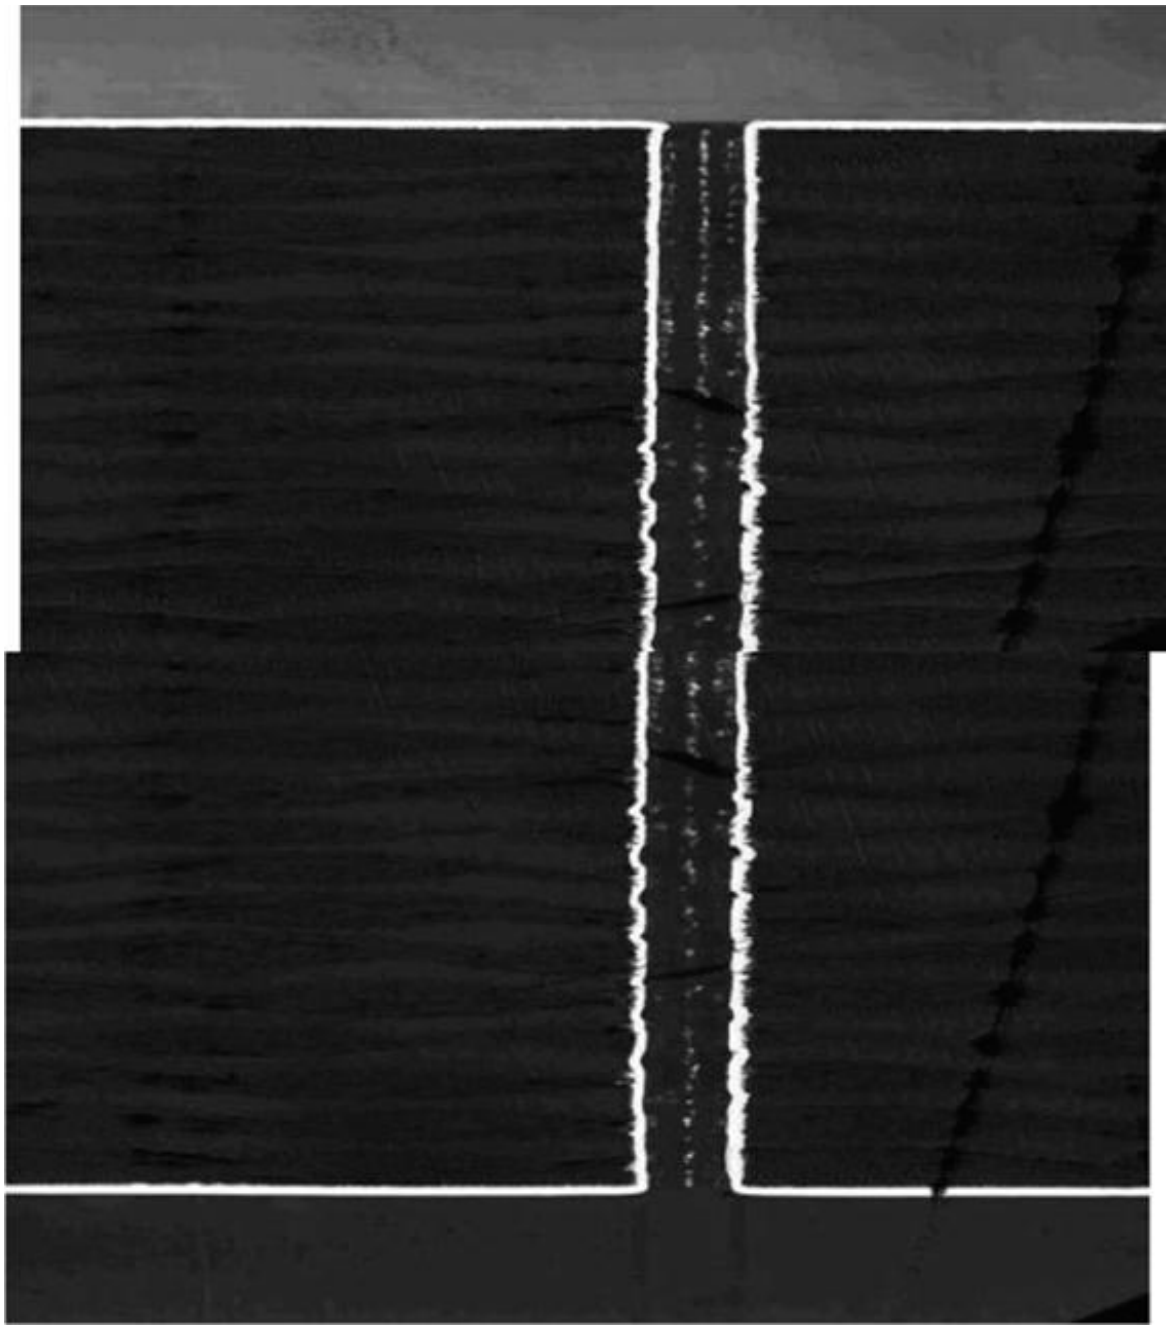

FIGURE 33.2 15:1 aspect ratio plated at 8 ASF in DC mode with greater than 85% TP.

33.3.2 Metallurgical Properties

Another challenge is to ensure that the deposit has the desired metallurgical properties, namely tensile strength and

elongation (T&E). Tensile strength in excess of 35,000 PSI and elongation in excess of 15 percent are desirable properties, to ensure that the plated copper can withstand the thermal excursions during manufacturing and assembly of the plated parts. T&E are directly affected by the crystal structure of the deposit. A fine-grained equiaxed (nondirectional) structure gives the highest T&E values.

33.3.3 PLATING PROCESS

The plating system, or process, should be designed to minimize thickness disparity and to deliver the desired physical properties of the plated copper, with minimum impact on productivity. All aspects of the plating process must be optimized toward that goal, these include:

- The plating solution
  - Inorganic plating chemicals
  - Organic additives
- Tank design
  - The plating tank, weir
  - Anode/type and placement
  - Cathode racking
  - Solution agitation
  - Part agitation
  - Filtration
  - Temperature
- Horizontal plating equipment
- Rectification
  - DC
  - Pulse

33.3.3.1 The Plating Solution. The plating solution is composed of both inorganic and organic chemicals. The chemicals in the bath have to be optimized for the intended use. The supplier should be able to guide the manufacturing site to the best chemical setup for their specific application.

33.3.3.1.1 Inorganic Chemicals. These consist of copper sulfate (g/L), sulfuric acid (g/L) and chloride ion (ppm). The copper sulfate contains the copper ion to be plated, the sulfuric acid supplies conductivity to the solution and the chloride ion serves a dual function: it plays a part in the corrosion of the anode and also in the adsorption/suppression of the carrier molecule.

The ratio of copper to acid varies based on the plating current density (CD). A low CD bath would use low copper concentration with high acid and the reverse is true for a high CD bath. A low CD bath uses longer plating times and does not require high copper ion concentration as the copper ion in the vicinity of the cathode is not readily depleted during plating; the high sulfuric, increases the conductivity needed for low current density plating.

The table below lists the inorganic ratios needed for different current densities of plating:

Component	Low CD Plating 5–20 ASF (0.5–2.0 A/dm)	Conventional Plating 20–40 ASF (2.0–4.0 A/dm)	High Speed Plating 40–150 ASF (4.0–15.0 A/dm)
Cu	1–2 oz/g (7–15 g/L)	2–3 oz/g (15–22 g/L)	7–8 oz/g (50–55 g/L)
$CuSO_4 \cdot 5H_2O$	4–8 oz/g (30–60 g/L)	8–12 oz/g (60–90 g/L)	28–32 oz/g (210–250 g/L)
H_2SO_4	20–32 oz/g (150–250 g/L)	12–20 oz/g (90–150 g/L)	7–10 oz/g (50–75 g/L)
Cl ion	40–80 ppm	40–80 ppm	40–80 ppm

33.3.3.1.2 Organic Additives. Ideally the organic additives should be continuously dosed into the plating solution based on ampere hours of plating. The dosing

pumps would be calibrated to deliver the desired volume of each component at specific ampere hour intervals. Organic additives are composed of

- Carriers
- Brighteners
- Levelers

Carriers increase the polarization resistance and are current suppressors. The suppression is a result of the carrier being adsorbed to the surface of the cathode; this results in increasing the effective thickness of the diffusion layer. The result is better organization. This gives rise to a deposit with a tighter grain structure. The carrier modified diffusion layer also improves plating distribution without burning the deposit.

The brightener is a grain refiner. Its random adsorption may produce a film that will suppress crystallographic differences. Alternatively brighteners may be adsorbed preferentially on particular active sites such as lattice kinks, growth steps, or tops of cones, or surface projections in general; growths at these locations are then blocked. The brightener produces a fine grained non directional (equiaxed) grain structure. It is the additive that directly affects the tensile strength and elongation properties of the deposit.

Levelers are small molecules that carry a partial charge that are attracted preferentially to the higher current density areas on the platting surface. Levelers, or leveling agents, are selective inhibitors present at low concentrations in the electrolyte as compared to the depositing metal. In case of a micro profile the diffusion layer does not follow the profile contour, but is maximum at the valleys and minimum at the peaks. Consequently, in absence of a leveling agent, depositing ions diffuse more rapidly to the peaks than to the valleys, and deposits grow more rapidly on the peaks,

resulting in an exaggerated profile. With good solution agitation, the leveler will accumulate more rapidly and readily at the peaks and it will inhibit growth or deposition. This allows the valleys to catch up to the peak, thus creating leveling.

33.3.3.2 Tank Design. Tank design is critical to the success of achieving the goals of thickness distribution and the physical properties of the deposit.

The tank material should be inert and nonconductive like polypropylene or PVC. The overall dimensions are based on the number of panels to be plated at any one time. The simplest plating bath would be a single plating cell with a single panel on a centrally located cathode bar with two anode bars one on either side of it. The length of the tank should be the panel width plus 12 to 16 in plus 8 to 12 in for the weir. The length may be expanded to allow for more panels to be racked on the cathode bar. The breadth—determines the anode to cathode distance—should be 18 to 30 in. 18 in will give 6 in between the anode basket and the panel and 30 in will give 12 in. The depth should be the depth of the panel plus 8 to 10 in from the top of the weir. This allows for better uniformity of solution agitation that is initiated from the bottom of the tank. The tank or bath may contain multiple plating cells (Fig. 33.3).

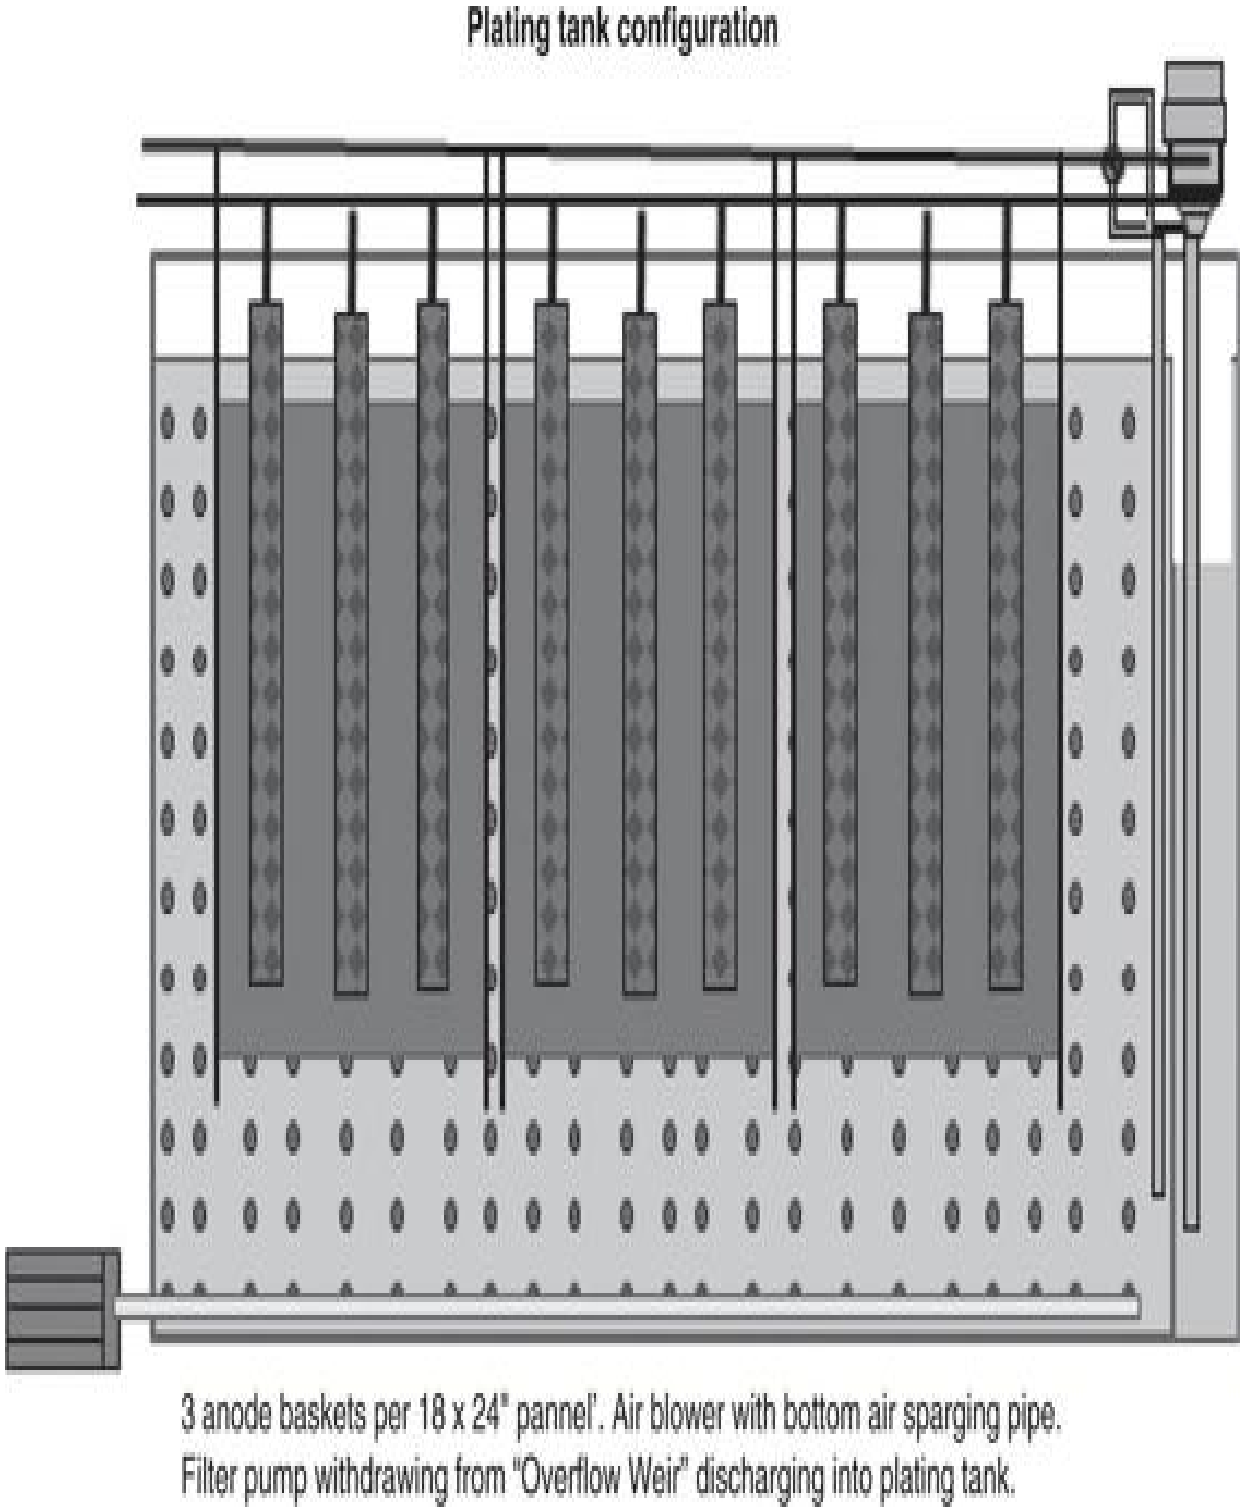

FIGURE 33.3 Tank configuration.

The weir should be located at the shorter end of the tank. It should create an 8 to 12-in well behind it; the height of the

weir should be 5 to 8 in below the surface of tank. The filtering pump should draw solution from the bottom of the weir well and return the solution to the plating area of the tank that in turn would overflow back into the well. The weir holds the solution level constant and allows suspended particulates to be forced thru the filtration system. In addition the overflow causes a certain amount of aeration which is beneficial in airless sparging systems.

33.3.3.3 Plating Materials and Equipment

33.3.3.3.1 The Anode. Anode types: Anodes may be one of two main categories: soluble anode or insoluble anode.

The soluble anode has been the staple of the industry. The anode is made of copper. Upon rectification the copper metal is oxidized to the copper ion and goes into solution. The copper ion is reduced to copper metal at the cathode where the plating occurs. Other than the source of copper the anode is positively charged when the rectifier is turned on and its location relative to the cathode has a direct impact on thickness distribution of the plated copper. For proper functioning the copper anodes must form an oxide film on the surface that helps the dissolution of the anode. New copper anodes must be filmed before utilization. This is accomplished by dummy plating at low CD for an extended time, per supplier recommendations.

One form of copper anode is a slab of copper (Fig. 33.4) with fixed starting dimensions. As the anode is used it dissolves and its dimension are reduced, and this would have an adverse effect on the plating thickness distribution. The reduced anodes will need to be replaced with new slabs. Replacing the anode is wasteful and not replacing it gives poor results. The alternative, which prevails in the industry, is to use a titanium basket (Fig. 33.5) with round or rectangular cross-section, full of copper balls. As the balls are used up the basket is replenished maintaining a constant area for the anode. The only downside to the balls is that

over time the balls at the bottom of the basket are reduced in size while the top has the full dimension of the copper ball. Anode maintenance would need to be performed periodically to remove the small balls. This is necessary as the small balls get buried in sludge, which is a natural byproduct of the dissolution of the anode. To prevent the sludge from getting into the plating solution all anodes are contained in a polypropylene anode bag. The bag should be loose, not napped and 2 to 3 in longer than the basket. The bags should be replaced periodically depending on usage.

FIGURE 33.4 Slab copper anodes.

FIGURE 33.5 Titanium anode baskets.

The alternative to a soluble copper anode is an insoluble anode. This anode serves the function of being positively charged and it will repel the copper ions toward the negatively charged cathode, and its location in respect to the cathode has a direct impact on thickness distribution, but it is not a source of copper ions. The common form of the anode is an expanded titanium mesh that is coated with what is referred to as mixed metal oxide coating (MMO) (Fig. 33.6). The primary component of the MMO is iridium oxide. These anodes produce oxygen gas during operation. If, MMO/Ti anodes are used, a source of copper must be added to the system. The most common source is CuO. CuO is dissolved external to the plating cell and is added based on ampere hours of plating. The MMO/Ti anode offers a constant area and does not require anode maintenance, in addition it does not require an anode film and eliminates the need for dummy plating.

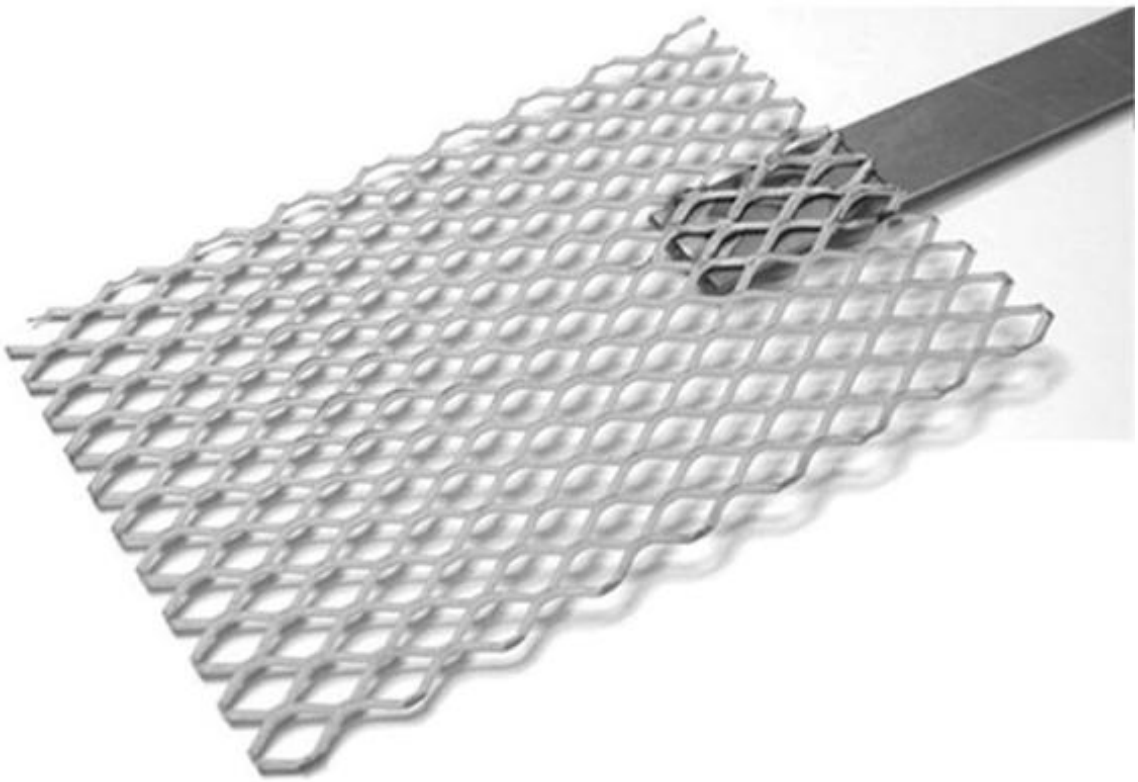

FIGURE 33.6 Insoluble anode.

MMO/Ti anodes have been adapted successfully in conventional plating; however, their primary utilization is in both vertical and horizontal conveyorized plating equipment.

Anode placement: The current initiates at the anode and is pulled in by the cathode. Areas of the cathodes that are closer to the anode source will plate more than areas further out. Accordingly the number of anode sources (baskets) and their distribution play an important role in the degree of thickness uniformity. The number of anodes should be adjusted to the plating current load, this is a function of CD and platable area. The higher the load; example panel plating, would require more anode baskets; example would be 3 to 4 round baskets (2.5- to 3.5-in diameter) per 18 × 24-in panel. For reduced platable areas; example pattern plate, 2 to 3 baskets would be adequate (Fig. 33.7).

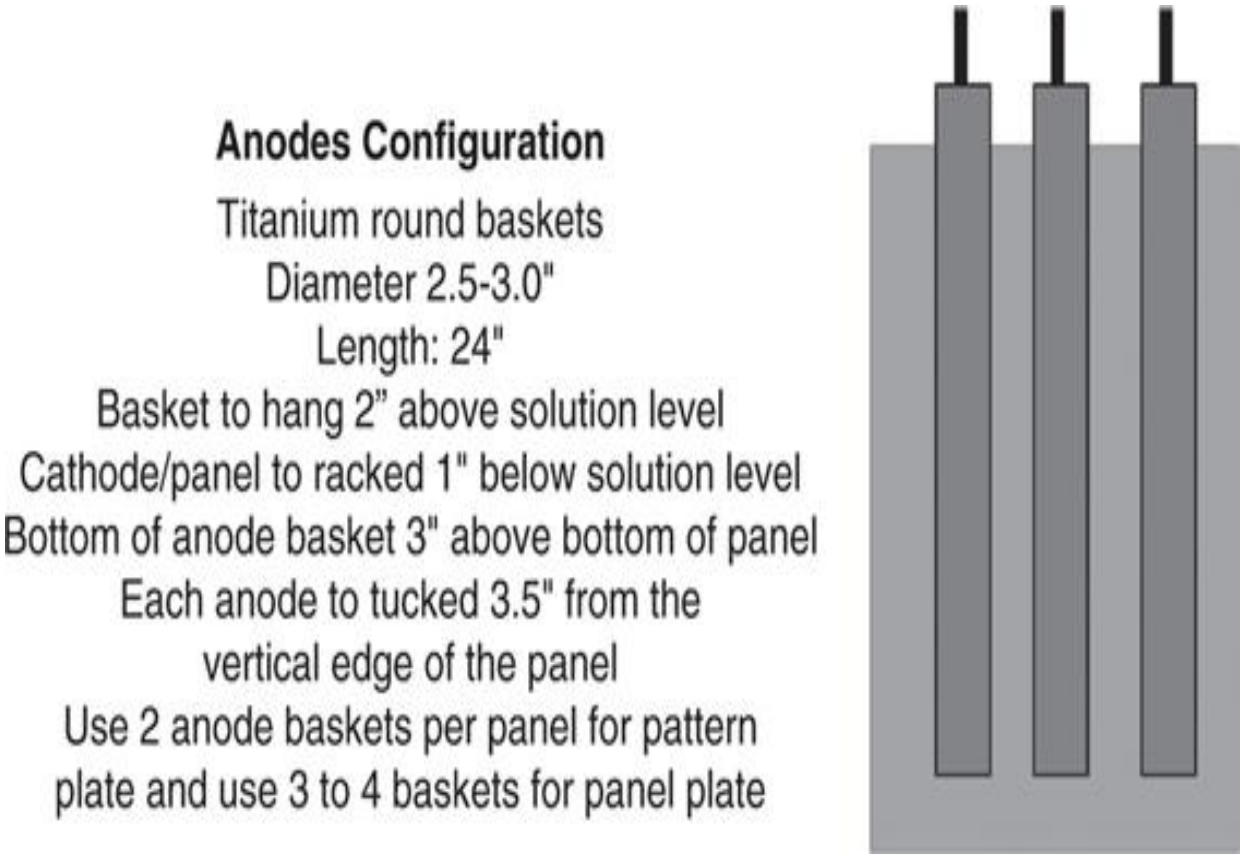

FIGURE 33.7 Anode placement.

Anodes should be evenly distributed throughout the anode bar. The anode should be 3 to 4 in shorter than the cathode and should be tucked into the cathode window by 3 to 4 in. This will reduce overplating at the bottom of the panel and at the vertical outside edges.

33.3.3.3.2 The Cathode. The cathode is composed of the panels to be plated on the cathode bar. The cathode bar, or the sum total of its agitation, should be equidistant from the front and back anode bars. Ideally the cathode window should be consistent commensurate with the anode configuration. The panels should be racked as close to each other as possible and should be racked within 1.0 in of the surface of the plating solution. Racking below solution level >1.0 will allow increased plating on the top edge. The cathode bar should be racked full with no gaps. If gaps are inevitable an appropriate dummy strip should be added to

protect the edges at the gap from overplating. Another approach would be to isolate any anodes that do not have complimentary cathodes across from them.

33.3.3.3.3 Cathodic Agitation. Cathodic agitation is recommended (1 to 3 in, through hole at 10 to 20 strokes per minute). The agitation offsets the solution flow rate front and back allowing for enhanced mass transfer thru the holes, like in getting alternately closer and further to the source of air sparging or e-ductor plume.

33.3.3.3.4 Solution Agitation. Solution agitation plays four important roles in plating:

1. It replenishes the copper ion in the immediate vicinity of the plating site (the diffusion layer). The primary source of replenishment of copper is “diffusion” which occurs naturally. When the rate of deposition is greater than the rate of diffusion, solution agitation must be implemented. It is more critical in baths with low copper concentrations. In absence of good copper ion replenishment the deposit would burn (not adherent and rough deposit).
2. Depending on the presence and the type of leveling component in the plating solution, agitation would sweep the leveler molecule across the surface of the panel where it is preferentially adsorbed to the high CD areas suppressing the plating thus creating leveling. This is particularly important in filling blind vias, by suppressing surface plating at the knee of the via and allowing the bottom of the via to plate faster and create filling.
3. In conjunction with cathodic agitation, solution agitation improves mass transfer thru the holes, a critical function when plating high aspect ratio holes.
4. The air maintains an oxidative environment in the solution and will oxidize any cuprous ion (Cu^{+}) to the desired cupric ion (Cu^{++}).

There are two common ways to agitate an acid copper plating solution, namely; air agitation and e-ductor agitation. The key is to produce uniform agitation at the cathode with the desired degree of turbulence/replenishment.

Air agitation is based on sparge pipes (Fig. 33.8) laid along the bottom of the tank below the cathode, in some instances a single pipe is used, with the cathodic agitation offsetting the flow front and back. In other cases two pipes are used one forcing air in front of the cathode and one forcing air behind the cathode. The source of air is an air blower; it should be sized to produce uniform air across the length of the cathode and to produce the desired degree of turbulence. In instances where transporting the leveling molecule is critical air agitation should be vigorous.

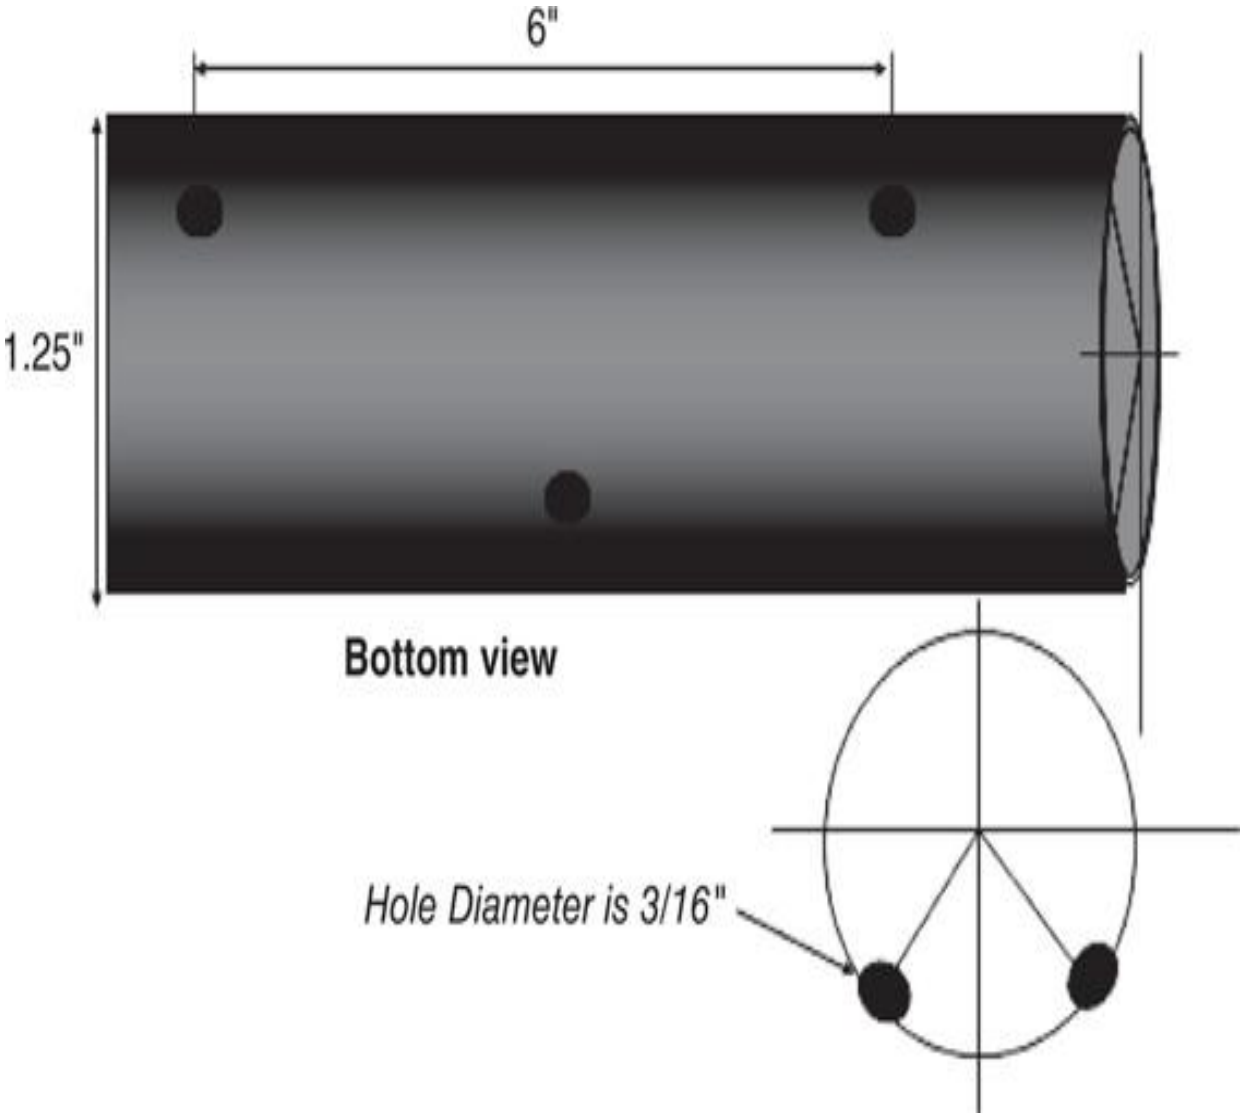

FIGURE 33.8 Forced-air sparger pipe details.

E-ductor agitation is based on the use of e-ductor nozzles (Fig. 33.9) spaced across a bottom manifold. The location and the spacing should be such that they produce uniform parallel flow (laminar) across the surface of the panel. Again here one may use a single manifold under the cathode or use dual manifolds one in front and one in the back of the cathode. Dual manifolds is the preferred arrangement. The location of the nozzles across each manifold should be such that nozzles on the one pipe are not directly across the nozzles on the opposing pipe.

FIGURE 33.9 Four inch- and 2.75-in e-ductor nozzles.

If e-ductors are used the depth of tank should allow for that; meaning the top of the e-ductor nozzle should be approximately 6 in below the bottom of the panel to be plated. In addition if the turbulence is inadequate to

minimize the cuprous ion; gentle air bubbling may be introduced in the weir or in a corner of the tank.

33.3.3.3.5 Part Agitation. Part agitation or cathodic agitation may be one of 2 types: “through-hole” agitation or “knife edge.” The more common “through hole” part agitation helps in solution exchange in the holes, particularly for higher aspect ratio holes. Getting copper ions to the plating sight or “mass transfer” is critical to the thickness distribution of the plated copper. Thru hole agitation does not alter the anode to cathode relative locations, it only alters the solution flow front and back by bring the cathode closer or further to the source of solution agitation.

Knife edge agitation helps in surface solution replenishment and in diffusing the lines of flux emanating from the anode toward the cathode. Increasing the anode to cathode distance preempts the need for knife edge agitation.

33.3.3.3.6 Filtration. Solid particulates in the electrolyte may be one of two types, inert or conductive. The inert particulates winding on the surface of the cathode would inhibit plating causing pitting. Conductive particulates at the cathode become nucleation sites and cause nodulation. Particle removal is a critical part of the plating system setup. It is achieved by continuous filtration through a polypropylene filter cartridge (polyspun) with 5 to 10 µm rating. The filtration intake is from behind the weir and returns into the main tank through a pipe running across the bottom of the tank centered under the cathode. The filter pump should be sized for 2 to 4 solution turnovers per hour STO/h.

33.3.3.3.7 Temperature. Temperature is a critical parameter for PCB plating; refer to vendor recommendations. Electrolytes operate in a relatively narrow range of temperature; example is 70 to 80°F. Maintaining the temperature within the specified limits has a direct impact on the quality of the deposit. If solution agitation is based on e-ductor flow; the temperature of the bath will rise from the

continuous pumping. Cooling will become the dominant temperature controlling factor. This is usually achieved utilizing a titanium cooling coil, connected to a chiller and appropriately located in the tank.

33.3.3.4 Rectification. Two main types of rectifiers are in use for copper plating namely direct current of DC rectifiers and periodic pulse PP rectifiers.

33.3.3.4.1 DC Rectifiers. Direct current rectifiers are the staple of the industry. The rectifier should be sized to supply the desired output, example if the platable area is limited a smaller rectifier would be the right choice, it is not advised to use a 200-A rectifier to plate at 10 to 20 A. Ripple (% AC; alternating current) should be less than 5 percent to ensure the deposit is fine grained adherent and equiaxed. High ripple would have an adverse effect on the physical properties of the deposit. The control accuracy or resolution should be 1 to 2 percent to ensure consistency of output. DC rectifiers use standard cable connections.

When plating with DC rectification the plater needs only to set the plating current density or amperes and plating time; with that he can readily calculate the amount of copper that will be plated.

33.3.3.4.2 Pulse Rectification. Here the current is supplied in pulses or burst. The rectifier is switched on and off in a controlled fashion in millisecond intervals. This pulsing has an effect on the diffusion layer and additive adsorption. The additives are desorbed in the off or reverse mode and readsorbed when the forward current is back on. The adsorption and desorption are not even everywhere. In the high-current density areas this process takes longer than the areas of lower CD. This helps even out the plating thickness between areas of varying CD on the part. Pulse rectifiers are connected to the plating cell with coaxial cables.

Pulse rectifiers also known as switch mode rectifiers produce a pulse wave. An example of a periodic pulse reverse (PPR) wave, would be to set the switch mode rectifier to the equivalent of 20 ASF in the positive mode for 10 to 20 ms and then to switch to a reverse at 3× or 60 ASF for 0.5 to 1.0 ms, respectively. For best results the switching should be instantaneous resulting in a square wave.

When using PPR the plater must set a program for the forward current and the reverse current, the forward millisecond time and the reverse time; he must also verify the shape of the wave. These are a lot of parameters to set up and will take a learning curve until a successful recipe is achieved for the product being plated. Changes in the product type may require a different wave setup.

Pulse plating produces a different crystal structure; it does not produce the same fine grained equiaxed structure that DC produces. The finished surface appears duller than DC. Attention must be paid to achieve the desired physical properties of T&E for the deposit. When properly set up PPR plating has a positive effect on thickness distribution; different switching programs may be needed for different plating configurations.

An optimized electrolyte in an optimized plating cell is the key to producing the desired copper physical properties and thickness distribution, in general the lower the CD of plating the better the thickness distribution of the deposit. Of course this would imply that the electrolyte used should be able to support the choice. This approach has a direct impact on productivity of the plating line and may not be a viable option.

The organic additive system must be chosen based on the type of work anticipated. Most suppliers offer more than one additive system geared toward meeting specific plating configurations.

33.3.3.5 Conveyorized Plating. Here, the panel is transported in a horizontal mode through the plating equipment with stationary anodes below and above it. The panel continues to plate as it travels, interfacing with one anode after the other. The panel comes off the end of the line plated.

Horizontal processing is suitable for high productivity manufacturing sites where large numbers of the same part are a common daily requirement.

The plating thickness is a function of time and current density. The dwell time is determined by the length of the plating module and the conveyor speed. Plating at 20 ASF for 60 min. in horizontal equipment running at 1 m/min. would require a plating module that is 60 m long. This length is not practical. Current density has to be increased to 40, 60, 80, and higher ASF. At 80 ASF, the equipment length needs to be only 15 m.

New chemical additives were formulated to accommodate high-current-density plating.

However, this current density offered new challenges: at high-current densities, most plating solutions lose throwing power. Another problem that was encountered early on was that the anode film particulates would land on the top side of the panel and eventually create nodulation. This did not occur on the bottom side.

Nodulation was resolved by taking the copper dissolution out of the module and replacing the standard anode with an inert or insoluble anode. Copper dissolution or oxidation was achieved by different means, such as the dissolution of copper oxide, or the use of external rectification.

33.3.3.5.1 Horizontal Processing Advantages. Advantages of horizontal plating: The most dramatic advantage of horizontal plating is the uniformity from panel to panel. All panels go through the equipment in an identical fashion. They all see the entire bank of anodes,

and they are in a single plating solution. All panels coming off a horizontal line are alike. If for some reason one edge of the panel has higher plating, then all panels will have the same edge equally high. In vertical plating, different panels are plated in different parts of the cell, in different positions in the rack, and even in different tanks or baths. Although vertically plated panels may all be within specifications, there will always be inherent variability that the shop has to contend with in downstream processing beyond the plating line.

Horizontal plating machines can be easily automated. Loaders and unloaders are usually integrated in the system. Automation of chemical analysis and dosing is incorporated with minimum cost increase. The equipment is easily linked to pre- and postprocesses. Horizontal processing lends itself well to continuous production flow and reduced cycle time.

Anode uniformity is a major advantage in horizontal plating. The size and geometry of an insoluble inert anode do not change. Anode variability and maintenance are eliminated. The latter is a very labor-intensive and hazardous activity is associated with vertical plating.

Horizontal equipment is completely enclosed. This minimizes the operator and shop personnel’s exposure to acid and chemical fumes and creates a better and safer working environment.

Horizontal plating gives superior surface thickness distribution. Variation of less than 10 percent across a panel-plated surface is normal. This is due to the anode’s close proximity to the cathode; usually, the anode-to-cathode spacing is between 8 and 10 mm, or 0.3 and 0.4 in.

33.3.3.5.2 Drawbacks of Horizontal Processing

1. The equipment requires a substantial investment and is a major deviation from standard vertical processing.
2. Panels processed must have one common dimension commensurate with the width of the conveyor.

3. If the equipment is used for pattern plating each order must clear the equipment before the next order with a different platable area can be introduced.
4. If soluble anodes are used; nodules on the top surface are a problem.
5. If insoluble anodes are used, allowance for anode gassing must be implemented.
6. The equipment must be operated at relatively high CD which reduces throwing power in the hole.
7. There is both a learning curve and engineering know-how that will be needed to run this equipment smoothly.
8. It requires a large parts inventory and trained equipment maintenance crew to ensure uninterrupted operation.
9. The equipment is integrated, and either it all works or it all doesn't.

33.3.3.6 High Aspect Ratio Plating

33.3.3.6.1 High Aspect Ratio Drilled Hole Issues. Pattern plating application pose a challenge to the electroplating process. Plating is accomplished using lower current densities (5 to 20 ASF) for extended plating times. It is a balance between the organic (with leveling component) and inorganic components (low copper high acid formulation) of the electrolyte coupled with the cell configuration where the cathode and anode are located to yield the best uniformity of flux lines and the solution and part agitation are designed for electrolyte replenishment and allow for maximum mass transfer thru the holes.

33.3.3.6.2 Blind Via Hole Fill. Blind vias that connect layer 1 to layer 2 or to layer 3 are an enabling technology for HDI (high-density interconnect) type boards. This activity started by conformal plating of the via (Fig. 33.10) and eventually developed into "via fill" (Fig. 33.11). Via fill makes for a robust connection with no chance of any voids during assembly. Vias with 1:1 aspect ratio are common, it is

possible to plate vias that are deeper than the diameter of the via up to 1.2:1.

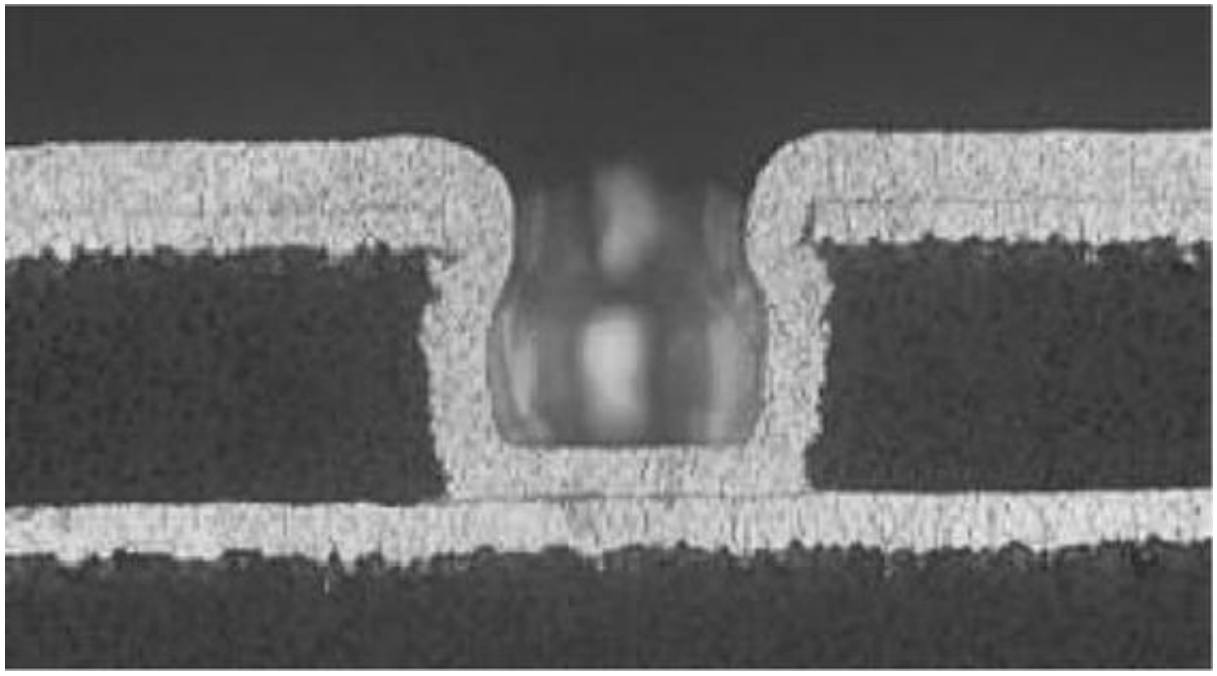

FIGURE 33.10 Blind via plating.

Successful via fill plating requires a specific electrolyte; the copper concentration is as high 50 to 60 g/L copper with low sulfuric acid at 30 to 60 g/L. This is combined with a unique organic additive combination with a prominent leveling component. The leveling component acts predominantly on the surface and suppresses the surface plating allowing the brightener and carrier combination to plate up from the bottom of the via, for filling to occur. Ideally the solution movement must be vigorous and parallel to the surface (laminar flow); this ensures adequate leveler replenishment at the surface of the via. Inadequate solution flow across the surface will produce conformal plating with no filling (Fig. 33.11).

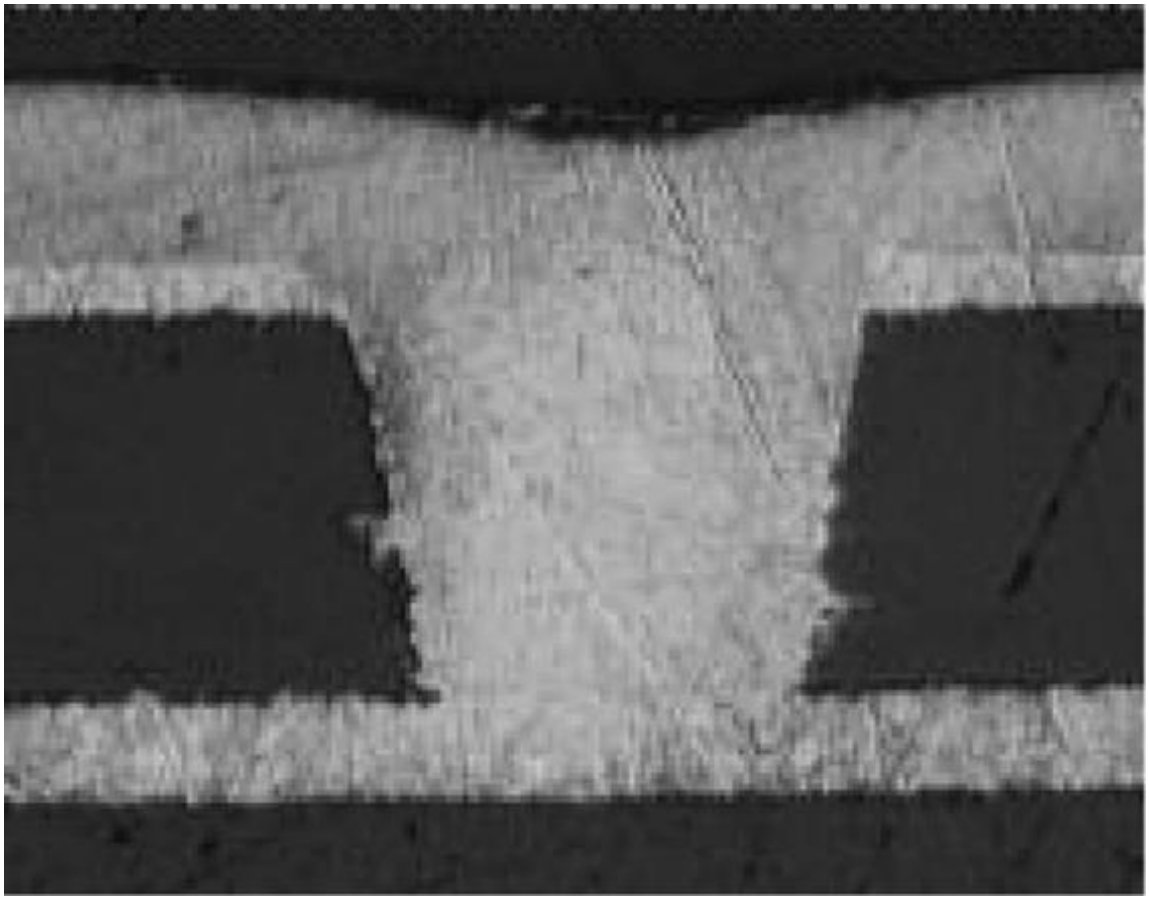

FIGURE 33.11 Blind via filling.

Blind via plating is presently done using both pattern (dot pattern) and full panel plating. Plating CD varies from 10 to 25 ASF, using a single setting example 12 ASF for 90 min, or a series of step up CDs, example 10 ASF for 30 min followed by 15 ASF for 20 min followed by 20 ASF for 20 min. The plating cycle should be optimized for the product and the equipment capabilities.

In the case of pattern plate, planarization after resist stripping is necessary to reduce the thickness of the copper on the surface above the via.

33.3.3.7 Bath Management and Control. With attention to solution management and control the electrolyte performance may be maintained for years. This may be divided into three areas:

1. Inorganic chemical control
2. Organic additives control
3. Contamination control

33.3.3.7.1 Inorganic Chemical Control. This involves the chemical analysis and control of the following:

- Copper sulfate
- Sulfuric acid
- Chloride ion

Titration methods are readily available for these analyses.

Copper sulfate concentration in baths that use soluble copper anodes will grow over time. Based on the operating range, the copper sulfate must be partially dumped to bring the copper sulfate in range. Insoluble anodes (Ti/MMO) have been used to plate out excess copper in the electrolyte. This method produces plated copper and avoids the generation of disposal waste.

In general the sulfuric acid and the chloride concentrations values remain consistent over time. The analysis is important during setup. It is also a way to ensure no extraneous chloride is being introduced into the bath.

33.3.3.7.2 Organic Additives Control. This involves the analysis and control of the following:

- Brightener
- Carrier
- Leveler

The organic additives have a direct impact on the physical properties and thickness distribution of the deposited copper.

Traditionally the hull cell was used to give an indication on the effect of brightener on the plated brass panel. A matte panel indicated no brightener and a fully bright panel

indicated adequate or excess brightener. For simpler additive systems (premixed carrier leveler and brightener), and with experience, this method can be effective.

With a better understanding of the role of each component and the availability of the additives in separate containers for the more sophisticated systems; a better method was needed. Cyclic voltammetric stripping (CVS) is now the method of choice for assessing the effective concentrations of the different additive components. CVS methods for analysis of each component are available and in use.

33.3.3.7.3 Organic Contamination. Sources of organic contaminants:

- Additive break down products particularly the carrier or suppressor.
- Extraneous organics brought into the bath such as the leaching of dry film components into the bath

The most practical way to get a handle on organic build up in the bath is to run a total organic carbon (TOC) analysis. For TOC values to be useful, a baseline needs to be established. The base line should be a fresh makeup simulation. Here the entire value (1×) comes from the additive contribution alone.

The upper limit for TOC should be established for each individual production environment, type of bath, bath loading, plating current density, type of product, etc. A good starting point is when the TOC value approaches 4× the original makeup value, a carbon treatment should be conducted. However, if there is an observed deterioration in the quality of the deposit the 4× value may be reduced to 3×, and so on.

The treatment is deemed successful if the TOC numbers drop to approximately 70 percent of the starting high TOC value. Once that is established then the shop will need to maintain the carbon-treat schedule.

Example: If the starting point the 1× is 300 ppm and the bath survives without adverse effects up to 4× (1200 ppm), and is then C-treated down to 70 percent (~850 ppm), these become the upper and lower limits that have to be maintained and the bath must be run between 850 and 1200 ppm.

In absence of TOC analytical capability, carbon-treatment based on electrolyte utilization can be set up. An example would be 100 to 120 Ah/L of bath for electrolytes using dry film pattern plate.

33.3.3.7.4 Carbon Treatment. C-treat can be conducted at two different levels:

1. Carbon treatment with no oxidant (C-polish)
2. Carbon Treatment with oxidant (C-treat)

Carbon polish involves circulating the bath through a bed of activated carbon in a carbolator, or an activated carbon filter at bath or room temperature. Carbon treatment involves the use of oxidants like hydrogen peroxide to break down the organic contaminants. This is usually done in a separate tank equipped with heating and mixing capabilities. The equivalent of 0.5 percent by volume of 35 percent hydrogen peroxide and activated carbon at ~2 g/L are added, with continuous solution agitation and heated at 120 to 140°F. Maintain temperature and mixing for approximately 4 h before cooling the bath. The cooled down bath is transferred back to the plating tank through a filter. The quantity of carbon and solution contact time, have to be established with the initial treatment. Once established the process is to be duplicated for every treatment thereafter.

33.3.3.8 Trouble Shooting Acid Copper

33.3.3.8.1 Corner Cracking. This occurs at the knee of the hole and is seen in cross-section after thermal shock. It indicates inferior crystal structure like coarse columnar

plating versus fine equiaxed crystals. It could also be the result of reduced plating at the knee of the hole due to over leveling. Both causes are corrected by adjusting the components of the organic additives.

33.3.3.8.2 Columnar Deposit. Insufficient brightener. Check and adjust additive concentrations and ratios.

33.3.3.8.3 Voiding in the Hole. Voids occur from one of the following:

- *Voids in the original metallization:* This needs to be fixed at the metallization process.
- *Voids due to air entrapment in the bore of a small hole:* This is resolved in the pretreatment “cleaner” step. The cleaner removes soils and oxidation and has an important function of wetting the hole. Vibration may be needed in the cleaner to ensure good wetting in the hole and to eliminate any entrapped air.
- *Voids from etch out due to voids in the tin (etch resist) plate:* Correction is to increase the thickness of the tin plate.

33.3.3.8.4 Roughness or Nodules. Nodules result from conductive particulates like anode sludge creating nucleation sites at the surface during the plating cycle. Corrective action; ensure the filtration system is operating properly. Check that no anode bags are torn or that the solution level is below the top of the bag.

33.3.3.8.5 Burning in the High CD Area. This is due to insufficient replenishment of copper ions. The easiest thing is to reduce the CD of plating, or to use an electrolyte with higher copper content that supports the desired CD of plating.

33.3.3.8.6 Poor Throwing Power in the Hole. The CD of plating is too high for the specific aspect ratio. Make sure that the electrolyte is designed to support good throw in the target aspect ratio, and CD range.

33.3.3.8.7 Poor Leveling. First ensure that the electrolyte used has leveling capabilities. Leveling on the surface is a function of solution replenishment/movement. More flow produces better leveling. Excessive leveling activity may cause step plating.

33.3.3.8.8 Inferior Thickness Distribution on the Surface. This can occur in pattern plate and to a lesser extent in panel plate. Thickness distribution can be enhanced by optimizing the cell geometry anode and cathode placement and solution and part agitation. Lower CD of plating reduces thickness variation. Electrolytes with the proper ratio of suppressor and leveling agents will give better thickness distribution.

33.3.3.8.9 T&E below Specified Values. The best values for tensile strength and elongation are achieved with a fine grained equiaxed crystal structure. This is achieved when the additives are operating in the optimum operating ranges. The brightener is the grain refiner. Other things that could impact T&E values is organic contamination and rectifier ripple (<10 percent). Contamination can be fixed by C-treating the electrolyte.

***33.3.3.9 Preplate Treatment*.** The pretreatment is composed of three steps: (1) the cleaner, (2) the microetch, and (3) the predip. The combined effect of the pretreatment is paramount to the success of the plating.

There is no room for compromise in these steps
